- local prostaglandin and nitric oxide release.

In the blood, renin converts angiotensinogen to inactive angiotensin I, which is further cleaved by angiotensin-converting enzyme (ACE) in lung and vascular endothelium into active ***angiotensin II (AII)***, which acts via two receptor types, AT_1 and AT_2. Binding of AII to AT_1 in the heart, blood vessels, kidney, adrenal cortex, lung, and brain leads to:

- rapid, powerful vasoconstriction
- stimulation of the adrenal zona glomerulosa to increase aldosterone production (over hours or days) leading to sodium (and water) absorption in the collecting duct
- vasoconstriction of efferent > afferent renal arterioles increasing glomerular capillary pressure to maintain GFR.

The renin–angiotensin system can be blocked at several points with renin inhibitors, ACE inhibitors, and angiotensin II receptor antagonists (AII-RAs). These are useful agents in the treatment of chronic kidney disease, hypertension, and heart failure. There are differences in action: AII-RAs are specific for AT_1 receptors, but ACE inhibitors also block kinin breakdown leading to an accumulation of kinins, causing a cough in some patients. In diabetes mellitus, absorption of excessively filtered glucose and sodium via SGLT-1 and SGLT-2 in the proximal tubules reduces sodium delivery at the JGA, which leads to activation of the renin–angiotensin axis and causes increased GFR. This is the hyperfiltration of diabetes, with an emerging therapeutic role for SGLT-2 inhibitors.

Erythropoietin

Erythropoietin (EPO) is the major stimulus for erythropoiesis, the synthesis of red cells. It is a glycoprotein produced principally by fibroblast-like cells in the renal interstitium. In ***hypoxia***, the α and the β subunits of hypoxia-inducible factor 2 (HIF-2) are expressed, forming a heterodimer causing erythropoietin gene transcription. Once formed, erythropoietin binds to its receptors on erythroid precursor cells, to maintain normal red cell synthesis. Under ***normal oxygen*** conditions, only the HIF-2-β subunit is constitutively expressed. The α subunit undergoes proline hydroxylation in the presence of iron and oxygen. The hydroxylated HIF-2-α subunit binds to von Hippel–Lindau protein, with subsequent degradation via proteasomes, so no erythropoietin is transcribed. This and other hydroxylation steps have an absolute requirement for oxygen and form the basis of oxygen sensing.

Loss of kidney substance with decreased erythropoietin production results in a normochromic, normocytic anaemia. Conversely, erythropoietin secretion may be increased in polycystic kidney disease, benign kidney cysts, or renal cell carcinoma leading to polycythaemia.

Recombinant human erythropoietin is used to treat anaemia in chronic kidney disease. In addition, there is emerging use of oral HIF stabilizers to promote endogenous erythropoietin production.

Vitamin D metabolism

Naturally occurring vitamin D (cholecalciferol) requires hydroxylation in the liver at position 25 and again by 1α-hydroxylase in the kidney to produce metabolically active 1,25-dihydroxycholecalciferol (1,25-$(OH)_2D_3$). Activity of 1α-hydroxylase is increased by:

- high plasma concentrations of PTH
- low concentrations of serum phosphate
- low concentrations of 1,25-$(OH)_2D_3$.

1α-hydroxylase activity is decreased by fibroblast growth factor 23 (FGF23), which is produced by osteocytes in response to high phosphate in CKD. (FGF23 increases phosphate excretion in the urine by downregulation of the sodium–phosphate co-transporter in the proximal tubule and decreases intestinal phosphate absorption). FGF23 is increasingly recognized as a possible mediator of bone mineral disease in CKD.

Both 1,25-dihydroxycholecalciferol and 25-hydroxycholecalciferol are degraded in part by being hydroxylated at position 24 by 24-hydroxylase. The activity of this enzyme is reduced by PTH and increased by 1,25-$(OH)_2D_3$ (which therefore promotes its own inactivation).

Reduced 1α-hydroxylase activity in CKD leads to relative deficiency of 1,25-$(OH)_2D_3$. As a result, gastrointestinal calcium and, to a lesser extent, phosphate absorption are reduced, and bone mineralization is impaired. Reduced gut calcium absorption leads to hypocalcaemia sensed by a specific calcium-sensing receptor (CaSR) on parathyroid glands, which in turn induces release of PTH. Reduced receptor binding alters the set-point for release of PTH when serum calcium falls. This combination contributes to the (common) hyperparathyroidism seen in patients with CKD.

Autocrine function

Prostaglandins

Prostaglandins are unsaturated, oxygenated fatty acids, derived from the enzymatic metabolism of arachidonic acid, mainly by constitutively expressed cyclo-oxygenase-1 (COX-1) or inducible COX-2. COX-1 is highly expressed in the collecting duct, while COX-2 expression is restricted to the macula densa. Both COX isoforms convert arachidonic acid into prostaglandin E_2 (PGE_2) in the collecting duct (leading to a natriuresis/diuresis); prostacyclin (PGI_2), and thromboxane A_2, a vasoconstrictor, are mainly synthesized in the glomerulus. These all maintain kidney blood flow and GFR in the face of vasoconstrictors such as angiotensin II, catecholamines, and α-adrenergic stimulation. Inhibition of prostaglandin synthesis by NSAIDs results in a fall in GFR, sometimes sufficient to cause AKI, particularly in the elderly, and in volume depletion, particularly when ACE inhibitors or AII-RAs are also used.

Nitric oxide

Nitric oxide, a molecular gas, is formed by the action of three isoforms of nitric oxide synthase (NOS), all of which are expressed in the kidney: eNOS is found in vessels, nNOS mainly in the macula densa and inner medullary collecting duct, and iNOS in several tubule segments. Nitric oxide binds soluble guanylate cyclase, enhancing the synthesis of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP), and mediates the following physiological actions in the kidney:

- regulation of kidney perfusion and glomerular pressure
- natriuresis, by inhibiting Na^+/K^+-ATPase and NHE3
- antagonism of AVP
- modulation of tubuloglomerular feedback.

INVESTIGATION OF KIDNEY AND URINARY TRACT DISEASE

The kidneys have a great deal of reserve; as a result, early stages of CKD are often asymptomatic, even as renally cleared metabolites begin to accumulate. It is not clear which metabolites

lead to specific symptoms, but products of protein catabolism (nitrogenous waste products) are thought to be important. These metabolites, also called uraemic toxins, must have a small molecular size since haemodialysis, which clears only relatively small molecules, improves symptoms. Little else is known with certainty.

Serum urea and creatinine concentrations are measured in CKD as surrogates of accumulating uraemic toxins because measurement is easy, and there is a rough correlation between urea and creatinine concentrations and symptoms. However, these substances are not particularly toxic in themselves.

Examination of the urine

Unless urine is visibly bloody (or cola-coloured, in cases of myoglobinuria or haemoglobinuria), macroscopic inspection of the urine is not helpful. Cloudy, offensive-smelling urine may denote infection, but this is not specific or sensitive and should be confirmed on culture.

Volume

Healthy adults will pass between 800 and 2500 mL of urine per 24 hours (roughly 1 mL/kg per hour). Usually, the minimum urine output capable of maintaining solute excretion for health (without accumulation) is around 650 mL per day. If the kidney loses concentrating capacity (as occurs in CKD or diabetes insipidus), higher urine volumes are needed for the same daily solute output, and urine outputs may increase well above 2500 mL. High daily volumes are also seen with glycosuria or increased protein catabolism following surgery, as the solute load requiring excretion is higher. ***Nocturia*** is a symptom of kidney disease as patients without the ability to concentrate solute into a small urine volume will wake needing to pass urine during the night.

Dipsticks (chemical testing)

Dipsticks are cheap and hugely helpful in the initial investigation of suspected kidney disease, using reagents fixed on pads that change colour on reacting with specific elements in urine.

Specific gravity and osmolality

Urine specific gravity (SG, where <1.008 is dilute and >1.020 is concentrated) is a measure of the weight of dissolved particles in urine, reflecting urine osmolality. Measurement of urine SG or osmolality can be helpful in confirming loss of concentrating ability. It can also be helpful in oliguric patients, when a high SG might suggest prerenal AKI, as opposed to established acute tubular necrosis (ATN) (see Chapter 27).

Urinary pH

Measurement of urinary pH (usually 5.5–6.5) is helpful in the investigation and treatment of renal tubular acidosis (see Chapter 27, 'Renal tubular acidosis' section).

Blood

Haematuria may come from any site within the urinary tract (Fig. 26.6):

- ***Overt bleeding from the urethra*** is suggested when blood is seen at the start of voiding and then the urine becomes clear.
- ***Blood diffusely present*** throughout the urine usually comes from the bladder or above.
- ***Blood only at the end of micturition*** suggests bleeding from the prostate or bladder base.

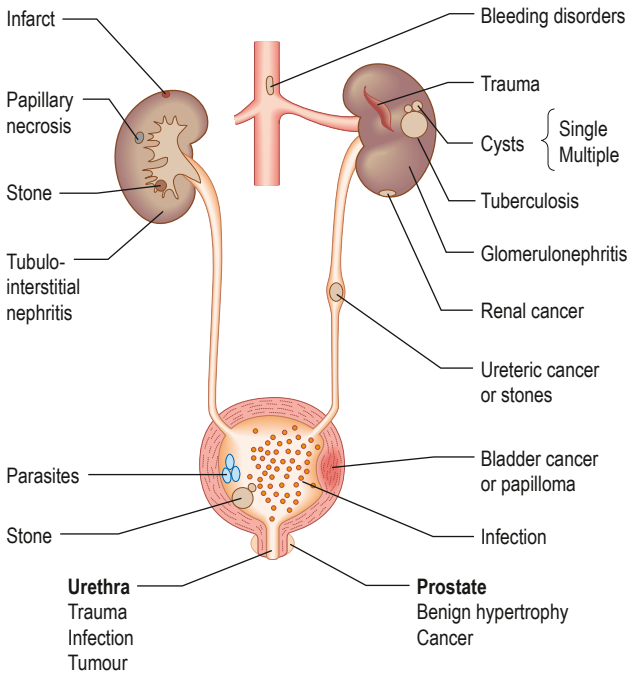

Fig. 26.6 Sites and causes of haematuria.

Females will commonly have dipstick-positive haematuria during a period; it is usually worth repeating testing after menstruation.

Once it is found on dipstick, a mid-stream sample can be spun at 2000 rpm and examined for red cells or casts on microscopy. Red cells (usually 1–2 per high-power field) are dysmorphic (altered in shape) if they originate from the early nephron (glomerular bleeding) and may be accompanied by red-cell casts. Casts are cylindrical bodies, moulded in the shape of the distal tubular lumen. Red-cell casts—even if only single—are suggestive of glomerulonephritis. A dipstick that is strongly positive for haematuria with no red cells seen on microscopy suggests haemoglobinuria or myoglobinuria.

Protein

Proteinuria is a common sign of kidney disease; normal excretion is less than 150 mg per day. Dipsticks will detect proteinuria from around 50 to 150 mg/L. If two separate urine samples find proteinuria on dipstick testing, a random urine protein:creatinine ratio (uPCR) should be measured. This convenient test has replaced timed 24-hour urine collections for proteinuria. An alternative is the albumin:creatinine ratio (uACR). As albumin is usually the dominant protein lost in the urine, patients who have albuminuria always have proteinuria (and uPCR will be higher than uACR). For people with diabetes, the urine ACR has prognostic significance and is the preferred screening test for ***microalbuminuria*** in early diabetic kidney disease. Both tests are expressed as mg protein per mmol creatinine. Generally, an uACR of 2.5 to 20 mg/mmol corresponds to albuminuria of 30 to 300 mg daily (crudely, multiply the result by 15 to approximate excretion in 24 h). Similarly, uPCR of 3 to 30 mg/mmol corresponds to urine protein excretion of 30 to 300 mg per day (multiply by a factor of 10). The uPCR assay is relatively cheap and identifies patients with both tubular and glomerular proteinuria. uACR or uPCR concentrations independently predict all-cause and cardiovascular mortality in the general population and allow risk stratification of patients with CKD for future kidney outcomes. Pyrexia, exercise, and an upright posture ***(postural proteinuria)*** all

increase urinary protein output but are benign. ***Urine electrophoresis and immunofixation*** are needed to detect light chains, which can be present in myeloma without a detectable serum paraprotein.

Electrolytes

Urinary electrolytes are unhelpful in CKD. The use of urinary sodium concentration in the distinction between pre-renal and intrinsic kidney disease is discussed in Chapter 27 ('Decreased extracellular volume' section).

Glucose

Glycosuria is uncommon, so a positive test for glucose should trigger diagnostic testing for diabetes mellitus.

Bacteria and pus cells

Dipstick tests for bacteriuria are based on the detection of ***nitrite*** produced from the reduction of urinary nitrate by bacteria, and on the detection of leucocyte esterase, an enzyme specific for neutrophils. Both tests have limitations. When positive, a mid-stream sample should be sent for microscopy, culture, and sensitivity (MC&S).

White blood cells (WBCs) and bacteria may be seen on microscopy. Urine tract infection (UTI) is suggested by 10 WBCs/mL or more in fresh mid-stream urine sample. However, not all pyuria is a UTI, and WBCs are also seen with kidney stones, tubulointerstitial nephritis, papillary necrosis, tuberculosis, and interstitial cystitis. White cell casts may occur.

Blood tests

The use of serum urea, creatinine, and GFR as measures of kidney function is discussed earlier (see 'Glomerular filtration rate' section). A general assessment of kidney disease might include the following:

Serum biochemistry

- Serum urea, electrolytes, and bicarbonate.
- Serum creatinine, with calculation of eGFR.
- Electrophoresis and immunofixation with serum-free light chains for myeloma.
- Calcium, phosphate, alkaline phosphatase, PTH, liver function, creatine kinase, lactate dehydrogenase.
- Blood glucose and HbA1C.

Haematology

- Full blood count, blood film, and ESR.
- Tests for sickle cell disease if relevant.

Immunology

- ***Complement components:*** low in active kidney disease due to systemic lupus erythematosus (SLE), mesangiocapillary glomerulonephritis, post-streptococcal glomerulonephritis, and cryoglobulinaemia.
- ***Autoantibody screening:*** SLE (e.g., ANA, anti-dsDNA), scleroderma (e.g., anti-Scl-70, anti-centromere, anti-RNA polymerase III), granulomatosis with polyangiitis and microscopic polyangiitis (e.g., c-ANCA, p-ANCA), Goodpasture's syndrome (anti-GBM). Anti-phospholipase A2 receptor antibodies in membranous nephropathy.
- ***Cryoglobulins*** in mesangiocapillary glomerulonephritis.
- ***Antibodies to streptococcal antigens*** (antistreptolysin O titre (ASOT), anti-DNAse B) if post-streptococcal glomerulonephritis (PSGN) is possible.
- ***Antibodies to hepatitis B and C*** may point to polyarteritis or membranous nephropathy (hepatitis B) or cryoglobulinaemic kidney disease (hepatitis C).
- ***Antibodies to HIV*** in HIV-associated kidney disease.

Imaging techniques

Ultrasonography

Ultrasound of the kidneys and bladder is safe and non-invasive, avoiding ionizing radiation and intravascular contrast medium. It is the imaging method of choice for:

- Assessing kidney size and symmetry. Normal-sized kidneys with abnormal function may suggest an acute cause. Kidneys scar as they fail and may shrink in length and volume.
- Ruling out obstruction, either of the bladder (bilateral hydronephrosis), ureters (unilateral hydronephrosis), or the kidney itself (pelvicalyceal dilation due to high ureteric or renal pelvis disease).
- Characterizing kidney masses as cystic (simple cysts, polycystic kidneys) or complex/solid (benign/malignant kidney tumours, infected collections).
- Guiding interventions aimed at relieving obstruction (percutaneous nephrostomy).
- ***Doppler ultrasonography (duplex)*** for confirming renal vein patency. Doppler for arterial disease in native kidneys is often unreliable.
- Bladder assessment: tumours, stones, post-micturition volume to assess bladder emptying.
- Contrast-enhanced ultrasound using gas-filled microbubbles may offer better visualization of organs and blood vessels.

Computed tomography

Unenhanced computed tomography (CT) is the first-line investigation for ***ureteric colic*** and suspected kidney calculi. It has superseded excretion urography (intravenous urography [IVU]/intravenous pyelography [IVP]). It is also used to:

- characterize kidney masses that are indeterminate on ultrasound imaging
- stage kidney and bladder tumours
- evaluate the retroperitoneum for tumours, retroperitoneal fibrosis (peri-aortitis), and other causes of ureteric obstruction
- assess kidney trauma
- visualize the renal arteries and veins with angiography.

Positron emission tomography (PET), using ^{18}F-fluorodeoxyglucose (FDG), is useful for detection of infection (e.g., in a cyst), inflammation, or tumours, and is often used in conjunction with CT (PET-CT).

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is used as an alternative to CT with no irradiation:

- to stage prostate (and renal and bladder) cancer
- to reconstruct the anatomy of the renal arteries using magnetic resonance ***angiography*** (MRA) with gadolinium contrast

Care is advised with gadolinium in patients with kidney insufficiency (eGFR < 30/mL) because of the risk of nephrogenic systemic fibrosis. However, with newer gadolinium-based contrast agents (e.g., gadobenate dimeglumine, gadoteridol, gadoterate meglumine, and gadobutrol), the risk for NSF is exceedingly low and the potential harm of withholding indicated diagnostic investigation may outweigh risk.

Plain radiography (X-ray)

A plain radiograph of the abdomen may be useful to identify kidney calcification or radiodense calculi in the kidney, renal pelvis, and the line of the ureters or bladder (Fig. 26.7).

Micturating cystourethrography

After bladder catheterization, contrast is instilled into the bladder. The catheter is then removed, and the patient screened during voiding to check for vesico-ureteric reflux and to study urethra and bladder emptying. It may be useful in children with recurrent urinary tract infection.

Aortography or renal arteriography

Conventional or digital subtraction angiography (DSA) has largely been replaced by CT or MR angiography. It may be used if fibromuscular dysplasia (FMD) suspected, to allow simultaneous therapeutic intervention.

Renal scintigraphy

Isotope studies are helpful for dynamic or static investigation of perfusion or excretion. Following venous injection of a bolus of tracer, emissions from the kidney are recorded by gamma camera. Technetium-labelled diethylenetriaminepenta-acetic acid (^{99m}Tc-DTPA) is excreted by glomerular filtration and can be used to confirm kidney perfusion. Dimercaptosuccinic acid labelled with technetium (^{99m}Tc-DMSA) is filtered by the glomerulus and then binds to proximal tubular cells. It is used in static studies and is useful to assess the relative contribution of function from asymmetric kidneys, and to highlight 'photon-deficient' areas (isotope not seen) suggestive of scars or infarction. Mercaptoacetyltriglycine (MAG3) labelled with technetium (^{99m}Tc) is excreted by tubular secretion, so resistance to flow in the pelvis or ureter (with obstruction) prolongs parenchymal transit. On whole-kidney renograms, the time–activity curve fails to fall after an initial peak, or continues to rise (Fig. 26.8), confirming hold-up to flow. Furosemide may be given to exaggerate urine output and emphasize delay to aid diagnosis.

Transcutaneous kidney biopsy

Kidney biopsy (Box 26.5) is carried out under ultrasound guidance and requires interpretation by a specialist pathologist. It is helpful in the investigation of the nephritic and nephrotic syndromes, acute and chronic kidney disease, haematuria after normal urological investigations, and kidney transplant dysfunction. Native kidney biopsy material is examined by conventional histochemical staining, by electron microscopy, and by immunoperoxidase or immunofluorescence. Techniques like *in situ* hybridization and polymerase chain reaction (PCR) analysis are also widely used. The complications of transcutaneous kidney biopsy are shown in Box 26.6.

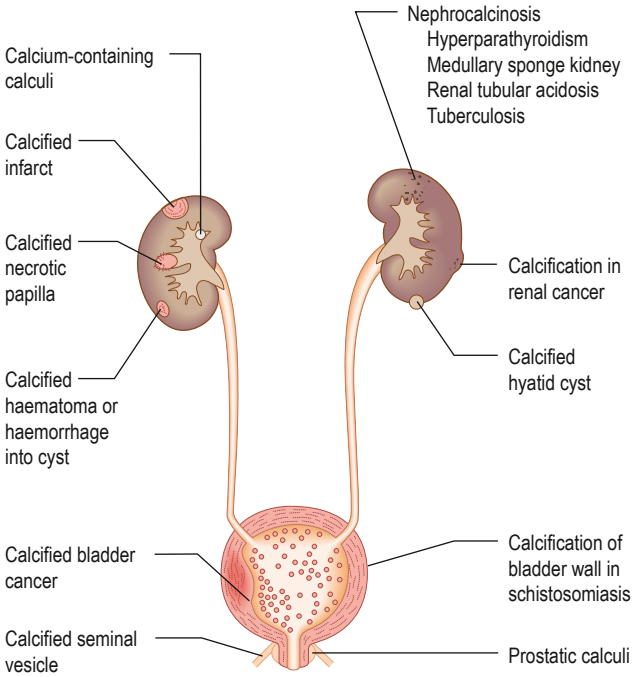

Fig. 26.7 Calcification in the kidney and urinary tract. Calculi can occur at any site.

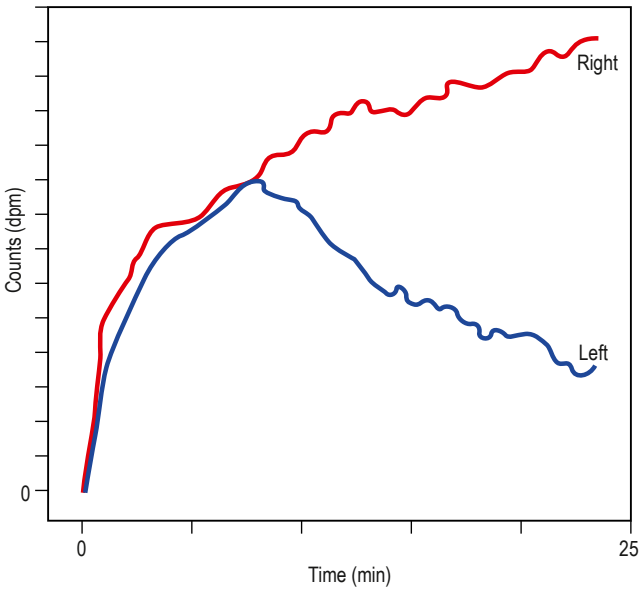

Fig. 26.8 Dynamic scintigram. Note the progressive rise of the right kidney curve to a plateau (in contrast to the normal left kidney curve) due to right-sided urinary tract obstruction.

THE GLOMERULUS AND GLOMERULAR DISEASE

The glomerular filtration barrier allows or prevents filtration in the glomerulus. It consists of the fenestrated endothelium, the GBM, and the terminally differentiated visceral epithelial cells known as podocytes (Figs. 26.2 and 26.9). Podocytes attach to the GBM by foot processes via adhesion molecules, such as $\alpha_3\beta_1$ and dystroglycans. Adjacent podocytes are joined laterally via their foot process by slit diaphragms. The various proteins comprising the slit diaphragm include nephrin, CD2-associated protein (CD2AP), canonical transient receptor potential channel 6 (TRPC6), podocin, P-cadherin, α- and β-catenin, and zonula occludens-1 (ZO-1). They co-localize within the subcellular domain to function as a molecular sieve. These proteins, in addition to providing structural support to the cytoskeletal proteins like filamentous actin, also provide signalling to maintain normal podocyte function. Abnormalities in any of these proteins result in the breakdown of the filtration barrier and consequent leak of macromolecules.

Box 26.5 Transcutaneous kidney biopsy

Before biopsy

- Check blood pressure, platelet count, and clotting are safe for biopsy
- Group and save for crossmatch if needed.
- Informed consent including benefits, risks, and other options if biopsy not performed.

Biopsy

- Patient lies prone with a pillow under the abdomen.
- Localize the kidney by ultrasound.
- Inject local anaesthetic along the planned biopsy track.
- Instruct the patient to hold a breath (prevent kidney movement) when biopsy is performed

After biopsy

- Apply dressing to the biopsy site.
- Bedrest after procedure, usually for at least 6 h.
- Monitor heart rate and blood pressure regularly.
- Advise the patient to represent for urgent care if macroscopic haematuria or symptoms of hypotension.

Box 26.6 Complications of transcutaneous kidney biopsy

- Macroscopic haematuria (up to 10%)
- Flank pain, can refer to shoulder tip
- Perirenal haematoma
- Arteriovenous aneurysm formation (approximately 20%), almost always of no clinical significance
- Profuse haematuria requiring transfusion (1%–3%)
- Profuse haematuria requiring radiological (embolization) or surgical (nephrectomy) intervention (approximately 1 in 400)
- Infection
- Mortality (approximately 0.1%)

Podocyte changes

The podocyte structure is maintained by actin, which supports the cytoskeleton. A rearrangement of the actin cytoskeleton leads to foot process effacement (flattening) and albumin leaks into the urine (Fig. 26.9). Recovery of the cytoskeleton reverses proteinuria. The cytoskeleton can be altered by:

- abnormalities of cytoskeletal proteins, e.g., α-actinin-4 mutations in hereditary focal segmental glomerular sclerosis
- injury to or abnormalities of slit diaphragm proteins
- changes in the GBM
- direct injury to podocytes by viral infection, drugs, toxins, or local activation of renin–angiotensin.

Glomerular disease

Glomerular disease is the third most common cause (after diabetes and hypertension) of kidney disease requiring renal replacement (end-stage kidney disease [ESKD]) in Europe and the USA, accounting for 10% to 15% of such patients. Glomerular diseases are characterized by:

- either immunologically mediated inflammatory glomerular injury or structural/functional glomerular damage without inflammation
- associated interstitial damage
- symmetrical kidney involvement
- secondary mechanisms of glomerular injury including fibrin deposition, platelet aggregation, neutrophil infiltration, and free radical-induced damage
- haemodynamic consequences that further disturb glomerular function.

Describing glomerular disease

The nomenclature relating to glomerular disease can be confusing, as descriptive histological terms overlap with clinical syndromes and more recent molecular insights into pathogenesis. Glomerular disease is usually described by kidney biopsy findings. Commonly used terms are shown in Box 26.7. If there is predominant inflammation, glomerular disease is described as a ***glomerulonephritis***. If inflammation is absent, the term ***glomerulopathy*** is used. There remains much overlap and the terms are often (wrongly) used interchangeably. It may be better to think about glomerular disease in terms of the component of the GBM that is predominantly affected:

- **Podocytes** (in the urinary compartment) are principally involved in glomerular diseases (usually glomerulopathies) that present as the ***nephrotic syndrome*****.**
- **Endothelial and mesangial cells** (in the endocapillary compartment) are principally involved in glomerular disease presenting as ***nephritis*** (glomerulonephritis), where haematuria, proteinuria, and often hypertension are evident.
- Podocytes, endothelial, and mesangial cells may be equally involved if a glomerulonephritis causes nephrosis.

Clinical classification of glomerular disease is also often used, although there is no complete correlation between histopathological types and clinical features. Four major glomerular syndromes are described:

- ***Nephrotic syndrome:*** proteinuria (>3.5 g/day), hypoalbuminaemia, oedema, lipiduria, and hyperlipidaemia. Podocyte malfunction or injury is often causative.
- ***Glomerulonephritis (nephritic syndrome)*** presents as one of:
  - ***Acute glomerulonephritis:*** abrupt onset glomerular haematuria (red blood cell casts or dysmorphic red blood cells), non-nephrotic-range proteinuria, oedema, hypertension, and transient kidney impairment
  - ***Rapidly progressive glomerulonephritis:*** features of acute nephritis, focal necrosis with or without crescents, and rapidly progressive kidney failure over weeks
- ***Mixed nephritic/nephrotic presentations:*** where glomerulonephritis is part of a systemic disease (e.g., lupus nephritis, cryoglobulinaemia, Henoch–Schönlein purpura), a nephritic syndrome is often associated with the nephrotic syndrome.
- ***Asymptomatic haematuria, proteinuria***, or both.

Investigation of glomerular diseases is shown in Box 26.8.

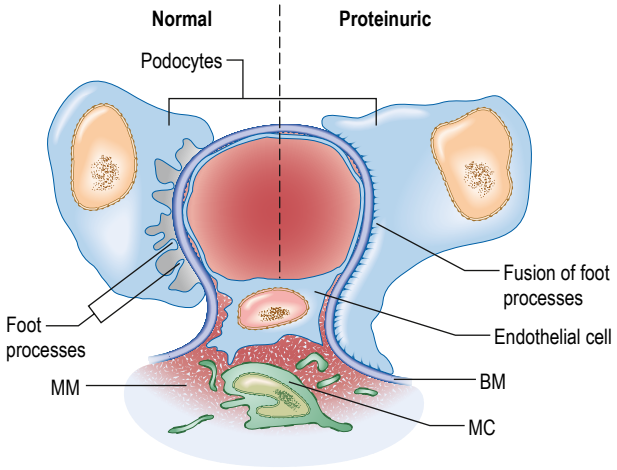

Fig. 26.9 A normal *(left)* and a proteinuric *(right)* glomerulus. A capillary loop shows normal glomerular morphology *(left)* including podocytes with pseudopodia (foot processes). In proteinuria *(right)*, fusion of foot processes is characteristic of many diseases. *BM,* Basement membrane; *MC,* mesangial cell; *MM,* mesangial matrix.

Box 26.7 Glomerular disease: commonly used terms

- ***Focal:*** some, but not all, glomeruli have the lesion
- ***Diffuse*** (global): most glomeruli (>75%) have the lesion
- ***Segmental:*** part, not all, of the glomerulus is affected (most focal lesions are also segmental, e.g., focal segmental glomerulosclerosis)
- ***Global:*** all glomeruli are symmetrically involved
- ***Proliferative:*** an increase in cell numbers due to hyperplasia of one or more of the resident glomerular cells with or without inflammation
- ***Membrane alterations:*** capillary wall thickening due to deposition of immune deposits or alterations in basement membrane
- ***Crescent formation:*** epithelial cell proliferation with mononuclear cell infiltration in Bowman's space

Box 26.8 Investigation of glomerular diseases

Investigations	Positive findings
Urine microscopy	Red cells, red-cell casts
Urinary protein	Nephrotic or sub–nephrotic-range proteinuria quantified by uACR or uPCR
Serum urea	May be increased
Serum creatinine	May be increased
Culture (throat swab, discharge from ear, swab from inflamed skin)	Nephritogenic organism (not always detected)
Antistreptolysin-O titre	Elevated in post-streptococcal nephritis
C3 and C4 concentrations	May be reduced
Antinuclear antibody (ANA)	Significant titre in systemic lupus erythematosus
Antinuclear cytoplasmic antibody (ANCA)	Positive in some vasculitides
Anti-glomerular basement membrane (anti-GBM)	Positive in anti-GBM disease (Goodpasture's syndrome)
Cryoglobulins	Increased in cryoglobulinaemia
Chest radiograph	Cardiomegaly, pulmonary oedema, pulmonary haemorrhage
Kidney imaging	Usually structurally normal renal tract
Kidney biopsy	Diagnosis of glomerulopathy

Nephrotic syndrome

Nephrotic syndrome is characterized by:

- hypoalbuminaemia
- >3.5 g proteinuria/day
- hyperlipidaemia
- salt and water retention, leading to oedema.

Pathophysiology

Hypoalbuminaemia

Loss of 3.5 g or more of urinary protein (largely albumin) per day leads to hypoalbuminaemia. Normal dietary protein intake in the UK is around 70 g daily and the normal liver can synthesize albumin at a rate of 10 to 12 g daily. How, then, does a daily urinary protein loss of 3.5 g result in hypoalbuminaemia? This can be partly explained by increased catabolism of reabsorbed protein, largely albumin, in the proximal tubules, even though the rate of albumin synthesis is increased.

Proteinuria

Proteinuria occurs due to the pathology of the glomerular barrier (podocytes, basement membrane, fenestrated endothelium, endothelial charge) allowing passage of more and larger molecules.

Hyperlipidaemia

Increased synthesis of lipoproteins (such as apolipoprotein B, C-III lipoprotein (a)) occurs as a direct consequence of a low plasma albumin. Low-density lipoprotein (LDL) increases, partly due to upregulation of a liver serine protease, ***pro-protein convertase subtilisin kexin-9 (PCSK9)***, which causes internalization of LDL receptors. There is no change (or a decrease) in high-density lipoprotein (HDL), meaning an increased LDL:HDL ratio. Very-low-density lipoprotein (VLDL) and/or intermediate-density lipoprotein (IDL) fractions also increase. Reduced clearance of the principal triglycerides bearing lipoprotein (chylomicrons and VLDL), as high plasma concentrations of free fatty acid (FFA) trigger release of appropriately sialylated angiopoietin-like 4 (ANGPTL4) protein from adipose tissue, heart, and skeletal muscles, inhibits lipoprotein lipase and results in hypertriglyceridaemia.

Oedema in hypoalbuminaemia

See Chapter 27 ('Increased extracellular volume' section).

Management

General measures

- ***Initial management*** should be with dietary sodium restriction and a loop diuretic (e.g., furosemide or bumetanide). There is little consensus on diuretic use in the nephrotic syndrome, but by convention unresponsive patients require the addition of a synergetic thiazide-like diuretic (such as metolazone) or an ENaC inhibitor such as amiloride. Nephrotic patients may malabsorb diuretics (as well as other drugs) owing to gut mucosal oedema, and intravenous administration may be needed. Patients are sometimes hypovolaemic, and moderate oedema may have to be accepted to avoid postural hypotension.
- ***Normal protein intake*** is advisable. A high-protein diet (80–90 g protein daily) increases proteinuria, which may be harmful in the long term.
- ***Hypercoagulable states*** predispose to venous thrombosis. The hypercoagulable state is due to an imbalance between naturally occurring pro-coagulant/pro-thrombotic factors (accelerated activated intrinsic pathway, fibrinogen, platelet function, and fibrin–platelet interaction) and anticoagulant/antithrombotic factors (reduced activity of antithrombin III, protein S and C) which promotes in situ thrombosis in deep veins or arteries. Prolonged bed rest should be avoided, as thromboembolism is common (particularly in membranous nephropathy). Long-term prophylactic anticoagulation may be indicated, and if renal vein thrombosis occurs, treatment dose anticoagulation is required.
- ***Sepsis*** is a major cause of death in nephrotic patients. Increased susceptibility to infection is partly due to loss of immunoglobulin in the urine. Pneumococcal infections are particularly common and pneumococcal vaccine should be given. Early detection and aggressive treatment of infections, rather than long-term antibiotic prophylaxis, constitute the best approach.
- ***Lipid abnormalities*** are responsible for an increase in the risk of cardiovascular disease in patients with proteinuria. Treatment of hypercholesterolaemia starts with an HMG-CoA reductase inhibitor ('statin').
- ***ACE inhibitors and/or angiotensin II receptor antagonists*** (AII-RAs) are indicated for their antiproteinuric properties in all

types of glomerulonephropathy. They reduce proteinuria by lowering glomerular capillary filtration pressure (a fall in efferent tone decreases the transglomerular capillary pressure) and therefore protein loss into the urinary space.

- ***SGLT-2 inhibitors*** may delay CKD progression and reduce proteinuria in kidney conditions associated with nephrotic-range proteinuria, with emerging evidence of disease-specific benefit.

Specific measures

Treat the underlying cause of urinary protein leak. **Box 26.9** shows the glomerular lesions commonly associated with the nephrotic syndrome.

Non-nephrotic range proteinuria

In asymptomatic patients, isolated proteinuria without haematuria is often an incidental finding. It is usually less than 1 g/day with normal kidney function. Over 50% of these patients have (benign) postural proteinuria, although it may be an early sign of a serious glomerular lesion such as membranous glomerulopathy, IgA nephropathy, FSGS, diabetic nephropathy or amyloidosis (see later). Mild and transient proteinuria may also accompany a febrile illness, congestive heart failure, or infectious diseases with no clinical significance.

Causes of proteinuria and nephrotic syndrome

Minimal-change nephropathy (minimal-change disease)

The name is derived from the fact that glomeruli appear normal on light microscopy (**Fig. 26.10**). However, on electron microscopy there is fusion of podocyte foot processes. Neither immune complexes nor anti-GBM antibody can be demonstrated by immunofluorescence.

Underlying pathophysiological mechanisms include:

- Immature differentiating CD34 stem cells (rather than mature T lymphocytes)
- Interleukin-13 (IL-13) affecting podocyte function
- Vascular endothelial growth factor (VEGF) production
- Upregulation of vascular hyposialylated-angiopoietin-like 4 (ANGPTL4)
- Atopy is present in 30% of cases of MCN, and allergic reactions can trigger nephrosis
- Drugs: NSAIDs, lithium, antibiotics (cephalosporins, rifampicin, ampicillin), bisphosphonates, and sulfasalazine
- Infection: hepatitis C virus, HIV, tuberculosis

Clinical features

MCN is responsible for most nephrotic syndrome in childhood. Proteinuria is usually 'highly selective': albumin is lost in the urine but not higher-molecular-weight proteins such as immunoglobulins. Oedema is usual and may present periorbitally. The condition accounts for 20% to 25% of cases of adult nephrotic syndrome. It is often regarded as a condition that does not lead to CKD (but see focal segmental glomerulosclerosis later).

Management

- Manage symptoms with general measures (see earlier).
- High-dose corticosteroid therapy with prednisolone 60 mg/m^2 daily (up to a maximum of 80 mg/day) for a maximum of 4 to 6 weeks, followed by 40 mg/m^2 every other day for a further 4 to 6 weeks reverses proteinuria in more than 95% of children. Response rates in adults are lower and response may occur only after many months. Spontaneous remission also occurs, and steroid therapy is usually withdrawn/withheld if urinary protein loss is insufficient to cause hypoalbuminaemia and oedema. In both children and adults, if remission lasts for 4 years after discontinuing steroid therapy, further relapse is rare.
- Two-thirds of children relapse after steroid therapy and further courses of corticosteroids are required. One-third of these patients regularly relapse on steroid withdrawal, so that a second-line agent should be added after repeat induction with steroids.
- Ciclosporin or tacrolimus may be effective (with or without steroids) but must be continued long-term to prevent relapse on stopping treatment. The antiproteinuric effect of these calcineurin inhibitors is normally attributed to its immunosuppressive action but may result from the stabilization of the actin cytoskeleton in kidney podocytes. Ciclosporin inhibits the calcineurin-mediated dephosphorylation of synaptopodin (a regulator of actin cytoskeleton) and protects it from cathepsin L-mediated degradation. These results have shed new light on the role of calcineurin signalling in proteinuric kidney diseases. Excretory function and ciclosporin and tacrolimus blood concentrations must be monitored as both drugs are potentially nephrotoxic.

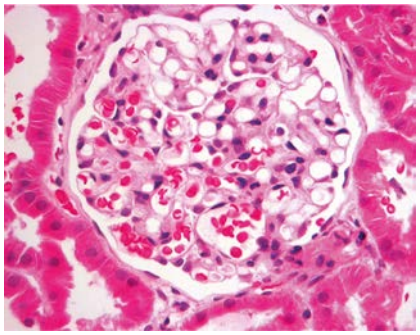

Fig. 26.10 Normal glomerulus on light microscopy in minimal-change nephropathy.

Box 26.9 Glomerulopathies associated with nephrotic syndrome

Clinical syndrome	Primary (kidney) disease	Secondary (systemic) disease
Nephrotic syndrome	Minimal-change nephropathy Congenital nephrotic syndrome Focal segmental glomerular sclerosis Membranous nephropathy	Amyloidosis Diabetic nephropathy
Mixed nephrotic/nephritic	Mesangiocapillary glomerulonephritis Mesangial proliferative glomerulonephritis	Systemic lupus erythematosus Cryoglobulinaemic disease Henoch–Schönlein syndrome Idiopathic fibrillary glomerulopathy Immunotactoid glomerulopathy Fibronectin glomerulonephropathy

- Rituximab, a depleting monoclonal antibody directed against CD20 on B lymphocytes, is increasingly used in steroid-unresponsive and frequently relapsing disease.
- Cyclophosphamide 1.5 to 2.0 mg/kg/day for 8 to 12 weeks with prednisolone 7.5 to 15 mg/day increases the likelihood of long-term remission. Steroid-unresponsive patients may respond. No more than two courses of cyclophosphamide should be prescribed in children because of the risk of side-effects, which include future infertility (azoospermia and premature ovarian failure).
- In corticosteroid-dependent children, the anthelminthic agent levamisole 2.5 mg/kg to a maximum of 150 mg on alternate days is also useful in maintenance of remission. Levamisole's mode of action is attributable to its direct effects on podocytes by inducing expression of glucocorticoid receptor (GR) and activated GR signalling in podocytes.

Congenital nephrotic syndrome

Congenital nephrotic syndrome (Finnish type) is an autosomal recessively inherited disorder due to mutations in the gene coding for a transmembrane protein, nephrin. Incidence is 1 in 8200 in Finland. Nephrin is a critical element of the filtration slit, and its loss of function results in massive proteinuria shortly after birth. The disorder can be diagnosed *in utero*, as increased α-fetoprotein in amniotic fluid is a common feature. This condition is characterized by relentless progression to ESKD. Other inherited nephrotic syndromes involve mutations in genes that encode other podocyte proteins, such as podocin, α-actinin 4, and Wilms' tumour suppressor gene. Congenital nephrotic syndrome patients are steroid-resistant. Mutation analysis in steroid-resistant nephrotic syndrome (SRNS) has identified more than 30 recessive or dominant genes, revealing the encoded proteins that are essential for glomerular function. Mutation analysis could be offered to all individuals who manifest with SRNS before the age of 25 years, for diagnosis and for exploration of possible therapies, as it may permit personalized treatment options based on genetic causation by way of 'precision medicine'.

Focal segmental glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) describes a sclerotic glomerular lesion that affects some but not all glomeruli (focal), and some but not all segments of each tuft (segmental).

- ***Primary FSGS*** is an unusual primary cause of the nephrotic syndrome.
- ***Secondary FSGS*** looks similar on light microscopy. Although proteinuria may be heavy, hypoalbuminaemia is *unusual.*

Primary focal segmental glomerulosclerosis

This disease usually presents with massive proteinuria (usually non-selective), haematuria, hypertension, and kidney impairment. The associated nephrotic syndrome is often resistant to steroid therapy. All age groups are affected. It usually recurs in transplanted kidneys, sometimes within days of transplantation, and particularly in patients with aggressive primary kidney disease.

Aetiology

A circulating permeability factor causes the increased protein leak: plasma from patients increases membrane permeability in isolated glomeruli. Kidneys transplanted into murine models of FSGS develop the lesion, but kidneys from FSGS-prone mice transplanted to a normal strain are protected. Removal of this factor by plasmapheresis results in transient amelioration of proteinuria. The identity of the permeability factor remains unknown but recent findings suggest that cardiotrophin-like cytokine 1 is a likely candidate. Soluble urokinase-like plasminogen activator receptor (SuPAR) was initially thought to be involved but now appears less likely based on recent experimental and clinical evidence.

Pathology

Segmental glomerulosclerosis is seen on light microscopy, which later progresses to global sclerosis. The deep glomeruli at the corticomedullary junction are affected first. These may be missed on transcutaneous biopsy, leading to a mistaken diagnosis of MCN (see earlier). A pathogenetic link may exist between MCN and FSGS, as a proportion of cases classified as having the former condition develop progressive CKD, which is unusual. Electron microscopy demonstrates primarily foot process effacement, occasionally in a patchy distribution. The degree of podocyte foot process effacement on electron microscopy can help distinguish between 'primary' and 'secondary' FSGS. If severe foot process effacement is present in normal and sclerosed glomeruli on electron microscopy, primary FSGS is more likely (this is not the case if foot process effacement is largely localized to sclerosed glomeruli alone).

Five histological variants of FSGS exist:

- ***Classic FSGS*** (Fig. 26.11A): the involved glomeruli show sclerotic segments in any location of the glomerulus.
- ***Tip FSGS/glomerular tip lesion*** (Fig. 26.11B): segmental sclerosis at the tubular pole of all affected glomeruli at a very early stage. These patients have a more favourable response to steroids and the disease runs a more benign course.
- ***Collapsing FSGS*** (Fig. 26.11C): podocytes are usually enlarged and coarsely vacuolated with wrinkled and collapsed capillary walls. Commonly seen in HIV infection when it is termed HIV-associated nephropathy (HIVAN; see later).
- ***Perihilar variant*** (Fig. 26.11D): perihilar sclerosis and hyalinosis in more than 50% of segmentally sclerotic glomeruli. Frequently observed with secondary FSGS.
- ***Cellular variant*** (Fig. 26.11E): at least one glomerulus with segmental hypercellularity (proliferation) that occludes the capillary lumen.

Management

- ***Prednisolone*** 0.5 to 2 mg/kg per day in most patients and continued for 6 months before the patient is considered resistant to therapy, which is common.
- ***Ciclosporin or tacrolimus*** may be effective in reducing or stopping urinary protein excretion. Relapse is very common, so long-term use is commonly required.
- ***Rituximab:*** B lymphocyte depletion therapy is an additional strategy used particularly when response to steroids and calcineurin inhibitors is poor. It induces partial and or complete remission in 30% to 50% of cases.
- ***Cyclophosphamide***, ***chlorambucil***, or ***azathioprine.*** In patients with mesangial hypercellularity and tip lesion, cyclophosphamide 1 to 1.5 mg/kg per day with 60 mg of prednisolone for 3 to 6 months, followed by maintenance prednisolone and azathioprine can be used.

About 50% progress to ESKD within 10 years of diagnosis, particularly if resistant to therapy. Recurrence following kidney transplantation is high with a poor prognosis. Plasmapheresis or immunoabsorption has been the mainstay of treatment in patients with post-transplant recurrence with modest results. Anti-CD80/86 (abatacept) has been tried with some success in patients with podocyte upregulation of CD80. Adrenocorticotrophic hormone (ACTH) gel applied topically has been used successfully in refractory cases of post-transplant FSGS.

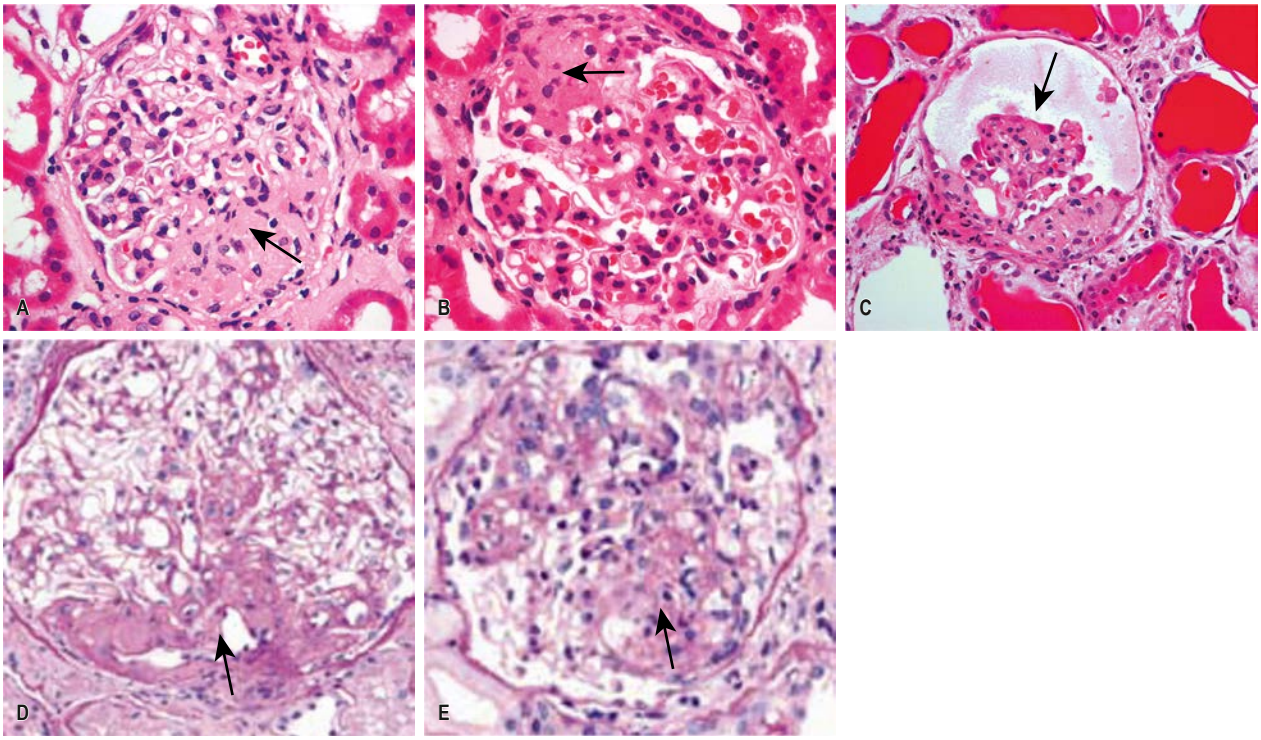

Fig. 26.11 Focal segmental glomerulosclerosis (FSGS). **(A)** Classic FSGS showing sclerotic segments in the glomerulus. **(B)** Glomerular tip lesions showing segmental sclerosis at the pole of the glomerulus. **(C)** Collapsing FSGS. **(D)** FSGS perihilar variant. **(E)** FSGS cellular variant. Arrows show the sclerotic segment in each light micrograph.

Secondary FSGS

Secondary FSGS with similar glomerular changes is seen as a ***secondary phenomenon*** when it occurs due to a reduction in functioning nephron number. In this context, FSGS represents a common final glomerular lesion in response to haemodynamic glomerular strain. As nephrons fail, increased flow through the remaining nephrons leads to glomerular hypertrophy, hyperfiltration, and hydraulic injury with secondary changes of FSGS. Associations include:

- ***reduced nephron number:*** nephrectomy, hypertension, obesity, ischaemia, sickle nephropathy, reflux nephropathy, chronic allograft nephropathy, IgA nephropathy, scarring following renal vasculitis
- ***mutations*** in specific podocyte genes
- ***viruses:*** HIV type 1, erythrovirus B19, cytomegalovirus, Epstein–Barr virus, simian virus 40
- ***drugs:*** heroin, all interferons, anabolic steroids, lithium, sirolimus, pamidronate, calcineurin inhibitors.

APOL1 gene mutations on chromosome 22 (selected due to protection against African trypanosomiasis in patients of African ancestry) are associated with podocyte injury hypothesized due to cationic action in response to insults such as hypertension, SLE, sickle cell trait or disease, HIV, and SARS-CoV-2. In a recent phase 2a clinical study, targeted inhibition of APOL1 channel function with oral inaxaplin reduced proteinuria by 47% in 13 patients with an APOL1 disease allele and FSGS. Results of ongoing trials are awaited.

HIV-associated nephropathy

Glomeruli are characteristically 'collapsed' on light microscopy (Fig. 26.11C): podocytes are enlarged, hyperplastic, and coarsely vacuolated, containing protein absorption droplets and overlying capillaries with varying degrees of wrinkling and collapse of the walls. Direct podocyte HIV-1 infection is associated with loss of podocyte-specific markers such as Wilms' tumour factor and synaptopodin. HIVAN presents with nephrotic-range proteinuria, oedema, and CKD, which can be rapid in progression. Anti-retroviral therapy (ART) may reverse the lesions and restores kidney function if treatment is commenced early.

Membranous glomerulopathy

Autoimmune membranous glomerulopathy occurs mainly in adults. It presents with asymptomatic proteinuria or nephrotic syndrome. Microscopic haematuria, hypertension, and/or kidney impairment may accompany the nephrotic syndrome. In membranous glomerulopathy, one-third of patients undergo spontaneous or therapy-related remission but, as in other glomerular diseases, hypertension and a greater degree of kidney impairment are poor prognostic signs. About 40% develop CKD, usually in association with persistent nephrotic-range proteinuria. Younger people, females, and those with asymptomatic moderate proteinuria at the time of presentation do best.

Pathogenesis

Most patients (75%) with idiopathic or autoimmune membranous nephropathy have been found to have under galactosylated immunoglobulin G4 (IgG4)-type autoantibodies against M type phospholipase A_2 receptor (PLA_2R), a glycoprotein constituent of normal glomeruli. PLA_2R is present in normal human podocytes and in immune deposits in patients with idiopathic membranous nephropathy, indicating that it could be a major autoantigen in this disease. It is linked to human leucocyte antigen (HLA)-DQA1. Other target antigens include:

- thrombospondin type 1 domain-containing 7A (THSD7A) in 3% of PLA_2R-positive and 10% of PLA_2R-negative patients
- exostosin ½ associated with membranous lupus nephritis
- neural epidermal growth factor-like 1 (NELL-1) associated with malignancy and leads to IgG1 co-dominant antibody deposition in the kidney
- serine protease HTRA1
- semaphorin 3B
- protocadherin 7
- netrin G1
- contactin 1
- neural cell adhesion molecule-1
- transforming growth factor beta receptor 3
- neural-derived neurotropic factor
- proprotein convertase subtilisin/kexin type 6 associated with NSAID use.

In secondary membranous nephropathy, where no detectable anti-PLA_2R or glomerular antigen staining can be found, glomerular histology is identical to that seen in autoimmune disease. Causes include:

- drugs, e.g., penicillamine, gold, NSAIDs, probenecid, mercury, captopril
- autoimmune disease, e.g., SLE, thyroiditis
- infection, e.g., hepatitis B, hepatitis C, schistosomiasis, *Plasmodium malariae*
- cancer, e.g., lung, colon, stomach, breast, lymphoma
- other, e.g., sarcoidosis, sickle cell disease.

On light microscopy, capillary loops appear thick. Using a periodic acid–Schiff or silver stain (which highlights basement membrane), 'spikes' of basement membrane are visible. On electron microscopy small, electron-dense deposits in the subepithelial aspects of the capillary walls are seen, encircled by perpendicular basement membrane spikes. Uniform granular capillary wall deposits of PLA_2R antigen and IgG subclasses (IgG4 is predominant in idiopathic membranous nephropathy), as well as complement C3, are seen on immunofluorescence. Late in the disease, deposits are surrounded by basement membrane and are undergoing resorption, which appears as uniform thickening of the capillary basement membrane on light microscopy (Fig. 26.12).

Management

As many as one-third or more of patients will undergo spontaneous remission within 6 to 12 months, particularly if kidney function is normal, anti-PLA_2R antibodies are low in titre, and proteinuria is modest. Patients with heavier proteinuria, progressive kidney dysfunction, and a high titre of anti-PLA_2R antibodies are considered for early treatment. Management includes:

- ACE inhibitors or AII-RAs at the maximum tolerated dose.
- If indicated: anticoagulation to prevent venous thromboembolism, diuretics, statin.
- Rituximab (anti-CD20): effective in autoimmune disease at inducing remission, maintaining or improving kidney function, and reducing proteinuria.
- Cyclophosphamide (1.5–2.5 mg/kg per day for 6–12 months with 1 mg/kg per day of oral prednisolone on alternate days for the first 2 months) OR chlorambucil (0.2 mg/kg per day in months 2, 4, and 6, alternating with oral prednisolone 0.4 mg/kg per day in months 1, 3, and 5).
- Ciclosporin or tacrolimus: treatment courses are longer and relapse is common. In recent trials, rituximab was superior to calcineurin therapy.
- Oral corticosteroids are of no benefit in isolation but may have an additive effect.

Amyloidosis

Amyloidosis is a systemic disorder of protein folding, in which normally soluble proteins or fragments are deposited extracellularly as abnormal, insoluble fibrils (usually β-pleated sheets that are resistant to proteolysis), causing progressive organ dysfunction and death. The disease may be acquired or inherited. Classification is based on the nature of the precursor plasma proteins (at least 20) that form the fibrillar deposits. The most common forms are AL amyloidosis (where abnormal protein may be derived from light chains or immunoglobulin) and AA amyloidosis (where deposits form from serum amyloid A protein). The kidney consequences are similar, even if systemic features differ.

Pathophysiology

AL amyloidosis (immunoglobulin light chain associated)

This is a plasma cell dyscrasia, related to multiple myeloma, in which clonal plasma cells in the bone marrow produce immunoglobulins that are amyloidogenic. This may be the outcome of destabilization of light chains owing to substitution of amino acids into the light chain variable region. There is a clonal dominance of amyloid light (AL) chains—either the dominant κ or γ isotype—which are excreted in the urine (as Bence Jones protein). This type of amyloid may be seen in association with other lymphoproliferative disorders, such as myeloma, Waldenström's macroglobulinaemia, or non-Hodgkin lymphoma. It rarely occurs before age 40 years.

Clinical features are related to the organs involved. As well as nephrotic syndrome, the heart may be affected (presenting with heart failure), and autonomic and sensory neuropathies are relatively common. Carpal tunnel syndrome with weakness and paraesthesia of the hands may be an early feature.

On examination, hepatomegaly and, rarely, splenomegaly, cardiomyopathy, polyneuropathy, and bruising may be seen. Macroglossia occurs in about 10% of cases and periorbital purpura in 15%.

Reactive systemic (secondary AA) amyloidosis

Serum amyloid A (SAA) is an acute-phase protein that rises in response to inflammatory stimuli in a similar way to C-reactive protein (CRP). Deposition is therefore related to chronic inflammatory disorders or chronic infection.

Clinical features depend on the nature of the underlying disorder. Chronic inflammatory disorders include rheumatoid arthritis, inflammatory bowel disease, untreated familial Mediterranean fever, and other rare autoinflammatory conditions such as cryopyrin-associated periodic syndromes, TNF receptor–associated periodic fever syndrome, mevalonate kinase deficiency/hyper-IgD and periodic fever syndrome, and deficiency of adenosine deaminase 2. In low- and middle-income countries, it is associated with infections including tuberculosis, bronchiectasis, and osteomyelitis. In high-income countries, it is seen in persons who inject drugs who may have chronic skin abscesses and sinus formation related to injection sites. AA amyloidosis often presents with nephrotic syndrome, CKD, hepatomegaly, and splenomegaly. Macroglossia is not a feature and cardiac involvement is rare.

Familial amyloidoses

These are autosomal dominant diseases where a mutant protein forms amyloid fibrils, usually starting in middle age. The most common form is due to a mutant transthyretin, leading to transthyretin-associated amyloidosis (ATTR). Transthyretin is a tetrameric protein with four identical subunits, which functions as a transport protein for thyroxine and retinol-binding protein and is mainly synthesized in the liver. Over 80 amino acid substitutions have been described which destabilize the protein, which precipitates following stimulation. Though it can cause nephrotic syndrome, kidney disease is less prevalent than with AL amyloidosis. Clinically, peripheral sensorimotor and autonomic neuropathy is common, with symptoms of autonomic dysfunction, diarrhoea, and weight loss. Cardiac problems are usually those of conduction. There may be a family history of unidentified neurological disease. Macroglossia does not occur.

Diagnosis

Diagnosis can be made clinically when features of amyloidosis are present elsewhere. On imaging, kidneys may be large. Scintigraphy with radiolabelled serum amyloid P (SAP) is a technique for quantitatively imaging amyloid deposits *in vivo* and is used to detect rate of regression or progression of amyloidosis over time.

Kidney biopsy is indicated in suspected kidney involvement. Widespread eosinophilic deposits are seen in the mesangium, capillary loops, and arteriolar walls. Deposits stain pink, with green birefringence under polarized light with Congo red (Fig. 26.13). On electron microscopy, characteristic fibrils of amyloid can be seen. Amyloid consisting of immunoglobulin light chains (AL amyloid) can be identified by immunohistochemistry in only 40% of cases, compared to almost 100% of patients with secondary amyloid (AA amyloid). If the primary presentation of amyloidosis is with non-renal disease, or if kidney histology cannot be obtained, amyloid deposits can be seen in tissues obtained from the rectum, gums, abdominal fat, or myocardium.

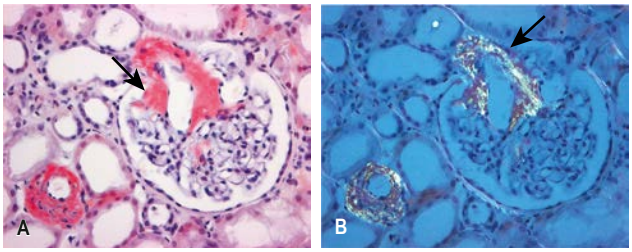

Fig. 26.13 Amyloid. **(A)** Light microscopy of eosinophilic amyloid deposits *(arrowed)*. **(B)** Congo red stain under polarized light showing apple green refringence.

Paraproteinaemia and light chains in the urine may be seen in AL amyloidosis, along with an increase in plasma cells on bone marrow biopsy. In secondary or reactive amyloidosis, there will be an underlying inflammatory disorder. Genetic testing for inherited amyloidosis should be undertaken where there is a relevant family history.

Management

Treatments that reduce production of the amyloidogenic protein can improve organ function and survival:

- AL amyloidosis: myeloma-directed therapy (e.g., bortezomib, rituximab), with or without stem cell transplantation.
- AA amyloidosis: treatment of the underlying inflammatory condition, colchicine in familial Mediterranean fever.
- ATTR amyloidosis: liver transplantation leads to complete disappearance of the mutant protein (transthyretin is predominantly synthesized in the liver) and is considered definitive therapy. However, new targeted therapies including Tafamidis and Diflunisal (tetramer stabilizers) and Patisiran (short interfering RNA inhibiting ATTR synthesis) are being used with some success.

Renoprotective measures should be started (see Box 26.10), as should relevant treatment for nephrotic syndrome and heart failure. If kidney failure progresses, the success of dialysis and kidney transplantation depends on the extent of amyloid deposition in extrarenal sites, especially the heart.

Diabetic nephropathy

Diabetic kidney disease is the leading cause of ESKD in high-income countries, arising largely as a complication of type 2 diabetes mellitus. Diabetic kidney disease occurs in about 20% to 30% of patients with both type 1 and type 2 diabetes. The natural history is similar from the onset of proteinuria, and the histological lesion is the same. Risk factors for nephropathy include poor glycaemic control, hypertension, male sex, ethnicity, and social deprivation.

Pathology

Glomerular hyperfiltration (GFR > 150 mL/min/1.73 m^2) and initial enlargement of kidney volume occur as local vasoactive factors increase flow. The GBM thickens and the mesangium expands. Progressive depletion of podocytes from the filtration barrier through apoptosis or detachment results in podocyturia early in the disease. Proteinuria evolves as filtration pressures rise and the filter is compromised. Later, glomerulosclerosis develops with nodules (Kimmelstiel–Wilson lesion) and hyaline deposits in glomerular arterioles (Fig. 26.14). Mesangial expansion and hyalinosis are partly due to amylin (β-islet-specific amyloid protein) deposits, with increasing proteinuria.

Box 26.10 Renoprotection

Goals of treatment

- Blood pressure <130/80 mmHg
- Proteinuria <0.3 g/24 h

Treatment

Patients with chronic kidney disease and proteinuria >1 g/24 h:

- Angiotensin-converting enzyme inhibitor increasing to maximum dose
- Angiotensin receptor antagonist if goals are not achieved[a]
- Finerenone
- Addition of diuretic to prevent hyperkalaemia and help to control blood pressure
- Addition of calcium-channel blocker (verapamil or diltiazem) if goals are not achieved

Patients with eGFR 20 ml/min/1.73 m^2 or more:

- SGLT-2 inhibitor
- GLP-1 agonist in type II diabetes

Additional management

- Statins to lower cholesterol to <4.5 mmol/L
- Smoking cessation (threefold higher rate of deterioration in chronic kidney disease)
- Treatment of diabetes (HbA_{1c} < 53 mmol/mol)
- Normal protein diet (0.8–1 g/kg body weight)

[a]In type 2 diabetes, start with angiotensin receptor antagonist.

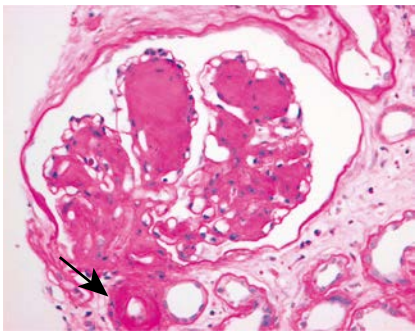

Fig. 26.14 Diabetes mellitus. Advanced diabetic glomerulopathy and arteriolar sclerosis *(arrowed)*.

The Renal Pathology Society has developed a consensus classification combining type 1 and type 2 diabetic nephropathies (Box 26.11). This discriminates lesions by various degrees of severity for international clinical practice.

Management

As in other kidney diseases, nearly the entire course of kidney disease in diabetes is clinically silent. The aim of medical intervention during this silent phase is to slow GFR decline over time (Box 26.10). Despite intensified metabolic and blood pressure control, many still go on to develop ESKD.

Management includes:

- ***Optimization of blood glucose concentrations:*** reduces the incidence of ESKD and other microvascular complications (the so-called 'legacy effect' of both type 1 and type 2 diabetes mellitus).
- ***SGLT-2 inhibitors:*** independent of benefits on glucose control, SGLT-2i (e.g., dapagliflozin, canagliflozin, empagliflozin) reduce CKD progression and reduce cardiovascular events (particularly heart failure) in those with type 2 diabetes and a GFR of ≥20 mL/min/1.73 m^2.

Box 26.11 Renal Pathology Society classification of types 1 and 2 diabetic nephropathy

Class	Name
I	• Isolated glomerular basement membrane thickening (>395 nm in females, >430 nm in males). • No mesangial expansion or mesangial matrix increase • Global glomerulosclerosis involving <50% of glomeruli
IIa	• Mild mesangial expansion
IIb	• Severe mesangial expansion (>25% of total mesangium contains areas of expansion larger than mean area of a capillary lumen)
III	• Nodular intercapillary glomerulosclerosis (≥1 Kimmelstiel–Wilson lesion) • <50% global glomerulosclerosis
IV	• >50% global glomerulosclerosis

- ***Glucagon-like peptide-1 agonists:*** independent of glucose control, GLP-1 (e.g., liraglutide, semaglutide, dulaglutide) offer renoprotection and enhanced weight loss, as well as cardiovascular protection in those with type 2 diabetes and CKD, if individualized glucose control is not optimized on other agents. Combination therapy with SGLT-2i appears to offer additive cardiovascular benefit.
- ***Blood pressure:*** <130/80 mmHg with ACE inhibitors or AII-RA.
- ***Renin-angiotensin blockade:*** ACE inhibitors or AII-RA should be used once microalbuminuria develops, even if blood pressure control is good.
- ***Treatment of dyslipidaemia.***
- ***Lifestyle:*** cessation of smoking, attention to salt intake, weight, and exercise optimization.
- ***Atrasentan:*** a selective endothelin A receptor (ET_AR) antagonist combined with renin–angiotensin system inhibitor is safe and effective in reducing albuminuria. Recent phase three trial data showed a reduced risk of renal events.

Glomerulonephritis

Glomerulonephritis (GN) is immunologically mediated, with involvement of cellular immunity (T lymphocytes, macrophages/dendritic cells), humoral immunity (antibodies, immune complexes, complement), and other inflammatory mediators (cytokines, chemokines, the coagulation cascade). The immune response can be directed against known target antigens, particularly when GN complicates infections, cancers, or drugs. The underlying antigenic target is more often unknown. Primary GN may occur in genetically susceptible individuals (associated with major histocompatibility complex (MHC) genes including *HLA-A1*, *B8*, *DR2*, and *DR3*), following environmental insults. Circulating autoantibodies and/or abnormalities in serum complement, and glomerular deposition of antibodies, immune complexes, complement, and fibrin characterize the condition. GN may present as:

- asymptomatic urinary abnormalities
- acute nephritis (nephritic syndrome)
- rapidly progressive glomerulonephritis.

The same histology can present in any of these ways, and these should be seen as clinical syndromes on a spectrum, rather than as distinct diseases.

Asymptomatic urinary abnormalities. Haematuria with or without sub–nephrotic-range proteinuria in an asymptomatic patient

may lead to the early discovery of potentially serious glomerular disease including SLE, Henoch–Schönlein purpura, post-infectious GN, and idiopathic hypercalciuria in children.

Acute nephritis (nephritic syndrome) classically presents as

- haematuria (macroscopic or microscopic), with red-cell casts on urine microscopy
- proteinuria
- hypertension
- oedema (periorbital, leg, sacral)
- temporary oliguria and uraemia.

Nephritis can present indolently or incidentally (Box 26.12). It is usually distinguished from rapidly progressive glomerulonephritis by the lack of cellular necrosis and crescent formation in the glomeruli seen on biopsy, and the rate at which kidney function declines.

Rapidly progressive glomerulonephritis is a syndrome which includes

- glomerular haematuria: red blood cell casts or dysmorphic red blood cells
- rapidly developing acute kidney failure over weeks to months
- focal glomerular necrosis with or without glomerular crescent development on kidney biopsy (Fig. 26.15).

The 'crescent' is an aggregate of macrophages and epithelial cells in Bowman's space. RPGN can develop with immune deposits (anti-GBM or immune complex type, e.g., SLE) or without immune deposits (pauci-immune, e.g., anti-proteinase 3 [PR3] or anti-myeloperoxidase–antineutrophil cytoplasmic antibodies [MPO-ANCA]-positive vasculitides). It can also develop as an idiopathic primary glomerular disease, or can be superimposed on secondary glomerular diseases such as IgA nephropathy, membranous GN, and post-infective GN. It can be classified based on the pattern of immune complex deposition in glomeruli (seen on immunofluorescence): linear, granular, and negative immunofluorescent patterns (Box 26.13).

Post-streptococcal glomerulonephritis

Acute nephritis 1 to 3 weeks after a streptococcal infection; for example, streptococcal throat infection, otitis media, cellulitis. The infecting organism is nephritogenic Lancefield group A β-haemolytic streptococcus. The latent interval between infection and the development of symptoms and signs of kidney involvement reflects the time taken for immune complex formation, deposition, and glomerular injury to occur. PSGN is now rare in high-income countries. Kidney biopsy shows diffuse, florid, acute inflammation in the glomerulus (without necrosis but occasionally with cellular crescents), with neutrophils and deposition of IgG and complement (Fig. 26.16).

Management

Includes blood pressure control, diuretics and salt restriction for oedema, and dialysis if indicated. If recovery is slow, corticosteroids may be helpful. The prognosis is usually good in children. A small number of adults develop hypertension and/or CKD. Evidence for long-term penicillin prophylaxis after the development of GN is lacking.

Non-streptococcal infective glomerulonephritis

GN occurs rarely in patients with infective endocarditis or infected ventriculoperitoneal shunts ***(shunt nephritis)***. Histological appearances resemble those of post-infectious GN but lesions are usually focal and segmental. Crescentic GN with AKI has been described, particularly with *Staphylococcus aureus* infection. Appropriate antibiotic therapy or surgical eradication of infection in fulminant cases usually results in a return of normal kidney function.

GN also occurs in association with visceral abscesses (mainly pulmonary). Complement concentrations are normal and immune deposits are absent on biopsy. Antibiotic therapy and surgical drainage of the abscess result in complete recovery of kidney function in approximately 50% of patients.

Box 26.12 Diseases commonly associated with acute nephritic syndrome

- Post-streptococcal glomerulonephritis
- Systemic lupus erythematosus (see Box 26.15)
- Henoch–Schönlein syndrome
- Non–streptococcal post-infectious glomerulonephritis, e.g., *Staphylococcus*, pneumococcus, *Legionella*, syphilis, mumps, varicella, hepatitis B and C, echovirus, Epstein–Barr virus, toxoplasmosis, malaria, schistosomiasis, trichinosis
- Infective endocarditis
- Shunt nephritis
- Visceral abscess
- Cryoglobulinaemia

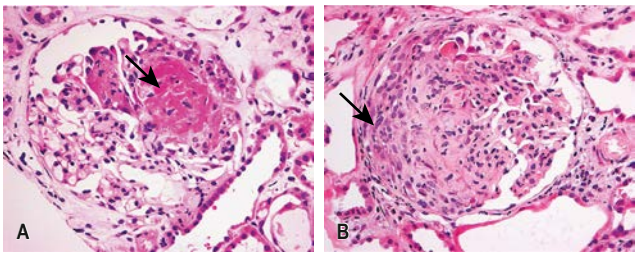

Fig. 26.15 Rapidly progressive glomerulonephritis (RPGN). *Arrows* show 'crescents' with aggregates of macrophages and epithelial cells in Bowman's space. **(A)** Focal necrotizing glomerulonephritis. **(B)** Crescentic glomerulonephritis.

Box 26.14 Oxford histological classification of IgA nephropathy

Histological variable	Description	Class
Mesangial hypercellularity	Average mesangial hypercellularity[a] >0.5	M1
	Average mesangial hypercellularity <0.5	M0
Segmental glomerulosclerosis	Part of glomerular tuft involved in sclerosis	S1
	No segmental glomerulosclerosis	S0
Endocapillary hypercellularity	Hypercellularity present with luminal narrowing	E1
	No hypercellularity	E0
Tubular atrophy/ interstitial fibrosis	>50% cortex	T2
	26%–50% cortex	T1
	0%–25% cortex	T0

[a]Mesangial hypercellularity is scored 0 for glomeruli with <4 mesangial cells per mesangial area; 1 for those with 4–5 cells; 2 for 6–7 cells; and 3 for ≥8 cells. The mean score for all glomeruli is obtained.

IgA nephropathy

IgA nephropathy (Fig. 26.17) is the most common form of GN worldwide. Demographic and family studies support a genetic contribution to pathogenesis but candidate gene studies are inconsistent. A genome-wide analysis study in European patients showed a strong association with the MHC/DQ and HLA-B loci on chromosome 6p.

Histology

There is a focal and segmental proliferative GN with mesangial deposits of polymeric IgA1. In some cases, IgG, IgM, and C3 are also seen in the glomerular mesangium. Superimposed crescent formation is frequent, particularly following macroscopic haematuria associated with upper respiratory tract infection (synpharyngitic).

An Oxford histological classification for IgA nephropathy is shown in Box 26.14. These features have prognostic significance independent of clinical features, both at the time of presentation and during follow-up.

Pathogenesis

The disease may be a result of several events, including:

- exaggerated bone marrow and tonsillar IgA1 immune response to viral or other antigens
- an abnormality in O-linked galactosylation in the hinge region of the IgA1 molecule
- functional abnormalities of two IgA receptors: CD89 expressed on blood myeloid cells and the transferring receptor (CD71) on mesangial cells
- circulating immune complexes composed of a glycan-specific IgG and a galactose-deficient IgA1 antibody.

IgA-rich immune complexes deposited in the glomerular mesangium induce mesangial cell activation and proliferation, as well as matrix synthesis and deposition. Removal of these complexes by bacterial proteases attenuates injury, and it is thought that glycan-specific autoantibodies, rather than IgA1 itself, play a key role in pathogenesis. Up to 50% of patients exhibit elevated serum IgA (polyclonal). Several diseases are associated with IgA deposits including Henoch–Schönlein purpura, chronic liver disease, malignancies (especially bronchial carcinoma), seronegative spondyloarthritis, coeliac disease, mycosis fungoides, and psoriasis.

Clinical features

IgA nephropathy usually presents with asymptomatic microscopic haematuria, or recurrent macroscopic haematuria with upper respiratory or gastrointestinal viral infection. Proteinuria also occurs and is nephrotic range in 5% of cases. Prognosis is usually good, especially in those with normal blood pressure, normal kidney function, and no proteinuria at presentation. Surprisingly, recurrent macroscopic haematuria is a good prognostic sign, although this may be

due to 'lead-time bias' as patients with overt haematuria come to medical attention at an earlier stage of their illness. The risk of eventual development of ESKD is about 25% in those with proteinuria of more than 1 g per day, elevated serum creatinine, hypertension, ACE gene polymorphism (DD isoform), and tubulointerstitial fibrosis on kidney biopsy.

Management

- All patients should receive an ACE inhibitor or an AII-RA, to reduce proteinuria and preserve kidney function.
- SGLT-2 inhibitors have shown benefit even in the absence of diabetes mellitus and are increasingly used with ACE or AII-RA as standard of care.
- Patients with proteinuria of >1–3 g/day, mild glomerular changes, and normal kidney function may be treated with steroids aiming to reduce proteinuria and stabilize kidney function. Oral targeted released budesonide (Nefecon) for 9 months has recently been shown to be effective in reducing proteinuria and decline in kidney function.
- In patients with higher-risk progressive disease with proteinuria of >750 mg/day and or eGFR < 60 mL/min/1.73 m^2, two separate randomized placebo-controlled studies have demonstrated benefit with low-dose oral methylprednisolone or mycophenolate.
- Tonsillectomy can reduce proteinuria and haematuria in those with recurrent tonsillitis.

Alport's syndrome

Alport's syndrome is a rare hereditary nephritis with haematuria, proteinuria (usually <1–2 g/day), progressive kidney disease, and high-frequency sensorineural deafness. Approximately 15% have ocular abnormalities including bilateral anterior lenticonus and macular or perimacular retinal flecks.

About 85% have an X-linked inherited mutation in the gene encoding the COL4α5 collagen chain, a critical component of the GBM. Penetrance is variable in females and depends on the type of mutation or degree of mosaicism following hybridization of the X chromosome. The remaining 15% of cases are due to autosomal recessive or dominant inherited mutations mainly affecting COL4α3 or 4 collagen chains. These mutations cause post-translational defects in α3, α4, and α5 chains, and result in incorrect assembly or folding of monomers, which are rapidly degraded. Over time, the basement membrane undergoes selective proteolysis, and glomerular membranes thicken unevenly, split, and ultimately deteriorate. Although the basement membrane is abnormal, podocyte function and the slit diaphragm are unaffected, and so proteinuria in Alport's syndrome is often mild and is the result of glomerular sclerosis, rather than primary loss of slit pores. In some patients with Alport's syndrome, a thin basement membrane, as seen in benign familial haematuria, is the only abnormality detected on histology. For this reason, the boundary between Alport's and benign familial haematuria has become increasingly vague. Thin basement disease (thinning of the glomerular capillary basement membrane on electron microscopy) which initially was thought to be a benign condition is now regarded as part of the inherited collagen 4 disease spectrum.

Management

Patients are treated with ACE inhibitors or AII-RAs to attenuate proteinuria. The disease is usually progressive and accounts for some 5% of cases of ESKD in childhood or adolescence. A recent study of bardoxolone methyl (anti-inflammatory and antioxidant inhibitor of proinflammatory cytokines) has demonstrated preservation of eGFR.

Anti-GBM glomerulonephritis

This condition is rare, with an incidence of 1 per 2 million. It accounts for 15% to 20% of RPGN although it represents less than 5% of all forms of GN. About two-thirds of these patients have ***Goodpasture's syndrome*** with associated lung haemorrhage.

Anti-GBM antibodies (detected by enzyme-linked immunosorbent assay [ELISA]) are present in serum and directed against the non-collagenous component of α3 (IV) and rarely α5 (IV) in the basement membrane. Anti-GBM glomerulonephritis is characterized by linear (Fig. 26.18A) capillary loop staining with IgG and C3, and extensive crescent formation. Anti-GBM disease never occurs in patients with Alport's syndrome; although it can develop after patients with Alport's receive a kidney transplant as anti-GBM alloantibodies evolve in response to the 'foreign' α3, α4, α5 (IV) collagen that was absent in the patient's own kidneys. Recently laminin-521, a novel target of autoantibodies has been identified in patients with lung haemorrhage.

The thymus expresses α3 (IV) peptides that eliminate autoreactive $CD4^+$ helper T cells and the few that escape deletion are kept in check by circulating regulatory (Treg) cells. Breakdown of this peripheral tolerance (the mechanism of which is unknown) results in

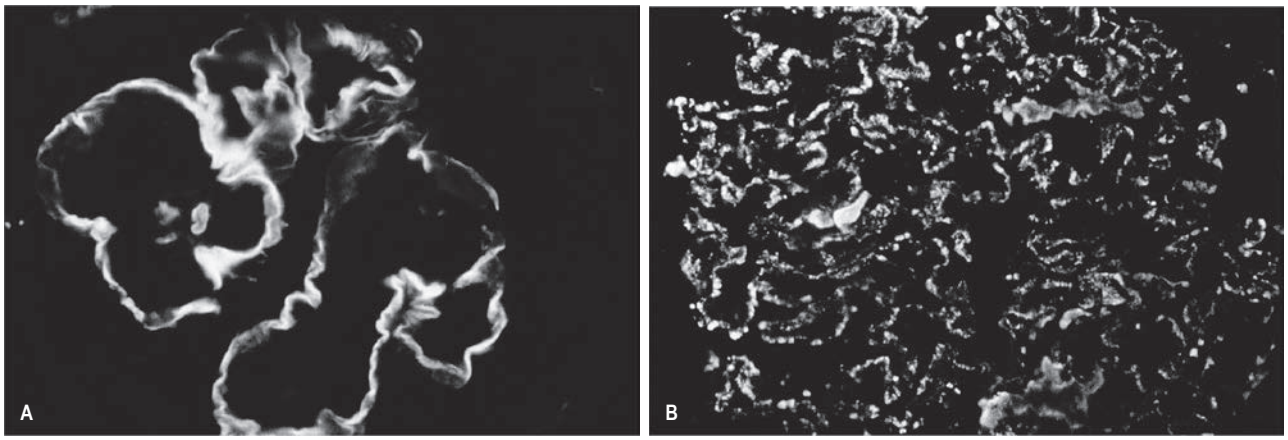

Fig. 26.18 Immunofluorescence. (A) Anti-glomerular basement membrane antibody (anti-GBM) deposition in a linear pattern typical of Goodpasture's syndrome. **(B)** Immune complex deposition in a diffuse granular pattern.

autoreactive $CD4^+$ cells producing anti-GBM antibodies. Since the $\alpha3$ (IV) non-collagenous epitope is hidden within the $\alpha3$, $\alpha4$, and $\alpha5$ (IV) promoter, it is presumed that an environmental factor, such as exposure to hydrocarbons or tobacco smoke, is required to reveal cryptic epitopes to the immune system.

The mechanism of kidney injury is complex. When anti-GBM antibody binds the basement membrane, it activates complement and proteases, causing disruption to the filtration barrier and Bowman's capsule, with proteinuria and the formation of crescents. Crescent formation is facilitated by IL-12 and interferon-gamma, which are produced by resident and infiltrating inflammatory cells.

Management involves:

- ***plasma exchange*** to remove circulating anti-GBM antibodies
- ***steroids*** to suppress inflammation from deposited antibody
- ***cyclophosphamide*** to suppress further antibody synthesis
- ***Imlidifase*** is an IgG-cleaving endopeptidase. In a small study of 15 patients with eGFR of less than 15 mL/min/1.73 m^2, the response rate was 67% compared to the 15% expected with current therapies in high-risk patients. Randomized trials are awaited.

Prognosis is determined by the extent of glomerular damage (measured by percentage of glomeruli containing crescents, serum creatinine, and need for dialysis) at treatment initiation. When oliguria occurs or serum creatinine is greater than 600 to 700 μmol/L, kidney failure is usually irreversible. Successfully treated disease does not recur. If left untreated, autoantibodies diminish spontaneously within 3 years and autoreactive T cells cannot be detected in convalescent patients. This suggests re-establishment of peripheral tolerance, which coincides with re-emergence of regulatory $FOXP3^+$-$CD25^+$ cells in the peripheral blood, which play a key role in inhibiting the autoimmune response. The emergence and persistence of these regulatory cells may underlie the 'single hit' nature of this condition.

ANCA-positive small-vessel vasculitis

Inflammation and necrosis of the blood vessel wall occur in many primary vasculitic disorders. The small-vessel vasculitides affecting the kidney include:

- ANCA-associated vasculitides:
  - granulomatosis with polyangiitis (GPA)
  - microscopic polyangiitis (MPA)
  - renal-limited vasculitis (without systemic features)
- eosinophilic granulomatosis with polyangiitis (frequently ANCA-negative).

GPA and MPA share a common pathology with focal necrotizing lesions affecting different vessels and organs:

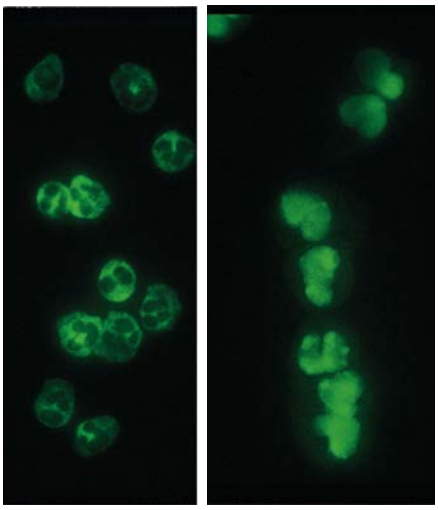
- Lungs: capillaritis causes lung haemorrhage
- Kidney: crescentic GN and/or focal necrotizing lesions causing AKI (Fig. 26.15)
- Skin (Fig. 26.19): purpuric rash or vasculitic ulceration.

Kidney histology is regarded as a 'gold standard' for diagnosis and prognosis in ANCA-associated GN. Classification is based on four categories of lesions:

- ***Focal:*** ≥50% normal glomeruli not affected by the disease process
- ***Crescentic:*** ≥50% of glomeruli with cellular crescents
- ***Mixed:*** a heterogeneous phenotype in which no glomerular feature predominates
- ***Sclerotic:*** ≥50% of glomeruli with global sclerosis

This system has been shown to have a prognostic value for 1- and 5-year kidney outcomes and may guide therapy.

Fig. 26.19 Vasculitic rash.



A B

Fig. 26.20 Antineutrophil cytoplasmic antibody (ANCA)-positive glomerulonephritis: immunofluorescence. **(A)** Cytoplasmic ANCA (cANCA). **(B)** Perinuclear ANCA (pANCA). *(From Schrier RW.* The Schrier Atlas of Diseases of the Kidney, Vol. IV: Systemic Diseases and the Kidney. *1999; Wiley–Blackwell, with permission.)*

There are two forms of ANCA: PR3-ANCA (cANCA) and MPO-ANCA (pANCA); Fig. 26.20. If ELISA and indirect immunofluorescence techniques are combined, diagnostic specificity is 99%. ANCA and anti-GBM antibodies can occur together; such patients tend to follow the natural history of anti-GBM disease.

PR3-ANCA positivity is found in the large majority (>90%) of patients with active GPA and in up to 50% of patients with MPA. ***MPO-ANCA positivity*** is present in most patients with renal-limited vasculitis and in a variable number of cases of MPA. Positivity for both types of ANCA antibodies occurs in up to 10% of patients, who have a variable clinical course and worse kidney outcome. Eosinophilic GPA may have either anti-MPO or anti-PR3-ANCA.

Drugs (e.g., propylthiouracil, hydralazine, minocycline, penicillamine) may induce vasculitis associated (most commonly) with MPO-ANCA, often in very high titres. Cases of drug-induced ANCA-associated vasculitis present with constitutional symptoms, arthralgia, and cutaneous vasculitis. Crescentic GN and lung haemorrhage also occur.

In patients with ANCA vasculitis, there is aberrant expression of PR3 and MPO in mature neutrophils, possibly due to disrupted

epigenetic silencing. Inappropriate expression of PR3 and MPO may alter the availability of these antigens by targeting these proteins to granules that are more readily exocytosed. Patients with anti-PR3 have autoantibodies to a peptide translated from the antisense DNA strand of PR3 (complementary PR3). This suggests that autoimmunity is initiated via a response against a complementary or antisense peptide, which then induces cross-reacting anti-idiotypic antibodies. Infection by fimbriated bacteria (e.g., *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*) can, through molecular mimicry, trigger cross-reactive autoimmunity to lysosomal membrane protein 2 (LAMP-2), a membrane protein co-localized with PR3 and MPO in the intracellular vesicles of neutrophils.

Management

The sooner treatment is instituted, the greater chance there is of recovery of kidney function. Pulmonary haemorrhage and kidney failure at presentation are associated with worse prognosis.

High-dose oral corticosteroids and ***intravenous pulsed cyclophosphamide*** induce remission. Once remission has been achieved, cyclophosphamide can be substituted with azathioprine, which was more effective than mycophenolate in a head-to-head comparison trial.

Rituximab is effective in inducing remission in the short term (6–12 months). Use of rituximab every 3 months in fixed doses has also been shown to be superior to azathioprine in the maintenance of remission.

Colonization of the upper respiratory tract with *S. aureus* increases the risk of relapse, and treatment with ***sulfamethoxazole/trimethoprim*** reduces relapse.

Avacopan is an orally administered small-molecule C5a receptor antagonist that selectively blocks the effects of C5a including neutrophil chemoattraction and activation. It has recently been approved for treatment of vasculitis as a steroid-sparing agent following a positive randomized controlled in which it was found to be superior to placebo with steroid taper at 12 months. It is an exciting development for patients at risk of glucocorticoid toxicity.

Up to 25% of patients with PR3-ANCA harbour antibodies against human plasminogen and/or tissue plasminogen activator. Their presence has been associated with venous thromboembolism and fibrinoid necrotic glomerular lesions, suggesting functional interference with fibrinolysis. However, a formal role for anticoagulation in patients with ANCA-associated GN remains uncertain.

Relapse after complete withdrawal of immunosuppression occurs relatively frequently, and long-term, relatively low-dose immunosuppression may be necessary.

The PEXIVAS study of more than 700 patients with severe ANCA-positive RPGN, with or without lung haemorrhage, demonstrated the addition of plasma exchange neither saved lives nor avoided ESKD. This study also demonstrated that lower-dose oral glucocorticoids than conventionally used significantly reduced serious infection rates without less effective disease control.

Long-term survival depends on early diagnosis, severity of disease, frailty and co-morbidities, response to therapy, and the adverse effects of immunosuppressive drugs, particularly the occurrence of infections. Overall survival in ANCA-associated vasculitis is 90%, 85%, and 78% at 1, 2, and 5 years, respectively.

Mixed nephritic and nephrotic syndrome

Injury involves mesangial cells, endothelium, the basement membrane, and podocytes in this heterogeneous group of conditions.

Mesangiocapillary (membranoproliferative) glomerulonephritis

Mesangiocapillary (membranoproliferative) glomerulonephritis (MCGN) is an uncommon lesion. It has three subtypes with a similar clinical phenotype: nephrotic syndrome, haematuria, hypertension, and kidney impairment. They also produce similar microscopic findings, although pathogenesis may be different. Electron microscopy defines:

- ***Type 1 MCGN or immune complex C3 nephropathy:*** mesangial cell proliferation, with mainly subendothelial immune deposition and apparent splitting of the capillary basement membrane, giving a 'tramline' effect. It can be associated with persistently reduced plasma concentrations of C3 and normal concentrations of C4, as well as activation of the classical complement cascade. It is often idiopathic but can occur with chronic infection (abscesses, infective endocarditis, infected ventriculoperitoneal shunt) or cryoglobulinaemia secondary to hepatitis C infections (Fig. 26.21A).

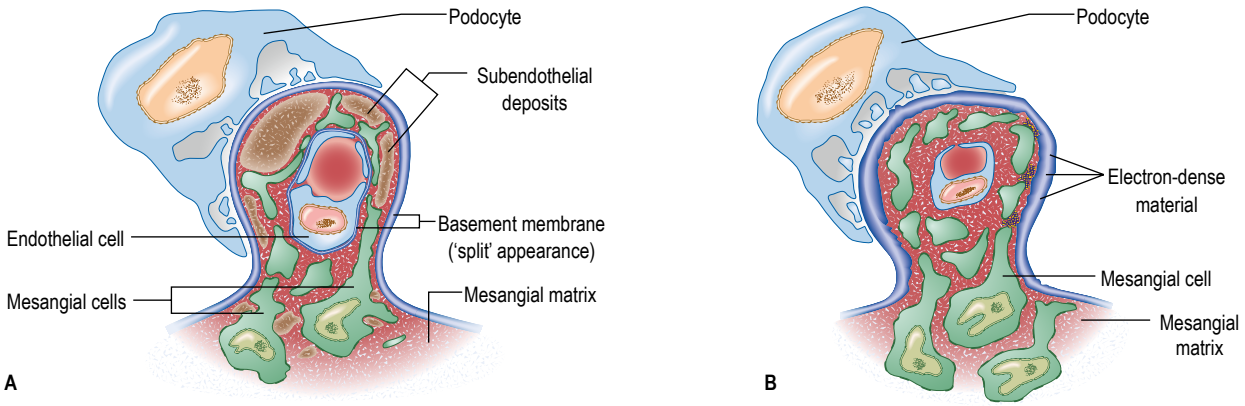


Fig. 26.21 Mesangiocapillary glomerulonephritis (MCGN). **(A)** Type 1 MCGN showing expanded mesangial matrix and mesangial cells, thickened capillary wall, large subendothelial deposits, and formation of a new layer of basement membrane (tramline effect). **(B)** Type 2 MCGN showing a variable glomerular appearance: electron-dense material has replaced Bowman's capsule, tubular basement membrane, and part of the capillary. There is proliferation of mesangial cells. *(After Marsh FP. Postgraduate Nephrology. Oxford: Butterworth–Heinemann; 1985.)*

- ***Type 2 MCGN, or C3 nephropathy:*** mesangial cell proliferation with electron-dense, linear (ribbon-like) intramembranous deposits that usually stain for C3 only (**Fig. 26.21B**). This ***dense deposit disease*** may be idiopathic or associated with factor H deficiency and partial lipodystrophy (loss of subcutaneous fat on the face and upper trunk). Alternatively, ***C3 nephropathy*** presents with low C3 concentrations (as in type 1 MCGN), due in this case to activation of the alternative complement cascade, where loss-of-function mutations in complement factor H or other factors allow uncontrolled alternative pathway activation. Autoantibodies to the C3 convertase enzyme (C3 nephritic factor) are present. Increasingly, monoclonal gammopathy is recognized with C3 nephropathy, which requires plasma cell clone depletion therapy. In patients of Cypriot origin, an autosomal dominant heterozygous duplication in the *CFHR5* gene (CFHR5 nephropathy) leads to a similar presentation.
- ***Type 3 MCGN*** has features of both type 1 and type 2 disease. Complement activation appears to be via the final common pathway of the cascade.

Most patients develop ESKD over several years. C3 nephropathy, particularly with an underlying genetic cause, recurs in a high proportion of kidney transplants, usually within the first year. This is less common (25%) in type 1 MCGN.

Management

In idiopathic MCGN with normal kidney function and non–nephrotic-range proteinuria, no specific therapy is required. Good blood pressure control, ideally with an ACE inhibitor or AII-RA, is of benefit.

In ***children*** with the nephritic syndrome and/or impaired kidney function, a trial of steroids may be warranted (alternate-day prednisolone 40 mg/m^2 for a period of 6–12 months). If no benefit is seen, this treatment is discontinued. Regular follow-up, with control of blood pressure, use of agents to reduce proteinuria, and correction of lipid abnormalities are necessary.

In ***adults*** with nephritic syndrome and/or kidney impairment, a trial of prednisolone with mycophenolate is recommended. Again, if no benefits are seen, treatment should be stopped. C3 nephropathy due to monoclonal gammopathy of renal significance requires treatment for underlying plasma cell dyscrasia. Treatment to slow the rate of progression of CKD is instituted (see 'Management of CKD' section). In C3 nephropathy, due to loss-of-function mutation in complement factor H, anti-C5 antibody (eculizumab) has been used successfully in several patients and in recurrence following transplantation. Several orally active complement B and C3 inhibitors are in trial after early promising results.

IgM nephropathy

This disorder is characterized by increased mesangial cellularity in most of the glomeruli, associated with granular immune deposits of IgM and complement. People present with episodic or persistent haematuria and the nephrotic syndrome. Unlike in minimal-change disease, the prognosis is not uniformly good, as steroid response is only 50%. Between 10% and 30% develop progressive kidney disease with evidence of secondary FSGS (see 'Secondary FSGS' section) on repeat biopsy.

C1q nephropathy

C1q nephropathy is very similar to IgM nephropathy in terms of presenting features and microscopic appearance, with the exception of C1q deposits in the mesangium. Sometimes, it is misdiagnosed as lupus nephritis, particularly in people with negative serology (so-called 'seronegative lupus'). The distinguishing features are intense C1q staining and absence of tubuloreticular inclusions (attributable to high circulating interferon-alfa) on electron microscopy.

Monoclonal gammopathy of renal significance

A monoclonal gammopathy of undetermined significance (MGUS) occurs in asymptomatic people with a paraprotein or M-band detected in blood (often incidentally). Kidney (usually glomerular) disease is increasingly recognized in association, related to deposition or precipitation of monotypic whole immunoglobulin or light chains in the kidney. Renal injury is driven by a clonal B-cell or plasma cell population.

The following are included under the term monoclonal gammopathy of renal significance (MGRS):

- ***deposition diseases:*** AL amyloid (see 'AL amyloidosis [immunoglobulin light chain associated]' section), immunotactoid and fibrillary GN, monoclonal immunoglobulin deposition diseases (MIDDs, including light chain and heavy chain DD), proliferative GN with monoclonal immunoglobulin deposition and light chain tubulopathy
- ***precipitation diseases:*** cryoglobulinaemic GN
- ***complement activation diseases:*** paraprotein-associated C3 nephropathy and atypical haemolytic uraemic syndrome (HUS, see 'Haemolytic uraemic syndrome' section).

Diagnosis is usually made in the context of a detectable paraprotein and characteristic kidney biopsy findings, and progression to ESKD is common unless treatment is given. Conventional immunosuppression is of no benefit, but clone-directed therapy with bortezomib, rituximab, or potentially daratumumab offers better outcomes.

Idiopathic fibrillary glomerulopathy

In this rare condition, microfibrillary structures are seen in the mesangium and glomerular capillary wall, visible on electron microscopy, and staining is positive for a specific marker, DNAJB9. Fibrils are larger than in amyloidosis (20–30 nm as opposed to 10 nm in diameter) and do not stain with Congo red. Patients present with proteinuria, mostly in the nephrotic range (60%), and microscopic haematuria (70%), hypertension, and CKD (50%) that may progress rapidly; 40% to 50% develop ESKD within 2 to 6 years. No treatment is known to be of benefit.

Immunotactoid glomerulopathy

In this disorder, microtubules that are much larger (30–40 nm in diameter) than the fibrils in fibrillary glomerulopathy are seen on electron microscopy. Most patients have circulating paraproteins, or monoclonal immunoglobulin deposition is seen in the glomeruli on immunofluorescence microscopy. A lymphoproliferative disease is the underlying cause in over 50% of cases. Clinical presentation and course are similar to fibrillary glomerulopathy. Complete or partial remission of the nephrotic syndrome can be achieved with chemotherapy in 80% of patients.

Fibronectin glomerulopathy

Glomerulonephritis due to fibrillar deposits is negative for Congo red staining. It is inherited as an autosomal dominant disorder and is associated with the massive deposition of fibronectin, a large dimeric glycoprotein consisting of two similar subunits (approximately 250 kDa in weight). The possible genetic abnormality in this disorder is a loss-of-function mutation in uteroglobin. It presents

with varying degrees of proteinuria seen first between the ages of 20 and 40, followed by hypertension, microscopic haematuria, and slow progression to ESKD in most patients.

Lysozyme nephropathy

A rare and under-recognized complication of chronic myelomonocytic leukaemia, other monocytic leukaemias, sarcoidosis, tuberculosis, and inflammatory bowel disease. Lysozyme, a small bactericidal cationic protein, is released into the circulation, filtered by the glomerulus, and reabsorbed by the proximal tubule, causing toxic tubular injury. Lysozyme concentrations in the blood are very high in all cases. The predominant abnormalities involve proximal tubular epithelial cells, which exhibit widespread degenerative changes including luminal ectasia, cytoplasmic simplification and vacuolization, irregular luminal profiles, loss of brush border, enlarged nuclei with prominent nucleoli, and focal apoptosis. Patient presents with AKI or CKD with superimposed AKI, and partial Fanconi syndrome. Early recognition and treatment of underlying cause result in satisfactory renal recovery.

Systemic lupus erythematosus (lupus nephritis)

Overt kidney disease occurs in at least one-third of patients with systemic lupus erythematosus (SLE) and 25% of those with lupus nephritis reach ESKD within 10 years. **Box 26.15** shows clinical and histological findings in class I to VI disease.

Serial biopsies show that in approximately 25% of patients, histological appearances change from one class to another. Immune deposits in the glomeruli and mesangium are characteristic of SLE (tubuloreticular structure in glomerular endothelial cells) and stain positive for IgG, IgM, IgA, and the complement components C3, C1q, and C4 on immunofluorescence.

Pathophysiology

SLE is a multifactorial, autoantigen-driven, T-cell dependent, B-cell mediated autoimmune disorder:

- Multiple circulating autoantibodies to cellular antigens (particularly anti-dsDNA, anti-Ro)
- Complement activation, which leads to reduced serum concentrations of C3, C4, and C1q. C1q is the first component of the classical complement cascade (see Chapter 6) involved in activation of complement and clearance of self-antigens generated during apoptosis.
- Nucleosomes (structures comprising DNA and histone, generated during apoptosis) are thought to be antigenic-generating nucleosome-specific T cells, antinucleosome antibodies, and nephritogenic immune complexes.
- Positively charged histone components of the nucleosome bind to the negatively charged heparan sulphate of the GBM, leading to an inflammatory reaction.
- T-helper 2 (Th2) cells, with basophils and B-cell survival factors (such as BLyS), enhance B-cell differentiation and survival, and stimulated nucleic acid–binding receptors promoting production of autoreactive antibodies.
- Type I and type II IFN-stimulated genes are up-regulated in the majority of adult SLE.
- Inflammation stimulates complement activation, mesangial cell proliferation, mesangial matrix expansion, and recruitment of inflammatory leucocytes.

Extraglomerular features of lupus nephritis include tubulointerstitial nephritis (in 75%), renal vein thrombosis, and renal artery stenosis. Thrombotic manifestations are associated with autoantibodies to phospholipids (lupus anticoagulant, anticardiolipin, beta-2 glycoprotein 1, see Chapter 40), and may present as infarction of glomerular segments, thrombotic microangiopathy, or vasculitis.

Management

Management depends on the clinical presentation. Hypertension should be treated. Disease activity, histology, and extrarenal manifestations guide therapy. ***Class I lupus nephritis*** requires no specific treatment. ***Class II*** usually runs a benign course, but some patients are treated with hydroxychloroquine and/or steroids alone. There have been several clinical trials with immunosuppressive agents in ***classes III, IV, and V***. Outcomes are affected by clinical characteristics, initial response to treatment, frequency of kidney flares, and irreversible damage on kidney biopsy. Steroids used

Box 26.15 Classification of lupus nephritis

Class	Histology	Clinical
I	***Minimal mesangial lupus nephritis:*** Immune deposits but normal light microscopy	Asymptomatic
II	***Mesangial proliferative lupus nephritis:*** Mesangial hypercellularity, matrix expansion	Mild CKD
III	***Focal lupus nephritis:*** Affects <50% of glomeruli Subepithelial deposits Subdivisions for active or chronic lesions	10%–20% of lupus nephritis Haematuria and proteinuria
IV	***Diffuse lupus nephritis:*** Affects >50% of glomeruli Segmental and global lesions Active and chronic lesions Subendothelial deposits	Most common form Severe kidney disease: progression to nephrotic syndrome, hypertension, and kidney failure
V	***Membranous lupus nephritis:*** Affects >50% of glomeruli Subepithelial deposits, C1q present Mesangial and small subendothelial deposits	10%–20% of lupus nephritis. Proteinuria and nephrotic syndrome. Can occur in combination with class III or IV
VI	***Advanced sclerosing lupus nephritis:*** ≥90% globally sclerosed glomeruli	Progression or healing following other stages Progressive CKD: no benefit to immunosuppression

(Modified from International Society of Nephrology/Renal Pathological Society 2004.)

for induction include intravenous methylprednisolone, followed by tapering oral prednisolone. Steroids are combined with one of the following:

- Mycophenolic acid analogues, e.g., MMF. Shown to be as effective as high-dose intravenous cyclophosphamide
- Voclosporin (plus MMF). A novel calcineurin inhibitor. Randomized control trial data demonstrated a fixed dose of 23.7 mg twice daily in combination with MMF and low-dose steroids led to a measurably better renal response compared to MMF and low-dose steroids alone, with a comparable safety profile. Unlike other calcineurin inhibitors, it does not require drug concentration monitoring.
- Low-dose cyclophosphamide.
- Belimumab (plus MMF or low-dose cyclophosphamide). A recombinant human IgG-1λ monoclonal antibody that inhibits B-cell activating factor (BAFF). Two randomized controlled trials have demonstrated belimumab combined with standard treatment is associated with an improved renal response. Recent immune profiling has shown that high baseline IgA2 anti-dsDNA antibodies are associated with a better treatment response to belimumab (after rituximab), with high baseline IL-6 concentrations conferring a poor response. Molecular prediction markers could guide precision-targeted therapies in the future.

Patients with patients with persistent disease activity or inadequate response to initial standard-of-care therapy are considered for B-cell depletion. Rituximab is a chimeric type 1 anti-CD20 antibody which causes B-depletion by complement-dependent cytotoxicity. Inconsistency in controlled trial data may be due to variable B-lymphocyte depletion. Obinutuzumab is a humanized type II anti-CD20 monoclonal antibody with direct B lymphocyte toxicity, which induces potent B-cell depletion and is well tolerated.

Chimeric antigen receptor T-cell (CAR-T cell) therapy is emerging as a potential treatment option in refractory disease. CAR-T cell therapy directed against CD19 (an early-stage B-lymphocyte surface marker) has been used successfully in an exploratory study of five patients with SLE patients refractory to other therapies, with drug-free remission after one year of follow-up, even after reappearance of B cells. CAR T-cell treatment was well tolerated with only mild cytokine-release syndrome.

Optimum duration of maintenance immunosuppression treatment is unclear. A randomized study of discontinuation of immunosuppression after 2 to 3 years of remission demonstrated a 25% relapse rate within a year in the absence of maintenance immunosuppression, compared to 12% when immunosuppression was continued. Although this study was unable to prove non-inferiority, 75% were able to discontinue treatment without relapse. Better molecular and histological markers are needed to identify patients with lupus nephritis who can safely discontinue immunosuppression.

Prognosis

Treatment leading to the normalization of proteinuria, hypertension, and kidney dysfunction indicates a good prognosis. The prognosis is better in patients with types I, II, and V disease. Glomerulosclerosis (type VI) usually predicts ESKD.

Cryoglobulinaemic kidney disease

Cryoglobulins (CGs) are individual or mixed immunoglobulins and complement components, which precipitate reversibly in the cold. Three types are recognized:

- ***Type I:*** monoclonal immunoglobulin, as is found in multiple myeloma and lymphoproliferative disorders.
- ***Type II:*** mixed monoclonal IgM and polyclonal IgG component. Most often, the monoclonal IgM is directed against the Fc portion of the polyclonal IgG ('rheumatoid factor'). Typically found in hepatitis C infections (80%–90% of cases) but also other infections and autoimmune disease.
- ***Type III:*** polyclonal IgM and IgG components in autoimmune disorders or infection, including hepatitis C.

Glomerular disease is more common in type II than in type III cryoglobulinaemia. In approximately 30% of these 'mixed' cryoglobulinaemias, no underlying or associated disease is found (essential cryoglobulinaemia). Glomerular pathological changes resemble those of MCGN (see Fig. 26.21).

Presentation is usually in the fourth or fifth decade of life. Systemic features include purpura, arthralgia, leg ulcers, Raynaud's phenomenon, evidence of systemic vasculitis, a polyneuropathy, and hepatic involvement. Glomerular disease typically presents as asymptomatic proteinuria, microscopic haematuria (or both), but presentation with an acute nephritic and nephrotic syndrome (most commonly) or features of CKD also occurs. Complement is consumed and cryoglobulins can be detected. Protein electrophoresis, rheumatoid factor, autoantibodies, and antiviral antibodies or mRNA of hepatitis C should be sought.

The underlying cause should be treated. As hepatitis C is the most common cause, antivirals are highly efficacious. Intensive plasma exchange or cryofiltration has been used in selected cases where vasculitis is limb-, organ- or life-threatening to achieve rapid removal of cryoglobulins. Uncontrolled studies of the anti-CD20 chimeric monoclonal antibody rituximab, which depletes B cells, appear promising.

Immunoglobulin A vasculitis (Henoch–Schönlein syndrome)

This clinical syndrome comprises a characteristic skin rash, abdominal colic, joint pain, and glomerulonephritis. Approximately 30% to 70% have clinical evidence of kidney disease with haematuria and/or proteinuria. The kidney disease is usually mild, but nephrotic syndrome and AKI can occur. The lesion is a focal segmental proliferative glomerulonephritis, sometimes with mesangial hypercellularity. In more severe cases, epithelial crescents may be present. Immunoglobulin deposition is mainly IgA in the glomerular mesangium distribution, similar to IgA nephropathy. There is no proven treatment; steroid therapy is ineffective for kidney involvement and management is usually supportive. In crescentic glomerulonephritis, aggressive immunosuppression has been tried with variable outcome.

Other glomerular disorders

Fabry's disease

This X-linked lysosomal storage disease results from a deficiency of the enzyme α-galactosidase. Glycosphingolipids (globotriaosylceramide) accumulate in many cells including podocytes in the kidney. Systemic features include angiokeratomas in the skin, cardiovascular disease, neuropathies, and progressive proteinuric CKD. Enzyme replacement with agalsidase (α-galactosidase) slows progression and injury to the heart, kidney, and skin. In certain cases, migalastat, an oral molecular chaperone, is effective.

Sickle cell nephropathy

Sickle cell disease is complicated relatively commonly by papillary sclerosis or necrosis, AVP-resistance (also referred to as 'nephrogenic diabetes insipidus'), and incomplete renal tubular acidosis. Glomerular lesions are rare and were historically traced to hepatitis B or C infection acquired through repeated blood transfusions. Occasionally, proteinuria or nephrotic syndrome with progressive

kidney disease is seen, particularly in *APOL1* G1/G2 gene variant. Rarely, membranous GN or mesangiocapillary glomerulonephritis with IgG deposits occurs. No form of effective therapy is known.

Glomerulopathy associated with pre-eclampsia

Presents with new hypertension and proteinuria after 20 weeks' gestation, often of rapid onset, and resolves after delivery. The glomerular lesion is characterized by marked endothelial swelling and obliteration of capillary lumina. In severe cases, there may be cortical necrosis or microangiopathic haemolysis. The disease is caused by abnormal placental development, which leads to an imbalance of pro- and anti-angiogenic factors, which are measurable in the maternal circulation prior to development of the clinical phenotype. An increase in soluble fms-like tyrosine kinase (sFlt1) antagonizes angiogenic factors including placental growth factor (PlGF) leading to systemic endothelial dysfunction. Concentrations of sFlt1 and PLGF can be used for prognosis and diagnosis. Delivery of the placenta is the only definitive treatment, the timing of which balances fetal maturity with maternal disease. Persistent proteinuria 6 months after delivery raises the possibility of undiagnosed CKD as a precipitant of pre-eclampsia, and warrants investigation.

Paraneoplastic glomerulonephritis

A rare complication of malignancy, paraneoplastic GN is usually misdiagnosed as idiopathic. Several cancers involve the glomerulus:

- ***Thymoma or Hodgkin lymphoma:*** polarization of the immune response towards a Th2 profile and possibly excessive production of IL-13 leads to the development of minimal change disease, mesangiocapillary GN, or membranous nephropathy.
- ***B-cell lymphoma and leukaemia:*** can induce injury via monoclonal immunoglobulin and cryoglobulin.
- ***Polycythaemia vera, essential thrombocythaemia, or primary myelofibrosis:*** severe thrombocytosis may induce FSGS, possibly due to elevated concentrations of platelet-derived growth factor.
- ***Myelodysplastic syndromes:*** autoimmunity can trigger a variety of glomerulonephritides.
- ***Epithelial carcinoma:*** glomerular inflammatory cells and subepithelial immune IgG1- and IgG2-containing complexes may aid the diagnosis of paraneoplastic membranous nephropathy.

KIDNEY INVOLVEMENT IN OTHER DISEASES

Polyarteritis nodosa

Polyarteritis nodosa (PAN) is a multisystem disorder (see also Chapter 32, 'Polyarteritis nodosa' section). Aneurysmal dilation of medium-sized arteries presents with hypertension, polyneuropathy, and ischaemic infarction of a number of organs including skin, gut, heart, and brain. Aneurysms may be seen on arteriography. PAN may be associated with drug use and hepatitis B infection. Typically, patients are ANCA-negative. PAN is typically with slowly progressive CKD, often accompanied by severe hypertension. Rapidly progressive kidney failure is rare. Treatment with immunosuppression is less effective than for microscopic polyangiitis.

Systemic sclerosis (scleroderma)

Systemic sclerosis (SSc) (see Chapter 32, 'Systemic sclerosis [scleroderma]' section) is a chronic multisystem disease characterized by fibrosis and vasculopathy of the skin and visceral organs. Plasmacytoid dendritic cells appear to produce high plasma concentrations of CXCL4, which is associated with both skin and lung fibrosis, as well as with pulmonary arterial hypertension.

Approximately 10% of SSc patients develop scleroderma renal crisis, characterized by accelerated hypertension, rapidly progressive kidney failure, and proteinuria. 'Onion skinning' in arcuate and interlobular arteries is seen on biopsy resulting from vessel intimal proliferation, fibrin thrombi, and fibrinoid necrosis. The treatment of choice is ACE inhibitors, which have led to a remarkable improvement in outcomes, though up to 30% of patients progress to ESKD.

Haemolytic uraemic syndrome

Haemolytic uraemic syndrome (HUS) is characterized by intravascular haemolysis with red cell fragmentation (microangiopathic haemolysis), thrombocytopenia, and AKI due to thrombosis in small arteries and arterioles (**Fig. 26.22**). These features are also seen in disseminated intravascular coagulation, but coagulation tests are typically normal in HUS.

Diarrhoea-associated HUS

Diarrhoea-associated HUS (D+ HUS) often follows a febrile illness, particularly gastroenteritis associated with *E. coli*, notably strain O157. The latter produces verocytotoxin (or Shiga toxin), with a pathogenic A unit that inhibits protein synthesis and initiates endothelial damage. B units facilitate entry of the A unit into the endothelial cells by binding to a receptor (Gb3) on the endothelial cell. Toxins are transported to and into endothelial cells from the gut on neutrophils. Most patients with D+ HUS recover kidney function but commonly require supportive care, including fluid and electrolyte balance, blood pressure control, nutritional support, and dialysis. Plasmapheresis is not beneficial. About 30% develop CKD with persistent proteinuria, and 5% develop ESKD.

Atypical HUS

Atypical HUS (aHUS) is a complement-driven illness linked to abnormalities in complement regulatory proteins leading to unopposed complement activation and development of HUS. Factor

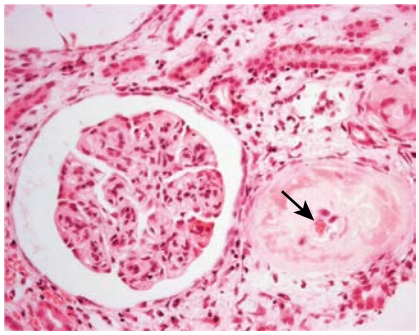

Fig. 26.22 Light microscopy of a typical haemolytic uraemic syndrome (HUS) kidney lesion. The *arrow* shows microthrombi.

H is a soluble protein produced by the liver, which regulates the activity of the alternative complement activation pathway; in particular, it protects host cell surfaces from complement-mediated damage. Factor I is a serine proteinase that plays a key role in inhibition of the alternative pathway amplification loop, which generates C3 convertase from C3b. CD46 (previously known as membrane co-factor protein, MCP) is highly expressed in the kidney and normally prevents glomerular C3 activation. Thrombomodulin has anti-inflammatory properties and plays a role in the inactivation of complement-derived anaphylatoxins. Deficiency of these factors can occur as an isolated phenomenon or due to autoantibody formation. Rarely, gain-of-function mutations can affect genes encoding the alternative pathway C3 convertase components, CFB and C3.

Severe hypertension and recurrence are frequent. The course of the disease is often indolent and progressive.

Management

Plasmapheresis or plasma infusion may be used at initiation of therapy, until thrombotic thrombocytopenic purpura (TTP) has been excluded and the diagnosis of aHUS is clear.

C5 activation is one of the critical steps in the activation of complement cascade. ***Eculizumab***, a monoclonal humanized anti-C5 antibody, has transformed outcomes, both at acute presentation and in prevention of recurrence in native kidneys and in transplants with 5-year ESKD survival improved from 40% in a control cohort to 86% in an eculizumab treated cohort. Biallelic pathogenic mutations in RNA processing genes, including EXOSC3, lead to eculizumab non-responsive aHUS, allowing targeted treatment to those who can benefit. Ravulizumab is an re-engineered form of eculizumab with an extended terminal elimination half-life allowing administration every 6 to 8 weeks (2–4 weeks with eculizumab). Liver transplantation is a potentially curative treatment in patients harbouring CFH and CFI mutations.

Sporadic cases of aHUS

These can be associated with pregnancy, SLE, scleroderma, malignant hypertension, metastatic cancer, HIV infection, and various drugs including oral contraceptives, ciclosporin, tacrolimus, chemotherapeutic agents (e.g., cisplatin, mitomycin C, bleomycin), and heparin. Management is supportive, with removal of the offending agent or specific treatment of the underlying cause. There is no evidence in favour of plasma infusion or plasmapheresis.

Streptococcus pneumoniae produces an enzyme (possibly neuraminidase) that can expose an antigen (Thomsen antigen) present on red blood cells, platelets, and glomeruli. Antibodies to the antigen result in an antigen–antibody reaction that can lead to HUS and anaemia. Awareness of this complication, judicious use of (washed) blood products, and avoidance of plasma infusion and plasmapheresis are warranted.

Cobalamin C disease is a hereditary disorder of vitamin B_{12} metabolism that may cause HUS and multiple organ damage in infants and, rarely, adults. It is caused by mutations in a gene encoding the methylmalonic aciduria and homocystinuria type C protein *(MMACHC)*. The resulting deficiency in methylcobalamin causes hyperhomocysteinaemia, decreased plasma methionine concentrations, and methylmalonic aciduria. Abnormal cobalamin C metabolism is associated with platelet activation, generation of reactive oxygen species, endothelial dysfunction, increased tissue factor expression, coagulation activation, and HUS. Parenteral hydroxocobalamin is the principal treatment for infants.

Thrombotic thrombocytopenic purpura

TTP (see Chapter 38, 'Thrombotic thrombocytopenic purpura' section) is characterized by microangiopathic haemolysis, neurological disturbance, and impaired kidney function. Distinction from aHUS requires measurement of serum activity of *ADAMTS13*. *ADAMTS13* activity is reduced in TTP, but normal in HUS and other conditions that cause thrombotic microangiopathy.

Antiphospholipid syndrome

Binding of antiphospholipid antibodies (aPL) to beta 2 glycoprotein I (β2GPI) induces endothelial cell–leucocyte adhesion and thrombus formation through the inhibition of endothelial nitric oxide synthase (eNOS). Antibodies may be primary, or secondary to infection (HIV, hepatitis C) or autoimmune disease (SLE).

A key clinical feature of antiphospholipid syndrome (APS) is recurrent thrombosis (both venous and arterial) in the presence of antiphospholipid antibodies (see Chapter 32, 'Antiphospholipid syndrome' section). Thrombotic microangiopathy is a rare but recognized. In some cases, a lupus nephritis-like lesion (usually mesangiocapillary GN) is seen. The only proven treatment for APS is systemic anticoagulation with warfarin as direct oral anticoagulants have inferior efficacy and increased bleeding risk. Use of steroids or plasmapheresis is reserved for patients with APS and life-threatening thrombotic microangiopathy.

Multiple myeloma

AKI is relatively common in myeloma, occurring in 20% to 30% of affected individuals at the time of diagnosis. It is often irreversible. Kidney involvement may present as:

- ***Light chain cast nephropathy:*** intratubular deposition of light chains, particularly kappa chains, which characteristically appear on histology as fractured casts with a giant cell reaction (Fig. 26.23)
- ***AL amyloidosis:*** deposition of amyloid fibrils of light chains (Congo-red positive)
- ***Light chain deposition disease:*** nodular glomerulosclerosis with granular deposits of usually lambda light chains (Congo red-negative)
- ***C3 nephropathy:*** a light chain variant of proliferative GN with monotypic immunoglobulin. Glomerular co-deposition of C3 is found in addition to monotypic light chain, implying complement activation via the alternative pathway
- ***Fanconi's syndrome:*** tubular toxicity due to light chains
- ***Hypercalcaemic nephropathy:*** bone resorption causing hypercalcaemia

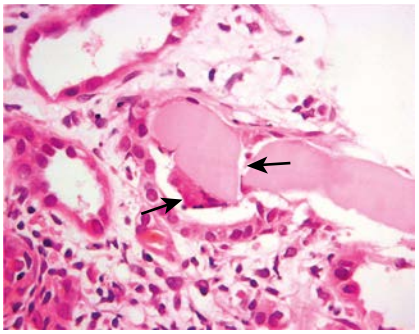

Fig. 26.23 Cast nephropathy in multiple myeloma. Light microscopy showing a characteristic fractured cast and giant cell reaction *(arrowed)*.

- ***Hyperuricaemic nephropathy:*** tumour lysis causing tubular crystallization of uric acid.

Treatment of the underlying myeloma is key to recovery (see Chapter 39, 'Myeloma' section). If a patient with cast nephropathy and severe AKI remains dialysis-dependent, prognosis is poor. Commencement of effective bortezomib-based chemotherapy decreases light chain production. Plasma exchange and high-cut-off haemodialysis are ineffective.

HYPERTENSION AND THE KIDNEY

Hypertension can be the cause or the result of kidney disease. It is often difficult to differentiate between the two on clinical grounds. Kidney function testing should be performed on all patients with hypertension, and kidney imaging may be indicated.

The ***mechanisms*** responsible for regulation of arterial blood pressure and the development of essential primary hypertension are unclear. Long-term regulation of arterial pressure is closely linked to the ability of the kidneys to excrete sufficient salt to maintain normal sodium balance, extracellular fluid volume, and normal blood volume at normotensive arterial pressures. Cross-transplantation experiments suggest that hypertension travels with the kidney, as hypertension develops in the normotensive recipient of a kidney genetically programmed for hypertension. Similarly, patients with ESKD due to hypertension become normotensive after receiving a kidney transplant from normotensive donors, provided the new kidney functions well.

One factor contributing to hypertension is the total number of nephrons per kidney ('nephron dose'). People with hypertension and normal kidney function have a significantly reduced number of nephrons in each kidney, and individual nephrons are enlarged because of glomerular hyperfiltration. Increased glomerular volume (a surrogate marker for reduced nephron number) is found in populations where hypertension is more common. Whether reduced nephron number is genetic or environmental in origin is unclear. Changes in the intrauterine environment may lead to reduced kidney volume, suggesting lower nephron number before birth, and hypertension in adult life.

Excess renal sympathetic activity may also contribute. Strategies to achieve bilateral renal sympathetic denervation were effective in patients with refractory hypertension in uncontrolled studies; to date, this benefit has not been borne out in controlled trial data.

Essential hypertension

Arterial pressure is a product of cardiac output and systemic vascular resistance (SVR). The compliance of systemic arteries is a critical component: 'stiff' (sclerotic) arteries cannot modulate pressure surges in systole, and systolic pressures rise. Over time, vessels (and the kidney) remodel:

- Small vessels and arterioles: intimal thickening with reduplication of the internal elastic lamina, hyalinization of the vessel wall
- Large vessels: concentric reduplication of the internal elastic lamina and endothelial proliferation produce an 'onion skin' appearance
- Kidney size: reduction in size of both kidneys. This may be asymmetrical if one major renal artery is more affected than the other
- Glomeruli: an increased proportion of sclerotic (scarred) glomeruli compared to age-matched controls.

Kidney function deteriorates with these changes though the risk of progression to advanced CKD varies with ethnicity. There is a fourfold higher incidence of ESKD due to hypertensive kidney disease in those of black African descent compared to white ethnicity. This difference may be due to overestimation of diagnosis, a higher incidence of hypertension (usually salt-sensitive), reduced nephron number, and/or a higher frequency of susceptibility alleles for ESKD. A genome-wide study found measurable associations between two sequence variants in the apolipoprotein L1 gene *(APOL1)* and non-diabetic nephropathy in African Americans with hypertension-attributed ESKD. These kidney disease risk variants are thought to have been positivity selected for evolutionary advantage in trypanosomal infection and protection from African sleeping sickness. Natural selection might therefore protect from one disease but allow another to develop.

In malignant hypertension arteriolar fibrinoid necrosis occurs, probably as a result of plasma entering the media of the vessel through splits in the intima. It is prominent in afferent glomerular arterioles. Fibrin deposition within small vessels is often associated with thrombocytopenia and red cell fragmentation on a peripheral blood film (microangiopathic haemolytic anaemia). Microscopic haematuria, proteinuria (usually modest, 1–3 g daily), and progressive CKD occur. If untreated, fewer than 10% of patients survive 2 years.

Management

The management of hypertension is described in Chapter 18. If treatment is effective before CKD has developed, the prognosis for kidney function is good, despite an initial fall in eGFR due to haemodynamic effects. Stabilization or improvement in kidney function, with healing of intrarenal arteriolar lesions and resolution of microangiopathic haemolysis, occurs with effective treatment of malignant hypertension.

Renal hypertension

Hypertension commonly complicates bilateral kidney disease such as chronic glomerulonephritis, reflux nephropathy, polycystic disease, and analgesic nephropathy. Two main mechanisms are responsible:

- activation of the renin–angiotensin–aldosterone system
- retention of salt and water as excretory function declines, leading to an increase in blood volume and blood pressure.

Hypertension occurs earlier, is more common, and tends to be more severe in patients with glomerular disease (GN) compared to tubulointerstitial diseases such as reflux or analgesic nephropathy.

Meticulous control of blood pressure may prevent ongoing or new vascular or parenchymal changes, and further deterioration of kidney function. There is good evidence that ACE inhibitors and angiotensin receptor antagonists offer additional renoprotective benefits for the same degree of blood pressure control as other agents, particularly when there is coexisting proteinuria.

RENOVASCULAR DISEASE

A fall in perfusion pressures in the afferent glomerular arterioles leads to increased production and release of renin from the juxtaglomerular apparatus. This causes an increase in angiotensin II, a potent vasoconstrictor, which also triggers aldosterone secretion, stimulates thirst, and leads to vascular smooth muscle hypertrophy and fibrosis in the kidney.

In renal artery stenosis, narrowing of the renal artery causes a fall in kidney perfusion pressure beyond the stenosis leading to angiotensin release, and increased salt and water. GFR is decreased. Urine from the ischaemic kidney is more concentrated, with a lower sodium concentration than urine from an unaffected kidney.

Renal artery stenosis is caused by one of two pathologies: ***atherosclerotic renovascular disease*** or ***fibromuscular dysplasia***.

Atherosclerotic renovascular disease

Atherosclerotic renovascular disease (ARVD) is a common cause of hypertension and CKD due to ischaemic nephropathy. Incidence increases with age:

- 5% in those under 60 years of age
- 16% in those over 60 years of age

Most commonly, the atherosclerotic lesion is ostial (within 1 cm of the origin of the renal artery) and usually associated with atherosclerotic vascular disease elsewhere. Patients with peripheral vascular disease (39%), coronary artery disease (10%–29%), congestive cardiac failure (34%), and aortic aneurysm (38%) have a high risk of significant renal artery stenosis. Many patients are asymptomatic and are discovered incidentally during investigation for other conditions. Aortography experience from the USA shows that 11% of asymptomatic patients have significant unilateral stenosis and 4% have bilateral disease. ARVD results in hypertension (present in 50%), sodium retention (ankle and flash pulmonary oedema), proteinuria (usually subnephrotic), and decreased GFR. Beyond the stenosis, affected kidneys demonstrate histological changes including vascular sclerosis, tubular atrophy, interstitial fibrosis with inflammatory cellular infiltrate, atubular glomeruli, cholesterol emboli, and secondary FSGS. These changes are often termed 'ischaemic nephropathy'. The affected kidney loses volume (as fibrosis replaces normal tissue) and becomes smaller on ultrasound measurement. These morphological changes are responsible for the fall in GFR whereas the arterial stenosis drives hypertension.

Renovascular disease should be considered in:

- patients with hypertension and/or CKD with abdominal or other audible bruits
- patients with kidney asymmetry, particularly where ultrasound suggests >1.5 cm difference in length
- recurrent flash pulmonary oedema without cardiopulmonary disease
- progressive CKD in patients with evidence of generalized atherosclerosis.

Screening

- ***Radionuclide studies:*** decreased kidney perfusion on the affected side (see 'Renal scintigraphy' section). In unilateral stenosis, a disproportionate fall in isotope uptake occurs on the affected side after administration of captopril. A normal result makes renovascular disease unlikely.
- ***Doppler ultrasound:*** higher renal artery velocity may mean a higher pressure differential across a stenosis. Operator dependency has led to a decline in use (in native kidneys) in clinical practice. Doppler also measures intrarenal vascular resistance, which can be valuable in predicting revascularization success. A resistive index of >80 is a predictor of poor response following intervention.
- ***MRA:*** used to visualize the renal arteries with good correlation between MRA findings and renal arteriography.
- ***CT:*** less expensive than MRA but less reliable. Also exposes patient to ionizing radiation and contrast injection.
- ***Renal arteriography:*** used to confirm the diagnosis and allow therapeutic intervention.

Management

The ***aims of treatment*** are to prevent decline in kidney function and to reverse salt and water overload. Most patients with ARVD will die a cardiovascular death and modifiable risk factors should be addressed. All patients with ARVD should be managed with a combination of aspirin, statin and optimal control of blood pressure, ideally with an ACE inhibitor or AII-RA. This is the paradox of ARVD: angiotensin drives kidney and cardiac events, so ACE inhibition is ideal medical therapy. However, because ACE inhibitors will cause a fall (often significant) in kidney perfusion beyond the stenosis, ACE inhibitors may cause AKI if there is bilateral, haemodynamically significant ARVD. Renal artery stenosis can progress to occlusion, particularly in patients with stenosis of more than 75%, as shown by serial angiography.

Revascularization offers definitive treatment of stenotic lesions in ARVD. Indications for revascularization are vessels with stenosis of >75% and recurrent flash pulmonary oedema, drug-resistant severe hypertension, ARVD affecting a solitary functioning kidney, patients with cardiac failure in whom ACE inhibition causes an unacceptable decline in kidney function, unexplained progressive CKD and dialysis-dependency. Options include transluminal angioplasty, stent insertion (sometimes the only endoscopic option when stenosis occurs close to the origin of the renal artery, making angioplasty technically difficult or impossible), reconstructive vascular surgery, and nephrectomy.

In several trials, renal artery stenting did not confer a significant benefit with respect to prevention of clinical events (cardiovascular events, progressive kidney dysfunction, or the need for RRT) when added to comprehensive medical therapy in people with atherosclerotic renal artery stenosis and hypertension or CKD. Up to 30% of renal artery interventions are complicated by atheroembolism, which may lead to further deterioration in kidney function.

Prognosis

Mortality is high from associated co-morbidities, and endothelial dysfunction. ARVD patients with ESKD have higher death rates than those with other causes of ESKD. Five-year survival is only 18% in patients with ESKD due to ARVD.

Fibromuscular dysplasia of the renal arteries

Fibromuscular dysplasia is often asymptomatic, typically occurring in younger females with hypertension. It is far less common than ARVD. FMD affects many arterial beds, including carotid and coronary arteries. Kidney function is often normal.

MRA (gadolinium-enhanced) reveals a characteristic string of beads appearance in the mid-renal artery (rather than the ostium in ARVD).

Angioplasty (occasionally with stent insertion) or, rarely surgery, was historically offered achieving cure (blood pressure <140/90 without treatment) rates of only 36% and 54%, respectively, in a study of over 2000 patients with blood pressure strongly related to

age. In addition, procedural complications were common: 12% after angioplasty and 17% after surgery. Current medical antihypertensive therapy is very effective and angioplasty is not usually performed.

Renal artery occlusion

This occurs from thrombosis *in situ*, usually in a damaged atherosclerotic vessel, or more commonly from embolization, for example, in atrial fibrillation. Leads to partial (wedge) or whole kidney infarction. Occlusion of a small branch artery may produce no symptoms but larger vessel occlusion can cause dull flank pain, macroscopic haematuria, and CKD. Intra-arterial thrombolytic therapy has been tried with mixed results.

Cholesterol embolization (atheroembolic kidney disease)

Showers of cholesterol-rich atheromatous material from ulcerated plaques reach the kidney from the aorta and/or renal arteries, particularly after catheterization of the abdominal aorta or attempts at renal artery angioplasty. Anticoagulants and thrombolytic agents also precipitate non-traumatic cholesterol embolization. Kidney failure from cholesterol emboli may be acute or slowly progressive. Clinical features include fever, eosinophilia, back and abdominal pain, and evidence of embolization elsewhere, such as to the retina or digits. Atheroembolic kidney disease occurs spontaneously in 25% of cases. It is more common in males, >70 years, and patients with cardiovascular disease. Over 80% have abnormal kidney function. Diagnosis can be confirmed by kidney biopsy (**Fig. 26.24**). The 2-year mortality is 30% and a similar percentage develop CKD. Acute/subacute presentations and co-morbidities including CKD, diabetes, heart failure, and gastrointestinal tract involvement are significant predictors of event occurrence. The risk of dialysis and death is 50% lower among those treated with statins.

Renal vein thrombosis

This is usually of insidious onset. It occurs in patients with an increased risk of venous thrombosis including nephrotic syndrome, renal cell carcinoma, and thrombophilia. Anticoagulation is indicated.

KIDNEY CALCULI AND NEPHROCALCINOSIS

Kidney and vesical calculi

Nephrolithiasis (kidney stones) usually occurs in the upper urinary tract. It is very common worldwide, with a lifetime risk of about 10%. Most stones are composed of calcium oxalate and phosphate (**Box 26.16**). Mixed infective stones, which account for about 15% of all calculi, are twice as common in females compared to males though the overall male to female ratio of stone disease is 2:1. Stone disease is frequently recurrent: more than 50% of patients will experience a second stone within 10 years of their first. The risk of recurrence increases if a metabolic or structural abnormality predisposes to stone formation and is not modified by treatment. Nephrolithiasis is not a benign condition; observational studies show an association with an increased risk of ESKD, bone diseases, hypertension, and myocardial infarction.

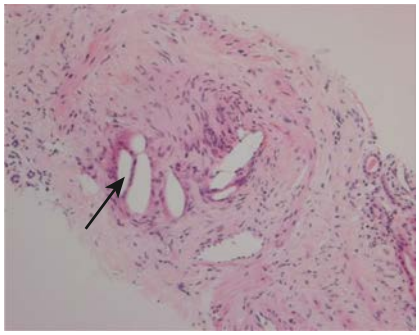

Fig. 26.24 Kidney cholesterol emboli showing characteristic cholesterol biconvex clefts *(arrowed)*.

Box 26.16 Type and frequency of kidney stones in the UK

Type of kidney stone	Percentage of stones
Calcium oxalate usually with calcium phosphate	65
Calcium phosphate alone	15
Magnesium ammonium phosphate (struvite)	10–15
Uric acid	3–5
Cystine	1–2

Aetiology

Stones form because solute concentrations exceed saturation, often in the context of a trigger or nidus to crystallize around. Inhibitors of crystal formation prevent stone formation in normal urine, despite the concentrations of stone-forming substances exceeding maximum solubility. Factors predisposing to stone formation are:

- ***Chemical composition of urine*** that favours stone crystallization.
- ***A concentrated urine*** resulting from dehydration (e.g., living/working in a hot climate or environment).
- ***Impairment of inhibitors that prevent crystallization*** in normal urine including inorganic magnesium, pyrophosphate, and citrate. Organic inhibitors include glycosaminoglycans and nephrocalcin (an acidic protein of tubular origin). Tamm–Horsfall protein may have a dual role in both inhibiting and promoting stone formation; it usually inhibits crystallization of urinary oxalate but in an undersialylated form promotes stone formation.

Recognized risk factors for stone formation are listed in **Box 26.17**.

Stones may be single or multiple, and vary enormously in size from minute, sand-like particles to staghorn calculi or large stone concretions in the bladder. They may be located within the kidney parenchyma or within the collecting system. Stones regularly cause obstruction, leading to hydronephrosis. A combination of obstruction and infection often causes lasting damage to the kidney.

Box 26.17 Risk factors for urinary tract stones

- Dehydration
- Hypercalcaemia
- Hypercalciuria
- Hyperoxaluria
- Hyperuricaemia and hyperuricosuria
- Infection
- Cystinuria
- Primary kidney disease (polycystic kidneys, medullary sponge kidneys, renal tubular acidosis)
- Drugs (see text)

Hypercalcaemia

If the GFR is normal, hypercalcaemia usually leads to hypercalciuria. Common causes of hypercalcaemia leading to stone formation are:

- primary hyperparathyroidism
- vitamin D ingestion
- sarcoidosis.

Hypercalciuria

This is the most common metabolic abnormality in calcium stone-formers. Approximately 8% of males excrete more than 7.5 mmol of calcium per day and calcium stone formation is more common in this group. In females, a 24-hour calcium excretion of more than 6.25 mmol makes stone formation more likely. About 90% of ionized calcium filtered by the kidney is reabsorbed, controlled largely by PTH. Causes of hypercalciuria include:

- hypercalcaemia
- high dietary calcium intake
- excessive resorption of calcium from the skeleton, e.g., prolonged immobilization or weightlessness
- idiopathic hypercalciuria: accelerated calcium transport, enhanced gut uptake, and increased urine excretion are thought to play a role.

Hyperoxaluria

Three autosomal recessive inborn errors of glyoxylate metabolism cause increased endogenous oxalate biosynthesis and calcium oxalate stone formation:

- ***Type 1:*** alanine–glyoxylate aminotransferase deficiency
- ***Type 2:*** glyoxylate reductase hydroxypyruvate reductase deficiency
- ***Type 3:*** 4-hydroxy-2-oxoglutarate aldolase 1 deficiency.

Widespread calcium oxalate crystal deposition in the kidneys leads to CKD in late teens or early twenties. Liver transplantation cures the metabolic defect.

More common causes of mild hyperoxaluria include:

- excess ingestion of oxalate-rich food, e.g., spinach, rhubarb, tea
- dietary calcium restriction with compensatory increased absorption of oxalate
- gastrointestinal disease (e.g., Crohn's), usually with intestinal resection, leads to increased colonic absorption of oxalate. Dehydration secondary to fluid loss from the gut may contribute.

Hyperuricaemia and hyperuricosuria

Uric acid stones account for 3% to 5% of all stones in the UK, but up to 40% in Israel. Uric acid is the end-point of purine metabolism. Hyperuricaemia increases uric acid excretion and stones can develop. Hyperuricaemia can occur as a primary defect, for example, idiopathic gout, or secondary to increased cell turnover, for example, myeloproliferative disease. Hyperuricosuria (>4 mmol/24 h on a low-purine diet) can occur without hyperuricaemia. Dehydration can also lead to uric acid stone formation. Patients with ileostomies are at particular risk due to a combination of dehydration in conjunction with gastrointestinal bicarbonate loss, which produces an acidic urine in which uric acid is less soluble. Some patients with calcium stones have hyperuricaemia and/or hyperuricosuria, with precipitation of calcium salts on an initial nidus of uric acid hypothesized.

Infective stones

Mixed infective stones are composed of magnesium ammonium phosphate (struvite) with variable amounts of calcium. Such stones are often large, forming a cast of the collecting system (staghorn calculus). Urinary tract infection with organisms that hydrolyze urea (e.g., *Proteus mirabilias*) leads to the formation of the strong base ammonium hydroxide. The availability of ammonium ions and the alkalinity of the urine favour stone formation. An increased production of mucoprotein from infection creates an organic matrix on which stone formation can occur.

Cystinuria

Cystinuria results in the formation of cystine stones (about 1%–2% of all stones).

Primary kidney disease

- ***Polycystic kidney disease*** (see 'Autosomal dominant polycystic kidney disease' section) has a high prevalence of stone disease.
- ***Medullary sponge kidney*** leads to dilation of collecting ducts with urinary stasis and calcification (Fig. 26.25). Approximately 20% have hypercalciuria and a similar proportion have a tubular acidification defect.
- ***Renal tubular acidosis***, either inherited and acquired, is associated with nephrocalcinosis and stone formation. Persistently alkaline urine and reduced urinary citrate excretion lead to stone formation, as there is less citrate to form a soluble complex with calcium in urine.

Drugs

Drugs can promote calcium stone formation (e.g., loop diuretics, antacids, glucocorticoids, theophylline, vitamins D and C, acetazolamide), uric acid stone formation (e.g., thiazides, salicylates), or precipitate into stones (e.g., indinavir, triamterene, sulfadiazine).

Other

Calcified papillae may mimic calculi, so causes of papillary necrosis such as analgesia misuse should be considered.

Clinical features

Most people with urinary tract calculi are asymptomatic. When symptoms exist (Box 26.18), pain is the most common symptom. It may be sharp or dull, constant, intermittent, or colicky. Classically, pain radiates from the flank to the iliac fossa, testis, or labia (in the distribution of the first lumbar nerve root). Ureteric colic occurs when a stone enters the ureter and either obstructs it or causes spasm during its passage down the ureter. Pallor, sweating and vomiting occur, and the patient is restless, trying to obtain relief from the pain. Fluids or diuretics (including alcohol) make the pain worse as peristaltic flow increases. Exertion may cause mobile calculi to move, precipitating pain and haematuria. Untreated, the pain of ureteric colic typically subsides after a few hours. When urinary tract

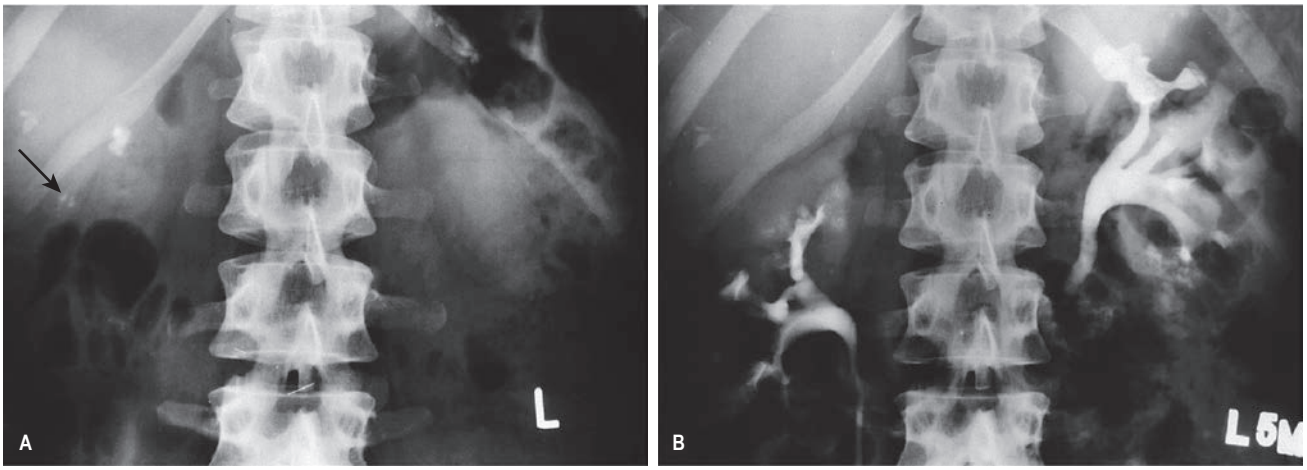

Fig. 26.25 Medullary sponge kidney. **(A)** Plain film showing 'spotty' calcification in the kidney *(arrowed)*. **(B)** Contrast reveals the calcification to be small calculi in the papillary zones.

Box 26.18 Clinical features of urinary tract stones

- Asymptomatic
- Pain, renal colic
- Haematuria
- Urinary tract infection
- Urinary tract obstruction

obstruction and infection are present, features of acute pyelonephritis or Gram-negative septicaemia may dominate the clinical picture.

Bladder stones

Bladder stones occur where stasis (e.g., bladder outflow obstruction), infection, and a nidus for stone formation (e.g., migratory stone, thrombus, foreign body) occur together. They are usually associated with bacteriuria and present with frequency, dysuria, and haematuria. Vaginal or perineal pain may occur if trigonitis is present. A calculus at the bladder neck or an obstruction in the urethra may cause bladder outflow obstruction, resulting in anuria and painful bladder distension.

Investigations

- ***Dipstick:*** test for red cells, protein, and glucose.
- ***Chemical analysis:*** of passed stones.
- ***Mid-stream specimen of urine:*** microscopy (crystals) and culture.
- ***Serum urea, electrolyte, creatinine (eGFR), and calcium concentrations.***
- ***Ultrasonography:*** kidney stones and kidney pelvis dilation (ureteric stones can be missed).
- ***Computed tomography of kidneys, ureters, and bladder (CT-KUB):*** sensitivity of >95% for detection of stones, see **Figs. 26.26 and 26.27**. CT has largely replaced plain radiographs and excretion urography.
- ***Excretion urography/intravenous pyelography:*** largely replaced with CT. Pure uric acid stones are radiolucent and show as filling defects. Mixed infective stones in which organic matrix predominates are barely radio-opaque.

Management

NSAIDs (e.g., diclofenac 50–75 mg i.m.) compare favourably with opiates (e.g., diamorphine, pethidine). Stones smaller than 0.5 cm diameter usually pass spontaneously, particularly if hydration is maintained (patients that can drink should aim for over 2.5 L intake/24 h). Alpha-blockers (e.g., tamsulosin) were thought to help expulsion of distal ureteral stones smaller than 6 mm (alpha receptors are predominantly present in the distal ureter and detrusor) but a randomized controlled trial has shown no benefit. Larger stones usually need urological or radiological intervention:

- Extracorporeal shock-wave lithotripsy (ESWL) fragments most stones, which then pass spontaneously
- Ureteroscopy with a YAG laser
- Percutaneous nephrolithotomy.

Investigation of the cause of stone formation

- ***Kidney imaging:*** for structural abnormalities of the urinary tract.
- ***Urine culture:*** for significant bacteriuria.
- ***Chemical analysis:*** of any passed stone (required for diagnosis of cystinuria or uric acid stone).
- ***Serum calcium:*** with investigation for cause if hypercalcaemia present (e.g., hyperparathyroidism, malignancy).
- ***Serum urate concentration:*** often elevated in uric acid stone-formers.
- ***Screening for cystinuria:*** a purple colour can be seen when sodium nitroprusside is added to an unacidified urine sample if cystinuria is present. Urine chromatography is required for definitive diagnosis.
- ***Urinary calcium, oxalate, and uric acid concentrations*** in two consecutive 24-hour urine samples. Aliquots are withdrawn for estimation of uric acid, after which the urine is acidified to prevent crystallization of calcium salts on the walls of the container, which would give falsely low results for urinary calcium and oxalate.
- ***Plasma bicarbonate:*** low in renal tubular acidosis. A urine pH that does not fall below 5.5 in metabolic acidosis is diagnostic (see Chapter 27, 'Renal tubular acidosis' section).

Prevention of recurrent stones

Idiopathic stone formers:

- High fluid intake: a daily urine volume of 2 to 2.5 L reduces saturation of solute.
- Reduction of animal protein intake to less than 50 g/day. Ingested protein is a source of purine, produces an acid load, and increases urinary calcium and oxalate excretion.

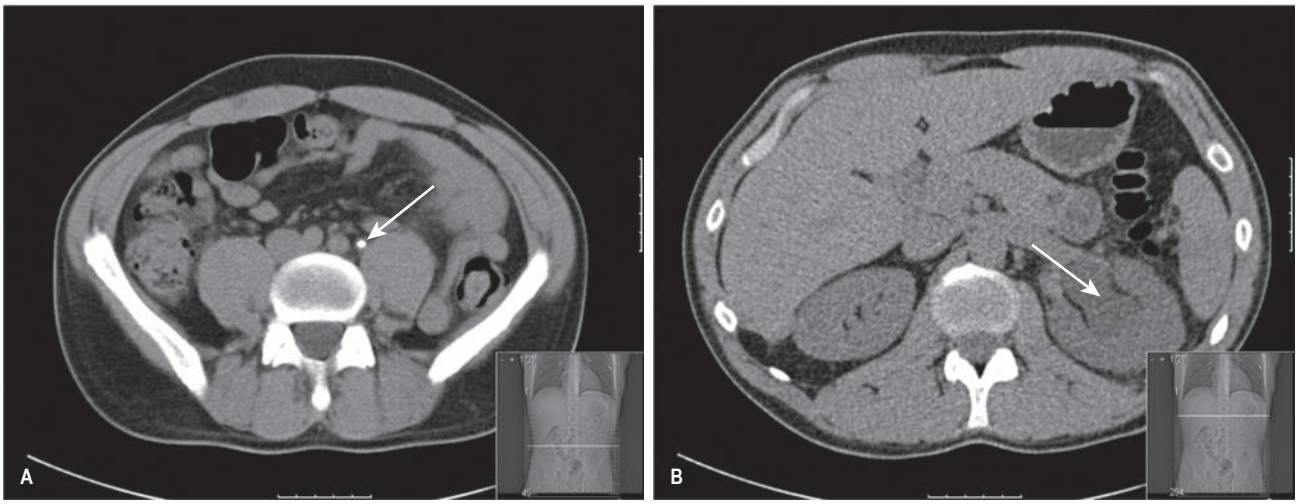

Fig. 26.26 Computed tomography of kidneys, ureters, and bladder (CT-KUB) in ureteric stone obstruction. **(A)** Left ureteric calculus *(arrowed)*. **(B)** A dilated renal pelvis *(arrowed)* proximal to the ureteric stone in A.

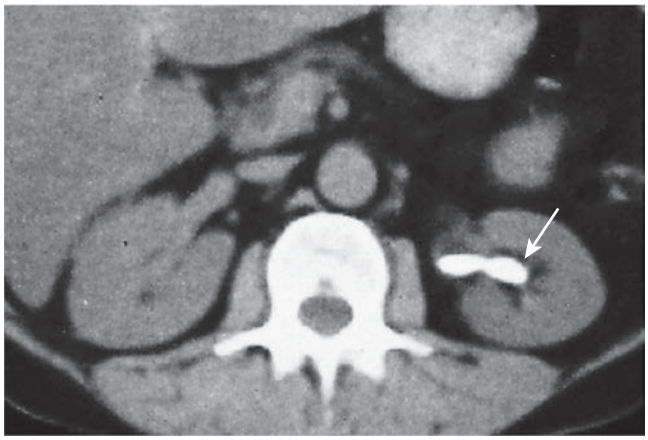

Fig. 26.27 CT scan showing a uric acid stone. The stone appears as a bright lesion in the left kidney *(arrowed)*.

Hypercalciuria:

- Dietary calcium restriction is inappropriate as restriction results in hyperabsorption of oxalate. Foods rich in oxalate should be avoided (nuts, spinach, chocolate, rhubarb). Patients in hard-water areas may benefit from drinking softened water.
- Limit salt intake to 50 mmol/day. Calcium excretion increases by 0.6 mmol/day for every 100 mmol Na^+ in the urine.
- Thiazide diuretic (e.g., bendroflumethiazide 2.5–5 mg) is hypothesized to reduce urinary calcium excretion due to mild volume contraction increasing proximal tubule calcium absorption. However, no benefit demonstrated in a randomized controlled trial.

Infective stones:

- Low-dose prophylactic antibiotics may prevent bacteriuria.

Uric acid stones:

- Allopurinol or febuxostat to maintain serum urate and urinary uric acid excretion in the normal range.
- Bicarbonate supplementation alkalinizes the urine making uric acid more soluble. However, alkalinization also facilitates precipitation of calcium oxalate and phosphate and so it is used with care.

Cystine stones:

- Can be prevented and will dissolve slowly with a high fluid intake, for example, 5 L of water in 24 hours. Patients also need to wake twice during the night to drink 500 mL or more of water. Understandably, many patients cannot tolerate this regimen. Alkalinization to a urine pH of 7 requires high doses of potassium citrate or bicarbonate. An alternative option is long-term use of penicillamine, which converts cystine to a more soluble penicillamine–cysteine complex. Side-effects include drug rashes, blood dyscrasias, and immune complex-mediated glomerulonephritis. Other cystine-binding drugs include captopril and tiopronin.

Hyperoxaluria:

- Lumasiran reduces concentrations of glycolate oxidase by targeting hydroxyacid oxidase 1 mRNA in hepatocytes through RNA interference. It is now available as first-line therapy for type 1 primary hyperoxaluria. Oral high-dose pyridoxine can also be used for type 1 disease (no therapeutic response in type 2). Unfortunately, there is currently no proven pharmacotherapy for 'idiopathic' hyperoxaluria present in up to 40% of stone-formers. Probiotic *Oxalobacter formigenes* has shown some promise.

Nephrocalcinosis

'Nephrocalcinosis' describes diffuse parenchymal calcification that is detectable radiologically (**Fig. 26.28**). The condition is typically painless. Hypertension and CKD commonly occur. The main causes of nephrocalcinosis are listed in **Box 26.19**.

Dystrophic calcification occurs following cortical necrosis. In ***hypercalcaemia and hyperoxaluria***, deposition of calcium oxalate results from the high concentrations of calcium and oxalate within the kidney. In ***renal tubular acidosis*** (see Chapter 27, 'Renal tubular acidosis' section), failure of urinary acidification favours calcium and oxalate precipitation in alkali urine, and a reduction in urinary citrate excretion reduces calcium chelation.

Management and prevention of nephrocalcinosis consist of treating the cause.

URINARY TRACT OBSTRUCTION

Urinary tract obstruction can occur at any point between the kidney and the urethral meatus. Obstruction can be partial or complete, and leads to delayed transit of urine, rising urinary tract (and intrarenal) pressure, and—if obstructing both kidneys—eventual kidney impairment.

Aetiology

Obstructing lesions may lie within the lumen, in the wall of the urinary tract or outside the wall causing obstruction by external pressure. Obstruction causing dilation of the renal pelvis and/or ureter is termed hydronephrosis. Causes of obstruction are shown in **Box 26.20**. In children, obstruction usually results from congenital abnormalities, for example, urethral valves. Pelvic tumours, pregnancy, and stones cause obstruction in females. In males, stones are the dominant cause in young adults, but bladder outflow obstruction from prostatic disease dominates later in life.

Pathophysiology

Urine continues to be formed despite obstruction to flow. This leads to:
- progressive rise in intraluminal pressure
- dilation proximal to the site of obstruction
- compression and thinning of the renal parenchyma, eventually reducing it to a thin rim and a decrease in kidney size.

Box 26.20 Causes of urinary tract obstruction

Within the lumen
- Calculus
- Blood clot
- Sloughed papilla: diabetes, analgesia misuse, sickle cell disease or trait
- Tumour of renal pelvis, ureter, or bladder

Within the wall
- Pelviureteric neuromuscular dysfunction: congenital, 10% bilateral
- Ureteric stricture: tuberculosis (especially after treatment), calculus, after surgery
- Ureterovesical stricture: congenital, ureterocele, calculus, schistosomiasis
- Congenital megaureter
- Congenital bladder neck obstruction
- Neuropathic bladder
- Urethral stricture: calculus, gonococcal, after instrumentation
- Congenital urethral valve
- Pin-hole meatus

Pressure from outside
- Pelviureteric compression: bands, aberrant vessels
- Tumours: retroperitoneal tumour, colon, pelvis, ovarian, cervix, malignant lymphadenopathy
- Diverticulitis
- Aortic aneurysm
- Retroperitoneal fibrosis: peri-aortitis, e.g., IgG4 disease
- Accidental ligation of ureter
- Retrocaval ureter: right-sided obstruction
- Prostatic obstruction
- Phimosis

Acute obstruction leads to transient renal arterial vasodilation, followed by vasoconstriction probably mediated mainly by angiotensin II and thromboxane A_2. Ischaemic interstitial damage mediated by free oxygen radicals and inflammatory cytokines compounds the damage due to pressure.

Clinical features

Symptoms

Loin pain occurs, which can be dull or sharp, and constant or intermittent. Pain can be worse if urine flow and volume increase as the collecting system distends. A high fluid intake or diuretics, including alcohol and coffee, may provoke pain. Anuria is strongly suggestive of complete bilateral obstruction or obstruction of a single kidney. Polyuria may occur in partial obstruction, as rising pressures impair tubular concentrating capacity. Infection is a major complication and may cause malaise, fever, and signs and symptoms of sepsis.

Acute bladder retention causes significant discomfort and distress. It may present as confusion and agitation in the elderly. Chronic bladder outflow obstruction can occur with few symptoms, though if due to prostate disease, symptoms of prostatism (hesitancy, poor stream, terminal dribbling, and a sense of incomplete bladder emptying) may be present. Infection is common (and may precipitate acute retention) with symptoms including frequency, urgency, urge incontinence, dysuria, and offensive urine.

Signs

On abdominal palpation, loin tenderness may be present. Occasionally an enlarged hydronephrotic kidney is palpable. In bladder retention, the enlarged bladder can be felt or percussed. Examination of the genitalia, prostate, and rectum are warranted as prostatic obstruction and pelvic malignancy are common causes of urinary tract obstruction.

Investigations

- ***Urinalysis:*** for haematuria.
- ***Mid-stream sample of urine:*** for infection.
- ***Kidney function:*** serum potassium, urea, and creatinine to assess for kidney injury.
- ***Haemoglobin:*** to assess for anaemia of chronic disease.
- ***Prostate-specific antigen*** (see Chapter 47, 'Benign conditions of the prostate' section).
- ***Ultrasonography*** is the investigation of choice to examine for upper urinary tract dilation. Stones in the ureter can be missed.
- ***Plain abdominal radiography*** may detect radiolucent stones/calcification but can miss radiolucent stones and stones lying over bone.
- ***CT scanning*** has a high sensitivity, can visualize radiolucent stones as small as 1 mm, and delineates the anatomy of any obstruction, local mass lesions, or lymphadenopathy.
- ***Excretion urography*** is now seldom used. A characteristic delayed nephrogram is seen on the obstructed side (owing to a reduction in GFR). With time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, and the site of obstruction with proximal dilation is seen (**Fig. 26.29**).
- ***Radionuclide studies*** (see 'Renal scintigraphy' section) have a role in chronic obstruction to differentiate true obstructive nephropathy from retention of tracer in a baggy, low-pressure, unobstructed pelvicalyceal system.
- ***Antegrade pyelography and ureterography*** define site and cause of obstruction.
- ***Retrograde ureterography***. Relief of ureteric obstruction from below may be possible at the same time. In obstruction due to neuromuscular dysfunction at the pelviureteric junction or retroperitoneal fibrosis, the collecting system may fill normally from below.
- ***Cystoscopy and urethroscopy*** can visualize obstructing lesions within the bladder and urethra directly.
- ***Urethrography*** involves introducing contrast medium into the bladder by catheterization or suprapubic bladder puncture and taking radiographs during voiding. It may be of value in the diagnosis of urethral valves.

Management

Treatment aims to:

- relieve the obstruction
- treat the underlying cause
- prevent and treat infection
- preserve kidney function.

An obstructed and infected urinary tract is a medical emergency and delay in treatment can lead to septicaemia. It should be managed with:

- Bladder catheterization for rapid relief of bladder outflow obstruction. If a urinary catheter cannot be passed urethrally, a suprapubic catheter should be placed.
- Image-guided percutaneous nephrostomy for obstructed and hydronephrotic kidneys.
- Cystoscopic (retrograde) stenting provided this can be done without delay to treatment.

In contrast, in partial urinary tract obstruction, particularly if spontaneous relief is expected—such as by passage of a calculus—immediate treatment may not be indicated.

Surgical management depends on the cause of the obstruction. Dialysis may be indicated for obstruction causing kidney failure.

Fig. 26.29 Intravenous urography 24 hours after injection of contrast. A delayed nephrogram and pyelogram are shown on the left side, with urinary tract dilation proximal to an obstruction. Within the same time period, contrast medium has disappeared from the normal right side.

Post-obstructive diuresis

This occurs after relief of obstruction at any site in the urinary tract. Massive diuresis may occur following relief of bilateral obstruction due to a combination of prior sodium and water retention, the osmotic effect of retained solutes, and defective tubular reabsorptive capacity. This diuresis is associated with increased blood volume and high concentrations of atrial natriuretic peptide (ANP). The diuresis is usually self-limiting, but a minority of patients develop severe sodium, water, and potassium depletion needing intravenous replacement. In milder cases, oral salt and potassium supplements, together with increased oral water intake, are sufficient.

Calculi

See 'Kidney calculi and nephrocalcinosis' section.

Pelviureteric junction obstruction

A functional disturbance in peristalsis of the collecting system, without mechanical obstruction, causing pelvic hydronephrosis (**Fig. 26.30**). In patients with recurrent loin pain or progressive kidney damage, surgical correction by open or percutaneous pyeloplasty is indicated.

Obstructive megaureter

This childhood condition (more common in males) may become evident only in adult life. It results from a region of defective peristalsis at the lower end of the ureter adjacent to the ureterovesical junction.

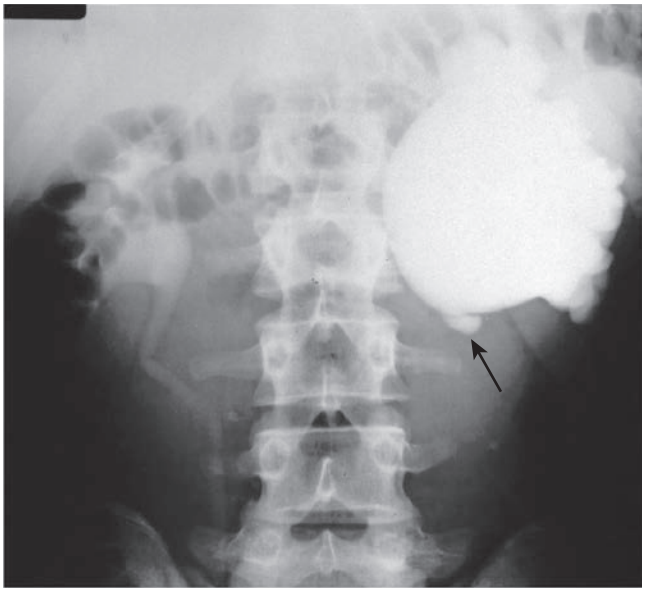

Fig. 26.30 Radiograph showing left pelviureteric junction obstruction *(arrowed)*.

It presents with urinary tract infection, flank pain, or haematuria. The diagnosis is made on imaging with ultrasound, CT, or, if necessary, ascending ureterography.

Excision of the abnormal portion of ureter with re-implantation into the bladder indicated in progressive deterioration in kidney function, bacteriuria that cannot be controlled by medical means, and recurrent stone formation.

Retroperitoneal fibrosis (chronic peri-aortitis)

Retroperitoneal fibrosis (RPF) is a descriptive term used when inflammatory fibrotic tissue encases the aorta and ureters. RPF is three times more common in males than in females and is an IgG4-related disease.

Extraluminal ureteric obstruction leads to unilateral or bilateral obstruction. The condition may extend from the level of the second lumbar vertebra to the pelvic brim. In up to 15% of patients, the fibrosis exists outside the retroperitoneum, consistent with it being a systemic condition. Mediastinal fibrosis, Riedel fibrosing thyroiditis, sclerosing cholangitis, fibrotic orbital pseudotumour, fibrotic arthropathy, and pleural, pericardial, and lung fibrosis have been reported in IgG4-related disease.

RPF is thought to be either an autoallergic inflammatory reaction to leaked material, probably ceroid material from atheromatous plaques, or a systemic autoimmune disease. There is an association with HLA-DRB1*03, an allele linked to various autoimmune diseases. RPF is possibly initiated as a vasa vasorum vasculitis in the aortic wall, which is often seen in chronic peri-aortitis. This inflammatory process causes medial wall thinning, promotes atherosclerosis, and extends into the surrounding retroperitoneum with a fibro-inflammatory reaction typical of chronic peri-aortitis. The autoimmune reaction to plaque antigens could be an epiphenomenon of this immune-mediated process. Activating antibodies against fibroblasts (detectable in one-third of patients) have also been implicated in the pathogenesis, as has the presence of IgG4-bearing plasma cells; the latter is a common finding in autoimmune chronic pancreatitis, a disorder sometimes associated with idiopathic retroperitoneal fibrosis. In addition, several infiltrating B cells

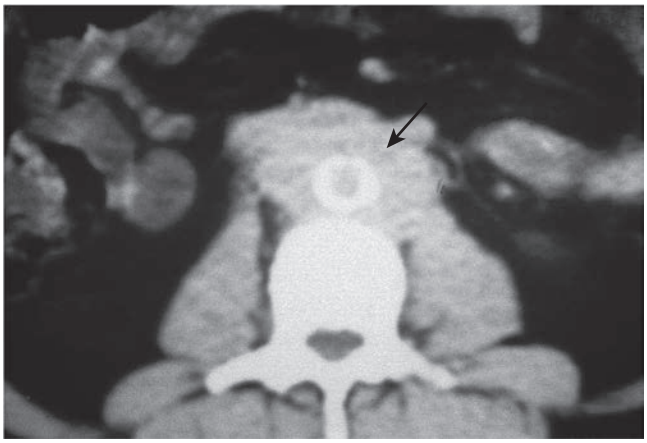

Fig. 26.31 Retroperitoneal fibrosis (peri-aortitis). Note the large mass *(arrowed)* surrounding the abdominal aorta on CT.

show clonal or oligoclonal immunoglobulin heavy chain rearrangement. These findings raise the possibility of RPF being a primary B-cell disorder.

Aetiology

Causes are many:

- Idiopathic in 60% to 70%.
- Secondary causes include:
  - Drugs: methysergide, lysergic acid, ergot-derived dopamine receptor agonists (cabergoline, bromocriptine, pergolide), ergotamine, methyldopa, hydralazine, beta-blockers.
  - Malignancy: colon, prostate, breast and stomach cancers, carcinoid, Hodgkin and non-Hodgkin lymphomas, sarcoma.
  - Infection: tuberculosis, syphilis, histoplasmosis, actinomycosis, fungal infection.
  - Surgery/radiotherapy: lymph node resection, colectomy, hysterectomy, aortic aneurysm repair.

Recognized associations include untreated abdominal aortic aneurysm, smoking, and asbestosis.

Clinical features and investigation

Presenting symptoms include malaise, low back pain, weight loss, testicular pain, claudication, and haematuria. Laboratory tests show normochromic anaemia, CKD, raised ESR, and increased CRP and serum IgG4 concentrations. Imaging with ultrasound shows a poorly circumscribed peri-aortic mass. Contrast-enhanced CT will also show the mass, as well as any tumour and lymphadenopathy (**Fig. 26.31**). MRI will demonstrate similar findings but does not require contrast. FDG-PET assesses the metabolic activity of the retroperitoneal mass; it also allows whole-body imaging and can detect occult malignant or infectious foci, particularly in secondary RPF.

Management

A biopsy is performed to exclude an underlying infection, lymphoma, or cancer. Initial management may involve decompressing obstructed ureters by stenting (anterograde or retrograde). Corticosteroids may reverse the obstructing inflammatory tissue, if only as a holding measure before definitive treatment of the underlying cause. Rituximab is effective in cases of proven IgG4-related disease. Response to treatment is assessed by serial measurements of ESR and repeat FDG-PET.

Obstruction is relieved surgically by ureterolysis. Long-term ureteric stent or stents can be used with chronic corticosteroid therapy,

but regular (usually 6-monthly) changes of the stent(s) are required if the peri-aortic mass does not regress.

Relapse after withdrawal of steroid therapy may occur and treatment may need to be continued for years. Mycophenolate or tamoxifen are also effective. Long-term follow-up is mandatory.

Benign prostatic hypertrophy

Benign prostatic hypertrophy is a common cause of urinary tract obstruction (see Chapter 47, 'Male health' section).

Prognosis of urinary tract obstruction

Prognosis is determined by aetiology and the stage at which obstruction is relieved. Four factors influence the extent of kidney damage and the degree and rapidity of recovery of kidney function after relief of obstruction:

- whether obstruction is partial or complete
- the duration of obstruction
- the presence or absence of infection
- the site of obstruction.

Complete obstruction for several weeks will lead to irreversible or only partially reversible kidney damage. If complete obstruction lasts several months, irreversible kidney damage occurs. Partial obstruction carries a better prognosis, depending on severity. Bacterial infection with obstruction increases kidney damage. Obstruction at or below the bladder neck leads to hypertrophy and trabeculation of the bladder without a rise in pressure within the upper urinary tract, in which case the kidneys are offered some protection from the effects of back-pressure.

DRUGS AND THE KIDNEY

The kidney eliminates many drugs, as well as the (often active) products of hepatic drug metabolism. Drug dosing often requires adjustment in CKD. Drugs can also impair kidney function either over time or acutely, for example, when an ACE inhibitor prevents an appropriate response to hypovolaemia.

Drug-induced impairment of the kidney can be caused by reduced kidney perfusion or direct kidney damage.

Causes of **reduced kidney perfusion** include:

- Hypovolaemia, e.g., loop diuretics such as furosemide.
- Salt and water loss, e.g., hypercalcaemia (adversely affects tubular salt and water conservation) induced by vitamin D therapy.
- Decrease in cardiac output which impairs kidney perfusion, e.g., beta-blocker.
- Decrease in kidney blood flow, e.g., ACE inhibitors, particularly in the presence of renovascular disease.

Direct kidney damage can be caused by:

- ***Acute tubular necrosis*** from prolonged or high-dose treatment with aminoglycosides (e.g., gentamicin, amikacin), amphotericin B, tenofovir, cisplatin, or calcineurin inhibitors. The combination of aminoglycosides with loop diuretics is particularly nephrotoxic.
- ***Crystal nephropathies*** caused by antivirals such as aciclovir and indinavir.
- ***Acute tubulointerstitial nephritis*** (see **Box 26.25**), a cell-mediated hypersensitivity nephritis occurring with many drugs including penicillins, cephalosporins, proton pump inhibitors, diuretics, sulphonamides, and NSAIDs (which have many other effects on the kidney. See **Box 26.21**).
- ***Chronic tubulointerstitial nephritis*** due to drugs (see **Box 26.26**).
- Drug-induced ***membranous glomerulonephritis*** e.g., penicillamine, gold, anti-TNF (see 'Membranous glomerulopathy' section).
- Retroperitoneal fibrosis with urinary tract obstruction secondary to medication (see 'Retroperitoneal fibrosis [chronic peri-aortitis]' section).

Box 26.21 Non-steroidal anti-inflammatory drugs and the kidney

Problem	Cause
Sodium and water retention	Reduced prostaglandin production
Acute tubulointerstitial nephritis	Hypersensitivity reaction
Nephrotic syndrome	Membranous glomerulopathy
Analgesic nephropathy	Papillary necrosis after chronic use
Acute kidney injury	Acute tubular necrosis
Hyperkalaemia	Decreased excretion of K^+

Using drugs in patients with impaired kidney function

See **Box 26.22**.

Absorption

Absorption can be unpredictable in uraemia, as gastric emptying may be delayed, and nausea and vomiting are frequent.

Metabolism

Drug metabolism by the kidney can be altered in CKD due to:

1. ***Reduced drug catabolism.*** Insulin catabolism is reduced in kidney disease meaning that insulin requirements in diabetes fall as kidney function declines.
2. ***Reduced conversion of a precursor to a more active metabolite.*** The 1α-hydroxylase enzyme responsible for conversion of 25-hydroxycholecalciferol to active 1,25-$(OH)_2D_3$ is in the kidney. In kidney disease, production of the enzyme declines, and deficiency of 1,25-$(OH)_2D_3$ results.

Protein binding

Reduced protein binding of a drug can increase its activity and potential for toxic side-effects. This occurs in hypoalbuminaemia (nephrotic syndrome) and when uraemic toxins bind to albumin and occupy drug-binding sites. Measurement of total plasma drug concentration (albumin-bound plus free drug) can give misleading results. For example, more free phenytoin than albumin-bound phenytoin is present in CKD for the same total plasma concentration, therefore lower total concentrations will control seizures.

Box 26.22 Safe prescribing in kidney disease

Adverse drug reactions are more than twice as common in patients with CKD compared to patients with normal kidney function. Safe prescribing in CKD demands knowledge of the clinical pharmacology of the drug and its metabolites in the context of reduced kidney function. Consider:

1. Is treatment indicated? Withhold if not.
2. Can the drug reach its site of action? For example, bacteriostatic concentrations of nitrofurantoin will not be attained in the urine in CKD with reduced glomerular filtration.
3. Is the drug's metabolism altered by CKD? If a drug or its metabolites undergo significant excretion by the kidneys, toxic accumulation may occur. Loading dose depends on the size of the patient and is unrelated to kidney function. After loading, avoidance of toxic concentrations requires administration of standard doses at longer time intervals, or smaller doses at the usual time intervals.
4. Is the drug toxic to the kidney? Toxicity is likely to be more significant if underlying CKD.
5. Is there a narrow therapeutic window? Should (can) blood concentrations of the drug be measured?
6. Is the drug a sodium or potassium salt? These are potentially hazardous when CKD is already complicated by salt (and water) overload or hyperkalaemia.
7. Can the dose be titrated? For example, observation of clinical effect, early detection of toxicity effects, measurement of drug concentrations, e.g., gentamicin.

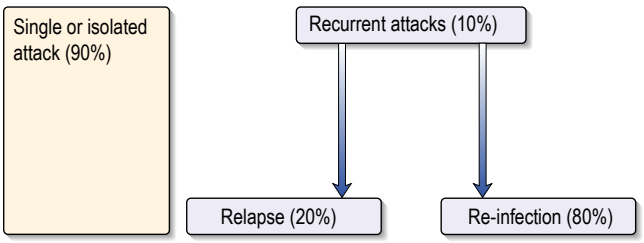

Fig. 26.32 **The natural history of urinary tract infection.**

Box 26.23 Organisms causing urinary tract infection

Organism	Approximate frequency (%)
Escherichia coli and other 'coliforms'	70
Proteus spp.	12
Staphylococcus saprophyticus or epidermidis[a]	10
Enterococcus faecalis[b]	6
Pseudomonas spp.	5
Klebsiella spp.	4

[a]More common in young females (20%–30%).
[b]More common in hospital practice.

Volume of distribution

Salt and water overload or depletion may occur in kidney disease. This affects the concentration of drug obtained from a given dose.

End-organ sensitivity

The renal response to drug treatment may be reduced in kidney disease. For example, thiazide diuretics may have little diuretic effect in patients with advanced CKD.

Drug elimination

Drugs eliminated by the kidneys are not excreted normally in CKD. This is usually more significant for water-soluble drugs (e.g., gentamicin), which are poorly absorbed from the gut, typically given by injection, and not metabolized by the liver, compared to lipid-soluble drugs (e.g., propranolol), which are well absorbed from the gut and principally metabolized by the liver.

Drugs affecting protein anabolism and catabolism

Tetracyclines, with the exception of doxycycline, have a catabolic effect. Increased nitrogenous waste products are not well cleared in advanced CKD and uraemia may be more marked. Corticosteroids have a catabolic effect and may lead to a disproportionate increase in serum urea compared to creatinine when used in high doses in CKD.

Changing kidney function

Patients with rapidly changing kidney function (e.g., evolving AKI, recovering ATN) and the removal of drugs by dialysis and haemofiltration will affect the dosage required.

URINARY TRACT INFECTION

Urinary tract infection (UTI) is common. Between 1% and 2% of patients presenting in primary care will have a UTI. Most UTIs occur in isolation (Fig. 26.32). UTI is most common in females, usually as cystitis. Half of all females have a UTI in their lifetime, most often occurring in a normal urinary tract. UTI is uncommon in males and children, often occurring in an abnormal urinary tract. UTI is not always uncomplicated; recurrent infection causes morbidity, and infection can lead to life-threatening Gram-negative septicaemia and kidney failure.

Aetiology and pathogenesis

Infection is most often caused by bacteria from a patient's own bowel flora (Box 26.23) and usually ascends the urethra. In females, the short urethra makes ascending infection more likely. Rarely, infection may arise from the bloodstream or lymphatics, or by direct extension, for example, vesico-colic fistula.

Bacterial virulence

How well an organism adheres to urothelium determines its virulence. The presence of flagella (for motility), aerobactin (used to acquire iron), haemolysin (to form pores), and most importantly, the presence of fimbriae (adhesins that attach organisms to the perineum and urothelium) on the bacterial cell surface make *E. coli* a common pathogen in UTI.

Innate host defence

Innate host defence prevents UTI in the following ways:

- ***Neutrophils.*** Bacterial adhesins activate receptors, e.g., Toll receptor 4 on the mucosal surface, resulting in IL-8 production and expression of its receptor CXCR1 on neutrophil surfaces. Activation of neutrophils is essential for bacterial killing.
- ***Urine osmolality and pH.*** Urinary osmolality >800 mOsm/kg and low or high pH reduce bacterial survival.
- ***Complement.*** Complement activation with mucosal IgA production by uroepithelium (acquired immunity) plays a major role in defence against UTI.
- ***Commensal organisms.*** Eradication of commensal organisms such as lactobacilli, corynebacteria, streptococci, and

bacteroides by spermicidal jelly or antibiotics results in overgrowth of *E. coli.*

- ***Urine flow.*** Good urine flow and normal micturition wash out bacteria. Urine stasis promotes UTI.
- ***Uroepithelium.*** Mannosylated Tamm–Horsfall proteins, present in the mucus and glycocalyx covering uroepithelium, have antibacterial properties and interfere with bacterial binding to uroepithelium. Cranberry juice and blueberry juice contain a large-molecular-weight factor (pro-anthrocyanidins) that prevents binding of *E. coli* to the uroepithelium.
- ***Blood group antigens.*** Females who are non-secretors of ABH blood group antigens are three to four times more likely to have recurrent UTIs.

Risk factors

- Female sex.
- New sexual activity, particularly in females.
- Indwelling urinary catheter or instrumentation of the urinary tract.
- Urinary tract stones.
- Urinary tract stasis (incomplete bladder emptying).
- Diabetes mellitus or immunosuppression.
- Pregnancy.

Clinical features

The most typical symptoms of lower UTI are:

- frequency of micturition by day and night
- dysuria (painful voiding)
- suprapubic pain and tenderness
- haematuria
- offensive urine.

These are the symptoms of bladder and urethral inflammation, or 'cystitis'. Loin pain and tenderness, with fever, night sweats, and rigors, suggest extension of infection to the renal pelvis and kidney, termed pyelitis or pyelonephritis. Localization of the site of infection based on symptoms alone is unreliable. UTI can also present with few or no symptoms (particularly in the immunocompromised), or with abdominal pain, fever, or haematuria in the absence of frequency and dysuria. In the elderly, new confusion may be the only symptom of UTI. Small children may not describe dysuria and symptoms are often 'atypical'. The possibility of UTI must always be considered in a febrile, sick child.

Diagnosis

Uncomplicated UTIs in females age ≤65 years can be diagnosed in those without known urinary tract abnormalities, recent urinary tract instrumentation, or systemic illness if they exhibit at least two of three key symptoms: dysuria, urgency, or frequency—along with an absence of vaginal discharge. Neither urine dipstick testing for leucocyte esterase nor urine culture enhances diagnostic sensitivity. Telephone-based protocols have outcomes similar to those of surgery-based diagnosis and treatment, and such methods are often preferred by patients. Patients with histories of uncomplicated UTIs can be taught to self-diagnose and initiate therapy.

Otherwise, diagnosis is based on culture of a clean-catch midstream specimen of urine and the presence or absence of pyuria. The criteria for the diagnosis of UTI are shown in **Box 26.24**. Most Gram-negative organisms reduce nitrates to nitrites and produce a red colour in the reagent square. False-negative results are common. Dipsticks that detect significant pyuria depend on the release of esterases from leucocytes. Dipstick tests that are positive for both nitrite and leucocyte esterase are highly predictive of acute infection (sensitivity of 75% and specificity of 82%).

Box 26.24 Criteria for the diagnosis of UTI

- Strongly symptomatic females: single isolate $>10^5$ cfu/L ($>10^2$ cfu/mL) in voided urine
- Males: 10^6 cfu/L (10^3 cfu/mL) of a pure or predominant organism
- Any single organism $>10^7$ cfu/L ($>10^4$ cfu/mL)
- *Escherichia coli (E.coli)* or *Staphylococcus saprophyticus* $>10^6$ cfu/L ($>10^3$ cfu/mL)
- Greater than 10^8 cfu/L ($>10^5$ cfu/mL) mixed growth with one dominant organism

CFU, Colony forming unit.

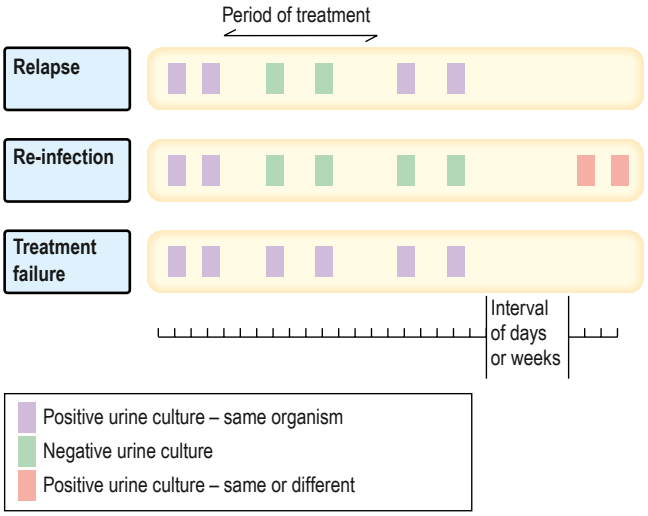

Fig. 26.33 A comparison of re-infection, relapse, and treatment failure in urinary tract infection.

Re-infection may be distinguished from relapsing infection (**Fig. 26.33**) in the following ways:

- ***Relapse*** is diagnosed by recurrence of bacteriuria with the same organism within 7 days of completion of antibacterial treatment. Treatment failure can occur with associated stones, scarred kidneys, polycystic kidney disease, or bacterial prostatitis.
- ***Re-infection*** is when bacteriuria is absent after treatment for at least 14 days, usually longer, followed by recurrence of infection with the same or different organisms. This is not due to failure to eradicate infection but is the result of re-invasion of a susceptible tract. Approximately 80% of recurrent infections are due to re-infection.

Where culture is negative and symptoms persist, consider:

- ***Abacteriuric frequency or dysuria ('urethral syndrome').*** This is caused by bladder trauma after intercourse, vaginitis, urethritis, and *Chlamydia* infection. Tuberculosis should be excluded in symptomatic 'sterile pyuria'.
- ***Interstitial cystitis.*** This is uncommon but distressing, affecting females over the age of 40. Patients present with frequency, dysuria, and often severe suprapubic pain but cultures are sterile. Cystoscopy shows inflammatory changes with ulceration of the bladder base. It is thought to be an autoimmune disorder. Treatments include oral prednisolone, bladder instillation of sodium cromoglicate or dimethyl sulphoxide, and bladder stretching

under anaesthesia. Unfortunately, relief of symptoms can be difficult to achieve.

- ***'Irritable bladder'.*** Predominant frequency and passage of small volumes of urine. It may occur after previous UTI.

Natural history

Serious morbidity is unusual. However, kidney scarring can result from recurrent UTI, and dissemination of infection as septicaemia can be fatal. In patients with a normal urinary tract (normal kidney imaging) outcomes are very good, and persistent or recurrent infection seldom results in serious kidney damage (uncomplicated UTI). In those with abnormal urinary tracts (stones or stasis), recurrence is more common, and outcomes are less good. The combination of infection and obstruction results in severe, sometimes rapid, kidney damage (obstructive pyonephrosis) and is a major cause of Gram-negative septicaemia from *Pseudomonas* and *Enterobacter* spp. Complicated and uncomplicated infection are compared in Fig. 26.34.

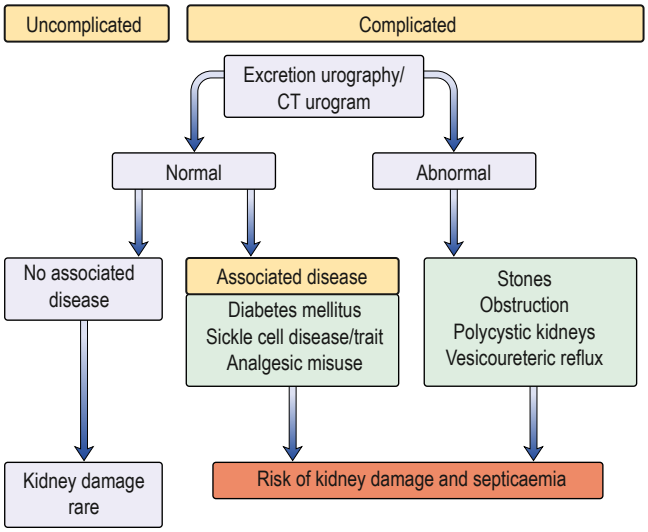

Fig. 26.34 Complicated versus uncomplicated urinary tract infection.

Acute pyelonephritis

Fever, loin pain with tenderness, and significant bacteriuria usually imply infection of the kidney (acute pyelonephritis). Small cortical abscesses and streaks of pus in the medulla can be present. Histologically, there is focal infiltration by polymorphonuclear leucocytes and many polymorphs in tubular lumina. Although, with antibiotics, significant permanent kidney damage in adults with normal urinary tracts is rare, CT scanning can show wedge-shaped areas of inflammation in the cortex (Fig. 26.35), where kidney function will be impaired.

Fig. 26.35 CT showing a wedge-shaped area of cortical loss *(arrowed)* following acute pyelonephritis.

Reflux nephropathy

This results from a combination of:

- vesico-ureteric reflux
- infection acquired in infancy or early childhood.

Normally, the vesico-ureteric junction acts as a one-way valve. Urine enters the bladder from above and the ureter is shut off during bladder contraction, thus preventing reflux of urine. In some infants and children—possibly even *in utero*—this valve mechanism is incompetent, and bladder voiding is associated with variable reflux of urine up the ureter. A secondary consequence is incomplete bladder emptying, as refluxed urine returns to the bladder after voiding. This latter event predisposes to infection, and the reflux of infected urine leads to kidney damage. Typically, there is papillary damage, tubulointerstitial nephritis, and cortical scarring in areas adjacent to 'clubbed calyces' (Fig. 26.36).

Diagnosis is based on CT scan of the kidneys, which shows irregular kidney outlines, clubbed calyces, and a variable reduction in kidney size. The condition may be unilateral or bilateral and may affect all or part of the kidney.

Reflux usually ceases around puberty with growth of the bladder base (a thickened bladder wall can prevent reflux with bladder contraction). Damage already done persists and progressive kidney fibrosis and further loss of function occur in severe cases, even in the absence of further infection.

Reflux nephropathy cannot occur in the absence of reflux, and it does not begin in adult life. Consequently, adult females with bacteriuria and a normal urogram can be reassured that kidney damage will not develop.

Chronic reflux nephropathy acquired in infancy predisposes to hypertension in later life and, if severe, is a relatively common cause of ESKD in childhood or adult life. Meticulous early detection and control of infection, with or without ureteral re-implantation to

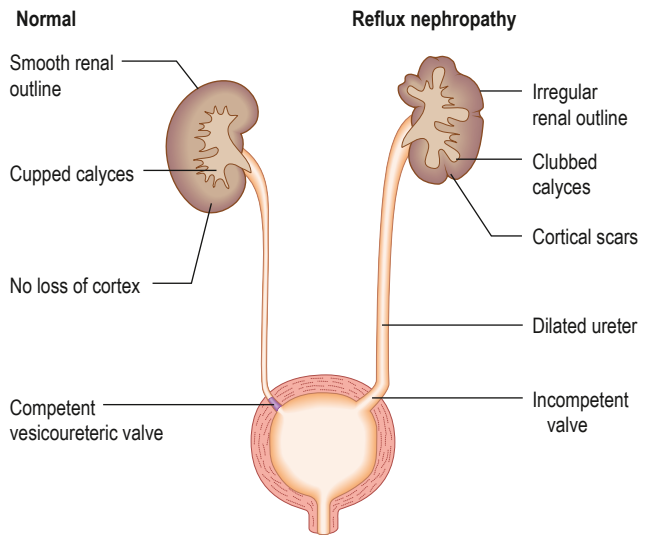

Fig. 26.36 Findings in patients with reflux nephropathy.

create a competent valve, can prevent further scarring and allow normal growth of the kidneys. No proof exists, however, that re-implantation surgery confers long-term benefit.

Continuous antibiotic prophylaxis compared with no treatment, significantly reduces the risk of symptomatic UTI in children with chronic reflux nephropathy but at the expense of increased risk for developing antimicrobial-resistant bacterial strains. However, it has not been shown to have a significant impact on the occurrence of new kidney scarring.

Investigations

Uncomplicated UTI usually does not require imaging. If infection is recurrent, unusually severe, affects males or children, or if the patient has diabetes or is immunosuppressed, UTI should be investigated.

- ***Ultrasound*** allows the detection of calculi, obstruction, abnormal urinary anatomy, and incomplete bladder emptying (post-micturition scan). It is helpful in the assessment of suspected pyelonephritis or an obstructed, infected kidney that may require drainage.
- ***CT*** is more sensitive than ultrasound. Contrast-enhanced CT allows different phases of excretion to be studied and can define extent of disease and identify significant complications or obstruction.
- ***MRI*** is particularly useful in those with iodinated contrast allergies, offering an ionizing radiation-free alternative for diagnosis.
- ***Nuclear medicine*** has a limited role in the evaluation of UTI in adults. Its main role is in the assessment of kidney function and detection of scars by DMSA scan, often prior to surgery.

Management

Management of a single isolated UTI

- ***Antibiotic*** choice should be guided by local susceptibilities. Typical antibiotics for females include trimethoprim (200 mg twice daily for 3 days) or nitrofurantoin (100 mg twice daily for 3 days). Fluoroquinolones offer no advantage in terms of cure rates. β-lactam antibiotics, e.g., amoxicillin–clavulanate, are less effective than the first-line recommendations. Patients who delay antibiotic treatment to encourage spontaneous resolution eventually receive antibiotics and have longer times to resolution. Males with uncomplicated UTIs should be treated as above but for 7 days.
- ***High fluid intake*** (>2 L daily) should be encouraged during treatment and for some subsequent weeks.
- ***Urine culture*** should be repeated 5 days after treatment.
- ***Acute pyelonephritis*** (fever, loin pain/tenderness) is usually managed with intravenous, for example aztreonam, cefuroxime, ciprofloxacin, or gentamicin, switching to oral therapy as symptoms improve. Intravenous fluids may be required. Kidney tract ultrasound examination is required to exclude an obstructed pyonephrosis requiring drainage by percutaneous nephrostomy.

Management of recurrent infection

Pre- and post-treatment urine cultures are necessary to confirm diagnosis and to establish whether recurrent infection is due to relapse or re-infection (Fig. 36.33).

- ***Relapse.*** A search should be made for a cause (e.g., stones or scarred kidneys). High-dose or prolonged treatment may be required. If this fails, long-term antibiotics may be necessary.
- ***Re-infection.*** This implies that the patient has a predisposition to peri-urethral colonization or poor bladder defence mechanisms. The use of a contraceptive diaphragm or spermicidal jelly may contribute, and alternative contraception should be offered. Atrophic vaginitis in postmenopausal females can be treated with topical oestrogen therapy.

  Preventative measures include:
- 2 L daily fluid intake
- voiding at 2- to 3-hour intervals, with double micturition if reflux is present
- voiding before bedtime and after intercourse
- avoidance of spermicidal jellies, bubble baths, and other chemicals when washing
- avoidance of constipation, which may impair bladder emptying.

Impaired bladder emptying on excretion urography/ultrasound requires urological assessment. If UTI continues to recur, treatment for 6 to 12 months with low-dose alternating monthly prophylaxis (trimethoprim 100 mg, co-trimoxazole 480 mg, cefalexin 125 mg, macrocrystalline nitrofurantoin) taken last thing at night when urine flow is low. Evidence for cranberry juice, D-mannose, and methenamine hippurate (Hipres) is limited.

Urinary infections in the presence of an indwelling catheter

Colonization of the bladder by a pathogen is common after a urinary catheter has been *in situ* for more than a few days, partly due to organisms forming biofilms. While the bladder catheter is in place, antibiotics are likely to be ineffective, with risk of antibiotic resistance developing. The patient should be treated only if there are symptoms or evidence of infection and the catheter should always be replaced. When changing catheters, a single dose of antibiotic (e.g., gentamicin) is recommended.

Infection by *Candida* is a complication of prolonged bladder catheterization. Treatment should be reserved for patients with evidence of invasive infection and those who are immunosuppressed. The catheter should be removed or replaced. In severe infections, continuous bladder irrigation with amphotericin may be useful.

Bacteriuria in pregnancy

Screening of asymptomatic pregnant females detects asymptomatic bacteriuria in 2% to 6%. Consider harmless outside of pregnancy, historical data associate asymptomatic bacteriuria in pregnancy with pyelonephritis and preterm labour. Ureteric dilation in response to gestational hormonal changes may allow ascending infection. Bacteriuria is therefore treated and eradication confirmed. Re-infection may require prophylactic therapy. Penicillins, nitrofurantoin (until 36 weeks'), and oral cephalosporins may be used safely in pregnancy. Tetracycline, trimethoprim (in the first trimester), and quinolones are avoided in pregnancy.

Bacterial prostatitis

Bacterial prostatitis is a relapsing infection that presents as perineal pain, recurrent epididymo-orchitis, and prostatic tenderness, with pus in expressed prostatic secretions. Treatment is for 4 to 6 weeks with drugs that penetrate the prostate, such as trimethoprim and ciprofloxacin. Long-term, low-dose treatment may be required. Prostadynia (prostatic pain in the absence of active infection) may persist after infection. Amitriptyline and carbamazepine may alleviate pain symptoms.

Kidney carbuncle

Kidney carbuncle is an abscess in the cortex caused by blood-borne staphylococcus, usually from a boil or carbuncle of the skin. It presents with a high, swinging fever, and loin pain, tenderness, and fullness. The urine shows no abnormality, as the abscess does not

communicate with the renal pelvis, more often extending into the perirenal tissue. Staphylococcal septicaemia is common. Diagnosis is by ultrasound or CT scanning. Treatment involves antibacterial therapy with flucloxacillin and surgical drainage.

Tuberculosis of the urinary tract

Tuberculosis of the urinary tract presents with frequency, dysuria, or haematuria. Cortical lesions result from haematogenous spread in the primary phase of infection. Most heal, but in some, infection persists and spreads to the papillae, with the formation of cavitating lesions and the discharge of mycobacteria into the urine. Infection of the ureters and bladder commonly follows, with the potential for development of ureteral strictures and a contracted bladder. Rarely, cold abscesses may form in the loin. In males, the disease may present with testicular or epididymal discomfort and thickening.

Diagnosis requires awareness, especially in patients with sterile pyuria. Imaging may show cavitating lesions in the papillary areas, commonly with calcification. There may also be evidence of ureteral obstruction with hydronephrosis. Culture of mycobacteria from early morning urine samples is not straightforward. Imaging may be normal in diffuse interstitial tuberculosis, when diagnosis is made instead by kidney biopsy, which demonstrates caseating granulomata with multinucleate giant cells and acid-fast bacilli on Ziehl–Neelsen staining (**Fig. 26.37**). Some patients present late with small, unobstructed kidneys, when the diagnosis is easy to miss.

Treatment is as for pulmonary tuberculosis (see Chapter 20, 'Tuberculosis/Management' section). Kidney ultrasonography and/or CT scanning should be carried out 2 to 3 months after treatment initiation, as ureteric strictures may develop in the healing phase.

Xanthogranulomatous pyelonephritis

This is an uncommon chronic interstitial infection of the kidney, most often due to *Proteus*, causing fever, weight loss, loin pain, and a palpable enlarged kidney. It is usually unilateral and associated with staghorn calculi and UTI. CT scanning shows radiolucent intrarenal abscesses. Nephrectomy is the treatment of choice as antibacterial treatment rarely eradicates infection.

TUBOLOINTERSTITIAL NEPHRITIS

Diseases of the kidney primarily affect the glomeruli, vasculature, or the substance of the kidney parenchyma, made up of tubules and the interstitium. Tubular and interstitial injury and recovery tend to go hand in hand.

Acute tubulointerstitial nephritis

In approximately 70% of cases, acute tubulointerstitial nephritis (TIN) is a hypersensitivity reaction to drugs (**Box 26.25**), most commonly penicillins, NSAIDs, or proton pump inhibitors.

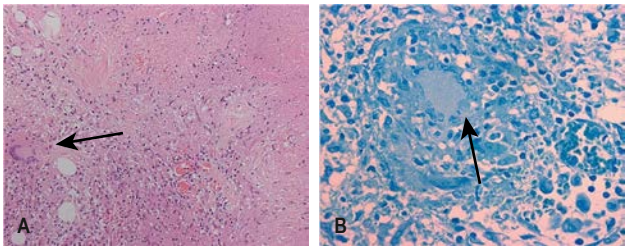

Fig. 26.37 Kidney tuberculosis. **(A)** Caseating granulomatous interstitial nephritis showing multinuclear giant cell *(arrowed)*. **(B)** Ziehl–Neelsen staining showing mycobacteria *(arrowed)*.

Box 26.25 Causes of acute tubulointerstitial nephritis

- Drugs (70%):
  - Antibiotics: cephalosporins, ciprofloxacin, erythromycin, penicillin, rifampicin, sulphonamides
  - Analgesics: NSAIDs
  - Diuretics: furosemide, thiazide diuretics
  - Miscellaneous: allopurinol, carbamazepine, cimetidine, phenytoin, proton pump inhibitors, sodium valproate
- Infection (15%):
  - Viruses, e.g., hantavirus
  - Bacteria, e.g., streptococci
- Idiopathic (8%)
- Tubulointerstitial nephritis with uveitis (TINU) (5%)
- Systemic inflammatory disorders, e.g.,:
  - Systemic lupus erythematosus (2%)
  - IgG4-related disorder

Drug-induced acute TIN

Patients may be asymptomatic (with impaired kidney function found incidentally), or present with fever, arthralgia, rash, and acute kidney injury. Many have eosinophilia and eosinophiluria. Kidney histology shows an intense interstitial cellular infiltrate, often including eosinophils, with variable tubular necrosis (**Fig. 26.38**). Urinary CXCL9 concentrations increase sevenfold and are an emerging diagnostic marker of drug-induced TIN. Rarely, NSAIDs cause a minimal-change lesion in addition to TIN and disease presents as nephrotic syndrome. Treatment involves stopping the offending drug. High-dose prednisolone (60 mg daily) may reduce risk of dialysis-requiring AKI and shorten time to recovery. Most patients make a good recovery in terms of kidney function, but some may be left with significant interstitial fibrosis and CKD.

Infection causing acute TIN

Acute pyelonephritis leads to tubular inflammation and a neutrophilic cellular infiltrate. TIN can complicate systemic infections with viruses (Hantavirus, Epstein–Barr virus, HIV, measles, adenovirus), bacteria (*Legionella*, *Leptospira*, streptococci, *Mycoplasma*, *Brucella*, *Chlamydia*) and others (*Leishmania*, *Toxoplasma*). Hantavirus causes haemorrhagic fever with TIN and can be fatal. Cytomegalovirus, polyoma (BK), and herpes simplex virus can cause acute TIN in a kidney transplant. Treatment involves eradication of infection with appropriate antibiotics or antiviral agents. In kidney transplantation, the immunosuppressive regimen is modified.

Acute TIN as part of multisystem inflammatory diseases

Several non-infectious inflammatory disorders (e.g., Sjögren's syndrome, SLE) can cause acute or chronic TIN rather than glomerulonephritis. Sjögren's syndrome can additionally present with

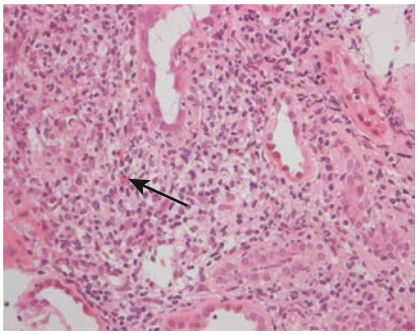

Fig. 26.38 **Tubulointerstitial nephritis showing diffuse interstitial infiltrate with red staining eosinophils *(arrowed)*.**

renal tubular acidosis. Sarcoidosis presents as granulomatous TIN in up to 20% of patients and associated hypercalcaemia causes AKI. These heterogeneous conditions with TIN generally respond to steroids.

TIN with uveitis syndrome

Patients with tubulointerstitial nephritis with uveitis (TINU) syndrome present with uveitis, an acute TIN, weight loss, anaemia, and a raised ESR. It is common in childhood, more frequently found in female, and can occur in adults. It may be associated with autoantibodies directed against modified CRP. A prolonged course of steroids leads to improvement in both kidney function and uveitis.

Chronic tubulointerstitial nephritis

The major causes of chronic TIN are given in **Box 26.26**. Patients present with any of polyuria, nocturia, proteinuria (usually <1 g daily), or uraemia. Chronic TIN may be linked with papillary necrosis (ischaemic damage to the papillae, which then slough into the calyces and urine) when associated with longstanding analgesic use, diabetes mellitus, and sickle cell disease or trait. A sloughed papilla may cause ureteric colic or produce acute ureteric obstruction. Visible and non-visible haematuria and sterile pyuria can occur. Histologically, a generalized chronic inflammatory cellular infiltration of the interstitium with tubular atrophy and generalized interstitial oedema or fibrosis is present. In many cases, no cause is found.

IgG4-related TIN is distinguished by very low concentrations of complement and increased serum IgG4. This may lead to immune complex formation.

Radiological appearances must be distinguished from reflux nephropathy (**Fig. 26.39**) and obstructive uropathy.

Tubular damage to the medullary area of the kidney leads to defects in urine concentration and sodium conservation with polyuria and salt wasting. Fibrosis progressing into the cortex leads to loss of excretory function and urea.

Analgesic nephropathy

The chronic consumption of large amounts of analgesics (classically, phenacetin but now NSAIDs) leads to chronic TIN and papillary necrosis. Analgesic nephropathy is more common in females and typically presents in middle age. Presentation may be with anaemia, CKD, UTI, haematuria, or urinary tract obstruction (owing to sloughing of a renal papilla). Salt- and water-wasting kidney disease may occur. Chronic analgesic use also predisposes to the development of uroepithelial tumours. Diagnosis is usually made on clinical grounds combined with the non-pathognomonic appearance of small, irregularly outlined kidneys on imaging.

? Box 26.26 Causes of chronic tubulointerstitial nephritis

Drugs/medication/toxins:
- All drug causes of acute tubulointerstitial nephritis (see **Box 26.25**)
- Ciclosporin
- 5-aminosalicylates
- Cadmium, lead, titanium
- Irradiation

Systemic disease:
- Diabetes mellitus
- Sickle cell disease or trait
- Systemic lupus erythematosus/vasculitis
- Sarcoidosis
- IgG4-related disease

Metabolic:
- Hyperuricaemia
- Nephrocalcinosis
- Hyperoxaluria

Infection:
- Human immunodeficiency virus
- Epstein–Barr virus

Miscellaneous:
- Hypertension
- Balkan nephropathy
- Herbal nephropathy
- Alport's syndrome

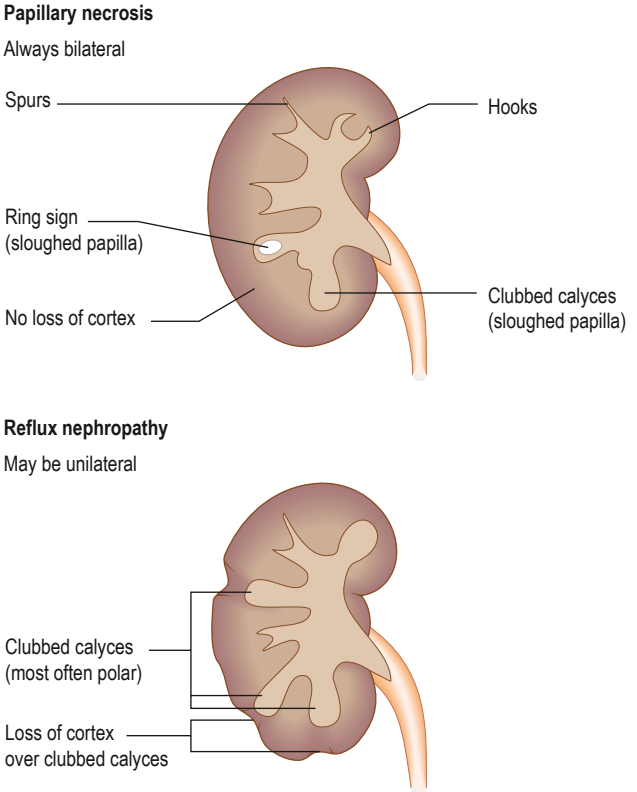

Fig. 26.39 **A comparison of the radiological appearances of papillary necrosis and reflux nephropathy.**

Patients should be encouraged to avoid NSAIDs. If necessary, dihydrocodeine or paracetamol may be offered as a reasonable alternative (this may stop further damage and even achieve an improvement). The development of flank pain or an unexpectedly

rapid deterioration in kidney function should prompt ultrasonography to screen for urinary tract obstruction due to a sloughed papilla.

Balkan nephropathy

Balkan nephropathy is a chronic TIN endemic in areas along the tributaries of the River Danube. Inhabitants of the low-lying plains, where the water supply comes from shallow wells, are affected, whereas the disease does not occur in hillside villages where surface water provides the supply. Chronic dietary poisoning by aristolochic acid is thought to be responsible for Balkan nephropathy and the urothelial cancers that accompany the diagnosis. The disease is insidious in onset, with mild proteinuria progressing to ESKD in 3 months to 10 years. There is no treatment.

Chinese herb nephropathy

Chinese herbal medicines may contain aristolochic acid, produced due to fungal contamination. Histology is similar to that of Balkan nephropathy, but the clinical course is aggressive, with relentless progression to ESKD and a high incidence of uroepithelial tumours.

Other forms of chronic TIN

These are rare (see **Box 26.26**). Diagnosis of all forms depends on a history of drug ingestion or industrial exposure to nephrotoxins. In patients with unexplained kidney impairment with normal-sized kidneys, kidney biopsy should be undertaken to exclude a treatable TIN, such as granulomatous TIN due to ***renal sarcoidosis*** (**Fig. 26.40**), which may be the first presentation of sarcoidosis. Renal sarcoidosis generally responds rapidly to steroids.

Hyperuricaemic nephropathy

Acute hyperuricaemic nephropathy causes AKI with very high serum urate concentrations as part of tumour lysis syndrome. It most commonly occurs following treatment of haematological malignancies but can occur prior. As tumour cells lyse in response to chemotherapy, large amounts of nucleoprotein are released with increased uric acid production. Kidney failure is due to intrarenal and extrarenal obstruction caused by deposition of uric acid crystals in the collecting ducts, pelvis, and ureters.

There may be flank pain or colic, and oliguria or anuria with increasing uraemia. Plasma urate concentrations (reference range 0.15–0.40 mmol/L) increase above 0.75 mmol/L and may be as high as 4.5 mmol/L.

Diagnosis is based on history and hyperuricaemia. Ultrasound may demonstrate extrarenal obstruction due to stones but may be normal.

Allopurinol 100 to 200 mg three times daily for 5 days is given prior to and throughout treatment with radiotherapy or cytotoxic drugs. A high rate of urine flow is maintained by oral or parenteral fluid, and the urine kept alkaline by the administration of sodium bicarbonate and acetazolamide, since uric acid is more soluble in alkaline than acidic mediums. ***Febuxostat***, a non-purine analogue inhibitor of xanthine oxidase, can be used if allopurinol cannot be tolerated and eGFR is more than 30 mL/min/1.73 m^2. ***Rasburicase***, a recombinant urate oxidase, and ***pegloticase***, a pegylated uricase, are successfully used to lower serum urate concentrations for both treatment and prevention. In severely oliguric or anuric patients, dialysis is required to lower plasma urate.

There is no convincing evidence for chronic hyperuricaemia nephropathy. However, a few observational studies have suggested that elevated concentrations of uric acid independently increase the risk for CKD, and that plasma urate reduction with allopurinol has a beneficial effect in slowing rate of CKD progression.

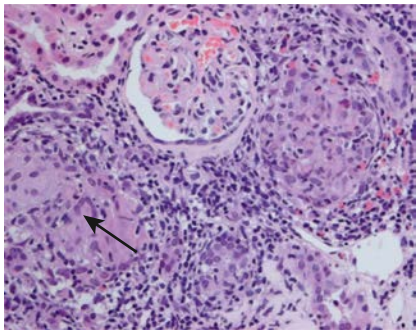

Fig. 26.40 Granulomatous tubulointerstitial nephritis. The granuloma consists of both giant cells *(arrowed)* and epithelioid cells. These findings are characteristic of renal sarcoid but can be seen in interstitial nephritis due to any cause (e.g., drug, infection)

ACUTE KIDNEY INJURY

The assessment and management of acute kidney injury (AKI) are detailed in Chapter 11 ('Acute kidney injury' section).

Causes of AKI due to pathology affecting the parenchyma of the kidney ('renal'-AKI) include:

- acute tubular necrosis
- acute cortical necrosis
- rhabdomyolysis
- acute phosphate nephropathy
- tumour lysis syndrome
- hepatorenal syndrome.

The role of contrast in AKI is unclear. The historical term 'contrast-induced nephropathy' has been replaced with 'contrast-associated nephropathy'.

Acute tubular necrosis

Acute tubular necrosis (ATN) (see **Box 26.27**) can occur due to:

- sustained under-perfusion and reduced kidney blood flow, leading to tubular cell death
- nephrotoxins causing direct injury and tubular cell death.

Factors involved in the development of ATN include:

1. Intrarenal microvascular vasoconstriction with falling delivery of O_2 and increasing tubular hypoxia
   - Vasoconstriction in response to endothelin, adenosine, thromboxane A2, leukotrienes, and sympathetic nerve activity
   - Impaired vasodilation due to reduced sensitivity to nitric oxide, prostaglandins (PGE2), acetylcholine, and bradykinin.
2. Increased endothelial and vascular smooth muscle cell structural damage
   - Increased leucocyte–endothelial adhesion, vascular congestion and obstruction, leucocyte activation, and inflammation.
3. Ischaemic injury results in rapid depletion of intracellular ATP stores, resulting in cell death either by necrosis or apoptosis, with:
   - increased cytosolic cell calcium concentration
   - induction of nitric oxide synthases with increased production of nitric oxide, causing cell death

Box 26.27 Some causes of acute tubular necrosis

- Haemorrhage
- Burns
- Diarrhoea and vomiting
- Fluid loss from fistulae
- Pancreatitis
- Diuretics
- Myocardial infarction
- Congestive cardiac failure
- Endotoxic shock
- Snake bite
- Myoglobinaemia
- Haemoglobinaemia: due to haemolysis, e.g., *falciparum* malaria
- Hepatorenal syndrome
- Radiological contrast agents
- Drugs: aminoglycosides, non-steroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, platinum derivatives
- Placental abruption, postpartum haemorrhage
- Pre-eclampsia

  - increased production of intracellular proteases such as calpain, which cause proteolysis of cytoskeletal proteins and cell wall collapse
  - loss of cell polarity. Integrins on the basolateral side of the cell are translocated to the apical surface, forming casts when combined with other desquamated cells
  - tubular obstruction by desquamated viable or necrotic cells and back-leak of tubular fluid.

4. Tubular cellular recovery
   - Tubular cells can regenerate rapidly to reform the disrupted tubular basement membrane, which explains the reversibility of ATN.
   - Growth factors, e.g., insulin-like growth factor 1, epidermal growth factor, hepatocyte growth factor, and their receptors are upregulated.

Kidney blood flow is reduced in ATN, particularly blood flow to the cortex. Ischaemic tubular damage contributes to a reduction in glomerular filtration as glomeruli contract through afferent arteriolar spasm, filtrate leaks back towards the glomerulus, and tubular obstruction evolves (Fig. 26.41).

Non-oliguric AKI is usually the result of a less severe kidney insult, otherwise oliguria is common. Recovery of kidney function typically occurs after 7 to 21 days, although it may be delayed by continuing sepsis. There is no evidence that intravenous mannitol, furosemide, or 'renal-dose' dopamine are effective treatments.

Acute cortical necrosis

Kidney hypoperfusion results in diversion of blood flow from the cortex to the medulla, with a drop in GFR. Medullary ischaemic damage is largely reversible because tubular cells have the capacity for regeneration. In contrast, glomerular ischaemic injury does not heal with regeneration, but with scarring—glomerulosclerosis. Prolonged cortical ischaemia may lead to irreversible loss of kidney function termed 'cortical necrosis'. This may be patchy or complete. Any cause of ATN, if sufficiently severe or prolonged, may lead to cortical necrosis. Cortical necrosis occurs more commonly where the vasculature and endothelium have been damaged (with or without coagulopathy), for example, HUS, endothelial disease in pregnancy.

Rhabdomyolysis

Rhabdomyolysis, or 'crush syndrome', occurs when skeletal muscle injury leads to release of intracellular myoglobin, a direct tubular toxin leading to ATN. Causes include trauma, compartment syndrome, excessive exertion (marathon runners), status epilepticus, and muscle toxins (statins, malaria and antimalarials, snake/insect venom). Rapid rises in potassium, phosphate, and lactate concentrations accompany elevated muscle enzymes; characteristically, creatine phosphokinase (CK) is massively elevated. Early and vigorous fluid resuscitation is vital (injured muscle sequesters large amounts of fluid, causing hypovolaemia). Inflamed, injured muscle may become ischaemic in compartments, and a careful examination for typical 'woody-hard' muscle compartments may indicate the need for fasciotomies to release at-risk muscle. Sodium bicarbonate used to alkalinize the urine may limit myoglobin-induced injury. A similar syndrome can arise with massive haemolysis, where the tubular toxin is haemoglobin rather than myoglobin, and the biochemical derangements seen with muscle injury may be absent.

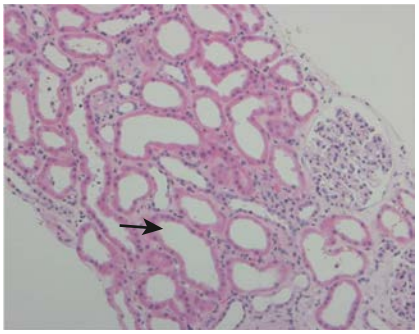

Fig. 26.41 Acute tubular necrosis. Effacement and loss of the proximal tubule brush border, patchy loss of tubular cells, and focal areas of proximal tubule dilation *(arrowed)*.

Acute phosphate nephropathy

Administration of oral sodium phosphate solution as bowel preparation for gastrointestinal investigations is a cause of AKI. Oral phosphate solution is contraindicated in patients with CKD, congestive heart failure, gastrointestinal obstruction, and pre-existing electrolyte disorders, for example, hypercalcaemia. Kidney biopsy shows abundant calcium phosphate deposits. Treatment is usually supportive, with dialysis if indicated, usually with good kidney recovery.

Tumour lysis syndrome

Tumour lysis syndrome complicates the initial treatment of cancer, most commonly lymphoproliferative tumours. Chemotherapy (including corticosteroids) causes rapid death of malignant cells with release of intracellular and membrane products including uric acid, potassium, and phosphate. A high filtered uric acid load leads to an obstructive crystal uropathy; serum urate may be four- or fivefold the upper limit of normal. The danger is hyperkalaemia. At-risk patients should be hydrated to maintain a good urine output (facilitating potassium excretion in the urine) and xanthine oxidase inhibitors, for example, allopurinol, may prevent uric acid formation. Rasburicase oxidizes uric acid to soluble allantoin and uric acid concentrations can be undetectable after administration.

Hepatorenal syndrome

Hepatorenal syndrome results from profound vasoconstriction with histologically normal kidneys. It only occurs once portal hypertension and ascites complicate liver disease. Patients are not hypovolaemic. Recovery is usually observed if successful liver transplantation is possible.

Contrast-associated acute kidney injury

In patients with impaired kidney function, iodinated radiological contrast media may cause kidney vasoconstriction and have a direct toxic effect on kidney tubules. However, a rise in serum creatinine concentration after contrast exposure is often non-specific, with other contributing factors including volume depletion, atheroembolization, and medication. Contrast-associated acute kidney injury may be a marker of an increased risk of serious adverse outcomes rather than a mediator of adverse outcomes and in many patients the effect is mild, transient, and fully reversible. Clinicians should therefore be cautious about withholding contrast in patients with kidney disease where it is indicated for diagnosis.

Risk factors for a creatinine rise in association with contrast use include:

- advanced CKD
- cardiac failure
- paraprotein kidney disease
- hypovolaemia or medications that reduce kidney perfusion e.g., ACE inhibitors, NSAIDs
- large amounts (>4 mL/kg, or repeated dosing) of contrast, e.g., angiography
- high-osmolality contrast agents.

Prevention is key: minimize the dose of contrast administered and use an iso-osmolar or low-osmolality contrast medium. Intravenous fluid (e.g., 1 L of 0.9% sodium chloride or 1.4% sodium bicarbonate 1–12 h before and 4–12 h after contrast) has shown benefit in observational studies, but randomized trial data are limited, and care is needed if coexisting hypertension or cardiac failure. N-acetylcysteine, dopamine, theophylline, and prophylactic haemodialysis (to remove contrast agent from the circulation) are of no benefit.

Renal replacement therapy in AKI

It is not clear when to start RRT in AKI. Early initiation has not been shown to improve outcomes and in up to 30% of cases there is kidney recovery without RRT. There are no data to favour haemodialysis over haemofiltration. However, in haemodynamically unstable patients, haemofiltration may be preferred as fluid volumes including nutrition, blood products, and antibiotics can be ultrafiltered with less swing in volume and more cardiovascular stability. More RRT is not necessarily better; two large trials have failed to show a survival benefit with augmented doses of RRT in critically ill patients. Peritoneal dialysis can be used in AKI, predominantly in low-income settings where haemodialysis may not be available. It has low efficiency (removing solutes slowly and less completely) and is not appropriate for patients with intra-abdominal causes or complications of AKI. The effect of increasing intra-abdominal pressure on lung function should also be considered.

CHRONIC KIDNEY DISEASE

CKD is a descriptive term and is used for a long-standing (>3 months) deterioration in kidney function of any underlying cause. A list of causes of CKD is given in **Box 26.28**. In many cases, there is no effective means to reverse the underlying disease. There are exceptions where reversal of CKD can occur:

- relief of urinary tract obstruction
- immunosuppressive therapy for glomerulonephritis or systemic vasculitis
- treatment of accelerated hypertension
- correction of critical narrowing of renal arteries.

Even if the underlying diagnosis cannot be reversed, the rate of deterioration in kidney function can be slowed.

? Box 26.28 Causes of chronic kidney disease

Congenital and inherited disease
- Polycystic kidney disease (adult and infantile forms)
- Medullary cystic disease
- Tuberous sclerosis
- Oxalosis
- Cystinosis
- Congenital obstructive uropathy

Glomerular disease
- Primary glomerulonephritides
- Secondary glomerular disease: for example, SLE, polyangiitis, granulomatosis with polyangiitis, amyloidosis, diabetic glomerulosclerosis, accelerated hypertension, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, systemic sclerosis, sickle cell disease

Vascular disease
- Hypertensive nephrosclerosis
- Renovascular disease
- Small- and medium-sized-vessel vasculitis

Tubulointerstitial disease
- Tubulointerstitial nephritis
- Reflux nephropathy
- Tuberculosis
- Schistosomiasis
- Nephrocalcinosis
- Multiple myeloma: myeloma kidney
- Balkan nephropathy
- Papillary necrosis: for example, due to diabetes, sickle cell disease and trait, analgesic nephropathy
- Chinese herb nephropathy

Urinary tract obstruction
- Renal tract stone disease
- Prostatic disease
- Pelvic tumours
- Retroperitoneal fibrosis
- Schistosomiasis

Staging and prevalence

CKD is staged according to estimated GFR, calculated according to eGFR (see 'Estimated GFR [eGFR]' section). Staging is intended to reflect severity, prognosis, and outcomes (**Fig. 26.42**).

Staging is increasingly complex:

- Patients are staged both on eGFR (prefix G) and albuminuria (prefix A), reflecting the fact that both parameters correlate with progressive kidney impairment and cardiovascular risk, e.g., G3bA3 disease.
- Stage G3 CKD has been divided into two stages (G3a and G3b) in recognition of the increased cardiovascular complications seen in more advanced disease.
- Cystatin C is a more accurate marker of GFR and can be used to better stratify risk in stage G3 CKD.

Confusingly, patients with stage G2 CKD are not thought to have disease unless there is other evidence of kidney damage, for example, haematuria, proteinuria, structurally abnormal kidneys, inherited kidney disease, or biopsy changes consistent with kidney disease.

CKD affects 11% to 15% of the world's population, with the majority at stage 3 (**Box 26.29**). Diagnosis of CKD is becoming more likely as people live longer and a high prevalence of CKD

GFR and ACR categories and risk of adverse outcomes			Description	ACR (mg/mmol) / description		
				<3	3–30	>30
				A1	A2	A3
GFR (mL/min/1.73 m²)	≥90	G1	Normal or increased GFR with other evidence of kidney damage	No CKD markers of kidney damage		
	60–89	G2	Slight decrease in GFR with other evidence of kidney damage			
	45–59	G3a	Moderate decrease in GFR with or without other evidence of kidney damage			
	30–44	G3b	Moderate to severe increase in GFR			
	15–29	G4	Severe decrease in GFR with or without other evidence of kidney damage			
	<15	G5	End-stage renal disease			

Increasing risk

Increasing risk

Fig. 26.42 Classification of chronic kidney disease (CKD) using glomerular filtration rate (GFR) and urinary albumin:creatinine (ACR) categories. *(Adapted with permission from Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group. KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease.* Kidney Int *2013; Suppl. 3:1–150.)*

Box 26.29 Prevalence of CKD

CKD stage	Age in years (% affected)			
	<65	65–74	75–84	≥85
3	1.4	15.4	29.4	30.9
4	0.04	0.4	1.3	2.4
5	0.03	0.2	0.1	0.1
Total	1.5	15.9	30.9	33.4

is found in population-based surveys in elderly patients. There is wide geographical variation in incidence, prevalence, and causes of CKD across the globe. For instance, the most common cause of GN in sub-Saharan Africa is malaria. Schistosomiasis is a common cause of CKD due to urinary tract obstruction in parts of the Middle East. The incidence of CKD varies between ethnic groups, with hypertensive nephropathy and stage G5 CKD being three to four times more common in people of black African descent in the UK and USA than it is in white populations. The prevalence of diabetes mellitus, and hence of diabetic nephropathy, is higher in those of Asian ethnicities compared to white ethnicities. Over 70% of all cases of CKD are due to diabetes mellitus, hypertension, or atherosclerosis.

Progression

CKD tends to progress, although rate of progression may be slow. The speed of decline tends to depend on the underlying disease and blood pressure control. Patients with chronic glomerular diseases tend to deteriorate more quickly than those with chronic tubulointerstitial nephropathies. Regardless of cause, there may be common pathways to disease progression in CKD:

1. Each kidney has roughly a million nephrons. In CKD, when many nephrons have failed and scarred, the burden of filtration falls to fewer functioning nephrons.
2. Functioning ('remnant') nephrons experience increased flow per nephron (hyperfiltration), as kidney blood flow has not changed, and adapt with glomerular hypertrophy and reduced arteriolar resistance.
3. Increased flow, increased pressure, and increased shear stress set in motion a vicious circle of raised intraglomerular capillary pressure and strain, which accelerates remnant nephron failure.
4. Increased flow and strain may be detected as new or increasing proteinuria.

Angiotensin II produced locally modulates intraglomerular capillary pressure and GFR, causing vasoconstriction of postglomerular arterioles, and increasing the glomerular hydraulic pressure and filtration fraction (see Fig. 26.43). In addition, it indirectly upregulates transforming growth factor-beta (TGF-β), a potent fibrogenic cytokine, increasing collagen synthesis and epithelial cell transdifferentiation to myofibroblasts that contribute to excessive matrix formation. Angiotensin II also upregulates plasminogen activator inhibitor-1 (PAI-1), which inhibits matrix proteolysis by plasmin, with accumulation of excessive matrix and scarring in the glomeruli and interstitium.

Proteinuria itself may be harmful in the tubulointerstitium. In disease, albumin in the urinary space carries bound fatty acids, growth factors, and cytokines. When reabsorbed in the proximal tubule and degraded, these carried molecules may cause proximal tubular cell activation and interstitial scarring.

The prognosis of CKD correlates with:

- hypertension, particularly if poorly controlled
- proteinuria
- the degree of scarring in the interstitium (not glomeruli).

Inhibition of angiotensin II and reduction of proteinuria with ACE inhibitors or angiotensin-receptor antagonists slow the rate of progression of CKD. SGLT2 inhibitors have shown marked efficacy in slowing the rate of decline of kidney function in several seminal trials and are now used alongside angiotensin II inhibition. Finerenone, a non-steroidal mineralocorticoid receptor antagonist, is a new drug used in combination with both angiotensin II and SGLT2 inhibitors to slow progression of CKD.

Complications of CKD

Anaemia

Anaemia impairs quality of life and wellbeing. A normochromic, normocytic anaemia develops due to variable mechanisms:

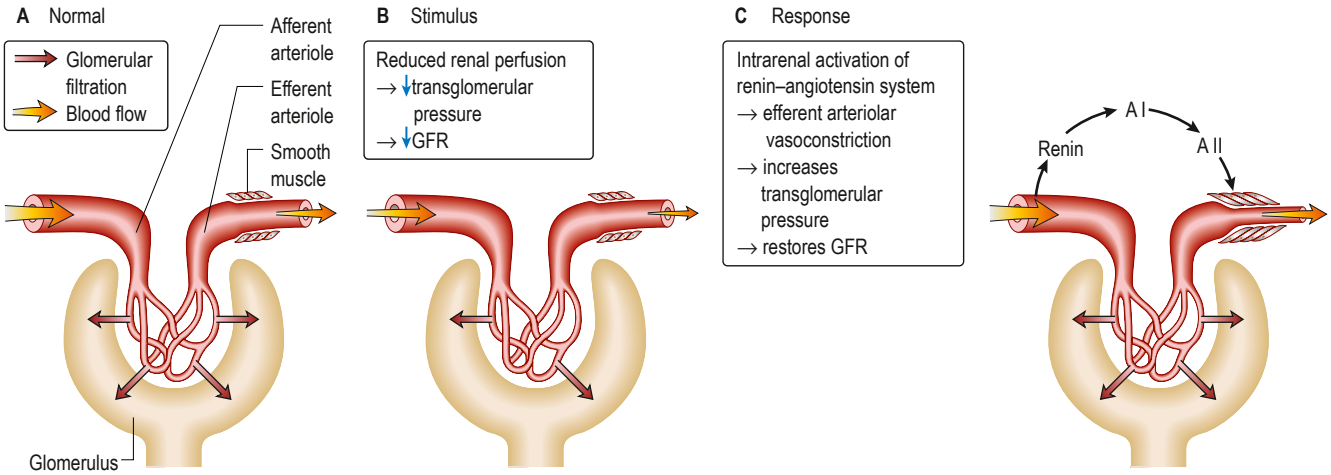

Fig. 26.43 Glomerular dynamics. Effect of the renin–angiotensin system. *AI,* Angiotensin I; *AII,* angiotensin II; *GFR,* glomerular filtration rate.

- ***Erythropoietin deficiency:*** the most significant mechanism in CKD.
- ***Increased blood loss:*** occult gastrointestinal bleeding, repeated blood sampling, blood loss during haemodialysis, or platelet dysfunction.
- ***Bone marrow dysfunction:*** toxins retained in CKD, or fibrosis secondary to hyperparathyroidism.
- ***Haematinic deficiency:*** decreased iron, vitamin B_{12}, or folate.
- ***Increased red-cell destruction:*** red cells have a shortened lifespan in uraemia, and haemodialysis may cause haemolysis.
- ***ACE inhibitors:*** interfering with the control of endogenous erythropoietin release.

Management

Synthetic (recombinant) human erythropoiesis-stimulating agents (ESAs) include epoetin-α or β, and long-acting darbepoetin-α. ESAs can be given subcutaneously or by intravenous injection. Supplemental intravenous iron may facilitate the response to erythropoietin and can be given prior to starting ESAs. Haemoglobin is monitored and the ESA dose adjusted to maintain a target haemoglobin of 100 to 120 g/L. Peripheral resistance increases in all patients, owing to loss of hypoxic vasodilation and to an increase in blood viscosity. Hypertension is a significant side-effect in 30% of patients new to ESAs requiring blood pressure monitoring and treatment if needed. Encephalopathy is rare.

Target haemoglobin is between 100 and 120 g/L. Studies in pre-dialysis CKD patients have not shown any benefit to a higher haemoglobin target (>120 g/L). Patients who ***fail to respond*** should be screened to exclude associated iron deficiency, bleeding, malignancy, infection, inflammation, or formation of anti-erythropoietin neutralizing antibodies. The increased demand for iron by the bone marrow is enormous when an ESA is started. Functional iron deficiency (poor mobilization of iron, despite adequate iron stores with ferritin >500 μg/L) is a common finding in patients with chronic inflammation. Synthesis of hepcidin, an acute phase reactant produced by the liver in response to cytokines (particularly IL-6), inhibits gastrointestinal iron absorption (see Chapter 38, 'Microcytic anaemia' section) and sequesters iron in the liver, preventing its release. Intravenous (rather than oral) iron supplements therefore optimize the response to ESAs in CKD. A trial has shown that high-dose intravenous iron and a target ferritin concentration of around 400 μg/L are safe and associated with a lower ESA requirement. Correcting anaemia with ESAs improves quality of life, exercise tolerance, and sexual and cognitive function in dialysis patients, and leads to regression of left ventricular hypertrophy. By avoiding blood transfusion, the risk of sensitization to HLA antigens, which may complicate future kidney transplantation, is reduced.

Reports of anti-erythropoietin antibody-mediated pure red-cell aplasia in patients receiving subcutaneous ESA therapy (particularly epoetin-α) have been described. Changes in the manufacturing process of the pre-filled syringes used to deliver ESAs have reduced the number of cases: the rubber stoppers interacted with the drug vehicle to act as an immunological adjuvant, stimulating anti-erythropoietin antibody production.

Oral agents that inhibit prolyl hydroxylase and prolong the life of hypoxia-inducible factor (HIF) 2α, a transcription factor for endogenous production of erythropoietin, include Roxadustat and Daprodustat. They are approved for use in predialysis CKD and patients on dialysis.

CKD mineral and bone disorder (CKD-MBD)

Once called 'renal osteodystrophy', the more appropriately termed mineral and bone disorder CKD-MBD encompasses:

- changes in calcium, phosphorus, PTH, FGF23, and vitamin D metabolism
- the various forms of bone disease that develop alone or in combination with CKD
- the vascular consequences, such as arterial stiffness and calcification.

Altered bone morphology in CKD (Fig. 26.44) includes:

- hyperparathyroid bone disease
- osteomalacia
- osteoporosis
- osteosclerosis
- adynamic bone disease.

Most patients with CKD are found on bone biopsy to have mixed bone disease. CKD-MBD is almost universal by stage G3b CKD.

Vascular calcification is common in CKD patients. Vascular smooth muscle cells, modulated by uraemia and/or phosphate, differentiate to an osteoblast-like phenotype and can synthesize and deposit matrix, which is then mineralized. Calcified vessel walls become increasingly stiff and non-compliant (leading to left ventricular hypertrophy over time), cardiac valves calcify, and soft-tissue calcium is deposited widely. There is an association between

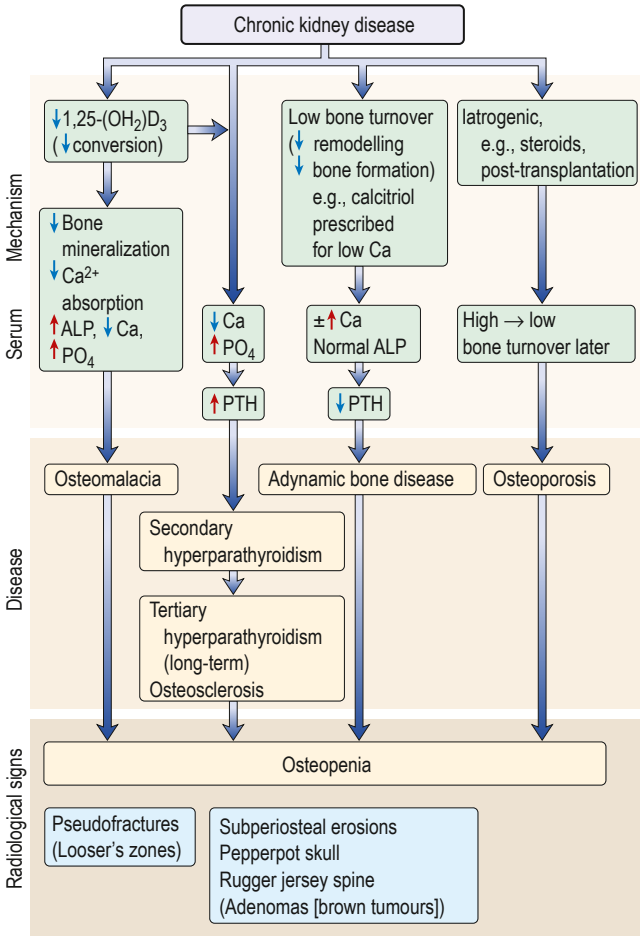

Fig. 26.44 Chronic kidney disease mineral and bone disorder (CKD-MB). Pathogenesis and radiological features of bone disease due to CKD. *ALP,* Alkaline phosphatase; *PTH,* parathyroid hormone.

vascular calcification and mortality in CKD, but a causal link has not yet been proven.

Pathogenesis

Phosphate excretion falls in the very early stages of CKD. Retained phosphate results in release of FGF23 and other phosphaturic agents by osteocytes as a compensatory mechanism. FGF23 causes phosphaturia, lowering plasma phosphate concentration to within the normal range. FGF23 also downregulates kidney 1α-hydroxylase, reducing the action of activated vitamin D in increasing intestinal absorption of phosphate. Despite consistently elevated concentrations of FGF23, phosphate concentrations in blood will increase as CKD progresses. Elevated FGF23 concentrations are the strongest independent predictor of mortality in patients with CKD. As CKD progresses, ***secondary hyperparathyroidism*** develops:

- Decreased renal production of 1α-hydroxylase results in reduced conversion of 25-$(OH)_2D_3$ to metabolically active 1,25-$(OH)_2D_3$ (1,25-dihydroxycholecalciferol).
- 1,25-$(OH)_2D_3$ deficiency results in reduced gut calcium absorption and a fall in serum calcium.
- Reduced activation of vitamin D receptors in the parathyroid glands by 1,25-$(OH)_2D_3$ increases the release of PTH.
- Calcium-sensing receptors in the parathyroid glands react rapidly to acute changes in extracellular calcium concentrations. Low calcium triggers PTH release.
- Retained phosphate also indirectly lowers ionized calcium (and probably directly via a putative but unrecognized phosphate receptor), resulting in increased PTH synthesis and release.
- PTH promotes reabsorption of calcium from bone and increases proximal tubular reabsorption of calcium. This mechanism attempts to reverse the hypocalcaemia caused by 1,25-$(OH)_2D_3$ deficiency and phosphate retention.

'Secondary' hyperparathyroidism leads to increased osteoclastic activity, cyst formation, and bone marrow fibrosis (osteitis fibrosa cystica). The typical biochemical findings are hypocalcaemia, hyperphosphataemia, an elevated PTH, and an increased serum alkaline phosphatase (marker of increased bone turnover). Radiologically, digital subperiosteal erosions and a 'pepperpot skull' are seen. Longstanding secondary hyperparathyroidism ultimately leads to hyperplasia of the glands with autonomous or ***tertiary hyperparathyroidism*** in which PTH release occurs independently of calcium or 1,25-$(OH)_2D_3$ control, and high bone turnover leads to hypercalcaemia.

Longstanding hyperparathyroidism causes increased bone density ***(osteosclerosis)***, seen particularly in the spine, where alternating bands of sclerotic and porotic bone give rise to a characteristic 'rugger jersey' radiograph appearance.

Deficiency of 1,25-$(OH)_2D_3$ and hypocalcaemia can also result in impaired mineralization of osteoid ***(osteomalacia)***.

'Adynamic bone disease' describes a state in which bone formation and resorption are depressed and the skeleton becomes inert. Bone turnover is reduced, usually where there is overtreatment with active vitamin D, low PTH (after surgical parathyroidectomy), accumulation of aluminium used as a phosphate binder, or diabetes. There may be hypercalcaemia, particularly if calcium intake is high (excess calcium cannot be laid down in bone). Serum alkaline phosphatase is normal and PTH is low. Radiographs and dual X-ray absorptiometry (DXA) scans show osteopenia. No treatment is of proven benefit.

Osteoporosis is commonly found in CKD, often after transplantation and the use of corticosteroids. Monitoring is with annual DXA scanning.

Management

The aim is to keep serum calcium and phosphate concentrations in the normal range as CKD progresses. Once dialysis is needed, PTH is kept within two- to threefold the upper limit of normal to ensure that bone turnover continues and adynamic bone does not develop. The less well-understood goal is to limit vascular calcification, by maintaining good bone health and avoiding calcium exposure.

Calcium, phosphate, and PTH should be measured 3-monthly. Imaging can define the extent of vascular calcification (e.g., spine or abdominal radiograph). Treatment and targets aim to reduce phosphate (and preferably limit calcium load), control PTH, and achieve a normal calcium.

Reduction of phosphate

- ***Dietary restriction.*** This is seldom effective alone because so many foods are phosphate-rich and phosphate-restricted diets lead to protein malnutrition.
- ***Gut phosphate binders.*** Sevelamer carbonate, lanthanum carbonate, calcium carbonate, calcium acetate, and ferric citrate all reduce phosphate absorption when taken with meals. In addition, sevelamer (unlike calcium-containing binders) attenuates vascular calcification and lowers cholesterol concentrations by 10% though it has not been shown to reduce mortality. Generally, adherence to phosphate binders is difficult.

- ***Tenapanor.*** A minimally absorbed, small-molecule inhibitor of the sodium/hydrogen exchanger isoform 3 (NHE3), inhibits both sodium and water transport locally in the gastrointestinal tract, as well as phosphate transport by indirectly inhibiting paracellular absorption of phosphate. It also downregulates intestinal phosphate transporters Na/Pi2b and reduces absorption directly. Clinically, utility has not yet been determined.

Control of PTH and achievement of normal calcium

- ***Calcitriol (1,25-dihydroxycholecalciferol) and vitamin D analogues.*** Include alfacalcidol, and novel vitamin D metabolites (22-oxacalcitriol, paricalcitol, doxercalciferol). They are given orally to suppress PTH once the concentration is three more times the upper reference limit. The newer vitamin D analogues, such as paricalcitol (19-nor-1,25 dihydroxyvitamin D_2), may be less likely to lead to hypercalcaemia, but utility over conventional and less expensive calcitriol or alfacalcidol remains to be established.
- ***Calcimimetic agents.*** Calcimimetics act by activating the calcium-sensing receptor, leading the parathyroid to respond as though serum calcium concentrations were high, reducing PTH synthesis and release. Agents include cinacalcet and etelcalcetide. These are used in secondary hyperparathyroidism to suppress PTH concentrations and lowering the calcium×phosphate product. The long-term safety and efficacy of these agents have been confirmed; however, survival benefit has not been shown.

Calciphylaxis

Also known as calcific uraemic arteriolopathy, this is a rare but serious life-threatening complication in CKD patients. It presents as painful skin patches, plaques, and ulcers, with non-healing eschars, panniculitis, and dermal necrosis. The characteristic feature on histology is vascular calcification and superimposed small-vessel thrombosis (Fig. 26.45). Risk factors include hyperparathyroidism, elevated serum phosphate, morbid obesity, and warfarin use (by inhibiting vitamin K-dependent carboxylation and activation of calcification inhibitor Matrix Gla Protein). Control of hyperparathyroidism with either surgical intervention or a calcimimetic agent is required. Sodium thiosulfate (an antioxidant) and bisphosphonates have been tried but have not been shown to be effective. Despite treatment, infection escalates risk, and as patients are often already frail, many die within a year of diagnosis.

Cardiovascular disease

CKD is a major risk factor for cardiovascular disease, and the greatly increased (16-fold) incidence of cardiovascular disease in CKD compared with the normal population has a significant impact on life expectancy. Sudden cardiac death, myocardial infarction, cardiac failure, stroke, and peripheral vascular disease all occur in excess as GFR declines (and the presence of proteinuria adds further to this risk). Kidney transplantation reverses the risk seen with stage G5 CKD.

Risk factors

- ***Hypertension:*** very common in CKD.
- ***Diabetes mellitus:*** the most common cause of CKD.
- ***Dyslipidaemia:*** universal in uraemia.
- ***Smoking:*** as common as the general population.

Ventricular hypertrophy is common in CKD, as is systolic and diastolic dysfunction. Left ventricular hypertrophy is a risk factor for early death in CKD, as in the general population. Systolic dysfunction is also a marker for early death. Myocardial fibrosis, abnormal myocyte function, calcium overload, hyperparathyroidism, and carnitine and selenium deficiencies all contribute to the systolic dysfunction seen in uraemic cardiomyopathy.

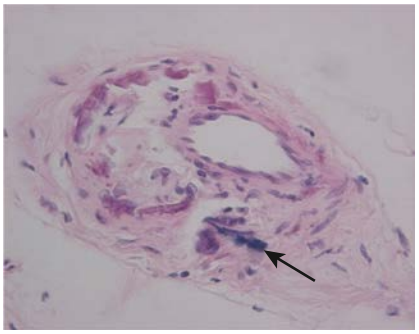

Fig. 26.45 Calciphylaxis. Characteristic arterial calcification of the skin microvasculature in the absence of vasculitic change *(arrowed)*.

Coronary artery and generalized vascular calcification

Traditional risk factors (e.g., smoking, diabetes) only partly explain the increased cardiovascular risk in patients with CKD. Coronary artery calcification is more common in patients with ESKD, and it is likely that this contributes to cardiovascular mortality. Peripheral vessel calcification increases vascular stiffness (reduced compliance), which manifests as increased pulse pressure, increased pulse wave velocity, and an increased afterload with advancing left ventricular hypertrophy. Risk factors related to calcification include:

- A raised (calcium × phosphate) product, which promotes calcification.
- Hyperparathyroidism, which increases intracellular calcium.
- Uraemia, which leads to loss of constitutive inhibitors of calcification, with vascular smooth muscle cells acquiring osteoblast-like characteristics.
- Inflammation, which inhibits fetuin: a glycoprotein synthesized by liver, and a potent inhibitor of vascular calcification.

Plain abdominal radiography (demonstrating 'pipe-stem' calcification of large arteries), electron beam or multislice CT of the coronary arteries, and vascular Doppler can all identify and quantify vascular calcification. Risk factor modification is comparable to that undertaken in patients without CKD, although clear evidence of benefit is less clear in CKD.

Other cardiovascular risk factors

Hyperhomocysteinaemia, *Chlamydophila pneumoniae* infection, malnutrition, inflammation, insulin resistance, oxidative stress, and elevated endogenous inhibitor of nitric oxide synthase and asymmetric dimethyl arginine (ADMA) all contribute to increased cardiovascular events. High ADMA concentrations in uraemia are caused in part by oxidative stress and offer an explanation for the 52% increase in risk of death and 34% increase in risk of cardiovascular events in patients with uraemia. Use of antioxidants, vitamin E, and acetylcysteine has been associated with reduced all-cause and cardiovascular mortality. However, trials to reduce concentrations of homocysteine with folic acid, B_6, and B_{12} supplementation have been unsuccessful.

The conclusion from a study of heart and kidney protection (SHARP) in over 9500 CKD patients was that around one-quarter of all heart attacks, strokes, and revascularizations could be avoided in CKD by using a combination of ezetimibe and simvastatin to

lower blood cholesterol. This combination did not, however, confer any survival advantage or prevent the development of ESKD.

The efficacy of coronary revascularization in stable coronary artery disease in patients with advanced CKD had historically been unclear as such patients were excluded from clinical trials. However, a recent randomized trial including over 750 patients with advanced kidney disease and moderate or severe ischemia on stress testing showed that an initial invasive strategy of coronary angiography and revascularization (if appropriate) added to medical therapy did not reduce death or non-fatal myocardial infarction compared to a conservative strategy of medical therapy alone and angiography reserved for only those in whom medical therapy failed. Clinical focus has therefore shifted to optimal medical therapy for ischaemic heart disease in patients with CKD, including those awaiting kidney transplantation.

Pericarditis

This usually occurs in two clinical settings:

- Uraemic pericarditis is a feature of severe, pre-terminal uraemia or of under-dialysis. Associated haemorrhagic pericardial effusion and atrial arrhythmias may occur. There is a risk of pericardial tamponade, and anticoagulants should be used with caution. Pericarditis may resolve with intensive dialysis.
- Dialysis pericarditis occurs because of an intercurrent illness or surgery in a patient receiving apparently adequate dialysis.

Skin disease

Pruritus (itching) is common and is caused by:

- accumulating nitrogenous waste products of protein catabolism (itching improves following dialysis)
- hypercalcaemia and hyperphosphataemia, or an elevated calcium × phosphate product
- hyperparathyroidism (even if calcium and phosphate concentrations are normal)
- iron deficiency.

Inadequate dialysis is a treatable cause of pruritus. However, for many, the cause of itching is unknown and no effective treatment exists.

Many patients with CKD suffer from dry skin, for which simple emollients are helpful. CKD may also cause porphyria cutanea tarda, a blistering, photosensitive skin rash. This results from a decrease in hepatic uroporphyrinogen decarboxylase combined with decreased clearance of porphyrins in the urine or by dialysis. Pseudoporphyria, a condition like porphyria cutanea tarda but without enzyme deficiency, is also seen with increased frequency in CKD.

Nephrogenic systemic fibrosis

Nephrogenic systemic fibrosis (NSF) is a systemic fibrosing skin disorder seen in patients with moderate to severe CKD (eGFR < 30 mL/min/1.73 m^2), particularly those on dialysis. Gadolinium-containing contrast agents, which are excreted exclusively by the kidney, have been implicated in over 95% of cases of NSF. Diagnosis is based on biopsy of an involved site, showing proliferation of dermal fibrocytes with excessive collagen deposition. Special testing may show gadolinium.

NSF is chronic and unremitting, with 30% having no improvement, 20% having modest improvement and 30% dying. No single or combination therapy offers benefit. Prevention is key and so high-risk (group I) gadolinium-based contrast agents should be avoided in patents with an eGFR below 30 mL/min/1.73 m^2. Lower-risk agents (from groups II and III) can be used if benefits outweigh risk.

Gastrointestinal complications

Hypergastrinaemia increases as GFR declines. Decreased gastric emptying, reflux oesophagitis, gastritis, and peptic ulceration are all common and the risk of gastrointestinal tract bleeding is increased. Constipation is particularly common in patients on continuous ambulatory peritoneal dialysis (CAPD).

Acute pancreatitis occurs more frequently, though elevations of serum amylase of up to three times the upper reference interval may be found in CKD without evidence of pancreatic disease due to retention of high-molecular-weight forms of amylase normally excreted in the urine.

Metabolic abnormalities

Gout

Urate is retained as GFR declines, and many drugs used to manage CKD increase the risk of gout. Nephrotoxic NSAIDs may be contraindicated due to CKD. Colchicine is helpful for an acute attack. Reduced-dose allopurinol or febuxostat are effective in prevention.

Insulin

Insulin is catabolized and to some extent excreted by the kidneys. Renal glucose production is also diminished with progressive CKD. For these reasons, insulin requirements in patients with diabetes decrease as CKD progresses. In contrast, end-organ resistance to insulin is a feature of advanced CKD, resulting in modestly impaired glucose tolerance. Insulin resistance may contribute to hypertension and lipid abnormalities.

Lipid metabolism

Abnormalities in lipid metabolism are common in CKD and include:

- impaired clearance of triglyceride-rich particles
- hypercholesterolaemia (particularly in advanced CKD).

The situation is further complicated in kidney failure when regular heparinization (in haemodialysis), excessive glucose absorption (in CAPD), and immunosuppressive drugs (in transplantation) all contribute to lipid abnormalities.

Endocrine abnormalities

These include:

- Hyperprolactinaemia, which may present with galactorrhoea.
- Decreased serum testosterone concentrations (seldom below normal reference limit), loss of libido, erectile dysfunction, and decreased spermatogenesis.
- Menstrual irregularities, oligomenorrhoea, or amenorrhoea.
- Complex abnormalities of growth hormone secretion and action, resulting in impaired growth in uraemic children (managed with recombinant growth hormone and insulin-like growth factor).
- Altered protein binding and increased thyroid-binding globulin loss with proteinuria make thyroid function tests difficult to interpret. Thyroid-stimulating hormone (TSH) is most commonly used to assess thyroid function. True hypothyroidism occurs with increased frequency in CKD.

Muscle dysfunction

Uraemia appears to interfere with muscle energy metabolism via an uncertain mechanism. Decreased physical fitness (cardiovascular deconditioning) is also a contributing factor.

Nervous system abnormalities

Uraemia affects on the central nervous system include depressed cerebral function, a decreased seizure threshold, asterixis, tremor, and myoclonus. Anxiety, depression, and impaired cognition also

occur. In people with very high blood urea prior to their first dialysis, sudden correction can cause ***dialysis disequilibrium:*** urea does not equilibrate rapidly across the blood–brain barrier, so blood urea falls with dialysis before urea in the central nervous system leading to rapid movement of water into the higher-urea environment, osmotic cerebral swelling and seizures. Dialysis disequilibrium can be avoided by correcting uraemia gradually using short, repeated haemodialysis treatments or by the use of peritoneal dialysis.

Increased circulating catecholamines lead to downregulation of α-receptors, impaired baroreceptor sensitivity, and impaired efferent vagal function in the autonomic nervous system. Overactivity of the sympathetic nervous system may contribute to hypertension in CKD. These abnormalities correct to some extent with regular dialysis and resolve after successful kidney transplantation.

Median nerve compression in the carpal tunnel is common, usually due to β_2-microglobulin-related amyloidosis. Advanced uraemia leads to a symmetrical polyneuropathy (which may recur in inadequately dialyzed patients).

Management of CKD

General principles

- Make a diagnosis and treat any modifiable underlying cause.
- Address cardiovascular risk factors: smoking cessation, obesity, and exercise.
- Avoid nephrotoxic drugs.
- Arrange follow-up, depending on the stage of CKD, to identify those most likely to progress early.

As stage G3 CKD progresses to stage G4 CKD, attention should be paid to correcting the complications associated with more advanced CKD and described earlier: anaemia, CKD-MBD, and metabolic abnormalities. Primary prevention of cardiovascular disease is a major part of CKD management at this stage.

Renoprotection

Preservation of kidney function and reduction in cardiovascular risk are key principles in the management of CKD (**Box 26.10**).

Correction of specific complications

Hyperkalaemia often responds to dietary restriction of potassium intake. Drugs that cause potassium retention should be stopped. Ion-exchange resins remove potassium in the gastrointestinal tract. Patiromer and sodium zirconium cyclosilicate are orally active, have been shown to control hyperkalaemia in phase 3 trials and are now available for clinical use. Emergency treatment of severe hyperkalaemia is described in Chapter 11 ('Hyperkalaemia/Management' section).

Correction of acidosis helps to address hyperkalaemia in CKD and may also decrease muscle catabolism. Sodium bicarbonate supplements (4.8 g of $NaHCO_3$ contains 57 mmol of both Na^+ and HCO_3) are effective, without significant risk of oedema or hypertension. Correction of metabolic acidosis with sodium bicarbonate at a mean dose of 1.8 g/day reduces rate of decline of GFR in advanced (stage G4 and G5) CKD. Calcium carbonate, also used as a phosphate binder, has a beneficial effect on acidosis.

Drug therapy should be reviewed and nephrotoxins avoided in patients with CKD. These include:

- tetracyclines (except for doxycycline)
- drugs excreted by the kidneys, such as gentamicin (prescribed only in the absence of any alternative, and drug concentrations monitored if feasible)
- NSAIDs

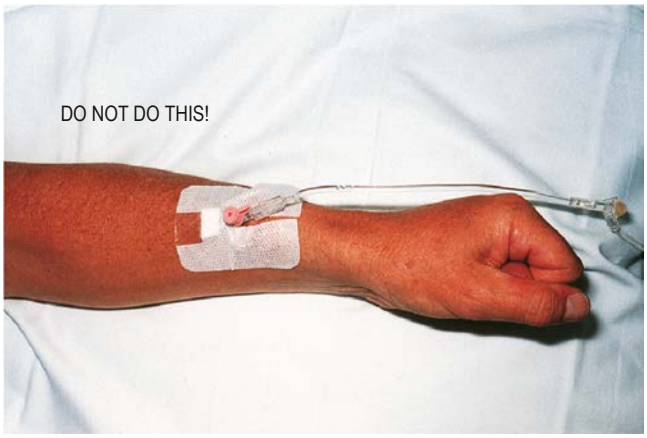

Fig. 26.46 Intravenous cannula in exactly the WRONG place. The cannula is shown in a right-handed patient with CKD, who will, in future, need a left (non-dominant arm) radiocephalic fistula.

- potassium-sparing agents, e.g., spironolactone, amiloride (and artificial salt substitutes which contain potassium).

Antibiotics, anticoagulants (particularly anti-thrombin oral anticoagulants, which currently lack a practical therapeutic monitoring), beta-blockers, oral hypoglycaemics, insulin, antidepressants, and analgesics (especially opioids, which can accumulate, leading to an opiate narcosis) often need dose adjustment in patients with CKD.

Early referral

Patients need time to adjust to the demands of CKD and its treatment, and to absorb information. Those who share in decisions and who are able to understand and choose treatments are better able to transition to dialysis or transplantation. As eGFR declines below 20 mL/min/1.73 m^2, a specialist team should counsel patients about diet, review medication, encourage risk factor modification, and support their choice about renal replacement (including the choice not to undertake dialysis). Where suitable, patients should be offered and prepared for ***pre-emptive living donor transplantation*** as the best option for RRT.

If patients opt for regular haemodialysis, an arteriovenous fistula should be fashioned in advance of the need for dialysis (with earliest planning in patients with diabetes and poor vasculature). Fistulae require several weeks to mature and become usable for vascular access. Veins required for future arteriovenous fistulae should not be rendered useless by cannulation (**Fig. 26.46**). Patients choosing peritoneal dialysis might have a buried catheter placed and left subcutaneously for some time, able to be externalized when dialysis is required.

Kidney replacement therapy

About 3 million people worldwide are either treated by haemodialysis or peritoneal dialysis or live with a functioning kidney transplant. In the UK, around 53 000 people receive treatment for kidney failure: 50% are transplanted, 42% are on haemodialysis, and 8% are on peritoneal dialysis.

Dialysis aims to mimic excretory function of normal kidneys by:

- eliminating nitrogenous and small molecular waste products
- maintaining normal electrolyte concentrations
- preventing systemic acidosis
- maintaining a normal extracellular volume.

Initiation of dialysis

It is not widely agreed *when* to start dialysis in patients with stage G5 CKD. Trials have suggested that early initiation is not associated

with improved survival or clinical outcomes. There is a general tendency to start dialysis at an eGFR close to 10 mL/min/1.73 m^2 but this decision is best shared with an individual patient, considering symptoms and life plans.

Some, particularly those who are frail or living with other comorbidities, may choose not to undergo dialysis as a shared, informed decision with their physician and families. For some, the *quantity* of extended life offered by dialysis is not matched by *quality* of life on dialysis. For others, events and complications of dialysis make the experience of treatment difficult and they choose to withdraw from dialysis. Respect for an individual's informed choice, support, and symptom control should be offered as part of end-of-life care.

Across the globe, RRT is expensive. Resources may be allocated to other pressing priorities, or available for a defined period only, or one form of RRT may available. Cost-effective, low-technology solutions to treat kidney failure are required.

Haemodialysis

Basic principles

Anticoagulated blood from a patient is pumped around an extracorporeal circuit and through a biocompatible, semipermeable membrane (the dialyzer, or 'artificial kidney') before being returned to the circulation. In the dialyzer, ultrapure dialysate flowing in the opposite direction is in close contact with blood. Small solutes (but not cells and larger-molecular-weight proteins) cross the membrane and move by diffusion down a concentration gradient (Fig. 26.47). A transmembrane pressure allows controlled fluid removal by ultrafiltration (and with fluid, more solute removal by convection). Over a standard 4-hour session, up to 80 L of blood (at around 300 mL/min) is circulated through the dialyzer. This provides an equivalent GFR of only 10 to 12 mL/min per 1.73 m^2. Box 26.30 describes a typical dialysate; dialysis is individually prescribed for each patient to obtain optimal results.

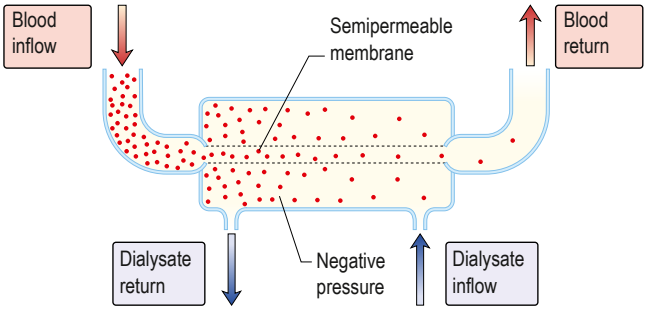

Fig. 26.47 Changes across a semipermeable dialysis membrane.

Box 26.30 Range of concentrations in standard dialysates used for haemodialysis

Dialysate	Range of concentration (mmol/L)
Sodium	130–145
Potassium	0.0–4.0
Calcium	1.0–1.6
Magnesium	0.25–0.85
Chloride	99–108
Bicarbonate	35–40
Glucose	0–10

Access

Effective dialysis needs blood flows of between 250 and 450 mL/min. To achieve this, a surgically fashioned ***arteriovenous fistula*** (AVF, Fig. 26.48) is formed using the radial or brachial artery and cephalic vein. Large-bore needles are inserted into the arterialized vein of the AVF to take blood to and from the dialysis machine. In patients with poor-quality veins or arterial disease (e.g., diabetes mellitus), synthetic arteriovenous grafts offer an alternative.

If AVF is not an immediate or viable option, a ***semi-permanent dual-lumen venous catheter*** can be inserted into the jugular or femoral vein via a subcutaneous tunnel. Although easy to place and suitable for immediate use, there is increased risk of bloodstream infection (with a foreign body directly accessing the circulation), catheter malfunction (thrombosis), and venous stenosis or occlusion compared to AVF. For urgent dialysis, a temporary (untunnelled) large-bore, double-lumen dialysis catheter may be inserted into a central vein—usually the jugular or femoral vein.

Aims

- ***Euvolaemia:*** an ideal or 'dry' weight is set for each individual patient. Each patient is weighed before each dialysis session and dialysis fluid losses are set with the aim of returning the patient to their 'dry weight' each time. Fluid gains between each dialysis session are the sum of fluid intake minus fluid losses over the interdialytic interval. For example, a patient who is anuric and drinks 1.5 L/day will gain 3 kg over 48 hours if no insensible or stool losses occur. This means they will be 3 kg above their dry weight before dialysis, and their dialysis prescription will be set to remove 3 L of fluid. In this way, dialysis delivers long-term volume and blood pressure control.
- ***Maintain electrolytes.*** A low dialysate potassium (1–3 mmol/L) means that dialysis confers a negative potassium balance (1–2 mmol/kg per session), allowing control of hyperkalaemia. Dialysate sodium is controlled (individualized between 137 and 141 mmol/L) to prevent large fluid shifts. Calcium concentration is set to prevent net calcium gain during dialysis.
- ***Prevent acidosis.*** Dialysate is buffered with bicarbonate (e.g., 36 mmol/L). This will diffuse into blood to correct acidosis during treatment.
- ***Balance dialysis frequency/duration with quality of life.*** On average, between 4 and 5 hours of dialysis, three times per week, will maintain volume and solute balance over time. However, recent evidence shows that more frequent dialysis (5–6 dialysis sessions per week) or longer treatment duration (6–8 h three times weekly) offers better quality of life, solute clearance, and cardiovascular health; though these benefits need to be balanced with the possibility of earlier loss of residual kidney function, vascular access loss, and quality-of-life impact. The provision of haemodialysis in the patient's home, rather than in a hospital setting, can help facilitate more intensive dialysis regimens. Shorter or less frequent dialysis is only sufficient in patients with ***residual kidney function*** (usually assessed by measuring 24 hours or 48 hours urine volume and clearance).
- ***Deliver enough dialysis*** (adequacy). The size, number, and nature of 'uraemic toxins' are not clear. The only true measures of dialysis adequacy are patient mortality and morbidity. Symptoms of under-dialysis are non-specific: insomnia, itch, fatigue (despite correction of anaemia), restless legs, and peripheral sensory neuropathy. Urea is used as a surrogate measure in adequacy calculations:

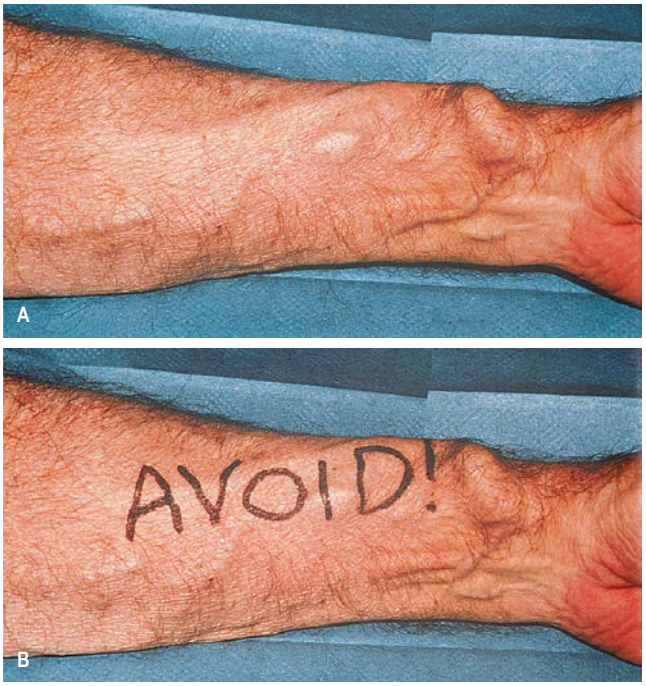

Fig. 26.48 Arteriovenous (radiocephalic) fistula. (A) Fistula in the left forearm. **(B)** A reminder for clinical teams about the presence of an existing arteriovenous fistula in a haemodialysis patient about to undergo surgery. To avoid thrombosis, the fistula should not be compressed during surgery.

- Urea reduction ratio (URR)—>65% reduction in serum urea concentration per dialysis session
- *eKt/V: K* = dialyzer clearance, *t* = duration of dialysis in minutes, *V* = urea distribution volume estimated as total body water. Minimum thresholds are required for well-nourished dialysis patients dialyzed three times per week. There are no trial data to show that a higher *eKt/V* than this minimum requirement associates with better outcomes.

Specific complications

- Access (AVF or catheter): malfunction, thrombosis, or bleeding.
- Bloodstream infections: may disseminate to soft tissue (septic arthritis), cardiac valves (endocarditis), or spinal column (vertebritis/discitis).
- Dialysis disequilibrium: dialysis is initiated with too rapid early urea removal. Subsequent movement of fluid towards the higher urea seen across the blood–brain barrier can cause cerebral oedema and seizures.
- Intradialytic hypotension: too rapid fluid removal exceeds refill of the circulation from the extravascular space.
- Dialysis-related amyloidosis: failure of clearance of β_2-microglobulin, a molecule of 11.8 kDa, leads to amyloid deposits causing median nerve compression in the carpal tunnel, dialysis arthropathy, bone cysts and fractures, pseudotumours, and gastrointestinal bleeding.

Haemofiltration

Haemofiltration differs from haemodialysis in that there is no dialysate. Plasma water (along with suspended solutes) is removed by convection across a high-flux semipermeable membrane and substitution fluid (with the desired biochemical composition) is infused to replace (large) fluid losses (Fig. 26.49). Haemofiltration may be preferred in the critical care setting, where haemodynamic instability is common. Modern dialysis machines have capacity to generate online ultra-pure water, which has minimized cost. It also means that filtration can be combined with dialysis as ***haemodiafiltration***, which increases middle molecule clearance (e.g., β_2-microglobulin) and prevents long-term dialysis complications in non-transplantable patients. Post-hoc analysis of several trials and recent randomized trial data suggest that haemodiafiltration confers a survival advantage, compared to haemodialysis.

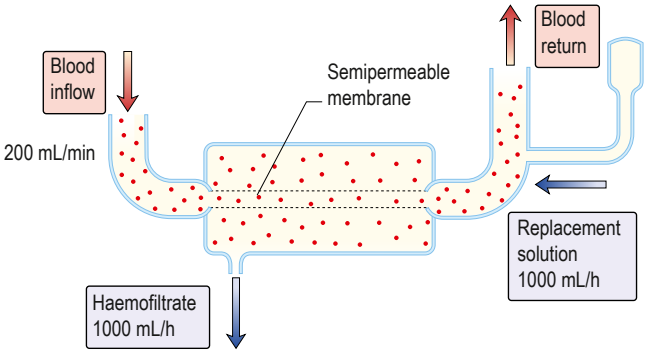

Fig. 26.49 Principles of haemofiltration.

Peritoneal dialysis

Peritoneal dialysis uses the peritoneal membrane as a semipermeable membrane, avoiding the need for extracorporeal circulation of blood. It is a simple, low-technology, effective treatment (Fig. 26.50).

- A soft catheter is placed through a skin tunnel into the peritoneal cavity through the midline of the anterior abdominal wall (Fig. 26.51).
- Dialysate is run into the peritoneal cavity, usually under gravity.
- Urea, creatinine, phosphate, and other uraemic toxins pass into the dialysate down their concentration gradients.
- Water (with solutes) moves into the peritoneal cavity by osmosis. Osmolarity, and therefore fluid removal, is controlled by the glucose or polymer (icodextrin) content of the dialysate (Box 26.31). More hypertonic solutions improve fluid removal.
- The dialysate fluid is exchanged regularly to repeat the process.

Continuous ambulatory peritoneal dialysis (CAPD): dialysate fluid is always present in peritoneal cavity and exchanged three to five times a day. Exchanges are performed by the patient (or trained carer) using a sterile no-touch technique to connect 1.5 to 3 L bags of dialysate to the peritoneal catheter. Each exchange takes 20 to 40 minutes.

Automated peritoneal dialysis (or nightly intermittent peritoneal dialysis): an exchange machine performs continuous low-volume exchanges at night while the patient is asleep. Dialysate can be left in the peritoneal cavity after the last exchange, adding extra dialysis time during the day.

Specific complications

- Bacterial peritonitis: fever, abdominal pain, and a cloudy peritoneal dialysate effluent (>100 cells/mm^3 on microscopy is suggestive) progressing to frank peritonitis. Rate of infection is about one episode every 2 patient-years. Peritoneal effluent is sent for culture and empirical antibiotic treatment is started while sensitivities are awaited. Common causative organisms are listed in Box 26.32.
- Catheter exit site infections: may progress to skin tunnel infections and peritonitis.

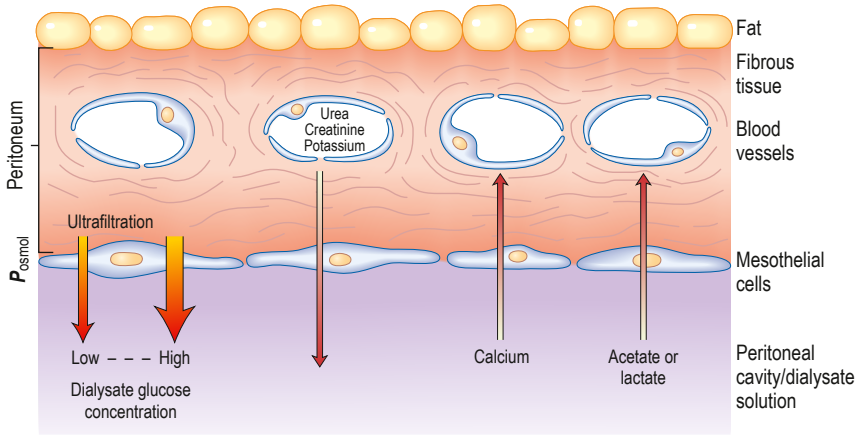

Fig. 26.50 Principles of peritoneal dialysis. Water moves into the peritoneal cavity, depending on the osmolarity of the dialysate.

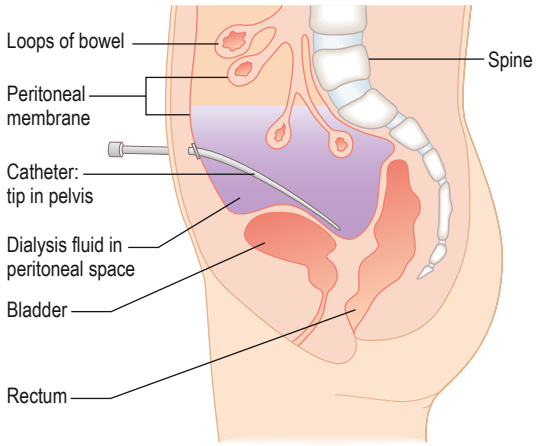

Fig. 26.51 The siting of a Tenckhoff peritoneal dialysis catheter.

- Constipation: may impair flow of dialysate in and out of the pelvis.
- Hernias: caused by raised intra-abdominal pressure. Dialysate can then 'leak' into the pleural cavity or scrotum (down a patent processus vaginalis).
- Sclerosing peritonitis: a potentially fatal complication in which long-term patients develop progressive thickening of the peritoneal membrane. This causes adhesions and strictures and repeated episodes of small bowel obstruction.

Adequacy

Most clinicians aim for a weekly *Kt/V* of 2.0 (see earlier), coupled with a creatinine clearance of 60 L per week. Once patients stop passing urine (and have no residual kidney function), peritoneal dialysis inadequacy becomes common, and a switch to haemodialysis may be required.

Dialysis in the frail

Dialysis can prolong life but individual patient benefit, especially for those who are frail, varies widely. Dialysis outcomes are poor in patients who are old and frail. Small studies suggest that mortality and quality-of-life outcomes are not improved by dialysis. In one study, over 50% died within the first year of initiating dialysis and around 30% had a decrease in functional status. Medical management of symptoms and end-of-life care should be provided for those who chose not to dialyze.

Box 26.31 Range of concentrations in standard continuous ambulatory peritoneal dialysates

Dialysate	Range of concentration (mmol/L)
Sodium	130–134
Potassium	0
Calcium	1.0–1.75
Magnesium	0.25–0.75
Chloride	95–104
Lactate	35–40
Glucose[a]	77–236
Total osmolality	356–511 mOsm/kg

[a]Glucose content is often expressed as g/dL of anhydrous glucose (e.g., 1.36% = 77 mmol/L). An even more hypertonic dialysate (6.36%) is available for acute (intermittent) peritoneal dialysis.

Box 26.32 Causes of continuous ambulatory peritoneal dialysis peritonitis

Cause	Approximate % of cases
Staphylococcus epidermidis	40–50
Gram-negative organisms: *Escherichia coli*, *Pseudomonas*, other	25
Staphylococcus aureus	15
Mycobacterium tuberculosis	2
Candida and other fungal species	2
No bacteria detected	20

Kidney transplantation

Successful kidney transplantation offers the potential for almost complete rehabilitation in ESKD.

- Survival is significantly better compared to dialysis patients on transplant waiting lists.
- Transplantation allows freedom from dietary and fluid restrictions.
- Anaemia and infertility are corrected.
- Need for parathyroidectomy is reduced.

It is the treatment of choice for all *appropriate* patients with ESKD. However, demand exceeds the supply of donor organs (in the UK, 44 per million population per year). Donor organs are a scarce and valuable resource that must be used optimally. The possibility of living donors, who can donate one kidney without impact on their long-term health, should be explored for all patients.

Kidney transplantation involves the anastomosis of an explanted human kidney on to the iliac vessels of the recipient (Fig. 26.52). The donor ureter is placed into the recipient's bladder. Unless the donor is genetically identical (i.e., an identical twin), immunosuppressive treatment is needed for as long as the transplant remains in place to prevent rejection. Patient and graft survival has steadily improved with:

- appropriate patient selection and assessment prior to transplantation
- better donor–recipient compatibility
- improvements in surgical techniques
- safer immunosuppressive regimens.

Some 80% of grafts survive for 5 to 10 years in the best centres, and 50% for 10 to 30 years. However, the half-life of kidney transplants is 13 to 16 years. The three most common causes of late graft loss are death of a patient with a functioning graft, recurrence of the original (or new) kidney disease, and chronic allograft nephropathy.

Considerations in successful kidney transplantation

ABO (blood group) compatibility between donor and recipient is preferred. ABO-incompatible kidney transplants (where donor and recipient have different blood groups) are successful with directed immunosuppression (including immunoadsorption to remove preformed antibodies, anti-CD20 antibodies to remove B lymphocytes, and intravenous pooled immunoglobulins for immunomodulation or anti-idiotypic antibodies).

Donor and recipient HLA mismatches should ideally be minimized. Nationwide matching schemes exist for kidneys retrieved from deceased donors. Complete compatibility at A, B, and DR loci offers the best long-term outcomes when compared to mismatched organs (i.e., antigens possessed by the donor and not possessed by the recipient). However, transplanting completely mismatched kidneys is performed routinely. With living donation, outcomes with a mismatched kidney are as good as, if not better than, matched deceased donor kidneys.

Pre-formed anti-HLA antibodies in recipients, resulting from sensitization from prior blood transfusions, kidney transplants, or pregnancy, predict less good outcomes. This is particularly true if existing antibodies are donor-specific (recipient anti-HLA antibodies against donor antigens). Transplantation can still be successful but pre-transplant strategies are necessary to minimize these antibodies. These include plasmapheresis, intravenous immunoglobulin, anti-B cell monoclonal antibody (rituximab), and IgG endopeptidase (which cleaves off IgG).

Most countries allow the removal of kidneys and other organs from patients who have suffered irretrievable brain damage ('brainstem death') while the heart is still beating (donation after brainstem death, DBD). Due to the shortage of solid organs and increasing numbers of patients waiting for them, several countries now allow the retrieval of organs after cardiac death (donation after cardiac death, DCD), with comparable results to 'heart-beating' donations. Increasing use is also made of expanded criteria donors (ECDs) that are aged over 60 years, or 55 and 59 years with co-morbidity including hypertension, diabetes, pre-retrieval AKI, and intracranial haemorrhage.

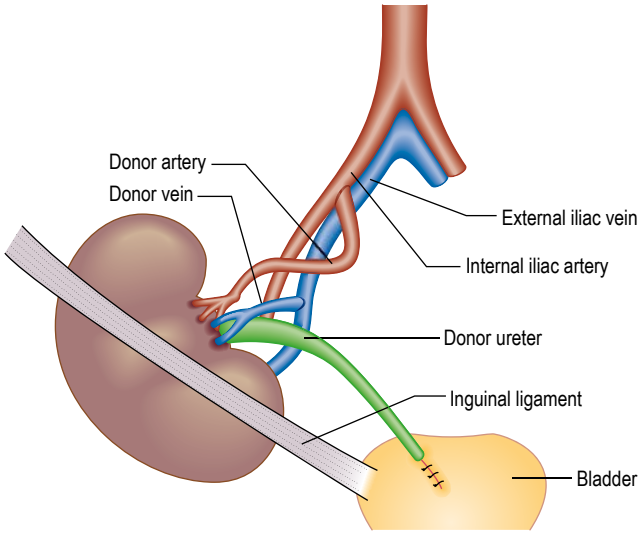

Fig. 26.52 Anatomy of a kidney transplant operation.

Living donation offers the best kidney outcomes. Potential living donors undergo comprehensive preoperative evaluation to ensure that they will come to no harm through donating a kidney to another person. Recent evidence suggests that live donors carry a statistically increased risk of CKD/ESKD post donation, but this risk is too low to be of clinical significance. All living donors should be consented carefully and monitored regularly.

Timing transplantation so that it takes place prior to dialysis initiation (pre-emptive transplantation) offers benefits to both recipient and graft.

Immunosuppression for transplantation

Long-term inhibition of the recipient immune system is needed to prevent 'non-self' immune-mediated injury to transplants. This is almost universally the case, except where living-related donation from an identical twin occurs. Some degree of immunological tolerance does develop, and the risk of rejection is highest in the first 3 months after transplantation. In the early months, rejection episodes occur in less than 20% of cadaver kidney recipients on current immunosuppression protocols, and most cases are reversible. A combination of immunosuppressive drugs is usually used (Box 26.33). Individualizing immunosuppression to a specific recipient remains an inexact science and preventing the complications of over-immunosuppression is as necessary as preventing rejection. Therapeutic drug monitoring is useful in delivering intense immunosuppression in the early post-transplant phase, with reduced drug doses/concentrations later.

Early complications

Early (technical) failure

Occlusion or stenosis of the arterial anastomosis, occlusion of the venous anastomosis and urinary leaks owing to damage to the lower ureter or to defects in the anastomosis between ureter and recipient bladder can occur.

Kidney transplant acute tubular necrosis

Delayed graft function resulting from ATN is the most common cause of deceased donor graft dysfunction (up to 40%–50%), particularly in kidneys from DCD or ECD donors (see earlier). Hypotension or loss of cardiac output prior to the death of the donor impacts the retrieved kidney. A prolonged 'cold ischaemia time' (the

Box 26.33 Immunosuppressive drugs used in kidney transplantation

Class	Examples	Mechanism of action	Clinical role	Side-effects
Calcineurin inhibitors	Ciclosporin Tacrolimus	Disrupt T-cell signalling	Used in most regimens	Nephrotoxicity (monitor concentrations) Hypertension Diabetes Hirsutism Virilization
Inhibitors of purine synthesis	Azathioprine Mycophenolate mofetil (MMF)	Inhibit purine synthesis and cell proliferation (especially lymphocytes)	Used in most regimens	Neutropenia Pancytopenia Deranged LFTs (azathioprine) Diarrhoea (MMF) Interaction with allopurinol (azathioprine)
Steroids	Prednisolone (oral) Methylprednisolone (i.v.)	Inhibit cytokine-regulated T-cell signalling	Used in most regimens. Dose tapers over weeks/months after transplantation. Methylprednisolone used on induction and to treat acute rejection	Osteoporosis Hypertension Diabetes Weight gain Poor wound healing Lipid abnormalities
Rapamycin inhibitor	Sirolimus	Inhibits cytokine-dependent cell proliferation	Alternative to calcineurin inhibitors	Delayed graft function Myelosuppression Impaired wound healing Thrombocytopenia Monitor concentrations
Anti-CD25 antibodies	Daclizumab Basiliximab	Monoclonal antibody, blocking IL-2	Given on induction	Well tolerated
Antibodies causing T-cell depletion	Anti-thymocyte globulin (ATG, polyclonal) OKT3 anti-CD3 antibody (monoclonal)	Destroy T cells	For steroid-resistant rejection May be used as induction agent for patients at high risk of rejection	Severe T-cell depletion (risk of sepsis) Late development of malignancy, e.g., lymphoma
Anti-CD52 antibody	Alemtuzumab	Depletes T and B cells	Used as induction agent	Risk of sepsis Malignancy
Anti-B7 antibody	Belatacept	Prevents engagement of B7 and CD28 Blocks co-stimulatory signal	Alternative to calcineurin inhibitors	Rejection Post-transplant lymphoma in EBV-negative patients
Anti-C5a antibody	Eculizumab	Inhibits complement activation by blocking activated C5	Post-transplant atypical HUS Antibody-mediated rejection	Infections, particularly meningococcal meningitis. Vaccinated against meningitis prior to use

EBV, Epstein–Barr virus; *HUS,* haemolytic uraemic syndrome; *IL-2,* interleukin 2; *LFTs,* liver function tests.

period during which the retrieved organ is cooled on ice in transit and awaits implantation) also leads to delayed graft function due to ATN. Finally, calcineurin inhibitors used to prevent rejection are themselves nephrotoxic and high peak and trough concentrations cause tubular injury. Kidneys transported on a perfusion machine, and controlled hypothermia in deceased donors prior to organ retrieval are associated with lower rates of delayed graft function.

Acute rejection

Acute rejection is seen in between 10% and 30% of transplant recipients and usually presents with declining kidney function within the first 3 months. Transplant biopsy (Fig. 26.53) confirms the diagnosis, severity, and type of rejection. It can be T cell or antibody-mediated and occur with or without endothelial injury ('vascular rejection'). Urinary measurement of RNA can be used as a marker of acute cellular rejection.

Cellular rejection may respond to high-dose intravenous corticosteroids, increased or switched calcineurin inhibition, or the use of T-cell–depleting agents such as anti-thymocyte globulin (ATG) or anti-CD52 antibody (Campath). Antibody-mediated rejection (diagnosed by the presence of circulating donor-specific anti-HLA antibodies and evidence of complement activation on kidney biopsy by C4d staining, Fig. 26.53B) is usually treated empirically by a combination of intravenous immunoglobulin (to neutralize and promote the clearance of anti-HLA antibodies), plasmapheresis (to remove antibodies), and anti-CD20 antibody administration (to deplete B lymphocytes), with variable success.

More than one episode of rejection within the first 3 months, vascular and/or antibody-mediated rejection, delayed rejection, requirement of dialysis within the first week after transplantation, and failure of serum creatinine to return to baseline after a rejection episode are associated with worse long-term outcomes.

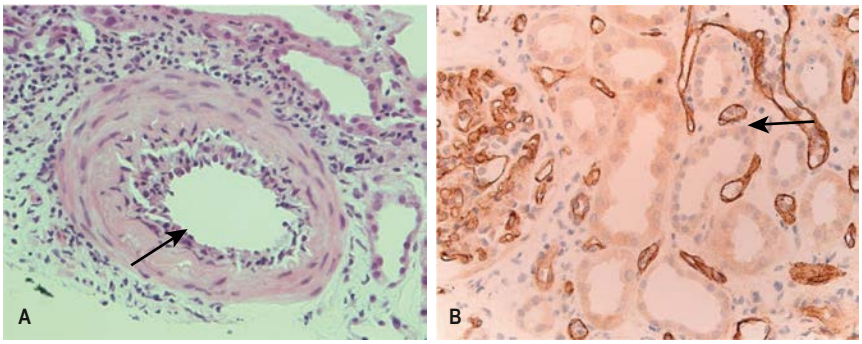

Fig. 26.53 Histology of kidney transplant in rejection. **(A)** Acute vascular rejection: the mononuclear inflammatory cell infiltrate is limited to the expanded intima and does not involve the entire vascular wall as in systemic vasculitis. The arrow indicates endothelialitis. **(B)** Antibody-mediated rejection: an acute tubular necrosis with capillary glomerulitis, and peritubular and glomerular capillary C4d positivity *(arrowed)*.

Infection

- Bacterial infections occur early (<1 month post transplant) and usually involve the urinary tract, wound, or chest.
- Cytomegalovirus infection develops weeks or months after transplantation. It occurs in 70% of cytomegalovirus-seronegative recipients from seropositive donors, and in patients receiving biological agents as induction or therapy for rejection, unless prophylaxis with valganciclovir is given.
- Opportunist infections including *Pneumocystis jirovecii* occur and prophylactic co-trimoxazole is given in the early months.
- Infections in the months after transplantation and are associated with heavier immunosuppressant burdens.
- Polyomavirus infection ***(BK nephropathy)*** can cause an aggressive TIN that may lead to graft loss. Immunosuppression is minimized in the hope of spontaneous viral clearance.

Late complications

- ***Post-transplantation lymphoproliferative disorders***, often associated with Epstein–Barr virus, are more frequent in patients who received profound immunosuppression. Immunization is minimized and standard chemotherapy offered, with mixed outcomes.
- ***Cancers*** which occur with increased frequency in patients receiving long-term immunosuppression include skin (basal and squamous cell), kidney, cervical, and vaginal malignancies.
- ***Cardiovascular disease*** causes 50% of patient deaths after transplantation. Hypertension, obesity, diabetes, insulin resistance, and lipid disorders all play a role, as does the history of CKD.
- ***Post-transplant osteoporosis*** may occur because of steroid use.
- ***Recurrent kidney disease*** is common. Primary FSGS often recurs and is a cause of early graft loss. Mesangiocapillary GN, diabetic nephropathy (unless simultaneous pancreas transplantation), and IgA nephropathy also commonly recur, with variable effects on long-term transplant survival.

Most grafts fail eventually through lasting immunological injury and/or immunosuppressant drug toxicity. A common histological finding is the combination of interstitial fibrosis and tubular atrophy (historically termed 'chronic allograft nephropathy'). There is a growing understanding of the role of subclinical chronic antibody-mediated rejection due to existing or *de novo* donor-specific antibodies, but non-immunological factors are also important. Progressive irreversible decline in graft function is associated with mild to modest proteinuria (<3 g/day), and interventions to change this trajectory currently lack evidence of benefit.

CYSTIC KIDNEY DISEASE

Solitary or multiple kidney cysts are common, especially with advancing age. One or more kidney cysts are found in 50% of those aged over 50 years. Cysts are often asymptomatic and are found on ultrasound examination performed for some other reason. They have no clinical significance, except in the differential diagnosis of kidney tumours. Occasionally, they may cause pain and/or haematuria if large, or bleeding may occur into a cyst. Cystic degeneration (the formation of multiple cysts that enlarge with time) occurs regularly in the non-functioning kidneys of patients with ESKD treated by dialysis and/or transplantation. These acquired cysts have malignant potential.

Autosomal dominant polycystic kidney disease

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited disorder that usually presents in adulthood. It is characterized by the development of multiple kidney cysts, variably associated with extrarenal (mainly hepatic and cardiovascular) abnormalities. ADPKD is the most common inherited nephropathy, with a prevalence rate ranging from 1:400 to 1:1000. It accounts for 3% to 10% of all patients commencing regular dialysis in high-income countries.

Mutations in *PKD1* (on chromosome 16) are responsible for 85% of cases, with mutations in *PKD2* (on chromosome 4) accounting for the remainder. These genetic abnormalities are distinct from autosomal recessive polycystic disease (due to mutations in the *PKHD1* gene on chromosome 6p21.1-p12), which is often lethal in early life.

PKD1 encodes polycystin 1, involved in cell–cell and/or cell–matrix interactions. *PKD2* encodes polycystin 2, which functions as a calcium ion channel. The polycystin complex occurs in cilia, responsible for sensing flow in the tubule. Disruption of the polycystin pathway results in reduced cytoplasmic calcium, which causes defective ciliary signalling and disoriented cell division in principal cells of the collecting duct leading to cyst formation. Extra-renal manifestations intracranial aneurysms, which can be associated with significant morbidity. Missense mutations in *GANAB*, encoding glucosidase II subunit α (GIIα) are associated with polycystic liver disease. The *GANAB* gene product GIIα is required for maturation and surface and ciliary localization of the ADPKD proteins (PKD1 and PKD2).

Progressive loss of kidney function is usually attributed to mechanical compression, apoptosis of the healthy tissue, and reactive fibrosis. Kidney function declines at a variable rate, depending on growth and size of cysts. Patients with rapidly growing cysts on MRI lose kidney function more rapidly.

Clinical features

Symptoms can occur from the second decade:

- loin pain and/or haematuria due to haemorrhage into a cyst, cyst infection, or stone formation
- loin or abdominal discomfort as the size of the kidneys increases
- subarachnoid haemorrhage associated with berry aneurysm rupture
- complications of hypertension
- complications of liver cysts (in around 50% of those with cysts)
- symptoms of anaemia and/or uraemia associated with CKD.

Complications and associations

- Pain from large cysts can be difficult to manage. Surgical decompression may offer some benefit in about two-thirds of patients.
- Cyst infection requires lipophilic antibiotics that penetrate infected cysts and are active against Gram-negative bacteria.
- Kidney calculi occur in 10% to 20%. They are often composed of uric acid and are radiolucent.
- Hypertension is an early and common feature. Intrarenal activation of the renin–angiotensin system is thought to be contributory, so ACE inhibitors and AII-RAs are logical first-line treatments. Early control of blood pressure is essential as left ventricular hypertrophy is common, and cardiovascular complications are a major cause of death.
- Progressive CKD is the most serious complication. At GFRs below 50 mL/min, the rate of decline in GFR averages 5 mL/min/1.73 m^2 each year, which is more rapid than in other primary kidney disorders. The probability of being alive without requiring dialysis or transplantation by the age of 70 years is in the order of 30%. Survival rates on haemodialysis and after kidney transplantation are better than those in patients with other primary kidney diseases.
- Approximately 30% of patients have hepatic cysts that can be complicated by massive enlargement with pain, and infection. More rarely, compression of the bile duct, portal vein, or hepatic venous outflow occurs.
- Asymptomatic intracranial aneurysm are found in about 10%, but prevalence is twice as high if there is a family history of aneurysms or intracranial haemorrhage. Screening for intracranial aneurysm in ADPKD is recommended for patients aged 18 to 40 years who have a positive family history.
- Mitral valve prolapse is found in 20%.

Fig. 26.54 Ultrasound image of a polycystic kidney. There is almost complete replacement of normal kidney tissue.

Box 26.34 Ultrasonographic diagnostic criteria for testing individuals at risk of autosomal dominant polycystic kidney disease (ADPKD)

Diagnostic criteria

- 15–39 years: ≥3 cysts (unilateral or bilateral)
- 40–59 years: ≥2 cysts in each kidney
- ≥60 years: ≥4 cysts in each kidney

ADPKD is excluded in patients meeting the following criteria:

- ≥40 years: <2 cysts
- 30–39 years: 0 cysts (excludes ADPKD in 98% of cases)

Negative ultrasound < 30 years:

- Unable to exclude ADPKD
- CT/MRI may have higher sensitivity for cysts
- Molecular genetic testing (if known mutation)

Diagnosis and screening

Physical examination commonly reveals large, irregular kidneys and possible hepatomegaly. Definitive diagnosis is established by ultrasound examination (Fig. 26.54 and Box 26.34). However, imaging techniques may be equivocal, especially in subjects under the age of 15 years. Several conditions can mimic the clinical and radiological appearance of ADPKD (Box 26.35).

Children and siblings of patients with ADPKD are offered screening. Affected individuals should have regular blood pressure checks and should be offered genetic counselling, including pre-implantation genetic diagnosis for females planning pregnancy. Gene linkage analysis can be utilized in many families.

Management

- ***Vasopressin receptor antagonists:*** inhibit cAMP in principal cells, reduce cyst growth, and slow progression of kidney disease. Approved for use if eGFR declines >3 mL/min/1.73 m^2 per year. Reversible liver toxicity requires close monitoring.
- ***Octreotide:*** a long-acting somatostatin analogue (which also inhibits cAMP) offers benefit in slowing growth of both liver and kidney cysts. However, lanreotide, an alternative somatostatin analogue, did not slow decline in kidney function in more than 300 patients with eGFR 30 to 60 mL/min/1.73 m^2 over 2.5 years of follow-up, despite a measurable effect on the rate of cyst growth.

Box 26.35 Conditions that clinically and radiologically mimic polycystic kidney disease

- Tuberous sclerosis: includes lymphangiomyomatosis and lymphangioleiomyomatosis, and can be associated with the *TSC2–PKD1* contiguous gene syndrome
- Von Hippel–Lindau syndrome
- Multicystic dysplastic kidney: a non-heritable unilateral syndrome or a systemic syndrome (e.g., prune belly syndrome)
- Juvenile nephronophthisis and medullary cystic kidney disease: can be autosomal recessive (presenting in the second decade of life) or autosomal dominant (presenting in the third to fourth decades)
- Glomerulocystic kidney disease: involves the expansion of Bowman's space, autosomal dominant
- Acquired cystic disease: associated end-stage kidney disease and hypokalaemia
- Renal-cell carcinoma: with cystic changes

- ***Blood pressure control:*** In patients eGFR > 60 mL/min/1.73 m^2, lower blood pressure (95–110/60–75 mmHg) is associated with slower increase in kidney volume, less albuminuria, and lower left ventricular mass compared to standard blood pressure (120–130/70–80 mmHg). However, the addition of an angiotensin receptor blocker to an ACE inhibitor (dual blockade) does not confer additional benefit.

Medullary cystic disease ('juvenile nephronophthisis')

Juvenile nephronophthisis is an autosomal recessive (or sporadic) condition which develops early in childhood. Mutations in the *NPHP1–4* genes, encoding nephrocystin and inversin (both co-localized in the cilia of the tubules) lead to multiple cyst formation. Polyuria, polydipsia, and growth retardation result from impaired tubular function. Medullary cystic disease is a similar condition that develops later in childhood, inherited as an autosomal dominant trait. Histological findings include interstitial inflammation and tubular atrophy, with later development of medullary cysts. Diagnosis is based on family history and kidney biopsy, and the cysts rarely being visible on imaging.

Medullary sponge kidney

Medullary sponge kidney is an uncommon cystic condition presenting with intermittent renal colic, passage of small stones, and haematuria. Although it is most often sporadic, affected families have been reported. Dilation of the collecting ducts in the papillae occurs, sometimes with cystic change. In severe cases, the medullary area has a sponge-like appearance. The condition may affect one or both kidneys, or only part of one kidney. Cyst formation is commonly associated with the development of small calculi within the cyst. In about 20% of patients, there is associated hypercalciuria or renal tubular acidosis. Hemi-hypertrophy of the skeleton has been described in this condition. CT or IVU (see **Fig. 26.25**) is diagnostic. Kidney function is usually well maintained. CKD is unusual, except where obstructive nephropathy develops owing to the presence of stones in the pelvis or ureters.

TUMOURS OF THE KIDNEY AND GENITOURINARY TRACT

Renal cell carcinoma

Renal cell carcinomas (RCCs) arise from proximal tubular epithelium. They are the most common kidney tumour in adults, accounting for 1% to 2% of all malignancies, and affect males more often than females (2:1). They usually present after 50 years of age and rarely before the age of 40. RCCs are highly vascular tumours. Microscopically, most are composed of large cells containing clear cytoplasm.

Clinical features

- Often asymptomatic and discovered incidentally
- Haematuria, loin pain, flank mass
- Malaise, anorexia, and weight loss (30%)
- Polycythaemia (5%)
- Hypertension (30%) due to renin secretion by the tumour
- Anaemia (30%) due to depression of erythropoietin
- Pyrexia (20%)
- Symptoms of metastases
- A left-sided varicocele due to renal vein invasion and testicular vein obstruction by a left-sided tumour (rare)

Diagnosis

Ultrasound may demonstrate a solid lesion. CT scanning is used to identify the lesion and involvement of the renal vein or inferior vena cava. MRI is used for tumour staging. Urine cytology for malignant cells is of no value. The ESR is usually raised. Liver biochemistry may be abnormal, returning to normal after surgery.

Management

A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery, such as partial nephrectomy, may be indicated. If metastases are present, nephrectomy may still be warranted since regression of metastases has been reported after removal of the main tumour mass. Medical management of RCC is discussed in Chapter 41 ('Renal cancer' section).

Von Hippel–Lindau (VHL) disease is an autosomal dominant disorder presenting with bilateral RCCs, retinal and cerebellar haemangioblastomas, phaeochromocytoma, pancreatic neuroendocrine tumours, and kidney cysts. VHL protein suppresses tumour activity by tagging hypoxia-inducible gene products (VEGF, TGF) for degradation. Inactivating mutations of the *VHL* gene lead to uncontrolled angiogenesis and neoplasia. Mutations of the same tumour suppressor gene are responsible for RCC and VHL.

Nephroblastoma (Wilms' tumour)

Usually seen within the first 3 years of life, Wilms' tumour presents as an (occasionally bilateral) abdominal mass, rarely with haematuria. Diagnosis is established by ultrasound, CT, or MRI. A combination of nephrectomy, radiotherapy, and chemotherapy has improved survival rates, even in children with metastatic disease. Overall, the 5-year survival rate is 90%.

Urothelial tumours

The calyces, pelvis, ureter, bladder, and urethra are lined by transitional cell epithelium. Transitional cell cancers account for about 3% of cancer mortality. They are uncommon below 40 years of age, and more common in males than females (4:1). Bladder tumours are

most prevalent, about 50 times as common as tumours of the ureter or renal pelvis. Predisposing factors include:

- cigarette smoking
- exposure to industrial carcinogens: β-naphthylamine and benzidine (petroleum, chemical, cable, and rubber industry workers), aristolochic acid (herbal weight-loss preparations)
- medication: phenacetin, cyclophosphamide
- chronic inflammation: schistosomiasis (usually squamous carcinoma).

Clinical features

Painless haematuria is the most common (80%) presenting symptom of bladder malignancy. Pain may occur from clot retention or local nerve involvement. Cystitis symptoms occur in the absence of significant bacteriuria. Flank pain may occur with urinary tract obstruction in ureteric lesions.

Investigations

- Urine cytology for malignant cells
- Urinary tumour markers
- Cystoscopy to assess tumour burden and for biopsy
- CT or MRI of the pelvis

Management

Medical management of urothelial and testicular tumours is outlined in Chapter 41 ('Urothelial [bladder and ureteric] cancer' and 'Testicular and ovarian germ cell tumours' sections).

DISEASES OF THE PROSTATE GLAND

Benign prostatic enlargement is discussed in Chapter 47 ('Benign conditions of the prostate' section). The pathogenesis, diagnosis, and prognosis of prostate cancer are described in Chapter 41 ('Prostate cancer' section).

THE URINARY TRACT IN THE ELDERLY

Progressive sclerosis of glomeruli occurs with ageing. Together with atheromatous renovascular disease, this accounts for a progressive reduction in GFR with age. A GFR of 50 to 60 mL/min/1.73 m^2 (about half the reference value for a young adult) may therefore be regarded as 'normal' in patients over 80 years of age. A reduction in muscle mass with ageing may mask this deterioration in kidney function as serum creatinine falls despite the decline in GFR. Accurate estimation of GFR in the elderly is necessary, particularly when prescribing drugs that are renally excreted.

Urinary tract infections

UTIs are common in advanced age, as impaired bladder emptying (e.g., due to prostatic disease or a neuropathic bladder) is more common. Symptoms may be atypical: confusion, incontinence, nocturia, offensive urine, or a vague change in wellbeing with little in the way of dysuria are common (see Chapter 49).

CORE SKILLS AND KNOWLEDGE

Learning about fluid and electrolyte disorders and acid–base physiology can be a daunting experience. However, these disorders form some of the most common presentations to hospital and may complicate a wide range of other conditions, and so all doctors need to be confident when approaching them.

This chapter reviews the physiology that underpins normal fluid, electrolyte, and acid–base balance, and discusses disorders of blood chemistry caused by dietary factors, underlying medical conditions, and medical treatments. These imbalances may be acute or chronic, may occur with varying degrees of severity, and may or may not be partially compensated by the body's regulatory mechanisms.

Key skills to master for undergraduates include:

- Comprehensively assessing a patient's fluid status and gaining confidence in prescribing intravenous fluids and diuretics appropriately
- Developing an appropriate diagnostic approach to abnormalities of common electrolytes including sodium and potassium
- Understanding the implications of an abnormal blood pH and diagnosing the common causes of acidosis and alkalosis.

These skills can be best learned by experience—particularly in assessing patients presenting to the hospital emergency department or who have been admitted to critical care units. Take the opportunity to review patients' fluid balance charts on ward rounds and try (with supervision) to practise prescribing intravenous fluids appropriately. Review the results of blood gas analyses and work through any abnormalities shown.

CLINICAL SKILLS

Assessing a patient's fluid status is a key skill for all doctors, requiring key clinical skills in history-taking (Box 27.1), examination (Fig. 27.1), and data interpretation (Box 27.2). Many patients are hypovolaemic on admission to hospital as a result of acute illness. Others will exhibit signs of increased extracellular volume and require diuretic therapy (see 'Clinical use of diuretics' section).

Assessing a patient's fluid status

Box 27.1 Clues to volume status in the history

	Increased extracellular volume	Decreased extracellular volume
Symptoms	Peripheral oedema Breathlessness on exercise Orthopnoea Paroxysmal nocturnal dyspnoea	Thirst Dizziness, especially on standing
Medical history	Heart failure Cirrhosis Advanced chronic kidney disease Intravenous fluid administration	Recent diarrhoea or vomiting Symptoms suggesting sepsis Use of diuretics

Box 27.2 Clues to volume status on basic investigations

Evidence for increased extracellular volume

- 'Haemodilution': fall in blood haemoglobin concentration and packed cell volume (haematocrit)
- Fluid overload on chest X-ray
- Evidence of volume overload or cardiac dysfunction on transthoracic echocardiogram

Evidence for decreased extracellular volume

- 'Haemoconcentration': rise in blood haemoglobin and packed cell volume (haematocrit)
- Acute kidney injury (see Chapter 26, 'Acute kidney injury' section)
- Disproportionate rise in serum urea compared with serum creatinine
- Changes in serum sodium and osmolality
- Concentrated urine: specific gravity (measured on dipstick) >1.035

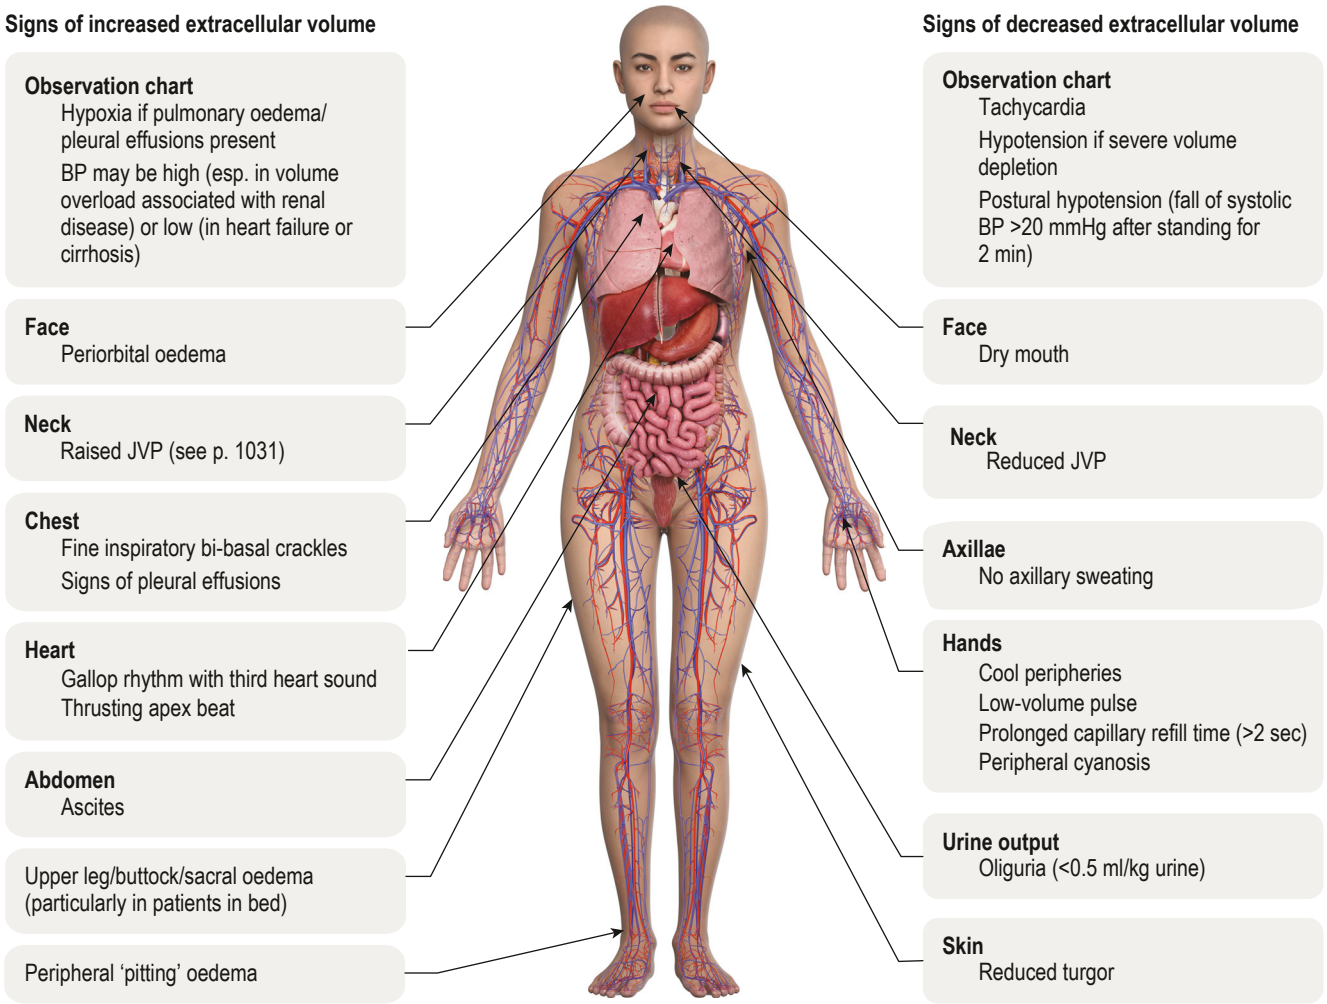

Fig. 27.1 Clues to volume status on clinical examination.

Fig. 27.2 The ABL800FLEX blood gas analyzer. *(From Al-Shaikh B, Stacey SG.* Essentials of Equipment in Anaesthesia, Critical Care and Peri-Operative Medicine, *5th edn. Edinburgh: Elsevier, 2019, Fig. 13.5, courtesy Radiometer Ltd.)*

Assessing acid–base disturbance

Arterial or venous blood gas analysis is readily carried out in most hospitals using table-top blood gas analyzers (Fig. 27.2), which measure:

- blood pH
- partial pressures of carbon dioxide (PCO_2) and oxygen (PO_2)
- calculated base excess (BE) and bicarbonate (HCO_3^-)
- blood electrolytes including sodium and potassium concentrations
- other molecules including glucose and lactate.

This information is vital in assessing respiratory failure, critical illness (failure to maintain blood pH in the normal range is often a poor prognostic marker), as well as chronic disorders affecting acid–base homeostasis.

A stepwise approach to interpreting blood gas analyses is shown in Fig. 27.3. Always go through a blood gas analysis report fully, describing all the abnormalities present, before pulling the different abnormalities together into a complete description.

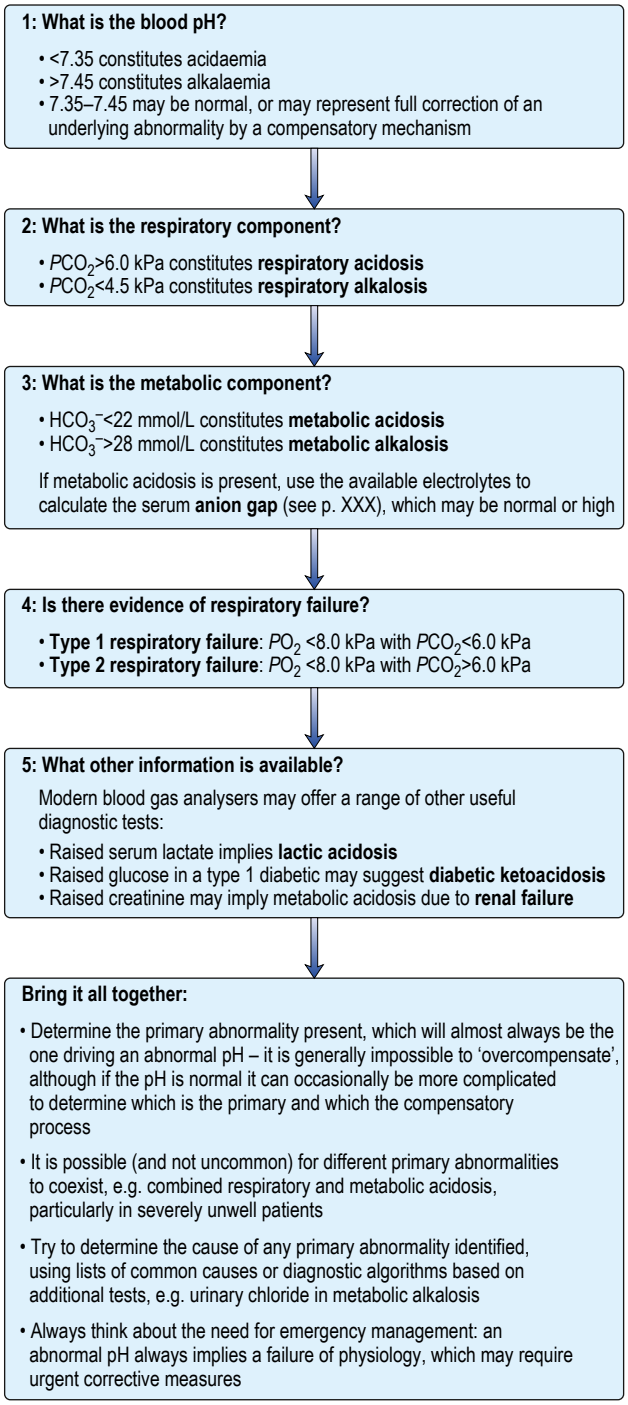

Fig. 27.3 Stepwise approach to interpreting blood gas analysis.

BACKGROUND

To understand the disorders described in this chapter, it is crucial to separate out:

- disorders of total extracellular volume (hyper- and hypovolaemia), which primarily relate to the increase or decrease of total body sodium
- disorders of blood osmolality (which, since sodium is the most abundant extracellular electrolyte, are generally encountered in clinical practice as hypo- and hypernatraemia); these conditions relate to inappropriate retention or loss of free water causing dilution or concentration of blood
- disorders in the serum concentrations of other major electrolytes including potassium, magnesium, and phosphate
- disorders of blood pH (acidaemia and alkalaemia), reflecting abnormal serum concentrations of hydrogen and bicarbonate ions and changes in the partial pressure of carbon dioxide.

Although this chapter deals with each of these groups in turn, it is important to remember how interconnected they are. For example, it would not be unusual to encounter a patient who is simultaneously hypervolaemic, hyponatraemic, hyperkalaemic, and acidaemic as a result of the same underlying disease process. Interventions must be individualized to address the particular physiological requirements of each patient. Once the underlying cause of abnormalities is diagnosed, this can be corrected while appropriate measures are put in place to support the body's physiological mechanisms to maintain homeostasis.

DISORDERS OF EXTRACELLULAR VOLUME

In normal healthy people, the total body water constitutes 50% to 60% of lean body weight in males and 45% to 50% in females. Thus in a healthy 70 kg male, total body water is approximately 42 L. This is contained in three major compartments:

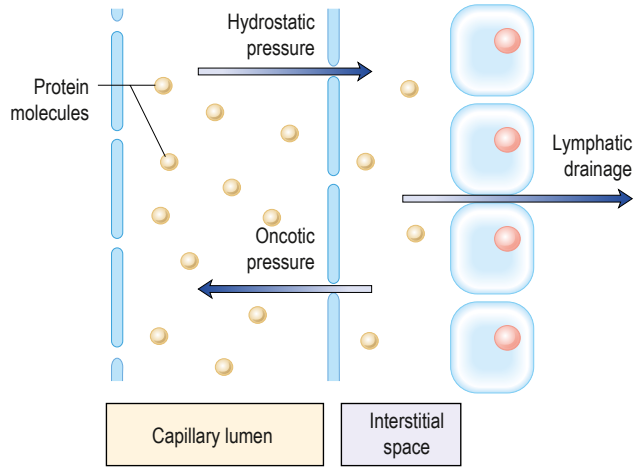

Fig. 27.4 Distribution of water between the vascular and extravascular (interstitial) spaces. This is determined by the equilibrium between hydrostatic pressure, which tends to force fluid out of the capillaries, and oncotic pressure, which acts to retain fluid within the vessel. The net flow of fluid outwards is balanced by 'suction' of fluid into the lymphatics, which returns it to the bloodstream. Similar principles govern the volume of the peritoneal and pleural spaces.

- intracellular fluid (28 L, about 35% of lean body weight) extracellular—the interstitial fluid that bathes the cells (9.4 L, about 12%)
- plasma (also extracellular) (4.6 L, about 4%–5%).

In addition, small amounts of water are contained in bone, dense connective tissue, and epithelial secretions, such as the digestive secretions and cerebrospinal fluid (CSF).

The intracellular and interstitial fluids are separated by the cell membrane; the interstitial fluid and plasma are separated by the capillary wall (Fig. 27.4). In the absence of solute, water molecules move randomly and in equal numbers in either direction across a semipermeable membrane. However, if solutes are added to one side of the membrane, intermolecular cohesive forces reduce the kinetic activity of the water molecules. As a result, water tends to stay in the solute-containing compartment because there is less free diffusion across the membrane. This ability to 'hold' water in the compartment can be measured as the osmotic pressure.

Osmotic pressure

Osmotic pressure is the primary determinant of the distribution of water among the three major compartments. The concentrations of the major solutes in the compartments differ, each having one solute that is primarily limited to that compartment and therefore determines its osmotic pressure:

- The ***intracellular fluid*** contains mainly potassium (K^+) (most intracellular Mg^{2+} is bound to proteins and therefore osmotically inactive).
- In the extracellular compartment, Na^+ salts predominate in the ***interstitial fluid***, along with proteins in the plasma.

Regulation of plasma volume is somewhat more complicated because of the tendency of the plasma proteins to hold water in the vascular space by an oncotic effect that is partly counterbalanced by the hydrostatic pressure in the capillaries that is generated by cardiac contraction (see Fig. 27.4). The composition of intracellular and extracellular fluids is shown in Box 27.3.

Osmotically active solutes cannot freely leave their compartment. The capillary wall, for example, is relatively impermeable to plasma proteins, and the cell membrane is 'impermeable' to Na^+ and K^+ because the Na^+/K^+-adenosine triphosphatase (ATPase) pump largely restricts Na^+ to the extracellular fluid and K^+ to the intracellular fluid. By contrast, Na^+ freely crosses the capillary wall and achieves similar concentrations in the interstitium and plasma; as a result, it does not contribute to fluid distribution between these compartments. Similarly, urea crosses both the capillary wall and the cell membrane, and is osmotically inactive. Thus, the retention of urea in kidney failure does not alter the distribution of the total body water.

Box 27.3 Electrolyte composition of intracellular and extracellular fluids (mmol/L)

	Plasma	Interstitial fluid	Intracellular fluid
Na^+	142	144	10
K^+	4	4	160
Ca^{2+}	2.5	2.5	1.5
Mg^{2+}	1.0	0.5	13
Cl^-	102	114	2
HCO_3^-	26	30	8
PO_4^{2-}	1.0	1.0	57
SO_4^{2-}	0.5	0.5	10
Organic acid	3	4	3
Protein	16	0	55

Body Na^+ stores are the primary determinant of extracellular fluid volume. Specialist imaging techniques (sodium magnetic resonance imaging, Na-MRI) have shown that remarkable amounts of Na are stored in the muscle, bones, and skin of hypertensive patients with hyperaldosteronism who are in effect chronic salt retainers.

Thus, the extracellular volume—and therefore tissue perfusion—are maintained by appropriate alterations in Na^+ excretion. For example, if Na^+ intake is increased, extra Na^+ will initially be added to the extracellular fluid. The associated increase in extracellular osmolality will cause water to move out of the cells, leading to extracellular volume expansion. Balance is restored by excretion of the excess Na^+ in the urine.

Regulation of extracellular volume

The extracellular volume is determined by the total body sodium content, which is closely controlled by the kidneys (Fig. 27.5). Plasma fluid (4.6 L in a 70 kg male) constitutes one-third of extracellular volume; of this, 85% (3.9 L) lies in the venous circulation, and only 15% (0.7 L) resides in the arteries.

The fullness of the arterial vascular compartment (***effective arterial blood volume***, EABV) is the primary determinant of renal sodium and water excretion: that is, the ***effective circulatory volume*** for the purposes of body fluid homeostasis.

The fullness of the arterial compartment depends on a relationship between cardiac output and peripheral arterial resistance. Thus, diminished EABV may occur when there is a fall in cardiac output or a fall in peripheral arterial resistance (an increase in the holding capacity of the arterial vascular tree). When the EABV is expanded, urinary Na^+ excretion is increased and can exceed 100 mmol/L. By contrast, the urine can be rendered virtually free of Na^+ in the presence of EABV depletion and normal kidney function.

These changes in Na^+ excretion can result from alterations both in the filtered load, determined primarily by the glomerular filtration rate (GFR), and in tubular reabsorption, which is affected by multiple factors. In general, changes in tubular reabsorption constitute the

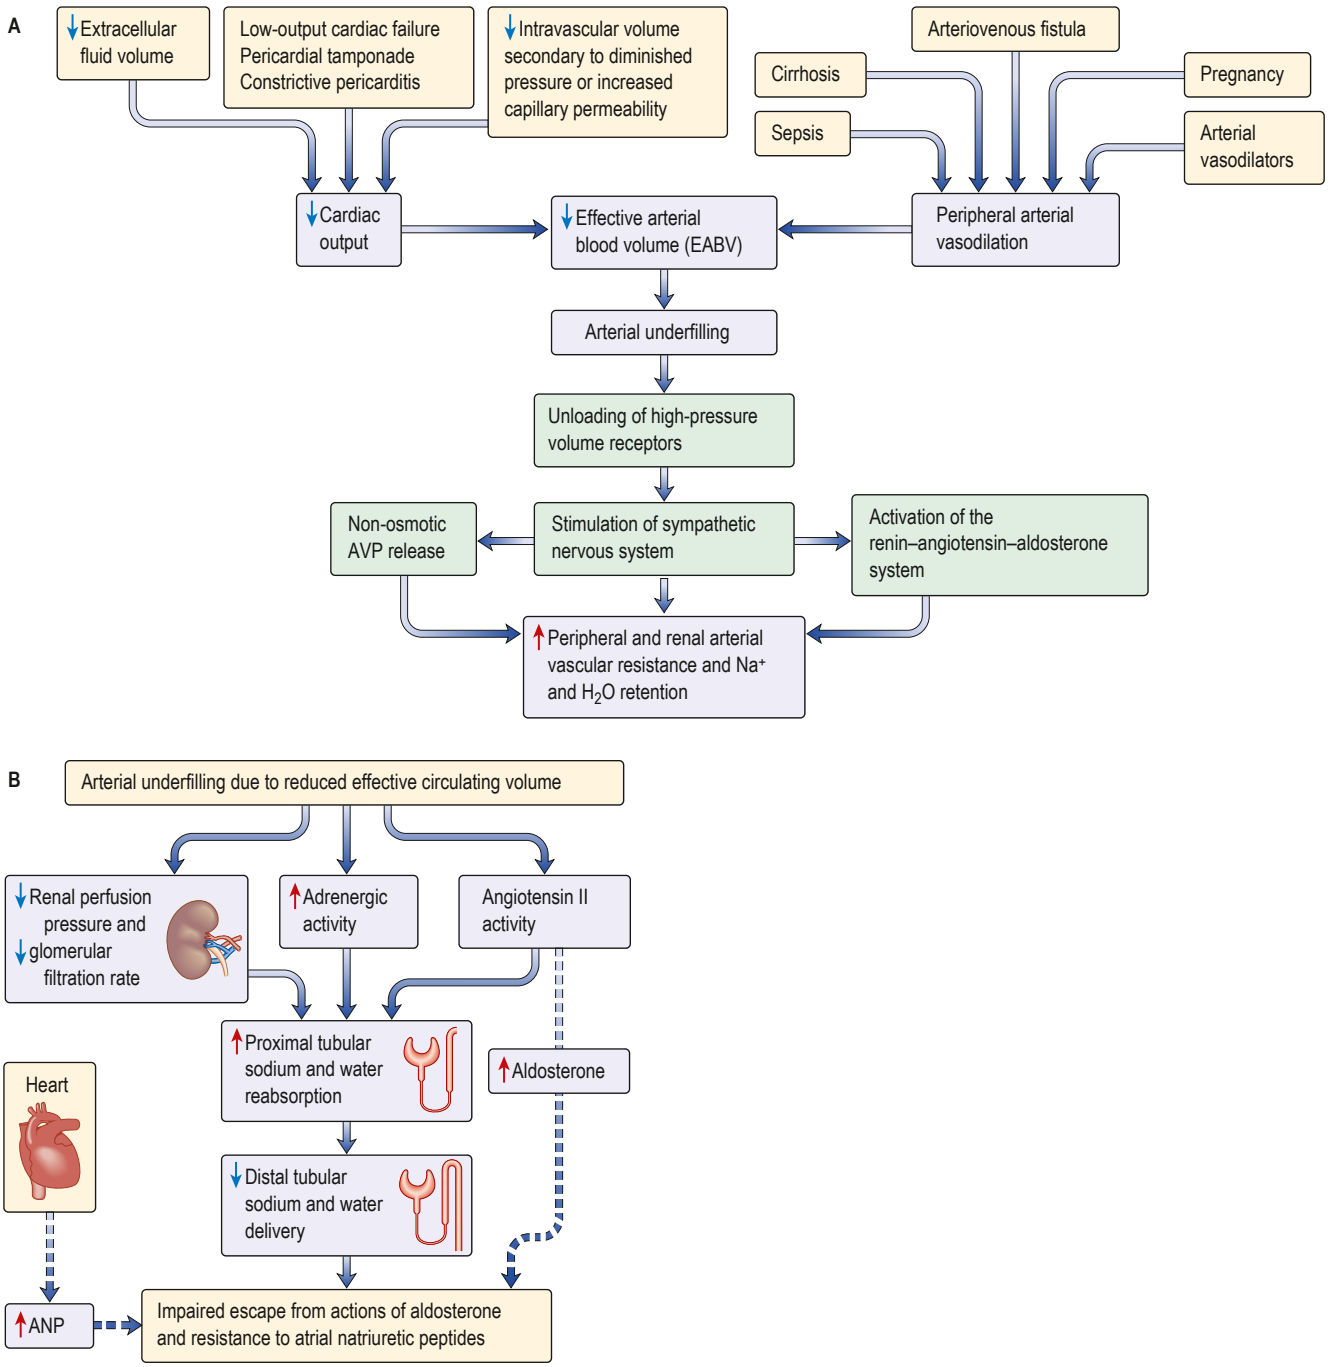

Fig. 27.5 Regulation of extracellular volume. **(A)** Sequence of events in which a decrease in cardiac output or peripheral arterial dilation initiates renal sodium and water retention. **(B)** Mechanism of impaired escape from the actions of aldosterone and resistance to atrial natriuretic peptides (ANP). *AVP,* Arginine vasopressin. *(Modified with permission from Schrier RW.* Renal and Electrolyte Disorders, *7th edn. Philadelphia: Lippincott Williams & Wilkins, 2010.)*

main adaptive response to fluctuations in the effective circulating volume. How this occurs can be appreciated from **Box 27.4** and **Fig. 27.6**, which describe the sites and determinants of segmental Na^+ reabsorption. Although the loop of Henle and distal tubules make a major overall contribution to net Na^+ handling, transport in these segments primarily varies with the amount of Na^+ delivered; that is, reabsorption is flow-dependent. In comparison, the neurohumoral regulation of Na^+ reabsorption according to body needs occurs primarily in the proximal tubules and collecting ducts. Diseases associated with malfunction of each section of the tubule are shown in **Box 27.5**.

Neurohumoral regulation of extracellular volume

This is mediated by volume receptors that sense changes in the EABV rather than alterations in the sodium concentration. These receptors are distributed in both kidney and cardiovascular tissues.

- ***Intrarenal receptors.*** Receptors in the walls of the afferent glomerular arterioles respond, via the juxtaglomerular apparatus, to changes in kidney perfusion, and control the activity of the renin–angiotensin–aldosterone system (see Chapter 26). In addition, sodium concentration in the distal tubule and sympathetic nerve activity alter renin release from the juxtaglomerular cells.

Box 27.4 Mechanisms of sodium transport in the various nephron segments

	Filtered Na reabsorbed (%)	Major mechanisms of luminal Na^+ entry	Major factors regulating transport
Proximal tubule	60–70	Na^+–H^+ exchange and co-transport of Na^+ with glucose, phosphate and other organic solutes	Angiotensin II Noradrenaline (norepinephrine)
Loop of Henle	20–25	Na^+–K^+–$2Cl^-$ co-transport	Flow Pressure natriuresis mediated by nitric oxide
Distal tubule	5	Na^+–Cl^- co-transport	Flow
Collecting ducts	4	Na^+ channels	Aldosterone Atrial natriuretic peptide

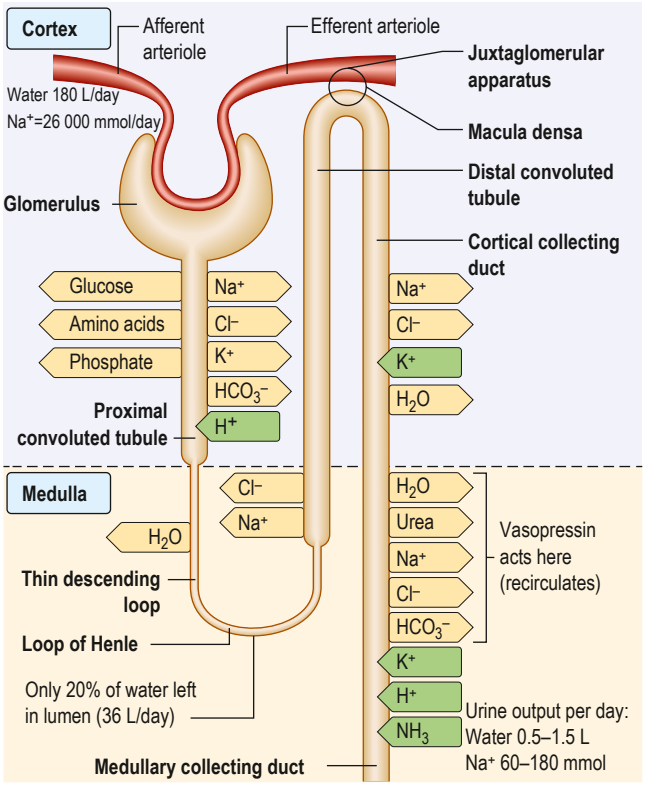

Fig. 27.6 The nephron—electrolyte and water exchange. Some 180 L of water and 26 000 mmol of sodium/day enter the nephrons via the afferent arterioles to the kidneys. Removal or addition of electrolytes results in the excretion of approximately 1 L of water and 60 to 180 mmol of sodium/day.

Prostaglandins I_2 and E_2 are generated within the kidney in response to angiotensin II, acting to maintain GFR and sodium and water excretion, and modulating the sodium-retaining effect of this hormone.

- ***Extrarenal receptors.*** These are located in the vascular tree in the left atrium and major thoracic veins, and in the carotid sinus body and aortic arch. These volume receptors respond to a slight reduction in effective circulating volume, which results in increased sympathetic nerve activity and a rise in catecholamines. In addition, volume receptors in the cardiac atria control the release of a powerful natriuretic hormone—atrial natriuretic peptide (ANP)—from granules located in the atrial walls (see Chapter 17).

High-pressure arterial receptors (carotid, aortic arch, juxtaglomerular apparatus) predominate over low-pressure volume receptors in volume control in mammals.

Aldosterone and ANP are responsible for day-to-day variations in Na^+ excretion, through their respective ability to augment and diminish Na^+ reabsorption in the collecting ducts.

- A ***salt load***, for example, leads to an increase in the effective circulatory and extracellular volume, raising both kidney perfusion pressure, and atrial and arterial filling pressure. The increase in the kidney perfusion pressure reduces the secretion of renin, and subsequently that of angiotensin II and aldosterone, whereas the rise in atrial and arterial filling pressure increases the release of ANP. ANP secretion also directly inhibits renin release. These factors combine to reduce Na^+ reabsorption in the collecting duct, thereby promoting excretion of excess Na^+.

Box 27.5 Major functions of each section of the tubule and associated diseases

Site	Function	Diseases associated with this section of nephron
Proximal convoluted tubule (PCT)	Early PCT: Solute reabsorption: glucose, amino acids, bicarbonate, phosphate, low-molecular-weight proteins Late PCT: Urate secretion/absorption Straight PCT: Secretion of drugs (loop and thiazide diuretics) and drug metabolites	Fanconi's syndrome: failure to reabsorb solutes and low-molecular-weight proteins. Leads to glycosuria, phosphaturia, aminoaciduria, and low-molecular-weight proteinuria. May be caused by drugs, myeloma, Wilson's disease and rare genetic diseases Type 2 renal tubular acidosis
Loop of Henle	Site of counter-current multiplier to hyper-concentrate the medullary interstitium, enabling control of final urine concentration	Bartter's syndrome
Distal convoluted tubule	Involvement in sodium and chloride transport, and calcium and magnesium reabsorption	Gitelman's syndrome Gordon's syndrome
Collecting ducts	Na^+ and water reabsorption Secretion of potassium Secretion of bicarbonate or H^+	Liddle's syndrome Pseudohypoaldosteronism type 1 AVP-resistance: resistance to actions of vasopressin. Leads to large volume of dilute urine with polyuria/polydipsia Syndrome of inappropriate antidiuretic hormone secretion (SIADH) Type 1 renal tubular acidosis

- By contrast, in patients with a ***low Na+*** intake or in those who become volume-depleted as a result of vomiting or diarrhoea, the ensuing decrease in effective volume enhances the activity of the renin–angiotensin–aldosterone system and reduces the secretion of ANP. The net effect is enhanced Na^+ reabsorption in the collecting ducts, leading to a fall in Na^+ excretion. This increases the extracellular volume towards normal.

With ***more marked hypovolaemia***, a decrease in GFR leads to an increase in proximal and thin ascending limb Na^+ reabsorption, which contributes to Na^+ retention. This is brought about by enhanced sympathetic activity acting directly on the kidneys and indirectly by stimulating the secretion of renin/angiotensin II (see **Fig. 27.5B**) and non-osmotic release of arginine vasopressin (AVP), also called vasopressin.

The regulation of salt excretion in response to rises or falls in vascular pressure acts to defend the body against changes in the effective circulating volume. Marked persistent hypovolaemia leads to systemic hypotension and increased salt and water absorption in the proximal tubules and ascending limb of Henle. This process is partly mediated by changes in interstitial hydrostatic pressure and local prostaglandin and nitric oxide production. These mechanisms are not always effective, and recurrent episodes of hypovolaemia may, over time, lead to chronic kidney disease (CKD), such as in the recently described syndrome Mesoamerican nephropathy, where recurrent episodes of heat-stress in agricultural workers along the Pacific coast in Central America is thought to be a cause.

Increased extracellular volume

Sodium and water are retained despite increased extracellular volume in oedematous conditions such as cardiac failure, hepatic cirrhosis, and hypoalbuminaemia.

Aetiology

In any condition where patients become oedematous, a key principle in explaining salt and water retention is the concept of 'arterial underfilling'. This may be due either to reduced cardiac output or diminished peripheral arterial resistance. Arterial underfilling in these settings leads to reduction of pressure or stretch (i.e., 'unloading' of arterial volume receptors), which results in activation of the sympathetic nervous system and the renin–angiotensin–aldosterone system, and non-osmotic release of AVP. These neurohumoral mediators promote salt and water retention in the face of increased extracellular volume (see **Fig. 27.5A**), a condition often described as 'secondary hyperaldosteronism'.

The mechanism for 'arterial underfilling' and subsequent sodium retention varies between different disease states:

- In ***heart failure***, reduction in cardiac output and the consequent fall in effective circulatory volume and arterial filling lead to sustained activation of the renin–angiotensin–aldosterone system, non-osmotic release of AVP, and increased activity of the renal sympathetic nerves via volume receptors and baroreceptors (see **Fig. 27.5B**).
- In ***hepatic cirrhosis***, the mechanism is complex, but involves peripheral vasodilation, due to increased nitric oxide generation from nitrogenous dietary substances, which are not effectively metabolized by the failing liver, resulting in reduced EABV and arterial filling. This leads to an activation of a chain of events that are common also to other conditions with marked peripheral vasodilation and heart failure (see **Fig. 27.5**).
- In ***nephrotic syndrome***, relative arterial underfilling was traditionally explained by loss of plasma protein in urine, causing loss of intravascular fluid into the interstitium. However, various animal and human studies have shown that the transcapillary oncotic gradient remains unchanged in nephrotic syndrome and movement of fluid from the vascular into the interstitial space is not explained by alterations in the transcapillary hydrostatic pressure gradient. Instead, the mechanism for oedema seen in nephrotic syndrome is increased capillary wall permeability (or 'hydraulic conductivity') caused by incompletely understood mechanisms affecting intercellular junctional complexes.

As well as relative arterial underfilling causing secondary hyperaldosteronism, nephrotic syndrome is also characterized by functional abnormalities in the kidney itself: in the cortical collecting duct, Na^+/K^+-ATPase expression and activity is increased threefold along the basolateral surface of cells (see **Fig. 27.6**), and activity of the amiloride-sensitive epithelial sodium channel (ENaC) activity is also increased.

- In ***protein-losing enteropathy***, uncompensated loss of plasma proteins in the intestine causes non-selective hypoproteinaemia (with reduced albumin and immunoglobulin levels) and loss of plasma oncotic pressure. Patients present with oedema, nutritional deficiencies, infections, and gastrointestinal symptoms including vomiting, diarrhoea, steatorrhea, and abdominal pain. The condition may be confirmed by the presence of elevated α1-antitrypsin levels in the stool. Underlying causes of intestinal protein loss including conditions which damage the intestinal mucosa (inflammatory, infective, malignancy) or block gastrointestinal lymphatic flow (through obstruction and lymphangiectasia).

The mechanism for patients becoming oedematous in each of these conditions relates to sodium delivery to the distal tubule:

- A combination of alpha-adrenergic stimulation, elevated angiotensin II, reduced kidney perfusion, and reduced GFR results in avid sodium absorption from the proximal tubules.
- Sodium delivery to the distal portion of the nephron is correspondingly reduced, so that under the influence of aldosterone, there is significant sodium reabsorption in the collecting duct.
- Patients continue to retain sodium in the face of expanded extracellular volume and become progressively oedematous (see **Fig. 27.5B**). They often display a substantial natriuresis when given spironolactone, which blocks aldosterone receptors.

Primary hyperaldosteronism and 'escape' from hypervolaemia

The physiology of secondary hyperaldosteronism described above differs somewhat from primary hyperaldosteronism, which is caused by intrinsic oversecretion of aldosterone, typically by an adrenal adenoma (see Chapter 34, 'Primary hyperaldosteronism' section). In such individuals, high doses of mineralocorticoids initially cause renal sodium retention so that the extracellular volume is increased by 1.5 to 2 L. However, renal sodium retention then ceases, sodium balance is re-established, and there is no detectable oedema. This 'escape' from mineralocorticoid-mediated sodium retention explains why oedema is not a characteristic feature of primary hyperaldosteronism. The escape is dependent on an increased delivery of sodium to the site of action of aldosterone in the collecting ducts, where aldosterone-dependent sodium reabsorption is overwhelmed and sodium excretion continues and sodium is not progressively retained. The increased distal sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in kidney perfusion pressure and GFR.

Other causes of sodium retention

Numerous drugs and various other physiological states can cause renal sodium retention, particularly in patients whose kidney function is already impaired. Typically the degree of oedema is more modest than in heart failure, cirrhosis, and nephrotic syndrome.

- ***Oestrogens*** cause mild sodium retention, due to a weak aldosterone-like effect. This is the reason for weight gain in females in the premenstrual phase.
- ***Mineralocorticoids and liquorice*** (the latter potentiating the sodium-retaining action of cortisol) have aldosterone-like actions.
- ***Non-steroidal anti-inflammatory drugs (NSAIDs)*** cause sodium retention in the presence of activation of the renin–angiotensin–aldosterone system.
- ***Thiazolidinediones*** have been associated with salt and water retention and are contraindicated in patients with heart failure. (By contrast, newer antidiabetic agents e.g., sodium–glucose co-transporter-2 inhibitors [Chapter 35, 'Sodium-glucose transporter 2 inhibitors ('flozins')' section] have established beneficial effects in patients with diabetes and heart failure.)
- Initiation of ***insulin*** treatment for type 1 diabetes, and ***re-feeding after malnutrition*** are both associated with the development of transient oedema. The mechanism is complex but involves up-regulation of ENaC in the principal cell of the collecting duct.
- ***A decreased GFR*** decreases the kidney's capacity to excrete sodium. This may be acute, as in the acute nephritic syndrome (see Chapter 26), or may occur as part of the presentation of CKD. In ***end-stage kidney failure***, extracellular volume is controlled by the balance between salt intake and its removal by dialysis.
- ***Idiopathic oedema*** sometimes occurs where there is no evidence of heart, liver, kidney, or endocrine disease. Females are more affected than males, and the condition may be caused by alterations in effective circulating volume related to posture, with sodium excretion reduced during the day and increased at night.
- Oedema is also caused by raised interstitial oncotic pressure as a result of increased capillary permeability to proteins. This can occur as part of a rare complement-deficiency syndrome; with therapeutic use of interleukin 2 in cancer chemotherapy; or in ovarian hyperstimulation syndrome.

Localized oedema

This does not reflect disturbances of extracellular volume control *per se* or relates to impaired local venous or lymphatic drainage. Examples include:

- ***lymphoedema*** affecting any part of the body where lymphatic drainage is impaired, for example, in the upper limb after surgical dissection of axillary lymph nodes during treatment for breast cancer
- ***post-thrombotic syndrome***, where venous drainage is chronically impaired following deep vein thrombosis (see Chapter 40, 'Post-thrombotic syndrome' section)
- facial oedema due to ***superior vena caval obstruction***.

Clinical features

Peripheral oedema is caused by expansion of the extracellular volume by at least 2 L (15%). The ankles are normally the first part of the body to be affected. Oedema may be noted in the face, particularly in the morning, or if the patient is in bed, oedema may accumulate in the sacral area. Expansion of the interstitial volume also causes pulmonary oedema, pleural effusions, pericardial effusion, and ascites. Substantial amounts of sodium and water may accumulate in the body without clinically obvious oedema or evidence of raised venous pressure. In particular, several litres may accumulate in the pleural space or as ascites; these spaces are then referred to as 'third spaces'.

Expansion of the blood volume causes a raised jugular venous pressure, cardiomegaly, added heart sounds, and basal crackles. Blood pressure is often elevated, but may be normal or low depending on the cause of hypervolaemia: in heart failure and cirrhosis, there may be hypotension in the face of volume overload, caused by low cardiac output or reduced peripheral vascular resistance, respectively.

Management

The underlying cause should be treated where possible. Heart failure, for example, should be treated and offending drugs such as NSAIDs withdrawn.

Sodium restriction has only a limited role but is useful in patients who are resistant to diuretics. Sodium intake can be reduced to approximately 100 mmol (2 g) daily; reductions below this are often difficult to achieve without affecting the palatability of food.

The mainstay of treatment is the use of ***diuretic agents***, which increase sodium, chloride, and water excretion in the kidney (**Box 27.6**). These agents act by interfering with membrane ion pumps that are present on numerous cell types; they mostly achieve specificity for the kidney by being secreted into the proximal tubule, resulting in much higher concentrations in the tubular fluid than in other parts of the body.

Clinical use of diuretics

Loop diuretics

These potent diuretics are useful in the treatment of any cause of systemic extracellular volume overload. They stimulate excretion of both sodium chloride and water by blocking the sodium–potassium-2-chloride (NKCC2) channel in the thick ascending limb of Henle (**Fig. 27.7**) and are useful in stimulating water excretion in states of relative water overload. They also act by causing increased venous capacitance, resulting in rapid clinical improvement in patients with left ventricular failure, preceding the diuresis. Although generally well-tolerated, unwanted effects include:

- urate retention, causing gout
- hypokalaemia
- hypercalciuria leading to increased risk of calcium-based kidney stones
- hypomagnesaemia
- decreased glucose tolerance
- allergic tubulointerstitial nephritis and other allergic reactions
- myalgia—especially with high-dose bumetanide
- ototoxicity (due to an action on sodium pump activity in the inner ear)—particularly with high-dose furosemide
- interference with excretion of lithium, resulting in toxicity.

There is little to choose between the drugs in this class. Bumetanide has a better oral bioavailability than furosemide, particularly in patients with severe peripheral oedema, and has more beneficial effects than furosemide on venous capacitance in left ventricular failure.

Thiazide diuretics

Thiazide diuretics are less potent than loop diuretics. They act by blocking a sodium chloride channel in the ***distal convoluted tubule*** (producing an induced form of Gitelman's syndrome, which is associated with reduced function of this channel; see Chapter 26) (**Fig. 27.8**). They cause relatively more urate retention, glucose intolerance and hypokalaemia than loop diuretics. They interfere

Box 27.6 Types and clinical uses of diuretics

Class	Major action	Examples	Clinical uses	Potency
Loop diuretics	↓ Na^+–Cl^-–K^+ co-transport in thick ascending limb of loop of Henle	Furosemide Bumetanide Torasemide	Volume overload (heart failure, nephrotic syndrome, CKD)	+++
Thiazide and related diuretics	↓ Na^+–Cl co-transport in early distal convoluted tubule	Bendroflumethiazide Chlortalidone Metolazone Indapamide	Hypertension Volume overload ('sequential nephron blockade') Hypercalciuria	++
Potassium-sparing diuretics	↓ Na^+ reabsorption (in exchange for K^+) in collecting duct (principal cells)	Aldosterone antagonists, e.g., spironolactone, eplerenone, finerenone Others: amiloride, triamterene	Hyperaldosteronism (primary and secondary) Bartter's syndrome Heart failure Cirrhosis with fluid overload Prevention of K^+ deficiency in combination with loop or thiazide	+
Carbonic anhydrase inhibitors	↓ Na^+ HCO_3^- reabsorption in proximal collecting duct ↓ Aqueous humour and CSF formation	Acetazolamide	Seldom used for diuretic effects Glaucoma Idiopathic intracranial hypertension (see Chapter 28, 'Idiopathic intracranial hypertension' section)	±
Vasopressin/AVP receptor blockers (aquaretics)	Block V2 receptor in collecting ducts producing free water diuresis	Lixivaptan Tolvaptan Satavaptan i.v. conivaptan (also blocks V_{1A})	SIADH Polycystic kidney disease Heart failure	+

CKD, Chronic kidney disease; *SIADH,* syndrome of inappropriate antidiuretic hormone secretion.

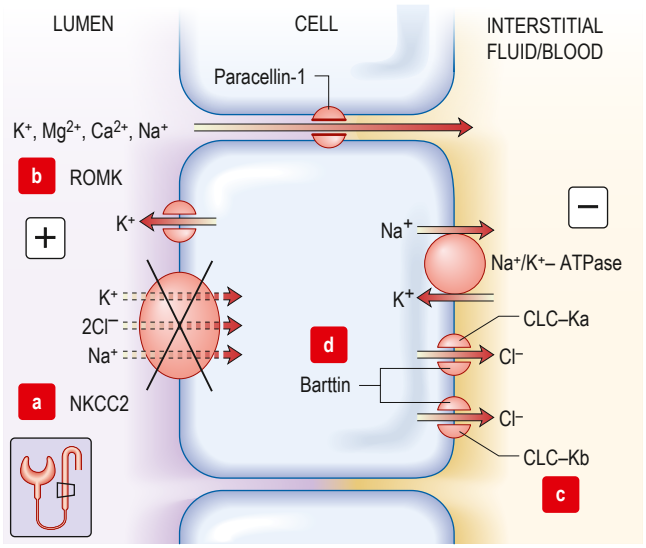

Fig. 27.7 Transport mechanisms in the thick ascending limb of the loop of Henle. Sodium chloride is reabsorbed in the thick ascending limb by the bumetanide-sensitive sodium–potassium-2–chloride co-transporter (NKCC2), which is the target of loop diuretics such as furosemide. The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na^+/K^+-ATPase and the kidney-specific basolateral chloride channel (CLC-Kb). The availability of luminal potassium is rate-limiting for NKCC2, and recycling of potassium through the ATP-regulated potassium channel (renal outer medulla K^+ channel, ROMK) ensures the efficient functioning of the NKCC2 and generates a lumen-positive transepithelial potential. Calcium and magnesium, along with potassium and sodium, are also absorbed paracellularly in the thick ascending loop. Bartter's syndrome: loss of function mutations for the different types of syndrome. **(a)** NKCC2 (type I). **(b)** ROMK (type II). **(c)** CLC-Kb (type III). **(d)** Barttin (type IV). In addition, type V may be caused by a gain-of-function mutation of the calcium-sensing receptor (not shown).

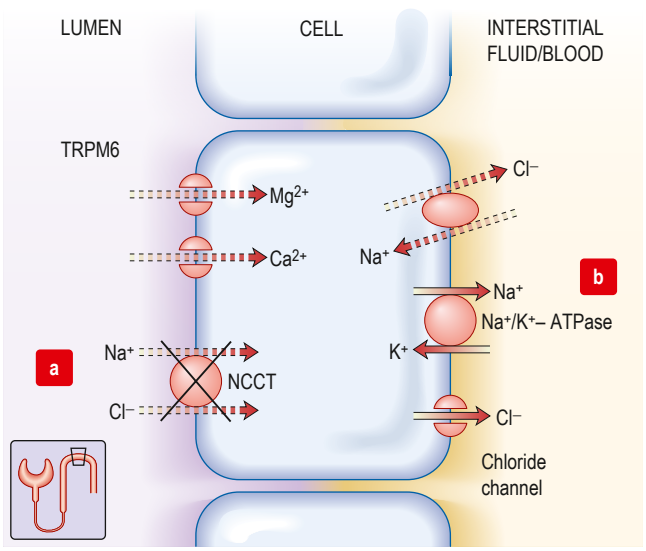

Fig. 27.8 Transport mechanisms in the distal convoluted tubule. **(a)** Sodium chloride is usually reabsorbed by the apical thiazide-sensitive sodium–chloride co-transporter (NCCT) in the distal convoluted tubule. **(b)** The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na^+/K^+-ATPase, and an undefined basolateral chloride channel. In this nephron segment, there is an apical calcium channel and a basolateral sodium-coupled exchanger. The mechanisms for the transport of magnesium are similar to those for calcium, involving TRPM6, a member of the transient receptor potential family. Mutation of NCCT leads to decreased reabsorption of sodium chloride and increased absorption of calcium (Gitelman's syndrome). Overactivity of NCCT leads to Gordon's syndrome.

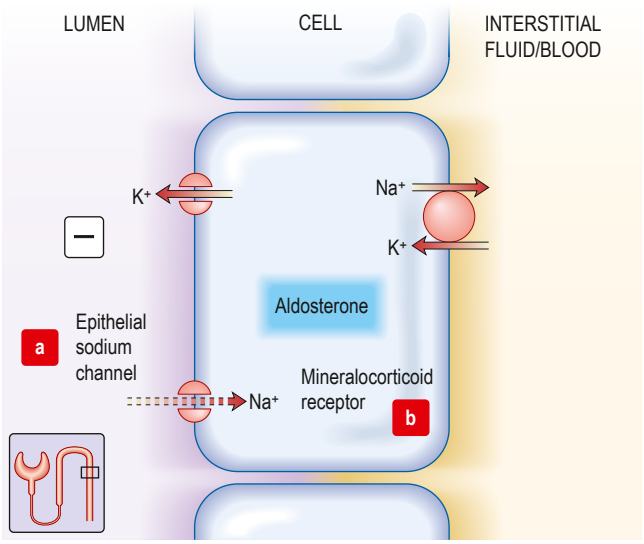

Fig. 27.9 Aldosterone-regulated transport in the cortical collecting ducts. Under normal conditions, the ENaC is the rate-limiting barrier for the normal entry of sodium from the lumen into the cell. The resulting lumen-negative transepithelial voltage (indicated by the minus sign) drives potassium secretion from the principal cells and proton secretion from the α-intercalated cells (see Fig. 27.15). **(a)** Site of action of amiloride and triamterene: mutation of the epithelial sodium channel gene (Liddle's syndrome) produces reabsorption of sodium and increased secretion of potassium (not shown). **(b)** Site of action of aldosterone antagonists: mutation of the gene encoding mineralocorticoid receptor leads to salt wasting and decreased secretion of potassium.

with water excretion and may cause hyponatraemia, particularly if combined with amiloride or triamterene. This effect is clinically useful in diabetes insipidus. Thiazides reduce peripheral vascular resistance by mechanisms that are not completely understood but do not appear to depend on their diuretic action, and are widely used in the treatment of hypertension. Thiazides reduce calcium excretion. This effect is useful in patients with idiopathic hypercalciuria but may cause hypercalcaemia. Numerous agents are available, with varying half-lives but little else to choose between them. Metolazone is not dependent for its action on glomerular filtration, and therefore retains its potency in kidney impairment.

Potassium-sparing diuretics

Potassium-sparing diuretics (Fig. 27.9) are unique among the class of diuretics in that (as their name suggests) they lead to hyperkalaemia rather than hypokalaemia. There are two types:

- ***Mineralocorticoid receptor antagonists (MRA).*** Mineralocorticoid receptors act as intracellular receptors and nuclear transcription factors. Following binding of ligands such as aldosterone the receptors interact with multiple different co-factors affecting gene transcription. They are present in the heart, kidney, bone marrow, and endothelium, and following activation have multiple effects including sodium reabsorption, potassium excretion, inflammation, and fibrosis. MRAs block the binding of aldosterone to the mineralocorticoid receptor. Two classes exist with different spectrums of biological activity:
  - Steroidal MRAs such as spironolactone and eplerenone have proven efficacy in reducing mortality in heart failure (in part by antagonizing the fibrotic effect of aldosterone on the heart). Eplerenone may be preferred because it is devoid of antiandrogenic or antiprogesterone properties.
  - Non-steroidal MRAs such as finerenone have recently been shown to slow the progression of kidney failure, lower proteinuria, and improve cardiovascular outcomes in patients with diabetes and CKD.
- ***Amiloride and triamterene***, which inhibit sodium uptake by blocking ENaC in the collecting duct and reduce renal potassium excretion by reducing lumen-negative transepithelial voltage. They may be used as potassium-sparing agents with thiazide or loop diuretics.

Carbonic anhydrase inhibitors

These are relatively weak diuretics and are seldom used, except in the treatment of glaucoma. They cause metabolic acidosis and hypokalaemia. Recent evidence suggests a role for acetazolamide in acute heart failure.

Sodium–glucose co-transporter 2 (SGLT2) inhibitors

These drugs, originally developed to provide glycaemic control in diabetes, have diuretic effects by blocking glucose and sodium reabsorption in the proximal tubule causing an osmotic diuresis and natriuresis, and by increasing sodium delivery to the juxtaglomerular apparatus, restoring normal tubule-glomerular feedback. Clinical trials have demonstrated significant cardiac and kidney protection and reduction in mortality in people with diabetes, heart failure, and CKD.

Resistance to diuretics

Resistance may occur as a result of:

- poor bioavailability
- reduced GFR, which may be due to decreased circulating volume despite oedema (e.g., nephrotic syndrome, cirrhosis with ascites) or intrinsic renal disease
- activation of sodium-retaining mechanisms, particularly aldosterone.

Intravenous administration of diuretics may be required to establish a diuresis, and high doses of loop diuretics are needed to achieve adequate concentrations in the tubule if GFR is depressed. However, the daily dose of furosemide must be limited to a maximum of 1.5 g for an adult because of ototoxicity. Intravenous albumin solutions are occasionally used to temporarily restore plasma oncotic pressure in the nephrotic syndrome and allow mobilization of oedema, but do not increase the natriuretic effect of loop diuretics.

Combinations of various classes of diuretics are extremely helpful in patients with resistant oedema, an approach referred to as ***'sequential nephron blockade'***. A loop diuretic plus a thiazide inhibit two major sites of sodium reabsorption; this effect may be further potentiated by addition of a potassium-sparing agent. Metolazone in combination with a loop diuretic is particularly useful in refractory congestive cardiac failure because its action is less dependent on glomerular filtration. However, this potent combination can cause severe electrolyte imbalance.

Effects on kidney function

All diuretics may increase plasma urea concentrations by increasing urea reabsorption in the medulla. In certain situations, diuretics also decrease GFR:

- Excessive diuresis causes volume depletion and pre-renal failure.
- Diuretics can cause allergic tubulointerstitial nephritis.
- Thiazides may directly cause a drop in GFR; the mechanism is complex and not fully understood.

Decreased extracellular volume

Deficiency of sodium and water causes shrinkage both of the interstitial space and of the blood volume, and may have profound effects on organ function.

Clinical features

Symptoms

Thirst, muscle cramps, nausea and vomiting, and postural dizziness occur. Severe depletion of circulating volume causes hypotension and impairs cerebral perfusion, causing confusion and eventual coma.

Signs

Signs can be divided into those due to loss of interstitial fluid and those due to loss of circulating volume.

- ***Loss of interstitial fluid*** leads to loss of skin elasticity ('turgor')—the rapidity with which the skin recoils to normal after being pinched. Skin turgor decreases with age, particularly at the peripheries making this test less useful in detecting fluid status. The turgor over the anterior triangle of the neck or on the forehead is less dependent on age and so may be more useful.
- ***Loss of circulating volume*** leads to decreased pressure in the venous and (if severe) arterial compartments.

Loss of up to 1 L of extracellular fluid in an adult may be compensated for by venoconstriction and may cause no physical signs. Loss of more than this amount causes the following:

- ***Postural hypotension.*** Normally, the blood pressure rises if a subject stands up, as a result of increased venous return due to venoconstriction (this maintains cerebral perfusion). Loss of extracellular fluid (underfill) prevents this and causes a fall in blood pressure. This is one of the earliest and most reliable signs of volume depletion, as long as the other causes of postural hypotension are excluded (**Box 27.7**).
- ***Low jugular venous pressure.*** In hypovolaemic patients, the jugular venous pulsation can be seen only with the patient lying completely flat, or even head down, because the right atrial pressure is lower than 5 cmH_2O.
- ***Peripheral venoconstriction.*** This causes cold skin with empty peripheral veins (which are difficult to cannulate just when the patient needs intravenous therapy the most.) This sign is often absent in sepsis, where peripheral vasodilation contributes to effective hypovolaemia.
- ***Tachycardia.*** This is not always a reliable sign. Beta-blockers and other antiarrhythmics may prevent tachycardia, and hypovolaemia may activate vagal mechanisms and actually cause bradycardia.

Aetiology

Salt and water may be lost from the kidneys, the gastrointestinal tract, or the skin (**Box 27.8**).

In addition, there are a number of situations where signs of volume depletion occur despite a normal or increased body content of sodium and water:

- Septicaemia causes vasodilation of both arterioles and veins, resulting in greatly increased capacitance of the vascular space and fall in peripheral venous resistance. In addition, increased capillary permeability to plasma proteins leads to loss of fluid from the vascular space to the interstitium.
- Diuretic treatment of heart failure or nephrotic syndrome may lead to rapid reduction in plasma volume. Mobilization of oedema may take much longer.
- There may be inappropriate diuretic treatment of oedema (e.g., when the cause is local rather than systemic), causing systemic hypovolaemia.

Investigations

Blood tests are, in general, not helpful in the assessment of extracellular volume. Plasma urea may be raised owing to increased urea reabsorption and, later, to pre-renal failure (when the creatinine rises as well), but this is very non-specific. Urinary sodium is low if the kidneys are functioning normally, but is misleading if the cause of the volume depletion involves the kidneys (e.g., diuretics, intrinsic kidney disease).

Assessment of volume status is shown in **Fig. 27.1** and **Boxes 27.1 and 27.2**.

Management

Distribution of different types of replacement fluid

Fig. 27.10 shows the relative effects on the compartments of the addition of identical volumes of water, saline, and colloid solutions. One litre of water given intravenously as 5% glucose (which is rapidly metabolized to generate energy, water, and carbon dioxide) is distributed equally into all compartments, whereas the same amount of 0.9% saline remains in the extracellular compartment. The latter

is thus the correct treatment for extracellular water depletion, with sodium keeping the water in this compartment. The addition of 1 L of a colloid solution (such as colloidal starch or gelatine) with its high oncotic pressure stays in the vascular compartment, and colloids were formerly commonly used in the treatment for hypovolaemia (although they are much less used now after studies did not demonstrate any clinical outcome benefits compared to crystalloid solutions such as saline).

Goals of fluid therapy

When prescribing intravenous fluid, the initial consideration should be the goal of therapy, which will be to guide the type, volume rate, and duration of fluid replacement, as well as clarify how response to therapy is assessed:

- ***Resuscitation fluids*** are required in the context of hypotension and critical illness. Typically boluses of crystalloid fluid are used and the blood pressure response assessed to determine whether further fluid is required (see Chapter 13).
- ***Replacement fluids*** are required when a disease state has led to losses of particular components of fluid, electrolytes, and other components of blood. The principles of fluid replacement are to estimate the likely total volume of losses, and to select a replacement fluid to replace what is missing (the composition of different types of replacement fluid is given in **Box 27.9**):
  - *Loss of whole blood* (haemorrhage) is treated by infusion of a combination of red cells and a plasma substitute, or (if unavailable) whole blood.
  - *Loss of plasma*, as occurs in burns or severe peritonitis, should be treated with human plasma or a plasma substitute.
  - *Loss of salt and water* (e.g., through vomiting, diarrhoea, or excessive diuresis) may be treated by oral salt and water administration (if mild) or intravenous crystalloid (if more severe). ***Normal saline*** contains large amounts of chloride, which can cause a normal anion-gap metabolic acidosis as well as renal vasoconstriction when administered in large quantities. Thus, the use of ***balanced crystalloids*** (Hartmann's solution or Plasma-Lyte) is generally preferred, especially in critically ill patients of those requiring large volumes of fluid; these solutions have been shown to result in a lower rate of the composite outcome of death from any cause, new renal-replacement therapy or persistent renal dysfunction than the use of saline.
  - *Loss of water alone* can occur in diabetes insipidus or in a patient who is unable to drink (e.g., after surgery). This causes extracellular volume depletion only in severe cases because the loss is spread evenly among all the compartments of body water. The correct treatment is to give large volumes of oral or nasogastric water. If intravenous treatment is required, water is given as 5% glucose with K^+ because pure water would lead to osmotic lysis of blood cells, although in severe hypernatraemia (see below), it is necessary to begin replacement with 0.9% saline to avoid correcting the osmolality too rapidly.
  - *Loss of other electrolytes* (e.g., potassium, magnesium, calcium) can be treated by oral supplementation, by addition of the relevant salts into bags of replacement intravenous fluids, or (if severe) by administration of concentrated electrolyte solutions (e.g., 10% calcium gluconate). Because of the risk of dysrhythmia, this is often done in a critical care unit with cardiac monitoring.
  - *Loss of H^+ or bicarbonate* resulting in alkalosis or acidosis, respectively, often resolves with treatment of the underlying condition. In advanced CKD, oral bicarbonate supplementation is often required to treat acidosis; occasionally intravenous bicarbonate if used in patients where profound gastrointestinal bicarbonate loss has caused a normal anion gap acidosis (see later in the chapter).
- Maintenance fluids are required in patients who are unable to drink, for instance those with upper gastrointestinal pathology

? Box 27.9 Assessment of volume status

Best achieved by simple clinical observations, which you should carry out yourself (see Fig. 27.1). Check:

- Jugular venous pressure
- Central venous pressure: both basal and after intravenous fluid challenge (see Chapter 13, 'Central venous pressure' section)
- Postural changes in blood pressure
- Chest X-ray
- Serial weights of the patient
- Urine output measurements at regular intervals

or who have been made 'nil by mouth' ahead of surgery. If all that is required is avoidance of fluid depletion, 1 to 2 L or a balanced crystalloid can be given over 24 hours, remembering that surgery is a stimulus to sodium and water retention and that over-replacement may be as dangerous as under-replacement.

Repeated clinical assessments are vital when large volumes of intravenous fluids are being administered. Severe hypovolaemia induces venoconstriction, which maintains venous return; over-rapid correction does not give time for this to reverse, resulting in signs of circulatory overload (e.g., pulmonary oedema), even if a total body extracellular fluid deficit remains. In less severe extracellular fluid depletion, fluid should be replaced at a rate of 1000 mL every 4 to 6 hours, with repeated clinical assessment.

DISORDERS OF SODIUM CONCENTRATION

These are generally best thought of as disorders of body water content. As discussed above, while total body sodium content is regulated by volume receptors; water content is adjusted to maintain a normal osmolality and (in the absence of abnormal osmotically active solutes) a normal sodium concentration. Disturbances of sodium concentration are caused by disturbances of water balance.

Regulation of water excretion

The chief mechanisms for regulating osmolality are thirst and the ability of the kidney to concentrate and dilute urine. Both mechanisms are principally controlled by intracellular osmoreceptors in the hypothalamus (and to some extent by volume receptors in capacitance vessels close to the heart, and via the renin–angiotensin system). Changes in the plasma Na^+ concentration and osmolality sensed by osmoreceptors influence both thirst sensation and the release of AVP (vasopressin) from the supraoptic and paraventricular nuclei of the anterior hypothalamus.

AVP plays a central role in urinary concentration by increasing the water permeability of the cortical and medullary collecting ducts. There are three major G-protein coupled receptors for vasopressin (AVP) which underlie its different physiological effects:

- ***V_{1A}*** found in vascular smooth muscle cells: activation induces vasoconstriction.
- ***V_{1B}*** found in the anterior pituitary and throughout the brain: this mediates the effect of AVP on the pituitary, leading to adrenocorticotrophic hormone (ACTH) release.
- ***V_2*** receptors in the principal cells of the kidney distal convoluting tubule and collecting ducts: these mediate the AVP response on urinary concentration.

The ability of AVP to increase the urine osmolality is first dependent on active transport of sodium in the ascending limb of the loop of Henle (which occurs constitutively and is not dependent on AVP). In the loop of Henle, active reabsorption of NaCl without water along with the counter-current multiplier has the effect of making the medullary interstitium highly concentrated, while also diluting the tubular fluid. The newly formed urine subsequently passes through this area of high osmolality as the distal collecting ducts flow through the medullary pyramids into the renal pelvis, so the large osmolar gradient between lumen and interstitium can be used to reabsorb water and concentrate the urine (Fig. 27.6).

Effect of AVP on the kidney

The cortical collecting duct has two cell types with very different functions:

- ***Principal cells*** (about 65%) have sodium and potassium channels in the apical membrane and, as in all sodium-reabsorbing cells, Na^+/K^+-ATPase pumps in the basolateral membrane. They are the primary targets of AVP (regulating osmolality), and also aldosterone (regulating extracellular volume).
- ***Intercalated cells*** play a role in hydrogen and bicarbonate handling and in potassium reabsorption and are not directly involved in sodium or water excretion.

AVP acts on V_2 (vasopressin) receptors located on the basolateral surface of principal cells, resulting in pre-formed cytoplasmic vesicles that contain unique water channels (called aquaporins) moving to, and then being inserted into, the luminal membrane. The water channels span the luminal membrane and permit water movement out of urine into the cells down a favourable osmotic gradient (Fig. 27.11). This water is then rapidly returned to the systemic circulation across the basolateral membrane. When the AVP effect has worn off, the water channels are removed from the luminal membrane by endocytosis and returned to the cytoplasm.

The effect is that in the absence of AVP, the collecting ducts are relatively impermeable to water and little is reabsorbed, resulting in dilute urine being excreted in the context of low plasma osmolality.

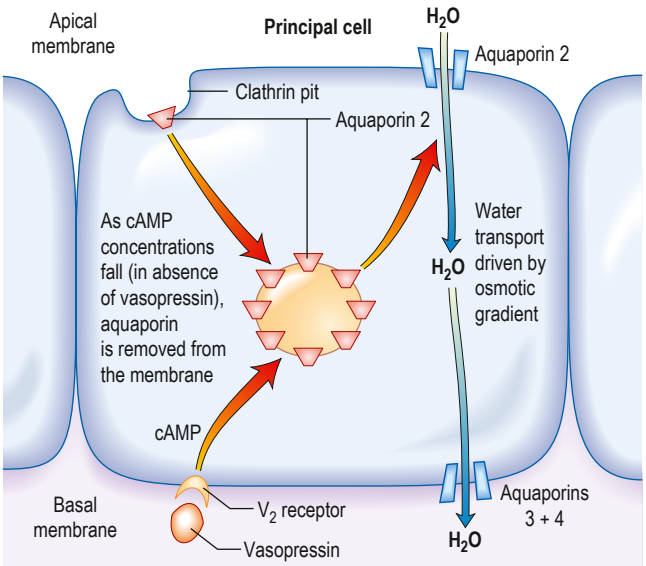

Fig. 27.11 Aquaporin-mediated water transport in the collecting duct. Stimulation of the vasopressin 2 receptor causes cyclic adenosine monophosphate (cAMP)-mediated insertion of the aquaporin into the apical membrane, allowing water transport down the osmotic gradient. *(Adapted from Connolly DL, Shanahan CM, Weissberg PL. Water channels in health and disease.* Lancet *1996; 347:211, with permission from Elsevier.)*

By contrast, the presence of AVP significantly increases the permeability of the collecting duct tubular cells when plasma osmolality is high, promoting water reabsorption down the favourable osmotic gradient. As a result, water is retained in the body, and a small volume of highly concentrated urine is passed.

Plasma osmolality and AVP release

The rate of AVP secretion is directly affected by plasma osmolality. At a plasma osmolality of <275 mosmol/kg (which usually represents a plasma Na^+ concentration of <135–137 mmol/L), there is essentially no circulating AVP. As the plasma osmolality rises above this threshold, the secretion of AVP increases progressively.

Two simple examples will illustrate the basic mechanisms of osmoregulation, which is so efficient that the plasma Na^+ concentration is normally maintained within 1% to 2% of its baseline value.

- ***Ingestion of a water load*** leads to an initial reduction in the plasma osmolality, thereby diminishing the release of AVP. The ensuing reduction in water reabsorption in the collecting ducts allows the excess water to be excreted in a dilute urine. This process is normally so efficient that volume regulation is not affected and there is no change in ANP release or in the activity of the renin–angiotensin–aldosterone system. Thus, a dilute urine is excreted and there is little alteration in the excretion of Na^+.
- ***Administration of both water and sodium*** (e.g., by giving intravenous 0.9% saline), by contrast, causes an increase in volume but no change in plasma osmolality. In this setting, ANP secretion is increased, aldosterone secretion is reduced, and AVP secretion does not change. The net effect is the appropriate excretion of the excess Na^+ in a relatively isoosmotic urine.

By contrast, ***water loss*** resulting from sweating is followed by a rise in both plasma osmolality and AVP secretion, causing water reabsorption in the collecting duct and the (appropriate) excretion of a small volume of concentrated urine. This renal effect of AVP minimizes further water loss but does not replace the existing water deficit; this is accomplished by the stimulation of thirst. The importance of thirst is illustrated by studies in patients with central diabetes insipidus, who are deficient in AVP. These patients often complain of marked polyuria, which is caused by an inability to appropriately reabsorb water in the collecting ducts. However, they do not typically become hypernatraemic because urinary water loss is offset by the thirst mechanism.

Clinical disorders of osmoregulation

Diabetes insipidus (see also Chapter 34, 'Diabetes insipidus' section) describes a failure in the mechanism of urinary concentration relating to AVP deficiency or resistance. Patients experience excessive polyuria and thirst, and are prone to becoming profoundly dehydrated and hyperosmolar if their access to water is restricted. There are two forms:

- ***AVP-deficiency (also referred to as 'cranial diabetes insipidus')*** occurs when AVP secretion is impaired. It usually occurs in the context of injury to the hypothalamus or pituitary, for example, after skull base neurosurgery. AVP-deficiency can be treated using desmopressin, a synthetic analogue of AVP (see Chapter 34, 'The thirst axis' section).
- ***AVP-resistance (also referred to as 'nephrogenic diabetes insipidus')*** occurs where the cortical tubular cells are resistant to the effects of AVP. The commonest cause is long-term lithium treatment for bipolar affective disorder.

? Box 27.10 Causes of hyponatraemia with decreased extracellular volume (hypovolaemia)

Extrarenal (urinary sodium <20 mmol/L)
- Vomiting
- Diarrhoea
- Haemorrhage
- Burns
- Pancreatitis

Kidney (urinary sodium >20 mmol/L)
- Diuretics
- Osmotic diuresis (e.g., hyperglycaemia, severe uraemia)
- Adrenocortical insufficiency
- Tubulointerstitial renal disease
- Recovery phase of acute tubular necrosis

By contrast, in the ***syndrome of inappropriate diuresis*** (***SIAD***, see also Chapter 34, 'Syndrome of inappropriate antidiuresis [SIAD]' section), there is impaired water excretion and dilutional hyponatraemia caused by the persistent presence of AVP. Correction of the hyponatraemia in this setting initially requires restriction of water intake.

AVP is also secreted by non-osmotic stimuli such as stress (e.g., surgery, trauma), markedly reduced effective circulatory volume (e.g., cardiac failure, hepatic cirrhosis), psychiatric disturbance, and nausea, irrespective of plasma osmolality. This is mediated by the effects of sympathetic overactivity on supraoptic and paraventricular nuclei. In addition to water retention, AVP release in these conditions promotes vasoconstriction owing to the activation of V_{1A} (vasopressin) receptors distributed in the vascular smooth muscle cells.

Hyponatraemia

Hyponatraemia (Na <135 mmol/L) is the most common biochemical abnormality in hospitalized patients, with up to 35% of inpatients developing hyponatraemia during their stay. There is often an associated disorder of extracellular volume, so that a clinical approach to hyponatraemia begins with establishing whether a patient has:

- hyponatraemia with hypovolaemia
- hyponatraemia with euvolaemia
- hyponatraemia with hypervolaemia.

Rarely, hyponatraemia may be a 'pseudo-hyponatraemia'. This occurs in hyperlipidaemia (either high cholesterol or high triglyceride) or hyperproteinaemia where there is a spuriously low measured sodium concentration, the sodium being confined to the aqueous phase but having its concentration expressed in terms of the total volume of plasma. In this situation, plasma osmolality is normal and therefore treatment of 'hyponatraemia' is unnecessary. Note that artefactual 'hyponatraemia', caused by taking blood from the limb into which fluid of low sodium concentration is being infused, should be excluded.

Hyponatraemia with hypovolaemia

This is due to salt loss in excess of water loss; the causes are listed in **Box 27.10**. In this situation, AVP secretion is initially suppressed (via the hypothalamic osmoreceptors) but, as fluid volume is lost, volume receptors override the osmoreceptors and stimulate both thirst and the release of AVP. This is an attempt by the body to defend circulating volume at the expense of osmolality.

With extrarenal losses and normal kidneys, the urinary excretion of sodium falls in response to the volume depletion, as does water

Box 27.11 Average concentrations and potential daily losses of water and electrolytes from the gut

	Na^+ (mmol/L)	K^+ (mmol/L)	Cl^- (mmol/L)	Volume (mL in 24 h)
Stomach	50	10	110	2500
Small intestine recent ileostomy	120	5	110	1500
Small intestine adapted ileostomy	50	4	25	500
Bile	140	5	105	500
Pancreatic juice	140	5	60	2000
Diarrhoea	130	10–30	95	1000–2000+

Box 27.12 Causes of hyponatraemia with normal extracellular volume (euvolaemia)

Abnormal arginine vasopressin (AVP) release
- Vagal neuropathy (failure of inhibition of AVP release)
- Deficiency of adrenocorticotrophic hormone (ACTH) or glucocorticoids (Addison's disease)
- Hypothyroidism
- Severe potassium depletion

Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
- See **Box 34.52**

Psychiatric illness
- 'Psychogenic polydipsia'
- Antidepressant therapy

Increased sensitivity to AVP
- Chlorpropamide
- Tolbutamide

AVP-like substances
- Oxytocin
- Desmopressin

Unmeasured osmotically active substances stimulating osmotic AVP release
- Glucose
- Chronic alcohol misuse
- Mannitol
- Sick-cell syndrome (leakage of intracellular ions)

excretion, leading to concentrated urine containing <10 mmol/L of sodium. However, in salt-wasting kidney disease, compensation cannot occur and the only physiological protection is increased water intake in response to thirst.

Clinical features

With sodium depletion, the clinical picture is usually dominated by features of volume depletion (see 'Decreased extracellular volume' section). The diagnosis is usually obvious where there is a history of gut losses, diabetes mellitus with significant hyperglycaemia causing osmotic diuresis, or diuretic abuse. Examination of the patient is often more helpful than the biochemical investigations, which include plasma and urine electrolytes and osmolality.

Box 27.11 shows the potential daily losses of water and electrolytes from the gut. Losses due to kidney or adrenocortical disease may be less easily identified but a urinary sodium concentration of >20 mmol/L, in the presence of clinically evident volume depletion, suggests a renal loss.

Management

This is directed at the primary cause whenever possible.

In a healthy patient:
- Give oral electrolyte–glucose mixtures (see Box 42.36).
- Increase salt intake with slow sodium 60 to 80 mmol/day.

In a patient with vomiting or severe volume depletion:
- Give intravenous fluid with potassium supplements.
- Correction of acid–base abnormalities is usually not required.

Hyponatraemia with euvolaemia

Hyponatraemia with euvolaemia (**Box 27.12**) results from an intake of water in excess of the kidneys' ability to excrete it (dilutional hyponatraemia); there is no change in body sodium content but the plasma osmolality is low.

- With normal kidney function, dilutional hyponatraemia is uncommon even if a patient drinks approximately 1 L per hour, although the term 'primary' or 'psychogenic polydipsia' is used to describe patients where hyponatraemia is driven by excessive water consumption. This can be demonstrated by evidence of large volume of highly dilute urine as the kidney responds appropriately by attempting to excrete all of the free water.
- Postoperative hyponatraemia is a common clinical problem (seen in almost 1% of patients), with *symptomatic* hyponatraemia occurring in 20% of these patients. Sometimes, this is exacerbated by inappropriate intravenous fluid administration, for example, over-generous administration of 5% glucose. Premenopausal females are at most risk for developing hyponatraemic encephalopathy postoperatively, with postoperative AVP values in young females being 40 times higher than in young males. To prevent iatrogenic hyponatraemia, hypotonic intravenous fluids should be avoided in favour of and administered 0.9% saline or balanced replacement fluids (e.g., Hartmann's solution) unless clinically contraindicated. The serum sodium should be measured daily in any patient receiving continuous parenteral fluid.
- Marathon runners who drink excess water can become hyponatraemic. Even so-called 'isotonic sports drinks' can lead to hyponatraemia, as they contain little sodium, their osmolality being made up with carbohydrates, which are metabolized into energy and water.
- Some degree of hyponatraemia is usual in acute oliguric kidney injury, while in CKD it is most often due to ill-given advice to 'push' fluids.

Syndrome of inappropriate AVP secretion

This is described in Chapter 34. There is inappropriate secretion of AVP, causing water retention and hyponatraemia.

Clinical features

Symptoms of hyponatraemia are common when hyponatraemia develops *acutely* (<48 h, often postoperatively). Overt neurological symptoms rarely occur until the serum sodium is less than 125 mmol/L, and are more usually associated with values around 115 mmol/L or lower, particularly when *chronic*. In elderly patients, however, even mild hyponatraemia with a serum sodium of 130 to 135 mmol/L has been associated with increased falls risk and subtle changes in cognition. They are due to the movement of water into brain cells in response to the fall in extracellular osmolality.

Hyponatraemic encephalopathy

Symptoms and signs include headache, confusion, and restlessness leading to drowsiness, myoclonic jerks, generalized convulsions, and eventually coma. Magnetic resonance imaging (MRI) of the brain may reveal cerebral oedema.

Risk factors for developing hyponatraemic encephalopathy

The brain's adaptation to hyponatraemia initially involves extrusion of blood and CSF, as well as sodium, potassium, and organic osmolytes, in order to decrease brain osmolality. Various factors can interfere with successful adaptation. These factors, rather than the absolute change in serum sodium, predict whether a patient will suffer hyponatraemic encephalopathy.

- ***Premenopausal females*** are more likely to develop encephalopathy than postmenopausal females and males because of inhibitory effects of sex hormones and the effects of vasopressin on cerebral circulation, resulting in vasoconstriction and hypoperfusion of the brain.
- ***Hypoxaemia*** is a major risk factor for hyponatraemic encephalopathy. Patients with hyponatraemia who develop hypoxia, from any cause, have a high risk of mortality. Hypoxia is the strongest predictor of mortality in patients with symptomatic hyponatraemia.

Investigations

The cause of hyponatraemia with apparently normal extracellular volume requires investigation:

- ***Plasma and urine electrolytes and osmolalities.*** The plasma concentrations of sodium, chloride, and urea are low, giving a low osmolality. The urine sodium concentration is usually high and the urine osmolality is typically higher than the plasma osmolality.
- ***Further investigations.*** These are needed to exclude Addison's disease and hypothyroidism.
- ***Potassium and magnesium depletion*** potentiate AVP release and are causes of diuretic-associated hyponatraemia.

SIADH is often over-diagnosed. Some causes are associated with a lower set-point for AVP release, rather than completely autonomous AVP release; an example is chronic alcohol use.

Management

The underlying cause should be corrected where possible (**Box 27.13**).

- ***Most patients.*** Most cases are simply managed by restriction of water intake (to 1000 or even 500 mL/day) with review of diuretic therapy. Magnesium and potassium deficiency must be corrected. In mild sodium deficiency (hypovolaemic hyponatraemia), 0.9% saline given slowly (1 L over 12 h) is sufficient.
- ***Acute onset with symptoms.*** This is an acute medical emergency and should be treated aggressively and immediately.

In patients who demonstrate severe neurological signs, such as fits, coma, or cerebral oedema, European guidelines suggest immediate infusion of 150 mL of ***hypertonic saline*** (3%, 513 mmol/L) over 20 minutes. Repeat measurement of sodium concentration allows repeat dosing, aiming for an increase in plasma osmolality by 5 mmol/L in the first hour, which is often enough to resolve symptoms. After the first hour (and achievement of the 5 mmol/L increase), sodium concentration should be repeated at 6, 12, and 24 hours; further hypertonic saline is not required unless symptoms persist.

Further management should be based around the cause of hyponatraemia, commonly comprising water restriction. The sodium concentration should not be allowed to rise by more than 10 mmol/L in the first 24 hours and 8 mmol/h during following 24 periods (especially in chronic hyponatraemia, where patients are especially at risk of osmotic demyelination if concentrations rise too fast). No further treatment is required once the sodium concentration reaches 130 mmol/L.

Box 27.13 Key points in the management of hyponatraemia

- Does the patient have symptomatic hyponatraemia (seizures/coma)?
  - Yes: involve critical care input early; 3% saline 150 mL with close monitoring and early repeat measurement. Aim for early increase of 5 mmol/L, avoiding excessive over-correction
- Always treat the underlying cause
- What is the volume status of the patient?
  - If hypovolaemic: rehydrate with 0.9% saline
  - If euvolaemic (SIADH): restrict fluid to 500–700 mL/day
  - If hypervolaemic (chronic kidney disease/heart failure): restrict fluid and salt, consider loop diuretic
- Is the hyponatraemia acute or chronic?
  - If acute: more likely to develop symptomatic hyponatraemia
  - If chronic: increased risk of osmotic demyelination due to rapid correction
- Check sodium levels frequently: may need to check Na every 1–2 h
- Correction must not exceed 10 mmol in first 24 h and 18 mmol in 48 h

Osmotic demyelination syndrome

A rapid rise in extracellular osmolality, particularly if there is an 'overshoot' to high serum sodium and osmolality, will result in the osmotic demyelination syndrome (ODS), formerly known as central pontine demyelination. This is a devastating neurological complication characterized by spastic quadriparesis, pseudobulbar palsy, and other features (e.g., parkinsonism) if there is also extrapontine myelinolysis. ODS is diagnosed by the appearance of characteristic hypointense lesions on T_1-weighted images and hyperintense lesions on T_2-weighted images on MRI; these can take 2 weeks or more to appear.

The pathophysiology of ODS is not fully understood. The most plausible explanation is that the brain loses organic osmolytes very quickly in order to adapt to hyponatraemia so that osmolarity is similar between the intracellular and extracellular compartments. However, neurons take up organic osmolytes slowly in the phase of rapid correction of hyponatraemia, resulting in a hypo-osmolar intracellular compartment and shrinkage of cerebral vascular endothelial cells. Consequently, the blood–brain barrier is functionally impaired, allowing lymphocytes, complement and cytokines to enter the brain, damage oligodendrocytes, activate microglial cells, and cause demyelination.

Prevention of ODS is based on avoiding rapid correction of hyponatraemia, especially where it is chronic. Factors predisposing to the development of ODS include alcohol excess, cirrhosis, malnutrition, hypokalaemia, hypoxaemia, and central nervous system radiation, and even greater care should be taken in correcting sodium in patients where these features are present. Even a modest water diuresis in the elderly with reduced muscle mass is large enough to cause a rapid rise in plasma sodium. If plasma sodium rises too quickly due to anticipated water diuresis, administration of desmopressin to stop the water diuresis is beneficial. If plasma sodium rises regardless, then it should be actively lowered again to the maximum limit of correction (<8 mmol/L per day) with the administration of 5% glucose solution.

Sodium correction using vasopressin antagonists

Vasopressin V_2 receptor antagonists, including tolvaptan and conivaptan, produce a selective water diuresis without affecting sodium and potassium excretion. They raise the plasma sodium concentration in patients with hyponatraemia caused by SIADH, heart failure, and cirrhosis, and are licensed in many countries for correction of euvolaemic hyponatraemia. They should be used with caution because of the risk of over-rapid Na correction, but may be particularly useful in patients with chronic hyponatraemia caused by SIADH (see Chapter 34).

Hyponatraemia with hypervolaemia

The common causes of hyponatraemia due to water excess are shown in **Box 27.14**. In all these conditions, there is usually an element of reduced GFR with avid reabsorption of sodium and chloride

Box 27.14 Causes of hyponatraemia with increased extracellular volume (hypervolaemia)

- Heart failure
- Liver failure
- Oliguric kidney injury
- Hypoalbuminaemia

Box 27.15 Causes of hypernatraemia

Arginine vasopressin (AVP) deficiency
- Pituitary diabetes insipidus

Iatrogenic
- Administration of hypertonic sodium solutions
- Administration of drugs with a high sodium content (e.g., piperacillin)
- Use of 8.4% sodium bicarbonate after cardiac arrest

Insensitivity to AVP (AVP-resistance)
- Lithium
- Tetracyclines
- Amphotericin B
- Acute tubular necrosis
- Osmotic diuresis
- Total parenteral nutrition
- Hyperosmolar hyperglycaemic state (see Chapter 11, 'Hyperosmolar hyperglycaemic state' section)

Plus
- Deficient water intake: impaired thirst or consciousness
- Excessive water loss through skin or lungs

in the proximal tubule. This leads to reduced delivery of chloride to the 'diluting' ascending limb of the loop of Henle and a reduced ability to generate 'free water', with a consequent inability to excrete dilute urine. This is commonly compounded by the administration of diuretics that block chloride reabsorption and interfere with the dilution of filtrate either in the loop of Henle (loop diuretics) or distally (thiazides). Oral fluid restriction is often required alongside diuretic therapy.

Hypernatraemia

This is much rarer than hyponatraemia and nearly always indicates a water deficit. Causes are listed in **Box 27.15**.

Hypernatraemia is always associated with increased plasma osmolality, which is a potent stimulus to thirst. None of the factors listed in **Box 27.15** causes hypernatraemia unless thirst sensation is abnormal or access to water is limited. For instance, a patient with diabetes insipidus will maintain a normal serum sodium concentration by maintaining a high water intake until an intercurrent illness prevents this. Thirst is frequently deficient in elderly people, making them more prone to water depletion. Hypernatraemia may occur in the presence of normal, reduced, or expanded extracellular volume, and does not necessarily imply that total body sodium is increased.

Clinical features

Symptoms of hypernatraemia are non-specific. Nausea, vomiting, fever, and confusion may occur. A history of longstanding polyuria, polydipsia, and thirst suggests diabetes insipidus. Assessment of extracellular volume status guides resuscitation. Mental state should be assessed. Convulsions occur in severe hypernatraemia.

Investigations

Simultaneous urine and plasma osmolality and sodium should be measured. Plasma osmolality is high in hypernatraemia. Passage of urine with an osmolality lower than that of plasma in this situation is clearly abnormal and indicates diabetes insipidus. In pituitary diabetes insipidus, urine osmolality will increase after administration of desmopressin; the drug (a vasopressin analogue) has no effect in AVP-resistance (see Chapter 34). If urine osmolality is high, this suggests either an osmotic diuresis due to an unmeasured solute (e.g., urea-induced diuresis caused by protein metabolism during parenteral feeding) or excessive extrarenal loss of water (e.g., heat stroke).

Management

Treatment is that of the underlying cause. For example:
- In AVP-deficiency (cranial diabetes insipidus), replace AVP in the form of desmopressin, a stable non-pressor analogue of AVP.
- Withdraw nephrotoxic drugs and replace water either orally or, if necessary, intravenously.

In ***severe*** (>170 mmol/L) hypernatraemia, 0.9% saline (150 mmol/L) should be used initially. Avoid too rapid a drop in serum sodium concentration; the aim is correction over 48 hours, as overrapid correction may lead to cerebral oedema.

In ***less severe*** (e.g., >150 mmol/L) hypernatraemia, the treatment is 5% glucose or 0.45% saline; the latter is obviously preferable in hyperosmolar diabetic coma. Very large volumes—5 L/day or more—may need to be given in diabetes insipidus.

If there is clinical evidence of volume depletion (see 'Decreased extracellular volume' section), this implies that there is a sodium deficit as well as a water deficit.

DISORDERS OF POTASSIUM CONCENTRATION

Regulation of serum potassium concentration

The World Health Organization (WHO) recommends a dietary intake of 90 mmol/day to reduce blood pressure; most people have a dietary intake of between 80 and 150 mmol daily, depending on fruit and vegetable intake. Most of the body's potassium (3500 mmol in an adult) is intracellular. Serum potassium levels are controlled by:
- uptake of K^+ into cells
- urinary excretion
- extrarenal losses (e.g., gastrointestinal).

Uptake of potassium into cells is governed by the activity of the Na^+/K^+-ATPase in the cell membrane and by H^+ concentration.

Uptake is ***stimulated*** by:
- insulin
- β-adrenergic stimulation
- alkalosis—K^+ exchanged for H^+ across cell membranes.

Uptake is ***decreased*** by:

- α-adrenergic stimulation
- acidosis
- cell damage or cell death—resulting in massive K^+ release.

The ***kidney*** plays a pivotal role in the maintenance of potassium balance by varying its secretion with changes in dietary intake. Over 90% of the filtered potassium is reabsorbed in the proximal tubule and the loop of Henle and <10% of the filtered load is delivered to the early distal tubule. Potassium absorption in the proximal tubule is entirely passive and follows that of sodium and water, while its reabsorption in the thick ascending limb of the loop of Henle is mediated by the sodium–potassium-2–chloride co-transporter. However, potassium is secreted by the principal cells in the cortical and outer medullary collecting tubule. Secretion in these segments is very tightly regulated in health and can be varied according to individual needs; it is responsible for most of urinary potassium excretion.

Renal excretion of potassium is increased by aldosterone, which stimulates K^+ and H^+ secretion in exchange for Na^+ in the principal cells of the collecting duct (see **Fig. 27.9**). Because H^+ and K^+ are interchangeable in the exchange mechanism, acidosis decreases, and alkalosis increases the secretion of K^+. Aldosterone secretion is stimulated by hyperkalaemia and increased angiotensin II levels, as well as by some drugs, and this acts to protect the body against hyperkalaemia and against extracellular volume depletion. The body adapts to dietary deficiency of potassium by reducing aldosterone secretion. However, because aldosterone is also influenced by volume status, conservation of potassium is relatively inefficient, and significant potassium depletion may therefore result from prolonged dietary deficiency.

A number of drugs affect K^+ homeostasis by affecting aldosterone release (e.g., heparin, NSAIDs) or by directly affecting how the kidney handles potassium (e.g., diuretics).

Other endogenous proteins and metabolites also affect potassium homeostasis. Klotho, an anti-ageing protein expressed in the distal tubule (and other organs), increases potassium excretion. CD63, a tetra-spanning protein, inhibits its excretion. Moreover, protein kinase A- and C-mediated phosphorylation inhibits conductance of K^+ channels in the principal cells of the collecting duct but the cytochrome P450-epoxygenase-mediated metabolite of arachidonic acid (11–12-epoxyeicosatrienoic acid) activates these channels and plays a role in overall potassium homeostasis.

Normally, only about 10% of daily potassium intake is excreted in the gastrointestinal tract. Vomit contains around 5 to 10 mmol/L of K^+, but prolonged vomiting causes hypokalaemia by inducing sodium depletion, stimulating aldosterone, which increases renal potassium excretion. Potassium is secreted by the colon, and diarrhoeal fluid contains 10 to 30 mmol/L of K^+; profuse diarrhoea can therefore induce marked hypokalaemia. Colorectal villous adenomas may rarely produce profuse diarrhoea and marked K^+ loss.

Hypokalaemia

Aetiology

Common causes

The most common causes of chronic hypokalaemia are diuretic treatment (particularly thiazides) and hyperaldosteronism. In hospitalized patients, acute hypokalaemia is most often caused by diuretic (thiazide or loop) use and intravenous fluids without potassium, and redistribution into cells, particularly in the case of diabetic ketoacidosis (see Chapter 35), where the use of fluids without potassium combined with insulin treatment can cause a rapid fall in the serum potassium. The common causes are shown in **Box 27.16**.

? Box 27.16 Causes of hypokalaemia

Increased renal excretion
(Urinary K^+ >20 mmol/day)
- Diuretics:
  - Thiazides
  - Loop diuretics

Increased aldosterone secretion
- Liver failure
- Heart failure
- Nephrotic syndrome
- Cushing's syndrome
- Conn's syndrome
- Adrenocorticotrophic hormone (ACTH)–producing tumours

Exogenous mineralocorticoid
- Corticosteroids
- Liquorice (potentiates actions of cortisol in the kidney)

Kidney disease
- Renal tubular acidosis types 1 and 2
- Renal tubular damage (diuretic phase)
- Nephrotoxicity:
  - Amphotericin
  - Aminoglycosides
  - Cytotoxic drugs
- Release of urinary tract obstruction
- Bartter's syndrome
- Liddle's syndrome
- Gitelman's syndrome

Reduced intake of K^+
- Intravenous fluids without K^+
- Dietary deficiency

Redistribution into cells
- β-Adrenergic stimulation
- Acute myocardial infarction
- Beta-agonists, e.g., salbutamol
- Insulin treatment, e.g., treatment of diabetic ketoacidosis
- Correction of megaloblastic anaemia, e.g., B_{12} deficiency
- Alkalosis
- Hypokalaemic periodic paralysis

Gastrointestinal losses
(Urinary K^+ <20 mmol/day)
- Vomiting
- Severe diarrhoea
- Purgative abuse
- Villous adenoma
- Ileostomy or ureterosigmoidostomy
- Fistulae
- Ileus/intestinal obstruction

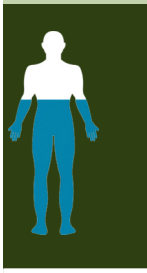
Rare causes

These rare causes are discussed in detail because they show the mechanisms of how diuretics can affect the kidney.

Bartter's syndrome

Bartter's syndrome (clinically similar to the effects of treatment with loop diuretics) consists of metabolic alkalosis, hypokalaemia, hypercalciuria, occasionally hypomagnesaemia (see 'Hypomagnesaemia' section), normal or low blood pressure, and an elevated plasma renin and aldosterone. The primary defect in this disorder is an impairment in sodium and chloride reabsorption in the thick ascending limb of the loop of Henle (see **Fig. 27.7**). Mutation in the genes encoding either the sodium–potassium-2–chloride co-transporter *(NKCC2)*, the ATP-regulated renal outer medullary potassium channel *(ROMK)* or kidney-specific basolateral chloride channels *(CLC-Kb)*—Bartter's syndrome types I, II, and III, respectively—causes loss of function of these channels, with consequent impairment of sodium and chloride reabsorption. Loss-of-function mutations of the protein Barttin cause type IV Bartter's syndrome, which is associated with sensorineural deafness and kidney failure.

In summary, these defects in sodium chloride transport initiate the following sequence, which is almost identical to that seen with chronic ingestion of a loop diuretic: the initial salt loss leads to mild volume depletion, resulting in activation of the renin–angiotensin–aldosterone system; the combination of hyperaldosteronism and increased distal flow (owing to the reabsorptive defect) enhances potassium and hydrogen secretion at the secretory sites in the collecting tubules, leading to hypokalaemia and metabolic alkalosis.



Diagnostic pointers include high urinary potassium and chloride despite low serum values, as well as increased plasma renin. Hyperplasia of the juxtaglomerular apparatus is seen on renal biopsy. Hypercalciuria is a common feature but magnesium wasting, though rare, also occurs. Differential diagnoses include diuretic abuse (where the urinary potassium and chloride concentrations are low) and primary hyperaldosteronism (where renin levels are low).

Treatment is with combinations of potassium supplements, amiloride, and rarely indometacin to block prostaglandin, which then restores vasoresponsiveness to angiotensin II and potassium.

Gitelman's syndrome

Gitelman's syndrome is characterized by hypokalaemia, metabolic alkalosis, hypocalciuria, hypomagnesaemia, normal blood pressure, and elevated plasma renin and aldosterone. There are striking similarities between Gitelman's syndrome and the biochemical abnormalities induced by chronic thiazide diuretic administration. Thiazides act in the distal convoluted tubule to inhibit the function of the apical sodium–chloride co-transporter (NCCT) (see **Fig. 27.8**). Analysis of the gene encoding the NCCT has identified loss-of-function mutations in Gitelman's syndrome.

Defective NCCT function leads to increased solute delivery to the collecting duct (as in Bartter's syndrome), with resultant solute wasting, volume contraction, and an aldosterone-mediated increase in potassium and hydrogen secretion. Impaired function of NCCT causes hypocalciuria. Impaired sodium reabsorption across the apical membrane, coupled with continued intracellular chloride efflux across the basolateral membrane, causes the cell to become hyperpolarized. This in turn stimulates calcium reabsorption via apical, voltage-activated calcium channels. Decreased intracellular sodium also facilitates calcium efflux via the basolateral sodium–calcium exchanger.

Treatment consists of potassium and magnesium supplementation ($MgCl_2$) and a potassium-sparing diuretic. Volume resuscitation is usually not necessary, because patients are not dehydrated.

Liddle's syndrome

This is characterized by potassium wasting, hypokalaemia, and alkalosis, but is associated with low renin and aldosterone production, and high blood pressure. There is a mutation in the gene encoding for the amiloride-sensitive ENaC in the distal tubule/collecting duct. This constitutive activation of the ENaC results in excessive sodium reabsorption with coupled potassium and hydrogen secretion. Unregulated sodium reabsorption across the collecting tubule causes volume expansion, inhibition of renin and aldosterone secretion, and development of low-renin hypertension (see **Fig. 27.9**).

Treatment consists of sodium restriction, along with amiloride or triamterene administration. Both are potassium-sparing diuretics that directly close the sodium channels. The mineralocorticoid antagonist spironolactone is ineffective, since the increase in sodium-channel activity is not mediated by aldosterone.

Clinical features

Hypokalaemia is usually asymptomatic but severe hypokalaemia (<2.5 mmol) causes muscle weakness. Potassium depletion may also cause symptomatic hyponatraemia.

Hypokalaemia is associated with an increased frequency of atrial and ventricular ectopic beats. This association may not always be causal because adrenergic activation (for instance, after myocardial infarction) results in both hypokalaemia and increased cardiac irritability. Hypokalaemia in patients without cardiac disease is unlikely to lead to serious arrhythmias.

Hypokalaemia seriously increases the risk of digoxin toxicity by increasing binding of digoxin to cardiac cells, potentiating its action, and decreasing its clearance.

Chronic hypokalaemia is associated with interstitial kidney disease but the pathogenesis is not completely understood.

Box 27.17 Treatment of hypokalaemia

Cause	Treatment
Dietary deficiency	Increase intake of fresh fruit/vegetables or oral potassium supplements (20–40 mmol daily)
Hyperaldosteronism, e.g., cirrhosis, thiazide therapy	Spironolactone/eplerenone Co-prescription of a potassium-sparing diuretic with a similar onset and duration of action
Intravenous fluid replacement	Add 20 mmol of K^+/L of fluid with monitoring Ensure potassium is checked at least daily until 48 h after potassium supplementation stopped

Management

The underlying cause should be identified and treated where possible. **Box 27.17** shows some examples.

Acute hypokalaemia may correct spontaneously. In most cases, withdrawal of oral diuretics or purgatives, accompanied by the oral administration of potassium supplements in the form of slow-release potassium or effervescent potassium, is all that is required. Intravenous potassium replacement is needed only in conditions such as cardiac arrhythmias, muscle weakness, or severe diabetic ketoacidosis. Intravenous replacement should be used cautiously and with regular monitoring in patients with impaired renal function. Pre-mixed intravenous fluids with potassium supplementation (e.g., 0.9% saline with 20 mmol potassium chloride) have replaced the addition of potassium ampoules to standard intravenous fluid to reduce the risk of medication errors.

The treatment of adrenal disorders is described in Chapter 34.

Failure to correct hypokalaemia may be due to concurrent hypomagnesaemia. Serum magnesium should be measured and any deficiency corrected.

Hyperkalaemia

Aetiology

Common causes

Acute self-limiting hyperkalaemia occurs normally after vigorous exercise and is of no pathological significance. Hyperkalaemia in all other situations is due either to increased release from cells or to failure of excretion (**Box 27.18**). The most common causes are renal impairment and drug interference with potassium excretion. The combination of angiotensin-converting enzyme (ACE) inhibitors with potassium-sparing diuretics or NSAIDs is particularly dangerous.

Rare causes

Hyporeninaemic hypoaldosteronism

This is also known as type 4 renal tubular acidosis (see 'Type 4 renal tubular acidosis' section). Hyperkalaemia occurs because of acidosis and hypoaldosteronism.

Box 27.18 Causes of hyperkalaemia

Decreased excretion
- Acute kidney injury[a]
- Drugs[a]:
  - Amiloride
  - Triamterene
  - Mineralocorticoid receptor antagonists
  - ACE inhibitors/angiotensin receptor blockers
  - NSAIDs
  - Ciclosporin
  - Heparin
- Aldosterone deficiency
- Hyporeninaemic hypoaldosteronism (RTA type 4)
- Addison's disease
- Acidosis[a]
- Gordon's syndrome

Increased release from cells
(Decreased Na^+/K^+-ATPase activity)
- Acidosis
- Diabetic ketoacidosis
- Rhabdomyolysis/tissue damage
- Tumour lysis
- Succinylcholine (amplified by muscle denervation)
- Digoxin poisoning
- Vigorous exercise (α-adrenergic; transient)

Increased extraneous load
- Potassium chloride
- Salt substitutes
- Transfusion of stored blood[a]

Spurious
- Increased *in vitro* release from abnormal cells
- Leukaemia
- Infectious mononucleosis
- Thrombocytosis
- Familial pseudohyperkalaemia, e.g., haemolysis in syringe
- Increased release from muscles
- Vigorous fist clenching during phlebotomy[a]

[a]Common causes.

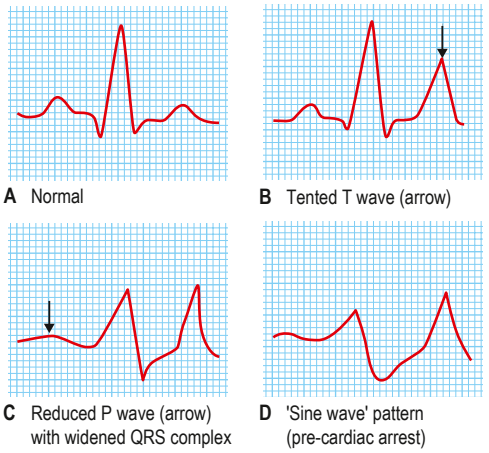


Fig. 27.12 Progressive ECG changes with increasing hyperkalaemia.

Hyperkalaemic periodic paralysis

Hyperkalaemic periodic paralysis (see Chapter 28) is precipitated by exercise, and is caused by an autosomal dominant mutation of the skeletal muscle sodium-channel gene.

Gordon's syndrome (familial hyperkalaemic hypertension, pseudohypoaldosteronism type 2)

This appears to be a mirror image of Gitelman's syndrome (see 'Gitelman's syndrome' section), in which primary renal retention of sodium causes hypertension, volume expansion, low renin/aldosterone, hyperkalaemia, and metabolic acidosis. There is also an increased sensitivity of sodium reabsorption to thiazide diuretics, suggesting that the thiazide-sensitive NCCT is involved (see **Fig. 27.8**). Genetic analyses, however, have excluded abnormalities in NCCT.

Suxamethonium and other depolarizing muscle relaxants

These cause release of potassium from cells. Induction of muscle paralysis during general anaesthesia may result in a rise of plasma potassium of up to 1 mmol/L. This is not usually a problem unless there is pre-existing hyperkalaemia.

Clinical features

Serum potassium of >7.0 mmol/L is a medical emergency and is associated with ECG changes (**Fig. 27.12**). Severe hyperkalaemia may be asymptomatic and may predispose to sudden death from asystolic cardiac arrest. Muscle weakness is often the only symptom, unless (as is commonly the case) the hyperkalaemia is associated with metabolic acidosis, causing Kussmaul respiration. Hyperkalaemia causes depolarization of cell membranes, leading to decreased cardiac excitability, hypotension, bradycardia, and eventual asystole.

Management

The acute management of hyperkalaemia is addressed in Chapter 11.

DISORDERS OF MAGNESIUM CONCENTRATION

Magnesium (Mg^{2+}) plays a pivotal role in many biological processes such as enzymatic reactions, gene transcription, bone remodelling, and neuromuscular stability. Approximately 99% of the Mg^{2+} in the body is in the intracellular compartment, mainly in bone (approximately 85%) and in muscle and soft tissues (approximately 14%). The other 1% is in the extracellular fluid.

Plasma magnesium levels are normally maintained within the range 0.7 to 1.1 mmol/L (1.4–2.2 mEq/L). The average daily magnesium intake is 15 mmol, which is absorbed mainly in the small intestine and, to a lesser extent, in the colon. In the healthy adult, there is no net gain or loss of magnesium from bone, so that balance is achieved by the urinary excretion of the net magnesium absorbed. The kidney reabsorbs between approximately 95% and 98% of the filtered Mg^{2+} and plays a major role in maintaining plasma Mg^{2+} concentrations within the normal range.

Control and renal handling of magnesium

Cortical thick ascending limb of Henle

Approximately 30% of Mg^{2+} is bound to plasma proteins but the remaining fraction is freely filterable. The major site of magnesium transport is the cortical thick ascending limb of the loop of Henle, where 65% to 70% of the filtered load is reabsorbed, with only 10% to 20% being reabsorbed in the proximal tubule (see **Fig. 27.7**). This transport is passive, paracellular and carried out by tight junction proteins (paracellin-1 and claudins). This process is driven by the lumen-positive electrochemical gradient, characteristic of this segment. This voltage gradient is created by the apical disproportionate net transport of two Cl^- to one Na^+ (by the bumetanide-sensitive sodium–potassium-2–chloride transporter) and the secretion of K^+ (via the ROMK) (see **Fig. 27.7**).

Loss-of-function mutations in these key reabsorptive processes lead to hypomagnesaemia as part of the distinctive clinical syndromes described later.

Bartter's syndrome

Hypomagnesaemia is rare in Bartter's syndrome (see 'Bartter's syndrome' section). This is because the transepithelial voltage, which is responsible for magnesium reabsorption, is preserved and any additional filtered magnesium will be offset by a compensatory increase in absorption in the distal convoluted tubule.

Familial hypomagnesaemia, hypercalciuria, and nephrocalcinosis

Familial hypomagnesaemia, hypercalciuria, and nephrocalcinosis (FHHNC) is characterized by excessive renal magnesium and calcium wasting; the main defect lies in the cortical thick ascending limb of Henle. Ten different mutations have been identified in a novel gene that encodes for paracellin-1 and claudins 16/19 complex, in the tight junction proteins.

Individuals develop bilateral nephrocalcinosis and progressive CKD. Patients also have elevated parathyroid hormone levels, which precedes any reduction in GFR. A substantial proportion of patients show incomplete distal renal tubular acidosis, hypocitraturia, and hyperuricaemia. Extrarenal involvement, such as myopia, nystagmus, and chorioretinitis, has been reported.

Distal convoluted tubule

The reabsorption rate in the distal convoluted tubule (DCT)—10%—is much lower than in the cTAL, but it defines the final urinary excretion, as there is no significant reabsorption in the collecting duct; 3% to 5% of filtered magnesium is finally excreted in the urine. Magnesium reabsorption in the DCT is transcellular and active (see Fig. 27.8).

Hypomagnesaemia

In addition to the familial causes described earlier, hypomagnesaemia most often develops as a result of deficient intake, defective gut absorption (associated with the use of proton pump inhibitors), or excessive gut or urinary loss (Box 27.19). It can also occur with acute pancreatitis, possibly owing to the formation of magnesium soaps in the areas of fat necrosis, and during drug treatment with aminoglycosides and cisplatinum compounds. Due to the severe effects of hypomagnesaemia, routine measurements of serum Mg^{2+} should be conducted in the critically ill, as well as in patients who are exposed to drugs and other conditions associated with Mg^{2+} deficiency.

Clinical features

Symptoms and signs (indicating a deficit of 0.5–1 mmol/kg) include irritability, tremor, ataxia, carpopedal spasm, hyper-reflexia, confusion, and seizures. An ECG may show a prolonged QT interval, broad flattened T waves, and occasional shortening of the ST segment.

Hypocalcaemia is often also present, and urinary calcium can help distinguish between causes of hypomagnesaemia: it is increased in cases associated with Bartter's syndrome, loop diuretics, and FHHNC and reduced in cases associated with Gitelman's syndrome and thiazide diuretics.

Box 27.19 Causes of hypomagnesaemia

Decreased magnesium absorption
- Malabsorption (severe)
- Malnutrition
- Alcohol excess
- Proton pump inhibitors

Increased renal excretion
- Drugs:
  - Loop diuretics
  - Thiazide diuretics
  - Digoxin
- Diabetic ketoacidosis
- Hyperaldosteronism
- SIADH
- Alcohol excess
- Hypercalciuria
- 1,25-dihydroxyvitamin D_3 deficiency
- Drug toxicity:
  - Amphotericin
  - Aminoglycosides
  - Cisplatin
  - Ciclosporin

Gut losses
- Prolonged nasogastric suction
- Excessive purgation
- Gastrointestinal/biliary fistulae
- Severe diarrhoea

Inherited tubular wasting
- Bartter's syndrome
- Familial hypomagnesaemia, hypercalciuria, and nephrocalcinosis
- Isolated dominant hypomagnesaemia
- Gitelman's syndrome
- Isolated recessive hypomagnesaemia
- Hypomagnesaemia with secondary hypocalcaemia
- EAST syndrome (Epilepsy, Ataxia, Sensorineural deafness and Tubulopathy)

Miscellaneous
- Acute pancreatitis

Box 27.20 Causes of hypermagnesaemia

- Impaired renal excretion:
  - Chronic kidney disease
  - Acute kidney injury
- Increased magnesium intake:
  - Purgatives, e.g., magnesium sulphate
  - Antacids, e.g., magnesium trisilicate
- Haemodialysis with high [Mg^{2+}] dialysate

Management

This involves the withdrawal of precipitating agents such as diuretics or purgatives. Oral magnesium replacement (e.g., magnesium glycerophosphate) is often ineffective due to poor absorption and diarrhoea, and if symptomatic (or with hypocalcaemia), intravenous replacement is generally preferred. This should be repeated daily and continued for 2 days after normal plasma levels have been achieved.

Relationship between hypomagnesaemia and plasma potassium

Magnesium depletion can lead to refractory hypokalaemia. The normal concentration of intracellular magnesium usually blocks secretory K^+ currents through ROMK channels. Magnesium depletion promotes K^+ loss by releasing ROMK from magnesium-mediated inhibition. Close monitoring, with potassium supplements if necessary, is required in patients presenting with primary symptomatic low plasma magnesium levels.

Hypermagnesaemia

This primarily occurs in patients with kidney disease who are given magnesium-containing laxatives or antacids. It can also be induced by magnesium-containing enemas. Causes are given in Box 27.20.

Clinical features

Symptoms and signs relate to neurological and cardiovascular depression, and include weakness with hyporeflexia proceeding to narcosis, respiratory paralysis, and cardiac conduction defects. Symptoms usually develop when the plasma magnesium level exceeds 2 mmol/L (4 mEq/L).

Management

Treatment requires withdrawal of any magnesium therapy. An intravenous injection of 10 mL of calcium gluconate 10% (2.25 mmol calcium) is given to antagonize the effects of hypermagnesaemia, along with glucose and insulin (as for hyperkalaemia) to lower the plasma magnesium level. Dialysis may be required in patients with severe kidney disease.

DISORDERS OF PHOSPHATE CONCENTRATION

Phosphate forms an essential part of most biochemical systems. The regulation of plasma phosphate level is both directly and closely linked to that of calcium.

About 85% of all body phosphorus is within bone, plasma phosphate normally ranging from 0.80 to 1.15 mmol/L and accounting for only 1% of the total body phosphate. Phosphate reabsorption from the glomerular filtrate occurs entirely and actively in the proximal tubule and is hormonally regulated. It is decreased by parathyroid hormone (PTH) via a cyclic adenosine monophosphate (cAMP)-dependent mechanism; thus, primary hyperparathyroidism is associated with low plasma levels of serum phosphate. Other factors that are known to control phosphate reabsorption in the proximal tubule are 1,25-dihydroxyvitamin D_3, sodium delivery to the proximal tubule, serum concentrations of calcium, bicarbonate, carbon dioxide tension, glucose, alanine, serotonin, dopamine and sympathetic activity.

Osteoblast-secreted phosphaturic factors (phosphatonins), such as fibroblast growth factor 23 (FGF23), matrix extracellular phosphoglycoprotein (MEPG), and frizzled-related protein 4 (FRP-4), play a role in phosphate homeostasis. FGF23 is the most extensively investigated phosphatonin. It binds to its receptor, FGFR1, in the kidney and causes phosphaturia; it also regulates vitamin D by inactivation of 1α-hydroxylase (CYP27B1) and upregulation of 24 hydroxylase (CYP24A1) enzymes, with the net result of low 1,25-vitamin D synthesis. Serum FGF23 is also the earliest marker of abnormal phosphate handling in CKD patients, occurring before changes in serum phosphate, calcium, or PTH (**Fig. 27.13**). FGF23 requires the enzyme Klotho for its activity. Loss-of-function mutation in either FGF23 or Klotho results in a similar phenotype of shortened lifespan, premature ageing, and hyperphosphataemia, and, as expected from the mode of action, increases 1,25 vitamin D levels.

Phosphate absorption is an active process carried out by a family of sodium–phosphate co-transporters (NPT) in the gut and kidneys. NPT2a and NPT2c are expressed in the brush border of the proximal tubule while NPT2b is expressed in lungs and intestine.

Under normal circumstances, plasma phosphate levels are kept constant; for example, after a phosphate-rich meal, the bone releases FGF23, which inhibits NPT2a and causes phosphate excretion. Moreover, phosphate in the plasma causes the release of PTH, which also inhibits NPT2a, NPT2c, and NHERF1, resulting in phosphaturia (see **Fig. 27.13**). These two principal mechanisms keep plasma phosphate levels within normal limits on a daily basis.

Hypophosphataemia

Significant hypophosphataemia (<0.4 mmol/L or <1.25 mg/dL) occurs in a number of clinical situations, owing to redistribution into cells, renal losses, or decreased intake (**Box 27.21**).

Clinical features include:

- muscle weakness, for example, diaphragmatic weakness, decreased cardiac contractility, skeletal muscle rhabdomyolysis. Diaphragmatic weakness may be severe in acute hypophosphataemia, and may impede the weaning of a patient from a ventilator
- a left shift in the oxyhaemoglobin dissociation curve (reduced 2,3-bisphosphoglycerate, 2,3-BPG) and rarely haemolysis
- confusion, seizures, and coma.

Aetiology

Hypophosphataemia related to parathyroid hormone

Primary hyperparathyroidism is a common cause of hypophosphataemia. Very rarely, gain-of-function mutations of the PTH1 receptor cause hypophosphataemia and Jansen's metaphyseal chondrodysplasia due to constitutive activation of PTH signalling, even in the presence of low or absent circulating PTH levels.

Hypophosphataemia related to vitamin D

Hypophosphataemia can be part of osteomalacia and rickets due to vitamin D deficiency, either dietary (globally, the most common cause) or genetic, and is usually accompanied by hypocalcaemia (calcipenic) and secondary hyperparathyroidism.

Vitamin D–dependent rickets type I

Also known as ***pseudo-vitamin D-deficient rickets***, this is caused by 1α-hydroxylase deficiency due to inactivating mutations in its gene. This condition manifests clinically in the first year of life with severe hypocalcaemia, often complicated by tetany, moderate hypophosphataemia, and enamel hypoplasia. The characteristic biochemical findings are normal serum levels of 25-hydroxyvitamin D, low values of 1,25-dihydroxyvitamin D and, usually, relatively high PTH levels. The treatment of choice is replacement therapy with calcitriol.

Vitamin D–dependent rickets type II

This is a form of vitamin D resistance and is known as ***hereditary vitamin D–resistant rickets***. It is an autosomal recessive disorder and is usually caused by loss-of-function mutations in the gene encoding the vitamin D receptor. The clinical manifestations vary widely, depending on the type of mutation within the vitamin D receptor and the amount of residual vitamin D receptor activity. Affected children usually develop rickets within the first 2 years of life, with alopecia in two-thirds of cases, which is due to lack of vitamin D receptor action within keratinocytes. The treatment involves calcitriol and calcium supplementation.

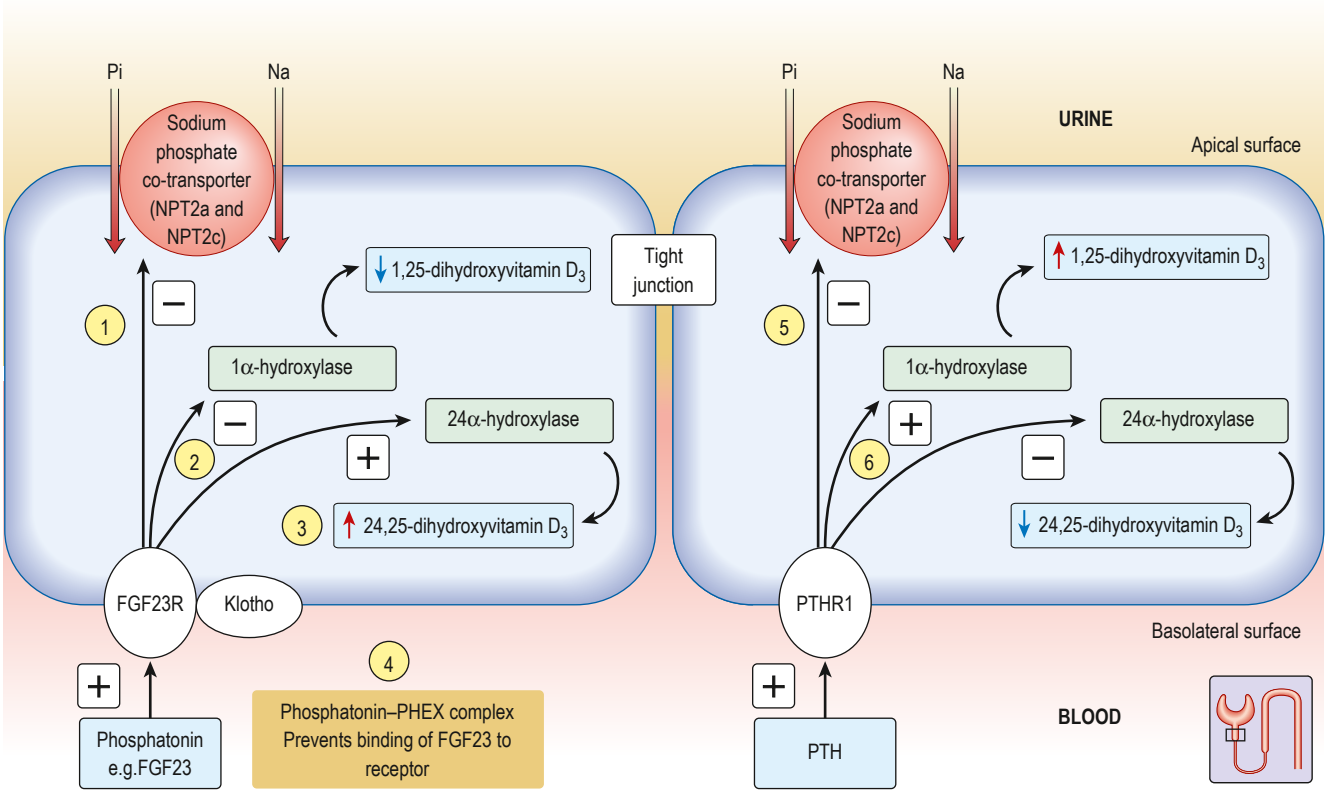

Fig. 27.13 PHEX and PTH regulation of phosphate transport and vitamin D metabolism in the proximal tubule. **(1)** Fibroblast growth factor 23 (FGF23) inhibits the sodium–phosphate co-transporter (NPT2a, c), causing phosphaturia. **(2)** Binding of FGF23 to the FGFR1–Klotho complex leads to lower levels of the active form of vitamin D (1,25-vitamin D) by inhibiting 1α-hydroxylase. **(3)** It also increases levels of inactive vitamin D (24,25-vitamin D) by stimulating 24α-hydroxylase. **(4)** PHEX (phosphate-regulating gene with homologies to endopeptidase on the X chromosome) acts as a competitive inhibitor, binding FGF23 and blocking its action. **(5)** Parathyroid hormone (PTH) also inhibits NPT2a, which leads to phosphaturia. **(6)** PTH has opposite effects on vitamin D metabolism compared with FGF23 by stimulating 1α-hydroxylase and inhibiting 24α-hydroxylase.

Box 27.21 Causes of hypophosphataemia

Redistribution
- Respiratory alkalosis
- Treatment of diabetic ketoacidosis (insulin drives phosphate into cells)
- Re-feeding (particularly with carbohydrate) after fasting or starvation
- After parathyroidectomy (hungry bone disease)

Decreased intake/absorption
- Diet
- Malabsorption
- Vomiting
- Gut phosphate binders, e.g., sevelamer
- Vitamin D deficiency
- Alcohol withdrawal

Renal losses
- Hyperparathyroidism
- Renal tubular defects
- Diuretics
- Tenofovir treatment

Hypophosphataemic rickets
- Vitamin D–dependent rickets types I and II
- Tumour-induced osteomalacia (TIO)
- Autosomal dominant and recessive
- X-linked dominant rickets (XLR)
- Dent's disease

Hypophosphataemia related to decreased renal reabsorption of phosphate

Excessive phosphatonins (FGF23)

This condition occurs in patients with ***tumour-induced osteomalacia*** (TIO), ***X-linked dominant hypophosphataemic rickets*** (XLR), and ***autosomal dominant hypophosphataemic rickets*** (ADHR). These syndromes have similar biochemical and osseous phenotypes. Patients have osteomalacia or rickets, reduced tubular phosphate reabsorption, hypophosphataemia, normal or low serum calcium, normal PTH and PTH-related protein concentrations, and normal or low 1,25-dihydroxyvitamin D_3.

In ***TIO***, there is excessive production of phosphaturic agents: for example, FGF23, MEPG, and FRP-4. The result is excess inhibition of the sodium–phosphate co-transporter in the proximal tubule and urinary phosphate wasting.

In ***ADHR***, FGF23 is mutated so that it is resistant to PHEX (phosphate-regulating gene with homologies to endopeptidases on the X chromosome) proteolysis.

In **XLR**, mutations in PHEX prevent binding to FGF23 and FRP-4, resulting in a net relative excess of phosphatonins.

Normal adaptive increases in 1,25-dihydroxyvitamin D_3 synthesis in response to low phosphate levels do not occur in TIO, ADHR, and XLR, aggravating phosphaturia (see Fig. 27.13).

Autosomal recessive hypophosphataemia with high FGF23 levels has been described in patients with mutations in the gene encoding dentin matrix protein 1 *(DMP1)*, which is a transcription factor produced by odontoblasts, osteoblasts, and osteocytes.

Reduced NPT2a/NHERF1 activity

Mutations in NPT2a (sodium–phosphate co-transporter 2a) and NHERF1 (sodium hydrogen regulator factor 1) have been identified in patients with low phosphate levels and a reduced ratio of the maximum tubular reabsorption of phosphate (TmP) normalized for GFR (TmP/GFR ratio). Heterozygous loss-of-function mutation in NPT2a and NHERF1 in patients is characterized by hypophosphataemia, low TmP/GFR, and normal PTH. Carriers of these mutations do not have hypercalcaemia, which means these mutations do not affect the action of PTH on bones.

Dent's disease

Dent's disease is the generally accepted name for a group of hereditary tubular disorders, including X-linked recessive nephrolithiasis with CKD, X-linked recessive hypophosphataemic rickets, and idiopathic low-molecular-weight proteinuria. It is characterized by low-molecular-weight proteinuria, hypercalciuria, hyperphosphaturia, nephrocalcinosis, kidney stones, and eventual kidney failure, with some patients developing rickets or osteomalacia.

Dent's disease is caused, in 60% of cases, by loss-of-function mutation of a proximal tubular endosomal chloride channel, CLC5. Mutations in OCRL1 occur in 15% of cases. This chloride channel, along with the proton pump, is essential for acidification of proximal tubular endosomes, required for normal endocytosis, degradation, and recycling of absorbed proteins, vitamins, and hormones. Defective endosomal acidification results in impaired endosomal degradation and recycling of endocytosed hormones such as PTH, causing the clinical phenotype of hyperparathyroidism. In addition, the receptors for reabsorption of low-molecular-weight proteins and albumin in the proximal tubules (megalin and cubilin) are decreased in Dent's disease, causing low-molecular-weight proteinuria and urinary leak of cytokines, hormones, and chemokines. The result is progressive kidney fibrosis and decline in kidney function.

Hypophosphataemia related to re-feeding syndrome

Hypophosphataemia may also occur as part of the 're-feeding syndrome' (see Chapter 25), which occurs in significantly malnourished patients who rapidly recommence feeding via oral, enteral, or parenteral routes.

Following starvation, the body's stores of phosphate are low due to reduced intake. After a carbohydrate load, insulin is released, which causes rapid cellular uptake of phosphate, along with potassium and magnesium, leading to a fall in the serum concentrations of these electrolytes.

Furthermore, insulin stimulates production of adenosine triphosphate (ATP) thus increasing the cellular requirement for phosphate. The inability to phosphorylate ADP to ATP due to inadequate phosphate concentrations leads to cardiac dysfunction and arrhythmias, respiratory failure due to weakness of the diaphragm, rhabdomyolysis, and seizures.

Re-feeding syndrome can be prevented by correcting electrolyte disturbances before re-feeding and avoiding rapid increases of caloric intake above the resting energy requirements.

Management is essentially supportive; patients may require hospitalization for electrolyte replacement and monitoring.

Diagnosis

Patients with hypophosphataemia should have their urinary fractional excretion of phosphate calculated from (urinary phosphate × serum creatinine)/(serum phosphate × urine creatinine). A value of <0.7 mmol/L indicates renal phosphate wasting. If PTH levels are high, then the patient is very likely to have hyperparathyroidism, either primary or secondary to vitamin D deficiency (acquired or genetic) or Dent's disease. If PTH levels are low, then the only possibility is gain-of-function mutation in PTH1R. If PTH levels are normal, then FGF23 concentrations can be measured: a high FGF23 concentration may indicate tumour-induced osteomalacia, or mutations in FGF23/Klotho, PHEX, or DMP1. Normal FGF23 and PTH levels point to mutations in NPT2a, NPT2c, and NHERF1.

Management

Oral phosphate supplementation and calcitriol (1,25-dihydroxyvitamin D) administration is required if there is vitamin D deficiency.

Treatment of ***acute hypophosphataemia*** is with intravenous phosphate at a maximum rate of 9 mmol every 12 hours. Repeated measurements of calcium and phosphate are required, as over-rapid administration of phosphate may lead to severe hypocalcaemia, particularly in the presence of alkalosis. ***Chronic hypophosphataemia*** can be corrected with oral effervescent sodium phosphate. The anti-FGF23 neutralizing antibody (burosumab) may be used to reverse the biochemical and clinical phenotypic manifestations in patients with X-linked osteomalacia or tumour-induced osteomalacia.

Hyperphosphataemia

Hyperphosphataemia is common in patients with CKD (see Chapter 26; Box 27.22), and is usually asymptomatic, but may be a cause of significant itching. Prolonged hyperphosphataemia causes hyperparathyroidism and periarticular and vascular calcification.

Familial tumoural calcinosis is characterized by calcifications of muscles, skin, eyelids, and vessels, as well as hyperostosis. In this condition, absence of glycosylation of FGF23 makes it unstable and more sensitive to proteolysis. This results in its deficiency and hyperphosphataemia due to increased renal phosphate reabsorption through increased NPT2a activity.

Usually, no treatment is required for acute hyperphosphataemia, as the causes are self-limiting. Treatment of chronic hyperphosphataemia in the context of CKD involves:

- reduction in phosphate intake
- use of gut-active phosphate binders such as sevelamer carbonate or calcium carbonate
- increased removal of phosphate through dialysis.

? Box 27.22 Causes of hyperphosphataemia

- Acute kidney injury
- Chronic kidney disease
- Phosphate-containing enemas
- Hyperparathyroidism/ pseudohyperparathyroidism
- Tumour lysis
- Rhabdomyolysis
- Familial tumoural calcinosis

Box 27.23 Relationship between [H⁺] and pH

pH	[H⁺] (nmol/L)

ACID–BASE DISORDERS

The concentration of hydrogen ions in both extracellular and intracellular compartments is extremely tightly controlled, and very small changes lead to major cell dysfunction. Blood pH is tightly regulated and is normally maintained at between 7.38 and 7.42. Any deviation from this range indicates a substantial change in the hydrogen ion concentration [H⁺] because blood pH is the negative logarithm of [H⁺] (Box 27.23). The [H⁺] at a physiological blood pH of 7.40 is 40 nmol/L. An increase in the [H⁺] (a fall in pH) is termed acidaemia. A decrease in [H⁺] (a rise in the blood pH) is termed alkalaemia. The disorders that cause these changes in the blood pH are acidosis and alkalosis, respectively.

Normal acid–base physiology

The normal adult diet contains 70 to 100 mmol of acid (H⁺). Throughout the body, there are buffers that minimize any changes in blood pH that these ingested hydrogen ions might cause. Such buffers include intracellular proteins (e.g., haemoglobin) and tissue components (e.g., the calcium carbonate and calcium phosphate in bone), as well as the bicarbonate–carbonic acid buffer pair generated by the hydration of carbon dioxide. This buffer pair is clinically most relevant, in part because its contribution can be measured and because alterations in this buffer pair reveal changes in all other buffer systems. Bicarbonate ions [HCO_3^-] and carbonic acid (H_2CO_3) exist in equilibrium; and in the presence of carbonic anhydrase, carbonic acid dissociates to carbon dioxide and water, as expressed in the following equation:

$$H^+HCO_3^- \rightleftarrows H_2CO_3 \xleftrightarrow{\text{carbonic anhydrase}} CO_2 + H_2O.$$

The addition of hydrogen ions drives the reaction to the right, decreasing the plasma bicarbonate concentration [HCO_3^-] and increasing the arterial carbon dioxide pressure (P_aCO_2). As shown in the following ***Henderson–Hasselbalch equation***, a fall in the plasma [HCO_3^-] increases [H⁺] and thus lowers blood pH:

$$[H^+] = \frac{181 \times P_aCO_2}{[HCO_3^-]}$$

where [H⁺] is expressed in nmol/L, P_aCO_2 in kilopascals, [HCO_3^-] in mmol/L and 181 is the dissociation coefficient of carbonic acid. Alternatively, the equation can be expressed as:

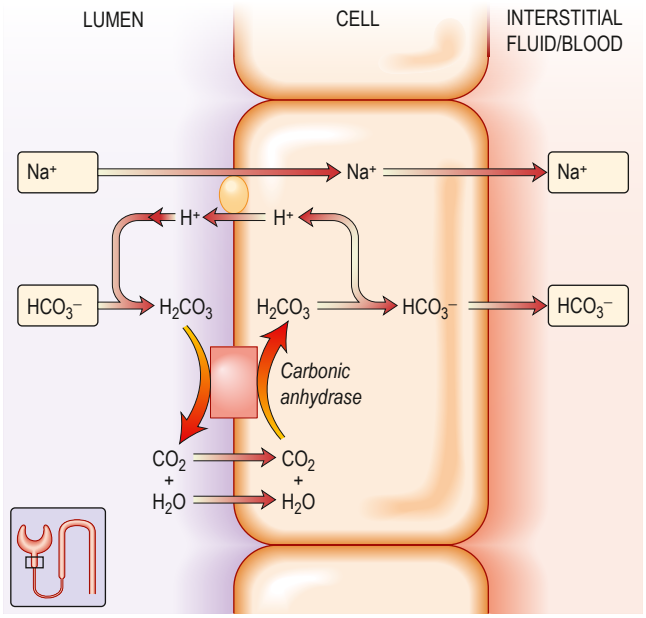

Fig. 27.14 Resorption of sodium bicarbonate (mainly proximal tubule). Bicarbonate is reclaimed by the secretion of H⁺ in exchange for Na⁺ into the tubule. This results in the formation of H_2CO_3, which is then broken down to CO_2. This is reabsorbed and converted back to H_2CO_3, which now dissociates into H⁺ and HCO_3^-. The net result is reabsorption of Na⁺ and HCO_3^-. This process is dependent on carbonic anhydrase within the cells and on the luminal surface of the tubular cell.

$$pH = pK + \frac{\log [HCO_3^-]}{[H_2CO_3]}$$

where pK = 6.1.

Although the acidaemia stimulates an increase in ventilation, which blunts this change in pH, increased ventilation does not regenerate the bicarbonate used in the buffering process. Thus, the bicarbonate used in the buffering process must be regenerated to maintain normal acid–base balance.

Consequently, the kidney must excrete hydrogen ions to return the plasma [HCO_3^-] to normal. Maintenance of a normal plasma [HCO_3^-] under physiological conditions depends not only on daily regeneration of bicarbonate but also on reabsorption of all bicarbonate filtered across the glomerular capillaries.

Renal reabsorption of bicarbonate

The plasma [HCO_3^-] is normally maintained at approximately 25 mmol/L. In individuals with a normal GFR (120 mL/min), about 4500 mmol of bicarbonate is filtered each day. If this filtered bicarbonate were not reabsorbed, the plasma [HCO_3^-] would fall, along with blood pH. Thus, maintenance of normal plasma [HCO_3^-] requires that essentially all of the bicarbonate in the glomerular filtrate be reabsorbed (Fig. 27.14).

The proximal convoluted tubule reclaims 85% to 90% of filtered bicarbonate; by contrast, the distal nephron reclaims very little. This difference is caused by the greater quantity of luminal (brush border) carbonic anhydrase in the proximal tubule than in the distal nephron. As a result of these quantitative differences, bicarbonate that escapes reabsorption in the proximal tubule is excreted in the urine.

Proximal tubular bicarbonate reabsorption is catalyzed by the Na^+/K^+-ATPase pump located in the basolateral cell membrane. By exchanging peritubular potassium ions for intracellular sodium

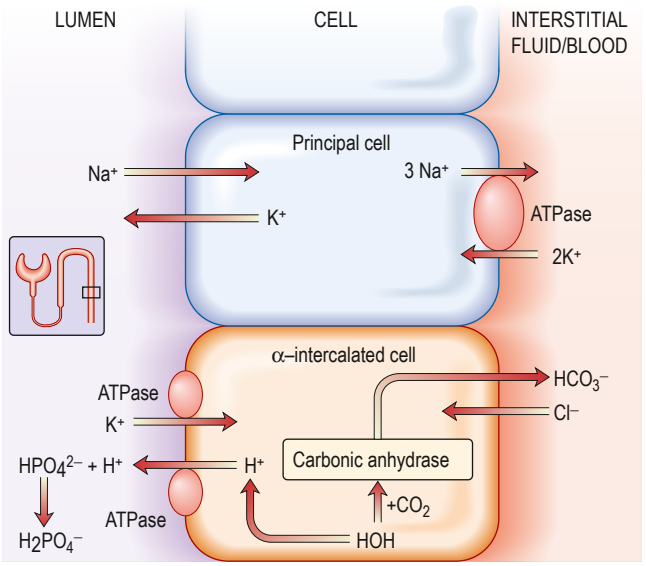

Fig. 27.15 Renal excretion of H^+. H^+ excretion is indirectly controlled by aldosterone in the cortical collecting ducts. Aldosterone enhances sodium absorption and potassium excretion by opening sodium channels and enhancing the activity of the Na^+/K^+-ATPase in the principal cell. These actions set up an electrochemical gradient favouring H^+ excretion. Aldosterone also facilitates H^+ excretion by stimulating H^+-ATPase in the intercalated cell.

ions, the pump keeps the intracellular sodium concentration low, allowing sodium ions to enter the cell by moving down the sodium concentration gradient from the tubule lumen to the cell interior. Hydrogen ions are transported in the opposite direction (at the Na^+–H^+ antiporter), thereby maintaining electroneutrality. Before bicarbonate enters the proximal tubule, it combines with secreted hydrogen ions, forming carbonic acid. In the presence of luminal carbonic anhydrase (CA-IV), carbonic acid rapidly dissociates into carbon dioxide and water, which can then rapidly enter the proximal tubular cell. In the cell, carbon dioxide is hydrated by cytosolic carbonic anhydrase (CA-II), ultimately forming bicarbonate, which is then transported down an electrical gradient from the cell interior, across the membrane into the peritubular fluid, and into the blood. In this process, each hydrogen ion secreted into the proximal tubule lumen is reabsorbed and can be resecreted; there is no net loss of hydrogen ions or net gain of bicarbonate ions.

Renal excretion of $[H^+]$

More acid is secreted into the proximal tubule (up to 4500 nmol of hydrogen ions each day) than in any other nephron segment (Fig. 27.15). However, the hydrogen ions secreted into the proximal tubule are almost completely reabsorbed with bicarbonate; consequently, proximal tubular hydrogen ion secretion does not contribute significantly to hydrogen ion elimination from the body. The excretion of the daily acid load requires hydrogen ion secretion in more distal nephron segments.

Most dietary hydrogen ions come from sulphur-containing amino acids that are metabolized to sulphuric acid (H_2SO_4), which then reacts with sodium bicarbonate as follows:

$$H_2SO_4 + 2NaHCO_3 \rightarrow Na_2SO_4 + 2CO_2 + 2H_2O.$$

Excess sulphate is excreted in the urine, whereas excess hydrogen ions are buffered by bicarbonate and lower the plasma $[HCO_3^-]$. This fall in plasma $[HCO_3^-]$ leads to a slight decrease in the blood pH, although a smaller decrease than would have occurred if buffer were unavailable. The subsequent excretion of hydrogen ions takes place primarily in the collecting duct and results in the regeneration of 1 mmol of bicarbonate for every mmol of hydrogen ions excreted in the urine.

The ***collecting duct*** has three types of cell:

- The ***principal cells*** with an aldosterone-sensitive Na^+ absorption site. These cells reabsorb Na^+ and H_2O and secrete K^+ under the influence of aldosterone.
- The ***α-intercalated cells***, which possess the proton pump for the active secretion of hydrogen ions in exchange for reabsorption of K^+ ions. Aldosterone increases H^+ ion secretion.
- The ***β-intercalated cells*** are mirror images of α-intercalated cells. Here the H^+-ATPase pump is located in the basolateral rather than the apical membrane, whereby H^+ ions are secreted into the peritubular capillary. The HCO_3^- ions, on the other hand, are secreted into the tubular lumen by an anion exchanger in the apical membrane.

Secretion of hydrogen ions from the cortical collecting ducts (CCD) is indirectly linked to sodium reabsorption.

- Aldosterone has several facilitating effects on hydrogen ion secretion. Aldosterone opens sodium channels in the luminal membrane of the ***principal cell*** and increases Na^+/K^+-ATPase activity. The subsequent movement of cationic sodium into the principal cell creates a negative charge within the tubule lumen. Potassium ions from the principal cells and hydrogen ions from the α-intercalated cells move out from the cells down the electrochemical gradient and into the lumen.
- Aldosterone also stimulates directly the H^+-ATPase in the α-intercalated cell, further enhancing hydrogen ion secretion. The H^+ to be secreted arises from the reassociation of H_2O and CO_2 in the presence of carbonic anhydrase; thus, a bicarbonate molecule is regenerated each time an H^+ is eliminated in the urine.

When hydrogen ions are secreted into the lumen of the collecting tubule, a tiny, but physiologically critical, fraction of these excess hydrogen ions remains in solution. Here, they increase the urinary $[H^+]$ and lower urinary pH below 4.0. Nevertheless, below this urine pH, inhibition of proton-secreting pumps, such as H^+-ATPase, severely restricts kidney secretion of more hydrogen ions. Consequently, secretion of hydrogen ions depends on the presence of buffers in the urine that maintain the urine pH at a level higher than 4.0.

In the presence of alkali excess, the homeostatic needs are reversed. Although the kidney can excrete excess alkaline load by reducing reabsorption of filtered bicarbonate in the proximal and distal tubule, the collecting ducts also contribute by secreting bicarbonate brought about by switching to β-intercalated cells. This switch enables kidneys to secrete bicarbonate and conserve H^+ ions.

Buffer systems in acid excretion

Two buffer systems are involved in acid excretion: the titratable acids, such as phosphate, and the ammonia system. Each system is responsible for excreting about half of the daily acid load of 50 to 100 mmol under physiological conditions (see Fig. 27.15).

Titratable acid

A titratable acid is a filtered buffer substance having a conjugate anion that can be titrated within the pH range occurring physiologically in the urine. Phosphoric acid (pK_a 6.8) is the usual titratable urinary buffer. Hydrogen ions bind to the conjugate anions of the titratable acids and are excreted in the urine. For each hydrogen ion excreted in this form, a bicarbonate ion is regenerated within the cell and returned to the blood (see Fig. 27.15).

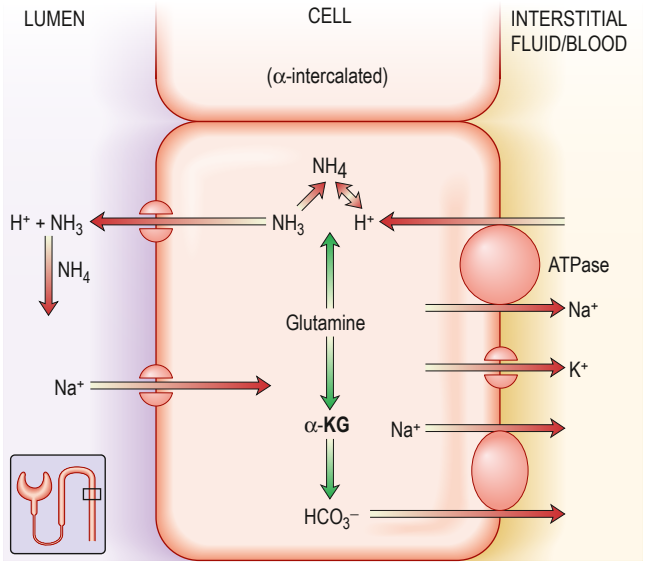

Fig. 27.16 The ammonia buffering system in the kidney. All ammonia used to buffer H^+ in the collecting duct is synthesized in the proximal convoluted tubule, and glutamine is the main source of this ammonia. As glutamine is metabolized, α-ketoglutarate (α-KG) is formed, which ultimately breaks down to bicarbonate that is then secreted into the peritubular fluid at an Na^+–HCO_3^- co-transporter.

Ammonium (NH_4^+)

In the setting of metabolic acidosis, titratable acids cannot increase significantly because the availability of titratable acid is fixed by the plasma concentration of the buffer and by the GFR. The ammonia buffer system, by contrast, can increase several hundred-fold when necessary. Consequently, impaired renal excretion of hydrogen ions is always associated with a defect in ammonium excretion (Fig. 27.16).

All ammonia used to buffer urinary hydrogen ions in the collecting tubule is synthesized in the proximal convoluted tubule. Glutamine is the primary source of ammonia. It undergoes deamination catalyzed by glutaminase, resulting in α-ketoglutaric acid (see Fig. 27.16) and ammonia. In the collecting duct, NH_3 reacts with the hydrogen ions secreted by the tubular cells to form ammonium. As ammonium (NH_4) is not lipid soluble, it is trapped in the lumen and excreted in the urine as ammonium chloride. Two conditions predominantly promote ammonia synthesis by the proximal tubular cell: systemic acidosis and hypokalaemia.

Aetiology of acid–base disturbance

Acid–base disturbance may be caused by:

- abnormal CO_2 removal in the lungs ('respiratory' acidosis and alkalosis)
- abnormalities in the regulation of bicarbonate and other buffers in the blood ('metabolic' acidosis and alkalosis).

Both may, and usually do, coexist. For instance, metabolic acidosis causes hyperventilation (via medullary), leading to increased removal of CO_2 in the lungs and partial compensation for the acidosis. Conversely, respiratory acidosis is accompanied by renal bicarbonate retention and a compensatory metabolic alkalosis. The situation is even more complex if a patient has both respiratory disease and a primary metabolic disturbance.

Box 27.24 Changes in arterial blood gases

	pH	P_aCO_2	HCO_3^-
Respiratory acidosis	N or ↓	↑↑	↑ (compensated)
Respiratory alkalosis	N or ↑	↓↓	↓ (slight)
Metabolic acidosis	N or ↓	↓	↓↓
Metabolic alkalosis	N or ↑	↑ (slight)	↑↑

Diagnosis

Clinical history and examination usually point to the correct diagnosis. Box 27.24 shows the typical blood changes, but in complicated patients the acid–base nomogram (Fig. 27.17) may be used to interpret the pH, P_aCO_2, and [HCO_3^-] measured in blood. If the values from a patient lie in one of the bands in the diagram, it is likely that only one abnormality is present. For example, if the P_aCO_2 is high (indicated by the curved lines running diagonally across the nomogram), a primary respiratory acidosis is present due to a failure to excrete CO_2. In this context, a normal [HCO_3^-] indicates the lack of metabolic compensation; consequently the pH remains abnormally low (typically seen in an acute respiratory acidosis before time has allowed metabolic compensation to occur). Rising serum [HCO_3^-] caused by metabolic compensation results in a move upwards and rightwards along the curved line; the pH normalizes but both P_aCO_2 and [HCO_3^-] remain abnormal (a chronic, or compensated respiratory acidosis).

Respiratory acidosis and alkalosis

Respiratory acidosis

This is caused by retention of CO_2, commonly seen in chronic obstructive pulmonary disease (COPD). The P_aCO_2 and [H^+] rise. Renal retention of bicarbonate may partly compensate, returning the [H^+] towards normal).

Respiratory alkalosis

Increased removal of CO_2 is caused by hyperventilation, so there is a fall in P_aCO_2 and [H^+].

Metabolic acidosis and alkalosis

Metabolic acidosis

This is due to the accumulation of any acid other than carbonic acid, and there is a primary decrease in the plasma [HCO_3^-]. Several disorders can lead to metabolic acidosis: acid administration, acid generation (e.g., lactic acidosis during shock or cardiac arrest), impaired acid excretion by the kidneys, or bicarbonate losses from the gastrointestinal tract or kidneys. Calculation of the plasma anion gap is extremely useful in narrowing this differential diagnosis.

Anion gap

The first step is to identify whether the acidosis is due to primary losses of bicarbonate, or addition of another acid. (Because HCO_3^- and Cl^- are the primary anions in blood, retention of $NaHCO_3^-$ is the physiological equivalent of retention of H^+Cl^-; Cl^- accumulates as HCO_3^- is lost, in order to maintain electrical neutrality.) Identification of whether the primary metabolic disturbance relates to Cl^-/HCO_3^- or another acid is achieved by calculation of the anion gap.

- The normal cations present in plasma are Na^+, K^+, Ca^{2+}, and Mg^{2+}.

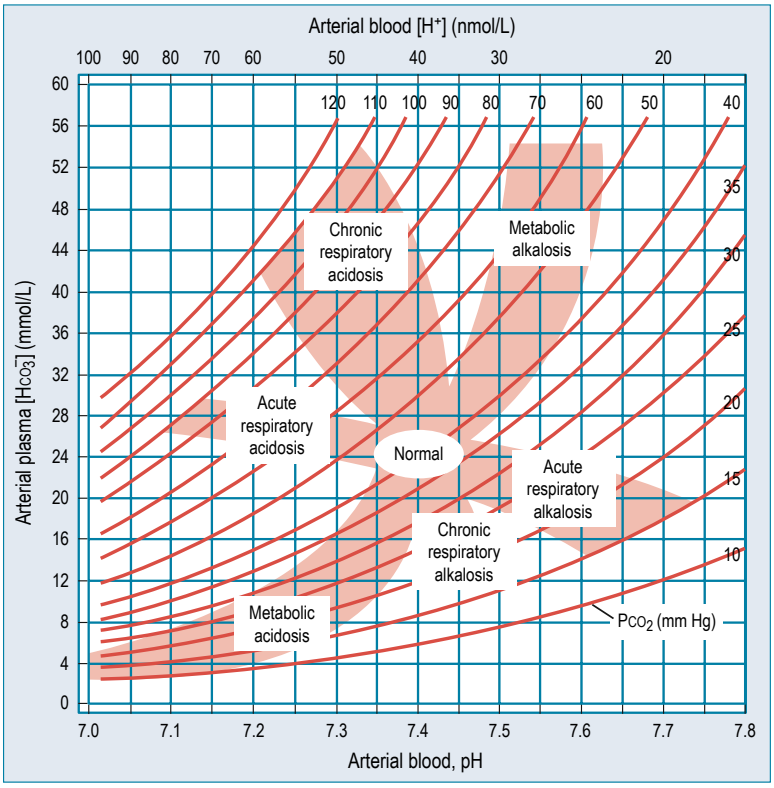

Fig. 27.17 The acid–base nomogram. This was derived from a large number of observations in patients with 'pure' respiratory or metabolic disturbances. The bands show the 95% confidence limits representing the individual varieties of acid–base disturbance. The curved lines represent the pCO_2. The central white box shows the approximate limits of arterial pH and PCO_2 in normal individuals.

- The normal anions present in plasma are Cl^-, HCO_3^- and negative charges present on albumin, phosphate, sulphate, lactate, and other organic acids.
- The sums of the positive and negative charges are equal.
- Measurement of plasma [Na^+], [K^+], [Cl^-], and [HCO_3^-] is usually easily available.

As there are more unmeasured anions than cations, the ***normal anion gap*** is 12 to 16 mmol/L, although calculations with more sensitive methods place this at 3 to 9 mmol/L. Albumin normally makes up the largest portion of these unmeasured anions. As a result, a fall in the plasma albumin concentration from the normal value of about 40 to 20 g/L may reduce the anion gap by as much as 6 mmol/L because each 1 g/L of albumin has a negative charge of 0.2 to 0.28 mmol/L.

Metabolic acidosis with a normal anion gap

If the anion gap is normal in the presence of acidosis, this suggests that H^+Cl^- is being retained or that $Na^+HCO_3^-$ is being lost. Causes of a normal-anion-gap acidosis are given in **Box 27.25**. In these conditions, plasma bicarbonate decreases and is replaced by chloride to maintain electroneutrality. Consequently, these disorders are sometimes referred to collectively as hyperchloraemic acidosis.

Renal tubular acidosis

The term 'renal tubular acidosis' (RTA) refers to systemic acidosis caused by impairment of the ability of the renal tubules to maintain acid–base balance. In patients with RTA, urinary pH is >5.5, even in the face of low blood pH, representing an inability to excrete adequate amounts of acid to maintain a normal blood pH.

? Box 27.25 Causes of metabolic acidosis with a normal anion gap

Increased gastrointestinal bicarbonate loss
- Diarrhoea
- Ileostomy
- Ureterosigmoidostomy

Increased renal bicarbonate loss
- Acetazolamide therapy
- Proximal (type 2) renal tubular acidosis
- Hyperparathyroidism
- Tubular damage, e.g., drugs, heavy metals, paraproteins

Decreased renal hydrogen ion excretion
- Distal (type 1) renal tubular acidosis
- Type 4 renal tubular acidosis (aldosterone deficiency)

Increased HCl production
- Ammonium chloride ingestion
- Increased catabolism of lysine, arginine

This group of disorders is uncommon and only rarely a cause of significant clinical disease.

Type 4 renal tubular acidosis

This results from a deficiency or unresponsiveness to aldosterone and, as such, type 4 RTA is also called 'hyporeninaemic hypoaldosteronism'. This is the most common form of RTA. The cardinal features are hyperkalaemia and acidosis occurring in a patient with mild CKD, usually caused by tubulointerstitial disease (e.g., reflux nephropathy) or diabetes. Hyperkalaemia maintains the acidosis through impairment of ammonia production in the

Box 27.26 Features of type 4 renal tubular acidosis (hyporeninaemic hypoaldosteronism)

- Hyperkalaemia (in the absence of drugs known to cause hyperkalaemia)
- Low plasma bicarbonate and hyperchloraemia
- Normal adrenocorticotrophic hormone (ACTH) stimulation test
- Low basal 24 h urinary aldosterone
- Subnormal response of plasma renin and plasma aldosterone to stimulation: samples taken over 2 h supine and again after 40 mg furosemide (80 mg if creatinine >120 μmol/L) and 4 h upright posture
- Correction of hyperkalaemia by fludrocortisone 0.1 mg daily

proximal tubule leading to a reduction in net acid excretion. Gordon's syndrome (see 'Gordon's syndrome [familial hyperkalaemic hypertension, pseudohypoaldosteronism type 2]' section) shares biochemical abnormalities but differs in having normal GFR and hypertension. Plasma renin and aldosterone are found to be low, even after measures that would normally stimulate their secretion. Features of type 4 RTA are shown in **Box 27.26**. An identical syndrome is caused by chronic ingestion of NSAIDs, which impair renin and aldosterone secretion. Treatment is with fludrocortisone, sodium bicarbonate, diuretics or gut-acting potassium binders, or a combination of these. Resolution of hyperkalaemia may correct the metabolic acidosis through increased ammonium excretion. Dietary potassium restriction alone is ineffective.

Type 3 renal tubular acidosis

This condition is vanishingly rare, and represents a combination of type 1 and type 2 RTA. Inherited type 3 RTA is caused by mutations resulting in carbonic anhydrase type II deficiency, which is characterized by osteopetrosis, RTA of mixed type, cerebral calcification, and learning difficulty.

Type 2 ('proximal') renal tubular acidosis

This is very rare in adult practice. It is caused by failure of sodium bicarbonate reabsorption in the proximal tubule. The cardinal features are acidosis, hypokalaemia, the inability to lower the urine pH below 5.5 despite systemic acidosis, and the appearance of bicarbonate in the urine despite a subnormal plasma bicarbonate. This disorder normally occurs as part of a generalized tubular defect ***(Fanconi's syndrome)***, together with other features of proximal tubular reabsorption such as glycosuria and amino-aciduria. Inherited forms of isolated type 2 RTA are described as both autosomal dominant and recessive patterns of inheritance, where putative mutations are in the Na^+–H^+ antiporter in the apical membrane and Na^+–HCO_3^- co-transporter in the basolateral membrane of proximal tubular cells, respectively. Treatment is with sodium bicarbonate; massive doses may be required to overcome the renal 'leak'.

Type 1 ('distal') renal tubular acidosis

This is due to a failure of H^+ excretion in the distal tubule (**Box 27.27**). It consists of:

- acidosis
- hypokalaemia (few exceptions)
- inability to lower the urine pH below 5.3 despite systemic acidosis
- low urinary ammonium production.

These features may be present only in the face of increased acid production, hence the need for an acid load test in diagnosis (**Box 27.28**). Other features include:

- low urinary citrate (owing to increased citrate absorption in the proximal tubule, where it can be converted to bicarbonate)

Box 27.27 Causes of type 1 distal renal tubular acidosis

Primary
- Idiopathic
- Genetic
- Marfan's syndrome
- Ehlers–Danlos syndrome
- Sickle cell anaemia

Nephrocalcinosis
- Chronic hypercalcaemia
- Medullary sponge kidney

Hypergammaglobulinaemic states
- Amyloidosis[a]
- Cryoglobulinaemia
- Chronic liver disease

Drugs and toxins
- Amphotericin B
- Lithium carbonate
- NSAIDs

[a]May also cause proximal renal tubular acidosis.

Box 27.28 Diagnosis of renal tubular acidosis

Plasma HCO_3^- < 21 mmol/L, urine pH > 5.3 = renal tubular acidosis.

Distal RTA: defect in dietary acid excretion. Urine pH always >5.5

Proximal RTA: defect in bicarbonate reabsorption. Urine pH variable

Bicarbonate infusion test (rarely performed)

Differentiates between proximal and distal RTA:
- Use a bicarbonate infusion (0.5–1 mmol/kg per hour) to raise serum bicarbonate to 18–20 mmol/L.
- If urine pH rises to >7.5 and the fractional excretion of bicarbonate (Fe HCO_3) rises to >15%, the defect is bicarbonate reabsorption and the diagnosis is proximal RTA.
- If there is little change in urine pH and fractional excretion of bicarbonate remains low, the diagnosis is distal RTA.

Acid load test (rarely performed)

Required if plasma HCO_3^- is >21 mmol/L but there is suspicion of partial RTA (e.g., nephrocalcinosis-associated diseases):
- Give 100 mg/kg ammonium chloride by mouth.
- Check urine pH hourly and plasma HCO_3^- at 3 h.
- Plasma HCO_3^- should drop below 21 mmol/L unless the patient vomits (in which case the test should be repeated with an antiemetic).
- If urine pH remains >5.3 despite a plasma HCO_3^- of 21 mmol/L, the diagnosis is confirmed.

- hypercalciuria.

These abnormalities result in osteomalacia, renal stone formation, and recurrent urinary infections:

- ***Osteomalacia*** is caused by buffering of H^+ by Ca^{2+} in bone, resulting in depletion of calcium from bone.
- ***Renal stone formation*** is caused by hypercalciuria, hypocitraturia (citrate inhibits calcium phosphate precipitation), and alkaline urine (which favours precipitation of calcium phosphate).
- ***Recurrent urinary infections*** are caused by kidney stones.

Both autosomal dominant and recessive inheritance patterns have been reported in primary distal RTA. In autosomal recessive distal RTA, a substantial proportion of patients have sensorineural deafness, and this is associated with a loss-of-function mutation in the H^+-ATPase at the apical surface of intercalated cells.

Treatment is with sodium bicarbonate, potassium supplements, and citrate. Thiazide diuretics are useful because they cause volume contraction and increased proximal sodium bicarbonate reabsorption.

Urinary anion gap

Another useful tool in the evaluation of metabolic acidosis with a normal anion gap is the urinary anion gap:

$$\text{URINARY ANION GAP} = \{\text{urinary } [Na^+] + \text{urinary } [K^+]\} - \text{urinary } [Cl^-].$$

Box 27.29 Causes of metabolic acidosis with an increased anion gap: think GOLD MARK

- Glycols (ethylene and propylene): ingestions
- Oxoproline (pyroglutamic acid): chronic paracetamol ingestion
- L-lactate: type A and type B
- D-lactate: small bowel bacterial overgrowth
- Methanol: acute ingestion (see Chapter 15, 'Methanol' section)
- Aspirin: salicylate overdose (see Chapter 15, 'Salicylates' section)
- Renal failure: accumulation of organic acids
- Ketoacidosis: diabetic, starvation, alcohol

(From Mehta AN, Emmett JB, Emmett M. GOLD MARK: an anion gap mnemonic for the 21st century. Lancet *2008; 372(9642):892).*

Here, the largest unmeasured cation is ammonium, and so raised urinary ammonium will result in a reduced urinary anion gap. This calculation can be used to distinguish between

- the normal-anion-gap acidosis caused by diarrhoea (or other gastrointestinal alkali loss), where the kidneys function appropriately, secreting lots of ammonium (also driven by hypokalaemia), and the urinary anion gap is reduced
- the normal-anion-gap acidosis caused by distal RTA where impaired acid secretion in the distal tubule prevents generation of ammonium and the anion gap is normal or increased.

In both disorders, the plasma [K^+] is characteristically low.

Metabolic acidosis with a high anion gap

If the anion gap is increased, there is an unmeasured anion present in increased quantities. This is either one of the acids normally present in small but unmeasured quantities, such as lactate, or an exogenous acid. See later and **Box 27.29** for causes of a high-anion-gap acidosis.

Chronic kidney disease

Chronic acidosis is most often caused by CKD, in which there is a failure to excrete fixed acid. Up to 40 mmol of hydrogen ions may accumulate daily. These are buffered by bone, in exchange for calcium. Chronic acidosis is therefore a major risk factor for renal osteodystrophy and hypercalciuria.

Chronic acidosis has also been shown to be a risk factor for muscle wasting in kidney failure, and may also contribute to the inexorable progression of some types of kidney disease.

Kidney disease causes acidosis in several ways:

- Reduction in the number of functioning nephrons from any cause decreases the capacity to excrete ammonia and H^+ in the urine.
- Tubular disease in particular may cause bicarbonate wasting, so acidosis is a particular feature of those types of CKD in which the distal tubules are particularly affected such as reflux nephropathy and chronic obstructive uropathy.

Uraemic acidosis should be corrected because of the effects on growth, muscle turnover, and bones. Oral sodium bicarbonate 2 to 3 mmol/kg daily is usually enough to maintain serum bicarbonate above 20 mmol/L but may contribute to sodium overload. Calcium carbonate improves acidosis and also acts as a phosphate binder and calcium supplement, and is commonly used. Acidosis in end-stage kidney disease is usually fully corrected by adequate dialysis.

Lactic acidosis

Increased lactic acid production occurs when cellular respiration is abnormal, because of either a lack of oxygen in the tissues ***('type A')*** or a metabolic abnormality, such as that induced by drugs such as metformin ***('type B')***. The most common cause in clinical practice is type A lactic acidosis, occurring in septic or cardiogenic shock. Significant acidosis can occur despite a normal blood pressure and P_aCO_2, owing to splanchnic and peripheral vasoconstriction. Acidosis worsens cardiac function and vasoconstriction further, contributing to a downward spiral and fulminant production of lactic acid.

Raised serum D-lactate occurs with fermentation of glucose by abnormal bowel flora in the short gut syndrome.

Ketoacidosis

See also Chapter 35. There is a high-anion-gap acidosis due to the accumulation of acetoacetic and hydroxybutyric acids, owing to increased production and some reduced peripheral utilization in diabetic ketoacidosis. Ketoacidosis without hyperglycaemia occurs in starvation and after alcohol overdose.

Mixed metabolic acidosis

Both types of acidosis may coexist. For instance, cholera would be expected to cause a normal-anion-gap acidosis owing to massive gastrointestinal losses of bicarbonate, but the anion gap is often increased owing to kidney failure and lactic acidosis as a result of hypovolaemia.

To help ascertain if there is an additional normal-anion-gap acidosis as well as, for example, a ketoacidosis, the delta anion gap can be calculated. This is the difference between the upper reference value of the anion gap and the calculated anion gap. This value should equal the fall in the bicarbonate concentration from the lower limit of normal. If the bicarbonate is significantly ***lower*** than predicted (>5 mmol/L), then an additional normal-anion-gap ***acidosis*** must be present. Similarly, if the bicarbonate is >5 mmol/L ***higher*** than expected, an additional normal-anion-gap ***alkalosis*** must be present.

Clinical features of acidosis

Clinically, the most obvious effect is stimulation of respiration, leading to the clinical sign of 'air hunger', or Kussmaul respiration.

Acidosis increases delivery of oxygen to the tissues by shifting the oxyhaemoglobin dissociation curve to the right, but it also leads to inhibition of 2,3-BPG production, which returns the curve towards normal. Cardiovascular dysfunction is common in acidotic patients, although it is often difficult to dissociate the numerous possible causes of this. Acidosis is negatively inotropic. Severe acidosis also causes venoconstriction, resulting in redistribution of blood from the peripheries to the central circulation, and increased systemic venous pressure, which may worsen pulmonary oedema caused by myocardial depression. Arteriolar vasodilatation also occurs, further contributing to hypotension.

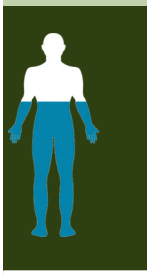
Cerebral dysfunction is variable. Severe acidosis is often associated with confusion and fits, but numerous other possible causes are usually present.

As mentioned earlier, acidosis stimulates potassium loss from cells, which may lead to potassium deficiency if kidney function is normal, or to hyperkalaemia if renal potassium excretion is impaired.

General treatment of acidosis

Treatment should be aimed at correcting the primary cause. In lactic acidosis caused by poor tissue perfusion ('type A'), treatment should be aimed at maximizing oxygen delivery to the tissues by protecting the airway, and improving breathing and circulation. This may require inotropic agents, mechanical ventilation, and invasive monitoring. In other forms of acidosis, treatment is directed at the underlying disorder—for example:

- insulin in diabetic ketoacidosis
- treatment of methanol and ethylene glycol poisoning with ethanol



- removal of salicylate by dialysis.

The question of whether severe acidosis should be treated with bicarbonate is controversial:

- Rapid correction of acidosis may result in tetany and fits owing to a rapid decrease in ionized calcium.
- Administration of sodium bicarbonate (8.4%) provides 1 mmol/mL of sodium, which may lead to extracellular volume expansion, exacerbating pulmonary oedema.
- Bicarbonate therapy increases CO_2 production and will therefore correct acidosis only if ventilation can be increased to remove the added CO_2 load.
- The increased amounts of CO_2 generated may diffuse more readily into cells than bicarbonate, worsening intracellular acidosis.

Administration of sodium bicarbonate (50 mmol, as 50 mL of 8.4% sodium bicarbonate i.v.) is still occasionally given during cardiac arrest and is often necessary before arrhythmias can be corrected. Correction of hyperkalaemia associated with acidosis is also of undoubted benefit. In other situations, there is no clinical evidence to show that correction of acidosis improves outcome, but sodium bicarbonate is sometimes administered in severe acidosis using intravenous 1.26% (150 mmol/L) bicarbonate infused over 2 to 3 hours with electrolyte and pH monitoring.

Metabolic alkalosis

Metabolic alkalosis is common, comprising half of all the acid–base disorders in hospitalized patients, with most cases associated with vomiting, hypovolaemia, the use of diuretics, and nasogastric suction. The mortality associated with metabolic alkalosis is substantial; the mortality rate is 45% in patients with an arterial pH of 7.55 and 80% when the pH is over 7.65. Although this relationship is not necessarily causal, severe alkalosis should be viewed with concern.

Classification and definitions

Metabolic alkalosis has been classified on the basis of underlying pathophysiology (**Box 27.30**):

- ***chloride depletion***, the most common cause, which can be corrected without potassium repletion
- ***potassium depletion***, usually with mineralocorticoid excess
- metabolic alkalosis due to ***both potassium and chloride depletion***.

? Box 27.30 Causes of metabolic alkalosis

Chloride depletion
- Gastric losses: vomiting, mechanical drainage, bulimia
- Chloruretic diuretics, e.g., bumetanide, furosemide, chlorothiazide, metolazone
- Diarrhoeal states: villous adenoma, congenital chloridorrhoea
- Cystic fibrosis (high sweat chloride)

Potassium depletion/ mineralocorticoid excess
- Primary aldosteronism
- Secondary aldosteronism
- Apparent mineralocorticoid excess: primary deoxycorticosterone excess: 11α- and 17α-hydroxylase deficiencies
- Drugs: liquorice (glycyrrhizic acid) as a confection or flavouring, carbenoxolone
- Liddle's syndrome
- Bartter's and Gitelman's syndromes and their variants
- Laxative abuse, clay ingestion

Hypercalcaemic states
- Hypercalcaemia of malignancy
- Acute or chronic milk–alkali syndrome

Others
- Amoxicillin or penicillin therapy
- Bicarbonate ingestion: massive or smaller ingestion with kidney disease
- Recovery from starvation
- Hypoalbuminaemia

Chloride may be lost from the gut, kidney, or skin. The loss of gastric fluid rich in acid results in alkalosis because bicarbonate generated during the production of gastric acid returns to the circulation. In Zollinger–Ellison syndrome (see Chapter 22) or gastric outflow obstruction, these losses can be massive. Although sodium and potassium loss in the gastric juice is variable, the obligate urinary loss of these cations is intensified by bicarbonaturia, which occurs during disequilibrium.

Chloruretic agents including most diuretics directly produce loss of chloride, sodium, and fluid in the urine. These losses in turn promote metabolic alkalosis by several mechanisms:

- Diuretic-induced increases in sodium delivery to the distal nephron enhance potassium and hydrogen ion secretion.
- Extracellular volume contraction stimulates renin and aldosterone secretion, which blunts sodium losses but accelerates potassium and hydrogen ion secretion.
- Potassium depletion augments bicarbonate reabsorption in the proximal tubule and stimulates ammonia production, which in turn will increase urinary net acid excretion.

Urinary losses of chloride exceed those for sodium and are associated with alkalosis, even when potassium depletion is prevented. The cessation of events that generate alkalosis is not necessarily accompanied by resolution of the alkalosis. A widely accepted hypothesis for the maintenance of alkalosis is chloride depletion rather than volume depletion. Although normal functioning of the proximal tubule is essential for bicarbonate absorption, the collecting duct appears to be the major segment of the nephron for altered electrolyte and proton transport in both maintenance and recovery from metabolic alkalosis. During maintenance, the α-intercalated cells in the CCD do not secrete bicarbonate because insufficient chloride is available for bicarbonate exchange. When chloride is administered and luminal or cellular chloride concentration increases, bicarbonate is promptly excreted and alkalosis is corrected.

Metabolic alkalosis in ***hypokalaemia*** is generated primarily by an increased intracellular shift of hydrogen ion, causing intracellular acidosis. Potassium depletion is also associated with enhanced ammonia production and increased obligate net acid excretion. This is the corollary to the acidosis seen with hyperkalaemia in type 4 RTA. Infusion of potassium alone can correct systemic alkalosis and intracellular acidosis as cells exchange extracellular potassium for intracellular hydrogen, which can then buffer extracellular bicarbonate.

Milk–alkali syndrome, in which both bicarbonate and calcium are ingested, produces alkalosis by vomiting, calcium-induced bicarbonate absorption, and reduced GFR.

Clinical features

The symptoms of metabolic alkalosis *per se* are difficult to separate from those of chloride, volume, or potassium depletion. Tetany, apathy, confusion, drowsiness, cardiac arrhythmias, and neuromuscular irritability are common when alkalosis is severe. The oxyhaemoglobin dissociation curve is shifted to the left. Respiration may be depressed.

Management

Chloride-responsive metabolic alkalosis

Although replacement of the chloride deficit is essential in chloride depletion states, selection of the accompanying cation—sodium or potassium—is dependent on the assessment of extracellular fluid volume status (see Fig. 27.1), the presence or absence of associated potassium depletion, and the degree and reversibility of any

depression of GFR. Since chloride and extracellular volume depletion coexist, isotonic (0.9%) saline solution is generally appropriate therapy. If kidney function is normal, bicarbonate will be excreted, and metabolic alkalosis will be rapidly corrected as soon as chloride is made available.

Chloride-resistant metabolic alkalosis

Metabolic alkalosis due to potassium depletion is managed by correction of the underlying cause (see 'Hypokalaemia' section). Mild to moderate alkalosis requires oral potassium chloride administration. However, the presence of a cardiac arrhythmia or generalized weakness requires intravenous potassium chloride, typically alongside chloride administration in the form of 0.9% saline with added potassium chloride (KCl).

CORE SKILLS AND KNOWLEDGE

Neurology is a large subject covering many conditions that have serious effects on the daily lives of patients and their families. We are now in an exciting era of rapid therapeutic expansion in neurology, much of which is based on insights from basic neuroscience, but multidisciplinary long-term coordinated care remains essential to improve the lives of patients. Neurology spans conditions as diverse as cognitive disorders involving higher-level mental functioning, to disorders of peripheral nerve and skeletal muscle. Many neurological disorders affect multiple domains both within and outside the nervous system, and cause complex, interacting problems that a patient and their care team must grapple with. It remains a firmly clinical specialty, and a good neurologist has mastery of clinical skills but more importantly needs to forge a close partnership with the patient.

Key skills in neurology include:

- Distilling information gathered from careful history-taking and physical examination into a well-defined clinical syndrome, suggesting likely diagnoses and a rational approach to investigation
- Managing neurological emergencies including seizures, coma, central nervous system infection, spinal cord compression, and acute neuromuscular weakness
- Managing disability and complex, chronic, or progressive disease, working with other health professionals and in partnership with patients to help them achieve good quality of life and effective symptom control.

Opportunities for learning neurology include attending ward rounds on a stroke unit or with acute neurology teams, practising neurological examination with consenting patients, attending a range of general and specialist neurology clinics, and observing specialist neurological investigations such as electrophysiology or lumbar puncture.

CLINICAL SKILLS

Pattern recognition in neurology—interpretation of history, symptoms, and examination—is very reliable. Practical experience is vital. There are three critical questions in formulating a clinical diagnosis:

- What is/are the site(s) of the lesion(s)?
- What is the likely pathology?
- Does a recognizable disease fit this pattern?

History

Neurological differential diagnosis relies heavily on a carefully taken history. Patterns emerge from the history that will suggest the likely causes, site and extent of disease. Most of the information will emerge from listening to the patient's narrative account. A collateral history is often vital in cases where the patient has cognitive impairment or has had altered awareness. An approach to history-taking in neurology is shown in **Box 28.1**.

Examination

If the neurological history focuses primarily on the likely *cause* of the neurological disease, the examination focuses on the likely *anatomical location* of the lesion. The diagram above illustrates a basic approach to focused examination of the nervous system with key signs to elicit or exclude.

An overview of the neurological examination is provided in **Boxes 28.2 and 28.3**; more details are provided in sections covering individual components of the nervous system, below. A focused examination should be guided by the history, and much useful information can be gained simply from observing the patient. It is necessary to practise the neurological examination in order to become deft and appreciate the range of normal.

Putting it all together

Information from the history and examination should be used together in order to answer the questions in **Box 28.4**, which will lead to a diagnostic formulation, encompassing both the anatomical location and the possible underlying aetiology. Investigations should be directed at refining the clinical impression, which becomes the basis for transfer of information and management.

Box 28.1 Taking a history in neurology

Presenting symptoms

- Pattern—constant, episodic, progressive
- Time course—hyperacute, acute, subacute, chronic
- Onset—sequence of events when symptoms first began, or each time they recur
- Duration of symptoms, and any previous episodes
- Triggers—warm baths may worsen symptoms caused by demyelination; cold wind and chewing can trigger trigeminal neuralgia; dietary stimuli, tiredness, or stress can trigger migraines

Screening questions for other relevant features

- Systemic symptoms—fever (may suggest infection), weight loss, and anorexia (may suggest malignancy with paraneoplastic neurological phenomena)
- Raised intracranial pressure symptoms—headaches worse on waking, lying flat, or Valsalva manoeuvre; vomiting; diplopia
- Visual symptoms—blurring, diplopia, flashing lights
- Bulbar symptoms—changes in speech and difficulty swallowing
- Motor symptoms—weakness, stiffness, abnormal gait, tremor
- Sensory symptoms—loss of sensation, neuropathic ('tingling' or 'electric') pain
- Loss of coordination—dizziness, staggering gait, loss of fine motor control, altered speech
- Autonomic symptoms—postural dizziness, faecal incontinence, urinary retention
- Loss of consciousness—features suggesting a neurological cause include aura, muscle jerking, tongue biting, incontinence, and a drowsy post-ictal phase.
- Disturbance of higher functions—personality change, cognitive decline, loss of executive control, disinhibition, psychiatric symptoms

Past medical history

- Atherosclerotic risk factors—hypertension, diabetes, other cardiovascular disease
- Risk factors for embolic disease—atrial fibrillation, patent foramen ovale
- Diabetes—time since diagnosis, degree of glycaemic control, presence of other complications
- Malignancies, systemic inflammatory disorders, immunosuppressive conditions, e.g., HIV
- History of anxiety, depression, or other psychiatric disorders

Box 28.1 Taking a history in neurology—cont'd

Medication history
- Use of neuroactive medications, for instance antipsychotics

Family history
- History of inherited neurological disorders such as Huntington's chorea, myotonic dystrophy, and Charcot–Marie–Tooth disease in close relatives

Social history
- Occupation
- Family circumstances, caring responsibilities

Disability and effect on lifestyle
- Mobility
- Ability to perform activities of daily living
- Current provision of carers

Lifestyle factors
- Smoking, alcohol consumption, use of illegal drugs

Safety
- Do they drive?
- What is their employment? Might their illness pose a risk to themselves or others?
- Do they have caring responsibilities? Is support needed for any dependents or children?
- Do they take baths or go swimming alone? Any other potentially risky leisure activities?

General features
- Level of consciousness
- Affect
- Obvious deformity or disability
- Signs of systemic illness e.g., sepsis

Olfaction (CN I)

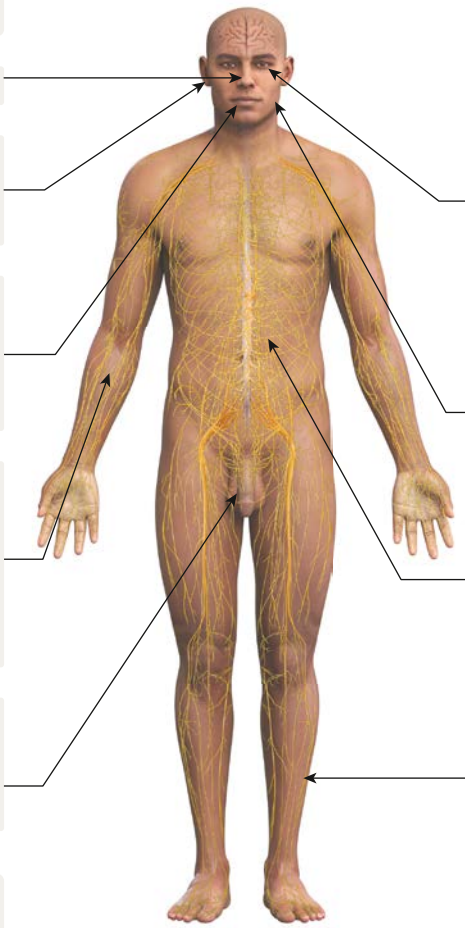
Hearing (CN VIII)
- Rinne's test
- Weber's test

Lower cranial nerves
- Speech
- Swallow
- Gag reflex
- Tongue

Upper limbs
- Posture (extensor, flexor)
- Fasciculation, wasting
- Tone, power
- Sensation
- Coordination
- Reflexes

Sphincter control (cord lesion, cauda equina)
- Urinary retention
- Faecal incontinence

Gait
- Hemiplegic (e.g., stroke)
- Spastic (e.g., cord lesions)
- High stepping (peripheral neuropathy)
- Waddling (myopathic)
- Shuffling (Parkinsonism)
- Ataxic (cerebellar)



Speech
- Language problems (aphasia)
  - Expressive (Broca's)
  - Receptive (Wernicke's)
- Voice problems (dysarthria, dysphonia)
  - Bulbar palsy (LMN)
  - Pseudobulbar palsy (UMN)

Eyes
- Visual fields
- Acuity, colour (CN II)
- Movements (CN III, IV, VI)
- Light reflex, accommodation (CN III)
- Ptosis (CN III)

Face
- Sensation (CN V)
- Movements (CN VII)
  - Whole face (LMN)
  - Upper face spared (UMN)

Trunk
- Dermatomal rash (shingles)
- Sensory level (spinal cord lesion)

Lower limbs
- Posture (extensor, flexor)
- Fasciculation, wasting
- Tone, power
- Sensation (dermatomes)
- Coordination
- Reflexes
- Planters

Movements
- Slow, hesitant (Parkinsonism)
- Dance-like, writhing (chorea)
- Repetitive, absent (epileptiform)

Higher cortical functions
- Aphasia (impaired naming)
- Agnosia (impaired recognition)
- Apraxia (impaired skillful movements)
- Loss of executive function
- Personality change

BACKGROUND

Neurology is a broad clinical specialty that requires good clinical skills and a rational diagnostic approach to link underlying pathophysiological processes with a diverse range of clinical syndromes. The skills required cannot be replaced with investigations or imaging alone. Many neurological diagnoses are life-changing chronic or progressive conditions, and some are life-limiting. Neurologists are privileged to look after patients facing these challenges, to hear their stories, to treat where possible, and to help people through the journey where treatments are limited. The value of careful listening and empathy cannot be over-emphasized, both when gathering information to reach a diagnosis, and when working to achieve the best possible therapeutic outcome.

We are entering an era of burgeoning therapeutics, and many conditions previously regarded as devastating now have effective treatments. Many other treatments will emerge in the coming decades. It is an exciting time to work in the field, and remaining up-to-date is vital to ensure the best possible outcome for patients. Disorders causing significant cognitive or physical disability require close cooperation with allied health professionals, primary care, psychiatrists, and community services.

Neurology covers the whole spectrum of healthcare, from primary care where many common conditions (such as headache) are initially managed, to acute inpatient settings, outpatient clinics, day-care units, and more highly specialized tertiary and quaternary care units. Some 17% of general practitioner consultations and 10% of emergency department visits are for neurological symptoms; 19% of all hospital admissions are for neurological disorders and 25% of chronic disability in adults below the age of 64 is due to neurological disease (**Box 28.5**).

FUNCTIONAL NEUROANATOMY

Neuron and synapse

The neuron is the functional unit of the entire nervous system (**Fig. 28.1**). Its cell body and axon terminate in a synapse. The size and type of each group of neurons vary. A thoracic spinal cord α-motor neuron has an axonal length of more than 1 metre and innervates between several hundred and 2000 muscle fibres in one leg—a motor unit. By contrast, some spinal or intracerebral interneurons have axons shorter than 100 μm, terminating on one neuronal cell body.

Neurotransmitters

Neurotransmitters are excitatory (acetylcholine, noradrenaline [norepinephrine], adrenaline [epinephrine], 5-hydroxytryptamine [5-HT, serotonin], dopamine, glutamate, and aspartate) or inhibitory (γ-aminobutyric acid [GABA], histamine and glycine). Neuropeptides, such as vasopressin, adrenocorticotrophic hormone (ACTH), substance P, and opioid peptides, as well as the purines adenosine triphosphate (ATP) and adenosine monophosphate (AMP) are both excitatory and inhibitory.

Synaptic transmission is mediated by neurotransmitters released by action potentials passing down an axon. Neurotransmitters activate postsynaptic receptors and are removed by transporter proteins. The neurotransmitter–receptor reaction increases ionic permeability and propagates a further action potential. Axonal electrical activity and synaptic chemical release are the basis of neurological function.

Box 28.2 Ten-part neurological examination

1. ***State of consciousness, arousal, appearance***
2. ***Mental state, attitude, insight***
3. ***Cognitive function***—orientation, recall, level of intellect, language, other cortical problems, e.g., apraxia
4. ***Gait and balance tests, including tandem walking and Romberg's test***
5. ***Neck***—stiffness, palpation, and auscultation of carotids
6. ***Cranial nerves*** (see **Box 28.6**)
   - I. Ask about sense of smell
   - II. Check visual acuity, fields, pupillary light reflexes, and accommodation
   - III, IV, VI. Eye movements (cross/H)—smooth pursuit and saccades
   - V. Check facial sensation in 3 divisions; assess power of muscles of mastication
   - VII. Observe facial expression and test facial muscle strength
   - VIII. Check hearing; Rinne's and Weber's tests
   - IX–X. Say 'ah' and observe palatal movement; gag reflex only if necessary
   - XI. Check sternocleidomastoid (turn head against resistance) and trapezius (shrug) power
   - XII. Protrude tongue and move from side to side
7. ***Motor system***

   Upper limbs:
   - Wasting and fasciculation
   - Posture of arms: drift, rebound, tremor
   - Tone: spasticity, clonus, extrapyramidal rigidity
   - Power: 0–5 scale (see **Box 28.3**)
   - Tendon reflexes: + or ++ normal; +++ pathological; 0 = absent with reinforcement

   Thorax and abdomen:
   - Respiration
   - Thoracic and abdominal muscles

   Lower limbs:
   - Wasting and fasciculation
   - Tone, power, and tendon reflexes
   - Plantar responses
8. ***Coordination and fine movements***

   Finger-nose and heel-shin testing; repetitive movements
9. ***Sensory system***
   - Chart area of sensory loss; start in area with abnormal sensation and move stimulus towards normal area to demarcate boundaries

   Posterior columns:
   - Vibration (128 Hz tuning fork)
   - Joint position—small movements of distal interphalangeal joints in toes and fingers
   - Light touch—use cotton wool

   Spinothalamic tracts:
   - Pain: use a split orange-stick or a single-use pin (never a hypodermic needle)

   Temperature: warm and cold objects

   Cortical sensory loss—dysgraphaesthesia and astereognosis
10. ***Specialized tests*** as required e.g., Hallpike for vertigo, Phalen's test, and so on

Box 28.3 Muscle power: the Medical Research Council (MRC) scale

Grade	Definition
5	Normal power
4	Active movement against gravity and resistance
3	Active movement against gravity only
2	Active movement with gravity eliminated
1	Flicker of contraction
0	No contraction

Box 28.4 Formulating a diagnosis in neurology

Is the lesion global or focal?
- **Global** lesions affect all (or most) brain functions, and typically affect cognition and consciousness
- **Focal** lesions affect one region of the body and resultant signs may be asymmetric

What is the timescale?
- **Immediate onset** symptoms are usually vascular (ischaemia or haemorrhage), or electrical (epilepsy) in aetiology
- **Rapidly progressive** symptoms (over days) may represent infective (e.g., meningitis) or inflammatory (e.g., demyelinating) disease
- **Slowly progressive** symptoms tend to be caused by degenerative diseases

Do motor lesions affect the upper or the lower motor neuron?
- **Upper motor neuron (UMN) signs** include increased tone (spasticity), weakness, increased reflexes, and upgoing plantars—a 'pyramidal' pattern of weakness where stronger muscles (upper limb flexors, lower limb extensors) overwhelm weaker ones
- **Lower motor neuron (LMN) signs** include flaccid weakness, decreased or absent reflexes, wasting, and fasciculations

Where is the lesion?
- **Cerebral cortex/internal capsule:** contralateral UMN signs
- **Cerebellum:** nystagmus, impaired balance/coordination
- **Brainstem:** impaired consciousness, global signs, cranial nerve abnormalities
- **Spinal cord:** UMN paraplegia/quadriplegia with sensory level
- **Nerve root:** LMN myotomal signs; dermatomal sensory loss
- **Single peripheral nerve:** LMN signs and sensory loss according to distribution of nerve
- **Peripheral nerves, diffuse:** 'length dependent' LMN signs (worst in feet), 'glove and stocking' sensory loss
- **Neuromuscular junction/muscle:** only motor signs present. Fatiguability common, wasting and fasciculations

Is there a functional component?
- Are there elements that don't fit within standard neuroanatomical patterns of disease?
- Are there positive features of a functional component? Hoover's sign (involuntary extension of the 'paralyzed' leg when raising the other leg against resistance) or entrainment of a tremor
- Beware of searching for 'stressors' or underlying triggers for functional disease; these are not universally present and can obscure the assessment
- Functional elements commonly exist alongside organic disease

Box 28.5 UK incidence of common neurological conditions

Conditions	Events per 100 000/year
Migraine	400
Stroke	240
Dementia over age of 85	68
Epilepsy	50
Parkinson's disease	19
Severe brain injury and subdural haematoma	13
All central nervous system tumours	9
Trigeminal neuralgia	8
Meningitis	7
Multiple sclerosis	7
Myasthenia, all muscle and motor neuron disease	5

PATTERNS OF NEUROLOGICAL DISEASE

Neurological symptoms and signs suggest the area of the nervous system that is malfunctioning (e.g., aphasia—dominant frontal lobe, hemiparesis—the internal capsule, or a Bell's palsy—VIIth cranial (facial) nerve).

Focal lesions of the cortex, and lesions throughout the nervous system, cause symptoms and signs by two processes:
- ***Suppression or destruction of neurons*** and surrounding structures (Fig. 28.2). This is the most common process: part of the system simply fails to work.
- ***Synchronous discharge of neurons*** by *irritative* lesions (Fig. 28.3), for example cortical lesions, causes epilepsy, either focal or generalized.

Essential elements of neuroanatomy

For clinical purposes, the complexity of neuroanatomy must be reduced to its core elements:
- cortical regions controlling higher behaviour
- cranial nerves
- three systems of motor control:
  - corticospinal or pyramidal system
  - extrapyramidal system
  - cerebellum
- the lower motor neuron (LMN)
- sensory pathways and pain
- control of the bladder and sexual function.

CORTICAL DISEASE

The cerebral cortex plays a key role in basic movement and sensation, as well as controlling higher functions such as language, memory, learning, consciousness, and emotion. Discrete cortical lesions most commonly arise from strokes but may also be caused by a variety of other pathologies including malignant disease, localized infection, or demyelinating lesions affecting cortical connections. While many higher functions are localized within the cortex so that anatomically defined lesions cause specific pattern of disease, work on neuronal networks, functional imaging, and plasticity questions the traditional views of highly specific localization of cortical function.

Cortical disorders of communication

The concept of cerebral dominance arose from a simple observation: right-handed stroke patients with acquired language disorders had destructive lesions within the left hemisphere. Right-handed (and 70% of left-handed) people have language function on the left. More specifically, destructive lesions within the dominant frontotemporo-parietal region cause disorders of communication:
- spoken language—***aphasia***, also called ***dysphasia***
- writing—***agraphia***
- reading—acquired ***alexia***.

Aphasia

Aphasia is loss of, or defective language from damage to, the speech centres within the dominant hemisphere. Numerous varieties have been described:

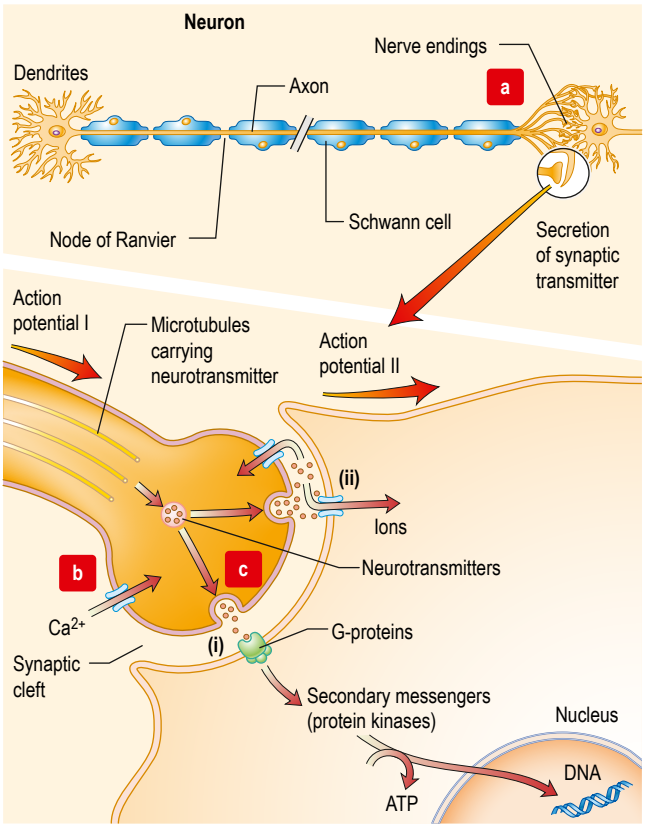


Fig. 28.1 The functional unit: neuron and neurotransmitters. (a) ***The action potential***—that is, the nerve impulse—travels down the axon. Microtubules carry neurotransmitters to nerve endings. **(b)** ***Action potential I*** depolarizes the synaptic membrane, opening voltage-gated calcium channels. **(c)** Influx of calcium ions causes vesicles to fuse with the membrane, allowing neurotransmitter binding to receptors **(i)** and activation of secondary messengers that modulate gene transcription and also open ligand-gated channels **(ii)**. This allows ions to enter, depolarize the membrane, and ***initiate action potential II***.

Site of lesion	Disorder	R	L
Frontal, either	Intellectual impairment Personality change Urinary incontinence Monoparesis or hemiparesis		
Frontal, left	Broca's aphasia		
Temporo-parietal, left	Acalculia Alexia Agraphia Wernicke's aphasia Right-left disorientation Homonymous field defect		
Temporal, right	Failure to recognize faces Homonymous field defect		
Parietal, either	Contralateral sensory loss or neglect Agraphaesthesia Homonymous field defect		
Parietal, right	Confusional states Dressing apraxia Failure to recognize faces		
Parietal, left	Limb apraxia		
Occipital/ occipitoparietal	Visual field defects Visuospatial defects Disturbances of visual recognition		

Fig. 28.2 Principal features of destructive cortical lesions in a right-handed individual.

Broca's (expressive, anterior) aphasia

Damage in the dominant frontal lobe causes reduced speech fluency with relatively preserved comprehension. The patient makes great efforts to initiate language, which becomes reduced to a few disjointed words with failure to construct sentences (sometimes described as ***telegrammatic***). Patients who recover say they knew what they wanted to say but could not get the words out.

Wernicke's (receptive, posterior) aphasia

Dominant hemisphere temporo-parietal damage leaves fluency of language unaffected but words are muddled. This varies from insertion of a few incorrect or unnecessary words into speech to a profuse outpouring of jargon (non-existent words). Severe jargon aphasia is bizarre and often mistaken for psychotic behaviour.

Patients who recover from Wernicke's aphasia say that they found speech, both their own and others', like an unintelligible foreign language—that is, incomprehensible—but they could neither stop speaking nor understand speech.

Nominal (anomic) aphasia

This means difficulty in naming objects. Naming difficulty is an early feature in all types of aphasia. This is often tested in practice by asking patient to name parts of a watch; a more sensitive test utilizes pictures to test low-frequency words, such as rhinoceros, violin, tricycle, or ladybird. Cultural and linguistic differences need to be taken into account.

Global (central) aphasia

This means the combination of the expressive problems of Broca's aphasia and the loss of comprehension of Wernicke's, with loss of both language production and understanding. It is due to widespread damage to speech areas and is the most common aphasia after a severe left hemisphere infarct. Writing and reading are also affected.

Conduction aphasia

Damage to the arcuate fasciculus, that connects Wernicke's with Broca's area, can lead to difficulty with repetition.

Site of lesion	Effects	R	L
Frontal	Focal motor seizures of contralateral limbs Conjugate deviation of head and eyes away from the lesion		
Temporal	Formed visual hallucinations Complex partial seizures Memory disturbances (e.g. *déjà vu*)		
Parietal Parieto-occipital	Focal sensory seizures of contralateral limbs Crude visual hallucinations (e.g. shapes in one part of the field)		
Occipital	Visual disturbances (e.g. flashes)		

Fig. 28.3 Effects of irritative cortical lesions.

Cortical disorders of movement

Hemiparesis

Hemiparesis describes weakness or inability to move one side of the body, and may arise from destructive lesions affecting the primary motor cortex or its main axonal connections, which run through the internal capsule, brainstem, and spinal cord.

Apraxia

Apraxia is a disorder of motor planning, affecting learned purposeful movement, and not explained by weakness or sensory loss. Dominant hemisphere lesions, particularly involving the parietal lobe, cause various types of (bilateral) ***limb apraxia***, including ***ideomotor apraxia*** (inability to imitate meaningless gestures, or to pantomime an action, such as 'pretend to brush your teeth').

More unusual forms of apraxia arise from lesions of the non-dominant hemisphere: failure to put on clothing correctly ***(dressing apraxia)***, or inability to draw simple shapes ***(constructional apraxia)***.

Cortical disorders of sensation and perception

Inattention and neglect

Disorders of the non-dominant hemisphere are often difficult to recognize. There are abnormalities of perception of internal and external space. Examples are loss of way in familiar surroundings, visual inattention, or neglect (where patients fail to respond to stimuli in one side of their visual space or on one side of their body).

Cortical visual loss

This describes loss of vision stemming from damage to one (hemianopia) or both (cortical blindness) occipital lobes. See Chapter 31.

Cortical disorders of memory

Like most brain functions, memory has a modular organization, with different aspects of memory dependent on functionally and anatomically distinct brain networks. Three distinct processes are required: learning, storage, and subsequent retrieval of learned information. There is a fundamental distinction between ***explicit*** memory, which can be consciously accessed, such as long-term memory for events (***episodic*** memory) and knowledge of word meaning (***semantic*** memory) on the one hand, and ***implicit*** memory, which is not conscious: for example, how to ride a bike (Fig. 28.4). The term 'short-term' memory is frequently misunderstood and refers to ***working*** memory lasting seconds only: for example, phone numbers or digit span.

Disorders of memory can result from damage to the medial structures of the temporal lobes and their connections—the hippocampi, fornices, and mammillary bodies, as well as from damage to the thalamus and frontal lobe. The distributed anatomical basis of memory means that bilateral lesions are necessary to cause ***amnesia***. Impairment of episodic memory usually results in a temporal memory gradient: recent and new memories are mainly affected, with relative preservation of distant memories.

Memory loss (the amnestic syndrome) is frequently a symptom of dementia, especially Alzheimer's disease (see 'Alzheimer's disease' section), but also occurs as an isolated entity (Box 28.6).

Cortical disorders of executive function

Lesions of the frontal lobes may be associated with inability to plan, solve problems, focus attention, or juggle different tasks. There may be associated difficulties in regulating emotional responses or in controlling behaviour, and patients with frontal lobe lesions may be described by those who know them as having a changed personality.

CRANIAL NERVE LESIONS

See Box 28.7 and Fig. 28.5

General principles

Cranial nerve deficits may be produced by ***supranuclear***, ***nuclear***, or ***infranuclear*** lesions:

- An ***infranuclear*** or ***nuclear*** lesion of a motor nerve will produce a lower motor neuron pattern of deficit characterized by flaccid paralysis (e.g., bulbar palsy). The nucleus or tract of the nerve may be affected within the substance of the brainstem, or the cranial nerve after it has exited the brainstem.
- A ***supranuclear lesion*** produces an upper motor neuron (UMN) deficit (e.g., pseudobulbar palsy or supranuclear gaze palsy). The LMN pathways remain intact (e.g., intact vestibulo-ocular reflex [VOR] with a supranuclear gaze palsy; brisk jaw jerk with pseudobulbar palsy).

I: Olfactory nerve

This sensory nerve arises from olfactory (smell) receptors within nasal mucosa. Branches pierce the cribriform plate and synapse in the olfactory bulb. The olfactory tract passes to the olfactory cortex in the inferior temporal lobe.

Anosmia (loss of the sense of smell) is caused by head injury (shearing of olfactory neurons as they pass through the cribriform plate at the skull base) or tumours of the olfactory groove

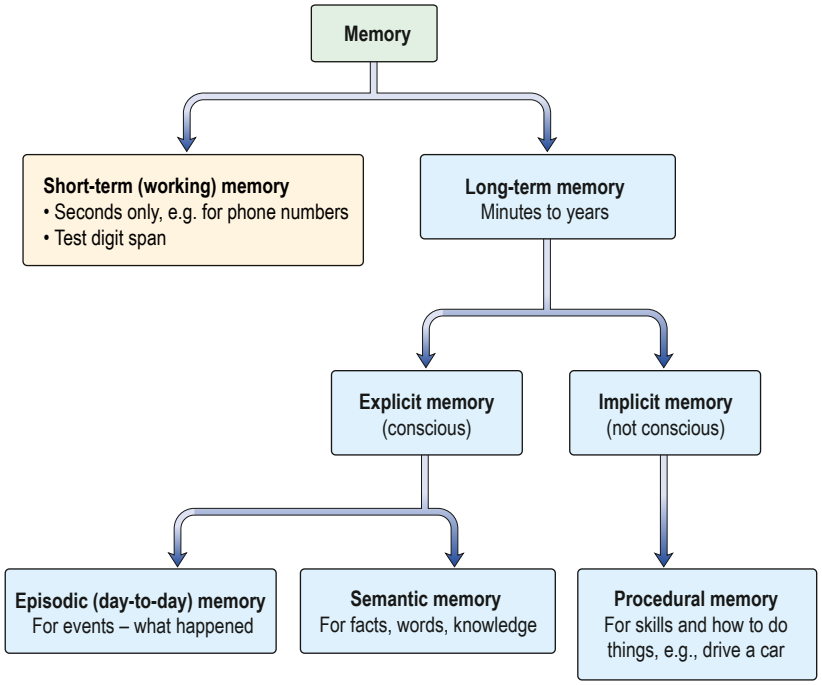

Fig. 28.4 **Types of memory.**

? Box 28.6 Causes of an amnestic syndrome[a]

- Dementia (note: multiple cognitive domains affected, not memory in isolation)
- Amnestic mild cognitive impairment (see 'Mild cognitive impairment' section)
- Alcohol—thiamine deficiency (Wernicke–Korsakoff's syndrome)
- Head injury (severe)
- Anoxic brain damage and that following carbon monoxide poisoning
- Stroke, including bilateral thalamic infarction, subarachnoid haemorrhage, diffuse small-vessel disease, and post-cardiac surgery
- Viral, paraneoplastic, and autoimmune encephalitis
- Drugs—psychotropics, anticholinergics, and solvent abuse
- Bilateral invasive tumours
- Temporal lobe epilepsy and temporal lobectomy
- Following hypoglycaemia
- Temporary amnesia: transient global amnesia, transient epileptic amnesia, post-traumatic amnesia
- Dissociative (functional/psychogenic)

[a]Amnesia must be distinguished from delirium.

i Box 28.7 Cranial nerves

Number	Name	Main clinical action
I	Olfactory	Smell
II	Optic	Vision, fields, afferent light reflex
III	Oculomotor	Eyelid elevation, eye elevation, adduction, depression in abduction, efferent pupil—light reflex
IV	Trochlear	Eye intorsion, depression in adduction
V	Trigeminal	Facial (and corneal) sensation, mastication muscles
VI	Abducens	Eye abduction
VII	Facial	Facial movement, taste fibres
VIII	Vestibulocochlear	Balance and hearing
IX	Glossopharyngeal	Sensation—soft palate, taste fibres
X	Vagus	Cough, palatal and vocal cord movements
XI	Accessory	Head turning, shoulder shrugging
XII	Hypoglossal	Tongue movement

(e.g., meningioma). Olfaction is lost or diminished after upper respiratory infections and with local disorders of the nose (this is usually temporary). Many patients with gradual-onset anosmia over many years may be unaware of the deficit: for example, in Parkinson's disease, where anosmia precedes motor symptoms by many years but is often not noticed by the patient.

Detailed smell testing is difficult in routine clinical practice and rarely performed. Adequate testing requires use of commercially available kits, such as scratch and sniff cards or odour-filled pens with forced multiple-choice identification.

II: Optic nerve and visual system

Light regulated by the pupillary aperture is converted into action potentials by retinal photoreceptors (rods and cones), which transmit information via bipolar cells to retinal ganglion cells (see Chapter 31). The lens, under control of the ciliary muscle, produces the image (inverted) on the retina. Retinal ganglion cells collectively form the optic nerve (1 in **Fig. 28.6**), and their axons decussate at the optic chiasm (2), where fibres from the nasal retina cross and join with uncrossed fibres originating in the temporal retina to form the optic tract (3). Each optic tract thus carries information from the contralateral visual hemifield.

From the lateral geniculate body, fibres pass in the optic radiation in two divisions through the parietal and temporal lobes (4 and 5) to reach the visual cortex of the occipital lobe (6 and 7), which is

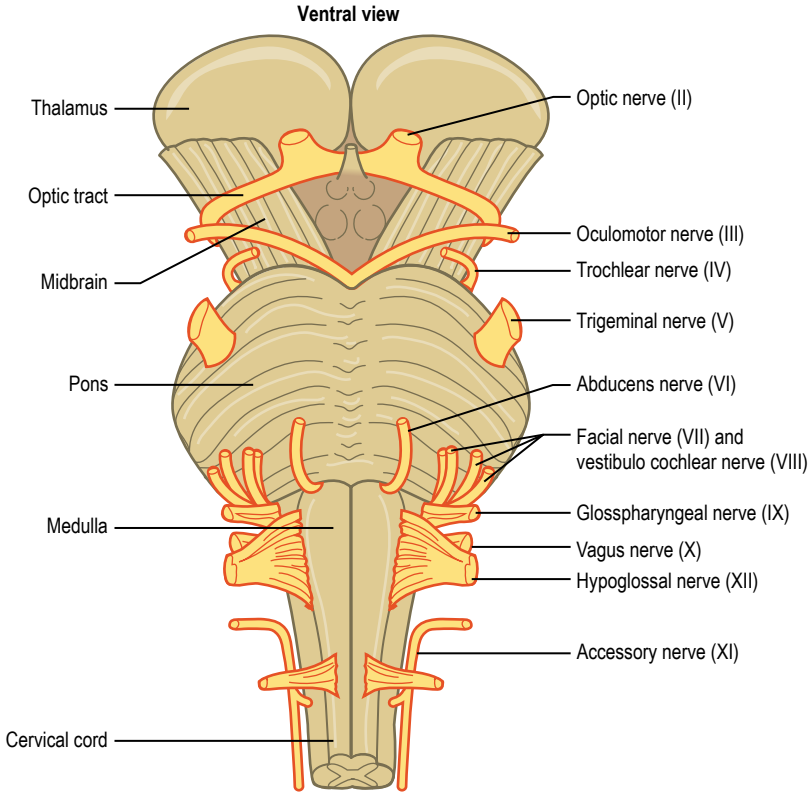

Fig. 28.5 Cranial nerves exiting the brainstem.

somatotopically organized with macular vision located at the occipital pole.

Beyond the visual cortex, visual information is further processed by neighbouring visual association areas to detect lines, orientation, shapes, movement, colour, and depth; there is even a distinct area responsible for face recognition.

Visual acuity

Visual acuity is assessed in each eye with a Snellen chart and/or Near Vision Reading Types, as described in Chapter 31.

Visual field defects

Visual fields are assessed at the bedside by confrontation—comparing the examiner's and patient's fields, one eye at a time and quadrant by quadrant. Patience and good technique are required to produce reliable results. White and red targets (traditionally, hatpins) are used to assess peripheral and central fields, respectively, although in practice a fingertip is often substituted as a cruder screening test. More detailed quantification of fields may be obtained using Goldmann (manual) or Humphrey (automated) perimetry testing.

Field defects (shown in **Fig. 28.6**) are described as hemianopic when half the field is affected and quadrantanopic when a quadrant is affected. Lesions posterior to the optic chiasm produce ***homonymous*** field defects, indicating involvement of the same part of the visual field in both eyes, as information from the two visual hemifields is separated beyond this point. Lesions damaging decussating nasal fibres at the optic chiasm cause bitemporal defects.

Retinal and local eye lesions

See Chapter 31.

Optic nerve lesions

Unilateral visual loss, commencing with a central or paracentral (off-centre) scotoma, is the hallmark of an optic nerve lesion. Because most fibres in the optic nerve subserve macular vision, lesions within the nerve disproportionately affect central vision and colour vision. A total optic nerve lesion causes unilateral blindness with loss of pupillary light reflex. Examination findings in optic neuropathy are:

- reduced acuity in the affected eye
- a scotoma (usually central)
- impaired colour vision (red desaturation)
- an afferent pupillary defect (see below)
- optic atrophy—pale disc (develops late).
  Causes are listed in **Box 28.7**.

Optic nerve head oedema

Papilloedema means swelling of the optic discs caused by raised intracranial pressure (ICP). Inflammation, infiltration, and ischaemia of the optic nerve can also cause optic disc swelling **(papillitis)**, usually unilaterally; systemic diseases and toxins can cause bilateral disc swelling. Causes of disc swelling are shown in **Box 28.8**.

Papilloedema

The earliest signs of papilloedema are disc pinkness, with blurring and heaping up of disc margins, nasal first. There is loss of spontaneous pulsation of retinal veins within the disc. The physiological cup becomes obliterated, and the disc is engorged with dilated vessels. Small haemorrhages often surround the disc.

Various conditions simulate true disc swelling. Marked hypermetropic (long-sighted) refractive errors make a disc appear pink, distant, and ill-defined; myopia will cause tilted discs that can look oval-shaped. Myelinated nerve fibres at disc margins and hyaline

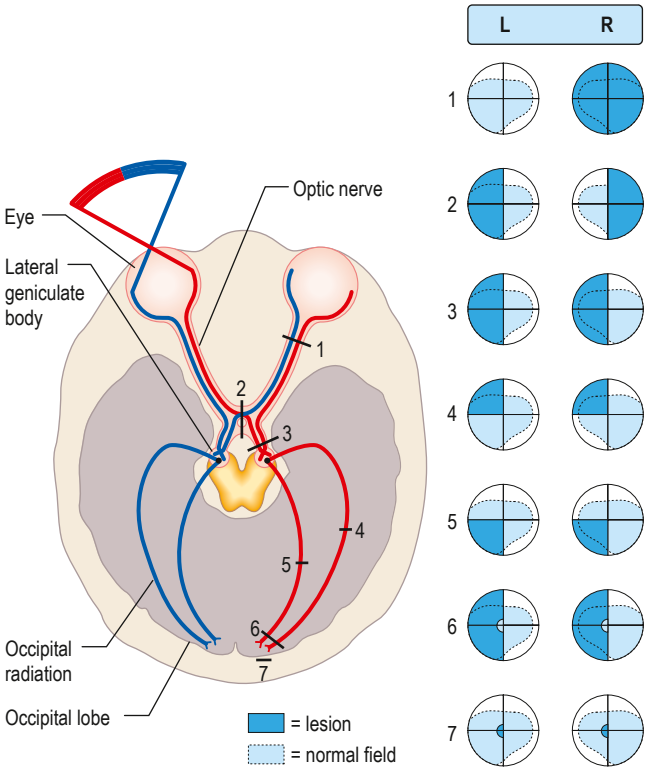

Fig. 28.6 The visual pathway. **(1)** Mononuclear field loss—complete optic nerve lesion. **(2)** Bitemporal hemianopia—chiasmal lesion. **(3)** Homonymous hemianopia—optic tract lesion. **(4)** Homonymous quadrantanopia—temporal lesion. **(5)** Homonymous quadrantanopia—parietal lesion. **(6)** Homonymous hemianopia with macular sparing—occipital cortex or optic radiation. **(7)** Homonymous hemianopia (hemiscotoma)—occipital pole lesion.

bodies (drusen; see Chapter 31) can be mistaken for disc swelling (pseudopapilloedema).

Optical coherence tomography (OCT) is useful to distinguish disc swelling from pseudopapilloedema and for monitoring.

Papilloedema produces few, if any, visual symptoms until the late stages, other than momentary visual obscurations with changes in posture. The blind spot is enlarged but this is not noticed by the patient. The underlying disease is the source of the patient's symptoms in the initial stages. However, over time, or with fulminant papilloedema, progressive and permanent constriction of visual fields occurs, ultimately culminating in optic atrophy and visual loss.

Inflammatory optic neuropathy (optic neuritis)

Optic neuritis is one of the most common causes of subacute visual loss. Symptoms may vary from a mild fogging of central vision with colour desaturation to a dense central scotoma, but very rarely complete blindness. Pain on eye movements is almost universal. Two-thirds of patients have retrobulbar neuritis, in which the optic disc appears normal, despite severe visual loss. The remainder will have anterior optic neuritis (or papillitis) with disc swelling in the acute phase. Optic atrophy develops in spite of good visual recovery, with disc pallor and detectable slowing of conduction in the anterior visual pathways on visual-evoked potentials.

A plaque of demyelination within the optic nerve is the most common cause in Western populations. Dedicated magnetic resonance imaging (MRI) of the optic nerves may show the inflammatory plaque, and imaging of the brain may show additional inflammatory lesions, which confer a higher risk of developing multiple sclerosis (MS).

? Box 28.8 Causes of optic disc swelling

- Raised intracranial pressure (papilloedema)
  - Brain tumour, abscess, or haemorrhage
  - Idiopathic intracranial hypertension
  - Hydrocephalus
  - Venous sinus thrombosis
- Optic neuropathies
  - Optic neuritis (papillitis)
  - Ischaemic optic neuropathy, e.g., giant cell arteritis
  - Toxic optic neuropathy, e.g., methanol
  - Infective optic neuropathies
- Central retinal vein occlusion
- Orbital mass lesions
- Malignant hypertension
- Metabolic causes
  - Hypercapnia, chronic hypoxia, hypocalcaemia
- Retinal vasculitis, e.g., systemic lupus erythematosus
- Disc infiltration
  - Leukaemia, sarcoidosis, optic nerve glioma

Approximately 50% of patients go on to develop MS with prolonged follow-up (see 'Multiple sclerosis' section). Recovery of visual acuity to 6/9 or better occurs in 95% of typical cases over months; recovery time is improved by high-dose intravenous or oral steroids given acutely. Bilateral, unusually severe, or sequential optic neuritis raises suspicion of neuromyelitis optica (NMO) spectrum disorders (see 'Neuromyelitis optica' section).

Optic neuritis may also be caused by infective or other inflammatory disorders, such as sarcoidosis or vasculitides (see **Box 28.9**).

Anterior ischaemic optic neuropathy

The anterior part of the optic nerve is supplied by the posterior ciliary arteries, occlusion, or hypoperfusion of which leads to infarction of all or part of the optic nerve head. There is sudden or stuttering 'altitudinal' visual loss (typically, the lower half of the visual field) with pallid disc swelling, later replaced by optic atrophy. The other eye is affected later in one-third of cases.

Individuals with small hypermetropic discs seem to be predisposed, and often there are relatively few vascular risk factors. A period of hypotension overnight frequently seems to be the trigger. Less commonly, arteritis is the cause, as in giant cell arteritis (GCA; see Chapter 32, 'Giant cell arteritis' section).

Optic atrophy

Optic atrophy means disc pallor, from loss of axons, glial proliferation, and decreased vascularity. This may eventually develop following any type of optic neuropathy of sufficient severity to damage axons extensively within the nerve, including chronic papilloedema.

Optic chiasm

Bitemporal hemianopia or quadrantanopia occurs with compression of the chiasm from above or below. Common causes are:

- pituitary tumours (see Chapter 34, 'Pituitary space-occupying lesions and tumours' section)
- meningioma
- craniopharyngioma.

Optic tract and optic radiation

Optic tract lesions (rare) cause a homonymous hemianopia (loss of the contralateral visual field in both eyes). Optic radiation lesions cause homonymous quadrantanopic defects. Temporal lobe lesions

Box 28.9 Causes of optic neuropathy

- Inflammatory (optic neuritis), e.g., demyelination, sarcoidosis, vasculitis
- Optic nerve trauma or compression, e.g., glioma, meningioma, aneurysm, bone disorders affecting orbit
- Toxic, e.g., tobacco/alcohol, ethambutol, methyl alcohol, quinine, hydroxy chloroquine, radiation
- Ischaemic optic neuropathy, e.g., giant cell arteritis
- Hereditary optic neuropathies, e.g., Leber's
- Nutritional deficiency, e.g., vitamins B_1 and B_{12}
- Infection, e.g., orbital cellulitis, syphilis, tuberculosis
- Neurodegenerative disorders, e.g., leukodystrophies
- Papilloedema and its causes (see **Box 28.8**)

(e.g., tumour, infarction) cause upper quadrantic defects, and parietal lobe lesions cause lower quadrantic defects. Middle cerebral artery territory strokes often involve both divisions of the optic radiation and result in a homonymous hemianopia (**Fig. 28.6**).

Occipital cortex

Homonymous hemianopic defects are produced by unilateral posterior cerebral artery infarction (see Chapter 29). The macular cortex (at each occipital pole) may be spared, probably because of collateral blood supply from the middle cerebral artery.

Widespread bilateral occipital lobe damage by infarction (***'top of the basilar'*** syndrome, occlusion of the rostral basilar artery), trauma, or coning causes ***cortical blindness*** (Anton syndrome). The patient cannot see but characteristically lacks insight into this; he or she may even deny it. Pupillary responses remain normal because the phylogenetically ancient pathway to the pretectal nuclei is intact (see below).

Pupils

A slight difference between the size of each pupil (up to 1 mm) is common ***(physiological anisocoria)*** and does not vary with differing light levels. The pupil tends to become smaller and irregular in old age (senile miosis); anisocoria is more pronounced. ***Convergence*** becomes sluggish with ageing.

Pupillary reactions to light and accommodation may be tested (**Fig. 28.7**). A bright torch (not an ophthalmoscope light!) should be used to test the pupillary light reaction.

Afferent pupillary defect (APD). A complete optic nerve lesion causes a dilated pupil and an APD. For a left APD:

- The pupil is unreactive to light (i.e., the direct reflex is absent).
- The consensual reflex (constriction of the right pupil when the left is illuminated) is absent. Conversely, the left pupil constricts when light is shone in the intact right eye: that is, the consensual reflex of the right eye remains intact.

Relative afferent pupillary defect (RAPD). This occurs with incomplete damage to one optic nerve relative to the other. An RAPD is a sensitive sign of optic nerve pathology and can provide evidence of an optic nerve lesion, even after recovery of vision. For a left RAPD:

- Direct and indirect reflexes are intact in each eye but differ in relative strength.
- As the pupillary light reflex responds to the average illumination detected, when the light is swung from the left to the normal right eye the strength of the afferent signal increases, and so both pupils constrict slightly via a strong consensual response. Both pupils dilate slightly when the torch is swung back to the left eye, as the amount of illumination detected by the abnormal optic nerve is lower.

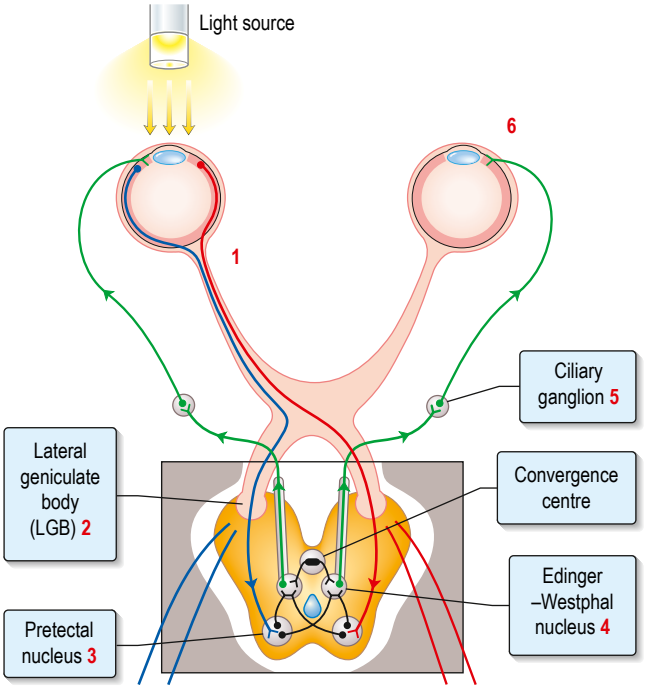

Fig. 28.7 Pupillary light reflex. *Afferent pathway:* **(1)** Light activates optic nerve axons. **(2)** Axons (some decussating at the chiasm) pass through each lateral geniculate body, and **(3)** synapse at pretectal nuclei. ***Efferent pathway:*** **(4)** Action potentials pass to Edinger–Westphal nuclei of the IIIrd nerve, then, **(5)** via parasympathetic neurons in IIIrd nerves to cause **(6)** pupil constriction.

Horner's syndrome

The sympathetic nervous supply to the eye is a three-neuron pathway originating in the hypothalamus and descending by way of the brainstem and cervical cord to the T1 nerve root, paravertebral sympathetic chain and, via the carotid artery wall, to the eye. Damage to any part of the pathway results in Horner's syndrome (**Box 28.10**). This is significant not only because it affects vision but also because it may indicate serious underlying pathology.

The clinical features of Horner's syndrome are:

- unilateral miosis (constricted pupil)
- partial ptosis
- loss of sweating on the same side (extent depending on the level of the lesion)
- possible subtle conjunctival injection and enophthalmos.

The miosis is most easily seen in low light, as the pupil cannot dilate, and may not be apparent in bright light.

Tonic pupil (Adie pupil)

This is a dilated, often irregular, pupil, and is more frequent in women; it is common and usually unilateral. There is no (or very slow) reaction to bright light and also incomplete constriction to convergence. This is due to denervation in the ciliary ganglion, of unknown cause, and has no other pathological significance. A tonic pupil is sometimes associated with diminished or absent tendon reflexes (Holmes–Adie syndrome).

Argyll Robertson pupil

Now rarely seen in clinical practice, an Argyll Robertson pupil is small and irregular; it is fixed to light but accommodates. The lesion is in the brainstem surrounding the aqueduct of Sylvius. Once

Box 28.10 Causes of Horner's syndrome

Hypothalamic, hemisphere, and brainstem lesions
- Massive cerebral infarction
- Brainstem demyelination or lateral medullary infarction

Cervical cord
- Syringomyelia and cord tumours

T1 root
- Apical lung tumour or tuberculosis
- Cervical rib
- Brachial plexus trauma or inflammation

Sympathetic chain and carotid artery in neck
- Following thyroid/laryngeal/carotid surgery
- Carotid artery dissection

- Cervical sympathectomy

Miscellaneous
- Congenital
- Cluster headache, usually transient
- Idiopathic

considered diagnostic of neurosyphilis, it is now only occasionally seen in diabetes or MS.

III, IV, VI: Oculomotor, trochlear, and abducens nerves

These cranial nerves supply the extraocular muscles and disorders commonly result in abnormal eye movements and diplopia (double vision) due to breakdown of conjugate eye movements. Diplopia may also occur with local orbital lesions or myasthenia gravis (MG).

Examination of eye movements

Pursuit (slow) eye movements and saccadic (fast) eye movements are tested separately. The examiner assesses the range of eye movements in all directions and asks the patient to report double vision. Jerky pursuit movements with saccadic intrusion (i.e., brief, fast saccades interspersed with slower pursuit movements), overshoot on saccadic movements, and nystagmus may indicate cerebellar or brainstem pathology.

Control of eye movements

Fast voluntary eye movements originate in the frontal eye fields. Fibres descend and cross in the midbrain to end in the superior colliculus, which also independently initiates reflexive saccades. The superior colliculus also receives inputs from the retina, the visual cortex (pathway concerned with tracking objects), and the inferior colliculus (tracking auditory stimuli). The superior colliculus sends fibres to centres for horizontal gaze (paramedian pontine reticular formation, PPRF) and vertical gaze (in the midbrain reticular formation).

Conjugate horizontal eye movements are coordinated from each PPRF via the medial longitudinal fasciculus (MLF; Fig. 28.8). Fibres from the PPRF pass to the ipsilateral VIth nerve nucleus (lateral rectus), which also sends interneurons through the contralateral MLF to the opposite IIIrd nerve nucleus (medial rectus subnucleus), thus linking the eyes for lateral gaze.

Abnormalities of conjugate horizontal gaze

A destructive lesion on one side allows the eyes to be driven by the intact opposite pathway. A left frontal destructive lesion (e.g., an infarct) leads to failure of conjugate lateral gaze to the right. In an acute lesion, the eyes are often deviated to the side of the lesion, past the midline, and therefore look towards the left (normal) limbs; there is usually a contralateral (i.e., right) hemiparesis. An irritative lesion (i.e., a seizure) affecting the frontal eye field will drive a gaze deviation towards the opposite side.

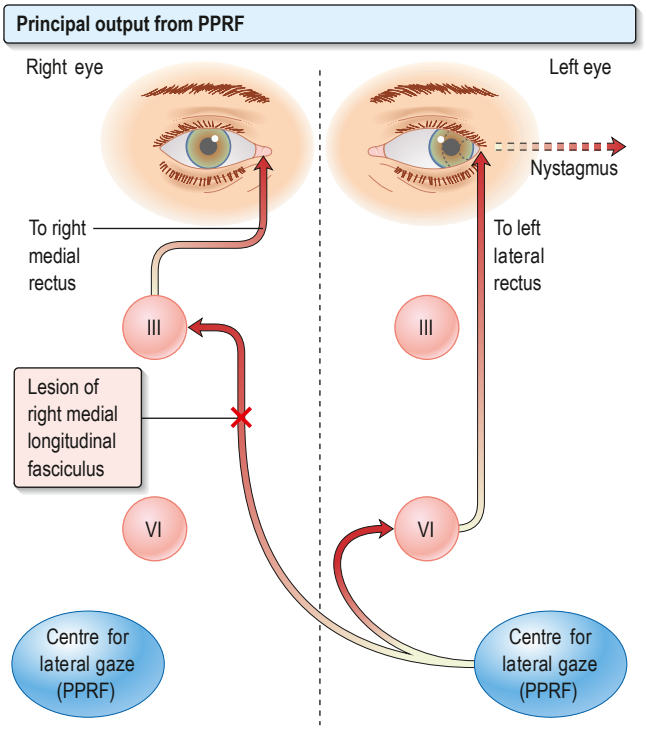

Fig. 28.8 Paramedian pontine reticular formation (PPRF) and internuclear ophthalmoplegia. Impulses from the PPRF pass via the ipsilateral VIth nerve nucleus to the lateral rectus muscle (**ab**duction), and via the medial longitudinal fasciculus to the opposite third nerve nucleus and thus to the opposite medial rectus muscle (**ad**duction). A lesion of the medial longitudinal fasciculus (X) causes failure of or slow **ad**duction in the right eye, and nystagmus in the left eye with left lateral gaze.

In the brainstem, a unilateral destructive lesion involving the PPRF leads to failure of conjugate lateral gaze *towards* that side. There is usually a contralateral hemiparesis, and lateral gaze is deviated towards the side of the paralyzed limbs.

Internuclear ophthalmoplegia

Damage to one MLF causes internuclear ophthalmoplegia (INO), a common complex brainstem eye movement disorder seen frequently in MS. In a right INO, there is a lesion of the right MLF (see Fig. 28.8). On attempted left lateral gaze, the right eye fails to **ad**duct or does so slowly in comparison to the **ab**ducting eye. The left eye develops nystagmus in **ab**duction. The side of the lesion is on the side of impaired **ad**duction. Bilateral INO is almost pathognomonic of MS. A subtle INO is more apparent on testing fast saccadic eye movements, asking the patient to look from one of the examiner's hands to the other.

One and a half syndrome

Pontine infarction involving the PPRF, VIth nerve nucleus, and MLF on one side results in an ipsilateral horizontal gaze palsy and an INO, so that abduction of the opposite eye (with nystagmus) is the only horizontal eye movement possible. Vertical gaze and convergence are preserved, as they have distinct neural control mechanisms.

Vestibulo-ocular (doll's eye) reflexes

Examination is of diagnostic value in coma (see Chapter 11, 'The unconscious patient' section) and assessment of vertigo (see 'Vertigo' section).

Abnormalities of vertical gaze

Failure of upgaze may be caused by dorsal midbrain lesions, such as pinealoma or infarct. When the pupillary light reflex fails in addition, this is called Parinaud's syndrome. Defective vertical gaze also develops in certain degenerative disorders (e.g., progressive supranuclear palsy [PSP]). Some impairment of upgaze occurs as part of normal ageing.

A supranuclear gaze palsy, either horizontal or vertical, will be overcome by testing the VOR, as the brainstem nuclei and LMN pathways subserving the reflex are intact. An impaired VOR implies a nuclear or infranuclear cause.

Nystagmus

Nystagmus is rhythmic oscillation of eye movement; it is a sign of disease of the retina, cerebellum, and/or vestibular systems and their connections. Nystagmus is either ***jerk*** or ***pendular***. Nystagmus must be sustained within binocular gaze to be of diagnostic value; a few beats at the extremes of gaze are normal.

Jerk nystagmus

Jerk nystagmus (usual in neurological disease) is a fast/slow oscillation. This is seen in vestibular, VIIIth nerve, brainstem, and cerebellar lesions. The direction of nystagmus is decided by the fast component, a reflex attempt to correct the slower, primary drift.

- ***Horizontal or rotary jerk nystagmus*** may be either of peripheral (vestibular) or central origin (VIIIth nerve, brainstem, cerebellum, and connections).
  - In peripheral lesions, nystagmus is usually acute and transient (minutes or hours) and associated with severe prostrating vertigo. Peripheral nystagmus obeys Alexander's law: the nystagmus is unidirectional, and the amplitude increases with eye movement in the direction of the fast phase, away from the side of the lesion.
  - In central lesions, nystagmus tends to be long lasting (weeks, months, or more). Vertigo caused by central lesions tends to wane after days or weeks, the nystagmus outlasting it.
  - Gaze-evoked nystagmus (left-beating on looking left and right-beating on looking right) is one of the most common types of nystagmus seen and often related to brainstem or cerebellar disorders.
  - A small amount of end-point nystagmus on far lateral gaze is normal.
- ***Vertical jerk nystagmus*** is typically caused by central lesions.
- ***Down-beat jerk nystagmus*** is a rarity caused by lesions around the foramen magnum (e.g., meningioma, cerebellar ectopia).
- ***Pendular nystagmus*** describes movements to and fro, similar in velocity and amplitude. Pendular nystagmus is usually vertical and present in all directions of gaze. The causes are generally ocular (e.g., poor visual fixation from longstanding, severe visual impairment) or congenital.

III: Oculomotor nerve lesions

The nucleus of the IIIrd nerve lies ventral to the aqueduct in the midbrain. It supplies four external ocular muscles (superior, inferior and medial recti, and inferior oblique) and levator palpebrae superioris (which lifts the eyelid), and effects parasympathetic constriction of the pupil. Causes of a IIIrd nerve lesion are listed in **Box 28.11**.

Signs of a complete IIIrd nerve palsy include:

- unilateral complete ptosis (levator weakness)
- deviation of the eye down and out (unopposed lateral rectus and superior oblique)
- a fixed and dilated pupil.

? Box 28.11 Some causes of a IIIrd nerve lesion

- Aneurysm of the posterior communicating artery
- Infarction of IIIrd nerve, e.g., diabetes, atheroma
- Coning of the temporal lobe
- Midbrain infarction
- Midbrain tumour (primary or secondary)

Patients do not complain of diplopia as the ptosis effectively covers the eye. ***Sparing of the pupil*** indicates that parasympathetic fibres are undamaged; these run in a discrete bundle on the surface of the nerve, and so the pupil is of normal size and reacts normally. Diabetic IIIrd nerve infarction is usually painless and pupil-sparing, unlike compression by a posterior communicating artery aneurysm. Differentiation of 'medical' and 'surgical' causes of a third nerve palsy based on sparing of the pupil is only reliable in the presence of complete third nerve extraocular muscle dysfunction. In the presence of a divisional or incomplete palsy, urgent brain imaging is warranted regardless of pupillary involvement.

IV: Trochlear nerve lesions

The trochlear nerve supplies the superior oblique muscle. The patient complains of torsional diplopia (two objects at an angle) when attempting to look down (e.g., descending stairs); the head is tilted away from that side. The trochlear nerve emerges from the 'wrong' (dorsal) side of the brainstem, and is the cranial nerve with the longest intracranial course; it is thus particularly susceptible to damage from traumatic brain injury (TBI), often with bilateral trochlear nerve palsies occurring.

VI: Abducens nerve lesions

The abducens nerve supplies the lateral rectus muscle (**ab**duction). Lesions cause horizontal diplopia when looking into the distance, which is maximal when looking to the side of the lesion. The eye cannot be fully abducted and an esotropia (inward eye deviation) may be visible in the primary position.

The VIth nerve has a long intracranial course. It can be damaged in the brainstem (e.g., by MS or infarction). In raised ICP (from any cause), it is compressed against the tip of the petrous temporal bone (this may be bilateral), resulting in a false localizing sign. The nerve sheath may be infiltrated by tumours, particularly nasopharyngeal carcinoma. Microvascular ischaemia of the nerve may occur in diabetes with acute onset, followed by recovery within 3 months in most cases.

Complete external ophthalmoplegia

Complete external ophthalmoplegia describes an immobile eye when IIIrd, IVth and VIth nerves are paralyzed at the orbital apex (e.g., by metastasis) or within the cavernous sinus (e.g., by sinus thrombosis or meningioma). Lesions at the orbital apex will usually be accompanied by visual loss from optic nerve involvement.

Wernicke's encephalopathy due to thiamine deficiency (see Chapter 30, 'Wernicke-Korsakoff syndrome' section) may cause a complex eye movement disorder or complete ophthalmoplegia, as may neuromuscular junction (NMJ) disorders such as myasthenia, botulism, and some myopathies or metabolic disorders.

V: Trigeminal nerve

The trigeminal is the largest cranial nerve; it is mainly sensory with a motor component to the muscles of mastication.

Sensory fibres (**Fig. 28.9**; see also **Fig. 28.14**) of the three divisions—ophthalmic (V_1), maxillary (V_2), and mandibular (V_3)—pass

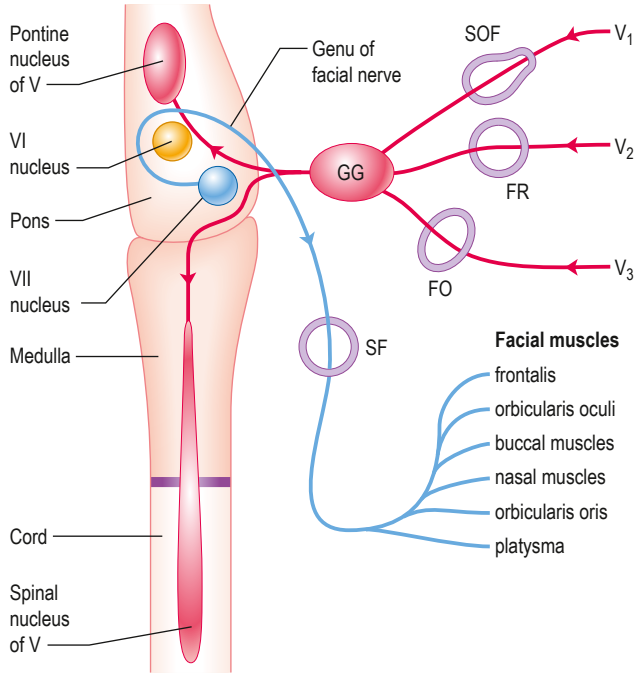

Fig. 28.9 Sensory input of fifth nerve (red) and motor output of the VIIth nerve (blue). *FO,* Foramen ovale; *FR,* foramen rotundum; *GG,* Gasserian ganglion; *SF,* stylomastoid foramen; *SOF,* superior orbital fissure.

to the trigeminal (Gasserian) ganglion at the apex of the petrous temporal bone. Ascending fibres transmitting light touch enter the fifth nucleus in the pons. Descending central fibres carrying pain and temperature form the spinal tract of V, to end in the spinal fifth nucleus that extends from the medulla into the cervical cord.

Clinical features of a Vth nerve lesion

A complete Vth nerve lesion causes unilateral sensory loss on the face, scalp anterior to the vertex, and the anterior two-thirds of the tongue and buccal mucosa; the jaw deviates to that side as the mouth opens (motor fibres). Diminution of the corneal reflex is an early and sometimes isolated sign of a Vth nerve lesion.

Aetiology

- ***Brainstem pathology*** (infarction, demyelination, or tumour) may damage the nucleus, with light touch and spinothalamic pathways sometimes being differentially involved. An 'onion-skin' pattern of sensory loss, in concentric rings, is often seen.
- ***Cerebellopontine angle tumours*** (acoustic neuroma or meningioma) may compress the nerve and also affect the VIIth and VIIIth nerves, producing facial weakness and deafness.
- ***Cavernous sinus and skull base pathology*** (tumour or infection) may affect the ganglion and proximal branches.
- ***Peripheral branches*** may be picked off individually, for example the ominous 'numb chin syndrome' seen with a breast cancer metastasis in the mandible.

Trigeminal neuralgia

Trigeminal neuralgia is discussed with facial pain (see 'Facial pain' section).

Trigeminal sensory neuropathy/neuronopathy

This causes gradually progressive facial sensory loss and tingling with normal imaging. The condition is probably heterogeneous in aetiology but may have an autoimmune basis, with inflammation of the trigeminal ganglion, occurring mainly in association with mixed and undifferentiated connective tissue disease and primary Sjögren's syndrome.

VII: Facial nerve

The VIIth nerve is largely motor, supplying muscles of facial expression. It carries sensory taste fibres from the anterior two-thirds of the tongue via the chorda tympani and supplies motor fibres to the stapedius muscle. The VIIth nerve (see **Fig. 28.9**) arises from its nucleus in the pons and leaves the skull through the stylomastoid foramen. Neurons in each VIIth nucleus supplying the upper face (principally frontalis) receive bilateral supranuclear innervation.

Unilateral facial weakness

Upper motor neuron lesions

These cause weakness of the lower part of the face on the opposite side. Frontalis is spared: normal furrowing of the brow is preserved; eye closure and blinking are largely unaffected. The earliest sign is slowing of movement of one side of the face: for example, on baring the teeth. There is sometimes relative preservation of spontaneous emotional movement (e.g., smiling) compared with voluntary movement. The most common cause of a UMN lesion is hemispheric stroke with contralateral hemiparesis affecting face, arm, and leg.

Lower motor neuron lesions

A complete unilateral LMN VIIth lesion causes weakness (ipsilateral) of all facial expression muscles. The angle of the mouth falls; unilateral dribbling develops. Frowning (frontalis) and eye closure are weak. Corneal exposure and ulceration occur if the eye does not close during sleep. Taste sensation is frequently also impaired. Sites of LMN lesions resulting in facial weakness can be differentiated by the presence of additional signs suggesting the site of the lesion:

Pons. Here the VIIth nerve loops around the VIth (abducens) nucleus (see **Fig. 28.9**), leading to a lateral rectus palsy (see 'VI: Abducens nerve lesions' section) with unilateral LMN facial weakness. When the neighbouring PPRF and corticospinal tract are involved, there is the combination of:

- LMN facial weakness
- failure of conjugate lateral gaze (towards lesion)
- contralateral hemiparesis.

Causes include pontine tumours (e.g., glioma), MS, and infarction.

Cerebellopontine angle (CPA). The neighbouring Vth, VIth, and VIIIth nerves are compressed with VII in the CPA; for example, by acoustic neuroma, meningioma, or metastasis.

Petrous temporal bone. The nerve may be damaged within the bony facial canal, within which lies the sensory geniculate ganglion (receiving taste fibres from the anterior two-thirds of the tongue via the chorda tympani). As well as LMN facial weakness, lesions in this region cause:

- loss of taste on the anterior two-thirds of the tongue
- hyperacusis (loud noise distortion—paralysis of stapedius).

Processes affecting the petrous temporal part of the facial nerve include:

- Bell's palsy (see below)
- trauma
- middle ear infection
- herpes zoster (Ramsay Hunt syndrome; see Chapter 42, 'Varicella [chickenpox] and herpes zoster [shingles]' section).

Skull base, parotid gland, and within the face. The facial nerve can be compressed by skull base tumours and in Paget's disease of bone. Branches of VII may be damaged by parotid gland tumours as the nerve traverses the parotid, and by sarcoidosis (see Chapter 20, 'Sarcoidosis' section) and trauma.

Bell's palsy

This common (37 per 100 000 incidence), idiopathic acute facial palsy is due to inflammation and swelling of the nerve within the tight petrous bone facial canal. In many cases, viral infection or herpes simplex reactivation is believed to be the cause but typically there is no established method of confirming this. Unilateral LMN facial weakness develops over 24 to 48 hours, sometimes with lost or altered taste on the tongue, and hyperacusis. Pain behind the ear is common at onset. Patients often suspect a stroke and may be very distressed. Vague altered facial sensation is often reported, although examination of facial sensation is normal.

Diagnosis is made on clinical grounds and tests are usually not required. The ear (and palate) should be examined for vesicles (see Ramsay Hunt syndrome later), hearing loss, or evidence of local pathology such as cholesteatoma or malignant otitis externa; parotid tumours should be excluded. Cases with the following features require brain imaging: slow, insidious onset; a hyperacute onset (stroke); continued worsening after 3 weeks; no improvement within 4 months. Involvement of other cranial nerves means facial weakness is not due to Bell's palsy. Lyme disease may account for one-quarter of cases of facial palsy in endemic areas and facial palsy may also be seen in HIV seroconversion.

(***Bell's phenomenon*** is the upward conjugate eye movement that occurs normally when the eyes are closed but is more visible when the orbicularis oculi muscle is weak.)

Complete, or almost complete, recovery over 4 to 12 weeks occurs in at least 85% of patients, even without specific treatment. Patients should be reassured that the prognosis is good and that the condition is unlikely to recur.

Associated inability to blink and lacrimal gland involvement may lead to exposure keratitis. Use of lubricating eye ointment is often required and patients should be advised to tape the eye closed carefully at night. For more severe facial weakness with complete inability to close the eye, early ophthalmological assessment is necessary and lateral tarsorrhaphy and/or insertion of a gold weight into the upper lid may be required until recovery occurs.

Early treatment with corticosteroids (prednisolone 60 mg for 1 week) improves outcome if started within 72 hours of onset. The latest evidence does not support use of antiviral agents.

Recovery sometimes takes up to a year if axons have to regrow rather than just remyelinate, in which case aberrant re-innervation of facial muscles (e.g., mouth twitching with blinking) is a frequent late complication. Facial physiotherapy, Botulinum toxin injections, and even plastic surgery may be helpful where recovery is not complete. Bell's palsy rarely recurs; if it does, this should prompt a search for an alternative cause.

Ramsay Hunt syndrome

This is herpes zoster (shingles) of the geniculate ganglion. There is a facial palsy (identical to Bell's) with vesicles around the external auditory meatus and/or the soft palate (sensory twigs from VII). Deafness and vertigo/unsteadiness may occur. Complete recovery is less likely than in Bell's. Antiviral treatment (aciclovir/valaciclovir) is usually given with steroids.

Bilateral facial weakness

Bilateral facial palsy is rare, accounting for less than 1% of cases of facial palsy, but is more likely than unilateral palsies to have an identifiable underlying cause. Paradoxically, bilateral weakness is often less clinically apparent than unilateral weakness, as there is no facial asymmetry.

Causes include:

- infections:
  - Lyme disease (bilateral in 25%—Bannwarth's syndrome)
  - viral: human immunodeficiency virus (HIV) seroconversion, Epstein–Barr virus
  - mastoiditis (bilateral)
  - diphtheria and botulism (rare)
- neuromuscular disorders as part of more generalized weakness:
  - Guillain–Barré syndrome (occasionally facial diplegia occurs with no other weakness)
  - myasthenia
  - myotonic dystrophy and facioscapulohumeral dystrophy
- sarcoidosis and other granulomatous disorders
- skull-base trauma and tumours
- pontine lesions, such as gliomas
- congenital and genetic causes (Gelsolin gene mutations).

Hemifacial spasm

Hemifacial spasm (HFS) is an irregular, painless unilateral spasm of facial muscles, usually occurring after middle age. It starts in the orbicularis oculi and usually progresses gradually over the years to involve other facial muscles on the same side. It varies from a mild to a severe, disfiguring spasm.

HFS is usually caused by compression of the root entry zone of the facial nerve, generally by vascular structures such as the vertebral or basilar arteries or their branches (a mechanism similar to that of trigeminal neuralgia; see 'Facial pain' section). Other lesions at or near the cerebellopontine angle, including tumours and demyelinating plaques, are the cause in approximately 1% of cases.

Occasionally, HFS may occur with ipsilateral trigeminal neuralgia, one symptom usually preceding the other: a combination called ***tic convulsif***. The paroxysms of pain and spasm occur independently. A compressive cause, such as a vascular loop or other structural lesion, is usually identified.

Management

Mild cases require no treatment. Botulinum toxin injection into affected muscles every 3 to 4 months is now the standard treatment. Drugs (e.g., carbamazepine) are of little value. Decompression of the VIIth nerve in the CPA is sometimes helpful. Surgical decompression of the facial nerve in the posterior fossa involves interposing a non-resorbable sponge between the nerve and any adjacent vascular loop identified at operation. The procedure results in complete resolution of symptoms in up to 90% of cases but is associated with a risk of facial weakness or deafness.

Other involuntary facial movements

Myokymia of orbicularis oculi is an irritating twitch, usually of the lower eyelid. It is a normal phenomenon but sometimes a cause of anxiety. More extensive facial myokymia may result from intrinsic brainstem pathology.

Tics and tardive dyskinesia frequently involve facial or perioral muscles (see 'Neuroleptics and movement disorders' section).

Blepharospasm is a form of focal dystonia affecting orbicularis oculi.

VIII: Vestibulocochlear nerve

Auditory fibres from the spiral organ of Corti within the cochlea pass to the cochlear nuclei in the pons. Fibres from these nuclei cross the midline and pass upwards via the medial lemnisci to the medial geniculate bodies and then to the temporal cortex.

Symptoms of a cochlear nerve lesion are deafness and tinnitus (see Chapter 21). Sensorineural and conductive deafness can be distinguished with tuning fork tests, for example Rinne's and Weber's (using a 512 Hz, not 128 Hz, tuning fork; see Chapter 21).

Basic investigations of cochlear lesions

- Pure tone audiometry and auditory thresholds.
- Auditory-evoked potentials (recording responses from repetitive clicks via scalp electrodes; lesion levels are determined from the response pattern).

Causes of deafness

These are listed in **Boxes 28.12** and **21.4**.

Vertigo and the vestibular system

The vestibular system of the inner ear detects head movements and has three primary functions:

- to stabilize gaze during head movements, for example looking ahead while running (the VOR)
- to control posture and balance
- to facilitate perception of orientation and motion.

Nerve impulses generated by movement of hair cells within the three semicircular canals detect head motion in the three planes (yaw/pitch/roll). Balance is maintained by integrating information from:

- the vestibular system
- the visual system
- the somatosensory system—proprioception from limbs, trunk, and neck.

The ***main symptoms*** of vestibular lesions are vertigo and loss of balance.

Vertigo

Vertigo is the illusion of movement of the subject or surroundings, typically rotatory, and should be distinguished from other types of non-specific dizziness. It can be described to patients as being similar to the sensation one feels after getting off a child's roundabout or after spinning on the spot and suddenly stopping. Some people, particularly with chronic vertigo, describe feeling like they are on the deck of a ship.

Vomiting may accompany acute vertigo. Vertigo is always made worse by head movements and patients prefer to remain still and maintain visual fixation. Walking is unsteady. Nystagmus (see 'Nystagmus' section) is the principal sign.

The dizzy patient

Complaints of 'dizziness' require careful history-taking and may signify:

- vertigo
- pre-syncopal sensations due to transient cerebral hypoperfusion, for example orthostatic light-headedness
- unsteadiness or disequilibrium, for example cerebellar or postural stability disorders
- non-specific 'dizziness', for example due to medication or anxiety and hyperventilation.

? Box 28.12 Some causes of vertigo and hearing loss

Conditions	Symptom(s)
Benign paroxysmal positional vertigo	V
Vestibular neuronitis	V
Ménière's disease	V, D
Alcohol, antiepileptic drug intoxication	V
Cerebellar lesions	V
Focal (temporal lobe) seizures	V
Migraine	V+ phonophobia
Brainstem ischaemia	V, occasionally D
Multiple sclerosis	V, occasionally D
Mumps, intrauterine rubella and congenital syphilis	D
Advancing age (presbycusis) and otosclerosis	D
Acoustic trauma	D
Congenital/genetic	D
Gentamicin, furosemide	V, D
Middle and external ear disease	V, D
Cerebellopontine angle lesions, e.g., acoustic neuroma	V, D
Carcinomatous meningitis, sarcoidosis, and tuberculous meningitis	V, D

D, Hearing loss; *V*, vertigo.

Causes of vertigo

Vertigo indicates a disturbance of the vestibular apparatus or brainstem and associated neural pathways (see **Box 28.12**). Causes:

- ***Peripheral causes*** (vestibular system) are common. Deafness and tinnitus accompanying vertigo indicate involvement of the ear or cochlear nerve (see Chapter 21).
- ***Central causes*** (brainstem and connections) are rarer. Other clinical features, such as diplopia, weakness, cerebellar signs, or cranial nerve palsies, may help localize the lesion.

Peripheral (vestibular) disorders

Vestibular disorders are fully discussed elsewhere (see Chapter 21). Attack duration and frequency, as well as trigger factors, help the clinician distinguish on history between different pathological causes. The ability to perform a Hallpike test, head impulse test, and Epley particle repositioning manoeuvre are invaluable skills for all clinicians (see Chapter 21; **Fig. 28.10** and see **Fig. 21.7**).

The most commonly encountered peripheral causes of vertigo are:

- ***benign paroxysmal positional vertigo*** (BPPV)—frequent attacks lasting seconds only, provoked by turning the head in bed (see Chapter 21). Hallpike test abnormal
- ***vestibular neuronitis***—acute onset lasting days or weeks; non-recurrent. Head impulse test will be abnormal
- ***Ménière's disease***—recurrent attacks lasting minutes or hours, usually accompanied by hearing loss, tinnitus, and a feeling of fullness in the ear
- ***trauma***—vestibular disruption following head injury; patients may also have BPPV
- ***CPA mass lesions and tumours***, such as vestibular nerve schwannomas, may cause vertigo by compressing the vestibular nerve, but rarely do so in the absence of unilateral deafness and tinnitus.

Central causes of vertigo

Vertigo may be a manifestation of brainstem or cerebellar pathology, including:

- ***infarcts*** involving the vestibular nuclei in the medulla (e.g., the lateral medullary syndrome), or the cerebellum
- ***demyelination*** involving the brainstem
- ***posterior fossa mass lesions***—such as tumours, haemorrhage or vascular malformations
- ***migrainous vertigo*** (see 'Migraine' section)—lasts hours, occurring every few weeks or months; headache may be absent
- ***drugs***—such as anticonvulsant toxicity and alcohol.

Although central vertigo occasionally occurs in isolation with brainstem or cerebellar pathology, including in a stroke, it is more typically a single component of a more complex clinical picture, associated with other symptoms or examination findings. The brainstem nuclei and tracts are tightly packed into a small space and most pathological processes affect multiple contiguous neural pathways, resulting, for example, in diplopia, eye movement disorders, cranial nerve palsies, cerebellar signs, or hemiparesis. These should be carefully sought.

Very rarely, an AICA or labyrinthine territory infarct will present with acute onset peripheral vertigo and deafness, through direct infarction of the labyrinth or LMN vestibular pathways. As always, the history is key.

Basic investigations for vestibular problems

Bedside assessment is usually sufficient to make a diagnosis in the majority of patients:

- examination of eye movements for nystagmus (see 'Nystagmus' section)
- assessment of hearing and otoscopic examination of the ear (see Chapter 21)
- head impulse (thrust) test—to assess the VOR and identify a unilateral vestibulopathy (see **Fig. 28.10**)
- Hallpike manoeuvre—a positioning test to stimulate the posterior semicircular canal and trigger an attack in BPPV (see **Fig. 21.7**).

The ***HINTS examination*** has high sensitivity and specificity for differentiating between central and peripheral causes of acute onset vertigo, but should only be used on patients who have persistent vertigo (symptomatic at the time of examination), ongoing nystagmus, and an otherwise completely normal neurological examination. The HINTS exam suggests a central cause of vertigo (and brain imaging is required) if any of the following apply:

- **H**ead **I**mpulse test normal (a corrective saccade is not generated with a central lesion; note however that bilateral corrective saccades may be central)
- **N**ystagmus—vertical or pure torsional nystagmus, or nystagmus that changes direction with gaze, is central (note if there is no nystagmus, then HINTS cannot be used)
- **T**est of **S**kew abnormal—ask the patient to look at your nose, then quickly cover each eye in turn. If there is a vertical or diagonal corrective movement as you uncover the eye, then the vertigo is likely to be central.

Of note, in the validation study the HINTS examination was performed by a neuro-ophthalmologist with specialist equipment. Therefore, it is important to exercise caution: acute onset persistent vertigo in someone with vascular risk factors, especially if they have been given vestibular sedatives that suppress the nystagmus, may warrant an MRI brain even if HINTS appears to suggest a peripheral cause.

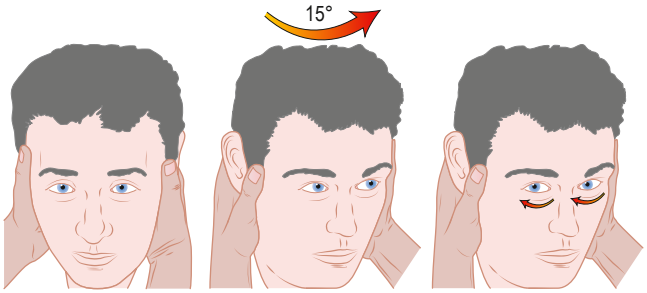

Fig. 28.10 The head impulse test. When tested on the normal side, a patient can maintain fixation on a distant object as the examiner rapidly turns the patient's head sideways through about 15 degrees. If there is unilateral vestibulopathy, the patient cannot maintain fixation on the target and can be observed to make a voluntary eye movement (a saccade) back to the target after the head impulse, as shown on the right. It is essential for the head to be turned as rapidly as possible; otherwise, smooth pursuit eye movements will compensate for the head turn.

Specialist testing is occasionally required to assess vestibular function and hearing. This includes:

- caloric testing—irrigation of the external auditory meatus with cold and then warm water to stimulate the horizontal semicircular canal and induce nystagmus; labyrinthine function is tested in each ear separately
- electro-nystagmography—to quantify and characterize nystagmus under different conditions, for example in a rotating chair
- posturography—assesses body sway on a moving platform
- pure-tone audiograms
- high-definition MRI—provides the best structural imaging of the brainstem and CPA, and is useful where a central cause of vertigo is suspected.

Vestibular neuronitis

Vestibular neuronitis is a common but poorly understood problem. It is an acute attack of isolated vertigo with nystagmus, often with vomiting, and is believed to follow viral infections. The examination findings are distinct:

- there will be unidirectional horizontal nystagmus with a torsional component, that follows Alexander's law
- the head impulse test will be abnormal in one direction.

The disturbance lasts for several days or weeks, is self-limiting and rarely recurs. The nystagmus typically settles but the head impulse test will remain abnormal. Vestibular neuronitis is sometimes followed by BPPV (see Chapter 21, 'Benign paroxysmal positional vertigo' section). Deafness is absent (except in the case of true labyrinthitis, see Chapter 21). Acute treatment is with vestibular sedatives, but these should be stopped after the first few days to allow central compensation to occur. Some patients will go on to develop chronic symptoms, and early consideration should be given to vestibular rehabilitation.

Lower cranial nerves IX, X, XI, XII

The glossopharyngeal (IX), vagus (X), and accessory (XI) nerves arise in the medulla and leave the skull through the jugular foramen. The hypoglossal (XII) nerve arises in the medulla, to leave the skull base via the hypoglossal foramen. Outside the skull, the four cranial nerves lie together, close to the carotid artery and sympathetic trunk.

Glossopharyngeal (IX)

This nerve is largely sensory, supplying sensation and taste from the posterior third of the tongue and the pharynx (afferent pathway of gag reflex). Motor fibres supply the stylopharyngeus muscle, and parasympathetic fibres supply the parotid.

Vagus (X)

The vagus is a mixed nerve, largely motor, which supplies striated muscle of the pharynx (efferent gag reflex pathway), larynx (including vocal cords via recurrent laryngeal nerves), and upper oesophagus. There are sensory fibres from the larynx. Parasympathetic fibres supply the heart and abdominal viscera.

Accessory (XI)

The accessory nerve, a complex motor nerve, supplies the trapezius and sternomastoid muscles.

Hypoglossal (XII)

The hypoglossal nerve is a motor nerve to tongue muscles.

IXth and Xth nerve lesions

Principal causes of IXth, Xth, XIth, and XIIth nerve lesions are listed in **Box 28.13**.

Isolated lesions of IXth and Xth nerves are unusual, since disease at the jugular foramen affects both nerves and sometimes XI.

A unilateral IXth nerve lesion causes diminished sensation on the same side of the pharynx and is hard to recognize in isolation. A Xth nerve palsy produces ipsilateral failure of voluntary and reflex elevation of the soft palate (which is drawn to the opposite side) and ipsilateral vocal cords.

Bilateral lesions of IXth and Xth nerves cause palatal weakness, reduced palatal sensation, an absent gag reflex, dysphonia, and choking with nasal regurgitation. ***Bulbar palsy*** is a general term describing palatal, pharyngeal, and tongue weakness of LMN or muscle origin.

Recurrent laryngeal nerve lesions. Paralysis of this branch of each vagus causes hoarseness (dysphonia) and failure of the forceful, explosive part of coughing ('bovine cough'). There is no visible palatal weakness; vocal cord paralysis is seen endoscopically. Bilateral acute lesions (e.g., postoperatively) cause respiratory obstruction—an emergency.

The left recurrent laryngeal nerve (looping beneath the aorta) is damaged more commonly than the right.

Causes of recurrent laryngeal nerve lesions include:

- mediastinal primary tumours (e.g., thymoma)
- secondary spread from bronchial carcinoma
- aortic aneurysm
- trauma or surgery of neck or thorax.

XIth nerve lesions

XIth nerve lesions cause weakness of sternomastoid (rotation of the head and neck to the opposite side) and trapezius (shoulder shrugging). Nerve section (e.g., following lymph node biopsy in the neck posterior triangle) is followed by persistent neuralgic pain.

XIIth nerve lesions

LMN lesions of XII lead to unilateral tongue weakness, wasting, and fasciculation. The protruded tongue deviates towards the weaker side. The XIIth nerve runs close to the carotid artery and carotid dissection is a common cause of acute unilateral XIIth nerve palsy. Bilateral supranuclear (UMN) lesions produce slow, limited tongue movements and a stiff tongue that cannot be protruded far. Fasciculation is absent.

Box 28.13 Principal causes of IXth, Xth, XIth, and XIIth nerve lesions

Within brainstem

- Infarction
- Syringobulbia
- Motor neuron disease (motor fibres)

Around skull base

- Nasopharyngeal carcinoma
- Glomus tumour
- Neurofibroma
- Jugular venous thrombosis
- Trauma

Within neck and nasopharynx

- Nasopharyngeal carcinoma
- Metastases
- Carotid artery dissection (XII)
- Trauma
- Lymph node biopsy in posterior triangle (XI)

Bulbar and pseudobulbar palsy

Bulbar palsy

This is LMN weakness of muscles whose cranial nerve nuclei lie in the medulla (the bulb). Paralysis of bulbar muscles is caused by disease of lower cranial nerve nuclei, lesions of IXth, Xth, and XIIth nerves (see **Box 28.13**), malfunction of their NMJs (e.g., MG, botulism), or disease of muscles themselves (e.g., dystrophies). Findings include a wasted, flaccid tongue that looks large because it is baggy; there may be fasciculations.

Pseudobulbar palsy

Describes bilateral supranuclear (UMN) lesions of lower cranial nerves producing weakness of the tongue and pharyngeal muscles. This resembles, superficially, a bulbar palsy: hence pseudobulbar. Findings are a stiff, slow, spastic tongue (not wasted but small), dysarthria, and dysphagia. Gag and palatal reflexes are preserved and the jaw jerk exaggerated. Emotional lability (inappropriate laughing or crying) often accompanies pseudobulbar palsy. Principal causes are:

- motor neuron disease (MND), often both UMN and LMN lesions (i.e., elements of both pseudobulbar and bulbar palsy)
- cerebrovascular disease, typically following multiple infarcts
- neurodegenerative disorders such as PSP (see 'Atypical parkinsonism' section)
- severe TBI
- MS, mainly as a late event.

Difficulty swallowing, dysarthria, and drooling also develop in later stages of Parkinson's disease.

Dropped head syndrome

As the name suggests, weakness of neck extensors causes neck flexion and inability to hold the head up. Seen mainly in the elderly, it is often due to isolated neck extensor myopathy of uncertain cause but may be a presenting feature of MND, myasthenia, or various myopathic disorders.

DISORDERS OF MOTOR CONTROL SYSTEMS

There are three systems, each of which interacts by feedback loops with the other two, with sensory input from the reticular formation:

- ***The corticospinal*** (or ***pyramidal*****) *system*** enables purposeful, skilled, intricate, strong, and organized movements. Defective function is recognized by a distinct pattern of signs—loss of skilled voluntary movement, spasticity, and reflex change—seen, for example, in a hemiparesis, hemiplegia, or paraparesis.
- ***The extrapyramidal system*** facilitates fast, fluid movements that the corticospinal system has generated. Defective function produces slowness (bradykinesia), stiffness (rigidity), and/or disorders of movement (rest tremor, chorea, and other dyskinesias). One feature (e.g., stiffness, tremor, or chorea) will often predominate.
- ***The cerebellum*** and its connections have a role coordinating smooth and learned movement, initiated by the corticospinal system, and in posture and balance control. Cerebellar disease leads to unsteady and jerky movements (ataxia), with characteristic limb signs of past-pointing, action tremor and incoordination, gait ataxia, and/or truncal ataxia.

Corticospinal (pyramidal) system

The corticospinal tracts originate in neurons of the cortex and terminate at motor nuclei of cranial nerves and spinal cord anterior horn cells. The pathways of particular clinical significance (Fig. 28.11) congregate in the internal capsule and cross in the medulla (decussation of the pyramids), passing to the contralateral cord as the lateral corticospinal tracts. This is the pyramidal system, disease of which causes UMN lesions. 'Pyramidal' is simply a descriptive term that draws together anatomy and characteristic physical signs; it is used interchangeably with the term UMN.

A proportion of the corticospinal outflow is uncrossed (anterior corticospinal tracts). This is of no relevance in practice.

Characteristics of pyramidal lesions

Signs of an early pyramidal lesion may be minimal (Box 28.14). Weakness, spasticity, or changes in reflexes can predominate, or be present in isolation.

Pyramidal drift of an upper limb

Normally, the outstretched upper limbs are held symmetrically, when the eyes are closed. With a pyramidal lesion, when both upper limbs are held outstretched, palms uppermost, the affected limb drifts downwards and pronates. This sign, with slowing of fast finger movements, is an early one, sometimes occurring before weakness and/or reflex changes become apparent.

Weakness and loss of skilled movement

A unilateral pyramidal lesion above the decussation in the medulla causes weakness of the opposite limbs. When acute and complete, this weakness will be immediate and total: a hemiplegia—for example, following an internal capsule infarct. With time, or a slowly progressive lesion (e.g., a hemisphere glioma), a spastic hemiparesis with a characteristic (pyramidal) pattern emerges, and the characteristic posture of someone with dense pyramidal weakness will be seen: in the upper limb, flexors are stronger than extensors, whereas in the lower limb, extensors are stronger than flexors. In the presence of dense weakness such as after a stroke, the arm is held flexed at the elbow and the wrist flexed across the body. The fingers are curled up. The leg is extended and toes point down, with the foot inverted. There is also loss of skilled movement; fine finger and toe control diminishes. Wasting (except from disuse) is not a feature. When a UMN lesion is below the decussation of the pyramids—in the cervical cord, for example—hemiparesis is on the same side as the lesion.

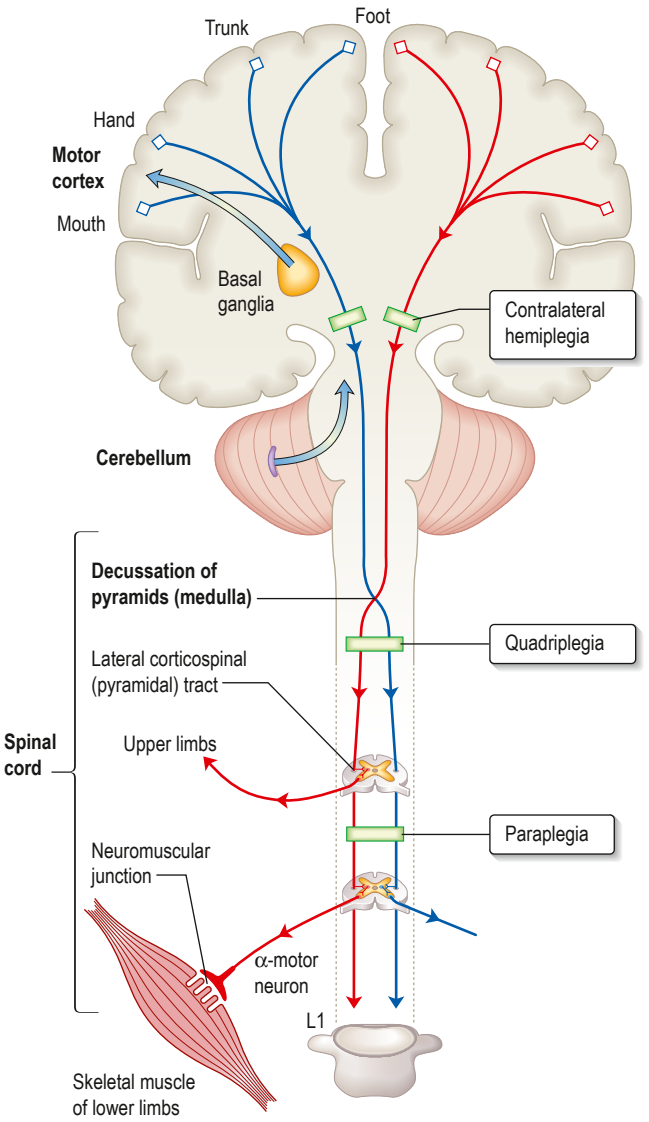

Fig. 28.11 **The motor (corticospinal, pyramidal) system.**

Box 28.14 Features of upper motor neuron lesions

- Drift of upper limb
- Weakness with characteristic pyramidal distribution
- Changes in tone: flaccid–spastic
- Exaggerated muscle stretch reflexes
- Extensor plantar response
- Loss of skilled finger/toe movements
- Loss of abdominal reflexes
- No muscle wasting
- Normal electrical excitability of muscle

Changes in tone and tendon reflexes

An acute lesion of one pyramidal tract (e.g., internal capsule stroke) causes initially flaccid paralysis with loss of tendon reflexes. Increase in tone follows, usually within several days, due to loss of inhibitory effects of the corticospinal pathways and an increase in spinal reflex activity. This increase in tone (spasticity) is most easily detectable in stronger muscles. Spasticity is characterized by sudden ***changing resistance*** to rapid passive movement—the clasp-knife effect. Relevant tendon reflexes become exaggerated; clonus may emerge.

Changes in superficial reflexes

The normal flexor plantar response becomes extensor. In a severe acute lesion, this extensor response can be elicited from a wide area of the foot. As recovery progresses, the receptive area diminishes until the lateral posterior third of the sole remains receptive to an orange-stick stimulus (the appropriate instrument). An extensor plantar response is certain when great toe dorsiflexion is accompanied by abduction of adjacent toes. Abdominal reflexes are abolished on the affected side.

Patterns of UMN disorders

There are three main patterns:

- ***Hemiparesis*** means weakness of the limbs on one side; it is usually caused by a lesion in the brain and occasionally in the cord. If the lesion affects the brain, limb weakness is commonly accompanied by facial weakness and dysarthria.
- ***Paraparesis*** means weakness of both lower limbs and is usually diagnostic of a cord lesion; bilateral medial brain lesions (e.g., parasagittal meningioma) occasionally cause paraparesis.
- ***Tetraparesis*** (also called ***quadriparesis***) means weakness of four limbs.

Hemiplegia, paraplegia, and tetraplegia (strictly) indicate *total* paralysis but are often used to describe severe weakness.

Hemiparesis

The level within the corticospinal system is recognized from particular features.

Motor cortex. Weakness and/or loss of skilled movement confined to one contralateral limb (an arm or a leg—monoparesis) or part of a limb (e.g., a clumsy hand) is typical of an isolated motor cortex lesion (e.g., an infarct or secondary neoplasm). A defect in cognitive function (e.g., aphasia) and focal epilepsy may occur.

Internal capsule. Corticospinal fibres are tightly packed in the internal capsule (about 1 cm^2); thus a small lesion causes a large deficit. A middle cerebral artery branch infarction (see Chapter 29) produces a sudden, dense, contralateral hemiplegia affecting face, arm, and leg.

Pons. A pontine lesion (e.g., an MS plaque) is rarely confined to the corticospinal tract. Adjacent structures such as VIth and VIIth nuclei, MLF, and PPRF are involved. Diplopia, facial weakness, INO, and/or a lateral gaze palsy occur with contralateral hemiparesis.

Spinal cord. A lesion of one lateral corticospinal tract (e.g., a cervical cord injury) causes an ipsilateral UMN lesion, the level being indicated by changes in reflexes (e.g., absent biceps with brisk triceps, C5/6), features of a Brown–Séquard syndrome (see 'Lesions of the sensory pathways' section) and muscle wasting at the level of the lesion.

Spastic paraparesis

Paraparesis indicates bilateral damage to corticospinal pathways, causing weakness and spasticity (or flaccid weakness in the initial phase of spinal shock after an acute cord insult). Cord compression (see 'Spinal cord compression' section) or cord diseases are the usual causes; cerebral lesions occasionally produce paraparesis. Paraparesis is a feature of many neurological conditions; finding the cause is crucial (see 'Lesions of the sensory pathways' section).

Extrapyramidal system

The extrapyramidal system is a general term for basal ganglia motor systems: that is, corpus striatum (caudate nucleus + globus pallidus + putamen), subthalamic nucleus (STN), substantia nigra, and parts of the thalamus. In basal ganglia/extrapyramidal disorders, two features (either or both) become apparent, in limbs and axial muscles:

- reduction in speed of movement ***(bradykinesia)*** or akinesia (no movement), with muscle rigidity
- involuntary ***hyperkinetic*** movements (tremor, chorea, dystonia, tics, myoclonus).

Extrapyramidal disorders are classified broadly into ***akinetic–rigid syndromes*** (see 'Movement disorders' section) where poverty of movement predominates, and ***hyperkinetic*** movement disorders where there are abnormal involuntary movements (see 'Hyperkinetic movement disorders' section).

The most common extrapyramidal disorder is Parkinson's disease.

Essential anatomy

The corpus striatum lies close to the substantia nigra, thalami, and subthalamic nuclei, lateral to the internal capsule (**Fig. 28.12**; see **Fig. 28.11**).

Function and dysfunction

Overall function of this system is modulation of cortical motor activity by a series of loops between cortex and basal ganglia (see **Fig. 28.12**). In involuntary movement disorders, there are specific changes in neurotransmitters (**Box 28.15**) rather than focal lesions seen on imaging or at postmortem.

Proposed model of principal pathways

1. ***Direct pathway*** from striatum to internal globus pallidus (GP*i*) and substantia nigra pars reticulata (SN*r*). Inhibitory ***synapse F***, GABA, and substance P.
2. ***Indirect pathway*** from striatum to external globus pallidus (GPe; inhibitory ***synapse C***, GABA, enkephalin), which projects to the STN instead of 'directly' to the thalamus (inhibitory ***synapse D***, GABA). Terminates in GP*i*–SN*r* (in excitatory ***synapse E***, glutamate).
3. ***Hyperdirect*** pathway from cortex to STN. Excitatory ***synapse J***, glutamate. STN excites GP*i*–SN*r* as in the indirect pathway.
4. **GP*i* and SN*r* to thalamus.** Inhibitory ***synapse G***, GABA.
5. **Thalamus to cortex.** Excitatory, ***synapse H***.
6. **Cortex to striatum.** Excitatory, glutamate.
7. **Dopaminergic modulation, both inhibitory and excitatory, from substantia nigra pars compacta (SNc) to striatum.** ***Synapse A***, dopamine, D_1, excitatory—activates the direct pathway; and ***synapse B***, D_2, inhibitory—inhibits the indirect pathway. The main role of SNc dopaminergic neurons is to coordinate the initiation of movement.

Ultimately, the direct pathway acts to disinhibit the thalamus which excites the motor cortex, selecting the desired motor programme, while indirect and hyperdirect pathways inhibit competing motor programmes via the thalamus. The model helps explain how basal ganglia disease can either reduce excitatory thalamo-cortical activity at synapse H—that is, movement—causing bradykinesia, or increase it, causing hyperkinetic disorders.

Parkinson's disease (PD). This is characterized by slowness, stiffness, and rest tremor (see 'Parkinsonian disorders' section). Degeneration in SNc causes loss of dopamine activity in the striatum. Dopamine is excitatory for synapse A and inhibitory for synapse B. Through the direct pathway, there is reduced activity at synapse F, leading to increased inhibitory output (G) and decreased cortical activity (H).

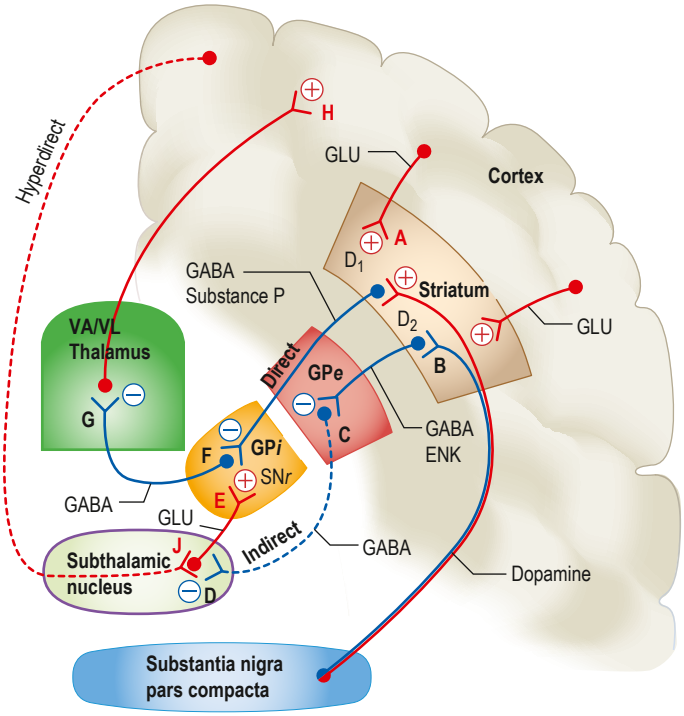

Fig. 28.12 Extrapyramidal system: connections and neurotransmitters. The *inhibitory pathways* are in blue (B, C, D, F, G) and the ***excitatory pathways*** are in red (A, E, H). *ENK,* Enkephalin; *GABA,* γ-aminobutyric acid; *GLU,* glutamate; *GPe,* external globus pallidus; *GPi,* internal globus pallidus; *SNr,* substantia nigra pars reticulata; *VA/VL,* ventral anterior and ventrolateral thalamic nuclei.

Box 28.15 Changes in neurotransmitters in Parkinson's and Huntington's diseases

Site	Neurotransmitter
Parkinson's	
Putamen	Dopamine ↓ 90% Noradrenaline (norepinephrine) ↓ 60% 5-HT ↓ 60%
Substantia nigra	Dopamine ↓ 90% GAD + GABA ↓↓
Cerebral cortex	GAD + GABA ↓↓
Huntington's	
Corpus striatum	Acetylcholine ↓↓ GABA ↓↓ Dopamine: normal GAD + GABA ↓↓

5-HT, 5-hydroxytryptamine; *GABA,* γ-aminobutyric acid; *GAD,* glutamic acid decarboxylase, the enzyme responsible for synthesizing GABA.

Also in PD, in the indirect pathway, dopamine deficiency results in disinhibition of neurons synapsing at C. This leads to reduced activity at D, and to increased activity of neurons in the STN. There is excess stimulation at synapse E, enhancing further inhibitory output of GP*m*–SN*r*.

The net effect via both pathways is to inhibit the ventral anterior (VA) and ventrolateral (VL) nuclei of the thalamus at synapse G. Cortical (motor) activity at H is thus reduced.

Levodopa helps slowness and tremor in PD (see 'Parkinsonian disorders' section) but induces unwanted dyskinesias by increasing dopamine activity at synapses A and B; it is thought to do this by reversing sequences in both direct and indirect pathways.

Hemiballismus (see 'Hyperkinetic movement disorders' section). Wild, flinging (ballistic) limb movements are caused by a lesion in the STN, typically a haemorrhage. This reduces excitatory activity at synapse E, reduces inhibition at G, with increased thalamo-cortical neuronal activity, and increases activity at H.

Cerebellum

The third system of motor control modulates coordination and learned movement patterns, rather than speed. Ataxia, that is unsteadiness, is characteristic.

The cerebellum receives afferents from:

- proprioceptive receptors (joints and muscles)
- vestibular nuclei
- basal ganglia
- the corticospinal system
- inferior olivary nuclei (relaying integrated sensory and motor information to cerebellum).

Efferents pass from the cerebellum to:

- each red nucleus
- vestibular nuclei
- basal ganglia
- the corticospinal system.

Each lateral cerebellar lobe coordinates movement of the ipsilateral limbs. The vermis (a midline structure) is concerned with maintenance of axial (midline) posture and balance.

Cerebellar lesions

Box 28.16 summarizes the main causes of cerebellar disease. Expanding lesions obstruct the aqueduct to cause hydrocephalus, with severe pressure headaches, vomiting, and papilloedema. Coning of the cerebellar tonsils (see 'Brain tumours'

Box 28.16 Principal causes of cerebellar syndromes

section) through the foramen magnum leads to respiratory arrest, sometimes within minutes/hours. Rarely, tonic seizures (attacks of limb stiffness) occur.

Lateral cerebellar hemisphere lesions

A lesion within one cerebellar lobe (e.g., tumour or infarction) causes disruption of the normal sequence of movements (dyssynergia) on the same side.

Posture and gait. The outstretched arm is held still in the early stages of a cerebellar lobar lesion (cf. the drift of pyramidal lesions), but there is rebound upward overshoot when the limb is pressed downwards and released. Gait becomes broad and ataxic, faltering towards the side of the lesion.

Tremor and ataxia. Movement is imprecise in direction, force, and distance (dysmetria). Rapid alternating movements (tapping, clapping, or rotary hand movements) become disorganized (dysdiadochokinesia). Intention tremor (action tremor that increases towards the target) and past-pointing (dysmetria) are seen, but speed of fine movement is preserved (cf. extrapyramidal and pyramidal lesions).

Nystagmus. Coarse horizontal nystagmus (see 'Nystagmus' section) develops with a lateral cerebellar lobe lesion. The fast component is always towards the side of the lesion. Horizontal gaze-evoked nystagmus may indicate a bilateral or diffuse cerebellar disorder. Saccadic eye movements are dysmetric (overshoot).

Dysarthria. Halting, jerking speech (scanning speech) develops.

Other signs. Titubation—rhythmic head tremor as either forward and back (yes–yes) movements or rotary (no–no) movements—can occur, mainly when cerebellar connections are involved (e.g., in essential tremor and MS. Hypotonia (floppy limbs) and depression of reflexes (with slow, pendular reflexes) are also sometimes seen.

Midline cerebellar lesions

Cerebellar vermis lesions have dramatic effects on trunk and axial muscles. There is difficulty standing and sitting unsupported (truncal ataxia), with a broad-based, ataxic gait. Lesions of the flocculonodular region cause vertigo and vomiting with gait ataxia if they extend to the roof of the IVth ventricle.

Tremor

Tremor means a regular and sinusoidal oscillation of the limbs, head, or trunk.

Postural tremor

Everyone has a physiological tremor (often barely perceptible) of the outstretched hands at 8 to 12 Hz. This is increased with anxiety, caffeine, hyperthyroidism, and drugs (e.g., sympathomimetics, sodium valproate, lamotrigine, lithium) and occurs in mercury poisoning. A higher-amplitude, postural tremor is seen in benign essential tremor (usually quite fast at 5–12 Hz).

Intention tremor

Tremor on action that worsens towards the target, with past-pointing and accompanying incoordination of rapid alternating movement (dysdiadochokinesia), occurs in cerebellar lobe disease and with lesions of cerebellar connections. Titubation (head tremor) and nystagmus may be present.

Rest tremor

Seen typically in Parkinson's disease, this tremor is noticeably worse at rest, usually 4 to 7 Hz (often pill-rolling, between thumb and forefinger). Unlike essential tremor, parkinsonian tremor is generally unilateral for the first few years.

Other tremors

Dystonic tremor occurs after the age of 50 and is a manifestation of dystonia that is often seen without dystonic posturing. It is generally unilateral (or asymmetric), affecting hand/arm or head, and worse with posture and certain tasks such as drinking, pouring liquids, or using cutlery or a pen. It is often mistaken for parkinsonian tremor. Holmes tremor (present at rest, action, and posture) is seen following lesions of the outflow pathway from the cerebellum to the thalamus, often involving the red nucleus (e.g., infarction, MS).

Dysarthria

Dysarthria is disordered articulation—slurred speech. Language is intact; dysarthria is best considered a disorder of complex motor control rather than of language. There are various patterns of dysarthria which may be caused by lesions affecting any part of the motor control systems or the muscles required for speech. Examples include the ***gravelly 'hot potato'*** speech of pseudobulbar palsy (see 'Bulbar and pseudobulbar palsy' section), the ***jerky 'scanning'*** ataxic speech of cerebellar lesions, the hypophonic ***monotone*** dysarthria of Parkinson's, and speech in myasthenia that ***fatigues*** and dies away. Many aphasic patients are also dysarthric, and may have apraxia of speech (effortful groping towards sounds) and altered prosody (rhythm, melody, and inflection of speech).

LOWER MOTOR NEURON LESIONS

The LMN is the pathway from anterior horn cell (or cranial nerve nucleus) via a peripheral nerve to muscle motor end-plates. The motor unit consists of one anterior horn cell, its single fast-conducting axon that leaves the cord via the anterior root, and the group of muscle fibres (100–2000) supplied via the nerve. Anterior horn cell activity is modulated by impulses from:

- corticospinal tracts
- the extrapyramidal system
- the cerebellum
- sensory afferents via posterior roots.

Clinical features of lower motor neuron lesions

These are seen in voluntary muscles that depend on an intact nerve supply for both contraction and metabolic integrity. Signs follow rapidly if the LMN is interrupted (Box 28.17).

Aetiology

Examples of LMN lesions at various levels include:

- cranial nerve nuclei (e.g., in pontine stroke) and anterior horn cell (MND)
- spinal root—***radiculopathy***, for example cervical and lumbar disc protrusion (see 'Plexus and nerve root lesions' section)
- peripheral (or cranial) nerve—trauma, entrapment (see 'Peripheral nerve lesions' section) and polyneuropathy ('Polyneuropathies [peripheral neuropathy]' section).

Spinal reflex arc

Components are illustrated in Fig. 28.13. The stretch reflex is the physiological basis for all tendon reflexes. In the knee jerk, a tap on the patellar tendon activates stretch receptors in the quadriceps. Impulses in first-order sensory neurons pass directly to LMNs (L3 and L4) that contract quadriceps. Loss of a tendon reflex is caused by a lesion anywhere along the spinal reflex path. The reflex lost indicates its level (Box 28.18).

Reinforcement. Distraction of the patient's attention, clenching teeth, or pulling interlocked fingers enhances reflex activity (Jendrassik manoeuvre). Such reinforcement manoeuvres should be done before a reflex is recorded as absent.

Assessing gait

Walking is a complex activity: sensory inputs from visual, balance, and proprioceptive sensory systems are integrated by each of the three motor control systems described above, and outputs are effected by activation of muscle via LMNs.

Change in walking pattern is a common complaint (Box 28.19). The ***pattern*** of gait is valuable diagnostically, and provides pointers to the site of any neurological lesion.

Spastic gait and hemiparesis

Spasticity (see 'Spastic paraparesis' section), more pronounced in extensor muscles and with or without weakness, causes stiff, effortful, and slow walking. Toes of shoes become scuffed, catching level ground. Pace shortens; a narrow base is maintained. Clonus—involuntary extensor rhythmic leg jerking—may occur.

In a hemiparesis, when spasticity is unilateral and weakness marked, the stiff, weak leg is circumducted and drags.

Parkinson's disease: shuffling gait

Stride length shortens and, in advanced forms, the gait slows to a shuffle. Posture is stooped and arm swing reduced (initially, unilaterally). Gait becomes festinant (hurried) with short, rapid steps. There is difficulty turning quickly (count the number of steps to turn around). Eventually, gait initiation difficulty and freezing episodes (sudden involuntary halts, such as when

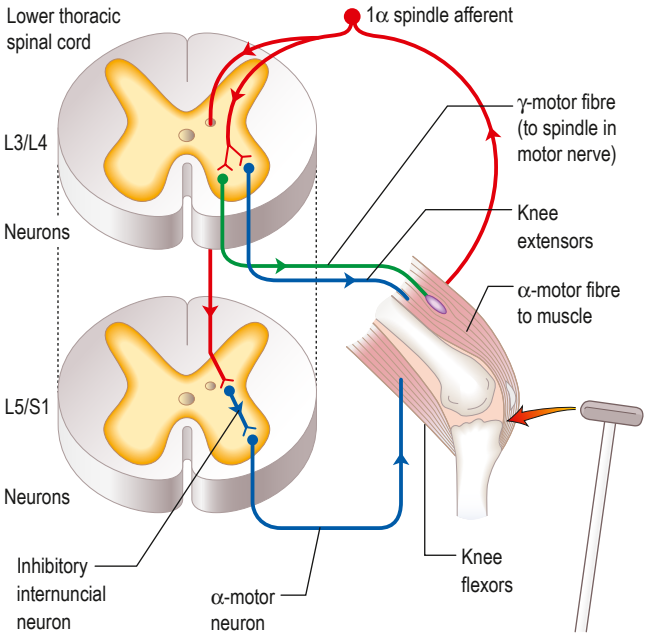

Fig. 28.13 Knee jerk: a spinal reflex arc. Sudden patellar tendon stretching generates sensory action potentials in 1α-muscle spindle afferents that synapse with γ-motor fibres to spindles and α-motor fibres. Motor action potentials cause brisk extensor muscle contraction; there is also inhibition of knee flexors.

Box 28.19 Common gait abnormalities

Cause	Gait abnormality
Stroke	Spastic/hemiparetic
Parkinson's disease	Shuffling/festinant
Cerebellar ataxia	Broad-based
Sensory neuropathy	Stamping
Position sensory loss	High-stepping
Distal weakness/foot drop	Slapping
Proximal weakness, e.g., myopathy	Waddling
Apraxia of gait, e.g., diffuse cerebrovascular disease	Incoordinated/gait initiation failure; *marche à petits pas*
Normal-pressure hydrocephalus	Hesitant
Arthritis and muscle pain	Antalgic

passing through a doorway) may develop. Falls are uncommon, except in late-stage disease, and may indicate a 'Parkinson's plus' syndrome.

Cerebellar ataxia: broad-based gait

In lateral cerebellar lobe disease (see 'Cerebellar lesions' section), stance becomes broad-based, unstable, and tremulous. Ataxia describes this incoordination. When walking, the person tends to veer to the side of the affected cerebellar lobe.

In disease of midline structures (cerebellar vermis), the trunk becomes unsteady without limb ataxia, and there is a tendency to fall backwards or sideways—truncal ataxia. Both stance and gait are affected.

Sensory ataxia: stamping gait

Peripheral sensory loss (e.g., polyneuropathy; see 'Polyneuropathies [peripheral neuropathy]' section) causes ataxia because of loss of ***proprioception*** (position sense). A broad-based, high-stepping, 'stamping' gait develops as feet are placed clumsily, relying in part on vision, so balance is worse in the dark. Romberg's test, first described in sensory ataxia of tabes dorsalis (see 'Tabes dorsalis' section), becomes positive.

Lower limb weakness: high-stepping and waddling gaits

When weakness is distal, affecting ankle dorsiflexors, such as in a common peroneal nerve palsy (see 'Common peroneal nerve palsy' section), gait becomes high-stepping to avoid tripping. The sole returns to the ground with an audible ***slap***.

Weakness of proximal leg muscles (e.g., polymyositis, muscular dystrophy) causes difficulty rising from sitting. Walking becomes a ***waddle***, the pelvis being poorly supported by each leg.

Gait apraxia

With frontal lobe disease (e.g., diffuse cerebrovascular disease, normal-pressure hydrocephalus), ***walking skills*** become disorganized, despite normal motor and sensory function when examined on the couch. The gait is shuffling with small steps ***(marche à petits pas)***, gait ignition failure and hesitancy with fear of falling. Unlike in the gait of Parkinson's disease, arm swing and posture are normal. Urinary incontinence and dementia are often present.

DISORDERS OF SENSORY PATHWAYS AND PAIN

Peripheral nerves and spinal roots

Peripheral nerves carry all modalities of sensation from either free or specialized nerve endings to dorsal roots and thence to the cord. Sensory distribution of spinal roots (dermatomes) is shown in Fig. 28.14.

Spinal cord

Dorsal columns

Axons in the dorsal columns whose cell bodies are in the ipsilateral gracile and cuneate nuclei in the medulla carry sensory modalities of vibration, joint position (proprioception), light touch, and two-point discrimination. Axons from second-order neurons then cross in the brainstem to form the medial lemniscus, passing to the thalamus (Fig. 28.15).

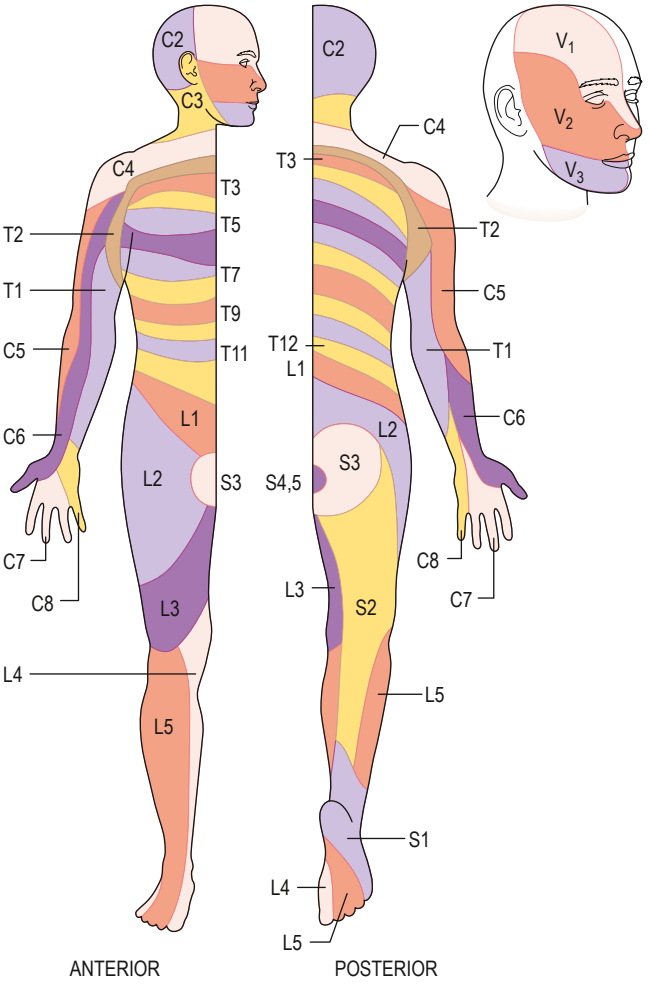

Fig. 28.14 Dermatomes of spinal roots and Vth nerve.

Spinothalamic tracts

Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross within the cord, and pass in the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex

Fibres from the thalamus pass to the parietal region sensory cortex (see Fig. 28.15). Connections exist between the thalamus, sensory cortex, and motor cortex.

Lesions of the sensory pathways

Altered sensation, tingling (paraesthesia), clumsiness, numbness, and pain are the principal symptoms of sensory lesions. The pattern and distribution point to the site of pathology (Fig. 28.16).

Peripheral nerve lesions

Symptoms are felt within the distribution of a peripheral nerve. Sectioning of a sensory nerve is followed by complete sensory loss. Nerve entrapment (see 'Electromyography and nerve conduction studies' section) causes numbness, pain, and tingling. Tapping the site of compression sometimes causes a sharp, electric shock-like pain in the distribution of the nerve, known as Tinel's sign, such as in carpal tunnel syndrome (CTS; see 'Carpal tunnel syndrome' section).

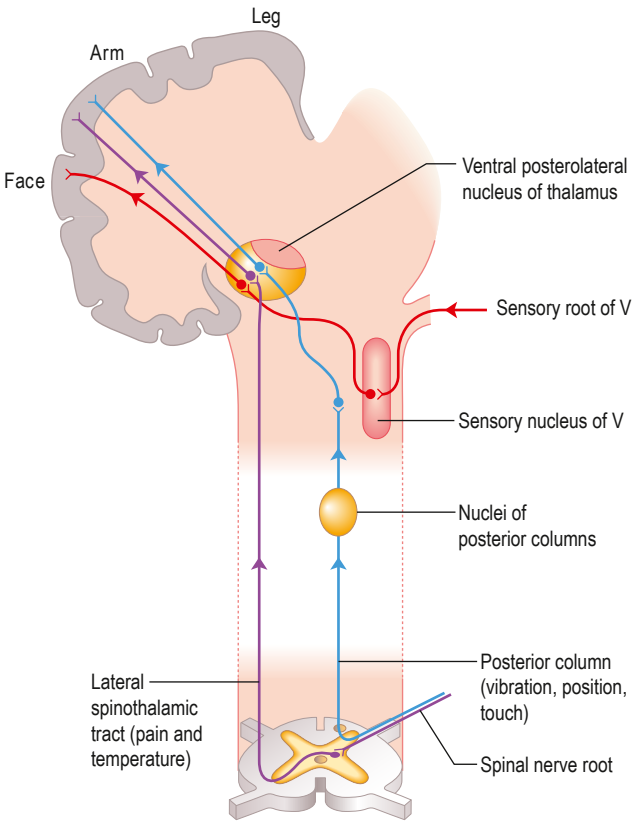

Fig. 28.15 Principal sensory pathways. Posterior columns remain uncrossed until the medulla. Spinothalamic tracts cross close to their entry into the cord.

Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:

- trigeminal neuralgia (see 'Facial pain' section)
- postherpetic neuralgia
- complex regional pain syndrome type II (causalgia)—chronic burning pain that occasionally follows peripheral nerve damage.

Spinal root lesions

Root pain

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch the root (e.g., straight-leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (see 'Cervical and lumbar degeneration' section) are common causes of root lesions.

Dorsal spinal root lesions

Sectioning of a dorsal root causes loss of all modalities of sensation within a dermatome (see Fig. 28.14). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

Spinal cord lesions

Dorsal column lesions

These cause:

- tingling
- electric shock-like sensations
- clumsiness
- numbness
- tight band-like sensations
- limb and gait ataxia.

Many lesions will be bilateral but these symptoms, even if lateralized, are often felt vaguely and without a clear sensory level. Position sense, vibration sense, light touch, and two-point discrimination are diminished below the lesion. Position sense loss produces a stamping gait (sensory ataxia; see 'Tabes dorsalis' section).

Lhermitte's phenomenon

Electric shock-like sensations radiate down the trunk and limbs on neck flexion. This points to a cervical cord lesion involving the dorsal columns. Lhermitte's is common in acute exacerbations of MS (see 'Multiple sclerosis' section), and also occurs in cervical myelopathy, subacute combined degeneration of the cord (see 'Vitamin deficiency neuropathies' section), radiation myelopathy, and cord compression.

Spinothalamic tract lesions

Pure spinothalamic spinal lesions cause contralateral loss of pain and temperature sensation with a clear level below the lesion. This is called ***dissociated*** sensory loss—pain and temperature are dissociated from light touch, which remains preserved. This is seen typically in syringomyelia where a cavity occupies the central cord (see 'Syringomyelia and syringobulbia' section).

The spinal level is modified by lamination of fibres within the spinothalamic tracts. Fibres from lower spinal roots lie superficially and are damaged first by compressive lesions from outside the cord. As an external compressive lesion (e.g., a mid-thoracic extradural meningioma; Fig. 28.17) enlarges, the spinal sensory level ascends as deeper fibres become involved. Conversely, a central cord lesion (e.g., a syrinx; see 'Syringomyelia and syringobulbia' section) affects deeper fibres first and the sensory loss may be *suspended*. Spinothalamic tract lesions cause loss of pain and temperature perception (e.g., painless burns). Perforating ulcers and neuropathic (Charcot) joints develop.

Spinal cord compression

Cord compression (see Fig. 28.17) causes progressive spastic paraparesis (or tetraparesis/quadriparesis) with sensory loss below the level of compression. Sphincter disturbance is common. Root pain is frequent but not invariable, felt characteristically at the level of compression. With thoracic cord compression (e.g., an extradural meningioma), pain radiates around the chest and is exacerbated by coughing and straining, as meningeal root sheaths are stretched.

Hemisection of the cord leads to the ***Brown–Séquard syndrome***. The patient complains of numbness on one side and weakness on the other. Damage affects ipsilateral spinothalamic tract (contralateral loss of pain and temperature), dorsal column (ipsilateral loss of vibration and position sense), and corticospinal tract (contralateral weakness and hyperreflexia). Paraparesis/spinal cord lesions are discussed in the 'Spastic paraparesis' section.

Pontine lesions

Since lesions (e.g., an MS plaque) lie above the decussation of the dorsal columns, and both medial lemniscus and spinothalamic tracts are close together, there is loss of all forms of sensation on the side opposite the lesion. Combinations of IIIrd, IVth, Vth, VIth, and VIIth cranial nerve nuclei are seen, and may indicate a level (see Fig. 28.15).

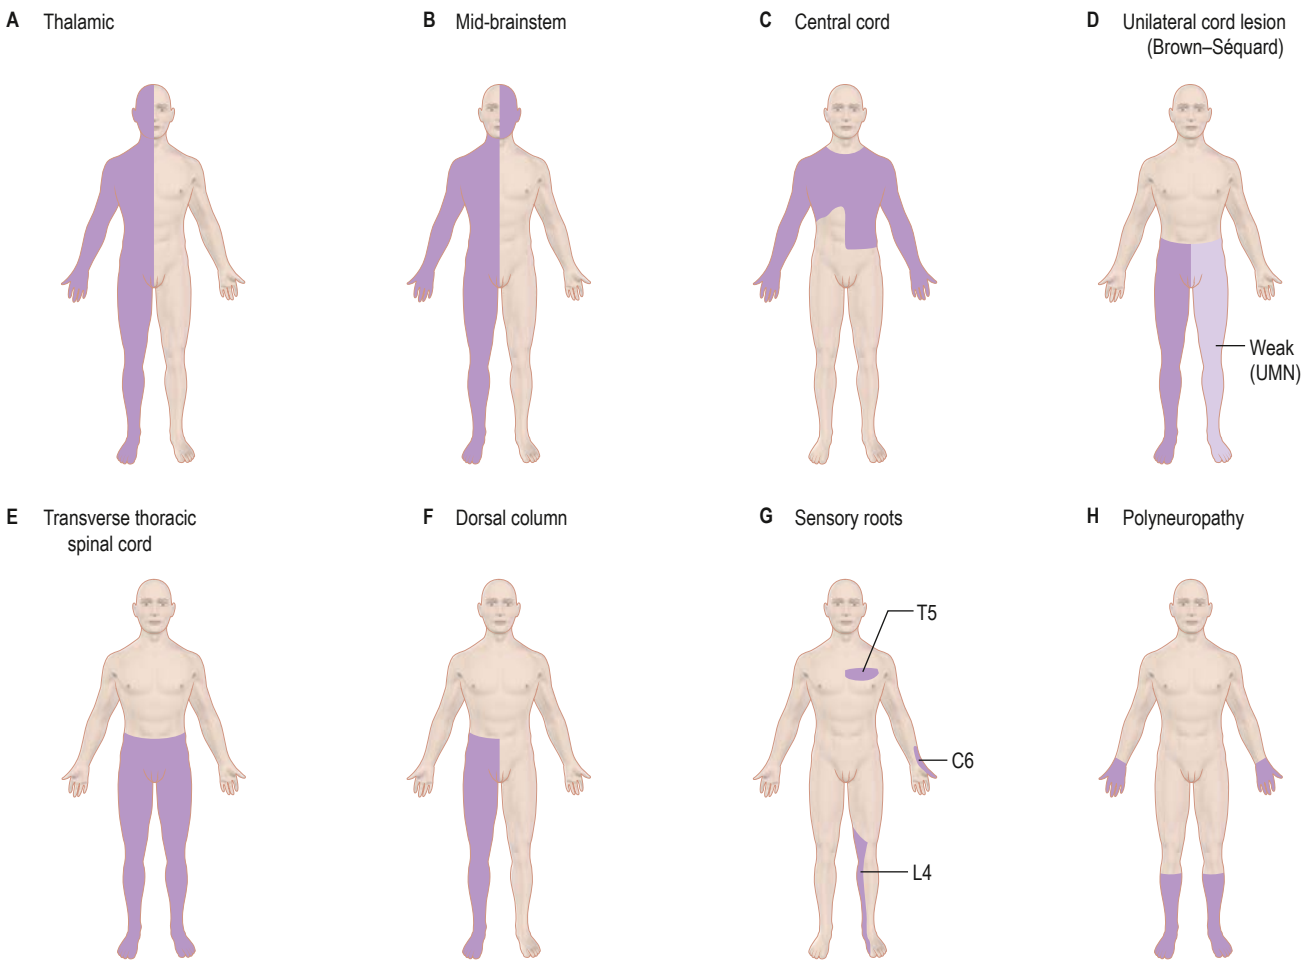

Fig. 28.16 Principal patterns of loss of sensation. (A) *Thalamic lesion:* sensory loss throughout opposite side (rare). **(B)** ***Brainstem lesion:*** contralateral sensory loss below face and ipsilateral loss on face. **(C)** ***Central cord lesion***, for example, syrinx: 'suspended' areas of loss, often asymmetrical and 'dissociated': That is, pain and temperature lost but light touch intact. **(D)** ***Hemisection of cord/ unilateral cord lesion*** —Brown–Séquard syndrome: contralateral spinothalamic (pain and temperature) loss with ipsilateral weakness and dorsal column loss below lesion. **(E)** ***Transverse cord lesion:*** loss of all modalities, including motor, below lesion. **(F)** ***Dorsal column lesion***, for example, multiple sclerosis: loss of proprioception, vibration, and light touch. **(G)** ***Individual sensory root lesions***, for example, C6, T5, L4. **(H)** ***Polyneuropathy:*** distal sensory loss. *UMN,* Upper motor neuron.

Thalamic lesions

Thalamic pain (also called ***central post-stroke pain*** or ***thalamic syndrome***) follows a small thalamic infarct. The patient has a stroke (hemiparesis and sensory loss). Weakness improves but deep-seated constant pain in the paretic limbs develops. Choreoathetotic movements occur. Secondary depression may lead to self-harm. Thalamic lesions can also cause diminished sensation alone, on the opposite side; this is less usual.

Parietal cortex lesions

Sensory loss, neglect of one side, apraxia (see 'Apraxia' section), and subtle disorders of sensation (dysgraphaesthesia, astereognosis) occur. Pain is not a feature of destructive cortical lesions. Irritative phenomena (e.g., focal sensory seizures from a parietal cortex glioma) cause tingling sensations in a limb or elsewhere.

Pain

Pain is an unpleasant, complex sensory and emotional experience. Acute pain serves a biological purpose (e.g., withdrawal) and is typically self-limiting, ceasing as healing ensues. Some forms of chronic pain (e.g., causalgia) outlast the period required for healing and may be permanent.

Essential physiology of pain

Pain perception is mediated by small-diameter myelinated A-delta and non-myelinated C fibres. Chemicals released following injury produce pain either by direct stimulation or by sensitization of nerve endings. A-delta fibres give rise to perception of sharp, immediate pain; slower-onset, more diffuse, and prolonged pain is mediated by slower-conducting C fibres.

Nociceptive (pain) impulses enter the cord via dorsal spinal roots forming synapses in the spinal cord dorsal horn (substance P and glutamate neurotransmitters). Second-order neurons then decussate to the contralateral side and ascend in the spinal cord via two main pathways: the spinothalamic tract (for pain localization) and the spinoreticular tract (mediation of the emotional component of pain; Fig. 28.18). Both pathways project via synapses in the thalamus to the sensory cortex and limbic system. There are projections to brainstem structures: the reticular formation (spinoreticular tract)

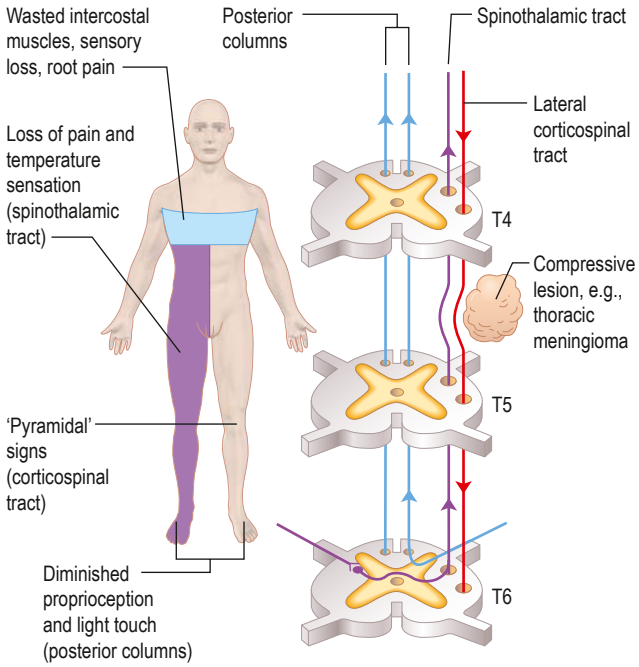

Fig. 28.17 Spinal cord compression: features and anatomy.

and periaqueductal grey (PAG) matter (spinothalamic tract), which modulates pain transmission via descending monoaminergic pathways to the spinal cord dorsal horn. The emotional and affective components of pain, mediated through cortical and limbic networks, are now recognized to be fundamental to pain perception.

Gate theory of pain

Gate theory proposes that transmission of afferent nociceptive (pain) impulses is regulated ('gated') in the spinal cord dorsal horn synapses by afferent impulses from non-nociceptive, large-diameter sensory fibres and descending pathways from the PAG and other brainstem structures. It explains the phenomenon of rubbing a painful area to ease the pain and is also the basis of transcutaneous electrical nerve stimulation (TENS) therapy. Similar gating and modulation of afferent pain signals occur in the brainstem under the influence of connections from the thalamus and limbic system.

Peripheral and central sensitization

Sensitization is an increase in the excitability of peripheral nociceptors and central pain pathways, causing normal sensory inputs such as light touch to produce abnormal responses: that is, pain (termed ***allodynia***). For example, warm water in a shower feels painfully burning on sunburnt skin and touching the scalp is painful during a migraine. This is an adaptive protective response to ensure that contact with an injured area is minimized. However, maladaptive responses to pain via this mechanism at the central or peripheral level may be the basis for chronic pain when it becomes permanent and out of proportion to the initial painful stimulus.

Plasticity and receptor changes

Pain results in neural plasticity changes and reorganization in pain pathways at spinal cord and cortical/brainstem level. These modulate pain and may be maladaptive in some cases, leading to maintenance of chronic pain. Molecular changes also occur in response to painful stimuli, including upregulation of sodium channels and receptor changes.

Types of pain

Nociceptive pain

Nociceptive pain results from physical damage to body tissues, and typically is sharp, aching, or throbbing. Nociceptive nerve fibres are irritated by inflammation, chemicals, or physical trauma. It tends to go away as the body part heals.

Neuropathic pain

Pain results directly from damage to, or dysfunction of, the pain/sensory pathways, such as in peripheral nerve damage, radiculopathy, post-stroke pain, and post-herpetic neuralgia (**Box 28.20**). It is common, affecting 6% to 8% of people. Clinically, the pain usually has an unpleasant burning, electrical, or stabbing quality, with allodynia being a frequent feature. It often becomes chronic due to peripheral and central sensitization processes.

Neurotransmitters and receptors involved in pain

These are involved in pain processing, explaining why a wide range of drug classes are helpful in treating pain.

- ***Excitatory neurotransmitters*** include substance P, glutamate, and calcitonin gene-related peptide (CGRP) in the dorsal horn of the spinal cord and peripherally.
- ***Gamma-aminobutyric acid (GABA)*** is a key inhibitory neurotransmitter.
- ***Opioid receptors***, activated by endogenous endorphins or opiate medications, are widely distributed in pain pathways, including in the spinal cord, peri-aqueductal grey matter, and other brainstem structures.
- ***Noradrenaline (norepinephrine)*** and 5-HT (serotonin) are distributed in descending regulatory pathways.
- ***The vanilloid receptor*** (TRPV1—transient receptor potential cation channel VI) on peripheral nociceptors is activated by capsaicin, the active constituent of chilli peppers.

Management of chronic pain

Chronic pain is gravely disabling, distressing, and difficult to treat. The management of chronic pain is covered in Chapter 50. Multidisciplinary pain clinics provide the best setting for long-term management.

BLADDER CONTROL AND SEXUAL DYSFUNCTION

Changes in micturition and failure of normal sexual activity due to neurological conditions are seen in sacral, spinal cord, and cortical disease.

Essential functions and anatomy

The bladder has two functions: storage and voiding. Afferent pathways (T12–S4) respond to pressure within the bladder and sensation from the genitalia. As the bladder distends, continence is

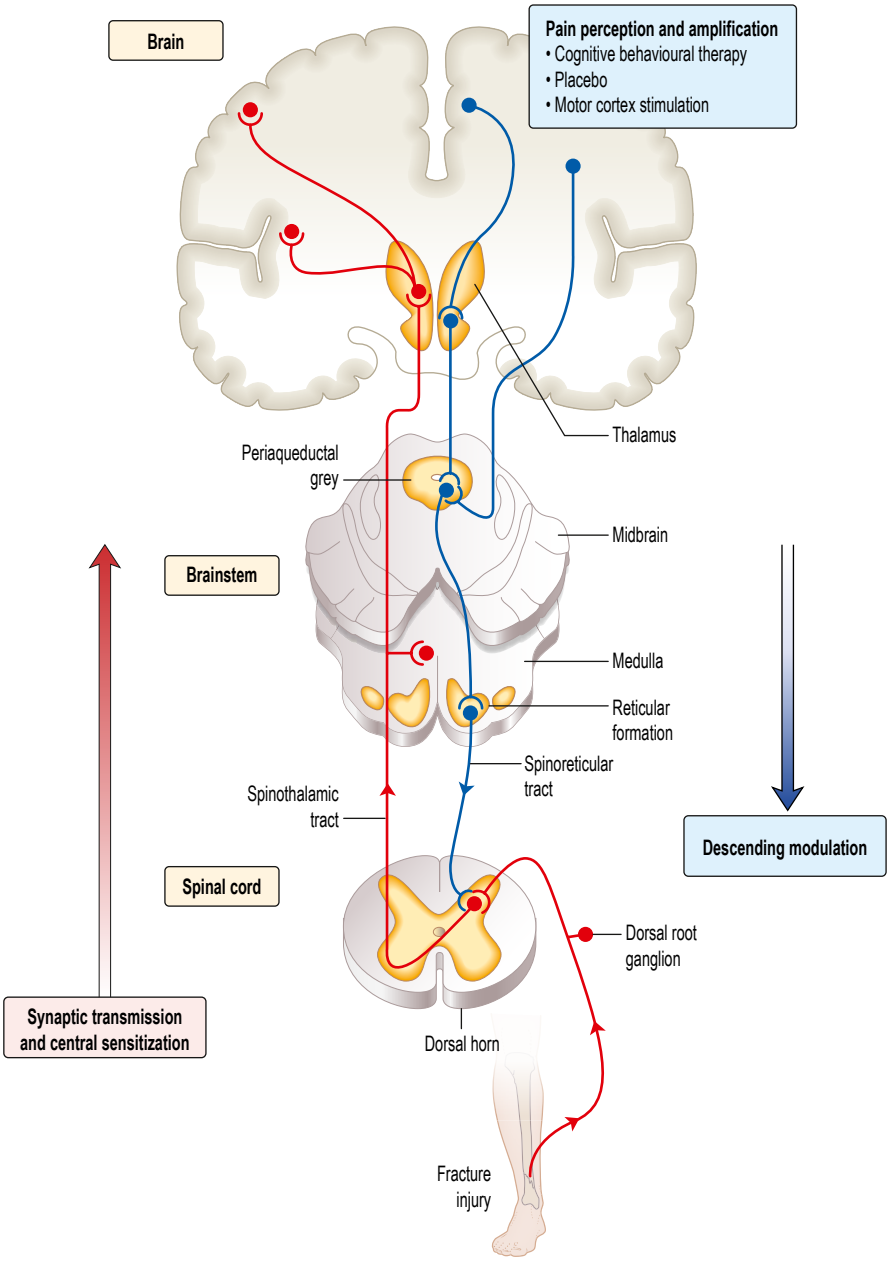

Fig. 28.18 **The spinothalamic and spinoreticular tracts in pain perception.**

maintained by suppression of parasympathetic outflow and reciprocal activation of sympathetic outflow. Both are under some voluntary control. Voiding takes place by parasympathetic activation of the detrusor, and relaxation of the internal sphincter (Box 28.21).

Cortical awareness of bladder fullness is located in the post-central gyrus, parasagittally, while initiation of micturition is in the pre-central gyrus. Voluntary control of micturition is located in the frontal cortex, parasagittally.

Neurological disorders of micturition

Urogenital tract disease is dealt with largely by urologists. Incontinence is common and easy to recognize; neurological causes are sometimes not obvious. These are:

- ***Cortical:***
  - Post-central lesions cause loss of the sense of bladder fullness.
  - Pre-central lesions cause difficulty in initiating micturition and an uninhibited bladder.
  - Frontal lesions cause socially inappropriate micturition.
- ***Spinal cord***. Bilateral UMN lesions (pyramidal tracts) cause urinary frequency and incontinence. The bladder is small and hypertonic: that is, sensitive to small changes in intravesical pressure. Detrusor-sphincter dyssynergia results in urinary retention that can cause hydronephrosis and acute or chronic kidney injury. Frontal lesions can also cause a hypertonic bladder.
- ***LMN***. Sacral lesions (conus medullaris, sacral root, and pelvic nerve—*bilateral*) and acute UMN lesions (spinal shock) cause a flaccid, atonic bladder, with retention and overflow incontinence (cauda equina; see 'Spinal stenosis' section).

Management. Assessment of both urological causes (e.g., calculi, prostatism, gynaecological problems) and potential neurological causes of incontinence is necessary. Intermittent

Box 28.20 Causes of neuropathic pain

Peripheral nerve injury
- Peripheral neuropathy—especially if small (pain) fibres are affected, e.g., diabetes, AL amyloidosis, HIV, chemotherapy (e.g., carboplatin neuropathy), vitamin deficiency, alcohol, Fabry's
- Vasculitic nerve lesions—for example, diabetic amyotrophy, vasculitic mononeuritis multiplex
- Nerve compression—carpal tunnel syndrome, meralgia paraesthetica
- Postherpetic neuralgia
- Nerve trauma or section—for example, phantom limb pain

Nerve root and plexus
- Trigeminal neuralgia
- Radiculopathy due to intervertebral disc prolapse
- Plexopathy—for example, inflammatory (brachial neuritis) or neoplastic infiltrative (e.g., breast cancer)

Central nervous system disorders
- Multiple sclerosis (pain is common in progressive forms)
- Post-stroke pain—for example, thalamic strokes
- Spinal cord lesions—intrinsic cord lesions, inflammatory or vascular (infarcts), especially
- Parkinson's disease

Box 28.21 Efferents to the bladder and genitalia

Nerve supply	Function
Parasympathetic S2–4	Bladder wall: contraction Internal sphincter: relaxation Penis/clitoris: engorgement
Sympathetic T12–L2	Bladder wall: relaxation Internal sphincter: contraction Orgasm, ejaculation
Pudendal nerves	External sphincter (skeletal muscle)

self-catheterization is used by many patients who have, for example, spinal cord lesions.

Male erectile dysfunction

Failure of penile erection often has mixed organic and psychological causes. Depression is common. Erectile dysfunction is described in Chapter 47 ('Loss of libido and erectile dysfunction' section).

INVESTIGATION OF NEUROLOGICAL DISEASE

Neurological investigations, such as brain scans, should not be a substitute for clinical evaluation through history-taking and examination. An experienced clinician will be able to make an accurate diagnosis in most patients without recourse to investigations: for example, in most individuals presenting with headache. However, cross-sectional imaging will allow confirmation of the anatomical localization of lesions and may reveal the presence of other clinically 'silent' lesions. Imaging does not always indicate the pathological nature of a visualized lesion (careful history-taking is essential in this regard) and therefore needs to be carefully interpreted in the clinical context. Neurophysiological investigations provide information about nervous system *function* and are more diagnostically helpful than imaging in some situations: for example, in patients with primary generalized epilepsies or peripheral nerve disorders.

Unnecessary or inappropriate use of investigations, particularly brain imaging, exposes patients to risk, such as radiation; is an inefficient use of resources; and may lead to identification of incidental findings that cause considerable anxiety (there is a 3% incidental abnormality rate for brain MRI scans). Clinicians should also be familiar with the range of normal in the population; for example, the high prevalence of white-matter hyperintensities on brain MRI in older people and the range of common non-specific electroencephalogram (EEG) changes.

Blood tests

Standard blood tests, such as full blood count, erythrocyte sedimentation rate (ESR), biochemistry, glucose/HbA_{1c}, C-reactive protein, creatine kinase, and protein electrophoresis, are helpful to identify underlying disorders such as diabetes, metabolic disorders, and other systemic disorders that may underlie neurological presentations (e.g., coma or peripheral neuropathy). Relevant tests are covered in disease-specific subsections.

Genetic tests

Several hundred neurogenetic disorders are now recognized and, for many of these, specific molecular genetic investigations are available for diagnostic and predictive testing (see Chapter 5). As genetic testing is complex and expensive, it should only be undertaken after senior specialist advice. Increasingly, there is a move to whole genome sequencing, usually examining virtual panels relevant to a particular phenotype. Informed patient consent is required, as a positive test may have implications for other family members. Predictive testing in non-affected, at-risk individuals should only be undertaken after detailed genetic counselling by a specialist.

Immunological tests

An increasing number of autoimmune neurological disorders are recognized, many of which are associated with specific antibody tests (see **Box 28.22**). Many of these are paraneoplastic syndromes but an increasing number of non-cancer-related autoimmune syndromes have been identified, such as forms of encephalitis or MG. In addition, monoclonal paraproteins associated with plasma cell dyscrasias may cause immune-mediated peripheral neuropathy.

Neuroimaging

See Chapter 8. Central nervous system imaging in stroke is covered in Chapter 29.

Lumbar puncture

This is explained in Chapter 11.

Neurophysiological investigations

Electroencephalography

Brain electrical activity (**Fig. 28.19**) is recorded from scalp electrodes (20 channels simultaneously). Its main use is to characterize epilepsy syndromes. Recordings are usually made between seizures (inter-ictal). Sleep-deprived EEG and 24-hour ambulatory EEG increase diagnostic sensitivity. Videotelemetry (VT) combines continuous EEG with video over several days to record the semiology and electrical characteristics of seizures. VT is invaluable diagnostically to identify seizure type where there is clinical uncertainty, and to pinpoint the seizure focus in focal epilepsies.

Epilepsy

Spikes, or spike-and-wave abnormalities, are hallmarks of epilepsy, but it is important to emphasize that patients with epilepsy often have a normal EEG between seizures (see 'Epilepsy and loss of consciousness' section).

Diffuse brain disorders

Slow-wave EEG abnormalities appear in encephalopathy (e.g., hepatic coma), encephalitis, and prion (Creutzfeldt–Jakob) diseases.

Brain death

The EEG is isoelectric (flat); EEG is not necessary to confirm brain death in many countries (see Chapter 13, 'Death by neurological criteria' section).

Box 28.22 Neurological autoantibody tests

Clinical disorder	Antibody (Ab) test
Paraneoplastic disorders: cerebellar ataxia, limbic encephalitis, opsoclonus–myoclonus, progressive encephalomyelitis with rigidity and myoclonus	Antineuronal antibodies including anti-Hu, Yo, Ma2/Ma1, CV2, Ri, Tr, amphiphysin
Teratoma-associated limbic encephalitis	NMDA Abs
Limbic encephalitis (non-paraneoplastic)	Anti-potassium channel, glycine Abs

[a]May also be paraneoplastic. *Abs,* antibodies.

Electromyography and nerve conduction studies

Electromyography (EMG) and nerve conduction studies (NCS) are skilled investigations of nerve function that are essential for investigation of peripheral nerve, anterior horn cell, NMJ, and to a lesser extent, muscle disorders. NCS are highly sensitive in identification of large fibre peripheral neuropathy, and assessment of the nerves affected and the type of pathology (axonal loss versus demyelinating). In mononeuropathies, the anatomical site of the lesion may be identified with considerable accuracy and prognostic information obtained.

Electromyography

A concentric needle electrode is inserted into voluntary muscle. Amplified recordings, on an oscilloscope, are also heard through a speaker. The main EMG features include:

- normal interference pattern
- denervation and re-innervation changes
- myopathic and myotonic features (see 'Myotonic dystrophy [DM]' section).

Single-fibre EMG is used for disorders of NMJ transmission.

Peripheral nerve conduction

Electrical stimulation of a peripheral nerve generates a nerve impulse that may be recorded (Fig. 28.20). Four measurements are of principal value in neuropathies and nerve entrapment:

- nerve conduction velocity
- distal motor latency
- sensory action potentials (SAPs)
- compound muscle action potentials (CMAPs).

Small action potential size (SAP and CMAP) indicates loss of axons. Conduction block and slowing of conduction velocity indicate demyelinating neuropathy, as saltatory conduction is lost with damage to the myelin sheath. Repetitive nerve stimulation is used to identify NMJ conduction disorders (myasthenia).

Cerebral-evoked potentials

Visual-evoked potentials (VEPs) record the interval visual stimuli take to reach the occipital cortex, and the amplitude of response. VEPs are used to confirm previous optic neuritis (see 'Optic neuritis'

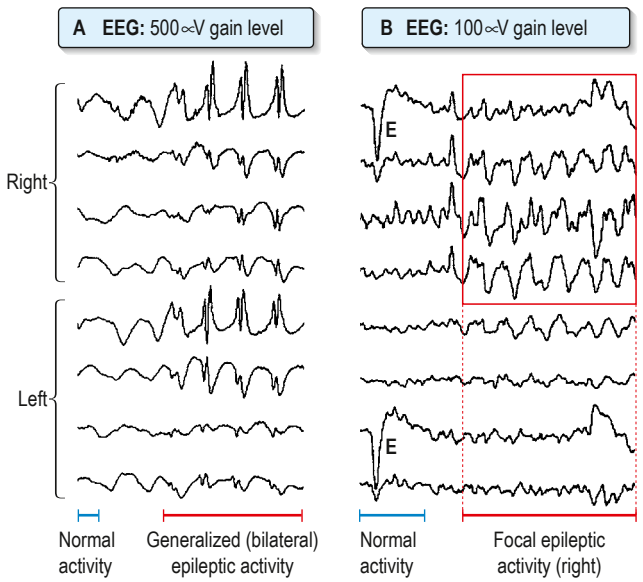

Fig. 28.19 Examples of EEG traces. **(A)** Normal activity followed by generalized epileptic spikes in all leads. **(B)** Normal activity followed by focal spikes in right leads. *E,* Eye-movement artefact.

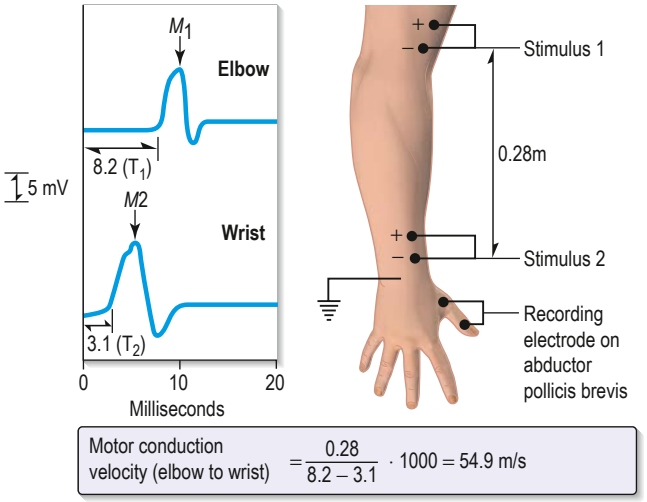

Fig. 28.20 Measurement of motor conduction velocity (MCV) in ulnar nerve. The recording electrode on abductor pollicis brevis measures the muscle action potential (M) from ulnar nerve stimulation at the elbow (stimulus 1) and wrist (stimulus 2). MCV calculation:
M_1 = muscle action potential (MAP) from stimulus 1.
M_2 = MAP from stimulus 2.
T_1 = time from elbow to recording electrode.
T_2 = time from wrist to recording electrode.

$$MCV = \frac{\text{distance (metres)}}{T_1 - T_2} \times 1000 = m/s$$

section in the 'Neuroinflammatory disorders' section); this leaves a delayed latency despite clinical recovery.

Similar techniques for auditory and somatosensory potentials (from a limb) are also used.

Biopsy

Interpretation of brain, tonsillar, muscle, and nerve histology requires specialist neuropathology services.

Brain and meninges

Brain biopsy (e.g., of a non-dominant frontal lobe) is rarely used to diagnose inflammatory and degenerative brain diseases. CT and MR stereotactic biopsies of intracranial lesions are standard procedures.

Muscle

Muscle biopsy (usually quadriceps), with light/electron microscopy and immunohistochemical analysis, is performed routinely for diagnosis of inflammatory, metabolic, and dystrophic disorders (see 'Muscle diseases' section).

Peripheral nerve

Nerve biopsy, usually of the (sensory) sural nerve or superficial sensory branch of the radial nerve, can be of value in the diagnosis of peripheral neuropathy: for example, if vasculitis, amyloid deposition, or malignant infiltration is suspected. There may be significant complications (wound healing and pain), so it should be undertaken only where all other investigations are non-diagnostic and where there is clinical evidence of a severe or progressive neuropathy.

Psychometric assessment

Psychometric testing, performed by neuropsychologists, assesses cognitive function in more detail than bedside testing during clinical examination. Decline in intellectual function, as compared with estimated pre-morbid IQ, is seen following brain injury or in dementia, for example. Individual cognitive domains, such as various types of memory, language, visuospatial function, and frontal executive function, are tested separately, as they may be differentially involved in different disorders, the pattern of involvement often being of considerable diagnostic value. Serial testing at intervals of 6 to 12 months may be needed to show clear evidence of progression in neurodegenerative disorders such as dementias.

NEUROLOGICAL CONDITIONS

Neurological conditions covered elsewhere in the book include:

- Stroke and intracerebral haemorrhage—see Chapter 29
- Coma and reduced consciousness—see Chapter 11
- Status epilepticus and acute symptomatic seizures—see Chapter 11
- Evaluation of acute headache, including intracranial haemorrhage and meningitis—see Chapter 11
- Functional neurological disorders—see Chapters 11 and 30

HEADACHE, MIGRAINE, AND FACIAL PAIN

Headache is an almost universal experience and one of the most common symptoms in medical practice. It varies from an infrequent and trivial nuisance to a pointer to serious disease. Headache symptoms are unpleasant, disabling, and common worldwide, and have a substantial economic impact because of time lost from work. The approach to acute headaches is discussed further in Chapter 11.

Mechanisms

Pain receptors are located at the base of the brain in arteries and veins, and throughout meninges, extracranial vessels, scalp, neck and facial muscles, paranasal sinuses, eyes, and teeth. Curiously, brain substance is almost devoid of pain receptors. Head pain is mediated by the Vth and IXth cranial nerves and upper cervical sensory roots.

Clinical approach to the patient with headache

In assessing patients with headache, the aim should be to make a confident diagnosis based on the history. Examination is helpful in excluding underlying medical disorders as a cause of headache, but will not distinguish between different types of primary headache.

There is an internationally agreed classification for headaches that defines all headache patterns. Headache is divided into:

- primary headache disorders such as migraine,
- secondary headaches due to underlying pathology such as raised ICP or meningitis (**Box 28.23**).

It is also useful to distinguish between episodic (recurrent) headache, single first headache episodes, and patients with chronic headache.

Box 28.23 Some causes of secondary headache

- Raised intracranial pressure, e.g., idiopathic intracranial hypertension, mass lesions
- Cerebral venous sinus thrombosis
- Cervical artery dissection
- Infections, e.g., meningitis, acute sinusitis
- Giant cell arteritis
- Intracranial haemorrhage, especially subarachnoid haemorrhage or subdural haematoma
- Low cerebrospinal fluid volume (low-pressure) headache
- Hypoxia or hypercapnia (obstructive sleep apnoea, nocturnal hypoventilation, carbon monoxide poisoning)
- Post-traumatic headache
- Cervicogenic headache
- Reversible cerebral vasoconstriction syndrome
- Cerebral vasculitis
- Acute glaucoma

In an outpatient clinic setting, most headaches will be benign. Fewer than 1% of outpatients with non-acute headache have a serious underlying cause but in the emergency department there will be a much higher prevalence of serious underlying pathology presenting with headache. New-onset severe headache in those without a previous headache history, especially in older patients (>50), requires exclusion of underlying pathology causing secondary headache.

There are some widely believed 'headache myths'. Headaches are not caused by hypertension, except rarely with malignant hypertension (see Chapter 18). Eye strain from refractive error does not cause headache and sinusitis is rarely the explanation for recurrent or chronic headache.

Taking a history for headaches

Ask about:

- Headache location (e.g., hemicranial), severity, and character (e.g., throbbing versus non-throbbing)
- Associated symptoms, e.g., nausea, photophobia, phonophobia, and motion sensitivity
- Presence of autonomic symptoms, e.g., tearing, conjunctival injection, ptosis, miosis, nasal congestion or rhinorrhoea, eyelid swelling, aural fullness, facial sweating, or swelling
- Relieving or exacerbating features, e.g., effect of posture
- Headache pattern: is headache episodic and part of a pattern of previous similar headaches? Age at onset and headache frequency
- Duration of headache episodes (helpful in distinguishing between different primary headache types)
- Triggers
- Pattern of analgesic use
- Family history of headache
- 'Red flag' symptoms (**Box 28.24**): fever (meningitis, sinusitis)
- Sudden onset, reaching maximum intensity in less than 1 minute (SAH)
- Features of raised ICP
- Jaw claudication (GCA).

Examination

Examination should include fundoscopy to look for papilloedema. In older patients, temporal arteries should be palpated for loss of pulsatility and tenderness that may be features of GCA. Fever and neck stiffness suggest meningitis. Examination is generally normal in patients with primary headache disorders.

Box 28.24 Red flag features that may indicate a secondary cause of headache

Older age (onset after age 50)
Systemic symptoms including fever, weight loss
Neurological deficits, change in cognition or personality, change in conscious level
Atypical aura (including weakness)
New onset seizures
New or recent onset headache with no prior history of similar headaches
Thunderclap onset
History of cancer, other significant systemic disease, or immunosuppression (including HIV)
Papilloedema
Valsalva headache (precipitated by coughing, exercise, sex)
Orthostatic changes in headache (worse either lying down or upright)
New headaches in pregnancy or puerperium
Painful or red eye; visual loss (other than classical migraine aura)
History of recent head injury
Substantial change in nature or pattern of headache

Investigations

Investigations, including brain imaging, do not contribute to the diagnosis of primary headache disorders. Neuroimaging is indicated only where history or examination suggests the possibility of an underlying secondary cause. Older patients with new-onset headache and those with 'red flag' symptoms (**Box 28.24**) should have brain imaging. In patients over 50 with new headache, inflammatory markers should be checked to exclude GCA.

In practice however brain imaging is frequently performed for 'reassurance'. If this is done, it is important to warn the patient of the 3% risk of incidental findings.

Primary headache disorders

Migraine

Migraine is the most common cause of episodic disabling headache (affecting 15%–20% of women and 5%–10% of men); in 90%, onset is before 40 years of age. Episodes of headache are associated with sensory sensitivity such as to light, sound, or movement, and sometimes with nausea and vomiting. There is a spectrum of severity between individuals and from one attack to another. Migraine is usually high-impact, with inability to function normally during episodes. Headache frequency in migraine varies from an occasional inconvenience to frequent headaches severely impacting on quality of life, and may transform into chronic daily headache.

Mechanisms

Genetic factors play a part in causing the neuronal hyperexcitability that is probably the biological basis of migraine. Migraine risk is usually polygenic but rare cases of familial hemiplegic migraine are channelopathies, associated with variants in genes encoding ion channels.

The pathophysiology of migraine is now thought to have a primarily neurogenic rather than vascular basis. Spreading cortical depression—a wave of neuronal depolarization followed by depressed activity slowly spreading anteriorly across the cerebral cortex from the occipital region—is thought to be the basis of the migraine aura. Activation of trigeminal pain neurons is the basis of the headache. The innervation of the large intracranial vessels and dura by the first division of the trigeminal nerve is known as the trigeminovascular system. Release of CGRP, substance P, and other vasoactive peptides, including 5-HT, by

activated trigeminovascular neurons causes painful meningeal inflammation and vasodilation. Peripheral and central sensitization of trigeminal neurons and brainstem pain pathways makes otherwise innocuous sensory stimuli (such as CSF pulsation and head movement) painful, and light and sound are perceived as uncomfortable.

Clinical features

Migraine without aura

Migraine typically starts around puberty with increasing prevalence into the fourth decade. There is a spectrum of severity and associated features, but attacks have recognizable core features (**Box 28.25**). Most migraine attacks are of sufficient severity to prevent sufferers continuing with normal activities; sleep usually helps. A 'washed-out' feeling follows the attack. The scalp may be tender to touch during episodes (allodynia) and the preference is to be still in a dark, quiet environment.

Some patients recognize changes in routine as trigger factors:

- Sleep (too little or too much).
- Stress (including letdown after a period of stress).
- Hormonal factors for women—changes in oestrogen levels, for example menstrual migraine (usually just before menses) and worsening with the oral contraceptive pill and menopause.
- Eating—skipping meals and alcohol. Contrary to popular belief, individual foods are rarely a trigger.
- Other—sensory stimuli, such as bright lights or loud sounds; physical exertion; and changes in weather patterns, for example stormy weather. Minor head injuries may trigger a worsening of migraine frequency and severity.

Migraine with aura

Approximately 25% of migraine sufferers experience focal neurological symptoms immediately preceding the headache phase in some or all attacks; this is termed migraine aura. Most never experience aura, and the presence of aura is therefore not required for a diagnosis of migraine. Aura usually evolves over 5 to 20 minutes, with symptoms changing as the wave of spreading neuronal depression moves across the surface of the cortex. It rarely lasts longer than 60 minutes and is followed immediately by the headache phase.

Visual aura is the most common type, with positive visual symptoms such as shimmering, teichopsia (zigzag lines, also called fortification spectra), and fragmentation of the image (like looking through a pane of broken glass) often accompanied by patches of loss of vision, which may move across the visual field (scotomas) and even evolve into hemianopia or tunnel vision. Positive sensory symptoms (mainly tingling), dysphasia and, rarely, loss of motor function may also occur, and may occur successively within the same episode of aura following the visual symptoms.

Box 28.25 Migraine: simplified diagnostic criteria

Headache lasting 4 hours to 3 days (untreated)

At least two of:

- Unilateral pain (may become holocranial later in attack)
- Throbbing-type pain
- Moderate to severe intensity
- Motion sensitivity (headache made worse with head movement or physical activity)

At least one of:

- Nausea/vomiting
- Photophobia/phonophobia
- Normal examination and no other cause of headache

Migraine aura usually presents no diagnostic difficulty, but problems with diagnosis may sometimes arise in men over the age of 50 who develop migraine aura for the first time without subsequent headache (sometimes referred to as acephalalgic migrainous aura). This is frequently misdiagnosed as a TIA (see Chapter 29). Distinguishing the two conditions is often difficult and relies on the characteristic evolution of symptoms over minutes and the presence of positive symptoms in aura, in contrast to TIA where symptom onset is acute and negative symptoms (visual loss as opposed to visual distortion and teichopsia) are the norm. There may also be a history of previous typical migraine aura in early adult life to help distinguish the conditions.

Migraine-related dizziness

Vertigo is now recognized as being a migrainous symptom in some individuals, with attacks lasting for hours in the context of migraine attacks. There is an overlap with what is sometimes described as basilar migraine, a poorly defined migraine subtype associated with brainstem aura-type symptoms before or during attacks, including perioral paraesthesiae, diplopia, unsteadiness and, rarely, reduced level of consciousness.

Familial hemiplegic migraine

This rare autosomal dominant disorder, a brain channelopathy, causes a hemiparesis and/or coma and headache, with recovery within 24 hours. Some patients have permanent cerebellar signs, as some forms are allelic with episodic ataxia. It is distinct from more common forms of migraine. Causative genes have been identified that cause a proportion of familial hemiplegic migraine cases, and include the α-1 subunit of the P/Q-type voltage-gated calcium channel *(CACNA1A)*, the α-2 subunit of the sodium/potassium-transporting ATPase *(ATP1A2)* and the neuronal sodium channel *(SCN1A)*.

Hemiplegic migraine (or migraine with motor aura) can also occur in a sporadic rather than familial fashion, although most of those affected will not have an identifiable brain channelopathy. The presence of new focal weakness or other atypical aura symptoms with a migraine should prompt brain imaging.

Management

General measures include:

- explanation
- avoidance of trigger factors and lifestyle modification (e.g., the importance of maintaining a regular routine, good sleep hygiene, regular meals, adequate hydration, stress management, and exercise).

Acute treatment of attacks

Analgesics, such as paracetamol 1 g, high-dose dispersible aspirin (900 mg), or an NSAID (e.g., naproxen 250–500 mg), are first-line treatment, with an antiemetic such as metoclopramide. The combined use of aspirin, paracetamol, and an antiemetic is often more effective than single agents. Antiemetics are useful even when there is no substantial nausea. Acute treatment should be taken as soon as possible after onset of headache. Patients should be aware that repeated use of analgesics leads to further headaches, and use of acute headache treatments should be limited to fewer than 12 days per month (see medication overuse headache, see 'Chronic daily headache' section).

Triptans (5-$HT_{1B/1D}$ agonists) are specific for migraine and may be effective where simple analgesics are insufficient. Sumatriptan was the first marketed; almotriptan, eletriptan, frovatriptan,

naratriptan, rizatriptan, and zolmitriptan are now available, with various routes of administration. Subcutaneous sumatriptan injection may be effective where vomiting prevents absorption of oral medication (note that nasal triptan sprays rely on gastrointestinal rather than nasal absorption). Triptans should be avoided when there is vascular disease, and like analgesics, they should not be overused.

CGRP modulates trigeminovascular pain transmission in migraine. Small molecule CGRP antagonists, known as gepants, have been shown to be effective abortive therapy for migraine. Availability of these drugs (e.g., rimegepant) is still limited but likely to increase. They may have a role in migraine prevention too, as initial data suggests that they do not cause medication overuse or rebound headache.

Status migrainosus

Severe, intractable migraine attacks lasting for longer than 72 hours, are known as status migrainosus. This is a reasonably common problem in the emergency department, and treatment options are based on limited evidence. Commonly tried treatments include intravenous fluids and dopamine receptor blockers (e.g., intravenous metoclopramide 10 mg or intramuscular prochlorperazine 12.5 mg; caution is required in young people who may develop acute dystonic reactions). Subcutaneous sumatriptan 3 to 6 mg could be given if a triptan has not already been tried for that migraine episode. Intravenous ketorolac 15 to 30 mg (an NSAID) is another option if available, and intravenous valproate 500 to 1000 mg can also be given (as a one-off dose). Parenteral corticosteroids may sometimes be used with the aim of preventing early relapse.

Migraine prevention

When migraine episodes are frequent (>4 per month, for example) and impacting on quality of life, migraine preventers should be offered. The key principles are that a period of 3 months' treatment, at an adequate dose, is usually necessary to judge efficacy, and up to 50% of patients will achieve a 50% reduction in headache frequency and severity after this time. These medications should be used in conjunction with a headache diary. Withdrawal of the medication should be attempted after 6 months because for some people the migraine frequency may be 'reset' beyond the treatment period, but the drug may need to be reintroduced if this fails. However, these medications will not be effective where ongoing analgesic overuse is an issue.

Treatment options for migraine prevention include:

- ***Tricyclics***, such as amitriptyline 10 mg, increasing weekly in 10 mg steps to 50 to 60 mg.
- ***Beta-blockers***, such as propranolol slow-release 80 to 160 mg daily.
- ***Anticonvulsants.*** Valproate (800 mg) or topiramate (100–200 mg daily) are generally the most effective options. For women of childbearing age, valproate should be avoided, and topiramate (when given for migraine) should be used with effective contraception.
- ***Candesartan.*** Up to 16 mg daily.
- ***Antidepressants***, such as venlafaxine up to 150 mg daily.
- ***Nonpharmacological treatments.*** Riboflavin 400 mg (vitamin B_2) daily has some evidence for use in migraine prevention, as does acupuncture.
- ***Botulinum toxin.*** This was recommended as a treatment for chronic migraine (see Chapter 42, 'Botulism' section). The technique involves 31 injections over the scalp and neck repeated every 3 months. Its effect is inconsistent.
- ***Greater occipital nerve blocks*** can be used for chronic migraine, occasionally on a regular basis but more commonly as a temporizing measure to allow titration of a migraine preventer medication and/or analgesia withdrawal. They are also useful in pregnancy.
- ***Pizotifen.*** This is rarely used. Flunarizine (a calcium channel blocker) and methysergide are used in refractory patients.
- ***CGRP antagonists.*** Monoclonal antibodies directed against the CGRP ligand or receptor (e.g., erenumab, fremanezumab, galcanezumab, and eptinezumab) have proven efficacy for reduction of migraine severity and frequency, but are very costly and are reserved for people who have failed to respond to multiple migraine preventers.

Tension-type headache

The exact pathogenesis of tension-type headache (TTH) remains unclear. There is overlap with migraine, and many headaches traditionally subsumed under this category probably, in fact, represent mild migraine. Since there are no diagnostic tests to separate TTH from mild migraine, it is difficult to know if the conditions are biologically distinct. In contrast to migraine, pain is usually of mild to moderate severity, bilateral and relatively featureless, with tight band sensations, pressure behind the eyes, and bursting sensations being described.

Depression is also a frequent co-morbid feature. TTH is often attributed to cervical spondylosis, refractive errors, or high blood pressure; evidence for such associations is poor.

Simple analgesics are often effective but overuse should be avoided. Physical treatments, such as massage, ice packs, and relaxation, are often recommended. Frequent or chronic TTH may respond to migraine suppression medications as above, with tricyclics often being used first line.

Trigeminal autonomic cephalalgias

The trigeminal autonomic cephalalgias are a group of primary headache disorders characterized by strictly unilateral trigeminal distribution pain (usually in the ophthalmic division of the nerve) and prominent ipsilateral autonomic features. Bilateral autonomic features are also common in migraine, but these rarer disorders should be suspected when headaches and autonomic symptoms are side-locked, always occurring and remaining on the same side of the head. Neuroimaging is mandatory for these patients, as some will have an underlying structural cause (particularly in the pituitary fossa).

Cluster headache

Cluster headache is distinct from migraine and much rarer (1 per 1000). It affects adults, mostly males aged between 20 and 40. Patients describe recurrent bouts (clusters) of excruciating unilateral retro-orbital pain with parasympathetic autonomic activation in the same eye, causing redness or tearing of the eye, nasal congestion, or even a transient Horner's syndrome. The pain is reputed to be the worst known to humans, and patients often contemplate, and sometimes commit, suicide, such is the severity of the pain. Unlike with migraine attacks, patients prefer to move about or rock rather than remain still.

Attacks are shorter than migraine, usually 30 to 90 minutes, and may occur several times per day. There is often a circadian pattern with headaches occurring at the same time of day, especially in sleep. Clusters last 1 to 2 months, with attacks most nights, before stopping completely and typically recurring a year or more later, often at the same time of year. Attacks are side-locked but they

can sometimes switch sides between 1 year and the next. Some patients unfortunately go on to develop chronic cluster headache without periodic remissions. Although the cause is not known, hypothalamic activation is seen on functional imaging studies during an attack.

Management. Analgesics are unhelpful. Subcutaneous sumatriptan is the drug of choice for acute treatment, as no other drug works quickly enough. High-flow oxygen is also used. Most prophylactic migraine drugs are unhelpful. Verapamil, lithium, and/or a short course of steroids help terminate a bout of cluster headaches.

Paroxysmal hemicrania, SUNCT and hemicrania continua

Paroxysmal hemicrania is a rare condition with similarities to cluster headache, differing mainly in that attacks are briefer (2–30 minutes) and more frequent (>5 per day, at any time of day) and do not occur in clusters. Women are more often affected than men. There is a rapid and complete response to indometacin.

Short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT) is very rare. Attacks are short, 5 seconds to 2 minutes, and very frequently occur in bouts. Distinguishing SUNCT from trigeminal neuralgia can be difficult, but there is no refractory period after a SUNCT attack and classically the trigeminal autonomic cephalalgias will arise in the distribution of the ophthalmic division of the trigeminal nerve (V_1) while trigeminal neuralgia typically affects V_2–V_3. Occasionally SUNCT attacks are so frequent that they can appear continuous and there is confusion with migraine.

Hemicrania continua is a continuous, strictly unilateral headache, sometimes with acute exacerbations and associated with ipsilateral autonomic features. Like paroxysmal hemicrania, there is a complete response to indometacin.

Other primary headache disorders

- ***Primary stabbing headache ('ice pick headache')*** involves momentary jabs or stabs of localized pain occurring either in the same spot or moving about the head. Symptoms wax and wane, and are more common in patients with other primary headache disorders, particularly migraine. Treatment is usually not needed but this type of headache responds well to indometacin.
- ***Primary cough headache*** is a sudden, sharp head pain on coughing. No underlying cause is found but intracranial pathology should be excluded. The problem often resolves spontaneously. Indometacin is the treatment of choice; LP with removal of CSF can help.
- ***Primary sex headache*** is characterized by explosive headache at or before orgasm. It often resolves spontaneously after several attacks. Investigation to exclude SAH is required after the first episode.
- ***Other varieties*** of primary headache include primary exertional headache, hypnic headache (headache triggered by sleep), nummular (coin-shaped) headache, and primary thunderclap headache.

Chronic daily headache

This is defined as headache on 15 or more days per month for at least 3 months. Up to 4% of the population are affected by daily or near-daily headache. Although there are many possible causes, including secondary headache disorders, in practice, primary headache disorders, particularly migraine, are responsible for the majority. Where migraine is the cause, the term chronic migraine is now preferred.

Overuse of analgesic medication or triptans (termed ***medication overuse headache***) is often a major factor leading to and maintaining chronicity, particularly in those with migrainous biology. Use of 15 or more doses per month of any simple analgesic, or 10 or more if triptans are being used, may eventually lead to transformation of episodic headache into chronic daily headache. Opioids are particularly problematic and will cause rebound headache or rapidly lead to medication overuse headache in susceptible individuals; opioids should be avoided entirely for headache treatment (and patients should be warned that some over-the-counter migraine preparations contain opioids).

Explanation that medication overuse is part of the problem is essential to help patients withdraw from or substantially reduce analgesic intake. This is a difficult process for many patients, especially as there may be a period of transient rebound worsening of headache after withdrawal. Concurrent introduction of migraine suppression medication (see above) may help withdrawal but will not be effective if patients cannot withdraw from frequent analgesic use. Occasionally, hospital admission for analgesic withdrawal with parenteral administration of dihydroergotamine is required.

Secondary headache disorders

Raised intracranial pressure headache

Any headache present on waking and made worse by coughing, straining, or sneezing may be due to raised intracranial pressure (ICP) caused by a mass lesion, hydrocephalus, or venous sinus thrombosis. Vomiting often accompanies pressure headaches. Visual obscurations (momentary bilateral visual loss with bending or coughing) are characteristic and seen in the presence of papilloedema. Occasionally, where ICP rises quickly, papilloedema may not be present.

Neuroimaging is mandatory if raised ICP is suspected. Where no mass lesion, venous sinus thrombosis, or hydrocephalus is detected on imaging in the presence of papilloedema, idiopathic intracranial hypertension may be the cause, and LP is performed to measure CSF opening pressure.

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH) probably results from reduced CSF resorption. IIH typically develops in younger, overweight female patients. Headaches and transient visual obscurations due to the florid papilloedema are the presenting features. A VIth nerve palsy may develop—a false localizing sign (see 'VI: Abducens nerve lesions' section). CSF pressure is very elevated, with normal constituents. Brain imaging is normal, although ventricles may be small and appear 'slit-like'.

Various drugs, such as tetracyclines and vitamin A supplements, have been implicated. Other causes of papilloedema (or pseudopapilloedema) should be excluded. Sagittal sinus thrombosis can cause a similar picture and should always be looked for on MR or CT venography.

IIH is usually self-limiting. However, optic nerve damage can result from longstanding or fulminant papilloedema with progressive loss of peripheral visual fields. Suspected IIH with visual loss should be managed without delay, with an early lumbar puncture for both diagnosis and therapeutic pressure-lowering. Regular monitoring of visual fields with perimetry is essential. Repeated LP, acetazolamide, thiazide diuretics, and topiramate are used to reduce

CSF production. Weight reduction is helpful. Ventriculoperitoneal shunt insertion or optic nerve sheath fenestration to protect vision is sometimes necessary.

Low-CSF-volume (low-pressure) headache

Although most often seen following dural puncture, CSF leaks may occur spontaneously, leading to postural headache, worse on standing or sitting, and relieved completely by lying flat. The patient may give a history of vigorous Valsalva, straining, or coughing just prior to onset. Pachymeningeal enhancement may be seen on MRI but is not always present. LP is generally avoided for obvious reasons but may reveal low opening pressure. Conservative measures that are sometimes effective include bed rest, caffeine (intravenous or oral), and good hydration. The site of the leak is usually within the spine; thus treatment consists of injection of autologous blood into the spinal epidural space to seal the leak (a 'blood patch'), or occasionally surgical repair of the dural tear.

Post-traumatic headache

Pre-existing migraine may worsen following head injury. *De novo* headache sometimes follows a minor head injury but post-traumatic headache is an ill-defined entity. Improvement over a few weeks is the norm, but where litigation is ongoing, symptoms can persist for long periods. Subdural haematoma and low-pressure headache need to be considered as a possible cause.

Other secondary headache disorders

See **Box 28.23**. It is worth considering medical causes of headaches, including obstructive sleep apnoea (causing morning headaches), and ocular causes (posterior scleritis or subacute angle-closure glaucoma occasionally present as 'headache' rather than eye pain).

New onset, sudden headaches should always prompt consideration of the following emergencies which require immediate specialist investigation and management:

- Subarachnoid haemorrhage (Chapter 11, 'Subarachnoid haemorrhage' section)—classically a 'thunderclap' onset
- Meningitis (Chapter 11, 'Meningitis' section)—when associated with vomiting, rash, and sepsis
- Intracerebral haemorrhage (Chapter 29, 'Intracerebral haemorrhage' section)—when associated with sudden onset focal neurological signs
- Cervical artery dissection (Chapter 29, 'Carotid and vertebral artery dissection' section)—classically causes neck pain radiating upwards; there may be a Horner's syndrome or other focal neurological signs
- GCA (Chapter 32, 'Giant cell arteritis' section)—when associated with scalp tenderness, visual loss, and raised inflammatory markers.

Facial pain

The face has many pain-sensitive structures: teeth, gums, sinuses, temporomandibular joints, jaw, and eyes. Dental causes are common and should always be considered. Facial pain is also caused by specific neurological conditions.

Trigeminal neuralgia

Trigeminal neuralgia typically starts in the sixth and seventh decades; hypertension is the main risk factor. Compression of the trigeminal nerve at or near the pons by an ectatic vascular loop is the usual cause. High-resolution MRI studies may demonstrate the vascular loop in contact with the nerve in a high proportion of cases. In younger patients, MS or a cerebellopontine angle tumour (acoustic schwannomas, meningiomas, epidermoids) is more likely to be the cause.

Clinical features

Paroxysms of knife-like or electric shock-like pain, lasting seconds, occur in the distribution of the Vth nerve. Pain tends to commence in the mandibular division (V_3) but may spread over time to involve the maxillary (V_2) and, occasionally, the ophthalmic divisions (V_1). Bilateral trigeminal neuralgia is rare (3%) and usually due to intrinsic brainstem pathology, such as demyelination. Episodes occur many times a day with a refractory period after each. They may be brought on by stimulation of one or more trigger zones in the face. Washing, shaving, a cold wind, and chewing are examples of trivial stimuli that provoke pain. The face may be screwed up in agony. Spontaneous remissions last months or years before (almost invariable) recurrence. There are no signs of Vth nerve dysfunction on examination.

Management

Carbamazepine (600–1200 mg daily) reduces the severity of attacks in the majority. Oxcarbazepine, lamotrigine and gabapentin are also used. If drugs fail or are not tolerated, a number of surgical options are available that, in general, are more effective than medical treatments. Percutaneous radiofrequency selective ablation of the trigeminal ganglion is performed as a day-case procedure; recurrence may occur after an average of 2 years. Microvascular decompression of the nerve in the posterior fossa has a high long-term success rate (approximately 90%).

Atypical facial pain

Facial pain differs from trigeminal neuralgia in quality and distribution, and trigger points are absent. The condition is probably heterogeneous in aetiology but is believed by some (on little evidence) to be a somatic manifestation of depression. Tricyclic antidepressants and drugs used in neuropathic pain are sometimes helpful.

Other causes of facial pain

Facial pain occurs in the trigeminal autonomic cephalgias (see above), occasionally in migraine and in carotid dissection.

Giant cell arteritis (temporal arteritis)

This is a granulomatous large-vessel arteritis seen almost exclusively in people over 50 with a poorly defined aetiology (see Chapter 32, 'Giant cell arteritis' section).

Clinical features

- ***Headache*.** This is almost invariable in GCA. Pain develops over inflamed superficial temporal and/or occipital arteries. Touching the skin over an inflamed vessel (e.g., when combing the hair) causes pain. Arterial pulsation is soon lost; the artery becomes hard, tortuous, and thickened. The scalp over inflamed vessels may become red. Rarely, gangrenous patches appear.
- ***Facial pain*.** Pain in the face, jaw, and mouth is caused by inflammation of facial, maxillary, and lingual branches of the external carotid artery in GCA. Pain is characteristically worse on eating (jaw claudication). Mouth opening and protruding the tongue become difficult. A painful, ischaemic tongue occurs rarely.
- ***Visual problems*.** Visual loss from arterial inflammation and occlusion occurs in 25% of untreated cases. Posterior ciliary artery occlusion causes anterior ischaemic optic neuropathy (AION) in three-quarters of these. The disc is swollen and pale; retinal branch vessels usually remain normal. The majority of cases of AION are non-arteritic but inflammatory markers must always

be checked and GCA considered; arteritic AION carries a worse prognosis. Other mechanisms of visual loss in GCA are central retinal artery occlusion (causing disc pallor and visible retinal ischaemia), cilioretinal artery occlusion, and posterior ischaemic optic neuropathy. All of these entities cause sudden monocular visual loss (partial or complete). Amaurosis fugax (see Chapter 29, 'Amaurosis fugax' section) may precede permanent blindness, and bilateral blindness may ensue, with the second eye being affected 1 to 2 weeks after the first.

Diagnosis and management

See Chapter 32 ('Giant cell arteritis' section).

EPILEPSY AND LOSS OF CONSCIOUSNESS

Epilepsy

An *epileptic seizure* can be defined as a sudden synchronous or excessive discharge of cerebral neurons causing symptoms or signs that are apparent either to the patient or to an observer. For example, a limited discharge affecting only part of the cortex may cause a subjective aura apparent only to the patient, or a generalized seizure may cause a convulsion witnessed by an observer of which the patient may be unaware. This definition excludes disorders such as migrainous aura that are more gradual in onset, and EEG discharges that do not have a clinical correlate.

The term *epilepsy* describes an ongoing liability to recurrent epileptic seizures. The emergency management of seizures is covered in Chapter 11.

Epidemiology

Epilepsy is common. Its population prevalence is 0.7% to 0.8% (higher in low and middle income countries). Approximately 500 000 people in the UK have epilepsy. The incidence of epilepsy is age-dependent; it is highest at the extremes of life, most cases starting before the age of 20 or after the age of 60. The cumulative incidence (lifetime risk) of epilepsy is over 3% and the lifetime risk of having a single seizure is 5%. The fact that the prevalence is much lower than the cumulative incidence in part reflects the fact that epilepsy often goes into remission.

Classification

The International League Against Epilepsy (ILAE) Commission on Classification and Terminology has published a classification system that allows for diagnosis at three levels (seizure types, epilepsy types, and epilepsy syndromes). It may not be possible in every case to make a diagnosis at all three levels, but accurate characterization of epilepsy allows for more effective intervention, helps with seizure risk management, and may identify an aetiology.

Classification of seizure types

Seizures are divided by clinical pattern into three main groups by seizure onset (**Box 28.26** and **Fig. 28.21**): ***generalized*** seizures, ***focal*** seizures, and ***unknown onset*** seizures.

- ***Generalized seizures*** arise at some point within and rapidly engage bilateral brain networks. They are usually associated with loss or impairment of consciousness (except in generalized myoclonic seizures). Generalized seizures may be:

Box 28.26 Classification of seizures

Generalized onset seizure	
Motor	**Non-motor (absence)**
Tonic–clonic Myoclonic Other: Clonic, tonic, atonic, myoclonic–tonic–clonic, myoclonic-atonic, epileptic spasms	Typical absence Atypical absence Other: Myoclonic, eyelid myoclonia with absence
Focal onset seizure	
Motor onset	**Non-motor onset**
Aware, impaired awareness (or unknown)	Aware, impaired awareness (or unknown)
Automatisms Clonic Hyperkinetic Myoclonic Tonic Other: Atonic, epileptic spasms	Autonomic Behaviour arrest (only if behaviour arrest throughout seizure) Cognitive Emotional Sensory
Focal to bilateral tonic–clonic	
Unknown onset seizure	
Motor	**Non-motor**
Tonic–clonic Epileptic spasms	Behaviour arrest

(Adapted from Fisher RS, Cross' JH, D'Souza C et al. Instruction manual for the ILAE 2017 operational classification of seizure types. Epilepsia *2017; 58:531-42. 'Fine print' seizure types mainly of interest to specialists are listed under 'other'.)*

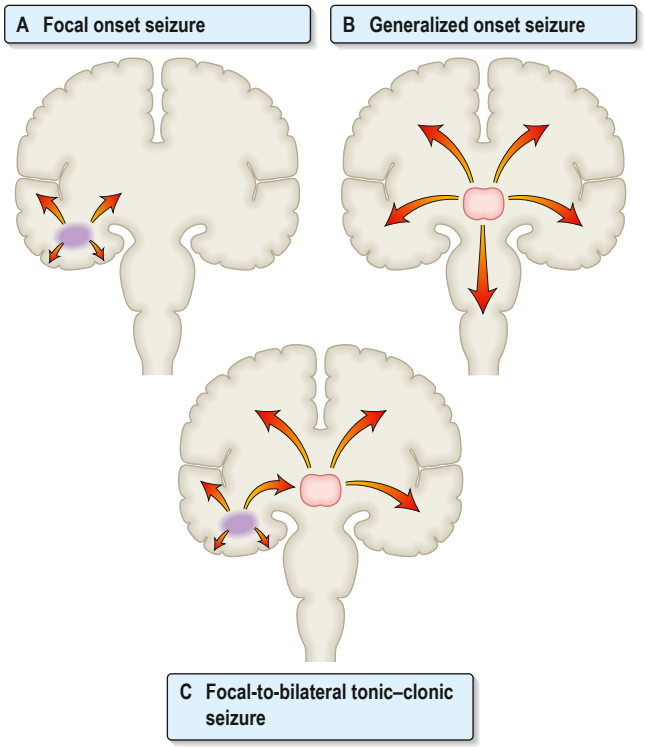

Fig. 28.21 Seizure types.

  - ***Motor***, for example generalized onset tonic-clonic seizure. The term 'generalized' is only used now when the seizure is reasonably believed to be generalized at onset (otherwise use the term 'bilateral tonic-clonic seizure')
  - ***Absences***
  - ***Generalized myoclonic seizures***
- A ***focal seizure*** is caused by electrical discharges originating in brain networks in one hemisphere. Focal seizures are further characterized based on:
  - ***Level of awareness*** (aware, impaired awareness, or unknown).
  - ***Motor or non-motor*** features at onset (automatisms, clonic movements, cognitive or emotional symptoms, etc). In general we are most interested in the features at onset as they correlate best (but not perfectly) with the onset zone of the epileptic activity. This can have implications for aetiological work-up and epilepsy surgery.
  - Where possible additional descriptors will be applied to clarify the nature of the cardinal features at onset, and subsequent features.
  - Laterality is important to identify.
  - A clinician may therefore describe a seizure, for example, as a '*focal impaired awareness autonomic seizure, with epigastric rising sensation, and right hand automatisms*'.
- ***Focal-to-bilateral tonic-clonic seizures*** were previously referred to as 'secondary generalized seizures'. These result from the spread of a focal onset seizure to involve both hemispheres. The patient may remember the initial focal seizure before losing consciousness, in which case this is called an ***aura***, and the focal onset can be inferred from the semiology; sometimes, however, the spread of electrical activity is so rapid that the patient does not experience any warning (in which case the onset will often be unknown).
- Many people will have ***unknown onset bilateral tonic-clonic seizures***, at least initially, before further information clarifies the situation. A useful rule of thumb is that seizures that occur upon waking, or in the morning, are more likely to be generalized onset seizures while most seizures arising from deep sleep (2–3 a.m.) will prove to be focal onset seizures.

Generalized seizure types

Typical absence seizures ('petit mal')

Epilepsy causing absences almost invariably begins in childhood. There is loss of awareness and a vacant expression for less than 10 seconds before returning abruptly to normal and continuing as though nothing had happened. Apart from slight fluttering of the eyelids, there are no motor manifestations. Each attack is accompanied by 3 Hz spike-and-wave EEG activity (see Fig. 28.19). Patients often do not realize they have had an attack but may have many per day; they may be identified as 'daydreaming' in class. Children with absence seizures may go on to develop generalized tonic-clonic seizures. Absences are never due to acquired lesions such as tumours; they are a manifestation of generalized epilepsies (typical absences are associated with the genetic generalized epilepsies [GGEs]). It is a common mistake to refer elderly patients having vacant spells as suspected new-onset absences: if these are seizures, they will be focal onset impaired awareness seizures (often arising from the temporal lobe).

Generalized onset tonic–clonic seizures ('grand mal')

Prodrome. There is no warning before generalized onset tonic–clonic seizures. When an aura is described, consider a *focal to bilateral tonic–clonic* seizure.

Tonic–clonic phase. An initial tonic stiffening is followed by the clonic phase with synchronous jerking of the limbs, reducing in frequency over about 2 minutes until the convulsion stops. The patient may utter an initial cry and then falls, sometimes suffering serious injury. The eyes remain open and the tongue is often bitten. There may be incontinence of urine or faeces.

Post-ictal phase. A period of flaccid unresponsiveness is followed by gradual return of awareness with confusion and drowsiness lasting 15 minutes to an hour or longer. Headache is common after a tonic-clonic seizure.

Myoclonic, tonic, and atonic seizures

Myoclonic seizures or 'jerks' take the form of momentary brief contractions of a muscle or muscle groups: for example, causing a sudden involuntary twitch of a finger or hand. They are common in GGEs. ***Tonic seizures*** consist of stiffening of the body with loss of consciousness, not followed by jerking. ***Atonic seizures*** involve a sudden collapse with loss of muscle tone and consciousness.

Focal seizure types

Focal aware seizures

These used to be called simple partial seizures. Awareness must be fully retained throughout, and the patient remembers the entire event (which could consist of motor phenomena such as focal clonic or myoclonic movements, or non-motor features such as spreading sensory disturbance).

Focal impaired awareness seizures

These usually arise from the temporal lobe (60%) or the frontal lobe. There is often a preceding aura followed by a period of complete or partial loss of awareness of surroundings, lasting for 1 to 2 minutes on average (as opposed to 10 seconds in absence seizures), which the patient generally does not remember subsequently. If awareness is impaired at any point, it is termed a focal impaired awareness seizure. The attack may be followed by a short period of post-ictal confusion or may develop into a *bilateral tonic–clonic* seizure.

Focal non-motor seizures

The nature of the initial symptoms helps to localize the seizure focus. Temporal lobe non-motor auras include cognitive symptoms such as déjà vu or jamais vu; emotional features such as fear (may be mistaken for panic attacks); sensory aura with olfactory, gustatory, or auditory hallucinations or vertigo; and autonomic symptoms such as abdominal rising sensation or nausea. Occipital lobe auras include visual phenomena such as zigzag lines and coloured scotomas. Some auras are vague or hard for patients to describe but they are generally stereotyped: that is, the same on each occasion.

Focal motor seizures

Motor phenomena include simple clonic movements, which often originate within the motor cortex. Jerking typically begins on one side of the mouth or in one hand, sometimes spreading to involve the entire side. This visible spread of activity is called the ***Jacksonian march*** of a seizure, and correlates with spread of seizure activity along the motor homunculus. Local temporary paralysis of the limbs affected sometimes follows: ***Todd's paralysis***. Automatisms are common in temporal lobe seizures. These are semi-purposeful stereotyped motions such as lip-smacking, fidgeting, or picking motions, or more complex motor behaviours such as walking in a

circle or undressing. Tonic posturing and the direction of any head turn are very important to note: frontal lobe seizures may cause early forced head and eye version away from the site of seizure onset, and involvement of the supplementary motor area results in asymmetrical tonic posturing of the limbs ('figure of 4' or 'fencing' posture) with extension of the contralateral arm. Unusual hyperkinetic seizures may appear bizarre (e.g., bicycling movements) but can arise from the frontal lobes.

Many focal seizures will have a combination of motor and non-motor features. For instance a mesial temporal lobe seizure may cause déjà vu and an epigastric rising sensation, followed by behavioural arrest, automatisms, and impaired awareness.

Epilepsia partialis continua

This refers to continuous focal jerking with retained awareness that continues for long periods of time (at least an hour, but frequently for days and sometimes even years). It usually arises from contralateral motor cortex, and the face and hand are most commonly involved. The affected limb will often be weak (a Todd's paresis) and there is a high chance of finding a structural cause.

Classification of epilepsy type

Once a seizure type has been identified, a decision needs to be made about whether there is an ongoing liability to seizures (by definition epilepsy), or whether the seizure risk was transient. This can be the case either with a first seizure (see below), as 50% of people with a first seizure will not go on to have another one, or if the patient has had *acute symptomatic seizures*, secondary to an acute event which may or may not lead to long-term epilepsy. If epilepsy is diagnosed, classifying the epilepsy type is usually simple:

- ***Generalized epilepsy***, where all the seizures originate at some point within, or rapidly engage, bilateral brain networks. The structures involved can be subcortical or cortical.
- ***Focal epilepsy***, where all the seizures are believed to arise from networks within one hemisphere. Evidence for this may be clinical (based on seizure semiology) or from EEG findings.
- ***Generalized and focal epilepsy*****.** Several severe childhood-onset epilepsy syndromes, such as Dravet and Lennox-Gastaut syndrome, that lead to multiple seizure types, can cause a mix of generalized and focal seizures.
- ***Unknown.***

Aetiology of epilepsy, and epilepsy syndromes

A precise epilepsy syndrome can only be identified for a subset of patients, but in all cases it is worth thinking about aetiology of epilepsy. Six aetiological categories are recognized in the ILAE classification (**Box 28.27**).

The range of causes of epilepsy is different at different ages and in different countries.

- ***Children and teenagers:*** genetic, perinatal structural, and metabolic disorders predominate
- ***Adults:*** hippocampal sclerosis is one of the most important causes of epilepsy; TBI is common in a younger adult population
- ***Internationally***, infections are the most common cause of epilepsy, in particular neurocysticercosis which accounts for 30% of cases of epilepsy in endemic areas
- ***Older ages (>60 years):*** vascular disease, dementia, and mass lesions such as neoplasms are important.

It is often necessary to distinguish between the cause of a seizure, and the aetiology of epilepsy. Virtually any insult to the brain can provoke a seizure (as opposed to causing an ongoing liability to seizures, or epilepsy).

? Box 28.27 Causes of epilepsy

- Genetic
  - Brain channelopathies (e.g., Dravet syndrome)
  - Genetic generalized epilepsies, e.g., juvenile myoclonic epilepsy
- Structural
  - Hippocampal sclerosis
  - Traumatic brain injury, brain surgery
  - Birth trauma
  - Developmental, e.g., neuronal migration abnormalities, cortical dysplasia
  - Intracranial mass lesions, e.g., tumour
  - Vascular, e.g., cerebral infarction, arteriovenous malformation, venous sinus thrombosis
  - Neurodegenerative disorders, e.g., Alzheimer's
- Metabolic
  - Leigh syndrome (mitochondrial disease)
  - Glucose transporter deficiency
  - Chronic alcohol use (note that a single episode of alcohol withdrawal is a cause of *seizures* but not of *epilepsy*)
- Infectious
  - Viral encephalitis
  - Cerebral tuberculosis
  - HIV
  - Neurocysticercosis
- Immune
  - NMDA receptor antibody
  - LGI-1 antibody-associated limbic encephalitis
- Unknown
  - One-third of all cases are of unknown aetiology

Epilepsy syndrome

An epilepsy syndrome can be assigned in a proportion of cases, where the seizure types and associated features, plus often characteristic EEG and/or imaging abnormalities, form part of a recognizable, distinct seizure disorder (e.g., juvenile myoclonic epilepsy, mesial temporal lobe epilepsy with hippocampal sclerosis). These often have prognostic, aetiological, or treatment implications. Some epilepsy syndromes have a single identifiable cause (e.g., Dravet syndrome, caused by variants in the *SCN1A* gene) while others will be a manifestation of multiple causes (e.g., Lennox-Gastaut syndrome, with multiple seizure types from early childhood, can be caused by various structural brain abnormalities or presumed genetic aetiologies). Many people with epilepsy, especially those with focal epilepsy with onset in adulthood, will not fall into a well-defined epilepsy syndrome.

Aetiology of generalized epilepsy

Presenting in childhood and early adult life, genetic generalized epilepsies (GGEs), account for up to 20% of all patients with epilepsy. The cause is thought to be polygenic with complex inheritance. This does not always mean that these epilepsies will run in the family, and so the term 'idiopathic generalized epilepsy' is often used synonymously with GGE. The brain is structurally normal but abnormalities of ion channels influencing neuronal firing, abnormalities of neurotransmitter release, and synaptic connections are probably the underlying molecular pathological substrates. They include:

- ***Childhood absence epilepsy:*** absence seizures. Spontaneous remission by age 18 is usual.

- ***Juvenile myoclonic epilepsy*** (JME; Box 28.28): this accounts for 10% of all epilepsy patients. Typically, myoclonic jerks start in the teenage years (and are usually ignored by the patient; ask about jerks when taking an epilepsy history), followed by generalized tonic–clonic seizures that bring the patient to medical attention. One-third of patients also have absences. Seizures and jerks often occur in the morning after waking. Lack of sleep, alcohol, and strobe or flickering lights are seizure triggers in JME. JME usually responds reasonably well to treatment, is associated with characteristic EEG abnormalities (3–6 Hz generalized polyspike and wave discharges), and requires life-long treatment.

Aetiology of focal seizures and focal epilepsy

Almost any process disrupting the cortical grey matter can cause acute symptomatic seizures, or go on to cause epilepsy. Seizures arise from the affected area of cortex, with or without *bilateral tonic–clonic* seizures (these may obscure the focal onset). A focal seizure onset often indicates a structural cause and detailed imaging is required to identify this. In general, the response to treatment is less good than with GGE.

Genetic

Many single-gene epilepsy disorders are due to mutations of voltage- or ligand-gated neuronal ion channels (channelopathies). Autosomal dominant nocturnal frontal lobe epilepsy is a familial disorder causing brief nocturnal frontal lobe seizures, often with onset in childhood. In a minority of cases, it is caused by variants in different subunits in the neuronal nicotinic acetylcholine receptor gene. However, monogenic epilepsy syndromes are relatively uncommon in clinical practice, especially compared to some other fields of neurology. Over 200 multisystemic genetic disorders, such as tuberous sclerosis and mitochondrial cytopathies, include epilepsy among their core features.

Structural

Hippocampal sclerosis. Hippocampal sclerosis (damage with scarring and atrophy of the hippocampus and surrounding cortex) is the main pathological substrate causing temporal lobe epilepsy and the leading cause of focal epilepsy in adults. Childhood febrile convulsions are the main risk factor. Hippocampal sclerosis is usually visible on MRI. Seizures can be quite refractory to treatment, in which case surgical resection of the damaged temporal lobe may be an option.

Traumatic brain injury. This may cause epilepsy, sometimes years after the event. The risk is not increased after mild injury (loss of consciousness or post-traumatic amnesia [PTA] <30 min). Depressed skull fracture, penetrating injury, and intracranial haemorrhage increase risk significantly. Early post-traumatic seizures (in the first week) are common and not necessarily indicative of long-term epilepsy risk.

Brain surgery. This is followed by seizures in up to 17% of cases. Prophylactic anticonvulsant use after surgery is not recommended.

Perinatal brain injury and cerebral palsy. Periventricular leukomalacia and brain haemorrhage associated with prematurity and fetal hypoxia, may cause early-onset epilepsy. One-third of children with cerebral palsy have epilepsy.

Developmental disorders. Neuronal migration defects during brain development, dysplastic areas of cerebral cortex, and hamartomas contribute to seizures in both infancy and adult life.

Brain tumours and other mass lesions. Mass lesions involving the cortex cause epilepsy. Seizures are one of the most common presenting features of brain tumours. Brain tumours cause 6% of cases of adult-onset epilepsy.

Vascular disorders. Stroke and small-vessel cerebrovascular disease is the most common cause of epilepsy after the age of 60. Cortical venous thrombosis or venous sinus thrombosis will often lead to epilepsy. Cavernous haemangiomas (cavernomas) usually present with epilepsy (Fig. 28.22); other vascular malformations (such as arteriovenous malformations [AVMs]) can also cause seizures.

Posterior reversible encephalopathy syndrome. This syndrome is caused by rapid rises in blood pressure and is characterized by the acute onset of headache, visual disturbance, altered mental status, and seizures. It may be seen in eclampsia, renal disease, autoimmune diseases (e.g., systemic lupus erythematosus [SLE]), or as a side-effect of certain medications. White matter changes are seen on CNS imaging, primarily affecting the occipital lobes; management is of hypertension and the underlying disorder; often carried out in a critical care environment. It is unusual for posterior reversible encephalopathy syndrome (PRES) to lead to chronic epilepsy although occasionally long-term sequelae are seen.

Neurodegenerative disorders involving the cerebral cortex, such as Alzheimer's disease, are associated with an increased risk of epilepsy.

Metabolic disorders

Genetic metabolic disorders, such as mitochondrial Leigh syndrome, or glucose transporter deficiency, can cause epilepsy. Transient metabolic abnormalities (hyponatraemia, hypoglycaemia, uraemia) mostly cause acute symptomatic seizures rather than epilepsy, but if severe or persistent enough to cause a brain injury, epilepsy may

Box 28.28 Juvenile myoclonic epilepsy

- 10% of all epilepsy patients
- Starts in teenage years
- Clinical features:
  - Myoclonic jerks
  - Generalized tonic–clonic seizures
  - Absences in one-third
  - Triggers: sleep deprivation, alcohol, strobe lighting
- Abnormal EEG
- Good response to treatment
- Requires life-long treatment

Fig. 28.22 Magnetic resonance T2-weighted image: frontal cavernoma *(arrowed)*.

ensue. Chronic alcohol use is a common cause of epilepsy. Alcohol withdrawal itself will cause acute symptomatic seizures, but over a long period of time, chronic alcohol use or repeated withdrawals will predispose to epilepsy and an ongoing seizure risk. Alcohol-induced hypoglycaemia and head injury also lead to seizures.

Infection

Seizures are often the presenting feature of encephalitis, cerebral abscess, and tuberculomas. They also occur in chronic meningitis (e.g., tuberculosis) and may rarely be the first sign of acute bacterial meningitis. Neurocysticercosis is a major cause of seizures in countries where the pork tapeworm is endemic, such as India and South America, where it causes up to 30% of all cases of epilepsy. HIV and complications of immunosuppression, such as cerebral toxoplasmosis, may also lead to seizures.

Immunological disorders

Autoimmune antibody-mediated encephalitis, such as that due to antibodies against potassium channels or NMDA or glycine receptors, typically presents with seizures, as may paraneoplastic limbic encephalitis (PLE).

Aetiology of (combined) generalized and focal epilepsy

Epilepsy caused by diffuse structural, genetic, or metabolic aetiologies can sometimes cause a mixture of generalized and focal seizures. These include some childhood-onset severe epilepsy syndromes.

Dravet syndrome, also known as severe myoclonic epilepsy of infancy, is one of the more common single-gene epilepsy disorders. It is a *channelopathy* caused by variants in the sodium channel gene, *SCN1A*; it presents in the first year of life with a mixture of generalized and focal onset seizures. The seizures are intractable and an *epileptic encephalopathy* develops, with cognitive and behavioural regression occurring partly as a result of the seizures themselves.

Lennox-Gastaut syndrome is another epileptic encephalopathy, with multiple causes, resulting in multiple seizure types (but particularly tonic seizures in sleep), cognitive decline and diffuse slow spike-and-wave and paroxysms of fast activity on EEG.

Diagnosis of the first fit and investigations

The diagnosis of a seizure is essentially a clinical one, based on taking a history from the patient and any witnesses (**Boxes 28.29 and 28.30**). It is a sad fact that seizures that happen in hospital are usually the most poorly described. It is useful for any witnesses (including healthcare professionals) to make a note of exactly what they saw, in plain language (avoid terms such as 'GTCS'). The usefulness of a video recording cannot be over-emphasized but the patient must have given consent for this in advance. Investigations have a limited role in distinguishing between a seizure and other causes of a blackout or attack (see Chapter 11, 'Dizziness and blackouts' section).

The majority of patients referred to a first fit clinic have not had a seizure. The most common error is to misdiagnose a syncopal blackout for a seizure.

Which investigations are needed?

Basic investigations in patients presenting with seizures (**Box 28.31**) are covered in Chapter 11.

Electroencephalography

EEG is most useful to categorize epilepsy and understand its cause, rather than as a means of confirming a doubtful diagnosis

Box 28.29 Diagnosis of a seizure: taking a history after an episode of loss of consciousness

Witness account is crucial.

- What happened:
  - Before
    - Aura—unusual sensations, taste or smell; rising sensation in the stomach; déjà vu or jamais vu; strong emotion
    - Pre-syncopal prodrome—feeling lightheaded, hot, black spots in the vision
  - During
    - Change in muscle tone (floppy/stiff)
    - Turn of the head or forced limb posture
    - Confusion/vacant appearance/loss of consciousness
    - Change in breathing pattern
    - Change in facial colour—pallor (syncope) or cyanosis (seizure)
    - Eyes open or closed; gaze deviation
    - Abnormal movements. Jerking/twitching/tremor/flailing. Both sides of the body or just one? Did it start in one place and travel? Were the movements rhythmical, and synchronous?
    - Automatisms (fiddling, picking, grimacing/lip-smacking)
    - Vocalizations
    - Incontinence
    - Tongue-biting (which part of the tongue, how severe?)
    - Duration of seizure
  - After
    - Post-ictal confusion and sleepiness
    - Rapid recovery in syncope
- Circumstances
  - Sleep (what time of night)/wakefulness
  - Position (lying/standing)
  - Seizure triggers? Sleep deprivation, alcohol binge, or drugs
  - Syncope triggers? Pain, heat, prolonged standing
- Epilepsy risk factors?
  - Childhood febrile convulsions
  - Significant head injury
  - Meningitis or encephalitis
  - Family history of epilepsy
- Previous unrecognized seizures?
  - Myoclonic jerks
  - Absences
  - Auras (focal seizures)
- Alcohol excess?
- Medication lowering seizure threshold?
- Hold a driving licence?

Box 28.30 Useful points when diagnosing epilepsy

- ***Diagnosis is a clinical one.*** Tests such as EEG have only a limited role in distinguishing between epilepsy and other attack types (unless an event is captured during the recording).
- ***Poor clinical discriminators between types of blackout:***
  - Urinary incontinence—may occur in both seizure and syncope
  - Injuries—may occur in both seizure and syncope (but less common in dissociative seizures)
- ***Good discriminators between types of blackout:***
  - Prolonged recovery period (seizure)—what is the first thing they remember after the seizure? If they woke up in hospital or with the paramedics around them often that indicates a prolonged recovery.
  - Bitten tongue—side of tongue usually (seizure); biting of the tip of the tongue is less specific
  - Colour change—pallor (syncope), cyanosis (seizure)
- ***Stereotyped attacks are usually due to epilepsy***

of epilepsy. EEG has a high false-negative rate in epilepsy (20%–40% even with provocation measures and awake and sleep recordings) and a low false-positive rate (1% of people without epilepsy have true epileptiform changes on EEG; however, other nonspecific abnormalities are common and should not be overinterpreted).

- ***EEG abnormalities in epilepsy:*** focal cortical spikes (e.g., over a temporal lobe) or generalized spike-and-wave activity (in GGE). Epileptic activity is continuous in status epilepticus.
- ***Sleep recordings or 24-hour ambulatory EEG*** increase sensitivity when routine EEG is normal.
- ***Continuous EEG videotelemetry*** is helpful for diagnosis in attacks of uncertain cause.

Brain imaging

MRI is indicated in most patients after a first seizure, particularly in focal-onset seizures and in older patients where the chance of a focal brain lesion is greatest. In patients below the age of 30 with a definite electroclinical diagnosis of GGE, brain imaging is not essential.

Box 28.31 Checklist after a first seizure

- Perform tests:
  - Blood tests and ECG
  - EEG
  - CT +/– MRI brain (most patients—see text)
- Avoid or remove precipitants: drugs, alcohol, sleep deprivation
- Give advice on safety: for example, avoid swimming, baths, working at heights
- Stop driving and ask the patient to inform the Driver and Vehicle Licensing Authority (DVLA; in the UK)
- Discuss recurrence risk and treatment

Recurrence risk after a first fit

About one-third of people will have a second seizure within 5 years. The risk of seizure recurrence is significantly increased by features of GGE on EEG, abnormal neurological examination, a first seizure that occurs in sleep, and the presence of structural brain lesions.

Diagnosing epilepsy

Epilepsy is diagnosed when:

- At least two unprovoked seizures occur, more than 24 hours apart
- Only one unprovoked seizure has occurred, but the risk of recurrence is similar to the risk after two seizures (suggested to be ≥60%). This will be the case when there is an established structural brain abnormality (e.g., an old stroke), or when the EEG shows clear epileptiform features.

Management

Acute management

The acute management of seizures, including ongoing continuous seizure activity (status epilepticus) is covered in Chapter 11.

Anti-seizure medications

Anti-seizure medications (ASMs; **Box 28.32**) are indicated when there is a firm clinical diagnosis of epilepsy and a substantial risk of recurrent seizures. Some general principles apply:

- Introduce ASMs at low dose and slowly titrate upwards until the seizures are controlled or side-effects become unacceptable. In emergency settings, rapid loading and faster titration may be appropriate.
- Aim for monotherapy; 70% of patients will have good seizure control with a single AED.

Box 28.32 Antiepileptic drugs and common seizure types

	Generalized epilepsy, with primarily GTCS	Focal epilepsy	Myoclonic seizures	Absence seizures
First-line	**Sodium valproate**[a] **Lamotrigine**[b] Levetiracetam	**Lamotrigine**[b] Levetiracetam Oxcarbazepine Carbamazepine	Sodium valproate[a] Levetiracetam	Ethosuximide Sodium valproate[a] Lamotrigine[b]
Second line and/or add-ons	Zonisamide Lacosamide Topiramate Perampanel Brivaracetam Clobazam Clonazepam Phenobarbital Primidone Phenytoin[c]	Lacosamide Zonisamide Topiramate Sodium valproate[a] Eslicarbazepine Clobazam Brivaracetam Cenobamate Perampanel Gabapentin Pregabalin Tiagabine Vigabatrin Phenobarbital Phenytoin[c]	Brivaracetam Topiramate Clonazepam Clobazam Lamotrigine[b] Piracetam Phenobarbital Lacosamide	Levetiracetam
May worsen attacks			Carbamazepine Ox/Eslicarbazepine Gabapentin Phenytoin[c] Vigabatrin Tiagabine	Carbamazepine Ox/Eslicarbazepine Phenytoin[c] Vigabatrin Tiagabine

[a]Sodium valproate should be avoided in women of childbearing age.
[b]Lamotrigine can also occasionally worsen myoclonic seizures, but nonetheless it is often used first-line for juvenile myoclonic epilepsy, especially in women of childbearing age.
[c]Phenytoin can be used for generalized epilepsies but sometimes has the potential to worsen generalized-onset seizure types.

- If seizures are not controlled with the first ASM, gradually introduce a second agent and then slowly withdraw the first ASM. If the patient is still not seizure-free, then combination therapy is required.
- Epilepsy is one of the few disorders where non-generic ('brand name') prescribing is justified to ensure consistent drug levels.
- Routine monitoring of ASM levels is not needed and should be reserved for assessing compliance and toxicity.
- Many of the older ASMs are enzyme inducers and will interact with many other medications, and with each other (phenytoin, phenobarbital, carbamazepine). Sodium valproate is a potent hepatic enzyme inhibitor. It particularly increases drug levels of lamotrigine, so if sodium valproate is added to lamotrigine caution must be taken to avoid toxicity. Carbapenem antibiotics interact with sodium valproate, profoundly lowering serum levels of valproate. New-generation ASMs have fewer interactions.
- Phenytoin is no longer considered a first-line ASM; it is now principally used in emergency control of seizures (see status epilepticus, Chapter 11, 'Status epilepticus' section)
- There is high-quality evidence from the Standard and New Antiepileptic Drugs (SANAD) trials to suggest that lamotrigine should be the first-line drug of choice in patients with focal epilepsy. The disadvantage of lamotrigine is that it must be titrated up slowly, or the risk of Stevens–Johnson syndrome increases.
- Sodium valproate was shown to be most effective in generalized epilepsies but should be avoided in women of childbearing age, for whom lamotrigine is the better choice. In children born to women taking valproate in pregnancy, around 10% develop birth defects, and up to 40% will have problems with learning or development. There are also now emerging concerns about the use of sodium valproate in men who may conceive children, although the evidence is limited and practice internationally remains variable.
- Levetiracetam is increasingly used in most types of epilepsy, and has advantages when rapid titration is desired, but it is not as free of side-effects as many clinicians believe (primarily effects on mood and occasionally psychosis).

Unwanted effects of drugs

Intoxication with most ASM causes unsteadiness, nystagmus, and drowsiness. For some agents, drug intoxication can provoke more seizures. Side-effects are more common with multiple ASM usage. Skin rashes are seen particularly with lamotrigine, carbamazepine, and phenytoin; Stevens–Johnson syndrome may occur, and patients must be counselled about this. A wide variety of idiosyncratic drug reactions may occur, such as blood dyscrasias or hyponatraemia with carbamazepine.

Epilepsy and driving

Patients should be asked to stop driving after a seizure and to inform the regulatory authorities if they hold a driving licence. After a seizure, a temporary driving ban until seizure-free is usual but regulations vary from country to country. Many driving regulatory bodies also suggest refraining from driving while withdrawing from AEDs.

Lifestyle and safety

People with epilepsy should be encouraged to lead lives as unrestricted as reasonably possible, though observing simple safety measures such as avoiding swimming and dangerous sports like rock climbing. Advice at home includes leaving bathroom and lavatory doors unlocked and taking showers rather than baths. Epilepsy triggers, such as sleep deprivation, excess alcohol, and drugs, should be avoided, as should strobe lighting where there is EEG evidence of a photo-paroxysmal response (seen in a minority of patients).

Drug withdrawal

Withdrawal of ASMs should be considered after a seizure-free period of at least 2 to 3 years, depending on the aetiology of epilepsy (and many recommend 5 years of seizure-freedom). There is a 50% seizure recurrence rate after withdrawal, so detailed discussion and explanation are essential.

Refractory epilepsy

- Seizures may persist despite treatment, especially with temporal lobe epilepsy. About 20% to 40% of patients with epilepsy will be treatment-refractory.
- Re-evaluate the diagnosis.
- Consider concordance.
- Combine ASMs and use the maximum tolerated dose.
- Refer to a specialist unit for consideration of epilepsy surgery.
- Other non-pharmacological treatments, such as vagal nerve stimulation and the ketogenic low-carbohydrate diet, may sometimes be useful.

Epilepsy surgery

Anterior temporal lobectomy will result in seizure freedom in 50% to 70% of selected patients with uncontrolled seizures caused by hippocampal sclerosis (defined by imaging and confirmed by EEG). Other patients with refractory focal epilepsy in whom a localized seizure onset zone can be identified can be considered for epilepsy surgery.

Other causes of blackouts

The distinction between a fit (seizure), a faint (syncope), a dissociative (non-epileptic) attack, or another type of 'funny turn' is primarily a clinical one, dependent on the history and an eyewitness account (**Boxes 28.29, 28.30, and 28.33**).

Syncope

Syncope is discussed in detail in Chapter 11.

Dissociative (non-epileptic) attacks

These are functional (or 'dissociative') seizure-like attacks that are not caused by abnormal electrical activity in the brain. They are a common problem in clinical practice, and can be difficult to diagnose and manage. Many patients are misdiagnosed with epilepsy. While in an emergency setting, it is safer to err on the side of treating as epilepsy if there is doubt or if there is no established diagnosis, over time patients are exposed to significant iatrogenic risks unless they are given an accurate diagnosis. Moreover, a long delay to diagnosis prevents access to the right treatments and confers a substantially worse prognosis.

Multiple terms are currently used, including non-epileptic attack disorder (NEAD; this is acceptable but defines the condition by what it is not, and as such can leave the patient with the impression that they have not been given a diagnosis). However, outdated and judgement-laden terms such as 'pseudoseizures' and 'hysterical seizures' should be avoided. Dissociative attacks are not consciously produced or 'faked', and it is vital that this is understood by the medical team and explained to the patient.

Box 28.33 Causes of blackouts and 'funny turns'

- Epilepsy
- Syncope:
  - Neurocardiogenic syncope (vasovagal)
  - Cardiac syncope (Stokes–Adams attacks)
  - Micturition syncope
  - Cough syncope
  - Postural hypotension
  - Carotid sinus syncope
- Non-epileptic attacks (dissociative seizures)
- Panic attacks and hyperventilation
- Hypoglycaemia
- Hydrocephalic attacks
- Basilar migraine
- Severe vertigo (e.g., Ménière's disease)
- Cataplexy, narcolepsy, sleep paralysis

The gold standard for diagnosis of non-epileptic attacks is a video-EEG recording, capturing a habitual attack and demonstrating that it is not accompanied by electrographic seizure activity. This may not be practically possible, especially as attacks can be infrequent, in which case an expert review of a video recording has reasonable diagnostic accuracy. There is no single reliable diagnostic feature to differentiate between epileptic and dissociative attacks, and some focal seizures such as those arising from the frontal lobe have very unusual features that can be a trap for the unwary.

Epileptic seizures however fall into a limited range of semiologies, and it is deviation from this pattern that raises the suspicion of dissociative attacks. Some indicators of a dissociative seizure include: a gradual onset with a waxing and waning course; eyes tightly closed; asynchronous bilateral limb movements; side-to-side head movements or pelvic thrusting; violent flailing movements of the limbs; swift recovery; subsequent recall for a period of unresponsiveness. Urinary incontinence and biting of the tip of the tongue (but less commonly severe biting involving the sides of the tongue) can be seen in NEAD (**Box 28.33**). Dissociative attacks are often more prolonged than epileptic seizure but this fact should not prevent the treatment of *status epilepticus* unless there is a high level of certainty around the diagnosis.

Skilful explanation of the diagnosis can be of significant therapeutic benefit. Dissociative attacks are events where the brain 'shuts down' or 'reboots', usually in response to being overwhelmed. Often the trigger, which can be emotional or physical (e.g., pain), may be difficult to identify; however, the brain can develop an automatic subconscious response over time where it goes into a dissociative state. Psychiatric co-morbidity may or may not be present, but where it coexists with NEAD it should be treated. Psychological therapies including cognitive behavioural therapy and mindfulness techniques such as grounding, and relaxation can be useful tools to treat dissociative attacks. There is further discussion of functional neurological disorders in the Acute medicine (Chapter 11) and Psychiatry (Chapter 30) chapters.

Sleep disorders

Myoclonic jerks when falling asleep are a normal phenomenon. Seizures may occur predominantly or solely during sleep.

Narcolepsy and cataplexy

Narcolepsy is caused by abnormalities of the brain neurotransmitter hypocretin (orexin), which is a regulator of sleep. CSF levels are usually low, thought in most cases to be due to autoimmune damage to the hypothalamic cells secreting the neurotransmitter. Narcolepsy is strongly associated with human leucocyte antigen (HLA)-DR2 and HLA-DQBl*0602 antigens. The prevalence is estimated at 30 to 50/100 000.

There are four main clinical features but not all patients have the full tetrad:

- ***Excessive daytime sleepiness (EDS).*** This is the usual presenting symptom and the main cause of disability. Patients have frequent irresistible sleep attacks during the day, often in inappropriate circumstances, for example during meals or conversations or while driving. EDS may be quantified with the Epworth Sleepiness Scale. Night-time sleep may be disrupted and, paradoxically, insomnia may occur.
- ***Cataplexy.*** This is sudden loss of muscle tone leading to head droop or even falling with intact awareness. Attacks are often set off by sudden surprise or emotion, for example laughter.
- ***Hypnagogic/hypnopompic hallucinations.*** These terms refer to dream-like hallucinations occurring while falling asleep or waking from sleep; these are often frightening.
- ***Sleep paralysis.*** A brief paralysis on waking or while falling asleep is due to intrusion of rapid eye movement (REM) atonia into wakefulness. This occasionally occurs in people without narcolepsy.

Diagnosis and management

Multiple sleep latency testing demonstrating a rapid transition from wakefulness to sleep and a short time to onset of REM sleep confirms the diagnosis.

Good sleep hygiene advice is necessary. Modafinil, dexamfetamine, and methylphenidate are used to treat EDS, often with only partial response. Antidepressants, particularly venlafaxine and clomipramine, can improve cataplexy. Sodium oxybate is also used and has effects against both narcolepsy and cataplexy.

Parasomnias

Disruptive motor or verbal behaviours occurring during sleep are divided into REM and non-REM parasomnias, depending on which stage of sleep they arise in. Non-REM parasomnias include sleepwalking, night terrors, and confusional arousals. REM parasomnias include recurrent isolated sleep paralysis (intrusion of REM-atonia into wakefulness) and REM sleep behaviour disorder (RBD), in which the mechanisms of REM sleep atonia fail and so dreams are enacted. RBD may be an early feature of Parkinson's disease.

Obstructive sleep apnoea

See Chapter 20 ('Obstructive sleep apnoea' section).

Restless leg syndrome (Willis–Ekbom disease)

Also known as Wittmaack–Ekbom's syndrome, this affects about 10% of adults, both women and men, and is also seen in children. Most people do not seek medical advice but it can be quite severe in 2% to 3%. The syndrome is characterized by an unpleasant sensation of 'wanting to move' the legs with throbbing or pulling, and usually occurs when the person is resting; it can be totally or partially relieved by stretching or walking. It occurs in the evenings or nighttime and appears to be more frequent in the elderly. The condition is usually idiopathic and there is a familial tendency. Low iron stores are a frequent association, and iron replacement can be very helpful. It has also been associated with pregnancy, neuropathy, spinal cord disease, and uraemia. Some drugs have been implicated.

For moderate to severe restless legs syndrome, gabapentin or pregabalin are now considered first-line, ahead of dopamine agonists. Some suggest a decreased use of alcohol or caffeine.

MOVEMENT DISORDERS

Disorders of movement are divided broadly into two categories:

- ***hypokinetic***—characterized by slowed movements with increased tone (parkinsonism)
- ***hyperkinetic***—excessive involuntary movements.

Both types may coexist; for example, in Parkinson's disease, where there are both slowed movements and tremor. Many of these disorders (not all) relate to dysfunction of the basal ganglia.

Parkinsonian disorders

Idiopathic Parkinson's disease

In 1817, James Parkinson, a physician in Hoxton, London, published *The Shaking Palsy*, describing this common worldwide condition that has a prevalence of 1/1000. Parkinson's disease (PD) is clinically and pathologically distinct from other parkinsonian syndromes.

Aetiology

The causes of idiopathic PD are still not fully understood. The relatively uniform worldwide prevalence suggests that a single environmental agent is not responsible. There may be multiple interacting risk factors, including genetic susceptibility.

Age and gender

Prevalence increases sharply with age, particularly over 70 years, with prevalence of 1 in 200 over age 80. Ageing changes are likely to be a factor in causation. Prevalence is higher in men (1.5:1 male to female).

Environmental factors

Epidemiological studies consistently show a small increased risk with rural living and drinking well water. Pesticide exposure has been implicated and pesticide-induced rodent models of PD exist, which increases biological plausibility of a link. The chemical compound methyl-phenyl tetrahydropyridine (MPTP), a potent mitochondrial toxin, causes severe parkinsonism, leading to suggestions that oxidative stress may be a factor leading to neuronal cell death in idiopathic PD. Studies consistently show that non-smokers have a higher risk of PD than smokers (even after controlling for shorter life expectancy in smokers), an observation that is difficult to explain.

Genetic factors

Idiopathic PD is not usually familial but twin studies show that there is a significant genetic component in early-onset PD (onset before 40). Several genetic loci for monogenic forms of PD have now been identified (**Box 28.34**), including autosomal dominant, autosomal recessive, and X-linked forms of PD. Most of these are rare but together they account for a reasonable proportion of early-onset and familial PD, and a small proportion (perhaps 1%–2%), of sporadic late-onset cases. The main significance of the monogenic forms of PD is that they provide insights into the pathophysiological mechanisms underlying PD that may be relevant to sporadic cases.

Aside from the rare disease-causing variants, polymorphisms in these and other genes may, in combination, constitute a susceptibility to PD that can be triggered by environmental factors or the ageing process. In particular, heterozygous variants in the glucocerebrosidase 1 *(GBA1)* gene are an important risk factor for PD (homozygous variants cause Gaucher disease).

Box 28.34 Selected Parkinson's disease (PD) genes

Gene	Protein	Inheritance	Comments
SNCA	α-Synuclein	AD	Rare but a major protein in Lewy bodies
LRRK2	Dardarin (a cytoplasmic kinase)	AD	The most common form of monogenic PD. Phenotype almost identical to sporadic PD. Found in 1% of apparently sporadic PD patients. High frequency in Jewish and North African Arab patients
PRKN	Parkin	AR	Responsible for most cases of juvenile PD and 20% of early-onset PD cases
PINK1	PTEN-induced kinase 1	AR	Rare. Protein involved in mitochondrial function

AD, Autosomal dominant; *AR,* autosomal recessive.

Pathology

The pathological hallmarks of PD are the presence of neuronal inclusions called Lewy bodies (see 'Dementia with Lewy bodies and Parkinson's disease dementia' section) and loss of the dopaminergic neurons from the pars compacta of the substantia nigra in the midbrain that project to the striatum of the basal ganglia (see **Fig. 28.12**). Lewy bodies contain tangles of α-synuclein and ubiquitin, and become gradually more widespread as the condition progresses, spreading from the lower brainstem and the olfactory bulb early in the disease, to the midbrain and then eventually into the cortex. Degeneration also occurs in other basal ganglia nuclei. The extent of nigrostriatal dopaminergic cell loss correlates with the degree of akinesia. Interestingly, α-synuclein deposition is also found in the sympathetic ganglia, the enteric nervous system, the GI tract itself, and even in the heart and skin. There is considerable interest in the involvement of the gut-brain axis in the pathogenesis of PD.

Clinical features

PD almost always presents with the typical motor symptoms of tremor and slowness of movement but it is likely that the pathological process starts many years before these symptoms develop. By the time of first presentation, on average 70% of dopaminergic nigrostriatal cells have already been lost.

Prodromal pre-motor symptoms

Patients develop a variety of non-specific non-motor symptoms during the approximately 7 years, sometimes longer, before the motor symptoms become manifest. These include:

- anosmia (present in 90%)—the olfactory bulb is one of the first structures to be affected
- constipation
- depression/anxiety (50%)
- aches and pains
- REM sleep behaviour disorder
- autonomic features—urinary urgency, hypotension
- restless legs syndrome.

Motor symptoms

These develop slowly and insidiously, and are often initially attributed to 'old age' by patients. The core motor features of PD are:

- bradykinesia
- tremor
- rigidity
- postural and gait disturbance.

Slowness causes difficulty rising from a chair or getting into or out of bed. Writing becomes small (micrographia) and spidery, tending to tail off. Relatives often notice other features: slowness and an impassive face. Idiopathic PD is almost always more prominent initially on one side. The diagnosis is usually evident from the overall appearance.

Bradykinesia

Poverty (akinesia) and slowing (bradykinesia) of movement are the cardinal clinical features of Parkinson's disease and the main cause of disability. The two terms are often used interchangeably. What distinguishes bradykinesia from slowness of movement from other causes is a progressive ***decrement*** in amplitude and speed of repetitive movements, such as opening and closing the hand or finger tapping.

There is difficulty initiating movement. The upper limb is usually affected first and symptoms are almost always unilateral for the first years. Rapid dexterous movements are impaired, causing difficulty writing (micrographia) and doing up buttons and zips, for example. Facial immobility gives a mask-like semblance of depression. Frequency of spontaneous blinking diminishes, producing a ***serpentine stare***.

Tremor

Tremor is the presenting symptom in 70% of patients. It typically starts in the fingers or hand (3–6 Hz) and is unilateral initially, spreading later to the leg on the same side and, after some years, to the opposite side. The tremor is present at rest, and reduces or stops completely when the hand is in motion. It is often described as ***pill-rolling*** because the patient appears to be rolling something between thumb and forefinger. As with most tremors, it is made worse by emotion or stress.

Rigidity

This is a sign rather than a symptom. Stiffness on passive limb movement is described as 'lead pipe', as it is present throughout the range of movement and, unlike spasticity, is not dependent on speed of movement. When stiffness occurs with tremor (not always visible), a ratchet-like jerkiness is felt, described as 'cogwheel' rigidity.

Postural and gait changes

A stooped posture is characteristic. Gait gradually becomes shuffling with small stride length, slow turns, freezing, and reduced arm swing. Postural stability eventually deteriorates, leading to falls, but this is a late-stage feature that should arouse suspicion of an alternative diagnosis if present during the first 5 years.

Speech and swallowing

Speech becomes quiet, indistinct, and flat. Drooling may be an embarrassing problem and swallowing difficulty is a late feature that may eventually lead to aspiration pneumonia as a terminal event.

Cognitive and psychiatric changes

Cognitive impairment is now recognized to be common in late-stage PD (80%) and may develop into dementia. Visual hallucinations and psychosis are not uncommon, and may herald evolving cognitive decline. Cholinesterase inhibitors may be helpful.

Depression is common, probably due to involvement of serotonergic and adrenergic systems, and is a cause of reduced quality of life in PD. Anxiety is also co-morbid with PD.

Clinical evolution of PD

Most patients respond well to treatment and there is generally a period of several years in which symptoms are well controlled with relatively little disability. Response to dopaminergic drugs is never lost but treatment-related fluctuations may develop (see below), which can be limiting, especially for patients with early age at onset. Eventually, usually by the mid-seventies, late-stage, treatment-unresponsive features, such as cognitive impairment, swallowing difficulty, loss of postural stability, and falls, start to emerge.

The rate of progression is very variable, with a benign form running over several decades. Usually, the course is over 10 to 20 years, death resulting from bronchopneumonia and immobility.

Diagnosis

There is no laboratory test; diagnosis is made by recognizing physical signs and distinguishing idiopathic PD from other parkinsonian syndromes. Patients with suspected PD should be referred to a specialist without initiation of treatment.

MRI is normal and not necessary in typical cases; it can provide clues about atypical parkinsonian disorders. Dopamine transporter imaging using SPECT (DaT scan) makes use of a radiolabelled ligand binding to dopaminergic terminals to assess the extent of nigrostriatal cell loss. It may occasionally be needed to distinguish PD from other causes of tremor or from drug-induced parkinsonism, but it cannot discriminate between PD and other akinetic–rigid syndromes. Cardiac MIBG scintigraphy demonstrates postganglionic cardiac sympathetic denervation in idiopathic Parkinson's disease and Dementia with Lewy Bodies (DLB), but not in other neurodegenerative disorders.

Management

Education about the condition is necessary and physical activity is beneficial and should be encouraged. Dopamine replacement with levodopa or a dopamine agonist improves motor symptoms and is the basis of pharmacological therapy. Treatment of non-motor symptoms, such as depression, constipation, pain, and sleep disorders, is also necessary and significantly improves quality of life.

Dopamine replacement may not always be needed in early-stage PD and is only started when symptoms begin to cause disability. The mechanism of action of drugs in PD is shown in Fig. 28.23.

Levodopa

Levodopa remains the most effective form of treatment and all patients with PD will eventually need it. It is combined with a dopa

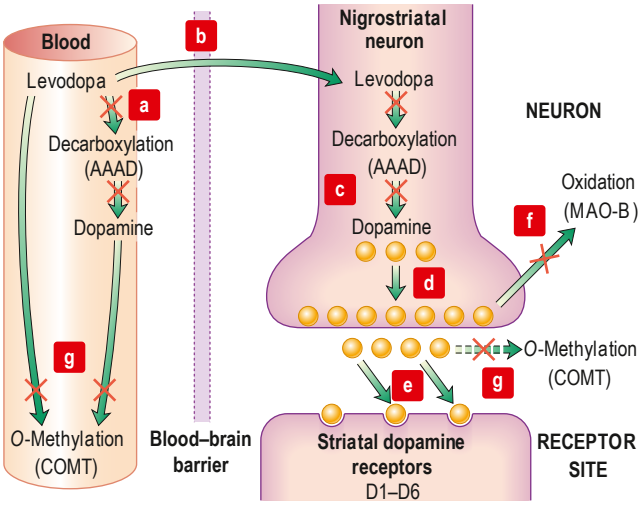

Fig. 28.23 Drugs in Parkinson's disease. Levodopa crosses the blood–brain barrier, enters the nigrostriatal neuron, and is converted to dopamine. **(a)** Carbidopa and benserazide reduce peripheral conversion of levodopa to dopamine, thus reducing the side-effects of circulating dopamine. **(b)** Dietary amino acids from high-protein meals can inhibit active transport across the blood–brain barrier by competing with levodopa. **(c)** Levodopa is converted (aromatic amino acid decarboxylase, AAAD) to dopamine. **(d)** Amantadine enhances dopamine release. **(e)** Dopamine agonists react with dopamine receptors. **(f)** Monoamine oxidase (MAO)-B inhibitors block dopamine breakdown. **(g)** Catechol-*O*-methyl transferase (COMT) inhibitors prolong dopamine activity by blocking breakdown.

decarboxylase inhibitor—benserazide (co-beneldopa) or carbidopa (co-careldopa)—to reduce the peripheral adverse effects (e.g., nausea and hypotension); 50 mg of levodopa (e.g., co-careldopa 62.5 mg) three times daily, increasing after 1 week to 100 mg three times daily, is a typical starting dose. The response is often dramatic.

Dopamine agonists

Dopamine agonists (DAs) may be used in combination with levodopa or as initial monotherapy in younger patients (below age 65–70) with mild to moderate impairment. Although less efficacious in symptom control than levodopa and generally less well tolerated, DAs are associated with fewer motor complications over a 5-year period. Non-ergot DAs (pramipexole and ropinirole or rotigotine via transdermal patch) are used in preference to ergot-derived drugs, which may be associated with fibrotic reactions, including cardiac valvular fibrosis.

Both DAs and levodopa can cause nausea, which abates with time. This is reduced by taking levodopa with meals upon initiation, but once established it should be taken on an empty stomach to maximize absorption. Domperidone can be used for short periods if required; the risk of cardiac side-effects precludes its routine use in all patients. Trimethobenzamide is an alternative in countries where domperidone is not available. Other antiemetics should not be used, as they may worsen symptoms by blocking central dopamine receptors.

Other drugs used in PD

- ***Monoamine oxidase (MAO)-B inhibitors*** (e.g., rasagiline, selegiline, and safinamide) reduce catabolism of dopamine in brain. They have a mild symptomatic effect, and the first two agents may be used in selected mild cases as monotherapy (or as adjuncts to levodopa). Safinamide is most often used as add-on therapy with levodopa to help with motor fluctuations.
- ***Amantadine*** has a modest anti-parkinsonian effect but is used mainly to improve dyskinesias in advanced disease.
- ***Antimuscarinics*** (e.g., ***orphenadrine***, ***procyclidine***, ***trihexyphenidyl***) may help tremor but are rarely used in PD except in younger patients. They have a high propensity to cause confusion and cognitive impairment in older patients.
- ***Apomorphine*** is a potent, short-acting DA administered subcutaneously by an autoinjector pen as intermittent 'rescue' injection for off periods or by continuous infusion pump. It is used in advanced PD.

Long-term response to treatment

As the disease progresses, medical therapy for PD becomes more difficult as higher doses of dopamine replacement therapy are required and response becomes more unpredictable with the development of motor fluctuations and dyskinesias; response to dopaminergic drugs is never lost, however.

Approximately 10% of patients per year develop motor complications in the form of 'wearing off' (the duration of effect of individual doses of levodopa becomes progressively shorter), dyskinesias (involuntary choreiform movements) and, eventually, 'on/off' phenomena (sudden, unpredictable transitions from mobile to immobile). Eventually, patients may alternate between the 'on' state with dopamine-induced dyskinesias and periods of complete immobility ('off').

Management of the motor complications of treatment represents one of the greatest challenges in the management of PD. Strategies include:

- dose fractionation of levodopa—increasing dose frequency
- addition of a catechol-*O*-methyl transferase (COMT) inhibitor such as ***entacapone*** or ***opicapone*** to prolong duration of action; entacapone is also available as a combined preparation with levodopa and carbidopa
- slow-release levodopa—mostly used for overnight symptoms, as absorption is erratic and difficult to predict, limiting effectiveness in control of daytime symptoms
- avoidance of protein-rich meals (which impair levodopa absorption) and taking doses at least 1 hour before or 2 hours after meals
- apomorphine continuous subcutaneous infusion (see above)
- deep brain stimulation (DBS) and levodopa intestinal gel (see below).

Deep brain stimulation

Stereotactic insertion of electrodes into the brain has proved to be a major therapeutic advance in selected patients (usually under age 70) with disabling dyskinesias and motor fluctuations not adequately controlled with medical therapy. Targets include:

- the STN—response similar to levodopa with reduction in dyskinesia
- the globus pallidus—improves dyskinesia but levodopa is still required for motor symptoms
- the thalamus—for tremor only.

Dopaminergic drugs can be reduced (but not withdrawn) after DBS. Approximately 10% of patients will be candidates at some point, usually patients with younger onset, as they have a higher rate of motor complications such as dyskinesia. There is a trend towards earlier use of DBS before motor complications become severe.

Levodopa intestinal gel infusion

Continuous infusion of this gel into the small intestine via a jejunostomy using a patient-operated pump is effective for selected patients with severe motor complications.

Tissue transplantation

Transplantation of embryonic mesencephalic dopaminergic cells directly into the putamen has produced mixed results but is potentially promising; research is ongoing to refine the technique. Stem cell and gene therapy approaches are in development.

Physiotherapy, occupational therapy, and physical aids

Physiotherapy, occupational therapy, and speech therapy all have a role to play in managing PD and reducing disability, speech and swallowing problems, and falls. Walking aids are often a hindrance early on, but later a frame or a tripod may help. A variety of external cueing techniques may help with freezing. Exercise is of proven benefit for patients with PD.

Other akinetic–rigid syndromes

Drug-induced parkinsonism

Dopamine-blocking or depleting drugs, particularly antipsychotics (with the exception of clozapine), can induce parkinsonism. These drugs also worsen symptoms in patients who already have PD, and may precipitate symptom onset in elderly patients in the presymptomatic phase. Antimuscarinic drugs reduce these symptoms, although tardive dyskinesia may be made worse.

Atypical parkinsonism

A number of neurodegenerative disorders affect the basal ganglia, causing prominent parkinsonism as part of the clinical picture; they may be mistaken for idiopathic PD in the early stages. These include:

- ***Multiple system atrophy (MSA).*** Autonomic and cerebellar symptoms occur in addition to parkinsonism. Either parkinsonism or cerebellar symptoms predominate; many patients have RBD. Stridor and sleep-disordered breathing can be dangerous features. Pathologically, α-synuclein-positive glial cytoplasmic inclusions are found in the basal ganglia, cerebellum, and motor cortex. Patients do not respond to levodopa therapy. Management is symptomatic and they have a poorer prognosis than patients with Parkinson's disease.
- ***Progressive supranuclear palsy*** (Steele–Richardson–Olszewski syndrome). This causes parkinsonism, postural instability with early falls, vertical supranuclear gaze palsy, pseudobulbar palsy, and dementia. Tau deposition is seen pathologically in the substantia nigra, STN, and midbrain ***(tauopathy).*** There is considerable clinical and pathological overlap between PSP and frontotemporal dementia (behavioural variant frontotemporal dementia, and non-fluent variant primary progressive aphasia; see 'Frontotemporal dementia' section).
- ***Corticobasal degeneration (CBD).*** Another tauopathy, in which alien limb phenomena, asymmetrical parkinsonism, apraxia, myoclonus, and dementia occur. Strictly speaking CBD is a postmortem diagnosis; the ***corticobasal syndrome*** can be associated with neuropathological features of CBD, PSP, or even Alzheimer's disease.

These disorders are relentlessly progressive; although they sometimes respond to levodopa, they usually cause death within a decade. 'Red flag' symptoms suggesting one of these disorders include:

- symmetrical presentation and absence of tremor
- levodopa unresponsiveness (or poor response)
- early falls (within first year)
- additional neurological features.

Hyperkinetic movement disorders

There are five hyperkinetic movement disorders, which can sometimes be difficult to separate from one another and may occur in combination.

- ***Tremor***—rhythmic sinusoidal oscillation of a body part.
- ***Chorea***—rapid, irregular movements flowing from one body part to another ('dance-like'); milder forms of chorea appear fidgety. ***Ballismus*** is a large amplitude, proximal flinging movement linked to chorea.
- ***Myoclonus***—brief, electric shock-like jerks.
- ***Tics***—stereotyped movements or vocalizations (may be temporarily suppressed).
- ***Dystonia***—sustained muscle spasms causing twisting movements and abnormal postures.

Dyskinesia encompasses a range of involuntary movements, including chorea, akathisia, and dystonia, but is often the preferred term when the movement disorder is drug-induced.

Essential tremor

This common condition, often inherited as an autosomal dominant trait, causes a bilateral, fast, low-amplitude tremor, mainly in the upper limbs. The head and voice are occasionally involved. Tremor is postural, such as when holding a glass or cutlery. Essential tremor occurs at any age. Tremor is slowly progressive but rarely produces severe disability. There may be a cerebellar-type action tremor component. Anxiety exacerbates the tremor, and alcohol suppresses it.

Treatment is often unnecessary or unsatisfactory. Many patients are reassured to find they do not have PD, with which essential tremor is often confused. Beta-blockers (propranolol), primidone or gabapentin may help. Sympathomimetics (e.g., salbutamol) make all tremors worse. Stereotactic thalamotomy and thalamic DBS are used in severe cases.

Chorea

There is a wide variety of possible causes of chorea. These include:

- systemic disease—hyperosmolar hyperglycaemic state, thyrotoxicosis, SLE, antiphospholipid syndrome, polycythaemia vera
- genetic disorders—Huntington's disease and genetic phenocopies, neuroacanthocytosis, benign hereditary chorea
- structural and vascular disorders affecting the basal ganglia
- drugs (e.g., levodopa, antipsychotics, and the oral contraceptive pill)
- post-infectious (Sydenham's chorea)—following months after streptococcal infection or as part of acute rheumatic fever
- pregnancy (chorea gravidarum).

Treatment is of the underlying cause but dopamine-blocking drugs, such as olanzapine and risperidone, and dopamine-depleting drugs (tetrabenazine), reduce chorea (as the prototypical *excessive* movement condition, the treatment is the *opposite* of PD).

Huntington's disease

Huntington's disease is a cause of chorea, usually presenting in middle life, initially with subtle 'fidgetiness' followed by development of progressive psychiatric and cognitive symptoms.

Oculomotor apraxia is an early clinical sign (delayed saccadic initiation).

Prevalence worldwide is about 5/100 000. HD is due to a CAG trinucleotide repeat expansion, which forms the basis of the diagnostic test. This results in translation of an expanded polyglutamine repeat sequence in huntingtin, the protein gene product, the function of which is unclear. The expansion is thought to be a toxic 'gain-of-function' mutation. Most adult-onset patients have 36 to 55 repeats and there is an inverse relationship between repeat length and age at onset, with juvenile-onset patients having over 60 repeats. Expansion of the unstable CAG repeat during meiosis, particularly spermatogenesis, is the molecular basis for the phenomenon of anticipation (a tendency for successive generations to have earlier onset and more severe disease), particularly when inherited from the father.

HD is inherited in an autosomal dominant manner with complete penetrance (all gene carriers will develop the disease eventually). Sufferers are often unaware of previous family history, owing to historical family breakdown. There is no disease-modifying treatment at present, although chorea can improve with treatment, such as risperidone or tetrabenazine, but progressive neurodegeneration leads to dementia and ultimately death after 10 to 20 years. Patients with small or intermediate-range expansions may present in old age with isolated chorea.

Absence of treatment results in a low take-up rate for presymptomatic testing in at-risk individuals. Test centres have protocols for counselling families and addressing ethical issues. Much research is being conducted into disease-modifying therapies, and an antisense oligonucleotide has been shown to engage with the target and lower concentrations of mutant huntingtin protein in CSF, but larger trials were halted early because of worsening clinical outcomes or failure to lower mutant HTT.

Hemiballismus

Hemiballismus describes violent swinging movements of one side, usually caused by infarction or haemorrhage in the contralateral STN.

Acute hemichorea–hemiballism also occurs after diabetic hyperosmolar hyperglycaemia, with signal change seen in the contralateral striatum on CT or MRI; it is thought to be due to osmotic shifts causing myelinolysis.

Myoclonus

Myoclonus refers to a brief, shock-like muscle contraction (or a brief loss of muscle tone—negative myoclonus). The word may indicate a movement disorder or an epileptic phenomenon. Myoclonus can arise from virtually every part of the nervous system, from the cortex to the peripheral nerve.

Cortical myoclonus is usually distal (hands and fingers especially) and stimulus sensitive (spontaneous but also triggered by touch or loud noises). It is caused by a wide variety of pathologies affecting the cerebral cortex; ***spinal and brainstem myoclonus*** are caused by localized lesions affecting these structures.

Primary myoclonus

Physiological myoclonus. Nocturnal myoclonus (hypnic jerks) consists of sudden jerks (often with a feeling of falling) on dropping off to sleep or waking; it is common and not pathological. Hiccups are a form of myoclonus affecting the diaphragm. The startle response is also a form of brainstem myoclonus.

Myoclonus-dystonia (DYT11). Myoclonic 'lightning jerks', often with dystonia, are inherited as a rare autosomal dominant disorder due to mutations in the ε-sarcoglycan gene.

Myoclonus in epilepsy

Myoclonic jerks occur in several forms of epilepsy, either as a primary seizure type, or as a fragment of epilepsy (see 'Epilepsy and loss of consciousness' section). An antiepileptic drug, such as valproate, may be helpful.

Progressive myoclonic epilepsy–ataxia syndromes

These rare conditions include genetic and metabolic disorders in which myoclonus accompanies progressive epilepsy, cognitive decline, and/or ataxia. ***Lafora body disease***, ***neuronal ceroid lipofuscinosis***, and ***Unverricht–Lundborg*** disease are examples.

Secondary myoclonus

Myoclonus may be seen in a wide variety of metabolic disorders, including hepatic and renal failure (asterixis—negative myoclonus), as part of several dementias and neurodegenerative disorders (e.g., Alzheimer's disease), and encephalitis.

Post-anoxic myoclonus can follow severe cerebral anoxia. A distinction must be drawn between early post-anoxic myoclonic status epilepticus, which is a very poor prognostic sign following hypoxic–ischaemic brain injury (HIBI), and delayed post-hypoxic Lance Adams myoclonus, which arises when the patient is awake and causes disabling action myoclonus but does not portend death.

Tics

Tics are common (15% lifetime prevalence), brief, stereotyped movements usually affecting the face or neck but which may involve any body part; they include vocal tics. Unlike other movement disorders, they may be transiently suppressed, leading to a build-up of anxiety and overflow after release.

Simple transient tics (e.g., blinking, sniffing, or facial grimacing) are common in childhood but may persist. Adult-onset tics are rare and usually have a secondary cause, or are functional. The borderland between normal and pathological is vague.

Tourette's syndrome

The most common cause of tics, characterized by multiple motor tics and at least one vocal tic, starts in childhood and persists longer than a year. Boys are affected more often than girls in a 3:1 ratio. Behavioural problems, including attention-deficit/hyperactivity disorder (ADHD) and obsessive–compulsive disorder (OCD), are common and may sometimes be the major cause of disability. There is sometimes explosive barking and grunting of obscenities (coprolalia) and gestures (copropraxia) or echolalia (copying what other people say). Many affected individuals never come to medical attention. The cause is not known but it may be a complex problem with changes in various neurotransmitters.

Dystonias

Dystonia (Box 28.35) is most usefully classified by aetiology into:

- ***primary dystonias***—where dystonia is the only, or main, clinical manifestation (usually genetic, or idiopathic)
- ***secondary dystonia***—due to brain injury, cerebral palsy, or drugs, for example
- ***hereditary degenerative dystonia***—part of a wider neurodegenerative disorder
- ***paroxysmal dystonias***—rare, mostly genetic, attacks of sudden involuntary movements with elements of dystonia and chorea.

Primary dystonias

Young-onset

DYT1 dystonia: mutations in the *DYT1* gene locus, seen particularly in the Ashkenazi Jewish population, cause limb-onset dystonia

Box 28.35 A classification of dystonias

- Generalized dystonia
- Primary torsion dystonia (PTD)
- Dopamine-responsive dystonia (DRD)
- Drug-induced dystonia (e.g., metoclopramide)
- Symptomatic dystonia (e.g., after encephalitis lethargica or in Wilson's disease)
- Paroxysmal dystonia (very rare, familial, with marked fluctuation)
- Focal dystonia
- Spasmodic torticollis
- Writer's cramp
- Oromandibular dystonia
- Blepharospasm
- Hemiplegic dystonia, e.g., following stroke
- Multiple sclerosis—rare

(usually foot), before the age of 28. Penetrance is low (autosomal dominant) and phenotype very variable, but the disorder often spreads over years to become generalized, and can result in severe disability. Cognitive function remains normal. The condition is rare and the definitive form of treatment for severe cases is DBS.

Dopa-responsive dystonia: in this rare disorder, dystonia is completely abolished by small doses of levodopa. Typically, dystonic walking begins in childhood and may resemble a spastic paraparesis or even present as cerebral palsy. Dominantly inherited mutations in the *GTP* cyclohydrolase gene on chromosome 14q26.3 (necessary for synthesis of a co-factor—tetrahydrobiopterin—needed for dopamine synthesis) lead to brain dopamine deficiency. Patients with dystonic gaits are sometimes given test doses of levodopa.

Adult onset

This is the most common type of primary dystonia. Onset is usually around 55 and dystonia is usually focal (restricted to one body part), particularly affecting the head and neck, unlike *DYT1* dystonia. Various patterns are recognized.

Torticollis—dystonic spasms gradually develop in neck muscles, causing the head to turn (torticollis) or to be drawn backwards (retrocollis). There may also be a jerky head tremor. A gentle touch with a fingertip at a specific site may relieve the spasm temporarily (sensory trick or 'geste antagoniste').

Writer's cramp and task-specific dystonias—there is a specific inability to perform a previously highly developed, repetitive, skilled movement, such as writing. The movement provokes dystonic posturing. Other functions of the hand remain normal. Overuse may lead to task-specific dystonias in certain occupations, such as musicians, typists, and even golfers.

Blepharospasm and oromandibular dystonia—these consist of spasms of forced blinking or involuntary movement of the mouth and tongue (e.g., lip-smacking and protrusion of the tongue and jaw). Speech may be affected.

Neuroleptics and movement disorders

Neuroleptics (antipsychotic drugs used to treat schizophrenia) and related drugs used as antiemetics (e.g., metoclopramide) can cause a variety of movement disorders:

- ***Akathisia.*** This is a restless, repetitive, and irresistible need to move.
- ***Parkinsonism.*** This is due to D_1 and D_2 dopamine receptor blockade (see above).
- ***Acute dystonic reactions.*** Spasmodic torticollis, trismus, and oculogyric crises (episodes of sustained upward gaze) develop, dramatically and unpredictably, after single doses.
- ***Tardive dyskinesia.*** These choreiform movements, often affecting the face and mouth with mouthing and lip-smacking grimaces, occur after several years of neuroleptic use. They often become temporarily worse when the drug is stopped or the dose reduced. Even if treatment ceases, resolution seldom follows. Atypical neuroleptics are less prone to cause this complication. Procyclidine, often prescribed for neuroleptic-induced parkinsonism, can make tardive dyskinesia more pronounced.

Wilson's disease

This rare and treatable disorder of copper metabolism is inherited as an autosomal recessive trait. Copper deposition occurs in the basal ganglia, cornea, and liver (see Chapter 23, 'Wilson's disease [progressive hepatolenticular degeneration]' section), where it can cause cirrhosis. Copper-coloured Kayser-Fleischer rings in the cornea are pathognomonic. All patients below age 50 with any hyperkinetic movement disorder or with liver cirrhosis should be screened for Wilson's disease (serum copper and caeruloplasmin should be checked). Intellectual impairment develops. Neurological damage is reversible with early treatment. Diagnosis and treatment with the chelating agent penicillamine are discussed in Chapter 23 ('Wilson's disease [progressive hepatolenticular degeneration]' section).

NEUROINFLAMMATORY DISORDERS

MS is by far the most common neuroinflammatory disorder in Western populations. Other CNS inflammatory conditions include post-infectious disorders such as acute disseminated encephalomyelitis (ADEM) and transverse myelitis (TM), distinct autoimmune disorders such as NMO and multisystem inflammatory disorders such as sarcoidosis and Behçet's disease.

Multiple sclerosis

Debates about the causes and mechanisms of MS still rage, but inflammation, myelin destruction, and axonal loss combine to generate neurological injury. Multiple plaques of demyelination are found throughout the brain and spinal cord, occurring sporadically over years (dissemination in space and time is crucial for diagnosis).

MS is a major cause of disability in young adults but several disease-modifying therapies are now available.

Epidemiology

- ***Prevalence.*** MS is a common neurological disorder with over 2 800 000 cases worldwide. In the UK, the prevalence is 1.2/1000. Approximately 80 000 people in the UK have MS.
- ***Gender.*** Women outnumber men by 2:1. There is evidence that this ratio is widening, with an increasing proportion of women being affected (partly accounted for by the increase in women smoking).
- ***Age.*** Presentation is typically between 20 and 40 years of age. Presentation after age 60 is rare, although diagnosis may sometimes be much delayed, occurring years after the initial symptoms.

Prevalence varies widely in different geographical regions and ethnic groups. This probably reflects both genetic (see below) and environmental influences in pathogenesis. MS is much more common in white populations and with increasing distance from the equator. Even within the UK, there is a north–south divide, prevalence being higher in Scotland than in southern England. Migration studies show that children moving from a low-risk to a high-risk area (e.g., the UK) develop a higher risk of MS, similar to the population of the country to which they migrate, indicating that environmental factors are a factor in pathogenesis.

Certain other autoimmune disorders occur with increased frequency in patients with MS and their relatives, indicating a genetic predisposition to autoimmunity.

Aetiology and pathogenesis

In its early stages, MS is a primarily immune-mediated disorder, with T cells, B cells, and macrophages interacting to cause focal demyelination; eventually neurodegeneration dominates. Traditionally viewed as a disease of white matter, grey matter involvement is increasingly recognized. The aetiology of MS is complex and not yet fully understood.

Genetic susceptibility

Multiple genes interact to confer an increased risk of MS, giving a complex polygenic inheritance pattern. Genetic differences between different populations probably account for part of the observed variation in MS incidence around the world.

Family studies show that there is a much-increased risk of MS in first-degree relatives of affected patients (approximately 5% lifetime risk of developing MS). Twin studies confirm a major genetic component to susceptibility, with 30% of monozygotic twins being concordant for MS in the UK and Canada versus 5% of dizygotic twins. However, even the twin concordance rate is much lower in southern latitudes, pointing to a gene-environment interaction.

Genes. Over 200 polymorphisms have been identified as conferring an increased risk of MS; many are close to genes encoding proteins involved in immune function and regulation, including the human leukocyte antigen (HLA) complex. The biggest risk is associated with the HLA-DRB1*15:01 allele, which appears to be associated with an earlier disease onset.

Environmental factors

Migration studies (see above) and twin studies indicate that environmental factors play a role in the development of MS but these factors are still largely unknown. Viral infections can precipitate MS relapses, and exposure to infectious agents at critical times in development may trigger MS in genetically susceptible individuals. There is evidence that exposure to Epstein–Barr virus (EBV) may be linked to MS; EBV seropositivity is higher in patients with MS than in the general population. Another theory states that exposure to infectious agents in childhood may reduce the risk of developing MS and other autoimmune disorders (the 'hygiene hypothesis'). There is good evidence that low levels of vitamin D and/or lack of sunlight exposure increase risk of MS, as does smoking tobacco.

Pathology

Plaques of demyelination, 2 to 10 mm in size, are the cardinal features (Fig. 28.24). Plaques occur in a perivenular distribution and arise anywhere in CNS white matter, but there is a predilection for distinct CNS sites: optic nerves, the juxtacortical and periventricular region, the corpus callosum, the brainstem and its cerebellar connections, and the cervical cord (corticospinal tracts and dorsal columns). MRI studies show that most inflammatory plaques are asymptomatic. Recent advances in pathology and MRI techniques show that the grey matter of the cortex is also affected from an early stage in MS, and normal-appearing grey and white matter can be diffusely damaged. Peripheral myelinated nerves are not directly affected in MS.

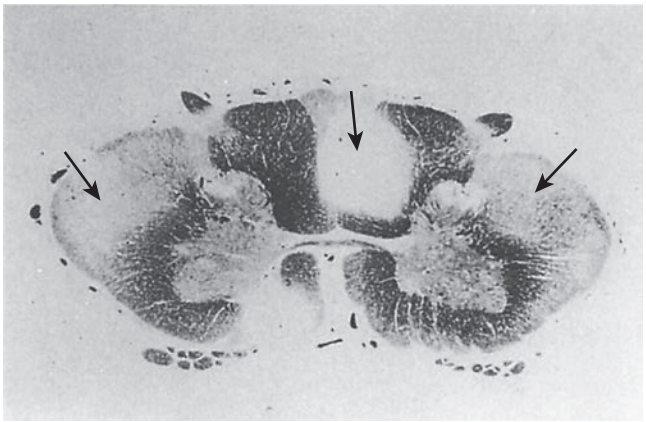

Fig. 28.24 Multiple sclerosis (MS). Cross-section of spinal cord showing MS plaques in posterior column and lateral corticospinal tracts *(arrowed)*. *(Courtesy of the late Professor Ian Macdonald.)*

Acute relapses are caused by focal inflammation, with a predominant T-cell infiltrate, causing oligodendrocyte damage and hence demyelination. Recovery follows as inflammation subsides and remyelination occurs. As the disease progresses, microglial activation and secondary permanent axonal destruction occur. Neurodegeneration is the pathological basis of the progressive disability seen in progressive forms of MS. The extent of grey matter damage correlates with the severity of disability and cognitive involvement. The exact relationship between the inflammatory lesions seen in early relapsing–remitting forms of MS and the progressive axonal loss of chronic forms of MS is disputed.

Clinical features

No single group of signs or symptoms is diagnostic. A wide variety of possible symptoms may occur, depending on the anatomical site of the lesions; MS has been described as a 'great imitator'. The clinical time course of attacks and tempo of evolution of symptoms are as helpful as the symptoms themselves in making the diagnosis of MS.

Types of MS

MS is divided into four clinical phenotypes (Fig. 28.25).

- ***Clinically isolated syndrome (CIS).*** See below. A neurological episode that is typical of MS, without prior attacks. The time course is characteristic: onset over days followed by a plateau for several weeks, and then typically recovery, either partial or (ostensibly) complete, over weeks.
- ***Relapsing–remitting MS (RRMS).*** Symptoms occur in attacks (relapses), disseminated in space and time. On average, patients have one relapse per year but occasionally many years may separate relapses (so-called benign MS—10% of patients, but the possibility of eventual severe worsening is not excluded). For every clinical relapse, there will be about 10 subclinical lesions noted on MRI brain. Neuronal damage accrues even when recovery seems complete, and eventually will translate into mounting disability.

- ***Secondary progressive MS (SPMS).*** This stage of MS consists of gradually worsening disability progressing slowly over years. On average, people with MS reach a progressive phase 10 to 20 years after onset. The transition is not sharp and there will be a gradual change from a predominance of (inflammatory) relapses to a predominance of progression; there can be movement from progression to relapses and back again. Patients with SPMS can be subcategorized as *active* (with clinical relapses or new MRI lesions) or not active. Patients with active SPMS may benefit from disease-modifying treatment.
- ***Primary progressive MS (PPMS)*** (10%–15%). This pattern is characterized by gradually worsening disability from the onset. Some patients may have superimposed relapses or evidence of new inflammatory MRI lesions, denoting *active* disease (the term 'relapsing-progressive MS' is no longer used). It typically presents later and is associated with fewer inflammatory changes on MRI.

In reality the relapsing and progressive forms of the disease exist along a continuous spectrum. There is increasing evidence that progression begins early in the disease course, and inflammatory relapses may re-emerge even after a period of progression independent of relapse activity. There is a move towards using a more flexible phenotypic classification, with the above categories modified by a description of inflammatory *activity* or inactivity (relapses or new MRI lesions), and the presence or absence of *progression*.

Severity is described by various terms, the most important being 'highly active MS' (unchanged or increased relapse rate or ongoing severe relapses despite treatment; or one relapse in the previous year and MRI evidence of disease activity) and 'rapidly evolving severe MS' (two disabling relapses within the last year and MRI evidence of significant disease activity).

Clinical presentations

Three characteristic common presentations of MS are optic neuropathy (neuritis), brainstem demyelination, and spinal cord lesions.

Optic neuritis

See 'Inflammatory optic neuropathy (optic neuritis)' section.

Brainstem demyelination

A relapse affecting the brainstem causes combinations of diplopia, vertigo, facial numbness/weakness, dysarthria, and dysphagia.

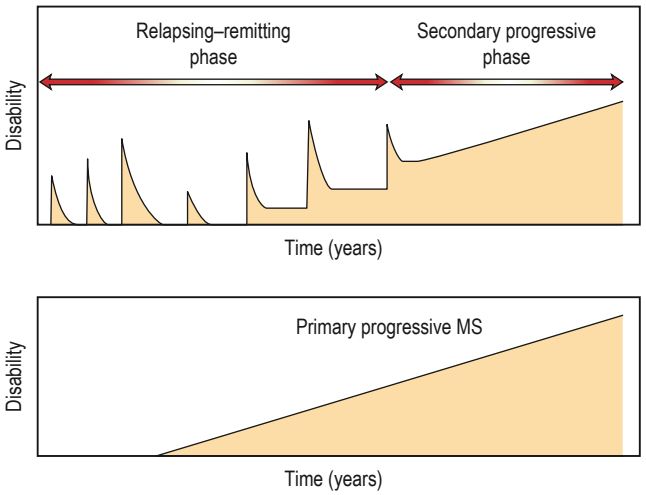

Fig. 28.25 Clinical patterns of multiple sclerosis.

Pyramidal signs in the limbs occur when the corticospinal tracts are involved. A typical picture is sudden diplopia, and vertigo with nystagmus, but without tinnitus or deafness. Bilateral INO (see 'Internuclear ophthalmoplegia' section) is virtually pathognomonic of MS.

Spinal cord lesions

Paraparesis developing over days or weeks is a typical result of a plaque in the cervical or thoracic cord, causing difficulty in walking and limb numbness with tingling, often asymmetric. Lhermitte's sign may be present (see 'Lhermitte's phenomenon' section). Sometimes, the arms are also involved in high cervical cord lesions. A tight band sensation around the abdomen or chest is common with thoracic cord lesions (the 'MS hug').

Common symptoms in MS

Disability and neurological impairments accumulate gradually over the years. Several symptoms are common and many can be improved with symptomatic treatments (Box 28.36).

Box 28.36 Symptomatic treatments in multiple sclerosis

Urinary symptoms
- Antimuscarinics for overactive bladder e.g., oxybutynin, tolterodine, solifenacin, trospium
- Alpha-blockers for urinary retention
- Desmopressin spray for nocturia
- Intermittent self-catheterization (ISC)
- Botulinum toxin type A intravesical injections (usually also require ISC)
- Sacral nerve stimulator
- Bladder training exercises
- Indwelling catheter

Spasticity
- Self-management, including stretching, physiotherapy, splinting
- Skeletal muscle relaxants: baclofen, tizanidine, clonazepam
- Gabapentin
- Botulinum toxin type A (electromyelography-guided injections) for focal spasticity
- Cannabis: oromucosal spray
- Intrathecal baclofen pump
- Intrathecal phenol—destructive procedure in advanced disease with paraplegia

Pain
- As for treatment of neuropathic pain
- Trigeminal neuralgia—carbamazepine, lamotrigine
- Lhermitte's—carbamazepine

Depression
- Cognitive behavioural therapy
- Antidepressants

Impaired mobility
- Physiotherapy ± walking aids
- Treat spasticity
- Functional electrical stimulation
- Fampridine—selected patients

Erectile dysfunction
- Sildenafil, tadalafil, or vardenafil

Tremor
- Beta-adrenoceptor-blocking drugs
- Botulinum toxin type A injections (head or arms)
- Deep brain stimulation for severe Holmes tremor

Fatigue
- Fatigue management programme, treat depression
- Amantadine, modafinil (often ineffective)

- Visual changes
- Sensory symptoms—often unusual, for example a sensation of water trickling down the skin. Sensory symptoms are the presenting feature in 40% of patients. Reduced vibration sensation and proprioception in the feet are among the most common abnormalities on examination, but examination may be normal despite significant sensory symptoms
- Clumsy/useless hand or limb—due to loss of proprioception (often a dorsal column spinal plaque)
- Unsteadiness or ataxia
- Weakness—can have a give-way character in MS
- Urinary symptoms—bladder hyper-reflexia causing urinary urgency and frequency, and/or urinary retention. Urinary tract infections are very common in people with MS
- Pain—neuropathic pain is common
- Fatigue—a common and often debilitating symptom, which can occur in patients with otherwise mild disease
- Spasticity
- Depression
- Cognitive impairment
- Sexual dysfunction
- Temperature sensitivity—temporary worsening of pre-existing symptoms with increases in body temperature, for example after exercise or a hot bath, is known as Uhthoff's phenomenon.

Unusual presentations

Epilepsy and trigeminal neuralgia (see 'Trigeminal neuralgia' section) occur more commonly in MS patients than in the general population. Paroxysmal symptoms, such as tonic spasms, are sometimes seen and are thought to represent ephaptic transmission along damaged axons.

Late-stage MS

Late MS causes severe disability with spastic tetraparesis, ataxia, optic atrophy, nystagmus, brainstem signs (e.g., bilateral INO), pseudobulbar palsy, and urinary incontinence. Cognitive impairment, often with frontal lobe features, can be prominent.

Diagnosis

Few other neurological diseases have a similar relapsing and remitting course. The diagnosis of MS requires two or more attacks affecting different parts of the CNS: that is, dissemination in time and space, and exclusion of other possible causes. History and support from investigations, particularly MRI, make the diagnosis. The 2017 McDonald criteria formalize the diagnostic features and can be useful in clinical practice when only one clinical attack has occurred, but there is ancillary evidence of dissemination in space and time (by MRI and/or CSF criteria). New revisions to the McDonald criteria are expected to be published in full in 2025.

When taking a history at the time of initial presentation, it is essential to ask about previous episodes of neurological symptoms, often years previously, that may represent episodes of unrecognized demyelination: for example, a severe episode of vertigo lasting weeks or loss of vision in one eye that gradually recovered.

Investigations

The purpose of investigations is to provide supportive evidence of dissemination in time and space (i.e., to show scattered demyelinating lesions that evolve over time), to exclude other diseases and to provide evidence of immunological disturbance.

- MRI of brain and cord is the definitive investigation, as it demonstrates areas of demyelination with high sensitivity. Multiple scattered plaques are usually seen (Fig. 28.26A), typically oval in shape, up to 2 cm in diameter, and often orientated perpendicular to the lateral ventricles. Acute lesions show gadolinium enhancement for 6 to 8 weeks. Occasionally, large 'tumefactive' (swollen) lesions are seen (Fig. 28.26B).
- Although a sensitive technique to demonstrate plaques (normal MRI in MS is possible but distinctly rare), it is limited by lower specificity. Over the age of 50, small ischaemic lesions may be difficult to distinguish from demyelination, and in younger patients other neuroinflammatory disorders such as sarcoidosis, Behçet syndrome, and vasculitis may produce similar imaging appearances. The presence of spinal cord lesions is quite specific for inflammatory disorders such as MS rather than ischaemic lesions, so cord imaging is often useful where there is diagnostic difficulty.
- Plaques are rarely visible on CT.
- CSF examination is often unnecessary with suggestive MRI and a compatible clinical picture. CSF analysis shows oligoclonal IgG bands in over 90% of cases but these are not specific for MS. The presence of unpaired oligoclonal bands, in CSF but not serum, provides evidence for dissemination in time as per the McDonald criteria. The CSF cell count may be raised during an acute relapse (5–60 mononuclear cells/mm^3).
- Evoked responses, for example visual-evoked responses in optic nerve lesions, may demonstrate clinically silent lesions. However, since the advent of MRI, they are less used in diagnosis.
- Blood tests are used to exclude other inflammatory disorders such as sarcoidosis or SLE, or other causes of paraparesis, for example adrenoleukodystrophy, HIV, human T-cell lymphotropic virus 1 (HTLV-1), and vitamin B_{12} deficiency.

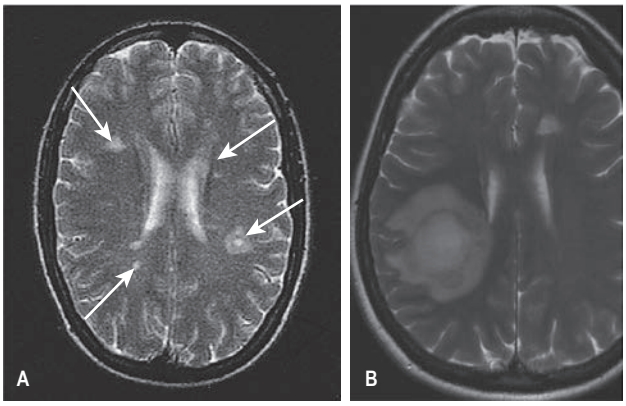

Fig. 28.26 Multiple sclerosis. (A) T2-weighted magnetic resonance image. Brain plaques are shown *(arrowed)*. Typical lesions are oval in shape, up to 2 cm in diameter, and often orientated perpendicular to the lateral ventricles. **(B)** Tumefactive multiple sclerosis lesion.

The clinically isolated syndrome

A first-ever episode of neurological symptoms suggestive of neuroinflammation is termed a 'clinically isolated syndrome' (CIS). A second clinical event indicative of a new lesion in a different anatomical location allows the diagnosis of MS to be confirmed. Alternatively, MS can still be diagnosed after a single attack, as per the 2017 McDonald criteria, if ancillary evidence is available to demonstrate dissemination in space and time.

- *Dissemination in space* can be demonstrated on MRI if lesions are present in at least two of the four MS-typical regions of the nervous system (periventricular, juxtacortical, infratentorial, and spinal cord).

- *Dissemination in time* can be inferred from the presence of both gadolinium-enhancing (acute) and non-enhancing (old) lesions, or by the appearance of new T2 hyperintense lesions on an interval scan.

Fewer people are diagnosed with CIS nowadays because the 2017 criteria have broadened the definition of MS. Occasionally patients with CIS who are felt to be at high risk of conversion to MS may be offered disease-modifying treatment from the time of first presentation.

The radiologically isolated syndrome

A radiologically isolated syndrome (RIS) is when MRI findings are highly suggestive of MS, with dissemination in space, but the patient has never had a clinical attack suggestive of MS. MS cannot be diagnosed unless and until a clinical event occurs; surveillance is usually suggested.

Management

The treatment landscape of MS has been transformed over the last decade. We now have highly effective therapies, that have high rates of success in relapse prevention. Although long-term data are limited, there is a growing body of evidence that early intensive treatment delays the onset of disability and slows secondary progression. The majority of treatments are still directed at relapsing–remitting MS, but there is now evidence of efficacy for some agents in active secondary progressive MS and early primary progressive MS.

General measures

Education, provision of appropriate written materials, and support from a multidisciplinary team, including an MS nurse specialist, are essentials. Physiotherapy and occupational therapy are helpful where there is persisting impairment between relapses. Infections should be treated early, as they may precipitate relapses or lead to worsening of existing symptoms (pseudo-relapses); urinary tract infections are particularly problematic for people with MS. Immunizations are safe and recommended (but not live vaccines if on disease-modifying drugs).

Acute relapses

Short courses of steroids, such as i.v. methylprednisolone 1 g/day for 3 days or high-dose oral steroids, are used for severe relapses. They speed recovery but do not influence long-term outcome.

Disease-modifying treatments

A 'watch-and-wait' strategy used to be common practice but is now rare. Newly diagnosed patients with RRMS (including those with a single clinical episode who meet McDonald criteria) should receive disease-modifying treatment (DMT, **Box 28.37**).

- ***Immunomodulatory drugs***, include the older generation of injectables (β-interferon, glatiramer acetate) and some oral agents (teriflunomide, dimethyl fumarate). These agents are of moderate efficacy. They reduce relapse rate by about one-third; the efficacy of dimethyl fumarate is slightly higher. The toxicity profile is better than with the newer high-efficacy agents, and they may be preferred for selected patients for this reason.
- ***Immunosuppressant drugs*** include oral agents and monoclonal antibodies.
  - *Oral:* Sphingosine 1-phosphate receptor modulators (fingolimod, siponimod) sequester lymphocytes in lymph nodes. These agents are of higher efficacy than the older generation injectables.
  - *Monoclonal antibodies* for MS are all of very high efficacy, reducing relapse rate by up to 70%. Natalizumab inhibits migration of leukocytes into the CNS. In the UK, it is approved for *rapidly evolving severe MS*. Patients who are seropositive for JC virus antibodies are at risk of developing the much-feared complication of progressive multifocal leukoencephalopathy (see Chapter 42, 'Progressive multifocal leucoencephalopathy' section). Ocrelizumab (intravenous) and ofatumumab (subcutaneous) are anti-CD20 monoclonal antibodies that deplete B-cells, binding to sites distinct from rituximab (also used for MS occasionally, off-label). The efficacy of these agents has challenged the conventional 'T-cell-driven' view of MS. In general, treatment with these agents is continued long term, with attendant risks of long-term immunosuppression, and indications for stopping are unclear.
- ***Immune reconstitution/induction therapies*** are given as short courses with the aim of 'resetting' the immune system. Alemtuzumab is a humanized anti-CD52 monoclonal antibody that non-selectively depletes white cells. It has very high efficacy, but secondary autoimmunity limits its use to the more severe cases. Cladribine, given orally, is a purine antimetabolite that selectively depletes T- and B-cells. It is of 'high' (rather than 'very high') efficacy. Autologous haematopoietic stem cell transplantation (AHSCT) is available for a small number of patients with highly active disease who have not responded to other treatments.
- ***Progressive disease:*** in the UK, historically DMTs have only been offered to ambulant patients with RRMS, but recent developments have expanded the options for patients with progressive disease. Siponimod is licensed for use in active SPMS, and ocrelizumab for early PPMS. Interferon β-1b is also licensed for active SPMS (with relapses), and can be used for this purpose when siponimod is contraindicated.

Eligibility criteria in the UK are complex and ever-changing, and access to different drugs varies across the world. The stepwise approach, of lower efficacy treatments first followed by more potent drugs if there is breakthrough disease, is now discouraged in favour of starting with intensive treatment from diagnosis, especially in highly active disease. Cost is a major barrier to treatment in the developing world.

Pregnancy does not affect long-term outcomes in MS, although there is an increase in relapse rate in the first few months postpartum. Effective therapy for MS should not be delayed because women may want families in the future; preconceptual counselling is vital, and an individualized plan is required for women trying to conceive. Several but not all DMTs need to be avoided in pregnancy (beta interferon and glatiramer acetate are safe; continuation of natalizumab can be considered as there is a high risk of rebound if stopped).

Other drugs and symptomatic therapies

- ***Vitamin D.*** There is some evidence that vitamin D supplementation may be beneficial in MS but this is still controversial. Some specialists advocate treatment with up to 4000 IU daily.
- ***Fampridine*** (4-aminopyridine, an oral potassium-channel blocker). This has been shown to improve walking significantly in selected patients with significant MS-related disability.
- ***Other symptomatic treatments.*** Symptomatic treatments are available for most complications of MS and significantly improve quality of life (see **Box 28.36**). Urinary urgency and frequency, pain, spasticity, and depression are all common and treatable.

Prognosis

The clinical course of MS is unpredictable; a high MR lesion load at initial presentation, high relapse rate, early onset of progression, male gender, and late presentation are poor prognostic features but

Box 28.37 Disease-modifying drugs used in multiple sclerosis

Drug	Mode of action	Administration	Efficacy	Reduction in relapse rate	Effect on disability	Adverse effects/comments
Immunomodulatory						
β-interferon (IFN-β1b and 1a)	Pleiotropic immune effects	s.c. alternate days or i.m. weekly	Moderate	33%	?	Flu-like symptoms
Glatiramer acetate	Pleiotropic immune effects	s.c. daily	Moderate	33%	?	Flu-like symptoms
Teriflunomide	Blocks proliferation of activated lymphocytes	Oral daily	Moderate	30%	?+	Abnormal liver enzymes
Dimethyl fumarate	Pleiotropic immune effects	Oral twice daily	High	50%	?+	Good safety record in psoriasis; well tolerated but one case of PML
Immunosuppressant						
Fingolimod	Sphingosine-1-phosphate receptor (S1-PR) ligand. Prevents T cells leaving lymph nodes	Oral daily	High	60%	?+	Bradycardia, OIs, PML
Siponimod	Sphingosine-1-phosphate receptor (S1-PR) ligand. Prevents T cells leaving lymph nodes	Oral daily	High	50%	+	*Used in active SPMS*
Natalizumab	mAb, blocks α-4 integrin vascular adhesion molecule. Prevents T cells entering CNS	i.v. monthly	Very high	68%	+	Rarely, PML (fatal) Hypersensitivity reactions
Ocrelizumab	mAb, anti-CD20 Depletes B cells	i.v. every 6 months	Very high	50% compared to IFNβ	+	Infusion reactions, OIs, hypogammaglobulinaemia with prolonged use *Licensed for RRMS and early PPMS*
Ofatumumab	mAb, anti-CD20 Depletes B cells	s.c. monthly	Very high	50% compared to teriflunomide	+	OIs, hypogammoglobulinaemia with prolonged use
Immune reconstitution/induction therapies						
Alemtuzumab	mAb, anti-CD52 Depletes T >B cells	i.v. once and repeat at 1 year	Very high	50% compared to IFNβ	+	Autoimmune disorders: Graves' disease and ITP, OIs
Cladribine	Purine analogue, antimetabolite, selective T- and B-cell depletion	Oral 8–10 days months 1–2, repeated at 1 year	High	58%	+	Lymphopaenia, OIs
Autologous haematopoietic stem cell transplantation			Very high	70% disease-free survival at 3 years	++	Dangers of induction chemotherapy

ITP, Immune thrombocytopenic purpura; *mAb,* monoclonal antibody; *OIs,* opportunistic infections; *PML,* progressive multifocal leukoencephalopathy.

not invariably so. There is wide variation in severity, but overall progression is slow. Many patients continue to live independent, productive lives; a minority become severely disabled. Life expectancy is reduced by 7 years on average. The precise effect of DMTs on the long-term clinical course remains unclear.

Other neuroinflammatory disorders

Transverse myelitis

Transverse myelitis (TM) is an acute inflammatory disorder affecting the spinal cord with cord swelling and loss of function. Typically, one or two spinal segments are affected with part or all of the cord area at that level involved (*transverse* indicates involvement of the whole cross-section of the cord at the affected level). *Longitudinally extensive transverse myelitis* (LETM) extends over three or more vertebral segments and raises the possibility of more unusual causes. Clinically, a myelopathy evolves over days, and recovery (often partial) follows over weeks or months. MRI shows cord swelling and oedema with gadolinium enhancement at the affected level(s). Usually, images are also taken of the brain to look for evidence of demyelination. CSF may be inflammatory with an excess of lymphocytes. The differential diagnosis

includes other causes of acute myelopathy (see 'Other spinal cord disorders' section). Causes include:

- ***Para- or post-infectious autoimmune inflammatory response.*** This is the most common cause and may follow viral infection or immunization, for example.
- ***Systemic inflammatory disorders***, for example, SLE, Sjögren's, sarcoidosis.
- ***Infection.*** This may be caused by viruses—for example, herpesviruses, such as varicella zoster or EBV, HIV, HTLV-1 and 2 (tropical spastic paraparesis); mycobacteria, e.g., tuberculosis; bacteria—e.g., syphilis and Lyme disease; or flatworms—e.g., schistosomiasis. In recent years outbreaks of *acute flaccid myelitis* (AFM), reminiscent clinically of acute paralytic polio, have been linked to outbreaks of viruses, particularly enterovirus D68, although evidence of direct viral injury is lacking. The clinical course of AFM is more rapid and aggressive than classical TM, with prominent anterior horn cell involvement from grey matter damage.
- ***Multiple sclerosis.*** TM may occur as part of a relapse or be a presenting feature of MS. If the brain MRI is normal, the risk of later development of MS is around 20%; in those that do develop MS with a normal brain MRI, prognosis is better than average.
- ***Neuromyelitis optica spectrum disorder*** and ***myelin oligodendrocyte glycoprotein antibody-associated disease (MOGAD)***—see below.
- ***Acute disseminated encephalomyelitis (ADEM).*** TM can be seen as part of ADEM—see below.

Treatment is usually with high-dose steroids or other immunomodulatory treatments (including plasma exchange and IVIG), or antimicrobial therapy in the case of specific infections. Involvement of the high cervical spine, particularly in longitudinally extensive cases or AFM, can necessitate intubation and ventilation. Specialist rehabilitation after an attack of TM is essential.

Neuromyelitis optica

This is a distinct inflammatory relapsing demyelinating disorder, previously thought to be a variant of MS. It is characterized by longitudinally extensive TM (>3 segments) and bilateral or recurrent optic neuritis. Brainstem involvement can occur, and the phenotype is expanding. Limited forms are seen, such as recurrent myelitis only. Serum antibodies to aquaporin-4 (AQP4) water channels account for the majority of cases; a proportion of the remainder have antibodies to myelin oligodendrocyte glycoprotein (MOG, see below). It is rarer than MS but there is a higher incidence in Asian and African Caribbean people.

Treatment with steroids and immunosuppressive drugs is essential from the time of diagnosis, as the relapse rate is high and relapses are much more disabling than in MS.

Acute disseminated encephalomyelitis

Acute disseminated encephalomyelitis is usually post-infectious, following infections such as measles, mycoplasma, mumps, and rubella, and occasionally 1 to 2 weeks after immunization. There is a monophasic illness with the acute appearance of multifocal neurological symptoms, often with encephalopathy. Imaging shows brain, brainstem, and often spinal cord inflammatory demyelinating lesions, which can become confluent; there is often swelling and there may be a haemorrhagic component. ADEM is caused by an immune-mediated host response to infection and occurs principally in children and young adults. Treatment is with steroids, moving on to plasma exchange or IVIG, and symptomatic measures such as anticonvulsants. Mild cases recover completely, but fulminant cases can be fatal, and survivors often have neurological sequelae.

Myelin oligodendrocyte glycoprotein antibody-associated disease

A recently recognized entity, that presents as a number of different inflammatory demyelinating CNS syndromes, linked to the presence of MOG antibodies. MOGAD may have a relapsing or monophasic course. Clinical syndromes include bilateral and recurrent optic neuritis, TM (often with involvement of the conus), and ADEM. MOG antibodies were first recognized in children with ADEM, and the presence of the antibody makes recurrence more likely. MOGAD can closely mimic NMO, and it can also present as a unilateral cortical encephalitis with headache, seizures, and focal neurology.

Autoimmune encephalitis

This group of disorders is increasingly being recognized. Autoantibodies directed against neuronal epitopes cause a subacute encephalitic illness: limbic encephalitis or panencephalitis. Limbic encephalitis presents over weeks or months with memory impairment, confusion, psychiatric disturbance, and seizures—usually temporal lobe seizures, reflecting involvement of the hippocampus and mesial temporal lobes.

Paraneoplastic limbic encephalitis (PLE). PLE is seen particularly with small-cell lung cancer and testicular tumours, and is associated with a variety of antibodies, including anti-Hu and anti-Ma2. Antibodies can be detected in 60% of cases. MRI usually shows a hippocampal high signal. PLE precedes the diagnosis of cancer in most cases and should prompt investigation to identify the tumour.

Anti-Voltage-gated potassium channel (VGKC) complex limbic encephalitis. Antibodies to the VGKC complex produce a variety of disorders, including a characteristic limbic encephalitis in association with antibodies to the leucine-rich glioma-inactivated 1 (LGI1) protein. Affected patients may present with typical faciobrachial dystonic seizures, in combination with confusion, agitation, and hyponatraemia. This usually occurs in patients over 50 years of age but is rarely associated with cancer (thymoma). Treatment is with high-dose steroids. Neuromyotonia and peripheral nerve hyperexcitability syndromes may also be seen with antibodies to contactin-associated protein 2 (CASPR2), another subunit of the VGKC-complex.

Anti-NMDA receptor antibody encephalitis. This presents as a panencephalitis characterized by complex psychiatric features, behavioural change, sleep disturbances, seizures, dysautonomia, and a prominent movement disorder, with orofacial and upper limb dyskinesias. Coma may follow. Patients are usually younger, and many have teratomas, such as ovarian.

Patients may respond to immunotherapy: steroids, intravenous immunoglobulin, and plasma exchange initially, followed by rituximab or cyclophosphamide. PLE responds less well to treatment, although treatment directed at any underlying tumour offers the best hope.

Neuroinflammation in systemic disease

A number of systemic inflammatory diseases can involve both the central and peripheral nervous system.

Neurosarcoidosis

Neurosarcoidosis, with or without systemic sarcoidosis, causes chronic meningoencephalitis, TM, cranial nerve palsies—particularly bilateral VIIth nerve lesions, polyneuropathy, and myopathy (see Chapter 20, 'Sarcoidosis' section). Diagnosis can be difficult if disease is confined to the CNS.

Behçet's disease

Behçet's principal features (see Chapter 32, 'Behçet's disease' section) are recurrent oral and/or genital ulceration, inflammatory ocular disease (uveitis; see Chapter 31, 'Uveitis' section), and neurological syndromes. Brainstem and cord lesions, aseptic meningitis, encephalitis, and cerebral venous thrombosis occur. There is a predilection for ethnic groups along the ancient 'Silk Road'—Turkey, the Middle East, and Asia. Behçet's is associated with the HLA-B51 allele.

Systemic lupus erythematosus

Neurological involvement in SLE takes protean forms, and 20% to 40% of patients with SLE may have some form of nervous system involvement. Manifestations include encephalopathy, neuropsychiatric illness, optic neuritis, aseptic meningitis, movement disorders, myelitis, and peripheral neuropathy. The underlying pathophysiology can include neuroinflammation (with antibody-, cell-, and cytokine-mediated mechanisms) and vascular disease (vasculitis is less common than thromboembolic disease, e.g., with antiphospholipid antibodies). Systemic complications of SLE (e.g., renal disease) can cause secondary neurological effects (e.g., PRES or metabolic encephalopathy).

NERVOUS SYSTEM INFECTION

Meningitis

Bacterial meningitis is a medical emergency requiring immediate intervention. It is covered in Chapter 11 ('Meningitis' section).

Chronic meningitis

Tuberculous meningitis (TBM) and ***cryptococcal meningitis*** typically commence with vague headache, lassitude, anorexia, and vomiting. Acute meningitis can occur but is unusual. Meningitic signs often take some weeks to develop. Drowsiness, focal signs (e.g., diplopia, papilloedema, hemiparesis, myelopathy), and seizures are common. Syphilis, sarcoidosis, and Behçet's also cause chronic meningitis. In some cases of chronic meningitis, an organism or underlying cause is never identified.

Investigation and management of tuberculous meningitis

TBM is a common and serious disease worldwide. Brain imaging, usually with MRI, may show meningeal enhancement, hydrocephalus, and tuberculomas, although it may remain normal. CSF pressure is raised, and microscopy reveals a high lymphocyte count with high protein and low glucose. In many cases, the sparse tuberculous organisms cannot be seen on staining and PCR testing should be performed, although results may be falsely negative. Repeated large-volume CSF examination is often necessary and it will be some weeks before cultures are confirmatory. Treatment with anti-tuberculosis drugs (see Chapter 20, 'Tuberculosis' section)—rifampicin, isoniazid, and pyrazinamide—must commence on a presumptive basis and continue for at least 9 months. Ethambutol is avoided in many cases of TBM because of its eye complications; a fluoroquinolone is typically used in its stead. Adjuvant corticosteroids, such as dexamethasone 0.4 mg/kg/day, are recommended and shown to reduce mortality; in complicated cases, an extended taper is often needed. Relapses and complications (e.g., seizures, hydrocephalus, infectious vasculitis) are common in TBM. The mortality remains over 50%, even with early treatment.

Malignant meningitis

Malignant cells can cause a subacute or chronic, non-infective, meningitic process. A meningitic syndrome, cranial nerve lesions, paraparesis, and root lesions are seen, often in confusing and fluctuating patterns. CSF cytology may demonstrate malignant cells but sensitivity is low, even with rapid analysis of large volumes (at least 10 mL) of fresh CSF. Up to three LPs may be needed to reach 90% sensitivity. In general, the prognosis is 3 to 4 months but occasionally intrathecal or systemic treatment can be helpful.

Cells in a sterile CSF (CSF pleocytosis)

A raised CSF cell count is sometimes present without an evident infecting organism in various conditions listed in **Box 28.38**.

Encephalitis

Encephalitis means acute inflammation of brain parenchyma. The commonest cause is viral infection, when fever (90%) and meningism are usual; in contrast to meningitis, however, the clinical picture is dominated by inflammation of brain parenchyma. Personality and behavioural change is a common early manifestation, which progresses to a reduced level of consciousness and even coma. Seizures (focal and generalized) are very common and focal neurological deficits, such as speech disturbance, often occur (especially in herpes simplex encephalitis, which is a medical emergency—see Chapter 11).

Autoimmune encephalitis is at least as common as infective encephalitis in the developed world, and is covered in the 'Autoimmune encephalitis' section.

? Box 28.38 Causes of sterile CSF pleocytosis

Infective
- Partially treated bacterial meningitis
- Viral meningitis
- Encephalitis, including HIV
- Tuberculous or fungal meningitis
- Intracranial abscess
- Parameningeal foci, e.g., paranasal sinus
- Syphilis
- Cerebral malaria
- Rarities, e.g., Lyme disease, Brucellosis, infective endocarditis, Mollaret meningitis

Non-infective
- Neoplastic meningitis
- Cerebral venous thrombosis
- Drugs (e.g., IVIG, co-trimoxazole)
- Systemic lupus erythematosus
- CNS inflammatory diseases including ADEM (or other post-infectious encephalitis), MS
- Rarities, e.g., CNS vasculitis, sarcoidosis, Behçet's syndrome, Vogt-Koyanagi-Harada syndrome

HIV and neurology

HIV-infected individuals frequently present with or develop neurological conditions. The HIV itself is directly neuroinvasive and neurovirulent. Immunosuppression leads to indolent, atypical clinical patterns (see Chapter 44, 'Neurological disease' section). HIV patients also have a high incidence of stroke. The pattern of disease has changed significantly with anti-retroviral (ART) therapy.

CNS and peripheral nerve disease in HIV

HIV seroconversion can cause meningitis, encephalitis, Guillain–Barré syndrome, and Bell's palsy.

Chronic meningitis occurs with fungi (e.g., Cryptococcus *neoformans* or *Aspergillus*), tuberculosis, *Listeria*, coliforms, or other organisms. Raised CSF pressure is common in cryptococcal meningitis.

AIDS–dementia complex (ADC). A progressive, HIV-related dementia, sometimes with cerebellar signs, is still seen where ART is unavailable.

Encephalitis and brain abscess. Toxoplasma, cytomegalovirus, herpes simplex, and other organisms cause severe encephalitis. Multiple brain abscesses develop in HIV infection, usually due to toxoplasmosis.

CNS lymphoma. This is typically fatal (see Chapter 39, 'Primary central nervous system lymphoma' section).

Progressive multifocal leukoencephalopathy (PML) is due to JC virus and occurs with very low CD4 counts (see Chapter 44, 'Neurological disease' section).

Spinal vacuolar myelopathy. This occurs in advanced disease.

Neurosyphilis is seen in all its forms in HIV.

Peripheral nerve disease. HIV-related peripheral neuropathy is common (70%) and can be difficult to distinguish from the effects of certain ART toxic to peripheral nerves. A polyradiculitis is frequently seen with CMV and other opportunistic infections.

Other infections and post-infectious inflammatory conditions

Other infections involving the CNS are discussed in Chapter 42: for example, rabies, tetanus, botulism, Lyme disease, and leprosy.

Herpes zoster (shingles)

This is caused by reactivation of varicella zoster virus (VZV), usually within dorsal root ganglia. Primary infection with VZV causes chickenpox, following which the virus remains latent in sensory ganglia. Development of shingles may indicate a decline in cell-mediated immunity, such as that due to age or malignancy.

Clinical patterns and complications

Dermatomal shingles. See Chapter 45 ('Herpes zoster [shingles]' section).

Postherpetic neuralgia. This is defined as pain lasting for more than 4 months after developing shingles; it occurs in 10% of patients (often elderly). Burning, intractable pain responds poorly to analgesics. Response to treatment is unsatisfactory but there is a trend towards gradual recovery over 2 years. Amitriptyline or gabapentin is commonly used, and topical lidocaine patches may help.

Cranial nerve involvement. Only cranial nerves with sensory fibres are affected, particularly the trigeminal and facial nerves. Ophthalmic herpes is due to involvement of V_1. This can lead to corneal scarring and secondary panophthalmitis. Involvement of the geniculate ganglion of the facial nerve, causing facial palsy with associated painful shingles rash, is also called Ramsay Hunt syndrome.

Myelitis. This may occur in the context of shingles, when the inflammatory process spreads from the dorsal root ganglion to the adjacent spinal cord.

Immunization. Older adults can be vaccinated against herpes zoster (even those who have had shingles previously), as it boosts immunity against VZV and reduces the incidence of shingles by about 50%.

Neurosyphilis

Many neurological symptoms occur, sometimes mixed (see also syphilis; Chapter 43).

Early neurosyphilis

Asymptomatic neurosyphilis

This means positive CSF serology without signs.

Meningovascular syphilis

This causes:

- subacute meningitis with cranial nerve palsies and papilloedema
- a gumma—a chronic expanding intracranial mass
- paraparesis—a spinal meningovasculitis.

Late neurosyphilis

Tabes dorsalis

Demyelination in dorsal roots causes a complex deafferentation syndrome. The elements of tabes are:

- lightning pains
- ataxia, stamping gait, reflex/sensory loss, wasting
- neuropathic (Charcot) joints
- Argyll Robertson pupils (see 'Argyll Robertson pupil' section)
- ptosis and optic atrophy.

'General paresis of the insane'

The grandiose title describes dementia and weakness. The dementia component is typically similar to that of Alzheimer's (see 'Alzheimer's disease' section). Progressive cognitive decline, seizures, brisk reflexes, extensor plantar reflexes, and tremor develop. Death follows within 3 years. Argyll Robertson pupils are a usual finding. GPI and tabes are rarities in the UK.

Other forms of neurosyphilis

In ***congenital*** neurosyphilis (acquired *in utero*), features of combined tabes and GPI develop in childhood: taboparesis.

Management

Penicillin is the treatment of choice for all stages of syphilis. Cytokine-mediated febrile (Jarisch–Herxheimer) reactions can occur; steroid cover may be given with penicillin. Established neurological disease is arrested but not reversed by treatment.

Neurocysticercosis

The pork tapeworm, *Taenia solium*, is endemic in Latin America, Africa, India, and much of South-east Asia (see Chapter 42, '*Taenia solium* and cysticercosis' section). Epilepsy is the most common clinical manifestation of neurocysticercosis, and the infection is one of the most common causes of epilepsy in endemic countries. Most infected people remain asymptomatic.

Brain CT and MRI show ring-enhancing lesions with surrounding oedema when the cyst dies, and later calcification. Multiple

cysts are often seen in both brain and skeletal muscle. Serological tests indicate infection but not activity. Biopsy of a lesion is rarely necessary. Management is primarily the control of seizures, and the anthelminthic agent, albendazole, is given in the presence of viable (non-calcified) or degenerating cysts (usually with steroid cover).

Subacute sclerosing panencephalitis

Persistence of measles antigen in the CNS is associated with this rare late sequela of measles. Progressive mental deterioration, fits, myoclonus, and pyramidal signs develop, typically in a child. Diagnosis is made by high measles antibody titre in blood and CSF. Measles immunization protects against subacute sclerosing panencephalitis (SSPE), which has now been almost eliminated in the UK.

Progressive rubella encephalitis

Some 10 years after primary rubella infection, this causes progressive cognitive impairment, fits, optic atrophy, cerebellar, and pyramidal signs. Antibody to rubella viral antigen is produced locally within the CNS. It is even rarer than SSPE.

Mollaret's meningitis

Recurrent, self-limiting episodes of aseptic meningitis (i.e., no bacterial cause is found) occur over many years. Herpes simplex virus type 2 has been shown to be the cause in most cases.

Whipple's disease

CNS Whipple's disease, due to *Tropheryma whipplei* infection, is characterized by neurological symptoms, such as myoclonus, dementia, and supranuclear ophthalmoplegia (see Chapter 22,

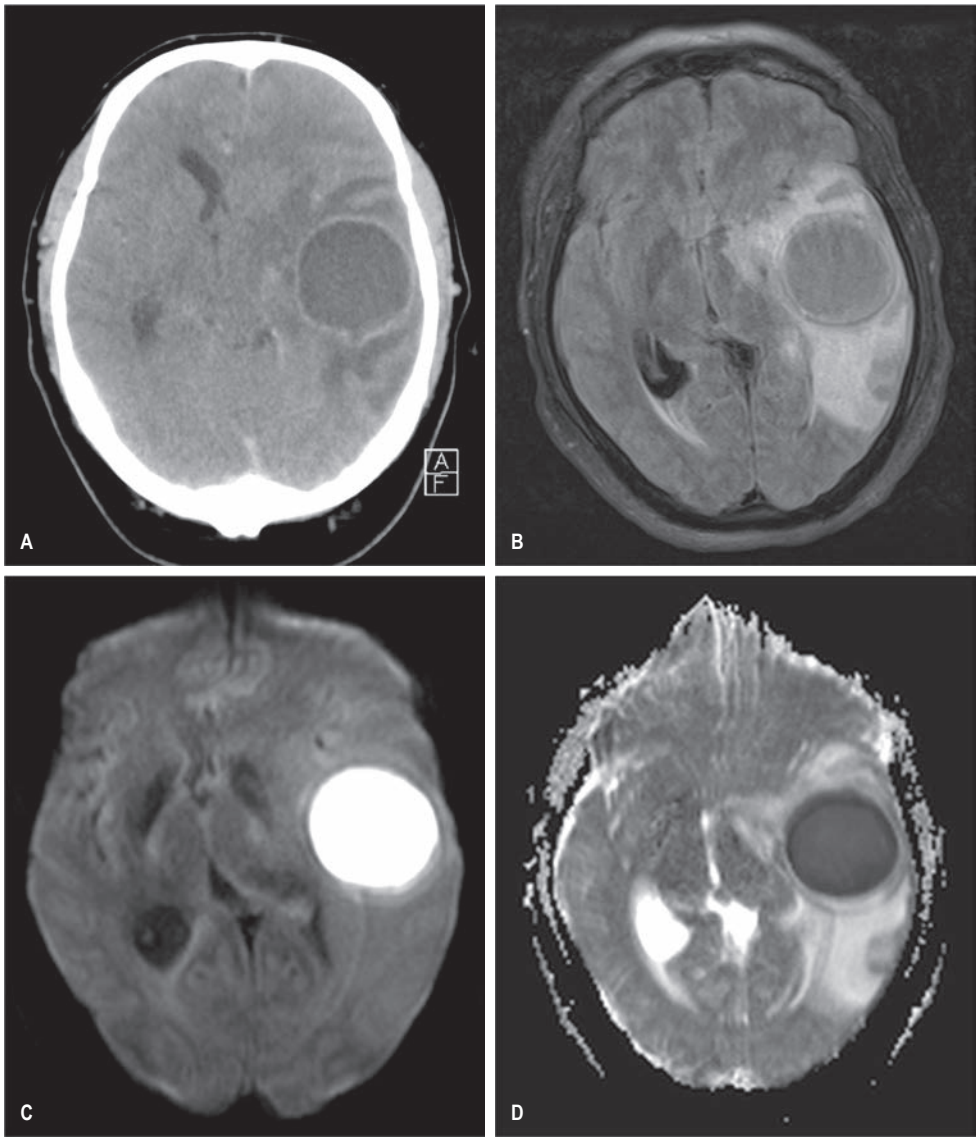

Fig. 28.27 Pyogenic cerebral abscess. **(A)** Axial post-contrast CT demonstrating a ring-enhancing lesion in the left temporoparietal region. **(B)** Subsequent T2-weighted fluid suppressed (FLAIR) images show the extent of surrounding oedema. MRI is also useful to characterize the lesion further. **(C)** Here, diffusion-weighted and **(D)** ADC map confirm restricted diffusion within the lesion, which is characteristic of intracranial pyogenic abscess.

'Whipple's disease' section). Diagnosis of CNS involvement is made by CSF PCR or brain biopsy.

Brain and spinal abscesses

Brain abscess

Focal bacterial infection behaves as any expanding mass. The typical bacteria found are *Streptococcus anginosus* and *Bacteroides* species (from the paranasal sinuses and teeth), and staphylococci (associated with penetrating trauma). Mixed infections are common. Multiple abscesses may develop, particularly in HIV infection. Fungi also cause brain abscesses. A parameningeal infective focus (e.g., ear, nose, paranasal sinus, skull fracture) or a distant source of infection (e.g., lung, heart, abdomen) may be present. Frequently, no underlying cause is found. An abscess is more than ten times rarer than a brain tumour in the UK.

Clinical features and management

Headache, focal signs (e.g., hemiparesis, aphasia, hemianopia), epilepsy, and raised ICP develop. Fever, leucocytosis, and raised inflammatory markers are common, but not invariable.

Urgent imaging is essential. MRI shows a ring-enhancing mass, usually with considerable surrounding oedema, and central restricted diffusion (**Fig. 28.27**). The search for a focus of infection should include a detailed examination of the skull, ears, paranasal sinuses and teeth, and distant sites such as heart and abdomen. LP is potentially dangerous and the risks and benefits should be weighed up; often CSF if obtained will be bland as the abscess is walled-off. Neurosurgical aspiration with stereotactic guidance allows the infective organism to be identified. Treatment is with high-dose antibiotics and, sometimes, surgical resection/decompression. Despite treatment, mortality remains high at approximately 25%. Epilepsy is common in survivors.

Brain tuberculoma

Tuberculosis causes chronic caseating intracranial granulomatous masses: tuberculomas. These are the most common intracranial masses in countries where tuberculosis is common, such as India. Brain tuberculomas either present as mass lesions *de novo* or develop during TBM; they are also found as symptomless intracranial calcification on imaging. Spinal cord tuberculomas also occur. Treatment is described in Chapter 20 ('Management' section in the 'Tuberculosis' section).

Subdural empyema and intracranial epidural abscess

Intracranial subdural empyema is a collection of subdural pus, usually secondary to local skull or middle ear infection, or following neurosurgery. Subdural pus is intensely epileptogenic and patients may present with intractable seizures and fever. Imaging is diagnostic.

In ***intracranial epidural abscess***, a layer of pus, 1 to 3 mm thick, tracks along the epidural space, causing sequential cranial nerve palsies. There is usually local infection: in the middle ear, for example. MRI shows the collection; CT is typically normal. Drainage is required, as are antibiotics.

Spinal epidural abscess

Staphylococcus aureus is the usual organism, reaching the spine via the bloodstream: for example, from a boil. Fever and back pain are followed by paraparesis and/or root lesions. Emergency imaging and antibiotics are essential and surgical decompression is often necessary.

Box 28.39 Common brain tumours

Tumour	Approximate frequency
Metastases	50%
Bronchus Breast Stomach Prostate Thyroid Kidney	
Primary malignant tumours of neuroepithelial tissues	15%
Adult-type diffuse gliomas Astrocytoma, IDH-mutant Oligodendroglioma, IDH mutant, and 1p/19q codeleted Glioblastoma, IDH-wildtype Ependymoma Primary cerebral lymphoma Medulloblastoma	
Benign tumours	35%
Meningioma Schwannoma Pituitary adenoma	

IDH, Isocitrate dehydrogenase.

BRAIN TUMOURS

Primary intracranial tumours account for 3% of all cancers. The most common tumours are outlined in **Box 28.39**, with ***cerebral metastases*** being more common than primary intracranial tumours (**Fig. 28.28**). Symptomless meningiomas (benign) are found quite commonly on imaging or at autopsy. The most recent 5th edition of the WHO classification of CNS tumours utilizes a combination of histological and molecular features to define tumour type and grade.

Gliomas

These tumours of neuroepithelial origin are usually seen within the hemispheres, but occasionally in the cerebellum, brainstem, or cord (**Fig. 28.29**). Their cause is unknown in most cases, and the main risk factors are rare genetic risk syndromes (e.g., neurofibromatosis) and exposure to ionizing radiation. They tend to spread by direct extension, virtually never metastasizing outside the CNS.

- ***Astrocytomas*** are gliomas that arise from astrocytes. They may be diffuse or circumscribed (e.g., pilocytic astrocytoma, a slow-growing and benign tumour typically seen in childhood, often in the cerebellum). Adult-type diffuse gliomas are classified first by isocitrate dehydrogenase (IDH) status (mutated or wild-type) and then by further molecular and histological features. IDH mutations indicate that a tumour is slower-growing, and when found in a high-grade tumour may indicate that the tumour has transformed from a low-grade lesion; an IDH-wildtype diffuse astrocytoma is always grade 4 and termed a ***glioblastoma***. Grade 4 glioblastoma causes death within several months.

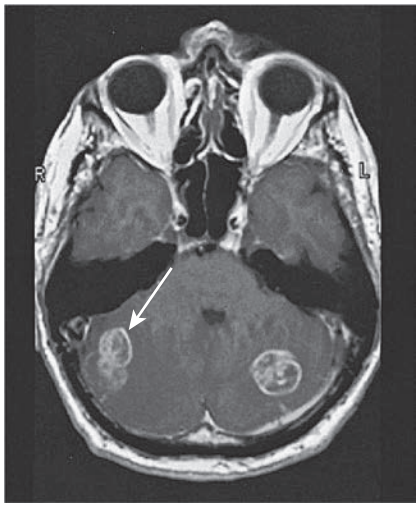

Fig. 28.28 **Bilateral cerebellar metastases *(arrowed)*: T1-weighted MRI.**

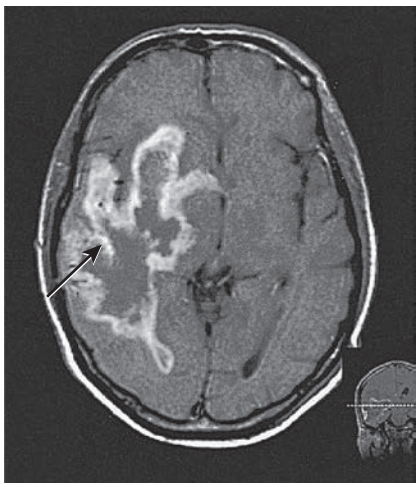

Fig. 28.29 **Cerebral glioblastoma: T1-weighted MRI.**

- ***Oligodendrogliomas*** arise from oligodendrocytes. They grow slowly, usually over several decades. Calcification is common. They are IDH-mutated and are distinguished from astrocytomas by the presence of the chromosomal 1p/19q co-deletion.

Meningiomas

These benign tumours (Fig. 28.30) arise from the arachnoid and may grow to a large size, usually over years. Those close to the skull erode bone or cause local hyperostosis. They often occur along the intracranial venous sinuses, which they may invade. They are unusual below the tentorium. Common sites are the parasagittal region, sphenoidal ridge, subfrontal region, pituitary fossa, and skull base.

Schwannomas

These solid benign tumours arise from Schwann cells and occur principally in the cerebellopontine angle, where they arise from the VIIIth nerve sheath (vestibular schwannoma, also known as acoustic neuroma; see Chapter 21, 'Vestibular schwannoma' section). They may be bilateral in neurofibromatosis type 2 (see 'Neurofibromatosis type 2' section).

Other neoplasms

Other less common neoplasms include cerebellar haemangioblastomas, ependymomas of the IVth ventricle, colloid cysts of the IIIrd ventricle, pinealomas, chordomas of the skull base, glomus tumours of the jugular bulb, medulloblastomas (a cerebellar childhood tumour), craniopharyngiomas and primary CNS lymphomas (Chapter 39, 'Primary central nervous system lymphoma' section). For pituitary tumours, see Chapter 34 ('Pituitary space–occupying lesions and tumours' section).

Clinical features

Mass lesions within the brain produce symptoms and signs by three mechanisms:

- direct effect—the brain is infiltrated and local function is impaired, producing focal neurological signs
- secondary effects of raised ICP and shift of intracranial contents (e.g., papilloedema, vomiting, headache)
- provocation of generalized and/or focal seizures.

Although neoplasms, either secondary or primary, are the most common mass lesions in the UK, cerebral abscess, tuberculoma, neurocysticercosis, and subdural and intracranial haematomas can also produce features that are clinically similar.

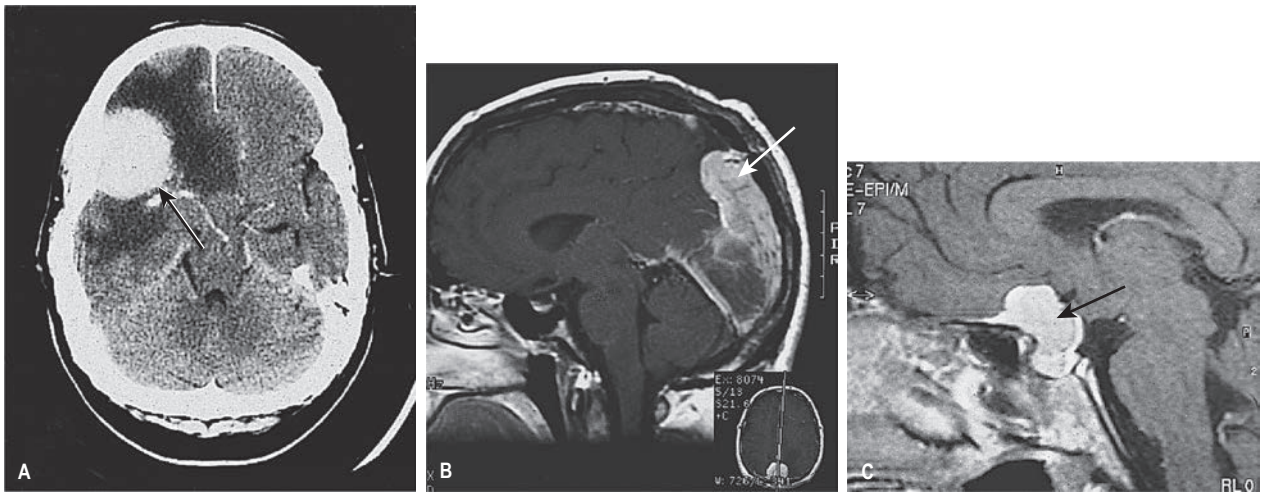

Fig. 28.30 **Meningiomas *(arrowed)*.** **(A)** Frontal: CT. **(B)** Falx meningioma (occipital): T1-weighted MRI. **(C)** Within sella and suprasellar extension: T1-weighted MRI.

Direct effects of mass lesions

The hallmark of a direct effect of a mass is local progressive deterioration of function. Tumours can occur anywhere within the brain. Three examples are given:

- ***A left frontal meningioma*** causing a developing frontal lobe syndrome over several years with vague disturbance of personality, apathy, and impaired intellect. This was followed by expressive aphasia, progressive right hemiparesis as the corticospinal pathways became involved, and then pressure headaches and papilloedema reflecting raised ICP.
- ***A right parietal lobe glioma*** causing a left homonymous field defect through involvement of the optic radiation. Cortical sensory loss in the left limbs and left hemiparesis followed over 3 months. Partial seizures (episodes of tingling of the left limbs) then developed.
- ***A left VIIIth nerve sheath neurofibroma (acoustic neuroma, schwannoma)*** in the cerebellopontine angle causing, over 3 years, progressive deafness (VIII), left facial numbness (V) and weakness (VII), followed by cerebellar ataxia on the same side.

With a hemisphere tumour, epilepsy and the direct effects commonly draw attention to the problem. The rate of progression varies greatly, from a few days or weeks in a highly malignant glioma, to several years with a slowly enlarging mass such as a meningioma. Cerebral oedema surrounds mass lesions; its effect is difficult to distinguish from that of the tumour itself.

Raised intracranial pressure

Raised ICP causing headache, vomiting, and papilloedema is a relatively unusual presentation of a mass lesion in the brain. These symptoms often imply hydrocephalus: obstruction to CSF pathways. Typically, this is produced early by posterior fossa masses that obstruct the aqueduct and IVth ventricle, but only later by lesions above the tentorium.

Shift of the intracranial contents produces features that coexist with the direct effects of any expanding mass:

- ***Distortion of the upper brainstem*** as midline structures are displaced either caudally or laterally by a hemisphere mass (see **Fig. 28.29**) causes impairment of consciousness, progressing to coning and death as the medulla and cerebellar tonsils are forced into the foramen magnum.
- ***False localizing signs***, termed false only because they do not point *directly* to the site of the mass, include:
  - ***A VIth nerve lesion***, first on the side of a mass and later bilaterally as the VIth nerve is compressed or stretched during its long intracranial course.
  - ***A IIIrd nerve lesion*** developing as the temporal lobe uncus herniates caudally, compressing the IIIrd nerve against the petroclinoid ligament. The first sign is ipsilateral pupil dilatation as parasympathetic fibres are compressed.
  - ***Hemiparesis*** on the same side as a hemisphere tumour—that is, the side that might not be expected—from compression of the contralateral cerebral peduncle on the edge of the tentorium (the Kernohan notch phenomenon).

Seizures

Seizures are a common presenting feature of malignant brain tumours. Focal seizures, with or without altered awareness, that may evolve into bilateral tonic–clonic seizures, are characteristic of many hemisphere masses, whether malignant or benign. The pattern of focal seizure is of localizing value (see 'Focal seizure types' section).

Investigations

Imaging

Both CT and MRI are useful in detecting brain tumours; MRI is superior for posterior fossa lesions. Benign and malignant tumours, brain abscess, tuberculosis, neurocysticercosis, and infarction have characteristic, but not entirely reliable, radiological appearances, and refined imaging techniques and biopsy are often necessary. MR angiography is used occasionally to define blood supply and MR spectroscopy to identify patterns typical of certain gliomas. PET is sometimes helpful to locate an occult primary tumour with brain metastases.

Routine tests

Since metastases are more common than primary tumours, routine tests, such as chest X-ray, and cross-sectional body imaging, should be performed.

Lumbar puncture

This is contraindicated when there is a space-occupying lesion with mass effect, or a mass in the posterior fossa, as withdrawing CSF may provoke immediate coning. CSF examination is rarely helpful unless there is meningeal infiltration (malignant meningitis).

Biopsy and tumour removal

Stereotactic biopsy via a skull burr hole is carried out to ascertain the histology of most suspected malignancies. With a benign tumour, such as a symptomatic, accessible meningioma, craniotomy and removal are usual.

Management

This is discussed in Chapter 41.

HYDROCEPHALUS

Hydrocephalus is an excessive accumulation of CSF within the head, caused by a disturbance of formation, flow or absorption. High pressure and ventricular dilation result (**Fig. 28.31**).

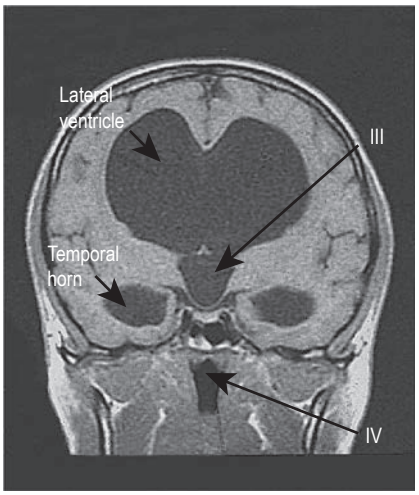

Fig. 28.31 Hydrocephalus with gross IIIrd, IVth, and lateral ventricle enlargement *(arrowed)*: T1-weighted MRI.

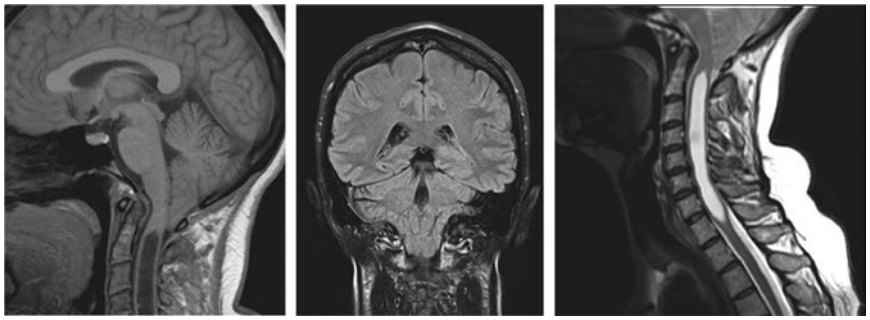

Fig. 28.32 **Chiari I malformation with spinal cord syrinx.**

Infantile hydrocephalus

Head enlargement in infancy occurs in 1 in 2000 live births. There are several causes:

- ***Chiari malformations.*** The cerebellar tonsils descend into the cervical canal (Fig. 28.32). Associated spina bifida is common. Syringomyelia may develop (see 'Syringomyelia and syringobulbia' section).
- ***Stenosis of the aqueduct of Sylvius.*** Aqueduct stenosis is either congenital (genetic) or acquired following neonatal meningitis/haemorrhage.
- ***Dandy–Walker syndrome.*** There is cerebellar hypoplasia and obstruction to IVth ventricle outflow foramina.

Hydrocephalus in adults

Hydrocephalus is sometimes an unsuspected finding on imaging. Stable childhood hydrocephalus can become apparent in adult life ('arrested hydrocephalus') but can suddenly decompensate. Combinations of headache, cognitive impairment, features of raised ICP, and ataxia develop, depending on how high the CSF pressure rises and how rapid the onset is. Elderly patients with more compliant brains may present with gradual-onset gait apraxia and subtle cognitive slowing.

Hydrocephalus may be caused by:

- ***posterior fossa and brainstem tumours*** obstructing the aqueduct or IVth ventricular outflow
- ***subarachnoid haemorrhage***, head injury, or meningitis (particularly tuberculous), causing obstruction of CSF flow and impaired reabsorption
- ***a IIIrd ventricle colloid cyst*** causing intermittent hydrocephalus—recurrent prostrating headaches with episodes of lower limb weakness, or, ominously, loss of consciousness
- ***choroid plexus papilloma*** (rare) secreting CSF.

Frequently, the underlying cause of hydrocephalus remains obscure.

Management

Ventriculoperitoneal shunting is necessary when progressive hydrocephalus causes symptoms. Removal of tumours is carried out when appropriate. Endoscopic IIIrd ventriculostomy may be performed.

Idiopathic normal pressure hydrocephalus

This describes a syndrome of enlarged lateral ventricles in elderly patients with the clinical triad of:

- a gait disorder—gait apraxia
- dementia
- urinary incontinence.

Ventriculoperitoneal shunting may be required, but the diagnosis of iNPH and selection of patients for shunting is a matter of some controversy. A trial of prolonged drainage of lumbar CSF over several days may predict response to shunt insertion. A sizeable number of patients identified as potentially having iNPH, often raised for the first time as a possibility on brain imaging based on non-specific imaging features, will instead turn out to have a neurodegenerative disorder.

Secondary normal pressure hydrocephalus is a form of communicating hydrocephalus secondary to reduced resorption of CSF, for instance following subarachnoid haemorrhage or prior meningitis.

BRAIN INJURY

Traumatic brain injury

In most Western countries, head injury accounts for about 250 hospital admissions per 100 000 population annually. Traumatic brain injury (TBI) describes injuries with potentially permanent consequences. For each 100 000 people, 10 die annually following TBI; 10 to 15 are transferred to a neurosurgical unit, the majority of these requiring rehabilitation for a prolonged period of 1 to 9 months. The prevalence of survivors with a major persisting handicap is around 100/100 000. Road traffic accidents and excessive alcohol use are the principal aetiological factors in this major cause of morbidity and mortality, in many countries.

Skull fractures

Linear skull fracture of the vault or base is one indication of the severity of a blow, but in itself is not necessarily associated with any brain injury. Healing of linear fractures takes place spontaneously. ***Depressed*** skull fracture is followed by a high incidence of post-traumatic epilepsy. Surgical elevation and debridement are usually necessary.

Principal local complications of skull fracture are:

- ***meningeal artery rupture*** causing extradural haematoma (see Chapter 11, 'Subdural and extradural bleeding' section)
- ***dural vein tears*** causing subdural haematoma (see Chapter 11, 'Subdural and extradural bleeding' section)
- ***CSF rhinorrhoea/otorrhoea*** and consequent meningitis.

Mechanisms of brain damage

Older classifications attempted to separate ***concussion***, transient coma for hours followed by apparent complete clinical recovery, from brain ***contusion***—that is, bruising—with prolonged coma,

focal signs, and lasting damage. Pathological support for this division is poor. Mechanisms of TBI are complex and interrelated:

- neuronal and axonal damage from direct trauma
- diffuse axonal injury—shearing and rotational stresses on decelerating brain, sometimes at the site opposite impact (the *contrecoup* effect)
- brain oedema and raised ICP
- brain hypoxia
- brain ischaemia.

Clinical course

In a mild TBI, a patient is stunned or dazed for a few seconds or minutes. Following this, the patient remains alert without post-traumatic amnesia (PTA). Headache can follow; complete recovery is usual.

In more serious injuries, duration of unconsciousness, and particularly of PTA, helps grade severity. PTA lasting more than 24 hours defines severe TBI. The Glasgow Coma Scale (GCS) is used to record the degree of coma; this has prognostic value. A GCS below 5/15 at 24 hours implies a serious injury; 50% of such patients die or remain in a vegetative or minimal conscious state (see 'Disorders of consciousness' section). However, prolonged coma of up to some weeks is occasionally followed by good recovery.

Recovery after severe TBI takes many weeks or months. During the first few weeks, patients are often intermittently restless or lethargic, and have focal deficits such as hemiparesis or aphasia. Gradually, they become more aware, though they may remain in PTA. PTA denotes a diffuse (but transient) confusional state, during which mechanisms of learning are particularly disrupted. The patient is unable to lay down any continuous memory despite being awake; it is not a pure amnestic syndrome, however, and behavioural disturbance is very common. After emergence from PTA, the patient will have little or no memory of that period. The state may last some weeks or more, and may not be obvious clinically: it is important not to miss it as it has crucial management and prognostic implications. PTA is one of the most reliable predictors of outcome: the longer the duration of PTA, the lower the likelihood of return to paid work.

Late sequelae

Sequelae of TBI are major causes of morbidity and can have serious social and medicolegal consequences. They include:

- ***Incomplete recovery***, for example cognitive impairment, hemiparesis.
- ***Post-traumatic epilepsy***.
- ***The post-traumatic (post-concussion) syndrome.*** This describes the vague complaints of headache, dizziness, and malaise that follow even minor head injuries. Litigation is frequently an issue. Depression is prominent. Symptoms may be prolonged.
- ***Benign paroxysmal positional vertigo*** (see Chapter 21).
- ***Chronic subdural haematoma*** (see Chapter 11, 'Subdural haematoma' section).
- ***Hydrocephalus*** (see 'Hydrocephalus' section).
- ***Chronic traumatic encephalopathy.*** This follows repeated and often minor injuries. It consists of cognitive impairment and extrapyramidal and pyramidal signs, seen typically in professional boxers, in whom it is often termed ***dementia pugilistica.*** Repeated concussions in athletes playing rugby and American football have also been implicated, and specific neuropathological findings have been identified in patients with CTE.

Management

Immediate management

Attention to the airway is vital. If there is coma, depressed fracture, or suspicion of intracranial haematoma, CT imaging and discussion with a neurosurgical unit are essential. Indications for CT vary from imaging all minor head injuries in some centres to more stringent criteria elsewhere.

In many severe TBI cases, assisted ventilation will be needed. ICP monitoring is valuable in comatose or sedated patients, and raised ICP requires careful treatment. Care of the unconscious patient is described in Chapter 13 ('Neurocritical care' section). Prophylactic antiepileptic drugs have been shown to be of no value in prevention of late post-traumatic epilepsy. Trials of various putative neuroprotective treatments have shown no benefits. For instance, induced hypothermia lowers ICP but has not been shown to improve outcomes and should not be used routinely.

Rehabilitation

TBI cases require skilled, prolonged, and energetic support. Survivors with severe physical and cognitive deficits require rehabilitation in specialized units. Rehabilitation includes care from a multidisciplinary team, including physiotherapists, occupational therapists, speech and language therapists, and clinical psychologists. Many survivors are left with cognitive problems (amnesia, neglect, disordered attention, and motivation) and behavioural/emotional problems (temper dysregulation, depression, and grief reactions). Long-term support for both patients and families is necessary.

Hypoxic–ischaemic brain injury

The incidence of hypoxic–ischaemic brain injury (HIBI) or hypoxic–ischaemic encephalopathy (HIE) is rising as the numbers of cardiac arrest survivors rise. Most patients with HIBI have had a period of both reduced perfusion of the brain and reduced oxygenation. HIBI can result from reduced perfusion during a cardiac arrest, from catastrophic haemorrhagic or multifocal ischaemic stroke, or from systemic vascular collapse. A purer anoxic insult is generated by carbon monoxide poisoning, drowning or asphyxiation, and prolonged hypothermia. The degree of brain injury suffered by these patients is highly variable, and recovery depends on multiple factors including the underlying aetiology, the age of the patient, the presence of co-morbidities, and the availability of specialist rehabilitation. The critical care management of acute brain injury is discussed in Chapter 13.

Disorders of consciousness

After severe TBI, diffuse HIBI, or other diffuse brain insults that disrupt widespread networks, some patients will exhibit disorders of consciousness. Consciousness consists of two components, alertness or wakefulness (the *level* of consciousness) and awareness (the *content* of consciousness). These components may be affected in tandem or differentially. The care of patients with long-term disorders of consciousness throws up ethical and legal dilemmas, and requires careful assessment and multidisciplinary decision-making.

Disorders of consciousness may be of short duration or last indefinitely. Prolonged disorders of consciousness (PDOC) last longer than 4 weeks. A proportion of patients in PDOC are young and otherwise fit, and so may survive for many years. Some have the potential to recover awareness and hence a degree of functional independence or communication. Identifying who these are requires an experienced MDT. Serial assessment is vital as fatigue and fluctuation can otherwise seriously skew the impression. The Coma Recovery Scale—Revised (CRS-R) is one example of a scoring system used for the documentation of responses in these patients.

Disorders of consciousness extend along a spectrum (Figs. 28.33 and 28.34) and comprise:

- ***Coma***, in which both the content and level of consciousness are severely reduced. The acute management of comatose patients is described in Chapter 11.
- ***Vegetative state*** (VS), which is usually a consequence of extensive cortical damage. Lower brainstem function is intact and so breathing is normal without the need for mechanical ventilation, and the patient appears *alert* with eye-opening and sleep–wake cycles. The 'vegetative' functions (breathing, sleep-wake cycle) are preserved, hence the name. However, there is no sign of *awareness* or response to environmental stimuli, except reflex movements. Feeding is supported by artificial means.
- ***Minimally conscious state*** (MCS) describes patients with limited, often fluctuating, awareness, with inconsistent but reproducible responses, for example movements in response to voice; crying or laughing in response to emotional stimuli; and vocalization in response to questions. A patient may emerge from VS into MCS, and the trajectory of any improvement is the most useful piece of information when trying to assess prognosis. In practice the border between VS and the lower reaches of MCS are blurred, and the term 'low awareness state' can be used to avoid erroneous precision.
- ***Continuing, Chronic, and Permanent MCS and VS:*** MCS and VS are defined as 'continuing' when they have been present for 4 weeks. VS can be considered 'chronic' if it has persisted for >3 months following a non-TBI, or >1 year following a TBI. 'Permanent' VS or MCS denotes that there is no chance of regaining awareness, and should only be diagnosed by a suitably qualified clinician. In general, in the UK, a disorder of consciousness will be considered permanent if there has been no change in trajectory for 6 months or longer, as measured by serial expert assessment. In the UK, the diagnosis of permanent VS no longer has legal relevance, but it can still be useful information for care teams. These definitions have changed over time and are different in different countries.
- ***Emergence from PDOC*** is characterized by demonstrating functional interactive communication (by any means) or functional object use. Anybody who has been in PDOC for more than a few months is likely to have severe permanent physical and cognitive disability, even if they emerge.

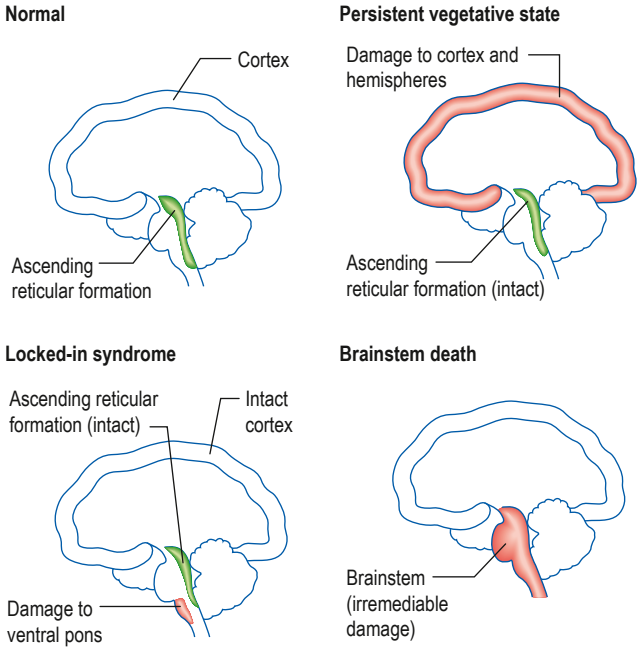

Fig. 28.33 Anatomy of vegetative state, locked-in syndrome, and brainstem death. *(Adapted from Bates D. Coma and brainstem death.* Medicine *2004; 32.)*

Locked-in syndrome is not a disorder of consciousness. Rather, consciousness is normal but voluntary movement is impossible, typically as a result of discrete brainstem pathology (Fig. 28.34). These patients can usually communicate using movements of the eyes or eyelids.

Brainstem death is discussed in Chapter 13 ('Death by neurological criteria' section).

Prognosis in brain injury and disorders of consciousness

Prognosis depends on the cause of PDOC or coma and the extent of brain damage sustained. Metabolic and toxic causes of coma have the best prognosis when the underlying problem can be corrected.

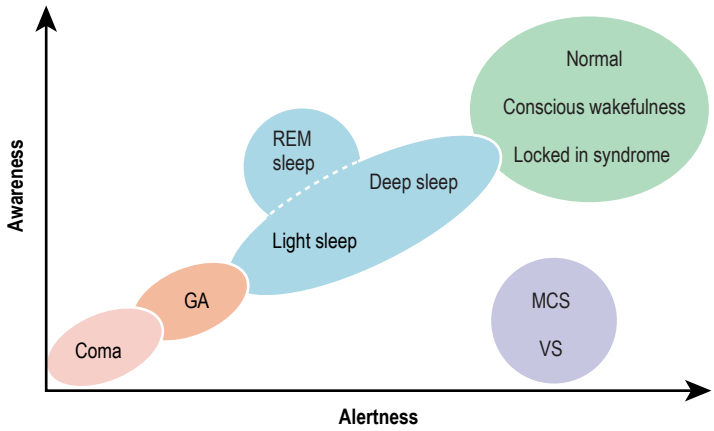

Fig. 28.34 Graphical representation of the disorders of consciousness, illustrating the dissociation between *alertness* and *awareness*. *GA,* General anaesthesia; *MCS,* minimally conscious state; *REM,* rapid eye movement; *VS,* vegetative state. *(Adapted from Laureys S. The neural correlate of (un)awareness: Lessons from the vegetative state.* Trends in Cognitive Science *2005; 556–559.)*

Prognosis after TBI is highly variable, owing to the heterogeneous nature of the condition, and many patients with TBI are young and have greater rehabilitation potential. Following HIBI, such as after cardiac arrest, only 11% make a good recovery. Of those patients who survive but do not regain consciousness soon after the injury, a substantial proportion will remain in a vegetative or minimally conscious state.

It is often useful when considering prognosis after brain injury to consider the best- and worst-case scenario in terms of recovery. The provision of ongoing supportive care (such as artificial hydration and nutrition) is governed in UK law not by the diagnosis of VS or MCS, or its judged permanence, but by considering whether the patient could ever regain a quality of life that they would themselves find acceptable. These decisions require a holistic consideration of *best interests* and discussions should not be delayed until a diagnosis of 'chronic' or 'permanent' VS is made.

SPINAL CORD DISEASE

The cord extends from C1, the junction with the medulla, to the lower vertebral body of L1, where it becomes the conus medullaris. Blood supply is from the anterior spinal artery and a plexus on the posterior cord. This network is supplied by the vertebral arteries and by several branches from lumbar and intercostal vessels, including the artery of Adamkiewicz (the largest anterior segmental medullary artery, arising in most people between T8 and L1 and supplying the lower spinal cord via its anastomosis with the anterior spinal artery).

Spinal cord compression

The principal features of chronic and subacute cord compression are spastic paraparesis or tetraparesis, radicular pain at the level of compression, and sensory loss below the compression (**Box 28.40**).

For example, in compression at T4, a band of pain radiates around the thorax, characteristically worse on coughing or straining. Spastic paraparesis develops over months or days, depending on underlying pathology; acute-onset processes will however cause an initial flaccid paraparesis before spasticity sets in. Numbness commencing in the feet rises to the level of compression. This is called the ***sensory level*** and is usually 2 to 3 dermatome levels below the level of anatomical compression. Retention of urine and constipation develop.

? Box 28.40 Causes of spinal cord compression

- Spinal cord tumours
  - Extramedullary, e.g., meningioma or neurofibroma
  - Intramedullary, e.g., ependymoma or glioma
- Vertebral body destruction by bone metastases, e.g., prostate primary
- Disc and vertebral lesions:
  - Chronic degenerative and acute central disc prolapse
  - Trauma
- Inflammatory:
  - Epidural abscess
  - Tuberculosis
  - Granulomatous
- Epidural haemorrhage/haematoma

Aetiology

Disc and vertebral lesions. Central cervical disc and thoracic disc protrusion cause cord compression (see Chapter 32, 'Pain in the lower back' section). Chronic compression due to cervical spondylotic myelopathy is frequently seen in clinical practice and is the most common cause of a spastic paraparesis in an elderly person.

Trauma. Any trauma to the back is potentially serious and the patient should be immobilized until the extent of the injury can be determined.

Spinal cord tumours. Extramedullary tumours, such as meningiomas and neurofibromas, cause cord compression (**Fig. 28.35** and **Box 28.41**) gradually over weeks to months, often with root pain and a sensory level. Vertebral body destruction by bony metastases, such as in prostate or breast cancer, is a common cause of spinal cord compression.

Intramedullary tumours (e.g., ependymomas) are less common and typically progress slowly, sometimes over many years. Sensory disturbances similar to syringomyelia may develop (see 'Syringomyelia and syringobulbia' section).

Tuberculosis. Spinal tuberculosis is the most common cause of cord compression in countries where the disease is common. There is destruction of vertebral bodies and disc spaces, with local spread of infection. Cord compression and paraparesis follow, culminating in paralysis: Pott's paraplegia.

Spinal epidural abscess.

Epidural haemorrhage and haematoma. These are rare sequelae of anticoagulant therapy, bleeding disorders, or trauma, and can follow LP when clotting is abnormal. A rapidly progressive cord or cauda equina lesion develops.

Fig. 28.35 Thoracic meningioma *(arrowed)* compressing the spinal cord: T2-weighted MRI.

i Box 28.41 Principal spinal cord neoplasms

Extradural
- Metastases:
  - Bronchus
  - Breast
  - Prostate
  - Lymphoma
  - Thyroid
  - Multiple myeloma

Intradural extramedullary
- Meningioma
- Nerve sheath tumours (schwannoma, neurofibroma)
- Lipoma

Intramedullary
- Ependymoma
- Astrocytoma
- Haemangioblastoma
- Intramedullary metastases

Management

Acute spinal cord compression is a medical emergency. Early diagnosis and treatment are vital. MRI is the imaging technique of choice. A trap for the unwary is imaging the wrong part of the spine: a lumbar spine MRI only covers the conus and the cauda equina, and if spinal cord compression is possible then the whole spine must be imaged, particularly in TB or cancer where multiple sites of compression are common.

Routine tests (e.g., chest X-ray) may indicate a primary neoplasm or infection. Surgical exploration is frequently necessary; if decompression is not performed promptly, irreversible cord damage ensues. Results are excellent if benign tumours and haematomas are removed early. Radiotherapy is used to treat cord malignancies, or compression due to inoperable malignant vertebral body disease causing cord compression.

Other spinal cord disorders

Inflammatory cord lesions (transverse myelitis)

See 'Transverse myelitis' section.

Anterior spinal artery occlusion

There is acute paraplegia and loss of spinothalamic (pain and temperature) sensation, with infarction of the anterior two-thirds of the spinal cord. This may result from aortic atherosclerosis, dissection, trauma, or cross-clamping in surgery. Vasculitis, emboli, haematological disorders causing thrombosis, and severe hypotension are other causes. Occlusion of the artery of Adamkiewicz, which supplies the thoracic anterior spinal artery, causes watershed infarction of the cord, typically at the T8 level where perfusion is relatively poor.

Arteriovenous malformations of the cord

Although rare and difficult to diagnose, spinal arteriovenous malformations (AVMs) are potentially curable. The two main types seen are dural arteriovenous fistulas (acquired) and true intramedullary AVMs (probably congenital but gradually enlarging). Dural arteriovenous fistulas occur mainly in middle-aged men due to formation of a direct connection between an artery and vein in a dural nerve root sleeve. This causes arterialization of veins with venous hypertension, and thus oedema and congestion of the spinal cord at and below the affected level. Presentation is with a gradually progressive myelopathy over months or a few years, often with thoracic back pain. MRI usually shows cord swelling (Fig. 28.36) and may show the enlarged arterialized veins over the surface of the cord.

Fig. 28.36 Dural arteriovenous fistulas.

Spinal angiography demonstrates the fistula and allows endovascular ablation with glue, often with complete resolution of symptoms if permanent neuronal damage has not already occurred.

Genetic disorders—hereditary spastic paraparesis

Several genetic disorders may present with a gradually evolving UMN syndrome resembling a myelopathy. Typically, spasticity and stiffness dominate the clinical picture rather than weakness, especially in hereditary spastic paraparesis (HSP). Muscle relaxants, such as baclofen, improve gait. There are more than 80 known genes associated with HSP, some causing 'pure' spasticity and others with associated neurological features, such as thinning of the corpus callosum.

Other genetic disorders such as adrenoleukodystrophy may cause a slowly progressive spastic paraparesis (including in manifesting female carriers), as can the spinocerebellar ataxias (SCAs) or presenilin-1 mutations.

Vitamin B_{12} deficiency

Subacute combined degeneration of the cord resulting from vitamin B_{12} deficiency (see Chapter 25, 'B vitamins' section) is the most common example of metabolic disease causing spinal cord damage. Abuse of nitrous oxide may precipitate functional B_{12} deficiency with normal serum B_{12} levels, diagnosed by demonstrating high serum homocysteine and/or methylmalonic acid concentrations. The dorsal columns are preferentially affected causing a marked sensory ataxia, but the term 'combined' refers to frequent additional involvement of the lateral columns (corticospinal tracts). Mixed upper and lower motor neuron signs are classically observed owing to peripheral nerve involvement. Emergency B_{12} replacement is mandatory (and must be initiated before replacement of folate, which can otherwise precipitate SACDC).

Other causes of a spastic paraparesis

MND may present initially with a spastic paraparesis before LMN features develop (see 'Motor neuron disease' section). Paraneoplastic disorders, radiotherapy, copper deficiency, liver failure, and rare toxins (e.g., lathyrism) may cause spinal cord damage. Not all causes of paraparesis relate to spinal cord pathology; beware a parasagittal cerebral meningioma presenting with a paraparesis due to bilateral compression of the leg area of the motor cortex.

Care of the patient with paraplegia

Where patients are left with a severe paraplegia, there are several issues to address in long-term care, and specialist nursing is vital.

Bladder management. The bladder does not empty and urinary retention results. Patients self-catheterize or develop reflex bladder emptying, helped by abdominal pressure. Early treatment of urine infections is essential. Chronic kidney disease may develop from chronic obstruction or repeated urinary tract infection.

Bowel function. Constipation and impaction must be avoided. Following acute paraplegia, manual evacuation is necessary; reflex emptying develops later.

Skin care. Risks of pressure ulcers and their sequelae are serious. Meticulous attention must be paid to cleanliness and regular turning. The sacrum, iliac crests, greater trochanters, heels, and malleoli should be inspected frequently. Pressure-relieving mattresses are useful initially until patients can turn themselves. If pressure ulcers develop, plastic surgery may be required. Pressure palsies, such as those of ulnar nerves, can occur.

Lower limbs. Passive physiotherapy helps to prevent contractures. Severe spasticity, with flexor or extensor spasms, may be helped by muscle relaxants such as baclofen or by botulinum toxin injections.

Rehabilitation. Many patients with traumatic paraplegia or tetraplegia return to self-sufficiency (especially if the level is at C7 or below). A specialist spinal rehabilitation unit is necessary. Lightweight, specially adapted wheelchairs provide independence. Tendon transfer operations may allow functional grip if hands are weak. Autonomic dysreflexia may be a problem. Patients with paraplegia have substantial practical, psychological, and sexual needs.

Syringomyelia and syringobulbia

A syrinx is a fluid-filled cavity within the spinal cord. Syringobulbia means a cavity in the brainstem. Syringomyelia is frequently associated with a Chiari malformation (see Fig. 28.32). The abnormality at the foramen magnum probably allows normal pulsatile CSF pressure waves to be transmitted to fragile tissues of the cervical cord and brainstem, causing secondary cavity formation. The syrinx is in continuity with the central canal of the cord. Syrinx formation may also follow spinal cord trauma or infection and lead to secondary damage years later, and can also be caused by intrinsic cord tumours.

Pathophysiology

The expanding cavity in the cord gradually destroys the neurons closest to the central canal: spinothalamic neurons, anterior horn cells, and lateral corticospinal tracts. In the medulla (syringobulbia), lower cranial nerve nuclei are affected.

Clinical features

Cases associated with the Chiari I malformation usually develop symptoms around the age of 20 to 30. Neck, upper back, and shoulder pain exacerbated by exertion or coughing is typical. Spinothalamic sensory loss—pain and temperature—leads to painless upper limb burns and trophic changes. Paraparesis develops. The following are typical signs of a substantial cervical syrinx (Fig. 28.37, and see Fig. 28.32):

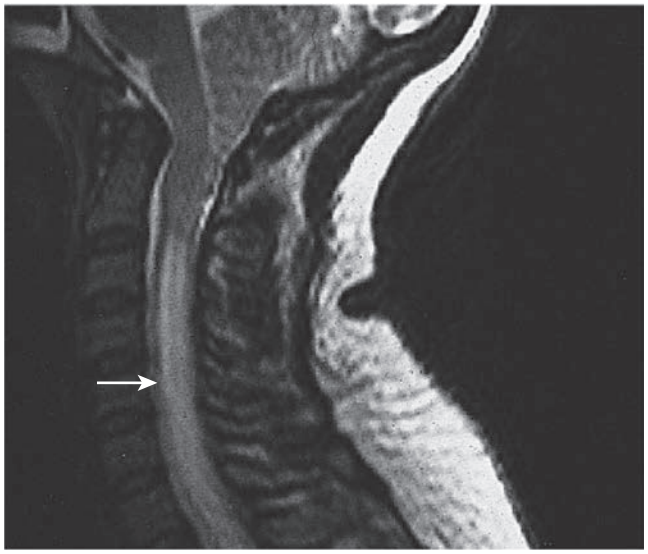

Fig. 28.37 Cervical syrinx—cavity within cord *(arrowed)*: T2-weighted MRI.

- ***a 'suspended' area of dissociated sensory loss***—that is spinothalamic loss in a cape-like distribution without loss of light touch
- ***loss of upper limb reflexes***
- ***muscle wasting*** in the hand and forearm
- ***spastic paraparesis***—initially mild
- ***brainstem signs***—as the syrinx extends into the brainstem (syringobulbia), there may be tongue atrophy and fasciculation, bulbar palsy, a Horner's syndrome, and impairment of facial sensation.

Investigations and management

MRI demonstrates the cavity and may shed light on the underlying cause. Syringomyelia is gradually progressive over several decades. Sudden deterioration sometimes follows minor trauma or occurs spontaneously. Surgical decompression of the foramen magnum in the presence of a Chiari often causes the syrinx to collapse.

DEMENTIA

Dementia is broadly a clinical syndrome of decline in neurocognitive function, of sufficient severity to cause significant functional impairment. One or more domains of cognition will be affected, including often episodic memory or language function, but also potentially frontal executive function, visuospatial function, praxis, social cognition, and complex attention. Unlike delirium, dementia is chronic and in most cases progressive (rather than acute and fluctuating).

There are multiple causes (Box 28.44), but the key ones are ***neurodegenerative***. The DSM-V diagnostic criteria for major neurocognitive disorder (intended to be synonymous with dementia) allow for non-progressive and even reversible dementia diagnoses, but in the majority of cases, these are more usefully described as dementia mimics, such as cognitive impairment from autoimmune encephalitis or hydrocephalus.

Dementia robs patients of their independence, and is a serious burden on carers and a major socioeconomic challenge for society as a whole.

Epidemiology

Dementia is common, and increasing in prevalence as a result of an ageing population and better case ascertainment. Age is the main risk factor, followed by family history. Over the age of 65, there is a 7% prevalence; over the age of 85, the prevalence rises to over 30%.

Clinical assessment

There are two main considerations:

- Does the patient have dementia?
- Is the pattern of cognitive deficits, tempo of progression, or associated features suggestive of a distinct cause? Cognitive problems need to be interpreted in the context of estimated premorbid abilities (e.g., based on educational attainments or occupation).

A well-taken history is the key to an accurate dementia diagnosis. Taking a collateral account from a relative or friend is essential. Patients may tend to downplay or deny symptoms (anosognosia) or

constantly look to the relative for answers (the 'head-turning sign'). See Box 28.42 for the key elements in history-taking.

Examination

Conversation with the patient during history-taking may be as revealing as formal cognitive assessment, but many patients hide deficits well behind an intact social façade.

Bedside cognitive assessment

The mini-mental state examination (MMSE) is commonly used as a quick screen of cognitive function but has its limitations, such as poor sensitivity for milder cognitive impairment and frontal lobe dysfunction, especially in those with high pre-morbid abilities. The Montreal Cognitive Assessment (MoCA) has greater sensitivity for mild cognitive impairment (MCI) and also incorporates some testing of executive function (the trail-making test) but is as short as the MMSE. Licensing and cost limit the use of both tools. The Addenbrooke's Cognitive Examination–III (ACE-III) is a tool developed to address the deficiencies of the MMSE, and is short enough to use in clinical practice. It has some value in diagnosing frontotemporal dementia as well as Alzheimer's disease, although none of these tools can be used in isolation to differentiate between dementia syndromes.

It is useful to ask patients to give an account of recent news events to assess episodic memory, and to ask about route-finding to assess topographical memory ('Can you tell me how to get from your home to the clinic?').

Individual cognitive domains can be tested separately in detail: for example, clock drawing for visuospatial (parietal lobe) function; naming and reading tasks for language function; verbal fluency, conceptual similarity (to test abstract thinking) and stop–go tasks, which are components of the Frontal Assessment Battery (FAB).

Check for primitive reflexes (frontal release signs), such as grasp, palmo-mental and pout reflexes, and perseveration or utilization behaviour with frontal lobe involvement.

Test:

- ideomotor limb praxis—copying hand gestures and miming tasks, e.g., 'Show me how you brush your teeth'.
- orofacial praxis, e.g., 'Show me how you would blow out a candle'.

A complete neurological examination (to look for evidence of papilloedema, parkinsonism, myoclonus, and gait disorders, for example), is also necessary, in addition to general examination and assessment of mental state.

Investigations

Investigations (Box 28.43) are aimed at identifying treatable causes and helping support a clinical diagnosis of dementia type. For most patients, this should include the elements listed below.

Blood tests. These are primarily to rule out reversible causes of cognitive impairment and should include a full blood count and measurement of vitamin B_{12}, thyroid function, urea and electrolytes, liver function, glucose, ESR, HIV, and syphilis serology.

Brain imaging. CT is adequate to exclude structural lesions (Fig. 28.38), such as tumours or hydrocephalus. The superior anatomical resolution of MRI can identify patterns of regional brain atrophy and so help to distinguish between different types of degenerative dementia (e.g., hippocampal atrophy in Alzheimer's disease (AD) versus temporal lobe and frontal atrophy in frontotemporal dementia). Imaging also allows assessment of brain 'vascular load'. MRI is always preferable to CT in patients with cognitive disorders. Serial volumetric imaging can be helpful to view the trajectory of atrophy over time.

Detailed neuropsychometric assessment. Appropriate in most patients, this allows quantification of the relative involvement of different cognitive domains and may be helpful if performed serially over time to assess progression.

CSF examination. Measurement of CSF protein biomarkers has been shown to be useful in distinguishing between different types of dementia; for example, in AD, CSF tau is raised and Aβ42 reduced (or the Aβ42:Aβ40 ratio is reduced). In Creutzfeldt–Jakob disease (CJD) and other rapidly progressive dementias, protein 14–3–3 is

Box 28.42 Taking a dementia history

- Memory:
  - Is the patient repetitive, e.g., with questions?
  - Is there a temporal gradient of amnesia—preservation of more distant memories with amnesia for recent events?
  - Is there difficulty learning to use new devices, e.g., computer, mobile phone?
- Functional ability:
  - Has work performance or ability to cook and do domestic tasks declined?
  - Has responsibility for finances and administration shifted to the partner?
  - Does the patient get easily muddled?
- Personality and frontal lobe function:
  - Has personality changed?
  - More aggressive/apathetic/lacking initiative
  - Lacking empathy
  - Disinhibition
  - Change in food preference or religiosity
- Language:
  - Difficulty with word finding or remembering names
- Visuospatial ability:
  - Does the patient get lost in familiar places?
  - Difficulty dressing, e.g., putting jacket on the wrong way round
- Psychiatric features:
  - Features of depression
  - Hallucinations (visual or auditory?)
- Tempo of progression
- Family history of dementia
- Alcohol and drug use
- Medication
- Any other neurological problems, e.g., parkinsonism, gait disorder, strokes

Box 28.43 Tests in dementia

Blood tests

- Full blood count, erythrocyte sedimentation rate, vitamin B_{12}
- Urea and electrolytes
- Glucose
- Liver biochemistry
- Serum calcium
- Thyroid stimulating hormone, T_3, T_4
- HIV serology
- Syphilis serology

Imaging

- CT or MRI brain scan

Other—selected patients only

- Cerebrospinal fluid—including tau and Aβ42 measurement
- Genetic studies, e.g., for AD and FTD genes, HD, prion mutations
- Electroencephalography
- Advanced brain imaging (e.g., FDG-PET, SPECT, amyloid PET, or DaTScan)
- Brain biopsy

Fig. 28.38 CT scan showing a large frontal meningioma presenting with apathy and frontal dementia.

increased. A new CSF assay for abnormal prion protein, ***real-time quaking-induced conversion (rt-QUIC)***, has proved to be highly sensitive and specific for CJD.

Specialist tests—in selected patients (e.g., those <65 years old, those with a positive family history or those with atypical features including rapid onset), more intensive investigation may be necessary. This may include EEG, genetic tests (e.g., for Huntington's, familial AD, and FTD genes), voltage-gated potassium channel antibodies, anti-neuronal antibodies (for paraneoplastic limbic encephalitis); or on rare occasions, brain biopsy may be appropriate.

New imaging modalities. Functional imaging (FDG-PET or SPECT) can sometimes be useful to identify areas of brain hypometabolism/hypoperfusion. Radionuclide scans, using radioactively labelled ligands that bind directly to amyloid, allow amyloid deposition in the brain to be directly visualized, and are used widely as a research tool for clinical trial enrolment. Amyloid imaging is now beginning to enter clinical practice in some specialist centres, but appropriate patient selection and interpretation is vital. A positive scan lends support to a diagnosis of Alzheimer's disease in the right clinical context, but amyloid deposition can arise as a co-pathology in patients with another cause of dementia, or in asymptomatic individuals.

Mild cognitive impairment

Mild cognitive impairment (MCI) is an intermediate state between normal cognition and dementia. Often mild memory impairment, greater than expected for age but not sufficient to be classified as dementia, is the only symptom ('amnestic MCI'). MCI may be a pre-dementia state, with 10% to 15% of patients per year developing overt dementia.

Causes and risk factors

There are many causes of dementia (Box 28.44), by far the most common being AD. Cause varies according to age (Fig. 28.39). Most commonly, multiple pathologies converge to cause dementia in older people although there will generally be a dominant aetiology.

Aetiologies are distinct from risk factors—and many risk factors for dementia have been identified, some of which are modifiable (Box 28.45). Many of these increase the risk for multiple dementia types (several vascular risk factors increase the risk of Alzheimer's disease as well as vascular dementia).

? Box 28.44 Causes of dementia

Degenerative
- Alzheimer's disease
- Dementia with Lewy bodies
- Frontotemporal dementia
- Huntington's disease
- Parkinson's disease
- Progressive supranuclear palsy
- Prion diseases, e.g., Creutzfeldt–Jakob

Vascular
- Vascular dementia
- CADASIL (Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy)

Metabolic[a]
- Liver failure

Toxic[a]
- Alcohol
- Heavy metals
- Recreational drugs (e.g., cocaine, solvents)
- Medications (e.g., chemotherapy)

Traumatic
- Severe or recurrent traumatic brain injury (including chronic traumatic encephalopathy)

Structural lesions[a]
- Hydrocephalus (including idiopathic normal pressure hydrocephalus)
- Tumours

Infections/Inflammatory[a]
- HIV
- Neurosyphilis
- Whipple's disease
- Autoimmune/paraneoplastic encephalitis
- Multiple sclerosis

Other
- Mixed dementia/multiple aetiologies

[a]Potentially reversible aetiologies, in which case the presentation is best classified as a dementia mimic.

Dementia syndromes

Alzheimer's disease

Although technically a definitive diagnosis can only be made by histopathology, in practice the clinical features are sufficiently characteristic that a diagnosis can usually be made with considerable accuracy in life, supported by diagnostic investigations. The key clinical features are:

- ***Memory impairment*.** Memory-led cognitive decline is the hallmark of Alzheimer's disease. Episodic (day-to-day) memory is affected. There is progressive loss of ability to learn, retain, and process new information. There is a characteristic temporal gradient, with relative preservation of remote memory and amnesia for more recent events. This type of recent memory relies on the hippocampus and related structures in the mesial temporal lobe, which is the area of the brain most severely affected in classical AD. This type of anterograde long-term memory deficit is often incorrectly termed 'short-term memory loss', which actually refers to loss of working memory: for example, digit span, which is preserved in the early stages of AD. Procedural (how to do things) and semantic (knowledge of general facts and concepts) memory is also spared until the later stages.

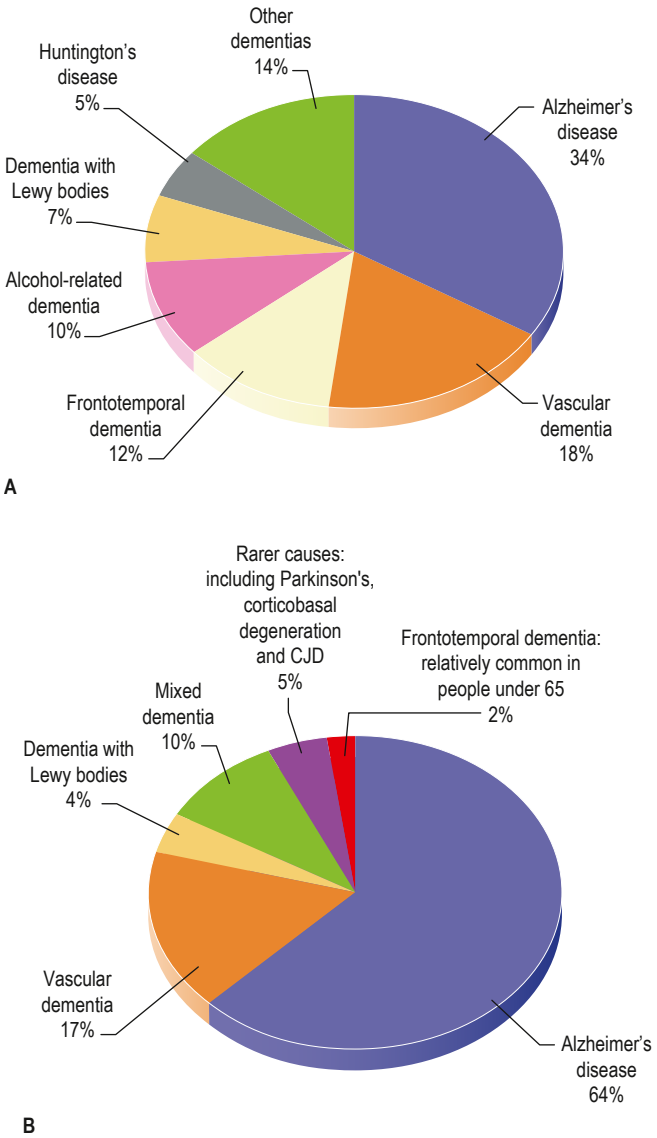

Fig. 28.39 Causes of dementia at different ages. **(A)** Under 65 years. **(B)** At 65 years or more. *CJD,* Creutzfeldt–Jakob disease. *(Data from Prince M, Knapp M, Guerchet M et al.* Alzheimer's Society Dementia UK Update. *London: Alzheimer's Society; 2014.)*

Box 28.45 Risk factors for dementia

- Age
- Genetic factors
- Hypertension
- Smoking
- Diabetes
- Chronic kidney disease
- Obesity
- Lack of physical activity
- Poor diet
- Alcohol excess
- Low levels of cognitive engagement
- Depression
- Traumatic brain injury
- Hearing loss
- Social isolation
- Air pollution

- ***Topographical disorientation***, or difficulty navigating, is frequently an early sign, as expected from the role of the hippocampus in topographical memory. There may be a history of getting lost.
- ***Aphasia.*** Language usually becomes impaired as the disease advances. Difficulty with word finding (anomia) is characteristic.
- ***Apraxia.*** Ability to carry out skilled motor activities is impaired (see 'Apraxia' section).
- ***Visuospatial dysfunction*** including difficulties with parking or filling out forms (parietal).
- ***Altered auditory processing.*** Inability to pick out a conversation in a noisy environment can be a very early sign of AD.
- ***Frontal executive dysfunction.*** Organizing, planning, and sequencing are impaired.
- ***Anosognosia.*** Lack of insight by the patient into their difficulties is common; they may be reluctant to seek medical attention but be brought to clinic by a family member. Where insight is preserved, depression is common.

- ***Personality change.*** In contrast to other dementias such as frontotemporal dementia, basic personality, and social behaviour remain intact until late AD, but more subtle behavioural and emotional changes are common.
- ***Tempo.*** Disease onset is insidious and often not noticed by family members initially. Progression is gradual but inexorable over a decade or longer, with eventual severe deficits in multiple cognitive domains.
- ***Atypical variants:***
  - ***Posterior cortical atrophy (PCA).*** The visual variant of AD is caused by initial involvement of the occipital lobes and occipitoparietal regions. Patients have complex visual symptoms that may be difficult to describe; they often say that it is easier to see distant than close-up objects. Visuoperceptive deficits manifest with difficulties recognizing faces or objects in spite of intact acuity; they will be unable to read fragmented letters. Visuospatial skills are also affected, as are nearby parietal functions (reading, praxis, numeracy), while memory is initially well preserved. The ***biparietal variant*** is a form of PCA where the dorsal ('where?') occipitoparietal stream is affected more than the ventral ('what?') occipitotemporal network. PCA is occasionally caused by other neurodegenerative pathologies (such as dementia with Lewy bodies, corticobasal degeneration, or prion disease).
  - ***Logopenic-variant primary progressive aphasia* (lvPPA).** Occasionally, AD will present with early language impairment and preserved episodic memory. There will be word-finding pauses, length-dependent difficulties with sentence repetition, and phonological errors in speech with intact comprehension and grammar.
  - ***Frontal variant*** AD causes prominent behavioural and/or dysexecutive features.
- ***Late non-cognitive features.*** Myoclonus may develop, sometimes followed by seizures (the cortex is the main site of pathology). Sleep–wake cycle reversal and incontinence may place a great strain on carers. Gegenhalten or paratonic rigidity (resistance to passive movement that increases with the velocity of the movement) may be seen, and seizures can occur. Overall motor function may be strikingly preserved, so patients are capable of wandering and getting lost. Swallowing may become impaired, leading to aspiration pneumonia—often a terminal event.

Investigations

MRI typically shows characteristic atrophy of mesial temporal lobe structures, including hippocampi, progressing eventually to generalized cerebral atrophy. Imaging may be normal in the early stages and selective regional atrophy is seen in AD variants, such as occipital lobe volume loss in PCA. Characteristic MRI and psychometric testing abnormalities are sufficient to make a diagnosis if the clinical picture is suggestive (a progressive amnestic cognitive disorder in an older person). CSF tau and β-amyloid measurement is helpful in cases of diagnostic difficulty, and there may be a role for amyloid PET (see above).

Molecular pathology

Although the cause of AD is still not known, a great deal is now understood about the molecular pathology. The pathological and biochemical hallmarks are:

- The deposition of β-amyloid (Aβ) in amyloid plaques in the cortex. The amyloid precursor protein (APP) is processed by secretase enzymes to form pathogenic $A\beta_{1–42}$ monomers, which polymerize into extracellular amyloid plaques (Fig. 28.40). Amyloid may also be laid down in cerebral blood vessels, leading to amyloid angiopathy, which frequently co-occurs with AD. Amyloid plaques are frequently associated with dystrophic neurites (swollen axons and dendrites) and an inflammatory response.
- Structural and conformational changes in tau protein, that is hyperphosphorylation and aggregation into paired helical filaments, lead to the formation of neurofibrillary tangles. These protein aggregates damage synapses and ultimately lead to neuronal death. Early pathological changes in the brain, including Aβ deposition, predate clinical symptoms, and diagnosis by up to 25 years.
- A basal forebrain cholinergic deficit occurs and may explain the therapeutic response to cholinesterase inhibitor drugs.

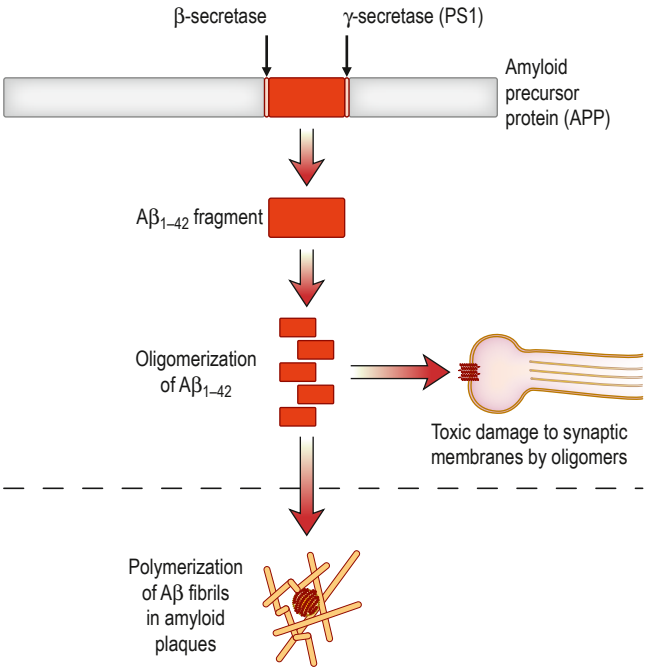

Fig. 28.40 Molecular pathogenesis of Alzheimer's disease. Processing of the amyloid precursor protein (APP) molecule by secretase enzymes releases $A\beta_{1–42}$ monomers, which are the building blocks of amyloid plaques. Aβ oligomers may damage synaptic membranes. Mutations in APP or γ-secretase (presenilin-1) cause genetic forms of Alzheimer's. Disruption of the balance between formation and degradation of $A\beta_{1–42}$ is thought to be a major problem.

Genetics of AD

A first-degree relative with AD confers a doubled lifetime risk of AD. There are rare autosomal dominant monogenic early-onset forms of familial AD with high penetrance, caused by mutations in specific genes; taken together, these account for only 1% of cases of AD.

Amyloid precursor protein (APP). Point mutations in the APP gene can cause AD, and the presence of three copies of the APP gene on chromosome 21 in Down's syndrome patients is responsible for the high incidence of AD in that condition (a majority of patients with Down's syndrome will develop AD by the sixth decade of life).

Presenilin (PS)-1 and 2. Mutations in these genes affect the γ-secretase enzyme function (see Fig. 28.40). PS1 mutations account for 50% of monogenic forms of AD. The PS1/2 and APP genes may be sequenced for mutations in selected early-onset cases (<65) with a family history.

Other genes. The E4 allele of the apolipoprotein E gene confers an increased risk of AD (2–3 times lifetime risk), especially if two copies of the E4 allele are inherited (8–12 times risk). Several other candidate genes have been identified as risk factors for AD, with modest effect size, in large genome-wide association studies.

Acquired risk factors

Age is the main risk factor for AD, as incidence increases exponentially with age. Vascular risk factors, including hypertension, diabetes, and dyslipidaemia also increase AD risk (and may be modifiable); head trauma, smoking, and air pollution also increase risk. AD shares risk factors with other causes of dementia (**Box 28.45**).

Dementia with Lewy bodies and Parkinson's disease dementia

Dementia with Lewy bodies (DLB) is characterized by the early onset of visual hallucinations, fluctuating cognition with variation in attention and alertness, REM sleep behaviour disorder, and parkinsonism. Delusions, dysautonomia, and transient loss of consciousness occur. The visual hallucinations often take the form of people or animals, or the sense of a presence ('extracampine hallucinations'). In REM sleep behaviour disorder, the normal atonia associated with REM sleep is lost and so dream enactment takes place. Memory loss may be absent in the early stages, and instead the cognitive profile is typified by deficits in attention and visuospatial function; unlike in other types of dementia, extreme cognitive fluctuations can occur, which can be mistakenly attributed to delirium. Lewy bodies, inclusions containing aggregates of the protein α-synuclein first described in Parkinson's disease, are found in the cortex.

In DLB, the cognitive features dominate; parkinsonism may evolve later and is typically mild. In Parkinson's disease dementia (PDD), cognitive problems are a late feature, occurring at least 1 year after onset and usually after the age of 75. Both conditions may respond to cholinesterase inhibitors. Patients with DLB/PDD may be very sensitive to neuroleptic drugs with dramatic worsening.

Vascular dementia

This common cause of dementia is due to several mechanisms, including multi-infarct dementia, cerebral small vessel disease, and post-stroke dementia. Most vascular dementias are of mixed cause. Vascular dementia is distinguished from AD by its clinical features and imaging (but the two frequently coexist). Cognition classically declines in a stepwise fashion, with the accumulation of new infarcts, but it can also be progressive. Cognitive decline may follow a clinically diagnosed stroke or strokes (post-stroke dementia), or may arise without a recent stroke. Apraxic gait disorder, extrapyramidal rigidity worse in the legs, and urinary incontinence are common additional features. Widespread small-vessel disease seen on MRI is the typical finding and may produce a variety of cognitive deficits, reflecting the site of ischaemic damage, but the most common is a frontal-subcortical profile, with slowed processing, reduced verbal fluency, and dysexecutive features.

Cerebral amyloid angiopathy can also cause significant small vessel disease and a vascular dementia, with or without coexistent Alzheimer's disease. Genetic cerebral angiopathies, such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), may cause a progressive subcortical dementia.

However, incidental cerebrovascular disease is a common finding in the elderly. Cognitive decline should not be ascribed to vascular dementia based purely on an imaging report.

Frontotemporal dementia

Frontotemporal dementia (FTD) is the term used to describe a group of neurodegenerative disorders characterized by asymmetric frontal lobe and temporal lobe atrophy, and changes in behaviour, personality, and/or language function. Onset is usually below the age of 65 and there is often a family history. FTD is considerably less common than AD, prevalence being approximately 10 per 100 000 before the age of 65. Some patients with FTD will also develop a motor syndrome (parkinsonism or MND), because of overlapping neuropathology.

There are three distinct clinical syndromes, depending on which anatomical region is affected first.

Behavioural variant FTD is the most common subtype, and characterized by personality change, emotional blunting, apathy, disinhibition, carelessness, and behavioural change with striking preservation of episodic memory.

The other two clinical subtypes are two variants of ***primary progressive aphasia***, and are characterized by progressive impairment of language function. (The classification here is confusing, with *logopenic variant PPA* being typically caused by Alzheimer's disease [see above], but the other two major subtypes, *non-fluent variant* and *semantic variant PPA*, being types of FTD.)

Semantic variant primary progressive aphasia (svPPA), with asymmetric atrophy of the dominant anteroinferior temporal lobe, produces progressive difficulty with comprehension of words (e.g., the patient will not be able to tell you what an owl is, or point to a picture of an owl). Speech will be fluent and well-structured but lacking in meaningful content. Eventually there is a profound loss of object knowledge (semantic knowledge), beyond just the words themselves (the patient will not know that daffodils are yellow). Insight is impaired.

Non-fluent variant primary progressive aphasia (nfvPPA) is associated with peri-Sylvian atrophy, with involvement of Broca's area (inferior frontal gyrus) and the insula. Speech is effortful and distorted, with loss of verbal fluency, and grammar is lost resulting in increasingly telegraphic speech ('expressive agrammatism'). Insight is preserved and the patient may be very frustrated or depressed.

The frontal and temporal presentations eventually merge as cognitive decline becomes more widespread.

Pathology

About 30% of cases are familial, with the majority of the heritability accounted for by autosomal dominant mutations in the microtubule-associated protein tau *(MAPT)*, progranulin (GRN), or chromosome 9 open reading frame 72 *(C9orf72)* genes. The pathology is heterogeneous, grouped together under the umbrella of 'frontotemporal lobar degeneration'. There are three major types defined by the deposition of an abnormally aggregated protein: phosphorylated tau (FTLD-tau), transactive response DNA-binding protein 43 (FTLD-TDP), or fused in sarcoma (FTLD-FUS).

Many patients with FTD will develop motor symptoms, either of motor neuron degeneration or parkinsonism. Fifteen percent of patients with FTD will develop overt MND, and others have features of parkinsonian disorders (PSP features are particularly common in patients with nfvPPA). These linked disorders are all caused by FTLD pathology.

There is no cure or specific treatment at present for FTD.

Prion diseases, including Creutzfeldt–Jakob disease

Prion diseases (see Chapter 42, 'Transmissible spongiform encephalopathies [prion diseases]' section) are transmissible neurodegenerative disorders with a long incubation period, caused by

accumulation of misfolded native prion protein (PrP^c). Misfolding and conformational change in PrP^c is caused either by exposure to the abnormal misfolded isoform of the protein (PrP^{sc}) or by mutations in the PrP gene *(PRNP)*, leading to toxic accumulation of PrP^{sc} as amyloid in beta-pleated sheets. Neuronal cell damage and 'spongiform' change in the brain result, the clinical correlate being a rapidly progressive dementia in most cases.

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is the most common prion disease in humans, the animal equivalents being bovine spongiform encephalopathy (BSE) in cattle and scrapie in sheep. CJD may be sporadic, iatrogenic, or familial.

Sporadic CJD (sCJD) is the most common form, occurring over the age of 50, with an incidence of approximately 1 per million. It is thought to be due to spontaneous stochastic conformational change in PrP^c to PrP^{sc} with a subsequent 'domino effect': PrP^{sc} replicates by auto-catalytic templating, inducing misfolding in other PrP molecules. A rapidly progressive dementia leads to death within 6 months of onset. Rapidly progressive cognitive decline should always lead to suspicion of CJD. The presence of myoclonus is also a clinical clue (present in 90%). Monoclonal antibodies and antisense oligonucleotide treatments are being studied.

Iatrogenic CJD is transmitted from neurosurgical instruments (prions are resistant to sterilization), transplant material (e.g., corneal grafts), and cadaveric pituitary–derived growth hormone taken from patients with CJD or presymptomatic CJD. Iatrogenic CJD has a long incubation period of several years.

Familial CJD (rare) is associated with PRNP gene mutations. Other genetic prion diseases, such as ***fatal familial insomnia***, also occur.

Variant CJD (vCJD) was first seen in the UK in 1995. vCJD patients are younger than sporadic cases, with a mean age of 29. Early symptoms are neuropsychiatric, followed by ataxia and dementia with myoclonus or chorea. vCJD has a longer course than sporadic CJD—up to several years. vCJD and BSE are caused by the same prion strain, and there is epidemiological and experimental evidence that vCJD is transmitted by consumption of BSE-contaminated beef. Transmission via blood transfusion may also occur. Most patients with vCJD and sporadic CJD have a specific polymorphism at codon 129 of the PRNP gene that leads to susceptibility.

Diagnostic evaluation

Neuropathological confirmation is required for definitive diagnosis of sporadic and acquired prion diseases, but brain biopsy should be avoided unless a treatable alternative is being considered. In sCJD, MRI typically shows high signal on DWI, FLAIR, and T2 in the caudate head, putamen, and along the cortex (cortical ribboning). A majority of patients will have periodic sharp wave complexes on EEG. However, the most useful diagnostic test is real-time quaking-induced conversion (RT-QuIC) on CSF samples: this is a 'seeding assay' that detects the presence of PrP^{sc} through an induced conformational change in recombinant prion protein. RT-QuIC is highly sensitive and specific for sporadic CJD. CSF tau and protein 14-3-3 are also used as adjunctive biomarkers but are less accurate than RT-QuIC.

Variant CJD cannot be confirmed with RT-QuIC, but tonsillar biopsy (confirming the presence of tissue PrP^{sc}) is diagnostic. MRI demonstrates FLAIR hyperintensity in the pulvinar of the thalamus bilaterally, or in both pulvinar and dorsomedial thalamus ('hockey stick sign').

Other dementias

Other neurodegenerative disorders may include dementia as one of their clinical manifestations. For example, CBD and PSP are intimately linked to frontotemporal dementia. Dementia may be a feature of a number of genetic and metabolic disorders, such as Huntington's disease (see 'Huntington's disease' section) and the leukodystrophies.

Management of dementia

It is rare for a reversible cause for a dementia presentation to be found, such as hydrocephalus or a frontal meningioma. Other disorders, such as limbic encephalitis or severe depression, may present as dementia mimics and every effort should be made to distinguish these treatable conditions from degenerative dementias.

Management is supportive, to preserve dignity and to provide care for as long as possible in the familiar home environment. The burden of illness frequently falls on relatives. Dementia clinical nurse specialists form a central part of the multidisciplinary team.

General measures. Some evidence suggests that participation in cognitively demanding activities in later life may protect against or delay the onset of dementia. Managing vascular risk factors may slow the progression of cognitive decline. There may be modest benefit from vitamin E in slowing progression of mild to moderate AD.

Cognitive enhancing drugs. These have a modest symptomatic benefit in AD, equivalent to an increase of 1 to 2 points on the MMSE. They are not disease-modifying, so do not slow or prevent progression. While there has been some dispute about the place for these drugs, they contribute to patients being able to prolong independence and remain at home for longer than might otherwise be the case.

- ***Acetylcholinesterase inhibitors*** (donepezil, rivastigmine, and galantamine) increase brain acetylcholine levels by inhibiting CNS acetylcholinesterase. Patients with AD have a central cholinergic deficit. There is usually a small but significant improvement in memory, cognition, and function. Cholinesterase inhibitors are also effective in DLB and Parkinson's dementia but not in FTD or vascular dementia. Side-effects, particularly cholinergic gastrointestinal symptoms, may be a problem. The presence of cardiac conduction deficits is a contraindication.
- ***Memantine*** is an NMDA receptor antagonist. It is used in moderate or severe AD or where cholinesterase inhibitors are not tolerated. There is some evidence that a combination of memantine and cholinesterase inhibitors is better than either used alone. It is generally well tolerated.

Disease-modifying treatments. It is possible that we are on the cusp of a revolution in dementia treatment, with the development of disease-modifying treatments that have shown evidence of target engagement. The most promising treatments so far are monoclonal antibodies directed against amyloid (Aβ) peptide. One of the barriers is the need to administer these therapies very early in the course of the disease for maximal efficacy, before significant irreversible neuronal damage has accumulated—in many cases, this will be before dementia can be clinically appreciated. Adverse effects caused by these agents include amyloid-related imaging abnormalities (ARIA), which are frequently asymptomatic but may occasionally cause life-threatening brain swelling.

- ***Aducanumab*** is a recombinant monoclonal antibody directed against amyloid beta, which has been shown to substantially

reduce amyloid plaques in the brain, but evidence of clinical efficacy has been inconsistent. It was the first agent to gain accelerated approval from the FDA in the USA, but has now been withdrawn by the manufacturer.

- ***Lecanemab*** is another mAb that binds to and clears Aβ. A phase 3 clinical trial in patients with early AD showed that lecanemab slowed cognitive decline by 27%. It has been approved in the USA.
- Other potential avenues being explored include agents that reduce the downstream effects of pathological Aβ signalling, inhibitors of secretase enzymes that process APP into Aβ fragments, and tau aggregation blockers.

Psychiatric and behavioural problems. Depression is common in dementia and may be difficult to distinguish from dementia symptoms, such as apathy and worsening cognitive function. A trial of an antidepressant is appropriate where depression is suspected. Distinguishing depressive pseudodementia from organic dementia can be difficult but is crucial. Behavioural disturbance (e.g., due to agitation or delusions) and hallucinations may occur in late-stage disease. Use of antipsychotic medications is associated with significantly increased stroke risk in patients with dementia and should be used only as a last resort.

Financial and legal issues. Patients may want to set up a Lasting Power of Attorney (if they retain mental capacity to do so in legal terms) to allow a spouse or relative to deal with their financial affairs on their behalf when they lose the capacity to do so. Patients and carers may be entitled to state financial benefits.

Driving. After a diagnosis of dementia, patients in the UK have a duty to inform the Driver and Vehicle Licensing Authority (DVLA), who may request a driving safety assessment.

MOTOR NEURON DISEASE

Motor neuron disease (MND) is a devastating condition causing progressive weakness and eventually death, usually as a result of respiratory failure or aspiration. It is relatively uncommon, with an annual incidence of 2/100000 (but a lifetime risk of 1/300). Presentation is usually between the ages of 50 and 75. Below age 70, men are affected more often than women. Amyotrophic lateral sclerosis (ALS) is the term more commonly used for MND in some countries.

Pathogenesis

MND predominantly affects lower and upper motor neurons in the ventral horn of the spinal cord, cranial nerve motor nuclei, and frontal cortex. However, other neuronal systems may also be affected; 15% of patients also develop FTD (see 'Frontotemporal dementia' section) and up to 50% have some measurable frontal lobe cognitive impairment. MND is usually sporadic and of unknown cause, with good epidemiological evidence for a multistep process underlying the pathogenesis (the nature of the individual steps remains unknown, although genetic factors may account for a few steps). Age, family history, and cigarette smoking are the main known risk factors.

Ubiquitinated cytoplasmic inclusions containing the RNA processing proteins TDP-43 and FUS are the pathological hallmarks found in axons, indicating that protein aggregation may be involved in pathogenesis, as with other neurodegenerative disorders. Altered RNA processing, oxidative neuronal damage, and glutamate-mediated excitotoxicity have also been implicated in pathogenesis.

Between 5% and 10% of cases of MND are familial. A hexanucleotide GGGGCC repeat expansion in the *C9ORF72* gene on chromosome 9 is the most common cause of familial MND in European populations, and causes MND, FTD, and MND-FTD overlap syndromes. Mutations in the free radical scavenging enzyme superoxide dismutase *(SOD-1)* account for 15% of familial MND cases in European populations but 30% in selected Asian populations; *SOD-1* MND is pathologically distinct and not associated with FTD. Mutations in a number of other genes, including some that cause both FTD and MND such as *TDP-43* and *FUS*, have been identified.

Clinical features

Three main clinical subtypes are seen. The sensory system is not involved but a proportion of patients do report some sensory symptoms (but should not have major sensory signs).

- ***Amyotrophic lateral sclerosis (ALS).*** This is the classical presentation with simultaneous involvement of upper and lower motor neurons, usually in one limb, spreading gradually to other muscles in adjacent regions of the body. The typical picture is one of progressive focal muscle weakness and wasting (e.g., in one hand), with muscle fasciculations due to spontaneous firing of abnormally large motor units formed by surviving axons branching to innervate muscle fibres that have lost their nerve supply. The 'split hand' sign (disproportionate wasting of the thenar eminence and first dorsal interosseous, with sparing of the hypothenar eminence) may be present. Approximately 25% of patients have bulbar-onset disease, with a worse prognosis than limb-onset ALS, in which case dysarthria, dysphagia, nasal regurgitation of fluids, and choking are the presenting symptoms. Examination often reveals UMN signs, such as brisk reflexes (a brisk reflex in a wasted muscle is a classic sign), extensor plantar responses, and spasticity. A fasciculating tongue with slow, stiff tongue movements and brisk jaw jerk is the classic finding in bulbar-onset disease. Sometimes, an asymmetric spastic paraparesis is the presenting feature, with LMN features developing months later. Relentless progression of signs and symptoms over months allows confirmation of a diagnosis that may initially be suspected.
- ***Progressive muscular atrophy (PMA).*** This is a pure LMN presentation with weakness, muscle wasting, and fasciculations, usually starting in one limb and gradually spreading to involve other adjacent spinal segments. Survival is longer than in ALS but most patients diagnosed with PMA in life have evidence of UMN involvement at postmortem, implying that these are different faces of the same disease.
- ***Primary lateral sclerosis (PLS)*** (rare, 1%–2%). This is the least common form of MND and is confined to UMNs, causing a slowly progressive tetraparesis and pseudobulbar palsy. Recent criteria for PLS require isolated UMN signs for longer than 4 years. Survival is longer than in ALS.

Many authors consider that PMA and PLS are all part of the clinical spectrum of ALS. Overt evidence of mixed UMN and LMN

Box 28.46 Gold Coast criteria for diagnosing ALS (2019)

Progressive motor impairment documented by history or repeated clinical assessment, preceded by normal function.
AND
Upper and lower motor neuron dysfunction in ≥1 body region, or lower motor neuron dysfunction in ≥2 body regions. If only one body region is affected, UMN and LMN dysfunction must both be present.
AND
Investigations have excluded other disease processes.

involvement will often emerge, meaning that the majority of patients who do not have both lower and upper motor neuron signs initially are best classified as having ***upper motor neuron predominant*** or ***lower motor neuron predominant ALS***.

Diagnosis

Diagnosis is largely clinical. Gold Coast Criteria for the diagnosis of ALS focus on the progression of motor impairment, having excluded other causes (**Box 28.46**). There are no diagnostic tests but investigations (such as MRI and NCS) allow exclusion of other disorders. Denervation of muscles due to degeneration of LMNs is confirmed by EMG, and may confirm subclinical involvement of muscle groups, such as paraspinal muscles, allowing an earlier diagnosis in some patients.

Cervical spondylosis causing radiculopathy with myelopathy (resulting in upper and lower motor neuron signs) can cause diagnostic difficulty. Motor neuropathies, such as multifocal motor neuropathy, can also appear like MND (see 'Multifocal motor neuropathy with conduction block' section).

Prognosis and management

Death due to MND usually occurs within 3 to 5 years, although there are rare cases who survive for a decade or longer.

No treatment has been shown to influence outcome substantially. Patients should be supported by a specialist multidisciplinary team with access to palliative care and a clinical nurse specialist. Non-invasive ventilatory support and feeding via a gastrostomy help prolong survival and improve quality of life. Medication options are limited:

Riluzole, a sodium-channel blocker that inhibits glutamate release, modestly slows progression and increases life expectancy. Real-world studies suggest it may increase median survival by 6 to 19 months.

Edaravone has been approved in only a few countries, including the USA. It is a free radical scavenger that has shown some beneficial effects in a subgroup of patients with early disease.

Sodium phenylbutyrate-taurursodiol (PB-TURSO) has been shown to modestly slow clinical deterioration in ALS. Availability is very limited and the cost is high.

Tofersen is an antisense oligonucleotide that silences *SOD-1* and has been shown to slow functional decline by a small amount in patients with ALS caused by *SOD-1* variants. It is given intrathecally and is only available in a few countries.

CONGENITAL DISORDERS

Cerebral palsy (CP) is an umbrella term encompassing disparate disorders that are caused by non-progressive abnormalities in fetal or infant brain development, and are characterized by permanent motor deficits observed in early life. It is the most common form of physical disability in childhood and most affected children survive into adulthood. A variety of intrauterine and neonatal cerebral insults may cause CP, including prematurity and its complications, hypoxia, intrauterine infections, and kernicterus. In many cases, no specific cause can be identified.

Clinical features

Failure to achieve normal milestones is usually the earliest feature. Specific motor syndromes become apparent later in childhood or, rarely, in adult life.

- ***Spastic*** subtypes, including spastic diplegia (lower limb spasticity, with scissoring of gait), hemiplegia (one hemisphere is hypotrophic and the contralateral, hemiparetic limbs small), or quadriplegia (all limbs are affected).
- ***Dyskinetic*** presentations include choreoathetotic CP (with chorea—rapid dancing movements, and athetosis—slow writhing distal movements) and dystonic CP.
- ***Ataxic CP*** can occasionally be linked to a genetic cause or congenital hypoplasia of the cerebellum.
- ***Co-morbidities*** such as epilepsy and learning difficulty are common and at least as disabling as the motor deficit.

Dysraphism

Failure of normal fusion of the fetal neural tube leads to a group of congenital anomalies. Folate deficiency during pregnancy is contributory and supplements should always be given (see Chapter 25). Antiepileptic drugs, such as valproate, are also implicated (see 'Management' section in the 'Epilepsy' section). Neural tube defects may be open or closed (covered by skin); if there is a communication with the skin, bacterial meningitis may follow.

- ***Anencephaly*** is a large defect that leaves the cranial neural tube exposed and is not compatible with survival.
- ***Encephalocele*** involves extrusion of brain and/or meninges through a midline skull defect; protrusion can be minor or massive.
- ***Spina bifida*** is failure of lumbosacral neural tube fusion.
  - ***Spina bifida occulta*** or closed spinal dysraphism is isolated failure of vertebral arch fusion (usually lumbar), often seen incidentally on X-rays (3% of the population). A dimple or a tuft of hair may overlie the anomaly; clinical abnormalities are unusual.
  - ***Myelomeningocele*** consists of elements of spinal cord and lumbosacral roots within a meningeal sac. This herniates through a vertebral defect. In severe cases, both lower limbs and sphincters are paralyzed. Many babies will have a Chiari II malformation (herniation of the cerebellar tonsils and brainstem in association with the myelomeningocele) and associated hydrocephalus. ***Meningocele*** is a meningeal defect alone. The defect should be closed in the first 72 hours after birth; fetal surgery may be considered.

NEUROGENETIC DISORDERS

Approximately 80% of the 20 000 to 30 000 human genes are expressed in the brain. It is therefore not surprising that of the 5000 or so Mendelian disorders of humans, a high proportion are neurological disorders. Several hundred neurological disease genes have been identified and molecular genetic testing is now part of the neurological diagnostic process. Many of these disorders are covered in individual disease sections of this chapter.

Neurocutaneous syndromes

Neurofibromatosis type 1 (von Recklinghausen's disease)

One of the most common neurogenetic disorders, neurofibromatosis type 1 (NF-1) has a prevalence of 1 in 3000. Inheritance is autosomal dominant, but 50% of cases are due to new mutations with no family history. The protein is called neurofibromin 1. NF-1 is characterized by multiple skin neurofibromas and pigmentation (*café-au-lait* patches—see Chapter 45, 'Café-au-lait macules' section, axillary freckling and Lisch nodules of the iris). The neurofibromas arise from the neurilemmal sheath.

Skin neurofibromas present as soft subcutaneous, sometimes pedunculated, lumps (see Chapter 45, 'Neurofibromatosis type 1' section). They increase in number throughout life. Plexiform neurofibromas (**Fig. 28.41**) may develop on major nerves and proximal nerve roots, sometimes involving the spinal cord. Treatment is surgical removal if pressure symptoms develop. Associated features include learning difficulties, malignant transformation of neurofibromas, and bone abnormalities including scoliosis and fibrous dysplasia.

Neurofibromatosis type 2

Neurofibromatosis type 2 (NF-2) is much less common than NF-1. It is also autosomal dominant; the gene product, merlin or schwannomin, is a cytoskeletal protein. Many neural tumours occur:

- vestibular schwannomas (usually bilateral) in 90%
- meningiomas
- gliomas (including optic nerve glioma)
- cutaneous neurofibromas (30%).

Tuberous sclerosis (epiloia)

Features of this rare multisystem, autosomal dominant condition include adenoma sebaceum, renal tumours, and glial overgrowth in the brain (cortical tubers and subependymal nodules). Epilepsy (70%) and learning difficulties (50%) are common complications.

Von Hippel–Lindau disease

This rare condition is dominantly inherited. Cerebellar, spinal, and retinal haemangioblastomas develop and can be surgically removed. Tumours—renal cell carcinoma and phaeochromocytomas—may also occur. Polycythaemia sometimes develops.

Hereditary ataxias

A wide variety of genetic disorders cause cerebellar ataxia as the sole or predominant clinical feature. In children, consideration needs to be given to potentially reversible inborn errors of metabolism, typically autosomal recessive; the rest are progressive heredodegenerative disorders that can be autosomal recessive, X-linked, mitochondrial, or autosomal dominant. Several of the common disorders are due to trinucleotide repeat insertions (see Chapter 5, 'Triplet repeat mutations and genetic anticipation' section).

Fig. 28.41 **Plexiform neurofibroma.**

Increasingly, investigation of hereditary ataxias is undertaken through whole genome sequencing.

Early-onset ataxia

Most early (<20 years of age) onset inherited ataxias are autosomal recessive. Friedreich's ataxia is by far the most common, caused by a GAA trinucleotide repeat expansion in the frataxin gene (involved in mitochondrial iron metabolism). Onset is in the early teens with progressive difficulty in walking due to cerebellar ataxia and sensory neuropathy. Associated features include scoliosis, cardiomyopathy, optic atrophy, areflexia, and diabetes.

Ataxia telangiectasia is caused by homozygous variants in a DNA repair gene (ataxia-telangiectasia mutated gene, *ATM*), presents earlier than Friedreich's and affected individuals have telangiectasias, immunodeficiency, and an increased risk of malignancy.

Metabolic ataxias should be ruled out in childhood-onset presentations, as they are potentially treatable. The presentation may be intermittent (e.g., urea cycle disorders). Ataxia with vitamin E deficiency is a rare recessive ataxia that can mimic Friedreich's and may respond to high-dose vitamin E supplementation. Wilson's disease can also cause ataxia and may present in childhood or later in life.

Late-onset ataxia

Adult-onset (>20 years of age) inherited ataxias are usually dominantly inherited SCAs and there are over 40 different genetic forms, several of which are caused by CAG trinucleotide repeats. Some are 'pure' cerebellar ataxias and others are associated with additional features, such as peripheral neuropathy, pyramidal and extrapyramidal signs, movement disorders, retinal disorders, and cognitive impairment. Cerebellar atrophy is a common but non-specific imaging finding.

- ***SCA3*** (Machado-Joseph disease), with a CAG repeat in the ataxin 3 *(ATXN3)* gene is the most common autosomal dominant SCA. Patients have progressive ataxia, with oculomotor

abnormalities, and may have other features including spasticity, neuropathy, extrapyramidal features, and cognitive impairment. In common with other polyglutamine repeat disorders, the disease demonstrates anticipation.

- ***SCA2*** is caused by a CAG repeat expansion in the ataxin 2 *(ATXN2)* gene. Typical age of onset is in the fourth decade of life with a large range. Some patients develop features of motor neuron degeneration.
- ***SCA6***, with a CAG repeat expansion in the voltage-gated calcium channel subunit alpha 1A *(CACNA1A)* gene, is a 'pure' ataxia. Onset can be between the ages of 20 and 65, and the disease accounts for a significant proportion of apparently sporadic late-adult-onset progressive cerebellar ataxia.
- The recessively inherited cerebellar ataxia, neuropathy, and vestibular areflexia syndrome ***(CANVAS)*** has recently been shown to be caused by homozygous intronic repeat expansions in the replication factor C subunit 1 *(RFC1)* gene. Patients often have a chronic cough with varying combinations of cerebellar ataxia, sensory ataxia, and vestibulopathy. It is likely under-recognized.

PARANEOPLASTIC SYNDROMES

Neurological disease may accompany malignancy in the absence of metastases. These paraneoplastic syndromes are associated in many cases with anti-neuronal antibodies, believed to be involved in the generation of signs and symptoms. Numerous anti-neuronal antibodies have been described.

Clinical presentations with a high risk of underlying tumour include:

- subacute cerebellar degeneration
- opsoclonus-myoclonus syndrome
- limbic encephalitis (see 'Autoimmune encephalitis' section)
- encephalomyelitis
- subacute sensory neuronopathy (affecting the DRG)
- Lambert–Eaton myasthenic syndrome (LEMS; see 'Lambert–Eaton myasthenic syndrome' section) and MG with thymoma
- chronic gastrointestinal pseudo-obstruction (enteric neuropathy)
- dermatomyositis.

In addition to these 'classical' paraneoplastic neurological syndromes, polyradiculoneuropathy, stiff person syndrome (SPS), myelopathy, neuromyotonia, and anti-NMDA receptor encephalitis can all be paraneoplastic.

The neurological syndrome usually precedes evidence of the neoplasm: often a small-cell lung cancer, thymoma, or breast or ovarian cancer. Diagnosis is based on the clinical pattern and antibody profile. A classical syndrome or positive onconeuronal antibody should prompt a search for cancer; the neoplasm may be occult as it is held at bay by the immune response that also causes the neurological manifestations. Sometimes, when a cancer is not found initially, serial testing is required. Treatment is directed at both the underlying cancer and the immune system; except in selected syndromes treatment is often unsatisfactory.

PERIPHERAL NERVE DISEASE

Mechanisms of damage to peripheral nerves

Peripheral nerves consist of two principal cellular structures: the nerve nucleus with its axon, and the myelin sheath, which is produced by Schwann cells between each node of Ranvier (see Fig. 28.1). Blood supply is via vasa nervorum. Several mechanisms, some coexisting, cause nerve damage.

Demyelination

Schwann cell damage leads to myelin sheath disruption. This causes a marked slowing of conduction, seen, for example, in Guillain–Barré syndrome (GBS) and many genetic neuropathies.

Axonal degeneration

Axon damage causes the nerve fibre to die back from the periphery. Conduction velocity initially remains normal (compare demyelination) because axonal continuity is maintained in surviving fibres. A wide range of toxic and metabolic disorders damage peripheral nerves, as their long axons (requiring cellular transport of proteins from cell body to nerve terminals) make them uniquely vulnerable. This explains the concept of length-dependent neuropathy with the longest, most vulnerable axons (to the toes) being affected first.

Compression

Focal demyelination at the point of compression causes disruption of conduction. This typically occurs in entrapment neuropathies, such as CTS.

Infarction

Microinfarction of vasa nervorum occurs in diabetes (along with other mechanisms of peripheral nerve damage) and arteritis, such as polyarteritis nodosa and eosinophilic granulomatosis with polyangiitis (see Chapter 32, 'Small-vessel vasculitis' section). Wallerian degeneration occurs distal to the infarct.

Infiltration

Infiltration of peripheral nerves occurs by inflammatory cells in leprosy, by granulomas, such as in sarcoid, and by neoplastic cells.

Nerve regeneration

Regeneration occurs either by remyelination—Schwann cells produce new myelin sheaths around an axon—or by axonal growth down the nerve sheath with sprouting from the axonal stump. Axonal growth takes place at up to 1 mm/day.

Types of peripheral nerve disease

See Fig. 28.42.

- ***Neuropathy*** simply means a pathological process affecting a peripheral nerve or nerves.
- ***Mononeuropathy*** means a process affecting a single nerve.
- ***Mononeuritis multiplex*** means that several individual nerves are affected.

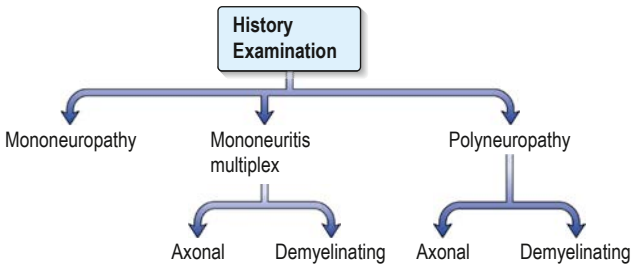

Fig. 28.42 Peripheral neuropathies. The type of neuropathy (axonal or demyelinating) can be assessed by electrical nerve studies (see 'Electromyography and nerve conduction studies' section).

- ***Polyneuropathy*** describes diffuse, typically symmetrical disease, usually commencing peripherally. The course may be acute, chronic, static, progressive, relapsing, or towards recovery. Polyneuropathies are motor, sensory, sensorimotor, and autonomic. They are classified broadly into demyelinating and axonal types, depending on which principal pathological process predominates. It is often impossible to separate these clinically. Many systemic diseases cause neuropathies. Widespread loss of tendon reflexes is typical, with distal weakness and distal sensory loss. ***Length-dependent*** distal dying-back axonopathies start at the toes and progress upwards; the fingertips are affected when the process reaches the knees.
- ***Radiculopathy*** means disease affecting nerve roots; ***plexopathy*** affects the brachial or lumbosacral plexus.
- ***Small fibre involvement*** may be seen with many neuropathies, particularly diabetic neuropathy, or may form an isolated small fibre neuropathy with prominent painful dysaesthesiae and burning. NCS only record from large fibres so will not detect a pure small fibre neuropathy.
- ***Neuronopathy*** affects the cell body (as in MND, or sensory ganglionopathy) rather than the peripheral axon or myelin sheath. The pattern is not length dependent, there may be global involvement (including the face) in sensory neuronopathy, and the distribution can be quite variable.

Diagnosis is made by clinical pattern, NCS/EMG, identification of systemic or genetic disease, and occasionally nerve biopsy (usually sural or radial). Diagnosis of small fibre neuropathy is often clinical but when confirmation is needed skin biopsy for intraepidermal nerve fibre density is useful. Identifying treatable causes and types of neuropathy is the main focus of work-up. Where there is an obvious cause with a chronic length-dependent neuropathy, extensive work-up is unnecessary, but if there is acute onset, rapid progression, or unclear cause, then more tests will be needed.

Clinical approach to neuropathy

The clinical approach to a patient with suspected neuropathy is summarized in **Box 28.47**.

i Box 28.47 Clinical approach to peripheral neuropathy

Is it a neuropathy?
- LMN weakness, worse distally or in a single nerve distribution
- Reduced or absent reflexes
- Sensory loss in the distribution of a single nerve, or in stocking/glove distribution
- Large fibre sensory involvement causes sensory ataxia; small fibre neuropathy presents with painful dysaesthesiae
- Differentials for flaccid weakness may include an acute cord lesion, muscle disease (more often proximal weakness but plexopathy/radiculopathy can also be proximal and muscle disorders occasionally cause distal weakness), neuromuscular junction disorder

What is the time course?
- Acute: GBS, some toxins (heavy metals), metabolic (B_1 deficiency, porphyria)
- Subacute: B_{12} deficiency, paraneoplastic, vasculitis, diabetic amyotrophy, vasculitis (often sequential involvement of individual nerves)
- Chronic: everything else (CIDP is occasionally relapsing)

What is the pattern?
- Mononeuropathy (often compressive)
- Mononeuritis multiplex (think vasculitis if painful, cryoglobulinaemia, leprosy)
- Polyneuropathy:
  - Symmetrical length-dependent neuropathy—usually axonal dying back but could be demyelinating, especially genetic
  - Proximal and distal weakness, symmetrical but non-length-dependent—consider demyelinating inflammatory neuropathy (GBS, CIDP)
  - Asymmetrical/patchy polyneuropathy—could be a confluent mononeuritis multiplex, or think about plexopathy/neuronopathy
- Plexopathy (diabetic amyotrophy, brachial neuritis, infiltrative, radiation)
- Radiculopathy (many potential causes but often compressive)
- Neuronopathy (sensory neuronopathy—think paraneoplastic, drugs, autoimmune including Sjögren's)
- Presence of cranial nerve involvement—rare in most neuropathies. Think GBS, occasionally CIDP, neoplastic/granulomatous causes, and MND. Reconsider muscle/neuromuscular junction process

Motor/sensory/autonomic involvement
- For pure motor syndromes, look very carefully for UMN signs to indicate ALS.
- Acute pure motor neuropathy can be GBS (acute motor axonal neuropathy variant), infection (botulism, diphtheria), porphyria (motor-predominant).
- More subacute or chronic motor neuropathies include lead toxicity, multifocal motor neuropathy with conduction block (MMN), distal hereditary motor neuropathy.
- Sensory involvement: is there prominent sensory ataxia (subacute combined degeneration of the cord, sensory neuronopathy)? Slowly progressive distal symmetrical sensory loss with sensory ataxia and tremor in an older person may indicate DADS (distal acquired demyelinating sensory neuropathy, often associated with an IgM paraprotein and antibodies to myelin-associated glycoprotein).
- Burning pain: implies a small fibre neuropathy (diabetes, Sjögren's, idiopathic, HSAN).
- The commonest cause of chronic late-onset pure sensory neuropathy/neuronopathy is probably *RFC1* gene mutation (CANVAS, see 'Late-onset ataxia' section).
- Marked autonomic involvement in a chronic neuropathy may suggest amyloidosis or diabetes. Acutely, autonomic involvement is seen in GBS.
- Most neuropathies are mixed sensorimotor but motor predominance (e.g., AIDP) vs sensory predominance (e.g., chemotherapy-induced polyneuropathy) should be noted.

Is it axonal or demyelinating?
- Demyelinating—immune mediated (GBS, CIDP, MMN, IgM paraproteinaemic neuropathy) or genetic (CMT1)
- Axonal—most other causes of neuropathy
- Mixed axonal and demyelinating features often seen in diabetic polyneuropathy

Associated features
- Pain—pain of nerve ischaemia in vasculitic neuropathy; burning/tingling pain with small fibre involvement
- Features of underlying systemic disease e.g., rash
- Nerve thickening (leprosy, genetic neuropathies)
- Joint/foot deformities (Charcot joints suggest chronicity; pes cavus implies neuropathy started during foot growth)
- Chronic cough—often predates the symptomatic neuropathy by decades in CANVAS
- UMN signs: for example, upgoing plantars and absent knee jerks. Seen in: motor neuron disease; subacute combined degeneration of the cord, Friedreich's ataxia, adrenomyeloneuropathy, HIV (or dual pathology)

ALS, Amyotrophic lateral sclerosis; *AIDP,* acute inflammatory demyelinating polyradiculoneuropathy; *CANVAS,* cerebellar ataxia with neuropathy and vestibular areflexia syndrome; *CIDP,* chronic inflammatory demyelinating polyradiculoneuropathy; *CMT,* Charcot–Marie–Tooth disease; *GBS,* Guillain-Barré syndrome; *HIV,* human immunodeficiency virus; *HSAN,* hereditary sensory and autonomic neuropathy; *MMN,* multifocal motor neuropathy with conduction block; *UMN,* upper motor neuron.

Box 28.48 Nerve compression and entrapment

Nerve	Entrapment/compression site
Median	Carpal tunnel (wrist)
Ulnar	Cubital tunnel (elbow)
Radial	Spiral groove (of humerus)
Posterior interosseous	Supinator muscle (forearm)
Lateral cutaneous of thigh	Inguinal ligament
Common peroneal	Neck of fibula
Posterior tibial	Tarsal tunnel (flexor retinaculum—foot)

Mononeuropathies

Peripheral nerve compression and entrapment

Nerves are vulnerable to mechanical compression at a few key sites (Box 28.48), such as the common peroneal nerve at the head of the fibula, or the ulnar nerve at the elbow. Entrapment develops in relatively tight anatomical passages, such as the carpal tunnel. Focal demyelination predominates at the compression site, and some distal axonal degeneration occurs.

These neuropathies are recognized largely by their clinical features. Diagnosis is confirmed by NCS.

The most common are mentioned here. All are seen more frequently in people with diabetes.

Carpal tunnel syndrome

This common mononeuropathy, median nerve entrapment at the wrist, is usually known as carpal tunnel syndrome (CTS). CTS is typically not associated with any underlying disease. It is, however, seen in:

- hypothyroidism
- pregnancy (third trimester)
- rheumatoid disease
- acromegaly
- amyloidosis.

Symptoms, signs, and management are discussed in Chapter 32 ('Carpal tunnel syndrome' section).

Ulnar nerve compression

The nerve is compressed in the cubital tunnel at the elbow. This follows prolonged or recurrent pressure and elbow fracture ('tardy ulnar palsy', as onset is very delayed).

There is clawing of the hand, wasting of interossei and hypothenar muscles, and weakness of interossei and medial two lumbricals with sensory loss in the little finger and splitting of the ring finger. Decompression and transposition of the nerve at the elbow are sometimes helpful but often disappointing.

Radial nerve compression

The radial nerve is compressed acutely against the humerus: for example, when the arm is draped over a hard chair for several hours, known as Saturday night palsy. Wrist drop and weakness of brachioradialis and finger extension follow. Recovery is usual, though not invariable, within 1 to 3 months.

Lateral cutaneous nerve of the thigh compression

This is also known as meralgia paraesthetica and is described in Chapter 32 ('Meralgia paraesthetica' section).

Common peroneal nerve palsy

The common peroneal nerve is compressed against the head of the fibula following prolonged squatting, yoga, pressure from a cast, prolonged bed rest or coma, or for no apparent reason. There is foot drop and weakness of ankle eversion. The ankle jerk (S1) is preserved. A patch of numbness develops on the anterolateral border of the dorsum of the foot and/or lateral calf. Confusion with an L5 motor radiculopathy may occur. Recovery is usual, though not invariable, within several months.

Hereditary neuropathy with pressure palsies (HNPP)

The genetic converse of Charcot–Marie–Tooth disease 1A (see 'Charcot–Marie–Tooth disease' section), this dominantly inherited disorder is due to deletion (as opposed to duplication) of a region of the *PMP-22* gene. Patients are susceptible to pressure palsies after minor compression episodes; even the brachial plexus may be involved. There is also a mild background neuropathy that develops gradually. Genetic testing can be performed.

Mononeuritis multiplex

Owing to the potential for serious and/or treatable causes, this pattern is a red flag, especially when neuropathies occur away from compression sites. Causes include:

- vasculitis, including eosinophilic granulomatosis with polyangiitis
- amyloidosis
- leprosy
- malignancy
- neurofibromatosis
- HIV and hepatitis C infection (cryoglobulinaemia)
- multifocal motor neuropathy with conduction block (MMN)/multifocal acquired demyelinating sensory and motor neuropathy (MADSAM)
- HNPP (see above)
- multiple compression neuropathies.

Several nerves, such as the ulnar, median, radial, and lateral popliteal, become affected sequentially or simultaneously. When multifocal neuropathy becomes confluent, there is difficulty distinguishing it from polyneuropathy. A carefully taken history will often reveal a mononeuritic onset, or asymmetrical polyneuropathy should raise a suspicion.

Polyneuropathies (peripheral neuropathy)

Many diseases cause polyneuropathy, by far the most common being diabetes. The diagnosis should not stop with identification of the polyneuropathy, but should involve a full diagnostic work-up to identify the underlying cause (Box 28.49). However, despite thorough investigation, the aetiology remains unknown in up to 50% of cases. Selected types of neuropathy are discussed below.

Clinical features. Duration, time course, distribution, and pattern of the different types of polyneuropathy vary considerably (Box 28.47).

Neurophysiological features. NCS allow separation into axonal and demyelinating forms. Demyelinating neuropathies are much more likely to be immune-mediated in aetiology and responsive to immunomodulation. With axonal neuropathies, the focus should be on finding a reversible metabolic or toxic cause.

Diagnostic investigations (in addition to neurophysiology). A stepped approach can be taken (Box 28.50).

Box 28.49 Causes of polyneuropathy

Demyelinating

Immune mediated
- Guillain–Barré syndrome
  - Acute inflammatory demyelinating polyradiculoneuropathy (AIDP)
  - Miller Fisher syndrome
- Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)
- Multifocal motor neuropathy with conduction block

Paraproteinaemic
- IgM paraproteinaemic neuropathies
  - Anti-MAG neuropathy
- POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) syndrome—can be mixed axonal/demyelinating

Hereditary
- Charcot–Marie–Tooth Disease (hereditary motor sensory neuropathy, HMSN) types 1 (AD), 4 (AR), and CMTX1
- Hereditary neuropathy with liability to pressure palsies (HNPP)
- Refsum disease

Toxic
- Selected drugs including amiodarone, tacrolimus, interferon-alpha, TNF-alpha blockers
- Immune checkpoint inhibitors

Axonal

Metabolic
- Diabetes mellitus (often have mixed axonal and demyelinating features)
- Uraemia
- Hepatic disease
- Thyroid disease
- Porphyria
- Vitamin/mineral deficiency:
  - B_1 (thiamine)
  - B_6 (pyridoxine; pyridoxine excess can also cause a sensory ganglionopathy)
  - B_{12}
  - Copper

Toxic
- Drugs (see **Box 28.52**)
- Alcohol
- Industrial toxins, e.g., lead, acrylamide

Infiltrative
- Amyloidosis (familial, senile, and AL)
- Malignancy, especially lymphoma

Hereditary
- Charcot–Marie–Tooth Type 2 (AD and AR)
- Hereditary motor neuropathy (HMN)
- Hereditary sensory and autonomic neuropathy (HSAN)
- CANVAS (cerebellar ataxia with neuropathy and vestibular areflexia syndrome)
- Friedreich's ataxia, ataxia-telangiectasia

Infective
- HIV
- Lyme disease
- Hepatitis B/C (commonly vasculitic neuropathy causing a mononeuritis multiplex)

Inflammatory/autoimmune
- Primary or secondary systemic vasculitis
- Non-systemic vasculitic neuropathy
- Neuropathies associated with systemic inflammatory diseases, e.g., Sjögren's syndrome (may be associated with a sensory neuropathy or neuronopathy)
- Paraneoplastic (may cause neuronopathy)
- Axonal GBS variants
  - Acute motor axonal neuropathy (AMAN)
  - Acute motor and sensory axonal neuropathy (AMSAN)

Other
- Idiopathic sensorimotor neuropathy
- Critical illness neuropathy
- Neuropathies associated with IgA or IgG paraproteins

Box 28.50 Investigations in peripheral neuropathy

Initial investigations
- Blood tests:
  - Full blood count, erythrocyte sedimentation rate, vitamin B_{12}, folate
  - Renal, liver, thyroid function, bone profile
  - Glucose, HbA_{1c}
  - Protein electrophoresis/immunofixation, immunoglobulins
  - Antinuclear antibody
  - HIV, hepatitis B + C
- Chest X-ray
- Urine: Bence Jones proteins

Selected patients
- Nerve conduction studies: to differentiate axonal from demyelinating forms
- Blood tests:
  - Anti-ganglioside antibodies
  - Anti-myelin-associated glycoprotein (anti-MAG) antibodies
  - Lyme disease
  - Cryoglobulins, vasculitis screen
  - Anti-Ro and anti-La
  - Porphyrins
  - Genetic tests (e.g., Friedreich's ataxia, CMT)
  - Serum-free light chains
  - Anti-neuronal antibodies
- Search for malignancy
- CSF analysis for protein (with demyelinating neuropathy)
- Nerve biopsy
- Labial salivary gland biopsy for Sjögren's
- Slit-skin smear for leprosy
- Skin biopsy for intraepidermal nerve fibre density (to diagnose small fibre neuropathy)

CMT, Charcot–Marie–Tooth disease.

Immune-mediated neuropathies

Guillain–Barré Syndrome

Guillain–Barré syndrome (GBS) is the most common cause of acute flaccid paralysis, and the most common acute polyneuropathy (3/100 000 per year). GBS describes any type of acute immune-mediated polyneuropathy, usually arising after an infection when the immune system reacts against epitopes on peripheral nerves that are similar to those on infectious agents (molecular mimicry).

Clinical features

The canonical syndrome is ***acute inflammatory demyelinating polyradiculoneuropathy*** (AIDP), in which symmetrical proximal and distal weakness progress rapidly, often associated with back pain and varying degrees of sensory loss, reaching nadir typically over 2 weeks (but a maximum of 4 weeks). While the legs are typically affected before the arms, this is not always the case, and many patterns of progression can be seen (including descending from the face). Descending paralysis should raise the differential of botulism but does not exclude GBS. Absent or reduced reflexes are a vital clue. Cranial nerve involvement is common. Bulbar and respiratory failure are much-feared complications, with about one in five patients requiring mechanical ventilation. Autonomic involvement is very common and can be fatal through inducing arrhythmias and blood pressure instability.

Several GBS variants are seen:

AIDP is the most common type of GBS in Western countries. The typical clinical picture is described above. Demyelinating features (slowed nerve conduction velocity, conduction block, temporal dispersion) will be seen on NCS.

Acute motor axonal neuropathy (AMAN) is frequently preceded by *Campylobacter jejuni* infection, and carries a worse prognosis than AIDP. Antibodies to various gangliosides (e.g., GM1) may be found. The damage is principally axonal and CSF protein is more likely to be normal than in AIDP.

Miller–Fisher syndrome consists of the triad of ataxia, areflexia, and ophthalmoplegia, and 90% of patients will have GQ1b antibodies. Pure MFS does not require immunomodulatory treatment and recovery is excellent. One-quarter of patients will develop clinical weakness as in GBS.

Diagnosis

The differential diagnosis includes other acute paralytic illnesses, such as botulism, cord compression, muscle disease, and myasthenia.

Diagnostic work-up includes a lumbar puncture, done mainly to exclude other causes (e.g., infective polyradiculitis). The classical finding is albuminocytological dissociation (elevated protein, often >1 g/L, with a normal white cell count). CSF protein may be normal early in the course of the illness in about one-third of patients.

Neurophysiological studies have a higher yield if done after at least one week of onset, and are not essential for diagnosis, but will delineate the type of GBS (e.g., axonal or demyelinating) and may be prognostically helpful.

Anti-ganglioside antibodies can shed light on the aetiopathogenesis but take too long to be useful diagnostically in the acute setting; an HIV test is mandatory as GBS can arise as a seroconversion illness. MR imaging may be needed to rule out other processes (e.g., cauda equina syndrome or acute myelitis); nerve root enhancement is a sensitive but non-specific sign of GBS.

Management and outcome

Management priorities in GBS include serial monitoring of weakness, bulbar function, respiratory function, and timely escalation to intensive care. Breathlessness or low oxygen saturations are a very late sign of respiratory muscle weakness and should not be relied upon: bedside spirometry is crucial. A forced vital capacity of less than 20 mL/kg or that has fallen by more than 30% from baseline warrants escalation to ITU. Cardiac monitoring is essential in patients with suspected dysautonomia. Thromboprophylaxis and avoidance of pressure ulcers are important.

Immunomodulatory treatment is warranted for patients who cannot walk unaided for more than 10 m, or who have rapidly progressive weakness, severe bulbar or autonomic dysfunction, or respiratory insufficiency. Treatment options include intravenous immunoglobulin (IVIG, 0.4 g/kg daily for 5 days), or plasma exchange (five sessions). The disease is almost always monophasic. Functional recovery is aided by expert rehabilitation, and is good in most cases but the course can be prolonged (recovery can continue for up to 3 years). Ten percent of patients will have ongoing severe motor impairments. The mortality of GBS is 5% even with modern treatment.

Chronic inflammatory demyelinating polyradiculoneuropathy

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) develops over months, causing progressive or relapsing proximal and distal limb weakness with sensory loss. Several variants, such as multifocal acquired demyelinating sensory and motor neuropathy (MADSAM), pure sensory and pure motor forms, occur. In some cases, cranial nerves may be involved.

There is no single diagnostic test but CSF protein is raised and patchy demyelination is usually seen on NCS. Some cases are associated with a serum paraprotein. Nerve biopsy is sometimes required. CIDP usually responds to long-term immunosuppression with steroids or to intravenous immunoglobulin.

Multifocal motor neuropathy with conduction block

A distal immune-mediated focal demyelinating motor neuropathy (often asymmetrical and predominantly in the hands) develops gradually over months with profuse fasciculation; hence there is confusion with MND (see 'Motor neuron disease' section). Conduction block and denervation are seen electrically. IgM antibodies to the ganglioside GM_1 are found in over 50% of cases.

Treatment is usually with regular intravenous immunoglobulin infusions that produce rapid but transient improvement. Steroids may cause the condition to worsen and should be avoided.

Paraproteinaemic neuropathies

Up to 70% of patients with a serum paraprotein have a neuropathy and some 10% of patients with no other identifiable cause for their neuropathy have a paraprotein. Most are associated with monoclonal gammopathy of unknown significance (MGUS; see Chapter 39, 'Monoclonal gammopathy of undetermined significance' section) but they are also seen in myeloma (see Chapter 39, 'Myeloma and other plasma cell disorders' section). The paraprotein may be pathogenic for the neuropathy (e.g., anti-MAG) or coincidental (particularly with non-IgM paraproteins associated with an axonal neuropathy).

IgM paraproteins: usually a demyelinating neuropathy. The paraproteins are often directed against myelin-associated glycoprotein (anti-MAG). The anti-MAG phenotype is a slowly progressive distal neuropathy with ataxia and prominent tremor (DADS—distal acquired demyelinating symmetric neuropathy). Anti-MAG neuropathy does not respond well to IVIG but may respond to rituximab, cyclophosphamide, or fludarabine. DADS can also be seen without a paraprotein in which case it is regarded as a CIDP variant.

POEMS syndrome (***P***olyneuropathy [demyelinating], ***O***rganomegaly [hepatomegaly 50%], ***E***ndocrinopathy [reduced testosterone usually], an ***M*** [para]protein band, and ***S***kin changes): probably caused by vascular endothelial growth factor (VEGF) release from a plasmacytoma. A mixed demyelinating and axonal neuropathy occurs. Treatment is of the plasmacytoma/plasma cell dyscrasia.

Primary AL amyloidosis causes an axonal painful neuropathy with autonomic dysfunction. Treatment is directed at the underlying plasma cell dyscrasia, without which prognosis is poor.

Cryoglobulinaemia causes a vasculitic neuropathy, presenting as painful mononeuritis multiplex or asymmetric polyneuropathy.

Metabolic, toxic, and vitamin deficiency neuropathies

Causes of the most common neuropathies are shown in **Box 28.49**.

Metabolic neuropathies

Diabetes mellitus

This is the most common cause of neuropathy in high income countries; 50% of patients with diabetes have neuropathy after 25 years. Good glycaemic control is protective against this microvascular complication of diabetes. Several varieties of neuropathy occur (see Chapter 35, 'Diabetic nephropathy' section):

- ***distal symmetrical sensorimotor neuropathy:*** slowly progressive, sensory loss predominates in a length-dependent stocking and glove distribution. Late cases are accompanied by weakness. The neuropathy may be asymptomatic and should be screened for regularly; it is related to diabetes duration and

glycaemic control. Mixed axonal and demyelinating features are frequently seen.

- ***mononeuropathy and multiple mononeuropathy (mononeuritis multiplex):***
  - cranial nerve lesions (e.g., medical third nerve palsy)
  - individual mononeuropathies (e.g., CTS) or mononeuritis multiplex
- ***diabetic amyotrophy*** or lumbosacral radiculoplexus neuropathy: a reversible vasculitic plexoneuropathy. There is pain followed by acute wasting and weakness of one leg, often associated with weight loss. Usually the weakness will plateau and then there will be some partial recovery; the contralateral leg or even the arms can become involved in some cases.
- ***autonomic neuropathy:*** postural hypotension, gastroparesis, and enteric neuropathy with constipation or diarrhoea can be intractable.

Diabetic neuropathy is typically not reversible with glycaemic control, but progression may be slowed with good management of the diabetes. Good footcare and control of neuropathic pain are the mainstays of treatment.

Uraemia

Progressive sensorimotor neuropathy develops in chronic uraemia. Response to dialysis is variable; the neuropathy may improve after transplantation.

Thyroid disease

A mild chronic sensorimotor neuropathy is sometimes seen in both hyperthyroidism and hypothyroidism. Myopathy also occurs in hyperthyroidism (see Chapter 34, 'Hyperthyroidism' section).

Porphyria

In acute intermittent porphyria (see Chapter 36, 'Porphyrias' section), there are episodes of a severe, mainly proximal neuropathy in the limbs, sometimes with abdominal pain, confusion, and coma. Alcohol, barbiturates, and intercurrent infection can precipitate attacks.

Amyloidosis

Polyneuropathy or multifocal neuropathy develops (see Chapter 39, 'Monoclonal gammopathies of clinical significance' section).

Toxic neuropathies

Alcohol

Polyneuropathy, mainly in the lower limbs, occurs with chronic alcohol use. It is a common cause of neuropathy. A myopathy may accompany it. For other neurological consequences of alcohol, see **Box 28.51**.

Drugs and industrial toxins

Many drugs (**Box 28.52**) and a wide variety of industrial toxins cause polyneuropathy. Toxins include:

- lead—motor neuropathy
- acrylamide (plastics industry), trichlorethylene, hexane, fat-soluble hydrocarbons, such as solvent abuse
- arsenic, thallium, and heavy metals.

Vitamin deficiency neuropathies

Vitamin deficiencies cause nervous system damage that is potentially reversible if treated early, and progressive if not. Deficiencies, often of multiple vitamins, develop in malnutrition.

Box 28.51 Neurological effects of ethyl alcohol

- Acute intoxication:
  - Disturbance of balance, gait, and speech
  - Coma
  - Head injury and sequelae
- Alcohol withdrawal:
  - Morning shakes
  - Tremor
  - Delirium tremens
- Thiamine deficiency:
  - Polyneuropathy
  - Wernicke–Korsakoff syndrome
- Epilepsy
- Acute intoxication
- Alcohol withdrawal
- Hypoglycaemia
- Cerebellar degeneration
- Cerebral infarction
- Cerebral atrophy, dementia
- Osmotic demyelination syndrome (ODS)
- Marchiafava–Bignami syndrome (corpus callosum degeneration, rare)

Box 28.52 Drug-related neuropathies

Drug	Neuropathy	Mode/site of action
Phenytoin	M	A
Chloramphenicol	S, M	A
Metronidazole	S, S/M	A
Isoniazid	S, S/M	A
Dapsone	M	A
Anti-retroviral drugs	S > M	A
Nitrofurantoin	S/M	A
Vincristine	S > M	A
Paclitaxel	S > M	A
Disulfiram	S, M	A
Cisplatin	S	A
Amiodarone	S, M	D, A
Chloroquine	S, M	A, D
Suramin	M > S	D, A
Immune checkpoint inhibitors	M > S	D

A, Axonal; *D*, demyelinating; *M*, motor; *S*, sensory.

Thiamine (vitamin B_1)

Dietary deficiency causes ***beriberi*** (see Chapter 25, 'Beriberi' section). Its principal features are polyneuropathy and cardiac failure. Thiamine deficiency also leads to Wernicke's encephalopathy and Korsakoff psychosis (see Chapter 30). Alcohol is the most common cause in Western countries and, rarely, anorexia nervosa or vomiting of pregnancy.

Pyridoxine (vitamin B_6)

Deficiency causes a mainly sensory neuropathy. In practical terms, this is seen as limb numbness developing during anti-tuberculosis therapy in slow isoniazid acetylators (see Chapter 20, 'Management' section in the "Tuberculosis' section). Prophylactic pyridoxine 10 mg daily is given with isoniazid.

Vitamin B_{12} (cobalamin)

Deficiency causes damage to the spinal cord, peripheral nerves, and brain.

Subacute combined degeneration of the cord (SACD). Combined cord and peripheral nerve damage is a sequela of pernicious anaemia and other causes of vitamin B_{12} deficiency (see Chapter 25, 'B vitamins' section). Nitrous oxide abuse causes functional B_{12} deficiency and can lead to SACD. Initially, there is numbness and tingling of fingers and toes; distal sensory loss, particularly of the posterior column; absent ankle jerks; and, with cord involvement, exaggerated knee jerks, and extensor plantars. Optic atrophy and retinal haemorrhage may occur. Rarely, neuropsychiatric changes are prominent. In later stages, sphincter disturbance, severe generalized weakness, and dementia develop.

Vitamin B_{12} levels should be checked; activated B_{12}, methylmalonic acid, and homocysteine levels may be particularly useful in the case of functional B_{12} deficiency, where the absolute levels may be normal. Parenteral B_{12} reverses nerve and cord damage although recovery may be incomplete; effect on the brain may be less impressive. Copper deficiency is a very rare cause of a similar picture.

Genetic neuropathies

Inherited neuropathy may occur as a 'pure' neuropathy disorder (e.g., Charcot–Marie–Tooth disease) or as part of a neurological multisystem disorder (e.g., spinocerebellar ataxia).

Charcot–Marie–Tooth disease

Charcot–Marie–Tooth (CMT) disease is a complex group of heterogeneous hereditary motor and sensory neuropathies (HMSNs) with multiple causative genes. Distal limb wasting and weakness typically progress slowly over many years, mostly in the legs, with development of pes cavus and variable loss of sensation and reflexes. In advanced disease, severe foot drop results but patients usually remain ambulant. Mild cases have pes cavus and toe clawing that can pass unnoticed.

- ***CMT1*** (HMSN1) is a group of autosomal dominant demyelinating neuropathies.
  - ***CMT 1A*** is the most common (70% of CMT; 1:2500 births), caused by duplication (or point mutation) of a 1.5 megabase portion of chromosome 17 encompassing the peripheral myelin protein 22 gene (*PMP-22*, 17p11.2). Deletions of the same portion of the gene cause HNPP, hereditary neuropathy with liability to pressure palsies (see 'Hereditary neuropathy with pressure palsies [HNPP]' section).
  - ***CMT 1B***—the second most common autosomal dominant demyelinating neuropathy due to mutations in the myelin protein zero gene *(MPZ)* on chromosome 1 (1q22).
- ***CMT 2*** *(HMSN 2)*—rare axonal polyneuropathies caused by a large number of different mutations, including *MFN2* or *KIFIB*; there is pes cavus with distal weakness and variable sensory loss. CMT2 can be AD or AR.
- ***CMTX1***—an X-linked dominant HMSN on chromosome Xq13.1; the gene product is a gap junction B1 protein (GJB1), also known as connexin 32. Nerve conduction velocity is in the intermediate range. Patients can also experience relapsing encephalopathy.
- ***CMT4*** is autosomal recessive with demyelinating pathology (very rare).

Hereditary motor neuropathy (HMN), also known as distal spinal muscular atrophy or distal hereditary motor neuropathy, is a rare cause of a pure motor syndrome, often affecting distal muscles and progressing slowly.

Hereditary sensory and autonomic neuropathies cause variable sensory loss, autonomic dysfunction, and neuropathic pain syndromes.

Other polyneuropathies

Neuropathy in cancer

Polyneuropathy or sensory neuronopathy is seen as a paraneoplastic syndrome (non-metastatic manifestation of malignancy). Many chemotherapy agents cause polyneuropathy. Polyneuropathy occurs in myeloma and other plasma cell dyscrasias via several mechanisms (see above). Individual nerves may be infiltrated with malignant cells, such as in lymphoma.

Neuropathies in systemic diseases

Vasculitic neuropathy occurs in SLE (see Chapter 32, 'Systemic lupus erythematosus' section), polyarteritis nodosa (Chapter 32, 'Polyarteritis nodosa' section), granulomatosis with eosinophilia (Chapter 32, 'Small-vessel vasculitis' section), and rheumatoid disease (Chapter 32, 'Rheumatoid arthritis' section). Non-systemic vasculitic neuropathy (localized only to the peripheral nerves) is much less common. Both multifocal neuropathy and a more confluent sensorimotor polyneuropathy occur. Vasculitic neuropathy responds to treatment with powerful immunosuppression including cyclophosphamide and rituximab; a nerve biopsy is often warranted prior to treatment.

Symmetrical axonal sensorimotor neuropathy is also more common in people with connective tissue disorders and other chronic inflammatory states; the exact pathogenesis is often opaque. Sjögren's syndrome can be associated with a sensory neuronopathy, or a more length-dependent sensory-predominant neuropathy.

Autonomic neuropathy

Autonomic neuropathy causes postural hypotension, urinary retention, erectile dysfunction, nocturnal diarrhoea, diminished sweating, impaired pupillary responses, and cardiac arrhythmias. This can develop in diabetes and amyloidosis (AL or TTR), and may complicate GBS. Many varieties of neuropathy cause autonomic problems in a mild form. Occasionally, such as with amyloidosis, a severe autonomic neuropathy may occur.

Neuromuscular weakness complicating critical illness

Some 50% of critically ill intensive care unit patients with multiple organ failure and/or sepsis develop an axonal polyneuropathy. This can delay ventilatory wean. Typically, distal weakness and absent reflexes are seen during recovery from critical illness. Resolution is usual.

Chronic sensorimotor neuropathy: no cause found

This situation is common. Progressive symmetrical numbness and tingling occur in hands and feet, spreading proximally in a glove and stocking distribution. Distal weakness also ascends. Tendon reflexes are lost. Symptoms may progress, remain static, or occasionally remit. Autonomic features are sometimes seen.

NCS usually show axonal degeneration. Nerve biopsy helps to classify selected cases: for example, diagnosing CIDP or unsuspected vasculitis.

Box 28.53 Common root and plexus problems

Nerve root
- Cervical and lumbar spondylosis
- Trauma
- Herpes zoster
- Tumours, e.g., neurofibroma, metastases
- Meningeal inflammation, e.g., syphilis, Lyme disease, arachnoiditis

Plexus
- Trauma
- Malignant infiltration
- Radiation damage
- Neuralgic amyotrophy (brachial neuritis)
- Diabetic amyotrophy (diabetic lumbosacral radiculoplexus neuropathy)
- Thoracic outlet syndrome (cervical rib)

Plexus and nerve root lesions

The common conditions that cause these are summarized in Box 28.53.

Cervical and lumbar degeneration

Spondylosis describes vertebral and ligamentous degenerative changes occurring during ageing or following trauma. Several factors produce neurological signs and symptoms:
- osteophytes—local overgrowth of bony spurs or bars
- thickening of spinal ligaments
- congenital narrowing of the spinal canal
- disc degeneration and protrusion (posterior and lateral protrusion: cord and root compression)
- vertebral collapse (osteoporosis, infection)
- rheumatoid synovitis (see Chapter 32, 'Rheumatoid arthritis' section)
- ischaemic changes within cord and nerve roots.

Narrowing of disc spaces, osteophytes, narrowing of exit foramina, and narrowing of the spinal canal are also seen on X-rays and MRI in the *symptomless* population, commonly in the mid- and lower cervical and lower lumbar region, and so imaging must not be over-interpreted.

Lateral cervical disc protrusion

The patient complains of pain in the arm. A C6-7 protrusion is the most common problem (Fig. 28.43). There is root pain that radiates to the C7 myotome (triceps, deep to scapula, and extensor aspect of forearm), with sensory disturbance, tingling, and numbness in the C7 dermatome.

In an established C7 root lesion, there is:
- weakness/wasting—triceps, wrist, and finger extensors
- loss of the triceps jerk (C7 reflex arc)
- C7 dermatome sensory loss.

Although the initial pain can be very severe, most cases recover with rest and analgesics. It is usual to immobilize the neck for a short time; gentle mobilization and physiotherapy should follow. Disc protrusion with root compression is seen on MRI. Root decompression is sometimes helpful.

Lateral lumbar disc protrusion

The L5 and S1 roots are commonly compressed by lateral prolapse of L4–L5 and L5–S1 discs; the root number below a disc interspace is compressed. There is low back pain and ***sciatica:*** pain radiating from the back to buttock and leg. Onset is typically acute. This can follow lifting, bending or minor injury. When pain follows such an event, it is tempting to ascribe the disc protrusion to it. However, commonly, lateral lumbar disc protrusion is spontaneous; lifting or injury is usually only brings forward an inevitable disc prolapse.

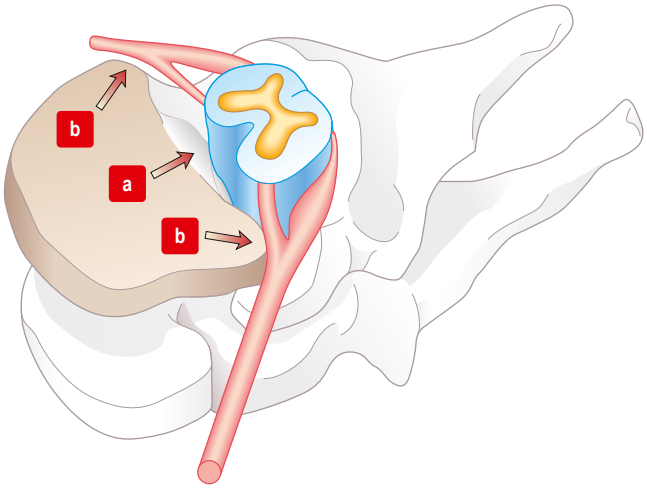

Fig. 28.43 Central and lateral disc protrusions. (a) Central disc protrusion compressing the cord. **(b)** Lateral disc protrusion compressing nerve roots.

Straight-leg raising is limited. There is reflex loss, such as ankle jerk in an S1 root lesion, and weakness of plantar flexion (S1) or great toe extension (L5); footdrop occurs in severe cases (L5). Sensory loss is found in the affected dermatome.

Most sciatica resolves with initial rest and analgesia, followed by early mobilization. MRI is sometimes appropriate. Surgery is indicated when a substantial persistent symptomatic disc lesion is shown.

Acute low back pain

Acute low back pain is extremely common. Often, pain is of disc or facet joint origin. Significant nerve root compression is unusual. Maintenance of activity and a trial of gentle manipulation are recommended (see also Chapter 32, 'Pain in the lower back' section).

Cervical spondylotic myelopathy

This is a relatively common disorder of older adults. Posterior disc protrusion (Fig. 28.44), common at C4–5, C5–6, and C6–7 levels, causes spinal cord compression. Congenital spinal canal narrowing, osteophytic bars, ligamentous thickening, and ischaemia are contributory. Usually, there are no or few neck symptoms. The patient complains of slowly progressive difficulty walking as a spastic paraparesis develops. There may be signs of myeloradiculopathy: LMN radicular signs at the level of the lesion (e.g., absent biceps and supinator jerks with a C5–6 disc protrusion), and brisk reflexes below the lesion (brisk triceps).

MRI demonstrates the level and extent of cord compression and T2 signal change is usually evident in the cervical cord at the point of maximal compression. Neck manipulation should be avoided.

Decompression by anterior cervical discectomy may be necessary when cord compression is severe or progressive. Improvement of the pyramidal signs may occur but is not guaranteed; progression is generally halted.

Spinal stenosis

A narrow spinal canal is developmental and frequently symptomless, but a congenital narrowing of the cervical canal predisposes the cervical cord to damage from minor disc protrusion later.

In the lumbosacral region, further narrowing of the canal by disc protrusion causes root pain and/or buttock and lower limb claudication. As the patient walks, nerve roots become hyperaemic and swell, producing buttock and lower limb pain with numbness (claudication). Surgical decompression is required.

Fig. 28.44 **C5/6 disc *(arrowed)* compressing the cord: T2-weighted MRI.**

Cauda equina syndrome

In severe cases of lumbar stenosis, or with large central disc herniations below the level of the conus, cauda equina syndrome may result, with bilateral leg weakness affecting multiple myotomes (L3–S1) and sphincter disturbance due to involvement of sacral nerve roots. This is a neurosurgical emergency.

Neuralgic amyotrophy (brachial neuritis)

Severe pain in the muscles around one shoulder is followed by wasting and weakness, usually of infraspinatus, supraspinatus, deltoid, and serratus anterior, evolving over several days. The cause is unknown but believed to be inflammatory; an allergic or viral basis is postulated. Rarely, a similar condition develops in distal upper limb muscles or in a lower limb. Recovery of wasted muscles is usual, but not invariable, over several months or years. There is no specific proven treatment.

Thoracic outlet syndrome

A fibrous band or cervical rib extending from the tip of the C7 transverse process towards the first rib compresses the lower brachial plexus roots, C8 and T1. There is forearm pain (ulnar border), T1 sensory loss, and thenar muscle wasting, principally of abductor pollicis brevis. A Horner's syndrome may develop. The rib or band can be excised. Frequency of this diagnosis varies widely; thoracic outlet problems are sometimes invoked to explain ill-defined arm symptoms, typically on poor evidence.

A rib or band can also produce subclavian artery or venous occlusion. Neurological and vascular problems rarely occur together.

Malignant infiltration and radiation plexopathy

Metastatic disease of nerve roots or the brachial or lumbosacral plexus causes a painful radiculopathy and/or plexopathy. An example is apical bronchial carcinoma (Pancoast's tumour) causing a T1 and sympathetic outflow lesion: wasting of small hand muscles, pain, and T1 sensory loss with an ipsilateral Horner's syndrome. This also occurs in apical tuberculosis.

In the upper limb, radiotherapy following breast cancer can produce a plexopathy. This is classically painless (as opposed to breast cancer metastases, which will produce a painful plexopathy). EMG in post-radiation plexopathy shows myokymia.

MUSCLE DISEASES

Definitions

- ***Myopathy*** means a disease of voluntary muscle.
- ***Myositis*** indicates inflammation.
- ***Muscular dystrophies*** are inherited disorders of muscle cells.
- ***Myasthenia*** means fatiguable (worse on exercise) weakness—seen in NMJ diseases.
- ***Myotonia*** is sustained contraction/slow relaxation.
- ***Skeletal muscle channelopathies*** are ion channel disorders of muscle cells.

Weakness is the predominant feature of muscle disease. A selection of these conditions is given in **Box 28.54**.

Pathophysiology

Muscle fibres are affected by:

- acute inflammation and fibre necrosis (e.g., polymyositis, infection)
- immunological damage (e.g., immune-mediated necrotizing myopathy)
- genetically determined metabolic failure (e.g., Duchenne muscular dystrophy)
- infiltration by inflammatory tissue (e.g., sarcoidosis)
- fibre hypertrophy and regeneration
- mitochondrial diseases
- ion channel disorders (e.g., chloride channel mutations in hereditary myotonias).

The NMJ is subject to immune-mediated damage (MG, LEMS), toxins (botulism, organophosphate poisoning), and genetic defects (congenital myasthenic syndrome).

Diagnosis

Clinical features, including the distribution of weakness, wasting or hypertrophy, and the tempo of progression and presence of family history contribute to a clinical diagnosis. Several investigations help make a definitive diagnosis.

Serum muscle enzymes

Serum creatine kinase (CK) is a marker of muscle fibre damage and is greatly elevated in many dystrophies, such as Duchenne, and in inflammatory muscle disorders, such as dermatomyositis. Elevated CK is not specific for muscle disease and can go up (usually to about 1000 IU/L) in MND, other neurogenic disorders, or after exercise; ethnicity has an effect on baseline CK.

Box 28.54 Muscle and neuromuscular junction disease: classification

Acquired
- Idiopathic inflammatory myopathy
  - Polymyositis (including anti-synthetase syndrome and overlap myositis)
  - Dermatomyositis
  - Immune-mediated necrotizing myopathy
  - Inclusion body myositis
- Other inflammatory
  - Viral, bacterial, and parasitic infection
  - Sarcoidosis
- Endocrine/toxic
  - Corticosteroids/Cushing's
  - Thyroid disease
  - Calcium disorders
  - Alcohol misuse
  - Drugs, e.g., statins, anti-retrovirals

Genetic
- Muscular dystrophies
  - Duchenne
  - Facioscapulohumeral
  - Limb girdle and others
- Myotonic dystrophy
  - Myotonic dystrophy type 1
  - Myotonic dystrophy type 2
- Skeletal muscle channelopathies
  - Myotonia congenita/paramyotonia congenita
  - Hypokalaemic/hyperkalaemic periodic paralysis
- Metabolic
  - Myophosphorylase deficiency (McArdle's syndrome)
  - Other defects of glycogen and fatty acid metabolism
  - Pompe disease
- Mitochondrial disease
- Congenital myopathies

Neuromuscular junction disorders
- Myasthenia gravis
- Lambert–Eaton myasthenic syndrome (LEMS)
- Botulism
- Congenital myasthenic syndrome

Neurogenetic tests

These are essential in muscular dystrophies and mitochondrial disease.

Electromyography

Characteristic EMG patterns are as follows:
- ***Myopathy***. Short-duration spiky polyphasic muscle action potentials are seen. Spontaneous fibrillation is occasionally recorded.
- ***Myotonic discharges***. A characteristic high-frequency whine is heard.
- ***Decrement and increment***. In MG, a characteristic decrement in evoked muscle action potential follows repetitive motor nerve stimulation. The reverse occurs, that is increment, following repetitive stimulation in LEMS (see 'Lambert–Eaton myasthenic syndrome' section).
- In ***denervation***, profuse fibrillation potentials are seen.

Muscle biopsy

Unlike neural tissue, skeletal muscle can be easily biopsied to provide a definitive diagnosis using powerful molecular immunohistochemical techniques. Histology and muscle histochemistry of fibre types demonstrate denervation, inflammation, and dystrophic changes. Electron microscopy is often valuable. In dystrophies, immunohistochemistry in specialist laboratories allows identification of the abnormal muscle protein and a precise molecular diagnosis.

Imaging

MRI shows ***signal changes*** within muscles in some cases of myositis, and fatty replacement of muscle in chronically damaged muscles.

Clinical approach to muscle disease

The clinical approach to patients with muscle disease is described in **Box 28.55**.

Inflammatory myopathies

Inflammatory myopathies, including polymyositis, dermatomyositis, immune-mediated necrotizing myopathy, and inclusion body myositis (IBM), are described in Chapter 32 ('Polymyositis and dermatomyositis' and 'Inclusion body myositis' sections). While IBM is often classified as an idiopathic inflammatory myopathy, it does not respond to immunosuppression and is a combined inflammatory and degenerative disease of muscle. Granulomatous muscle infiltration and inflammation may occur in sarcoidosis and other disorders such as rheumatoid arthritis, causing a mild myopathy. Viral myositis may also occur, and muscles may be involved in other infections such as neurocysticercosis (see Chapter 42, '*Taenia solium* and cysticercosis' section).

Metabolic and endocrine myopathies

Corticosteroids and Cushing's syndrome

Proximal weakness occurs with prolonged high-dose steroid therapy and in Cushing's syndrome (see Chapter 34, 'Cushing's syndrome' section). Selective type-2 fibre atrophy is seen on biopsy.

Thyroid disease

Several myopathies occur (see also Chapter 34, 'Hyperthyroidism' section). Thyrotoxicosis can be accompanied by severe proximal myopathy. There is also an association between thyrotoxicosis and MG, and thyrotoxicosis can cause an acquired hypokalaemic periodic paralysis. Both associations are seen more frequently in South-east Asia. In ophthalmic Graves' disease, there is swelling and lymphocytic infiltration of extraocular muscles (see Chapter 34, 'Graves' orbitopathy [ophthalmopathy]' section).

Hypothyroidism is sometimes associated with muscle pain and stiffness, resembling myotonia. A proximal myopathy also occurs.

Disorders of calcium and vitamin D metabolism

Proximal myopathy develops in hypocalcaemia, rickets, and osteomalacia (see Chapter 33, 'Rickets and osteomalacia' section).

Hypokalaemia

Acute hypokalaemia (e.g., with diuretics) causes flaccid paralysis reversed by potassium, given slowly (see Chapter 27, 'Hypokalaemia' section). Chronic hypokalaemia leads to mild, mainly proximal, weakness. (See also periodic paralysis; 'Hypokalaemic periodic paralysis' section).

Alcohol and drugs

Severe myopathy or rhabdomyolysis with muscle pain, necrosis, and myoglobinuria occurs in acute excess. A subacute proximal

Box 28.55 Clinical approach to muscle disease

Is it myopathy?

- Muscle weakness, typically proximal, and often symmetrical (with exceptions). Difficulty climbing stairs, rising from a seated or supine position; difficulty brushing hair or lifting arms above the head
- Distal weakness is less common. This may result in difficulty turning a key in a lock, or foot drop
- Reflexes will be reduced commensurate with the degree of weakness; if they are absent, that may be a sign of neuropathy. Muscle atrophy can ensue if the condition is chronic; rapid wasting is more common with a neurogenic process
- Myotonia (delayed relaxation after a forceful contraction; look for the slow-to-release handshake) may indicate dystrophic or non-dystrophic myotonias
- Cramps, contractures, stiffness, myoglobinuria may suggest a muscle disease
- NMJ disorders are accompanied by fatiguability and variability
- Dysphagia and dysarthria can be features of both nerve and muscle pathology; dysarthria always comes before dysphagia in motor neuron disease, so isolated oropharyngeal dysphagia is more likely to occur in myopathy or myasthenia (or from a non-neurological cause)
- Pain is not a feature of most muscle diseases. It can occur with metabolic myopathies, and fascial inflammation in idiopathic inflammatory myopathies will cause pain; otherwise, frequently the cause of pain will be rheumatological or secondary to altered forces in the presence of muscle weakness
- Sensory changes are absent

What is the time course?

- Acute/subacute: inflammatory myopathy, viral myositis, toxic insults, botulism
- Chronic and slowly progressive: muscular dystrophies, myotonic dystrophy, mitochondrial diseases
- Relapsing or variable: myasthenia gravis, metabolic myopathies, channelopathies

Age of onset

- At birth (floppy baby)—congenital myopathies including nemaline rod myopathy and central core disease; congenital muscular dystrophies (unlike the congenital myopathies, which tend to be static, congenital muscular dystrophies cause increased muscle breakdown with age); congenital myasthenic syndrome
- Childhood—congenital myopathies, endocrine/metabolic disorders, Pompe disease, juvenile dermatomyositis, Duchenne, Becker, FSHD, LGMD, Emery-Dreifuss muscular dystrophy, mitochondrial disorders
- Adulthood—a large number of disorders (including some that usually present in childhood but have a late-onset form)

Family history

- Autosomal dominant: myotonic dystrophy, FSHD, LGMD1, central core disease, oculopharyngeal muscular dystrophy
- Autosomal recessive: LGMD2, metabolic myopathies
- X-linked: Becker, Duchenne, Emery-Dreifuss muscular dystrophy
- Maternal transmission: mitochondrial

What is the pattern?

- Assess for involvement of the following muscle groups: ocular, facial, bulbar, neck, trunk, respiratory, shoulder girdle, hands/forearm, hip girdle, leg/foot
- Proximal weakness involving shoulder and hip girdles is the usual pattern
- Distal weakness may point to a specific disorder (weakness of long finger flexors in IBM, distal weakness in myotonic dystrophy, rare distal myopathies)
- Scapuloperoneal weakness (involvement of proximal arms and peroneal muscles) seen in FSHD (may be very asymmetrical), Emery-Dreifuss muscular dystrophy, Pompe disease
- Facial involvement in FSHD or myotonic dystrophy (myopathic facies). Can they whistle?
- Respiratory muscle involvement in Duchenne, Becker, Pompe disease, rapidly progressive inflammatory myopathies, and congenital myopathies
- Axial weakness in ryanodine receptor 1 myopathy; prominent neck extensor weakness in FSHD, idiopathic inflammatory myopathies, myotonic dystrophy, myasthenia gravis (beware: head drop can also be seen in MND)
- Ophthalmoplegia and/or ptosis may point to mitochondrial myopathy, myasthenia gravis, oculopharyngeal muscular dystrophy, or myotonic dystrophy (ptosis without ophthalmoplegia)

Provoking features

- Exercise-induced myalgia/rhabdomyolysis in metabolic myopathies
- Cold temperatures worsen myotonia congenita
- Drugs (e.g., aminoglycosides) and intercurrent illness can provoke a myasthenic crisis
- Large carbohydrate load can precipitate periodic paralysis

Associated features

- Recurrent rhabdomyolysis and myoglobinuria in metabolic myopathies
- Classical rash of dermatomyositis (see Chapter 32)
- Interstitial lung disease in antisynthetase syndrome (see Chapter 32) or features of systemic connective tissue disorder in overlap myositis (see Chapter 32)
- Contractures (inability to fully stretch a muscle because of fibrosis) are a feature of some types of inherited muscle disease (e.g., Emery-Dreifuss muscular dystrophy, calpainopathy—LGMD 2A/R1)
- Contractures can also refer to sustained painful muscle contractions, as seen in McArdle's disease
- Cardiac involvement can be a diagnostic pointer and also a worrying feature (arrhythmias in myotonic dystrophy, cardiomyopathy in Pompe disease, several muscular dystrophies; cardiac myositis can be a feature of anti-SRP necrotizing myopathy and rarely other types of inflammatory myopathy)
- Presence of frontal balding and cataracts in myotonic dystrophy; other multisystem features, e.g., diabetes, sensorineural hearing loss, epilepsy, in mitochondrial myopathies

FSHD, Facioscapulohumeral muscular dystrophy; *IBM,* inclusion body myositis; *MND,* motor neuron disease; *LGMD,* limb-girdle muscular dystrophy; *NMJ,* neuromuscular junction; *SRP,* signal recognition peptide.

myopathy occurs with chronic alcohol use. A similar acute myopathy occurs with cocaine, diamorphine, and amfetamine use.

Medications

Drug-induced muscle disorders include proximal myopathy (steroids), muscle weakness (lithium), painful muscles (fibrates), rhabdomyolysis (a fibrate combined with a statin, or interaction between statins and other drugs such as certain antibiotics), mitochondrial myopathy (zidovudine), and malignant hyperthermia (volatile anaesthetics, succinylcholine). Most respond to drug withdrawal. Immune checkpoint inhibitors, D-penicillamine, and TNF-alpha blockers can trigger an immune-mediated myopathy. Statins are also associated with immune-mediated necrotizing myopathy, in which case antibodies to 3-hydroxy-3-methyl-glutaryl-coenzyme A reductase (HMGCR) are found. The precise role of statins in the pathogenesis of this condition is unclear (and it can occur without prior statin exposure). Immunomodulatory therapies are necessary.

Myophosphorylase deficiency (McArdle's syndrome)

McArdle's syndrome is a muscle-only glycogenosis where there is a deficiency of muscle glycogen phosphorylase (PYGM). It presents with exercise intolerance, muscle cramps, fatigue, anaesthetic

problems, and myoglobinuria after exercise in adults; a 'second wind' phenomenon (improvement after 10 mins of exercise), as the switch to fatty acid metabolism is made, is classical. Diagnosis is made by genetic testing (or on a muscle biopsy, especially in atypical cases). Patients have a normal lifespan. Sucrose should be given before exercise, and regular mild-to-moderate aerobic exercise improves symptoms.

Acid maltase/acid alpha glucosidase deficiency (Pompe disease)

Pompe disease is an autosomal recessive lysosomal storage disease that leads to accumulation of glycogen within the lysosome (see Chapter 36). The classic form presents in infancy with hypotonia and hypertrophic cardiomyopathy, but a late-onset form with progressive limb-girdle weakness, respiratory failure, and bent spine also occurs. Acid maltase activity can be readily measured in a dry blood spot, prior to proceeding to genetic testing, and enzyme replacement therapies are available. A newborn screening programme is in place in many countries.

Malignant hyperthermia

Widespread skeletal muscle rigidity with hyperpyrexia as a sequel of volatile anaesthetics or succinylcholine (depolarizing neuromuscular blocking agent) is due in most cases to genetic defects in the pathways regulating sarcoplasmic reticulum calcium release. It is often inherited as a dominant trait, with variants in the muscle ryanodine receptor 1 *(RYR1)*, or the dihydropyridine receptor *(CACNA1S)*. Death during or following anaesthesia can occur in this rarity. Dantrolene is of some help for rigidity.

Neuromuscular junction disorders

Myasthenia gravis

Myasthenia gravis (MG) is an autoimmune disorder of NMJ transmission, characterized by weakness and fatiguability of proximal limb, bulbar, and ocular muscles, the latter sometimes in isolation. The prevalence is about 4 in 100 000. MG is twice as common in women as in men, with a peak age incidence around 30 and a second smaller peak in incidence in older men.

Antibodies to acetylcholine receptor protein (anti-AChR antibodies) are pathogenic. Immune complexes of anti-AChR IgG and complement are deposited at the postsynaptic membranes, causing destruction of AChRs. Antibodies against muscle-specific receptor tyrosine kinase (anti-MuSK antibodies) have been identified in anti-AChR antibody-negative cases.

Thymic hyperplasia is found in 70% of MG patients below the age of 40. In some 10%, a thymic tumour is found (paraneoplastic myasthenia), the incidence increasing with age. Thymoma-associated MG is more treatment-resistant.

There is an association between MG and other autoimmune disorders: thyroid disease, rheumatoid disease, pernicious anaemia, and SLE. Transient MG is sometimes caused by D-penicillamine treatment.

Clinical features

Weakness and fatiguability are typical. Limb muscles (proximal), extraocular muscles, speech, facial expression, and mastication muscles are commonly affected. Symptoms are worse towards the end of the day. Fluctuating diplopia and ptosis (often asymmetric) are frequent early symptoms, and symptoms may be confined to the eyes: ocular myasthenia. Respiratory and bulbar difficulties can occur in generalized myasthenia. Early complaints of fatigue are often dismissed.

Complex extraocular palsies, ptosis, and fatiguable proximal weakness are found on examination (prolonged upgaze should be checked and limb power tested after repetitive contractions). The reflexes are initially preserved but may be fatiguable: that is, they disappear following repetitive activity. Wasting is sometimes seen after many years.

Investigations

- ***Serum anti-AChR and anti-MuSK antibodies.*** Anti-AChR antibodies are present in some 80% to 90% of cases of generalized MG, and about 50% of cases of ocular MG. These antibodies are highly specific for MG and confirm the diagnosis. Anti-MuSK antibodies define a subgroup of MG patients (up to 10% in generalized disease) characterized by weakness predominantly in bulbar, facial, and neck muscles.
- ***Repetitive nerve stimulation and single-fibre EMG.*** A characteristic decrement occurs in the evoked muscle action potential during repetitive stimulation. Single-fibre EMG of orbicularis oculi is more sensitive but less specific than repetitive stimulation and shows block and jitter.
- ***Imaging and other tests.*** Mediastinal MRI or CT is needed to look for thymoma in all cases. Antibodies to striated muscle suggest a thymoma.

Course and management

MG fluctuates in severity; most cases have a protracted, life-long course. Respiratory impairment, nasal regurgitation, and dysphagia occur; emergency ventilation may be required. Simple monitoring tests, such as the duration for which an arm can be held outstretched, and the vital capacity, are useful.

Exacerbations are usually unpredictable and unprovoked but may be brought on by infections and by aminoglycosides and other drugs.

Drug treatment

Oral anticholinesterases

Pyridostigmine (60 mg tablet) is widely used. The duration of action is 3 to 4 hours, and the dose (usually 3–6 tablets daily) determined by response. Pyridostigmine prolongs acetylcholine action by inhibiting acetylcholinesterase. Overdose of anticholinesterases causes severe weakness (cholinergic crisis). Muscarinic side-effects, such as colic and diarrhoea, are common; oral propantheline (antimuscarinic) helps to control these. Anticholinesterases help weakness but do not alter the natural history of myasthenia.

Immunosuppressant drugs

These drugs are used in patients who are not fully controlled on pyridostigmine or who have severe weakness. Steroids are usually used and are the mainstay of treatment for myasthenia. There is improvement in 70%, although steroid dose should be increased slowly as there is a risk of steroid-dipping (an initial relapse triggered by steroids). Azathioprine, mycophenolate, and other immunosuppressants are introduced as steroid-sparing agents but take a long time to work.

Thymectomy

When a thymoma is present, the potential for malignancy makes surgery necessary but the myasthenia may not improve. In patients without thymoma, thymectomy improves myasthenia in patients with thymic hyperplasia and positive AChR antibodies. Practice varies but the evidence supports offering thymectomy to patients under the age of 50 with generalized AChR antibody-positive MG, with the aim of inducing remission, reducing the need for immunosuppression, and reducing hospital admissions.

It is not a cure and the effects take time; thymectomy should only be performed in patients with stable myasthenic symptoms. The benefits are less clear in older patients who have more atrophy of the thymus, but thymectomy can be considered on an individual basis; it can also be offered to patients with double-antibody-negative disease and patients with treatment-refractory ocular myasthenia.

Plasmapheresis and intravenous immunoglobulin

These produce a rapid dramatic response and are used in exacerbations and severe myasthenic crisis.

Biologics

Rituximab is used for treatment-refractory disease although the benefits for patients with MuSK antibodies seem to be greater than those with AChR antibodies. Eculizumab is a recombinant monoclonal antibody that reduces complement activation. It has been shown to be effective in trials of treatment-refractory MG but there is a significant increased risk of meningococcal disease. Ravulizumab is a similar agent with a longer half-life. Efgartigimod (an antibody fragment) and rozanolixizumab (monoclonal antibody) both block the neonatal Fc receptor and can be used as chronic immunotherapy or as a bridge therapy to minimize steroid exposure.

Other rare myasthenic syndromes exist, such as congenital myasthenia.

Lambert–Eaton myasthenic syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is a paraneoplastic manifestation of small-cell bronchial carcinoma due to defective acetylcholine release at the NMJ. A smaller proportion of cases are autoimmune without underlying malignancy. Proximal limb muscle weakness, mimicking a myopathy, sometimes with ocular/bulbar muscle involvement, develops, with some absent tendon reflexes: a cardinal sign. Weakness tends to improve after brief maximal muscle contraction, and absent reflexes return (compare myasthenia). More sustained exercise results in fatiguability. Diagnosis is confirmed by repetitive nerve stimulation (increment; see above). Antibodies to voltage-gated calcium channels are found in most cases (90%). Treatment with 3,4-diaminopyridine (DAP) is reasonably safe and effective.

Muscular dystrophies

These progressive, genetically determined disorders of skeletal and sometimes cardiac muscle have a complex clinical and neurogenetic classification.

Duchenne muscular dystrophy and Becker's muscular dystrophy

These are inherited as X-linked recessive disorders, though one-third of cases are spontaneous mutations. Duchenne muscular dystrophy (DMD) occurs in 1 in 3000 male infants. There is absence of the gene product *dystrophin*, a rod-shaped cytoskeletal muscle protein in DMD. In Becker's dystrophy, dystrophin is present but levels are low. DMD is usually obvious by the fourth year, and often causes death by the age of 20.

Dystrophin is essential for muscle cell membrane stability. Deficiency leads to reduction in three glycoproteins (α-, β-, and γ-sarcoglycans) in the dystrophin-associated protein complex (DAP complex) that links dystrophin to laminin within cell membranes.

Becker's muscular dystrophy is less severe than Duchenne and weakness only becomes apparent in young adults.

Clinical features

A boy with DMD is noticed to have difficulty running and rising to his feet; he uses his hands to climb up his legs (Gowers' sign). There is initially proximal limb weakness with calf pseudohypertrophy. The myocardium is affected. Severe disability is typical by the age of 10.

Investigations

The diagnosis is often suspected clinically. CK is grossly elevated (100–200 times normal). Biopsy shows variation in muscle fibre size, necrosis, regeneration and replacement by fat, and on immunochemical staining, absence of dystrophin.

Management

There is no curative treatment but steroids delay progression. New gene-editing therapies have been shown to increase dystrophin expression (but clinical benefit has not yet been established). Ataluren allows ribosomal read-through of a premature stop codon and so can be used for those patients with a nonsense mutation; it is approved in the UK and EU. Several other agents promote exon-skipping; access is limited. Physiotherapy helps prevent contractures in the later stages. Non-invasive respiratory support and multidisciplinary care improve life expectancy.

Carrier detection. Females with an affected brother have a 50% chance of carrying the DMD gene. In carriers, 70% have a raised CK, and usually EMG abnormalities and/or changes on biopsy. Carrier and prenatal diagnosis is available with genetic counselling.

Limb-girdle and facioscapulohumeral dystrophy

These less severe but disabling dystrophies are summarized in **Box 28.56**. There are many other varieties of dystrophy;

Box 28.56 Limb-girdle and facioscapulohumeral dystrophies

	Limb-girdle	Facioscapulohumeral
Inheritance	Recessive, dominant, or X-linked	Dominant, new mutations common
Onset	10–20 years	10–40 years
Muscles affected	Proximal: shoulders, pelvic girdle	Face, shoulders, scapular winging, upper arms, foot drop. Typically asymmetric
Progression	Severe disability <25 years	Life expectancy normal, slow progression
Associated features	Very variable. May include contractures, cardiac involvement, respiratory failure	Occasionally, deafness and retinal abnormalities
Diagnosis	Multiple genetic types Diagnosis on muscle biopsy, immunohistochemistry, and genetic testing	Genetic testing (muscle biopsy usually not required but may show inflammatory changes)

facioscapulohumeral dystrophy is one of the most common. Genes for numerous forms of limb-girdle muscular dystrophy have been identified. CK is usually moderately elevated.

Other inherited muscle disorders

- *Emery-Dreifuss muscular dystrophy* is a genetically heterogeneous group of disorders with onset in childhood, typified by early contractures, slowly progressive humeroperoneal weakness, and cardiac disease with cardiomyopathy and conduction defects.
- *Oculopharyngeal muscular dystrophy* causes progressive ptosis, ophthalmoplegia, dysphagia, and dysarthria starting in middle life; it mimics a mitochondrial myopathy.
- *Distal muscular dystrophies* such as Nonaka myopathy (hereditary IBM) start in the distal muscles and progress proximally.
- *Congenital myopathies* are caused by abnormalities of muscle development, and present with hypotonia in early life, often with breathing difficulties; they include central core disease (*RYR1* gene mutations) and nemaline rod myopathy (occasionally presents later in life).
- *Congenital muscular dystrophies* present in the first 2 years of life and cause progressive muscle breakdown over time; there may be associated central nervous system defects.

Myotonic syndromes

Myotonia denotes continued, involuntary muscle contraction after cessation of voluntary effort: that is, failure of muscle relaxation. EMG is characteristic (see 'Electromyography and nerve conduction studies' section). Myotonia can be caused by myotonic dystrophy, or by skeletal muscle channelopathies (myotonia congenita and paramyotonia congenita). Electrical myotonia can also be seen as a non-specific feature of other myopathies and with drug toxicity.

Myotonic dystrophy (DM)

This autosomal dominant condition is a genetic disorder with two different triple repeat mutations: most commonly, an expanded CTG repeat in a protein-kinase *(DMPK)* gene (DM1). There is a correlation between disease severity, age at onset, and approximate size of triplet repeat mutations. There is progressive distal muscle weakness, with ptosis, weakness, and thinning of the face and sternomastoids. Myotonia is typically present. Muscle disease is part of a syndrome comprising:

- cataracts
- frontal baldness
- cognitive impairment (mild)
- oesophageal dysfunction (and aspiration)
- cardiomyopathy and conduction defects (sudden death can occur in DM1)
- small pituitary fossa and hypogonadism
- glucose intolerance
- low serum IgG.

This gradually progressive condition usually becomes evident between 20 and 50 years. DM2 (or proximal myotonic myopathy—PROMM) is much less common. It is caused by an expanded CCTG repeat in a zinc finger protein gene. The clinical manifestations are similar to DM1 but less severe; there is more prominent proximal (hip-girdle) weakness.

Skeletal muscle channelopathies

Non-dystrophic myotonias

Myotonia congenita: clinical myotonia, usually mild, becomes evident in childhood, but may be ignored until much later in life. The gene, *CLCN1*, codes for a muscle chloride channel. The myotonia, which persists, is accentuated by rest and by cold. Warm-up phenomenon means the myotonia is relieved with repeated activity. Diffuse muscle hypertrophy occurs, meaning that although physically weak, the patient will have bulky muscles. Recessive and dominant forms occur.

Paramyotonia congenita worsens with exercise and cold and is caused by mutations in the sodium channel gene, *SCN4A*; it can be associated with hyperkalaemic periodic paralysis.

Hypokalaemic periodic paralysis

This disorder is characterized by generalized weakness, including that of bulbar muscles, which often starts after a heavy carbohydrate meal or following exertion. Attacks last for several hours. The disorder often first comes to light in the teenage years and tends to remit after the age of 35. Serum potassium is usually below 3.0 mmol/L in an attack. The weakness responds to (slow) intravenous potassium chloride. It is usually inherited as an autosomal dominant trait caused by mutation in a muscle voltage-gated calcium channel gene *(CACNA1S)*. Other mutations in the sodium channels *(SCN4A)* and potassium channels *(KCNE3)* also occur. Acetazolamide sometimes helps prevent attacks. Weakness can be caused by diuretics. A similar condition can also occur with thyrotoxicosis.

Andersen-Tawil syndrome presents with hypokalaemic periodic paralysis but is caused by mutations in a potassium channel gene, *KCNJ2*; patients have dysmorphic features and cardiac conduction defects that can lead to sudden death.

Hyperkalaemic periodic paralysis

This condition, also autosomal dominant, is characterized by attacks of weakness, sometimes with exercise. Attacks start in childhood and tend to remit after the age of 20; they last about 30 to 120 minutes. Myotonia may occur. Serum potassium is elevated. An attack can be terminated by intravenous calcium gluconate. There are point mutations in a muscle voltage-gated sodium-channel gene *(SCN4A)*. Acetazolamide or a thiazide diuretic can be helpful.

Stiff person syndrome

Stiff person syndrome (SPS) is a rare autoimmune disease, more common in females, causing axial muscle stiffness with abnormal posture, spasms, and falls. Attacks of stiffness are sometimes provoked by noise or emotion, but sometimes occur spontaneously. Between attacks, which last from hours to days or even weeks, the patient may appear normal.

Widespread muscle stiffness is typical during an attack; there are no other neurological signs. SPS has been mistaken for Parkinson's, dystonia, and functional neurological disorder. Anti-glutamic acid decarboxylase antibodies (anti-GAD) are found in very high titre in more than 50% of cases and are believed to be involved in the generation of muscle stiffness. Continuous motor activity in paraspinal muscles is seen on EMG.

Treatment with diazepam, other muscle relaxants, and intravenous immunoglobulin or plasma exchange can be helpful during attacks.

A form of SPS is also seen occasionally as a paraneoplastic condition associated with antibodies to the synaptic protein amphiphysin.

Mitochondrial diseases

These comprise a complex group of rare disorders involving muscle, peripheral nerves, and CNS, characterized by morphological

and biochemical abnormalities in mitochondria. Multisystemic involvement including diabetes, deafness, and cardiac involvement is common. Mitochondrial DNA is inherited maternally (see Chapter 5, 'Mitochondrial chromosome disorders' section), but many important mitochondrial proteins and functions are encoded in the nuclear genome (e.g., *POLG*). Therefore, inheritance of mitochondrial disorders can be autosomal dominant, autosomal recessive, X-linked, or maternal. The spectrum is wide, ranging from optic atrophy to myopathies, neuropathies, and encephalopathy.

- *MELAS* (*m*itochondrial *e*ncephalomyopathy, *l*actic *a*cidosis, *s*troke-like episodes) is one well-recognized form.
- Chronic progressive ophthalmoplegia (CPEO) is another.
- *MERRF* describes *m*yoclonic *e*pilepsy with abnormal muscle histology, the muscle appearance being described as *r*agged *r*ed *f*ibres.
- Leigh syndrome describes a subacute necrotizing encephalomyelopathy, usually in children.

CORE SKILLS AND KNOWLEDGE

Stroke medicine has developed as a subspecialty for doctors specializing in the acute management and rehabilitation of patients suffering a stroke. In the UK, stroke training is completed via a year of subspecialist training available to specialist trainees from parent specialties including neurology, geriatrics, rehabilitation medicine, or acute medicine.

Key skills in stroke medicine include:

- Outlining the key elements of a stroke history
- Applying the principles of hyperacute stroke management to clinical practice, for ischaemic and haemorrhagic stroke
- Developing a personalized secondary stroke prevention and rehabilitation strategy for individual stroke patients
- Explaining the principles of assessment and management of TIA.

Opportunities to learn stroke medicine include shadowing the on-call stroke doctors and witnessing acute stroke management (including thrombolysis and mechanical thrombectomy), attending ward rounds on an acute stroke unit, and observing the work of the multidisciplinary team in providing longer-term stroke rehabilitation.

BACKGROUND

Stroke is the second most common cause of death and a leading cause of disability worldwide, with one in four people over the age of 25 suffering a stroke in their lifetime. There is a 30% mortality rate and 40% dependency rate at 1 year after a stroke. The global burden of stroke disproportionately impacts middle- and low-income countries. Stroke rates are higher in Asian and Black African populations than in White populations. The incidence of stroke increases with age. However, stroke is not just a disease of older people, with one-quarter of all strokes occurring before the age of 65 years.

Definitions

Stroke is *defined* as a syndrome of rapid onset neurological deficit caused by focal cerebral, spinal, or retinal infarction or haemorrhage. Tissue injury is confirmed by neuroimaging. The clinical history is focused on rapidly establishing the onset of symptoms as well as determining risk factors for cerebrovascular disease (Box 29.1).

Transient ischaemic attack (TIA) refers to a brief episode of neurological dysfunction due to temporary focal cerebral or retinal ischaemia without infarction, such as a weak limb, aphasia, or loss of vision, usually lasting seconds or minutes with complete recovery. TIAs may herald a future stroke. Stroke and TIA are traditionally defined by the (arbitrary) duration of symptoms less than 24 hours (time-based definition); however, with the availability of advanced neuroimaging, a TIA may be differentiated by the absence of infarction on imaging (tissue-based definition).

PATHOGENESIS AND AETIOLOGY

The underlying pathology responsible for stroke is either infarction (85%) or haemorrhage (15%). Haemorrhagic stroke is outlined in detail in the 'Intracerebral haemorrhage' section. For further information on subarachnoid haemorrhage, extradural and subdural bleeding, refer to Chapter 11.

Infarction of brain tissue occurs due to a critical reduction in regional cerebral blood flow. This results in intracellular biochemical disturbance in the ischaemic tissues (with protein synthesis inhibition, lactic acidosis, and failure of ATP generation), causing anoxic depolarization, intracellular potassium efflux, and cell death (infarction). Major advances in therapy focus on early restoration of blood flow for salvageable brain tissue that has not yet infarcted. Notably, grey matter is more susceptible to ischaemia than white matter.

Cerebral autoregulation endeavours to compensate for reduced perfusion with dilation of leptomeningeal collateral blood vessels (Fig. 29.1). Blood flow can bypass the occluded vessel via the circle of Willis to supply leptomeningeal collaterals. This provides time to salvage ischaemic brain with thrombolysis or thrombectomy particularly as collateral failure often occurs over time.

Box 29.1 Taking a history in acute stroke

- A focused and rapid history is needed for hyperacute stroke to assess for thrombolysis and thrombectomy
- Collateral history is required if the patient is aphasic, disorientated, or drowsy
- A more comprehensive history can be obtained later

Presenting symptoms

- Time of symptom onset or last known to be well (provides guidance for thrombolysis and thrombectomy)
- Time of onset for a wake-up stroke is assumed to be when an individual fell asleep in the absence of advanced imaging to demonstrate otherwise
- Pattern of onset—acute and maximal at onset (embolic), stuttering or progressive (lacunar or haemorrhage)
- Triggers/activity at onset—Valsalva associated with patent foramen ovale-related stroke; migraine associated with specific triggers
- Orientation and alertness
- Localization
  - Anterior circulation symptoms: motor weakness, difficulty mobilizing, sensory loss, dysarthria, aphasia, neglect, dysphagia, apathy, abulia, and cognitive impairment
  - Posterior circulation symptoms: 5 Ds diplopia, dizziness (vertigo), dysphagia, dysarthria, drowsiness; ataxia, incoordination, sensory disturbance, nausea, vomiting, and visual loss

Screening questions for other relevant features

- Handedness—dominant or non-dominant
- Symptoms of raised intracranial pressure—vomiting or early morning headaches worse lying down, diplopia
- Systemic symptoms—malignancy (weight loss, nausea, etc.); inflammatory conditions (mouth ulcers, joint pains, alopecia, rash, muscle pain, jaw claudication, etc.) and fever (infections as triggers for stroke or vasculopathy due to meningitis or post-stroke complications)
- Urine and bowel incontinence or difficulty passing urine (urinary retention)
- Loss of consciousness, aura, muscle jerking, tongue biting, incontinence, and a drowsy post-ictal phase (features to suggest seizure as a stroke mimic)
- Disturbance of higher functions—personality change, cognitive decline, loss of executive control, disinhibition, psychiatric symptoms
- Positive symptoms such as visual flashing, spots, or tingling are more suggestive of stroke mimic such as migraine
- Pregnancy/postpartum (alternative aetiology and caution with secondary prevention therapy)
- Other symptoms (palpitations—atrial fibrillation; neck pain—dissection)

Past medical history

- History of previous TIA and/or stroke (ischaemic or haemorrhagic) and any residual deficit (contraindication to thrombolysis with recent stroke)
- Head injury (haemorrhage or dissection)
- Atherosclerotic risk factors—hypertension, diabetes, other cardiovascular disease; hypercholesterolemia
- Embolic risk factors—atrial fibrillation, patent foramen ovale, recent myocardial infarction, prosthetic heart valve
- Pre-existent cognitive impairment
- Diabetes—time since diagnosis, degree of glycaemic control, presence of other complications
- Malignancies, systemic inflammatory disorders, immunosuppressive conditions, e.g., HIV
- Recent COVID (SARS-CoV-2)
- Recent surgery/epidural (contraindication to thrombolysis)

Medication and allergies

- Anticoagulants and time last taken—contraindication to thrombolysis
- Antiplatelets, antihypertensives
- Hypoglycaemic agents
- Oral contraceptive or hormone replacement therapy (thrombosis risk)

Family history

- Cardiovascular disease
- Young onset dementia and small vessel disease (genetic disease)
- Young onset systemic disease including renal, eye, and hearing disease (genetic link)

Activities of daily living

- Modified Rankin Scale for measuring dependence

Lifestyle factors

- Smoking, alcohol or illicit drug consumption and obesity

Social history

- Driving
- Employment
- Type of dwelling (e.g., bungalow, care home)
- Stress or bereavement
- Family support and social network

Address concerns and expectations

Focused history for hyperacute stroke management (aim <10 minutes as time is brain)

TOAST classification

The TOAST trial ('**T**rial of **O**RG10172 in **A**cute **S**troke **T**reatment') was one of the first multicentre trials of acute stroke management carried out in the USA, and the classification system used in the trial (the 'TOAST classification') is the most widely used aetiological classification system for ischaemic stroke. The different subtypes of stroke are summarized in Box 29.2 below.

Large artery atherosclerosis

Atherosclerosis is the most common process contributing to stroke with increasing age, with large artery atherosclerosis associated with nearly 20% of ischaemic stroke. It involves a chronic inflammatory process with platelet activation and aggregation after atherosclerotic plaque disruption leading to thrombus formation, with distal embolization to cerebral vessels causing an acute thromboembolic stroke or TIA. Less commonly, gradual atherothrombotic vessel occlusion can occur leading to cerebral hypoperfusion and haemodynamic/hypoperfusion-related stroke. Alternatively, if this process occurs in the presence of adequate collateral circulation, patients may remain asymptomatic despite almost-complete vessel occlusion.

Arterial branch points, such as the origin of the great vessels arising from the aorta, the proximal internal carotid artery, and its distal intracranial branches, are particularly affected (Fig. 29.2). Populations from the Black or Asian ethnic groups tend to have more hypertension, diabetes, and a higher incidence of intracranial atherosclerosis compared with White populations (where extracranial atherosclerotic disease is more common). Carotid extracranial atherosclerosis is correlated with coronary artery and peripheral vascular atherosclerosis.

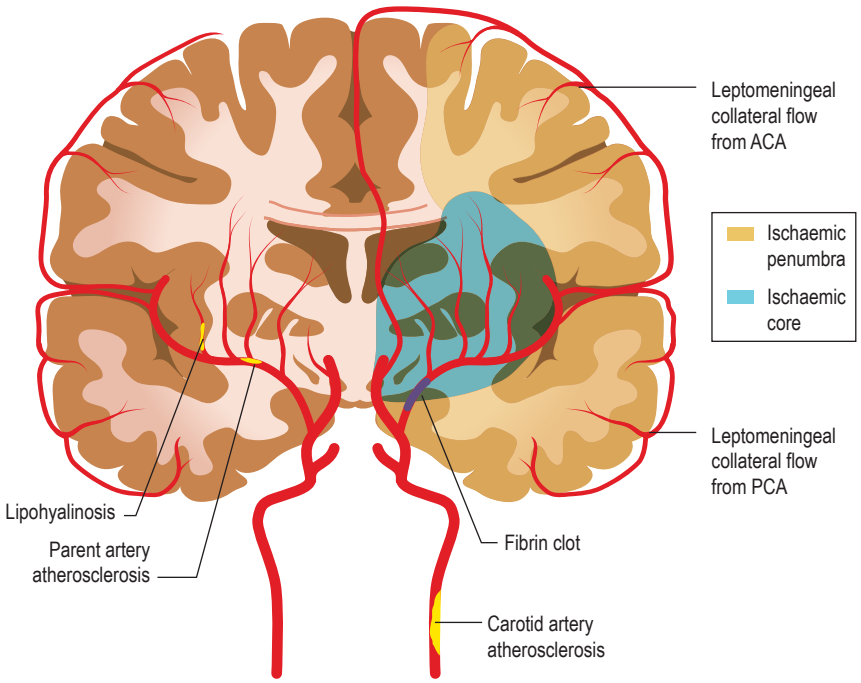

Fig. 29.1 **Collateral circulation.**

Box 29.2 Aetiology outlined based on TOAST classification

Large artery atherosclerosis
Carotid atherosclerotic disease >50% Intracranial atherosclerosis Aortic arch atheroma
Cardioembolism
High risk, e.g., atrial fibrillation or mechanical heart valve Medium risk, e.g., patent foramen ovale, bioprosthetic (non-mechanical) heart valve
Small vessel occlusion (lacune)
Other determined causes
Nonatherosclerotic vasculopathies (aortic or carotid dissection, CNS vasculitis primary or secondary such as giant cell vasculitis, infectious vasculopathy such as varicella zoster virus, illicit drug abuse, fibromuscular dysplasia, dolichoectasia) Hypercoagulable disorders (malignancy, antiphospholipid syndrome, thrombophilia, systemic lupus erythematosus, disseminated intravascular coagulopathy, hyperhomocystinaemia) Haematological disorders (essential thrombocytosis, polycythaemia rubra vera, sickle cell) Infections (HIV, neurosyphilis) Genetic causes (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy CADASIL, mitochondrial diseases, Fabry's disease) Sympathomimetic drugs (e.g., cocaine)
Undetermined
Two or more causes Negative evaluation Incomplete evaluation

The principal risk factors for atherosclerosis include older age, male sex, smoking, hypertension, hyperlipidaemia, diabetes, obesity, physical inactivity, a diet high in saturated fat, alcohol excess, chronic inflammatory disease, metabolic syndrome, and genetic/ethnic factors. (See Fig. 29.14, Risk factor attributable burden of stroke in the 'Secondary prevention' section.)

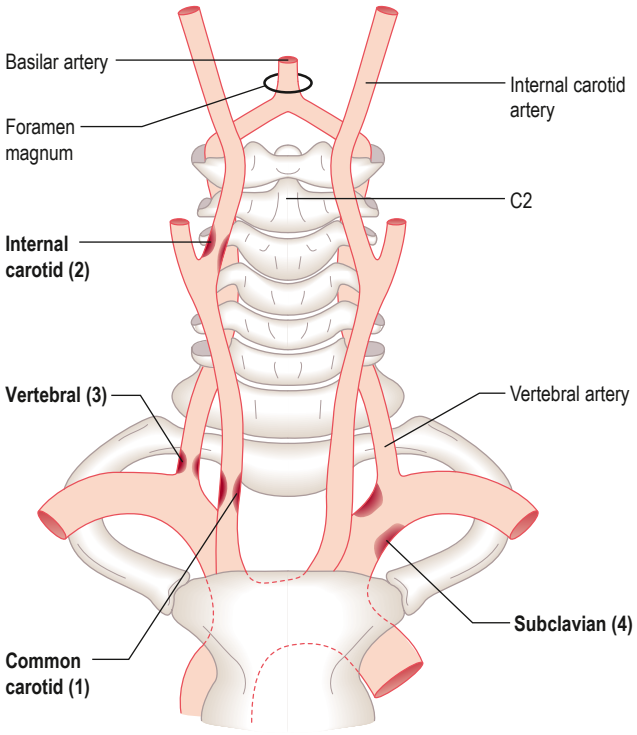

Fig. 29.2 **Principal sites of stenoses in extracerebral arteries.**

Cardioembolism

The heart is a common source of brain emboli, which travel from the heart to intracranial vessels causing occlusion and ischaemia (Fig. 29.3). Cardioembolism is responsible for a quarter of all ischaemic strokes. Infarcts in multiple vascular territories are very suggestive of a proximal source of emboli in the heart or aorta. Other features of cardioembolic stroke include wedge infarcts involving cortical and

subcortical tissue. Cardioembolic strokes often cause severe disability (Fig. 29.4).

Atrial fibrillation is the most common source with the left atrial appendage being the main source of thrombus. Other high-risk causes of cardioembolism include valvular heart disease, including rheumatic mitral valve stenosis and infective endocarditis. Mural thrombosis may occur in dilated cardiomyopathy or associated with akinetic left ventricle segments, although risk has reduced with coronary reperfusion therapy after myocardial infarction. Similarly, advances in therapy have led to a reduction in the thromboembolism risk associated with prosthetic heart valves (careful anticoagulation) and aortic arch atheroma (effective secondary prevention in high-risk patients).

Lower-risk causes include patent foramen ovale (PFO), a persistent remnant of the foramen ovale in the intra-atrial septum that is found in a quarter of the general population (see Chapter 17). While the majority of PFOs are asymptomatic, paradoxical embolism can occur via right-to-left shunting between the venous and arterial system. Likewise, pulmonary arteriovenous fistulas may also act as a conduit for paradoxical embolization. Rarer causes include atrial myxomas and iatrogenic causes, such as cardiac bypass and air embolism.

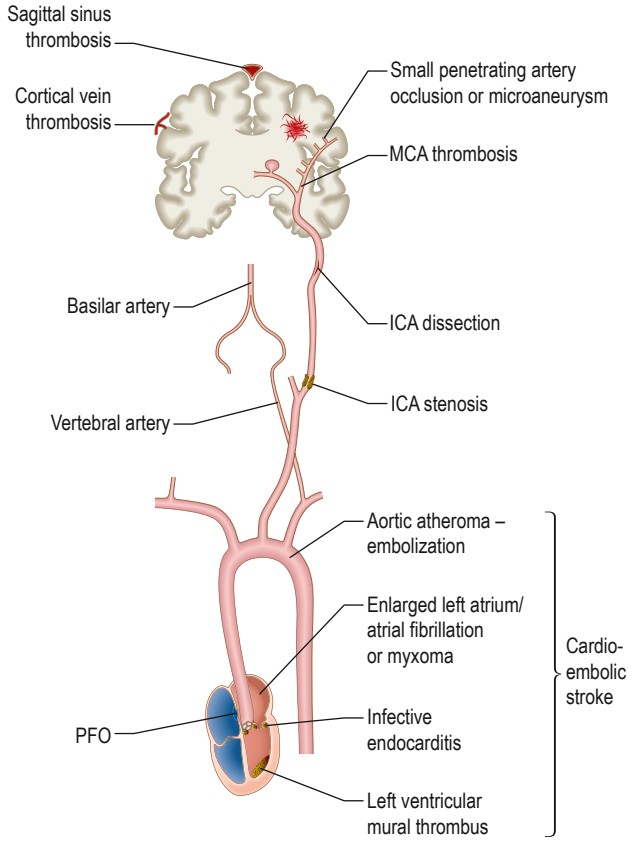

Fig. 29.3 Pathophysiology of ischaemic stroke.

Small vessel disease

Small vessel disease is the most prevalent brain disease, contributing to a quarter of all ischaemic strokes, 45% of dementia, and 80% of intracerebral haemorrhage (ICH) cases. Small penetrating arterial branches supply the deep brain parenchyma and are affected by a different pathological process: a diffuse vasculopathy—traditionally identified as lipohyalinosis but now recognized to include endothelial dysfunction and subtle increases in blood–brain barrier permeability. Other putative mechanisms include hypertensive arteriosclerosis, branch atheromatous disease, microembolism or cerebral hypoperfusion. The hallmark of this disease process is formation of lacunes (2–15 mm diameter fluid-filled areas of infarcted brain tissue in the deep cerebral white matter, basal ganglia, or pons). Neuroimaging may reveal gradual accumulation of white matter hyperintensities, perivascular spaces and cerebral microbleeds. Clinically, there may be stepwise deterioration associated with lacunar strokes, gradual cognitive impairment and gait impairment, or the disease may remain silent for many years. The related phenomenon of vascular dementia is discussed in more detail in Chapter 28. The most common risk factors include hypertension and diabetes. Smoking and excess alcohol contribute to a lesser extent. While lacunar infarcts are traditionally considered non-embolic, 10% to 15% may be embolic, and so the aetiological work-up must incorporate a search for common cardioembolic sources such as atrial fibrillation. More recently, cerebral amyloid angiopathy (CAA) is a recognized cause of small vessel disease with radiological features extending from

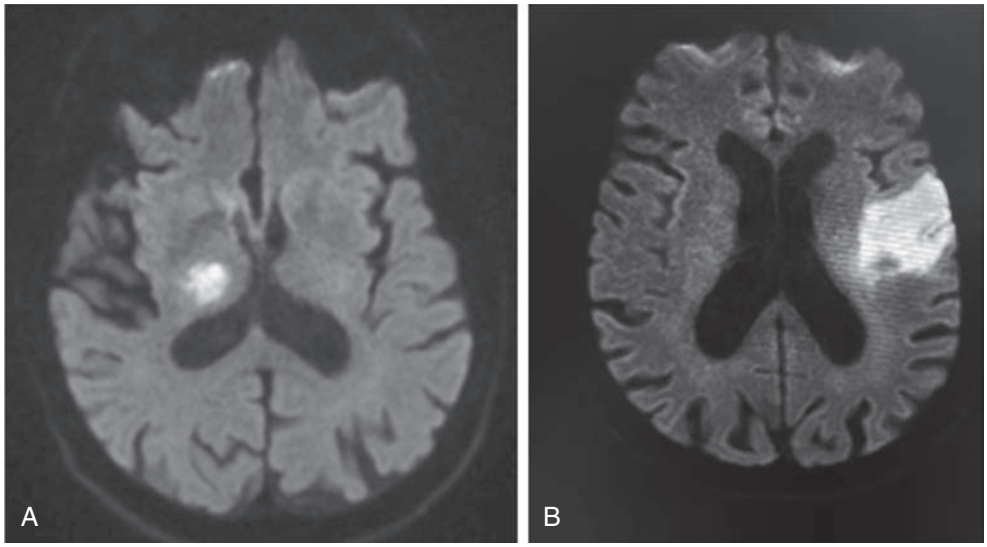

Fig. 29.4 Lacunar and embolic stroke pattern on neuroimaging. The left hand image **(A)** is the lacunar infarct in the right basal ganglia; the right hand image **(B)** is the embolic infarct of the left middle cerebral artery.

multispot white matter hyperintensities to centrum semi-ovale perivascular spaces as well as the more frequently recognized haemorrhagic manifestations (see 'Intracerebral haemorrhage' section).

Stroke of other determined aetiology

Carotid and vertebral artery dissection

Cervical artery dissection can occur at any age, but accounts for 5% to 25% of stroke cases in younger people, often with few established stroke risk factors. Dissection results from separation of arterial wall layers with an intramural haematoma, and this can lead to arterial stenosis, occlusion, or aneurysm formation. Thrombosis within the true lumen due to tissue factor release and platelet activation leads to embolization of the brain from the site of dissection, sometimes 2 to 3 weeks after the initial event.

It may be a sequelae of neck trauma (often trivial) or hyperextension; for example, after whiplash, osteopathic manipulation, hair washing in a salon, or exercise. Vascular abnormality (e.g., fibromuscular dysplasia) and collagen diseases (e.g., Marfan's) are well known to predispose to dissection.

Most dissections are in large extracranial neck vessels, with carotid stenosis typically occurring 2 to 3 cm beyond the carotid bulb, producing a tapering or flame-shaped stenosis and extending to the petrous canal on vascular imaging. Vertebral artery dissection typically occurs distally near the skull base and may extend intracranially. Pain in the neck or face is often the clue leading to diagnosis. Horner's syndrome may occur with carotid dissection, as the sympathetic plexus is intimately associated with the carotid artery in the neck. Neurological deficits vary or may be absent.

Venous stroke

Thrombosis within intracranial venous sinuses, such as the superior sagittal sinus, or in cortical veins is a rare form of stroke (see Chapter 11). This may occur in association with hypercoagulable states including pregnancy, thrombotic disorders, malignancy, obesity, oral contraceptive use, dehydration, and infections (COVID-19). Venous sinus thrombosis should be suspected in a stroke which does not follow the usual arterial territories. The most frequent presentations are headaches, seizures, focal neurological deficits, and encephalopathy.

Hypoperfusion

Systemic hypoperfusion states like reduced cardiac output and/or profound hypoxaemia may lead to border-zone infarction in the watershed areas between vascular territories, particularly if there is severe stenosis of proximal carotid vessels. It can affect either the superficial (fronto-parietal or parieto-occipital areas) or deep watershed territories—the latter causing 'rosary bead' appearance in neuroimaging.

There are many other stroke aetiologies, some requiring specific management for example infectious or inflammatory disease (see **Box 29.2**).

Stroke of undetermined aetiology

Approximately one-quarter of all strokes are cryptogenic without an identified source (not attributed to cardioembolism, small vessel disease, or large artery atherosclerosis). These can be further divided based on neuroimaging features into lacunar or embolic stroke patterns (**Fig. 29.4**). Embolic source of undetermined source (ESUS) may occur because of undiagnosed atrial fibrillation and complex aortic plaque among other causes.

STROKE CLASSIFICATION BY VASCULAR TERRITORY

Vascular anatomy

The circle of Willis is supplied by the two internal carotid arteries (the anterior circulation) and by the vertebrobasilar (posterior) circulation. The distribution of the anterior, middle, and posterior cerebral arteries that supply the cerebrum is shown in **Figs. 29.5 and 29.6**. Occasionally, posterior cerebral arteries arise from internal carotid arteries rather than basilar system—these are termed fetal posterior cerebral arteries. This is of relevance as an occipital infarction may arise from internal carotid artery atherosclerosis.

Knowledge of normal arterial anatomy and likely sites of atheromatous plaques and stenoses helps understanding of the main stroke syndromes. **Box 29.3** outlines the major vascular territories and their corresponding stroke syndromes. Principle motor and sensory pathways are shown in **Figs. 28.11 and 28.15**. Brainstem tracts are shown in **Fig. 29.7**.

Anterior circulation clinical stroke syndromes

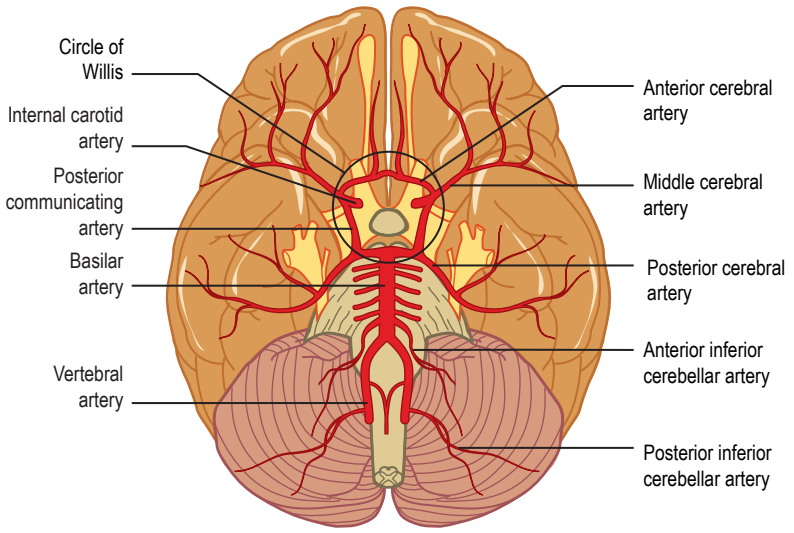
This includes infarcts in the territory of the internal carotid, middle cerebral (MCA), anterior cerebral (ACA), and ophthalmic arteries. Complete MCA occlusion results in a devastating stroke as multiple cortical areas are infarcted, with contralateral hemiplegia and facial weakness (primary motor cortex), hemisensory loss (primary sensory cortex), neglect syndromes (parietal lobe), eye deviation towards the affected side (frontal eye fields), aphasia (dominant hemisphere lesions) and hemianopia (optic radiation). Brain swelling of infarcted tissue leads to a high risk of death due to brain herniation—so-called 'malignant MCA infarction'. A similar picture to MCA stroke is caused by internal carotid occlusion, although collateral circulation may reduce the infarct size (see Fig. 26.31).

MCA branch occlusions produce fragments of the picture described above, such as hemiparesis, monoparesis, or aphasia. Occlusion of lenticulostriate perforating arteries (or MCA occlusion with collateral circulation protecting the cortex) causes infarction of deep subcortical structures such as the internal capsule, resulting in hemiplegia and hemisensory deficits. ACA infarcts are significantly less common than MCA infarcts and typically produce weakness affecting the leg more than arm, and frontal lobe deficits such as apathy or apraxia (see **Box 29.3** and Chapter 28).

Posterior circulation clinical stroke syndromes

Posterior cerebral artery (PCA) infarcts are typically embolic. Brainstem infarction causes complex signs, depending on the relationship of the infarct to cranial nerve nuclei, long tracts, and brainstem connections (Boxes 29.3 and 29.4; **Fig. 29.7**):

- The lateral medullary syndrome (Wallenberg's syndrome) is a common brainstem vascular syndrome presenting as acute vertigo with cerebellar and other signs, including Horner's syndrome (**Box 29.4**) (**Fig. 29.7**). It follows thromboembolism in the posterior



The circle of Willis is comprised of the following vessels:
- Anterior cerebral artery
- Middle cerebral artery
- Anterior communicating artery

→ Anterior circulation

- Posterior cerebral artery
- Vertebral artery
- Basilar artery

→ Posterior circulation

Anterior circulation - areas supplied by branches of internal carotid artery (anterior cerebral artery and middle cerebral artery)
Posterior circulation - areas supplied by branches of vertebral and basilar arteries (anterior inferior cerebellar artery, posterior inferior cerebellar artery, posterior cerebral artery).
Posterior communicating artery usually does not give rise to branches - it completes the circle of Willis

Fig. 29.5 Arteries supplying the brain and cord.

inferior cerebellar artery (PICA) or its branches, vertebral artery thromboembolism or dissection (see **Box 29.3**).

- Cerebellar infarcts occur in isolation or as part of a more extensive brainstem syndrome. Swelling of the cerebellum may cause brainstem compression and coma or obstructive hydrocephalus necessitating decompressive surgery.
- Basilar artery thrombosis is more common than embolism. The clinical picture depends on the level of the occlusion and the branch vessels affected. High lesions cause midbrain infarction, including coma and locked-in syndrome (see Chapter 28) or top of the basilar syndrome, with the PCA also affected, causing devastating midbrain, occipital lobe, and thalamic infarction (**Box 29.3**).
  - Contralateral homonymous hemianopia results from unilateral lesions, while bilateral lesions cause cortical blindness (Anton's syndrome) (**Box 29.3**). Neglect syndromes and visual agnosias are associated with involvement of more anterior visual association areas.
  - The PCA supplies the thalamus, and posteromedial temporal lobe and infarction of these structures causes confusion or memory impairment.

TRANSIENT ISCHAEMIC ATTACK

At least 15% of ischaemic strokes are preceded by a TIA. Early diagnosis and treatment of a TIA is imperative to prevent a stroke from occurring.

Clinical features

TIAs cause sudden loss of function (negative symptoms), usually lasting for minutes only, with complete recovery and no evidence of infarction on imaging (tissue-based definition). The symptom onset is abrupt and is often at maximal intensity at the time of onset. Focal neurological symptoms might include hemiparesis or hemisensory loss; speech disturbance (e.g., dysarthria or dysphasia); visual impairment (e.g., amaurosis fugax, diplopia, or hemianopia); and vertigo. See **Box 29.1**.

Amaurosis fugax

This is a sudden transient loss of vision in one eye. This is due to the passage of emboli through the retinal arteries, and the embolus is sometimes visible through an ophthalmoscope during an attack (Hollenhorst plaque). A TIA causing an episode of amaurosis fugax may be the first clinical evidence of internal carotid artery (ICA) stenosis—a warning sign of incipient ICA territory stroke. Carotid duplex or CT/MRI imaging of the carotid vessels should be part of the assessment. Evidence of a carotid stenosis ≥50% should prompt discussion with the vascular surgery team about consideration of carotid surgery (see 'Secondary prevention' section). Auscultation of the carotid artery (for detection of bruit suggesting carotid stenosis) is not recommended as it lacks both sensitivity and specificity.

Giant cell arteritis should also be considered as a potential cause of amaurosis fugax, and assessment should include asking about unilateral headache, scalp tenderness, and jaw claudication; and CRP/ESR must be checked. Suspicion of this serious condition should prompt referral for rheumatology review, consideration of a temporal artery biopsy, and early commencement of steroids.

TIA diagnosis

Diagnosis of TIA is often based solely on its description, and good history taking is therefore key. Collateral history from a bystander can be extremely helpful if they had witnessed the event. Transient loss of consciousness points towards an alternate diagnosis (not a TIA). MRI brain imaging is recommended, looking for evidence of acute infarction.

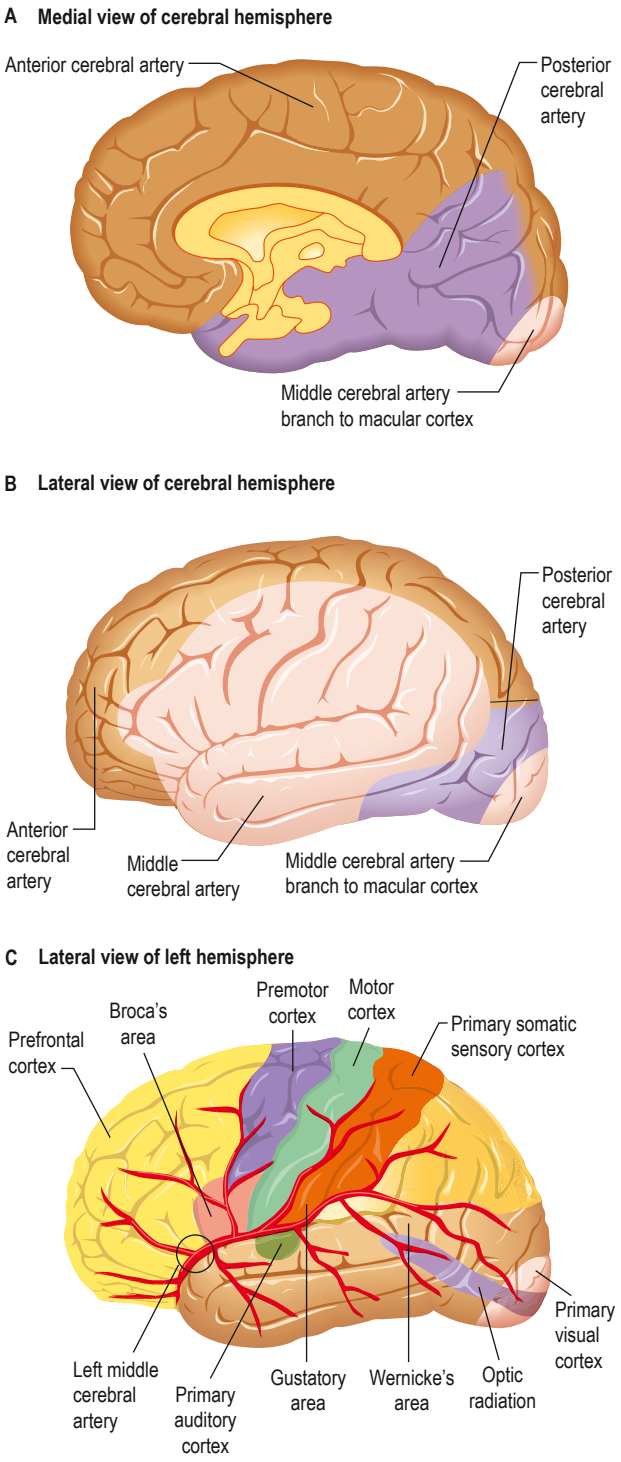


Fig. 29.6 The territories supplied by the three major cerebral arteries (A and B). (C) Cortical areas supplied by left middle cerebral artery branches (the dominant hemisphere in 95% of right-handed individuals.)

Differential diagnosis and stroke mimics

Approximately 50% of presentations to a TIA clinic are diagnosed as TIA mimics.

Migraine is the commonest mimic presenting to TIA clinics. Migraine often produces positive symptoms (e.g., headache, paraesthesia, visual flashes/fortification), but TIA often produces negative symptoms (weakness, numbness, loss of vision, etc.). The onset and evolution of symptoms is usually slower with migraine aura than TIA (minutes rather than seconds). Limb weakness is rarely due to migraine. It is important to remember that migraine is a diagnosis of exclusion.

Focal epilepsy is usually recognized by its positive features (e.g., limb jerking) and progression over minutes. In a TIA, involuntary limb movements can occur occasionally—***limb-shaking TIA***—and are pathognomonic of severe carotid stenosis causing transient focal cerebral hypoperfusion.

Other causes of TIA mimics are listed in **Box 29.5**. Careful history, examination, and focused investigations are essential to distinguish between these and a genuine TIA.

Prognosis

TIAs are associated with a cumulative early risk of stroke of 5.2% at 7 days. The risk is the highest in the first 24 hours after TIA. All patients with a suspected TIA event should be referred to a TIA clinic, with assessment, investigation, and management as an emergency, within 24 hours of symptoms. Historical scores such as the ABCD^2 score are no longer recommended for risk stratification. Early treatment of TIA reduces the risk of stroke by 80%, and includes early initiation of antiplatelet medication, statins, and blood pressure management (see 'Secondary prevention' section).

ACUTE ISCHAEMIC STROKE

Acute ischaemic stroke is a medical emergency. Hyperacute treatments for this condition are time sensitive, with significant advances in management options available over the last three decades.

Initial assessment should start with an ABCD approach in the emergency department. A rapid history and examination when assessing for hyperacute stroke therapy focuses on the following:

- time of onset (if known, or alternatively 'last known well' time)
- the clinical syndrome
- medications including anticoagulants
- past medical history including previous stroke or TIA
- vascular risk factors.

This is followed by a focused examination using the National Institute of Health Stroke Scale (NIHSS) (see **Box 29.6**) and establishing the pre-stroke level of function. The assessment should include focus on indications and contraindications for reperfusion therapies such as thrombolysis and/or thrombectomy. During this rapid assessment, bloods should be taken in parallel, and an intravenous cannula inserted (preferably avoiding the affected limb).

Once the initial assessment is complete (aim <10 mins), the patient undergoes rapid brain imaging. The choice of imaging modality will depend on the patient's presentation, time of onset, and eligibility for reperfusion therapies.

Imaging

The first aim of imaging with acute ischaemic stroke is to exclude haemorrhage. This usually involves first-line non-contrast CT head

Box 29.3 Major vascular territories with stroke syndromes

Some stroke clinical syndromes and associated vascular territories		
Vascular supply/region affected	**Neurological deficits**	**Diagram**
Anterior circulation		
Left MCA (dominant hemisphere)	Right-sided weakness involving face and arm > leg Right sensory loss Dysphasia Right visual field defect Gaze palsy (eye looks towards the affected hemisphere)	Right MCA (non-dominant)	Contralateral left-sided weakness involving face and arm > leg Visual and/or sensory neglect Left sensory loss Denial of disability Left visual field defect	ACA (medial and superior parts of the frontal lobe, and anterior parietal lobe)	Contralateral motor weakness—leg predominant (medial motor cortex leg area) Incontinence Abulia Amnesia (cingulate cortex)

Note: 95% of right-handed individuals have left-sided language dominance. Approximately 50% of left-handed individuals have left-handed language dominance.

(NCCT), although MRI head is also acceptable (but less accessible for many centres). The second aim of imaging in acute ischaemic stroke is to review the extent of ischaemic change if present. This can be done using a scoring system such as the ASPECTS (Alberta Stroke Programme Early CT Score) (**Fig. 29.8**) derived from the CT or MRI images. Typically, reperfusion therapies may not be offered if the extent of the ischemic change is already too extensive (e.g., very low ASPECTS score).

If the patient is a candidate for mechanical thrombectomy (MT), additional CT angiogram imaging (CTA) should be completed, looking for a thrombus occluding a large intracranial vessel (middle cerebral artery, internal carotid artery, or basilar artery). Some centres complete NCCT and CTA in all stroke admissions to assess all these factors in one sitting. This may be preferable, as it saves time during the initial assessment phase of management.

Newer techniques such as CT or MR perfusion (CTP or MRP), allow assessment of the area of ischaemia in more detail; for delineation of the ischaemic core and penumbra (**Fig. 29.9**).

The ischemic core refers to the part of the brain in acute ischaemic stroke with severely reduced blood flow, that has already infarcted and thus is thought to have irreversible neuronal damage. The surrounding brain tissue served by collateral vessels may have only moderately reduced perfusion despite a large vessel occlusion. This area is known as the penumbra where tissue damage is still

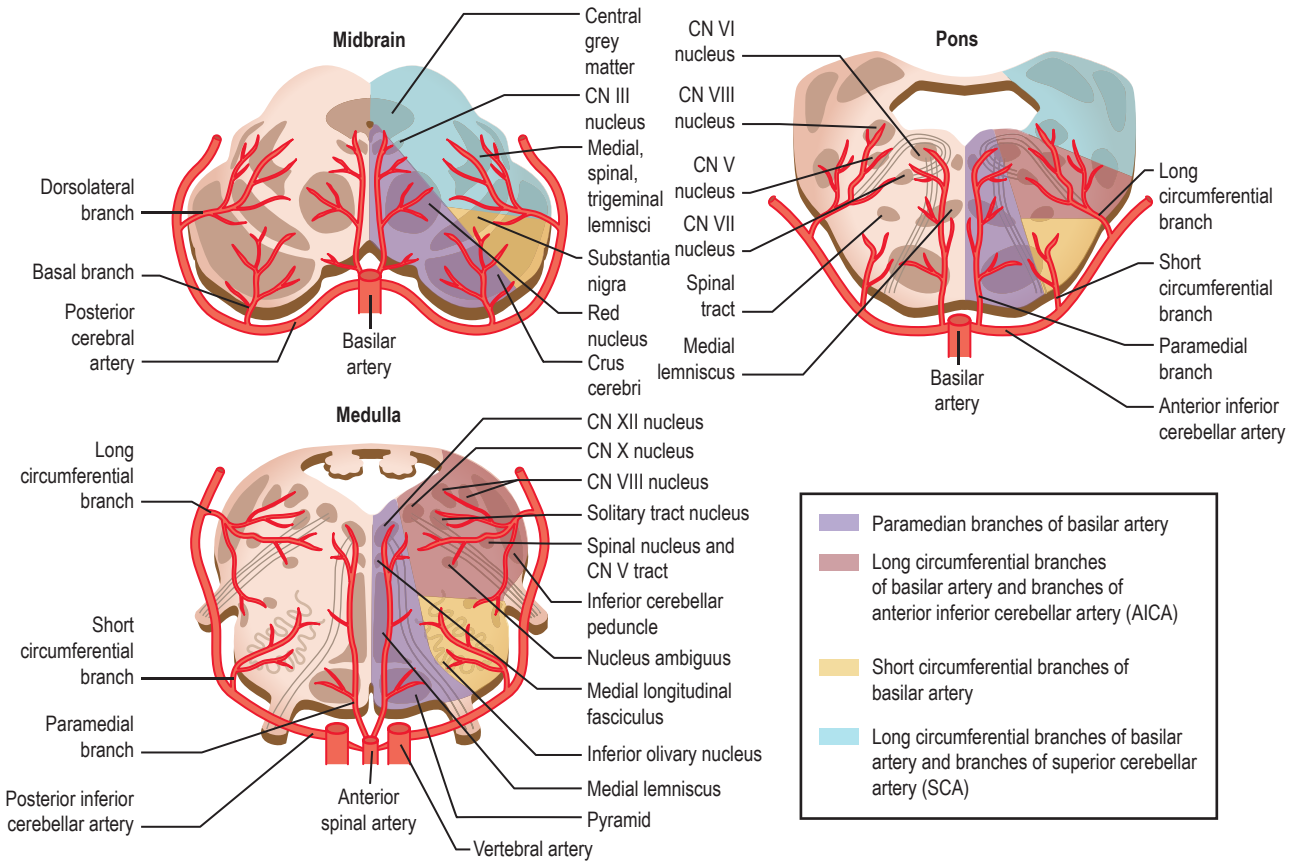

Fig. 29.7 Brainstem anatomy—tracts and nuclei. *(https://n.neurology.org/content/97/20_Supplement_2/S158.)*

Box 29.4 Features of brainstem infarction

Clinical feature	Structure involved
Hemiparesis or tetraparesis	Corticospinal tracts
Sensory loss	Medial lemniscus and spinothalamic tracts
Diplopia	Oculomotor system
Facial numbness	Vth nerve nuclei
Facial weakness	VIIth nerve nucleus
Nystagmus, vertigo	Vestibular connections
Dysphagia, dysarthria	IXth and Xth nerve nuclei
Dysarthria, ataxia, hiccups, vomiting	Brainstem and cerebellar connections
Horner's syndrome	Sympathetic fibres
Coma, altered consciousness	Reticular formation

potentially reversible if the occlusion can be targeted with reperfusion therapies.

CT or MR perfusion is typically performed in cases where patients have presented in a late window (beyond 4.5 hours; but within 24 hours of onset or last known well). This allows assessment of 'salvageable penumbral tissue' and allows careful use of reperfusion therapies if a favourable profile is seen (equating to a small core and large penumbra) (**Box 29.7**).

Box 29.5 TIA and stroke mimics

- Migraine (commonest)
- Syncope
- Focal seizure or Todd's paresis (after a seizure)
- Vestibular dysfunction/BPPV
- Metabolic (e.g., hypoglycaemia)
- Transient global amnesia
- Peripheral nerve disorder
- Amyloid spells
- Space occupying lesion (primary or metastases)
- Bell's palsy
- Postural hypotension
- Cardiac arrhythmia
- Subdural haematoma
- Anxiety/functional neurological disorder
- Acute episode of demyelination
- Intracranial infection (e.g., cerebral abscess, meningoencephalitis)
- Spinal cord lesions
- Paraneoplastic disorder
- Degenerative brain disease (e.g., primary progressive aphasia, spinocerebellar degeneration)
- Trigeminal neuralgia
- Medication (side-effects)

Box 29.6 NIHSS

1 a—Level of consciousness	0—Alert, keenly responsive 1—Not alert, but arousable by minor stimulation 2—Not alert; requires repeated stimulation 3—Unresponsive or responds only with reflex
1 b—Level of consciousness questions	0—Answers two questions correctly 1—Answers one question correctly 2—Answers neither question correctly
1 c—Level of consciousness commands	0—Performs both tasks correctly 1—Performs one task correctly 2—Performs neither task correctly
2—Best gaze	0—Normal 1—Partial gaze palsy 2—Forced gaze deviation
3—Visual	0—No visual loss 1—Partial hemianopia 2—Complete hemianopia 3—Bilateral hemianopia
4—Facial palsy	0—Normal symmetric movements 1—Minor paralysis 2—Partial paralysis 3—Complete paralysis
5—Motor arm—Left arm	0—No drift 1—Drift 2—Some effort against gravity 3—No effort against gravity 4—No movement
Motor arm—right arm	0—No drift 1—Drift 2—Some effort against gravity 3—No effort against gravity 4—No movement
6—Motor leg—left leg	0—No drift 1—Drift 2—Some effort against gravity 3—No effort against gravity 4—No movement
Motor leg—right leg	0—No drift 1—Drift 2—Some effort against gravity 3—No effort against gravity 4—No movement
7—Limb ataxia	0—Absent 1—Present in one limb 2—Present in two limbs
8—Sensory	0—Normal 1—Mild to moderate sensory loss 2—Severe or total sensory loss
9—Best language	0—No aphasia 1—Mild to moderate aphasia 2—Severe aphasia 3—Mute, global aphasia
9—Dysarthria	0—Normal 1—Mild to moderate dysarthria 2—Severe dysarthria
Extinction	0—No abnormality 1—Visual/tactile/auditory/spatial or personal inattention 2—Profound hemi-inattention or extinction
Score	0—42

If any of the above cannot be tested (e.g., amputation or intubation), score 9 for that domain and exclude that from the NIHSS score.

Artificial imaging (AI) solutions have been successfully developed to calculate an automated ASPECTS score, while also being able to detect an occlusion in a large vessel. These AI solutions are also able to calculate core and penumbra maps from CTP imaging (Fig. 29.9). External validation of this software is ongoing.

Intravenous thrombolysis

Intravenous thrombolysis (IVT) involves administering fibrinolytic treatment (tissue plasminogen activator) to dissolve the thrombus or embolus, thereby restoring perfusion to an affected area of brain. IVT has been shown to increase the odds of an excellent outcome after acute ischaemic stroke. The benefits are greater the earlier the treatment is given (Fig. 29.10). Of note, there is an increase in the risk of intracranial haemorrhage with this treatment, but the absolute risk of haemorrhage is less than the benefit of treatment with IVT (see schematic). The contraindications for IVT are listed in Box 29.8; these should be reviewed prior to proceeding with treatment. When the patient is being considered for IVT, the aim is to deliver this treatment within 30 minutes of the patient arriving in the emergency department. Benefits of thrombolysis are shown in Fig. 29.11.

IV thrombolysis windows

Thrombolytic drug options include i.v. alteplase (i.v. bolus and 1-hour infusion), or i.v. tenecteplase (i.v. bolus only), with the choice of agent left to the discretion of the treating team.

IVT is licensed for up to 4.5 hours after the onset of stroke. However, stroke guidelines advise an extension of the time window owing to advances in imaging (Box 29.8). For example, in wake-up strokes that happen during sleep, one method involves the use of perfusion imaging with evidence of small core and large penumbra (with significant mismatch) up to 9 hours from symptom onset.

Hyperacute MRI has been used in wake-up strokes to look for mismatch between diffusion-weighted imaging (DWI) and fluid-attenuated inversion recovery (FLAIR) sequences. MRI DWI sequences will pick up the core infarct within minutes. On the other hand, typically the MRI FLAIR sequences will not clearly show the infarct until approximately 4.5 hours. Therefore, an infarct that is present on DWI but is absent on FLAIR can be assumed to be in its early stages (as a surrogate for knowing the exact time of onset); and such patients can be offered IVT, if no contraindications.

Mechanical thrombectomy

MT is a procedure that involves directly removing the clot causing an occlusion of a large vessel (ICA, MCA, or basilar), using an arterial catheter inserted through the groin (or wrist) that directly accesses the intracranial occlusion. The clot is then removed using a device that can either aspirate or trap the clot using a retrievable stent system (Fig. 29.12). This treatment has revolutionized management of patients with large vessel occlusion who were previously more likely to have a poor outcome. Landmark trials published in 2015 assessed the efficacy of MT, in addition to standard treatment with IVT, in patients with anterior circulation large vessel occlusion. These trials demonstrated a significant increase in the proportion of patients who were alive and independent at 3 months after stroke, over and above IVT alone. Recent

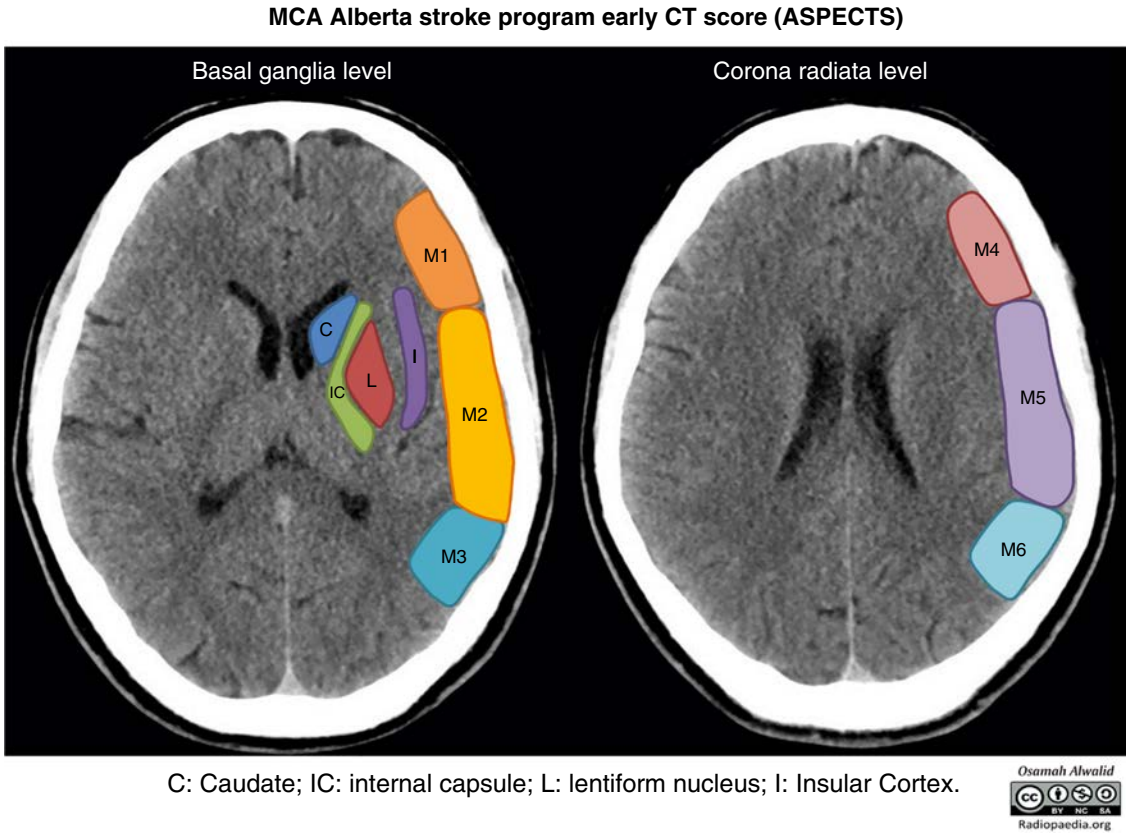

Fig. 29.8 Alberta Stroke Programme Early CT Score (ASPECTS). Calculation of the extent of early ischaemic changes using the ASPECTS score; 10 pre-specified (highlighted) areas are assessed, and 1 point subtracted for each area involved; with a maximum score of 10 (no ischaemia) and minimum score of 0 (extensive ischaemia). *(Credit: https://radiopaedia.org/articles/alberta-stroke-programme-early-ct-score-aspects?lang=gb.)*

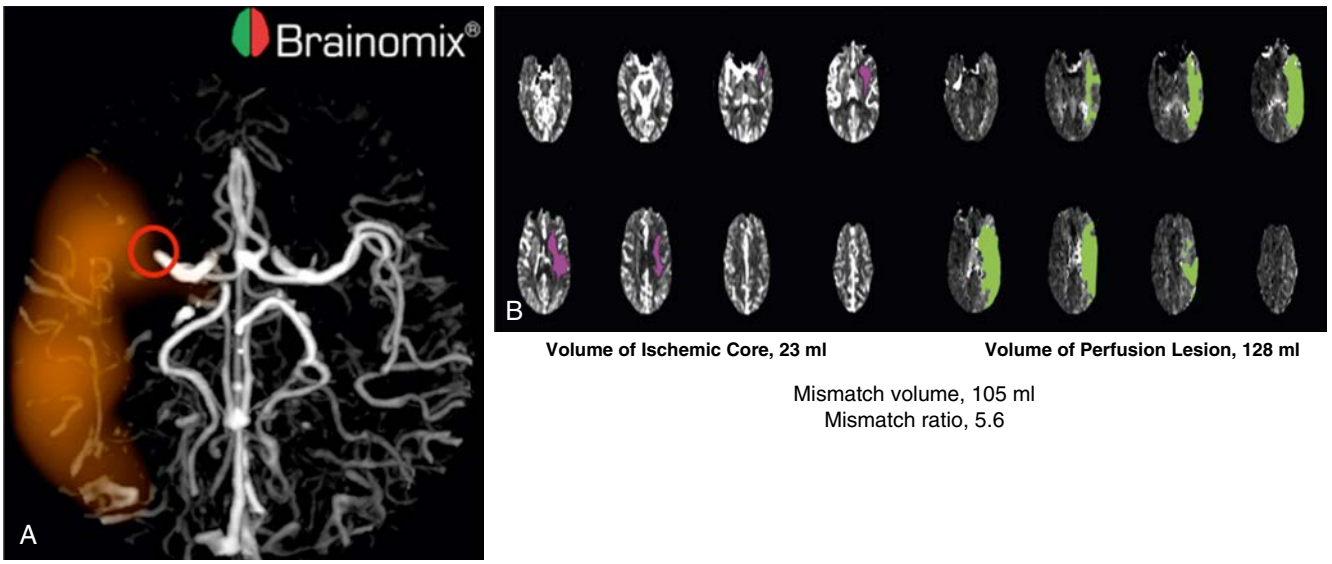

Fig. 29.9 Automated software: detection of large vessel occlusion and CT perfusion maps of core/penumbra. (A) Right middle cerebral artery large vessel occlusion using automated detection software. **(B)** Core-perfusion maps of left middle cerebral artery large vessel occlusion with small core 23 mL and large perfusion defect of 128 mL and mismatch volume of 105 mL (please note that these two scans are from different patients).

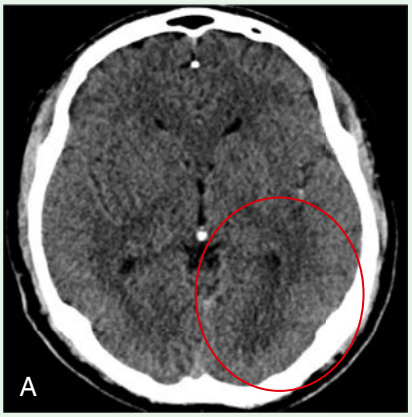
Box 29.7 Stroke imaging table

Brain parenchymal imaging
Assess for infarcted brain tissue, intracranial bleeding, tumour
Stroke is a clinical diagnosis and a normal non-contrast CT brain is common in the first few hours after acute stroke ***(see scan A below)***
Imaging may differentiate embolic and lacunar features especially MRI
(see over acute infarct on non-contrast CT and MRI diffusion weighted)
	• Non-contrast computed tomography (CT) brain ***(scan A below)***
	  • Consent needed for minimal risk radiation exposure in childbearing females
	• Magnetic resonance (MR) brain
	  • Principle imaging modality for TIA
	  • Issue with compatibility of pacemakers and metallic implants
	  • No exposure to radiation
	  • No known adverse effects to the fetus but use with caution

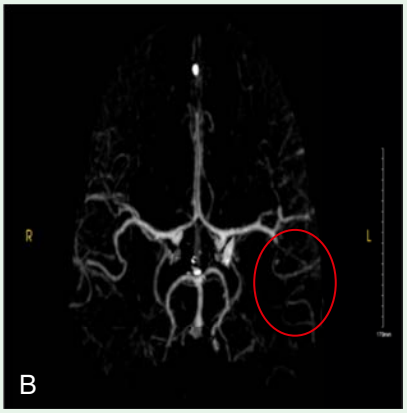
Vascular imaging—intracranial and extracranial
Assess for acute large or medium vessel occlusion or stenosis to determine aetiology such as atherosclerosis, dissection, thrombus, vasculitis, vasospasm, or moyamoya
(See over CT angiogram with left MCA large vessel occlusion)
	• CT angiography from aortic arch to brain ***(scan B below)***
	  • Caution with advanced kidney disease
	• MR angiography with or without contrast (gadolinium)
	  • Caution with advanced kidney disease (nephrogenic sclerosis)
	• Ultrasound Doppler to assess for carotid and vertebral disease
	  • No radiation exposure
	  • Limited access to upper neck near skull base
	  • User dependent

Perfusion imaging
To determine core to perfusion mismatch pre thrombectomy, thrombolysis, or for diagnostic purposes with mimics
	• CT or MR perfusion (requires injection of contrast, see ***scans C and D below***)
	• Automated software for CT perfusion
	  • Provides automated maps of perfusion estimating ischaemic core, penumbra, and mismatch
	  • Not externally validated

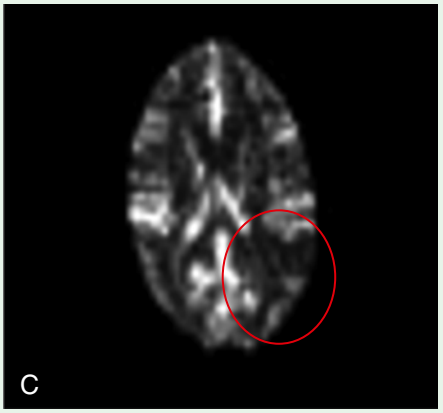
Contrast-enhanced imaging Assesses for tumour and vasculitis	• CT or MRI contrast-enhanced scan
Catheter angiogram or digital subtraction angiogram Completed during thrombectomy, after intracerebral bleed to assess for aneurysm or vascular malformation and the assess for cerebral vasculitis	• Catheter angiogram is associated with a 0–5 to 1% risk of major vascular and neurological complications as it involves direct catheterization of the large arteries of the neck and head



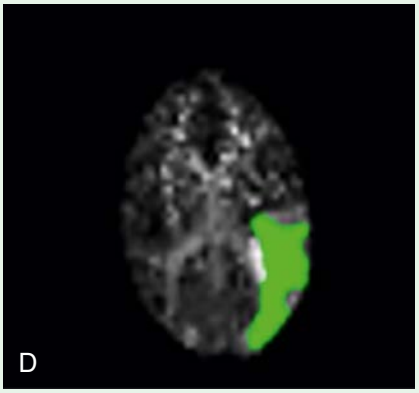
Non contrast CT scan showing a dense MCA in the Sylvian fissure (M2 segment)



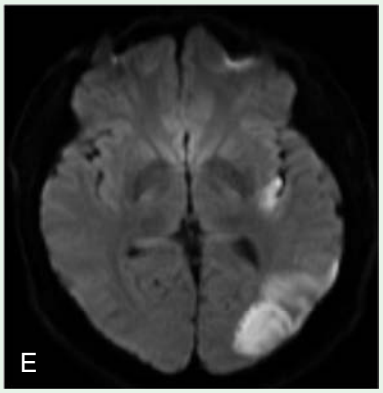
CT angiogram showing abrupt cut off of the M2 branch (arrow) with very poor visualisation of the vessel distal to the occlusion



CT Perfusion showing no area of core damage (i.e., no irreversible damage)



CT perfusion showing 'penumbra' (i.e., salvageable brain with prompt treatment e.g., i.v. thrombolysis +/- mechanical thrombectomy)



rt-PA was administered 2 hours after the onset of symptoms with recanalisation of M2. Diffusion weighted MRI done on day 6 showing left parieto-occipital lobe and left posterior insular cortex acute infarction, a much smaller area of infarction than the initial penumbra at risk

A and B, Reproduced from Ralston SH, Penman ID, Strachan MWJ et al. Davidson's Principles and Practice of Medicine, *23rd edn. Edinburgh: Elsevier; 2018. C–E Courtesy of Professor Adrian Dixon, Cambridge Radiology Department, UK. Adapted from Fig. 26.4 and Fig. 26.38.*

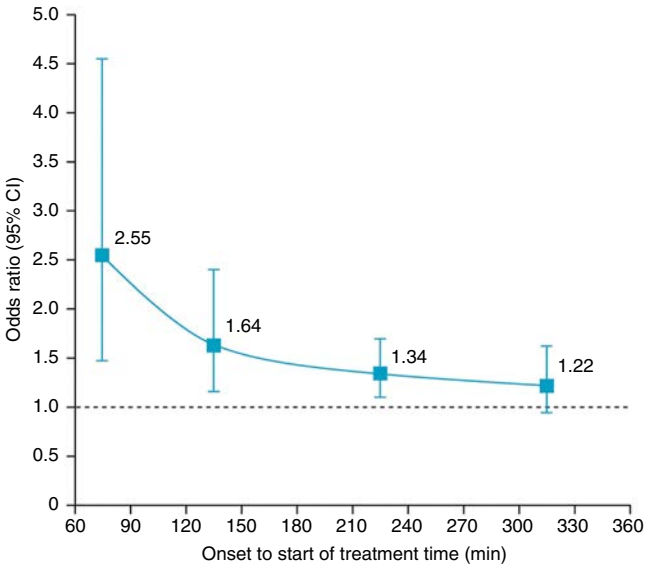


Fig. 29.10 Time is brain: Likelihood of an excellent outcome (no or minimum disability) after thrombolysis, depending on onset to treatment time.

evidence shows that this treatment can be delivered safely up to 24 hours after symptom onset in anterior and posterior circulation large vessel occlusion and is associated with excellent outcomes in selected patients. The number needed to treat (NNT) to reduce disability is 3, a number unmatched by most other medical interventions in medicine.

Most recent guidelines recommend that stroke patients with anterior circulation large vessel occlusion (ICA or MCA) on CTA and presenting with an NIHSS 6 or more, should be considered for MT. Beyond 12 hours, advanced imaging with CTP or MRI is recommended to demonstrate salvageable penumbra on perfusion imaging.

Posterior circulation MT (basilar) may be considered within 24 hours of onset for those with an NIHSS of 10 or more, with favourable imaging characteristics (e.g., good p-ASPECT—posterior circulation ASPECT).

MT is a game-changing treatment; however, resource and infrastructure deficits mean that availability is often limited. This results in significant inequity in access and a postcode lottery for patients with a large vessel occlusion causing stroke. This therefore remains a priority area for improvement for stroke services across the world.

STROKE UNIT CARE, REHABILITATION, AND RECOVERY

Acute stroke unit care

Acute stroke unit care is delivered in a geographically defined hospital-based unit, staffed by a specialized, multidisciplinary team including nurses, physicians, physiotherapists, occupational therapists, speech therapists, psychologists, dieticians, social workers, and others. Acute stroke unit care is associated with reduced mortality, disability, and institutionalization by approximately 25% compared to non-specialist hospital care. Early supported discharge to the community for those with mild to moderate disability is associated with improved outcomes, including reduced length of hospital stay and increased independence in daily activities compared to traditional in-hospital care (Box 29.9).

Post-stroke complications

A biopsychosocial approach to stroke care is essential. Assessment is routine for stroke complications (urinary tract infection, pneumonia, venous thromboembolism, pressure ulceration, and seizures) with targeted screening for delirium, cognitive impairment, depression, anxiety, and fatigue. Measures to reduce the risk of venous thromboembolism in immobile patients require further research but include early mobilization and intermittent pneumatic compression. Graduated compression stockings are not recommended. Prophylactic low-molecular-weight heparin reduces thromboembolism risk at the expense of increased symptomatic ICH.

Dysphagia

Dysphagia is associated with pneumonia and death. Early dysphagia screening (<4 hours) provides the opportunity for intervention including modified fluids, diet, and positioning. Enteral feeding for severe dysphagia is preferably within 1 to 2 days via nasogastric tube. Dysphagia often improves, as neurological pathways have bilateral cortical representation, so percutaneous gastrostomy is often deferred to the subacute phase (such as approximately 4 weeks).

Space occupying brain infarction/malignant hemispheric cerebral infarction

Occlusion of the internal carotid artery or proximal middle cerebral artery can lead to a large (malignant) hemispheric infarction with cerebral oedema. Raised intracranial pressure compresses leptomeningeal collateral circulation and leads to herniation of the temporal lobe onto the brainstem. It is more commonly seen in younger individuals and is associated with a high (>75%) mortality. Decompressive craniectomy involves removing part of the skull to allow the brain to swell (Fig. 29.13) and provided within 48 hours reduces the risk of death and poor outcomes, although most individuals who survive have substantial disability. Most benefit is seen in those under age 60 years.

Impairment of mobility

Gradual mobilization within 48 hours is recommended (short and frequent episodes) but very early intensive mobilization within 24 hours may be harmful especially for those with more severe strokes. Aerobic training is advised where feasible, in addition to resistance training and repetitive, task-specific rehabilitation activities such as repetitive walking practice. The multidisciplinary team should have expertise in multiple modalities which may provide benefits such as constraint-induced movement therapy, functional electrical stimulation, balance training, mirror therapy, mental practice, repetitive transcranial magnetic stimulation, vocational rehabilitation, and others.

Spasticity and pain

Botulinum injection will address severe spasticity, supported by dedicated physiotherapy techniques. These have better tolerance and efficacy than oral agents such as baclofen (gamma-aminobutyric acid B receptor agonist) or tizanidine (alpha-2 adrenergic receptor agonist), which are associated with sedation and abrupt withdrawal should be avoided. Neuropathic pain may be treated with gabapentin, pregabalin, amitriptyline, or duloxetine. Education on optimal shoulder position may reduce subluxation.

Box 29.8 Indications, contraindications, and dosing for thrombolytic therapy

Indications for TPA

Diagnosis of acute ischemic stroke causing new **disabling symptoms** to patient regardless of NIHSS score
Treat even if improving symptoms provided the deficit remains disabling
- Disabling symptoms definition
  - A deficit that, if unchanged, would prevent the patient from performing basic activities of daily living (i.e., bathing, ambulating, toileting, hygiene, and eating) or returning to work
- Non-disabling strokes are *excluded* unless there is large vessel occlusion
  - Isolated mild aphasia (patient still able to communicate meaningfully), isolated facial droop, mild cortical hand (especially non-dominant), mild hemi-motor loss or mild hemisensory loss, and mild hemiataxia (patient still able to ambulate)

Treatment can be started **within 4.5 hours of symptom onset**
OR
in the **Extended time window** (4.5–9 hours or wake-up strokes) **using advanced imaging** (CT perfusion/MRI)

Initial glucose levels >2.8 mmol/L
If glucose is ≤2.8 mmol/L, treat hypoglycaemia first then reassess

Absolute contraindications

Intracerebral haemorrhage on non-contrast CT brain

Severe hypertension (>185/110 mmHg) refractory to aggressive hyperacute antihypertensive treatment. Blood pressure must be <185/110 to commence TPA

Recent (<3 months) stroke, traumatic brain injury, intracerebral or intraspinal surgery

Known coagulopathy, bleeding disorder, severe cirrhosis, or platelet count <100 (Do not wait for a platelet count unless history is suggestive of a platelet disorder)

Anticoagulation treatment with warfarin with INR > 1.7

Direct oral anticoagulants (DOACs) within 48 hours for whom there is no specific coagulation test available
Longer time may be needed if abnormal renal function
- Specific coagulation tests include: calibrated anti–Xa-activity for factor Xa inhibitors, thrombin time for dabigatran, or the DOAC blood concentrations as available in your laboratory
- For patients with acute ischemic stroke of <4.5 hours who used dabigatran within the last 48 hours, reversal with Idarucizumab and subsequent thrombolysis maybe considered

Active internal bleeding

Recent (<10 days) cardiopulmonary resuscitation or obstetric delivery

Bacterial endocarditis or pericarditis

Symptoms suggestive of subarachnoid haemorrhage even if normal CT brain

Aortic dissection

Relative contraindications

Seizure at onset unless residual neurology is considered to be stroke related

Lumbar puncture within previous 7 days

Intracerebral neoplasm, arteriovenous malformation (AVM) or larger cerebral aneurysms

Blood glucose ≤2.8 mmol/L. Consider alteplase if deficits are not resolving with intravenous dextrose. Hyperglycaemia is not a contraindication

Recent major trauma (<14 days) with internal injuries or visceral biopsy

Recent (<14 days) gastrointestinal or genitourinary tract haemorrhage, or major surgery at a non-compressible site

History of intracranial haemorrhage. Consider if treatable cause (e.g., trauma, subarachnoid haemorrhage with aneurysm repair)

Acute pancreatitis

Recent (<7 days) puncture of a non-compressible blood vessel (e.g., subclavian vein)

Systemic malignancy with increased haemorrhage risk

Caution if recent (<3 months) myocardial infarction or pericarditis

Pregnancy

Caution is advised if there is a very large area of hypodensity on the non-contrast CT brain signifying an established recent infarct (>1/3 MCA)

Thrombolysis dosing

Dose of intravenous alteplase (tissue plasminogen activator)
- Total dose 0.9 mg/kg (max. 90 mg)
- 10% of the total dose by initial bolus over 1 minute
- Remainder is infused over 1 hour

Dose of intravenous tenecteplase
- The dose of tenecteplase is 0.25 mg/kg (maximum total dose 25 mg)
- Give in a single intravenous bolus over 5 seconds (saline flush as incompatible with dextrose)

Bowel and bladder dysfunction

Constipation is common and needs polypharmacy review (to stop aggravating medications), laxative treatment, and a structured bowel management programme. Urine incontinence, which occurs frequently, is addressed via behavioural interventions and adaptations such as bladder retraining prior to pharmacological intervention. Prolonged use of indwelling urinary catheters should be avoided.

Ongoing disability

Fatigue may be negotiated via self-management programmes. If there are ongoing swallow difficulties, comfort feeding or palliative care may be appropriate goals of care in certain circumstances. Significant social support may be needed on discharge. Reference must be made to national driving guidelines with onward referral of individuals with persistent disability to driving assessment and support services.

Goals of therapy

Rehabilitation can be delivered within the acute hospital setting, rehabilitation unit, and via early supported discharge facilitating transition to the community and integration of care. Goal-directed care with shared decision-making is central to recovery from stroke and directed by an individual patient's preferences and values. Rehabilitation provides activities to promote neuroplasticity, neural reorganization, and recovery, and facilitates compensation to overcome deficits in function. The International Classification of Functioning, Disability and Health (WHO 2001) provides a useful conceptual framework. This identifies stroke as a pathology causing impairment of body function, but furthermore recognizes limitations to activity and impact on participation in life providing targeted goals for rehabilitation. From the outset, communication and engagement with the patient, family, and carers is important to support effective, patient-centred rehabilitation and discharge planning.

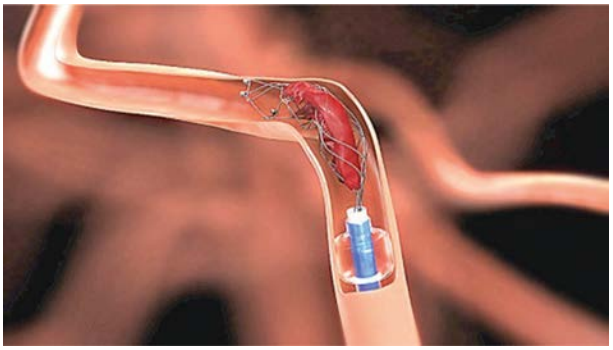

Fig. 29.12 Solitaire stentriever device for removing clot from intracranial vessel.

PRIMARY AND SECONDARY ISCHAEMIC STROKE PREVENTION

Secondary prevention of stroke

Ischaemic stroke is a complex and heterogeneous disease. A comprehensive approach to identify the underlying causal mechanism(s) is needed, to urgently inform targeted secondary stroke prevention. The highest risk of a further stroke is in the first 1 to 2 weeks after the index event, particularly for mechanisms such as high-grade carotid disease, intracranial stenosis, and atrial fibrillation. Atherosclerosis is the leading cause of stroke and therefore management of vascular risk factors is important across all age ranges and stroke subtypes. Treatment to reduce recurrence is called secondary prevention with comparable assessment and treatment for TIA and minor ischaemic stroke due to shared aetiology.

Primary prevention of stroke and cardiovascular disease

Primary prevention describes individual-level preventative strategies that target those at higher risk of stroke but without established disease. Population-based strategies are essential to address modifiable vascular risk factors, as the majority of stroke occurs in those at low to moderate cardiovascular disease risk. Risk factors, such as hypertension, smoking, abdominal obesity, high body mass index, poor diet, low physical activity, diabetes, excess alcohol consumption, high LDL cholesterol concentrations, kidney dysfunction, air pollution, and psychosocial factors may account for nearly 90% of the overall burden of stroke, with hypertension being the single most important risk factor (Fig. 29.14). On an individual level, anticoagulation for atrial fibrillation using risk stratification models (e.g., CHADS2 VASC score) is key for reducing cardioembolic strokes. With better population-based risk factor control, stroke incidence is reducing in older adults but despite this continues to increase in those under 50 years.

Personalized and goal-directed management of risk factors

Personalized medicine will ensure that treatment is targeted to each patient's unique needs, stroke aetiology, and co-morbidity profile (Box 29.2).

Lifestyle modifications

A healthy Mediterranean and low salt diet along with regular physical activity are cornerstones of treatment. Changing lifestyle requires behavioural change models instituted by the multidisciplinary team in partnership with the patient. Alcohol consumption should be minimized with smoking cessation essential. Specific physical activity targets, where feasible, entail low/moderate-intensity aerobic activity for 10 minutes on 4 days per week, or more vigorous aerobic activity for 20 minutes twice per week. Obesity is associated with cardiovascular disease and mortality. Targeting a healthy body mass index is advised on this basis, despite a lack of high-quality data for impact on stroke recurrence.

Box 29.9 Stroke management outline

Immediate general medical measures
- ABCDE (airway, breathing, circulation, disability, exposure) approach
- Assess Glasgow Coma Scale
- Apply monitors, check vital signs, obtain intravenous access, and send urgent laboratory tests
- Complete the standardized neurological examination using the NIHSS (Box 29.6)
- Consider intensive care and intubation for unconscious patients who are unable to protect their airway (e.g., GCS < 8)
- Proceed with urgent CT brain and CT angiogram
- Further testing such as electrocardiogram and chest radiograph are completed after acute stroke assessment, imaging, and thrombolysis unless clinically urgent (e.g., coexistent chest pain)

When haemorrhage is excluded, is thrombolysis appropriate (Box 29.7)?
- Immediate non-contrast CT brain imaging is needed (some centres use MRI)
- If no evidence of intracerebral haemorrhage, assess if patient fulfils indications for thrombolysis (disabling deficit within 4.5 hours)
- Check for contraindications to thrombolysis
- Do not wait for urgent laboratory test results before administration of thrombolysis unless coagulopathy suspected or other reason for clinical concern based on contraindication checklist
- Further urgent imaging with CT perfusion is required in the extended/unknown time window beyond 4.5 hours (known time of stroke onset 4.5–9 hours using perfusion imaging; wake-up strokes within 9 hours of the midpoint of sleep)
- MRI diffusion flair mismatch can be used to guide thrombolysis for strokes occurring during sleep with no clear time of onset and presenting to hospital within 4.5 hours of waking

When haemorrhage is excluded, is thrombectomy appropriate?
- CT angiogram is needed to confirm a large vessel occlusion and collateral status
- Is the patient presenting within 24 hours of symptom onset?
- Is there a significant deficit, usually NIHSS 6 or more?
- What is the pre-morbid modified Rankin score or dependency level of the patient? Consider excluding if severe dependency or short life expectancy indicating that the benefit of intervention may be limited.
- Is the non-contrast CT brain ASPECTS score very low identifying a very large established infarct with less potential for benefit?
- Refer rapidly. If in doubt, discuss with neuro-interventionist colleagues

Cerebral haemorrhage
- If the non-contrast CT brain confirms an intracerebral haemorrhage, implement a bundle of care including urgent blood pressure management, immediate reversal of anticoagulants, neurosurgical consultation, and avoidance of early do not resuscitate orders, where appropriate

Admit to the multidisciplinary stroke unit
- Urgent swallow assessment (<4 hours)
- Prophylaxis for venous thromboembolism
- Targeted blood pressure management (varies with thrombolysis administration and reperfusion status)
- Monitor and treat medical complications
- Early multidisciplinary review (physiotherapy, occupational therapy, speech and language specialist review etc.)
- Investigate aetiology (Box 29.2)
- Early initiation of secondary prevention measures (personalized, specific for aetiology, and goal directed)
- Lifestyle advise

Rehabilitation
- Commence in the acute stroke unit
- Referral onwards to community-based rehabilitation with early supported discharge or inpatient rehabilitation facilities
- Driving advice
- Refer to patient and community support groups

NIHSS, National Institute of Health Stroke Scale.

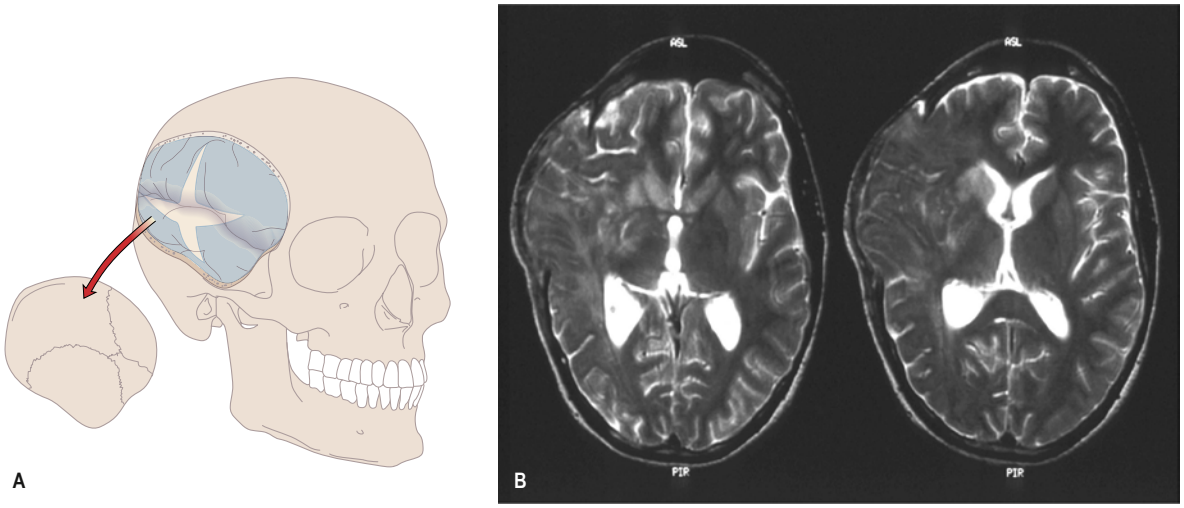

Fig. 29.13 Decompressive craniectomy for stroke. **(A)** Bone flap removed. **(B)** MRI scan showing brain swelling after bone flap removal.

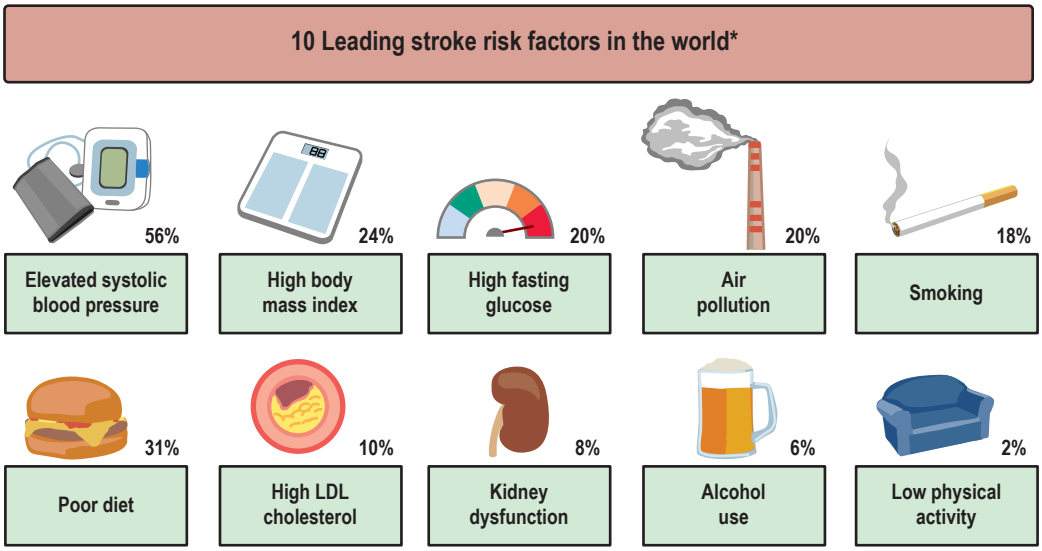
Smoking cessation

A strong association exists between smoking and stroke, with cessation associated with a 30% reduction in stroke recurrence. Behavioural intervention models increase smoking cessation and in combination with pharmacotherapy (e.g., varenicline, bupropion, nicotine replacement therapy) should be offered to all smokers (see Chapter 20 for further information on smoking cessation).

Pharmacological approaches

Blood pressure management

There is a linear relationship between blood pressure and stroke. Secondary prevention trials confirmed that lowering blood pressure is associated with reduced stroke and cardiovascular events proportionate to the magnitude of BP lowering.



*The sum of stroke burden attributable to the risk factors exceeds 100% because the effect of many of these risk factors overlap and are mediated partly or wholly through another risk factors.
Percentages show stroke-related disability-adjusted life years attributable to each risk factor.

Fig. 29.14 Burden of stroke attributable to risk factors. *(Credit: https://www.world-stroke.org/assets/downloads/WSO_Global_Stroke_Fact_Sheet.pdf.)*

A BP lowering target of <130/80 (or equivalent home BP reading <125/75) is recommended and well-tolerated, with a less intensive target such as 140–150 mmHg considered for those with orthostatic hypotension, bilateral severe carotid stenosis, or for frail older people.

Antihypertensive medication options should be personalized to the co-morbidity profile. Individualized treatment might mean choosing ACE inhibitors first line with coexistent systolic heart failure. Beta-blockers provide the least protection but may be beneficial for patients with ischemic heart disease or rate control of atrial fibrillation.

Mechanisms to improve compliance such as home or ambulatory BP monitoring can be instituted. Hypertension should be routinely treated with lifestyle modifications including the 'dietary approaches to stop hypertension' (DASH) diet, exercise, weight, and alcohol reduction.

Antiplatelet therapy

Single antiplatelet treatment long-term with clopidogrel 75 mg daily has replaced aspirin as first line in the absence of an indication for anticoagulation. Recent evidence supports the early use of dual antiplatelet therapy in patients with high-risk TIA or minor ischaemic stroke to reduce early stroke recurrence provided there is a low risk of bleeding. One such regimen combines aspirin 75 mg once daily with clopidogrel 75 mg once daily for NIHSS 0–3, after initial loading doses of 300 mg for aspirin and clopidogrel. Ticagrelor can be considered in this setting instead of clopidogrel (NIHSS 0–5). Single antiplatelet treatment is used from the outset in moderate to severe strokes.

The risk of haemorrhage is higher with dual antiplatelet treatment so treatment duration must be minimized, usually 21 days extending up to 3 months in limited circumstances such as stroke associated with intracranial stenosis. A proton pump inhibitor may reduce the risk of gastrointestinal haemorrhage with concurrent dual antiplatelet therapy.

Anticoagulation: atrial fibrillation and other conditions

Atrial fibrillation is associated with nearly a quarter of all strokes, therefore initial screening with an electrocardiogram and 24 hours of cardiac monitoring is essential. Prolonged monitoring for subclinical atrial fibrillation is recommended in embolic stroke, where the mechanism has not been determined after initial investigations. There is debate on the appropriate duration of prolonged monitoring in this setting with many suggesting at least 14 days. This can be carried out using an external monitoring device (>48 hours to 2 weeks or beyond) or an implantable loop monitor (ILR) positioned subcutaneously for up to 3 years. Atrial fibrillation may be confirmed on a single 12-lead electrocardiogram, based on more than 30 seconds of atrial fibrillation on intermittent (24-hour) cardiac monitoring or more than 5 minutes on implanted monitoring devices such as a pacemaker or ILR, according to consensus criteria.

Anticoagulation is recommended for persistent or paroxysmal atrial fibrillation and atrial flutter associated with stroke. Risk factors for atrial fibrillation include age over 50 years, frequent premature atrial contractions, dilated left atrium, high brain natriuretic peptide, hypertension, obesity, diabetes, and obstructive sleep apnoea with many factors serving as triggers (e.g., hyperthyroidism, cardiac surgery, and pneumonia).

Direct oral anticoagulants (DOACs), including direct thrombin or factor Xa inhibitors, are the standard of care after stroke (in preference to vitamin K antagonists) for non-valvular atrial fibrillation. DOACs are associated with better efficacy and safety having lower rates of intracranial haemorrhage, stroke, and thromboembolic events. DOACs are commenced once intracranial bleeding is excluded; immediately for TIA and as early as 48 hours for minor–moderate stroke. Anticoagulation for major stroke can be considered from 6 days after onset. Contraindications to DOACs must be considered along with drug interactions via cytochrome p450 or p-glycoprotein (e.g., anti-tuberculous and anti-epileptic medications). Modifiable

Box 29.10 Investigative work-up for ischaemic stroke

Laboratory	Routine labs; full blood count, full biochemical profile, thyroid function tests, lipids and glucose, HbA_{1c}, C-reactive protein, erythrocyte sedimentation rate, coagulation tests (prothrombin time, partial thromboplastin time)
Urine testing (as appropriate)	• Urine dipstick (infection, vasculitis) • Urine or serum toxicology (cocaine, amfetamines, may lead to vasospastic or vasculitic stroke) • Urine pregnancy testing (HCG)
Bladder ultrasound	• To assess the post void residual volume of urine
Hemodynamic monitoring	BP monitoring in hospital • Adhere to thrombolysis targets initially and secondary prevention targets on discharge • With differences in right and left arm blood pressure consider subclavian stenosis or aortic dissection
Electrocardiographic (ECG) monitoring to assess for atrial fibrillation	12-lead ECG; initial 24-hour cardiac monitor

Cardiac imaging
To assess for structural cardiac disease and aortic atherosclerosis particularly to elucidate an embolic stroke mechanism
	• Echocardiography
	  • Completed commonly for clinical or ECG evidence of cardiac disease or evidence of embolic stroke
	• Bubble echocardiogram with agitated saline bubble study in stroke patients 60 years and under to look for patent foramen ovale (PFO)
	  • One should consider appropriateness for PFO closure before screening for PFO
	• Transoesophageal echocardiography in selected cases
	  • Detection of PFO, atrial septal aneurysm, aortic arch atheroma, endocarditis, native and prosthetic valve abnormalities; for embolic stroke of unknown aetiology with multiple territory infarction or recurrent ischaemia where aetiology is not determined

Further tests to identify aetiology/manage risk factors	
Blood cultures	Consider if suspicion for endocarditis, infection, or with fever or raised CRP
Cardiac monitoring for embolic stroke	Prolonged external monitor—minimum 14 days or implantable loop monitor for atrial fibrillation detection
Haemodynamic monitoring to assess for BP control	Home BP monitoring or 24-hour ambulatory monitor
Other laboratory tests	• In cryptogenic stroke, testing for infections may be appropriate such as HIV, syphilis antibody, hepatitis B and C, VZV, or lyme, cryptococcus, and quantiferon (for TB) testing. The mechanism of stroke varies with each infection. Cryoglobulins may be considered • With anaemia and hypercalcaemia, check serum electrophoresis and immunoglobulins • Antiphospholipid screen: anti-cardiolipin antibodies (IgG and IgM), B-2 glycoprotein1, lupus anticoagulant (repeated after 3 months if elevated): consider these under age 50 years in absence of cardiovascular risk factors or if a history of miscarriages • An abnormal full blood count could prompt consideration for testing with a myeloproliferative neoplasm panel (such as thrombocytosis) • Autoimmune (ANA, ANCA, RF, anti-CCP, complement C3, C4) LDH, ferritin, fibrinogen, immunoglobulins, creatine kinase: consider if raised inflammatory markers, symptoms suggestive of vasculitis or systemic inflammatory disorder • Testing for heritable thrombophilia is not recommended in patients with stroke, regardless of age; except in selected cases such as neonatal stroke or prior history of venous thrombosis • In cerebral vein thrombosis, consider thrombophilia screening, testing for JAK2 mutation in the absence of clear provoking factors and a normal blood count, and testing for antiphospholipid syndrome
Lumbar puncture	• Consider lumbar puncture in an appropriate clinical context such as possible intracranial infectious cause of stroke, primary or secondary cerebral vasculitis • Clues include headache, cognitive impairment, seizures, or systemic symptoms • Cerebral vasculitis may cause elevated cerebrospinal fluid white cell count and protein
Sleep apnoea assessment	• Consider polysomnography which is the gold standard to calculate apnoea–hypopnoea index • Overnight oximetry is less sensitive for screening and will not differentiate central sleep apnoea
Cancer screening	• Appropriate body imaging or endoscopy where cancer is suggested by symptoms, laboratory findings, or multiterritory infarcts (Trousseau's sign) • D-dimer levels are a non-specific marker of cancer
Genetic and other testing	Genetic testing for monogenic causes of stroke in exceptional circumstances—for example CADASIL: mid-adult-onset cognitive decline, migraine with aura, neuropsychiatric disturbance, and diffuse white matter disease • Requires consent and counselling on implications

risk factors for bleeding should be addressed including uncontrolled hypertension, before DOACs are initiated. Falls are almost never a contraindication.

Exceptions where vitamin K antagonists are first line rather than DOAC include mechanical heart valve replacement, rheumatic moderate to severe mitral stenosis associated with atrial fibrillation or antiphospholipid syndrome with high-risk features and recurrent events. Vitamin K antagonists were the mainstay of treatment for renal failure with an estimated glomerular filtration of <15 mL/kg/1.73 m^2 (chronic kidney disease stage 5) and for individuals on dialysis, though certain DOACs are increasingly chosen for off-label use based on observational evidence. Recent evidence on atrial cardiopathy (a possible precursor of atrial fibrillation) and embolic stroke of undetermined aetiology (ESUS) identified no benefit

from anticoagulation therefore antiplatelets remain the mainstay of treatment.

Lipid management

Elevated LDL is a causal factor for atherosclerosis and aggressive LDL reduction in secondary prevention is associated with reduced mortality, cardiovascular events, and stroke. Statins prevent cholesterol synthesis via hydroxymethylglutaryl co-A reductase inhibition and are recommended for most stroke patients if not contraindicated (e.g., pregnancy). Statins provide particular benefit where atherosclerosis is present and for those with high cardiovascular risk and such patients should be started immediately on high-intensity statin therapy, such as atorvastatin 80 mg daily. Lower statin doses may be appropriate with potential drug interactions. For statin intolerance, use the maximally tolerated dose or trial the alternative high-intensity statin, rosuvastatin.

A target LDL <1.8 mmol/L should be reached within 1 to 3 months either with maximally tolerated statin therapy or addition of ezetimibe 10 mg daily. Ezetimibe inhibits dietary and biliary cholesterol absorption. Other LDL-lowering drugs may be considered via specialist services where LDL targets are not achieved; see Chapter 19 for discussion of these newer agents.

Diabetes

In patients with ischemic stroke and diabetes, a long-term target of HbA1c < 53 mmol/mol (<7%) is recommended for most people under age 65 without life-limiting comorbid illness to reduce the risk of microvascular complications (see Chapter 35). Antihyperglycemic agents associated with improved cardiovascular outcomes are preferred such as SGLT-2 inhibitors or glucagon-like peptide-1 receptor agonists (GLP-1RAs). GLP-1RAs (dulaglutide and semaglutide subcutaneous injection) reduce stroke risk in individuals with type 2 diabetes at high risk for cardiovascular disease. To date, SGLT-2 inhibitors have been shown to reduce cardiovascular disease and heart failure risk but not stroke.

Contraception and hormone replacement

The combined oral contraceptive pill should be avoided after a stroke. Similarly postmenopausal oestrogen therapy should be discouraged after stroke. Evidence is conflicting on the association between menopausal hormone replacement therapy and stroke; however, there may be a small increased risk particularly for higher oral oestrogen doses. See Chapter 47 for a fuller discussion.

Specific interventions

Carotid intervention

Multiple international guidelines recommend surgical carotid endarterectomy for individuals with recent anterior circulation non-disabling stroke who have symptomatic, ipsilateral, carotid stenosis of 50% to 99% using the North American Symptomatic Carotid Endarterectomy Trial (NASCET) measurement technique. Many factors impact on risk-benefit including co-morbidity, 5-year life-expectancy and plaque morphology including intraplaque haemorrhage on MRI. The optimal timing is between 2 and 14 days after the initial stroke. Endarterectomy is not recommended for complete carotid occlusion. Early surgical risks include stroke, myocardial infarction, haematoma, and cranial nerve injury due to traction, which usually recovers over months. Cerebral hyperperfusion syndrome can present postoperatively with headache and seizure after revascularization of a severe carotid stenosis if high blood pressure in the postoperative period is not controlled.

Carotid stenting is associated with a higher risk of stroke, especially in older patients, but a lower risk of myocardial infarction and cranial nerve injury. Stenting may be preferred in specific situations such as inaccessible carotid bifurcation or post-radiotherapy.

Optimizing vascular risk factors is the mainstay of treatment for carotid stenosis, along with other atherosclerotic stroke aetiologies such as aortic arch atheroma, vertebral or intracranial stenosis. Surgical intervention is not routine beyond carotid stenosis.

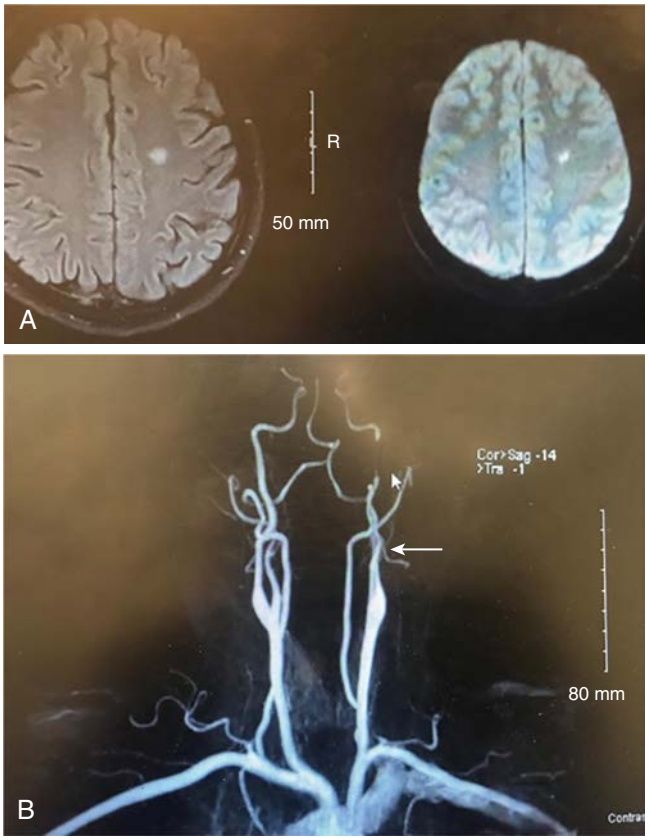


Fig. 29.15 MRI imaging of acute cerebral infarction (diffusion positive) and subsequent magnetic resonance angiography showing left extracranial carotid dissection. **(A)** Left subcortical acute infarct on MRI brain, hyperintense on flair and diffusion-weighted imaging. **(B)** Subsequent MRA confirms a left distal extracranial internal carotid dissection. This spares the carotid bulb which is the usual location of atherosclerotic occlusion.

Dissection of vessels

For extracranial cervical artery dissection (**Fig. 29.15**), antiplatelet or anticoagulant treatment is recommended for at least 3 months with assessment of recanalization at a later interval. Dual antiplatelet therapy is an option in the peri-stroke stroke period (first 21 days) for high-risk TIA and minor stroke. For intracranial arterial dissection, the potential risk of subarachnoid haemorrhage and aneurysm must be considered, with a preference therefore for antiplatelet treatment.

Embolic stroke of undetermined source

Antiplatelet therapy is recommended rather than anticoagulation.

Patent foramen ovale

Evidence confirms the benefit of PFO closure in stroke patients with embolic features under 60 years in the absence of another stroke mechanism (cryptogenic). The PASCAL classification is recommended for patient selection. Those with high-risk anatomical features such as atrial septal aneurysm and a large right-to-left shunt gain the most benefit. A multidisciplinary team discussion including cardiologists is recommended to inform decisions regarding PFO closure, the timing of which should be within 6 months post stroke. PFO closure is discussed further in Chapter 17.

Left atrial appendage occlusion

Thrombus in the left atrial appendage (a muscular, trabeculated pouch attached to the left atrium) is a primary cause of stroke associated with atrial fibrillation. A left atrial appendage occlusion (LAAO) device plugs off the left atrial appendage removing connection to the circulation. LAAO can be considered after cardioembolic stroke associated with non-valvular atrial fibrillation where anticoagulation is contraindicated due to a high bleeding risk (e.g., severe thrombocytopaenia or bleeding). Bleeding risk must be balanced with risk of device-related thrombosis. The risk of LAAO procedural complications is not trivial (4%–7%) despite the advancement in techniques.

Infective endocarditis

This is an uncommon stroke aetiology, but diagnosis requires a high index of suspicion. Over a third of patients with endocarditis have neurological manifestations, including stroke, and many more have covert ischaemic brain lesions. Infective endocarditis carries a high risk for haemorrhagic conversion of ischemic lesions, with rupture of mycotic aneurysms or septic necrotic arteritis. Targeted pathogen-specific antimicrobial therapy, as well as surgical intervention where appropriate, are the mainstay of treatment. Thrombolysis is contraindicated. Antithrombotics after endocarditis-related strokes are generally avoided due to the high haemorrhagic risk. Individualized decision-making is needed for those at high thrombotic risk such as mechanical prosthetic valves.

Cerebral venous sinus thrombosis

Anticoagulation with therapeutic heparin either low-molecular-weight heparin or unfractionated heparin are the treatment of choice in the acute phase even in the presence of secondary ICH. Despite limited evidence, endovascular thrombectomy may provide rescue treatment in highly selected cases. Anticoagulation with vitamin K antagonists is recommended to be continued for 3 to 12 months or indefinitely depending on aetiology. Evidence is also emerging for selected DOACs for this indication.

Vaccine-induced immune thrombotic thrombocytopaenia after certain adenoviral vector COVID (SARS-CoV-2) vaccinations is associated with unusual thrombosis including CVST. Therapy is different in this scenario. Non-heparin–based anticoagulation, DOAC, fondaparinux, or argatroban (parenteral direct thrombin inhibitor) are recommended, in conjunction with steroids, intravenous immunoglobulin, or plasmapheresis.

Other aetiologies

Inflammatory conditions (e.g., primary angiitis of the central nervous system and other secondary vasculitis) will require high-dose steroids and/or glucocorticoid-sparing agents. Infectious causes (e.g., varicella zoster, human immunodeficiency virus) will warrant antiviral treatment. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is the most common monogenic disorder causing stroke particularly in the young. Genetic testing after appropriate counselling, alongside intensive cardiovascular risk factor modification including antiplatelet therapy, are the mainstay of treatment, although with limited evidence. Identification of alternative genetic causes such as Fabry's disease may warrant enzyme replacement therapy.

Recurrent ischaemic stroke

For patients presenting with recurrent ischaemic stroke, a detailed reassessment of aetiology, compliance with treatment and secondary prevention is sensible. For cardioembolic stroke on DOAC, there is currently no evidence that switching to an alternative anticoagulant reduces stroke recurrence. Assess for a competing aetiology (e.g., atherosclerosis), review for drug–drug interactions and medication compliance, and ensure appropriate DOAC dosing. LAAO may be a useful adjunct in selected cases. Clopidogrel resistance may be considered in patients with stroke while taking clopidogrel, which is linked to a genetic polymorphism of cytochrome CYP2C19.

INTRACEREBRAL HAEMORRHAGE

Introduction

Spontaneous ICH is defined as non-traumatic bleeding in the brain parenchyma and is responsible for approximately 10% to 15% of strokes. It is associated with a higher mortality than ischaemic stroke (up to 50%) and most survivors face severe long-term disability. A large haematoma may act as a space-occupying lesion, causing raised intracranial pressure with brain displacement and herniation. The incidence is higher in Black African and Asian ethnic groups compared to White populations, potentially attributable to the higher occurrence of hypertension. Although the overall mortality from ICH is decreasing globally, the incidence in low-/middle-income countries is almost twice that of high-income countries and attributed to lack of awareness about primary preventive strategies and inadequate access to medical care.

Other types of intracranial bleeding (including subarachnoid and subdural bleeds) are covered in Chapter 12.

Aetiology (Fig. 29.16)

Hypertension

Hypertension is the most common risk factor for ICH accounting for approximately 70% to 80% of cases. Common locations for bleeding include the basal ganglia, thalamus, pons, cerebellum, and subcortical white matter. Deep perforator arteriopathy (degeneration of small, deep, penetrating arteries) relating to chronic hypertension and arteriosclerosis are the principal pathologies.

Cerebral amyloid angiopathy

Deposition of beta-amyloid in leptomeningeal and cortical small arteries, arterioles, and capillaries, in those over 50 years, can cause recurrent lobar ICH. CAA may also present with transient focal neurological episodes (amyloid spells) which are atypical for TIA. CAA is associated with apolipoprotein E genotypes E2 and Alzheimer's disease. The Boston criteria 2.0 provides a framework for the diagnosis of CAA. MRI with blood-sensitive sequences identify cerebral microbleeds, cortical superficial siderosis, and convexity subarachnoid haemorrhage with the latter two imaging characteristics particularly associated with a high risk of ICH reoccurrence.

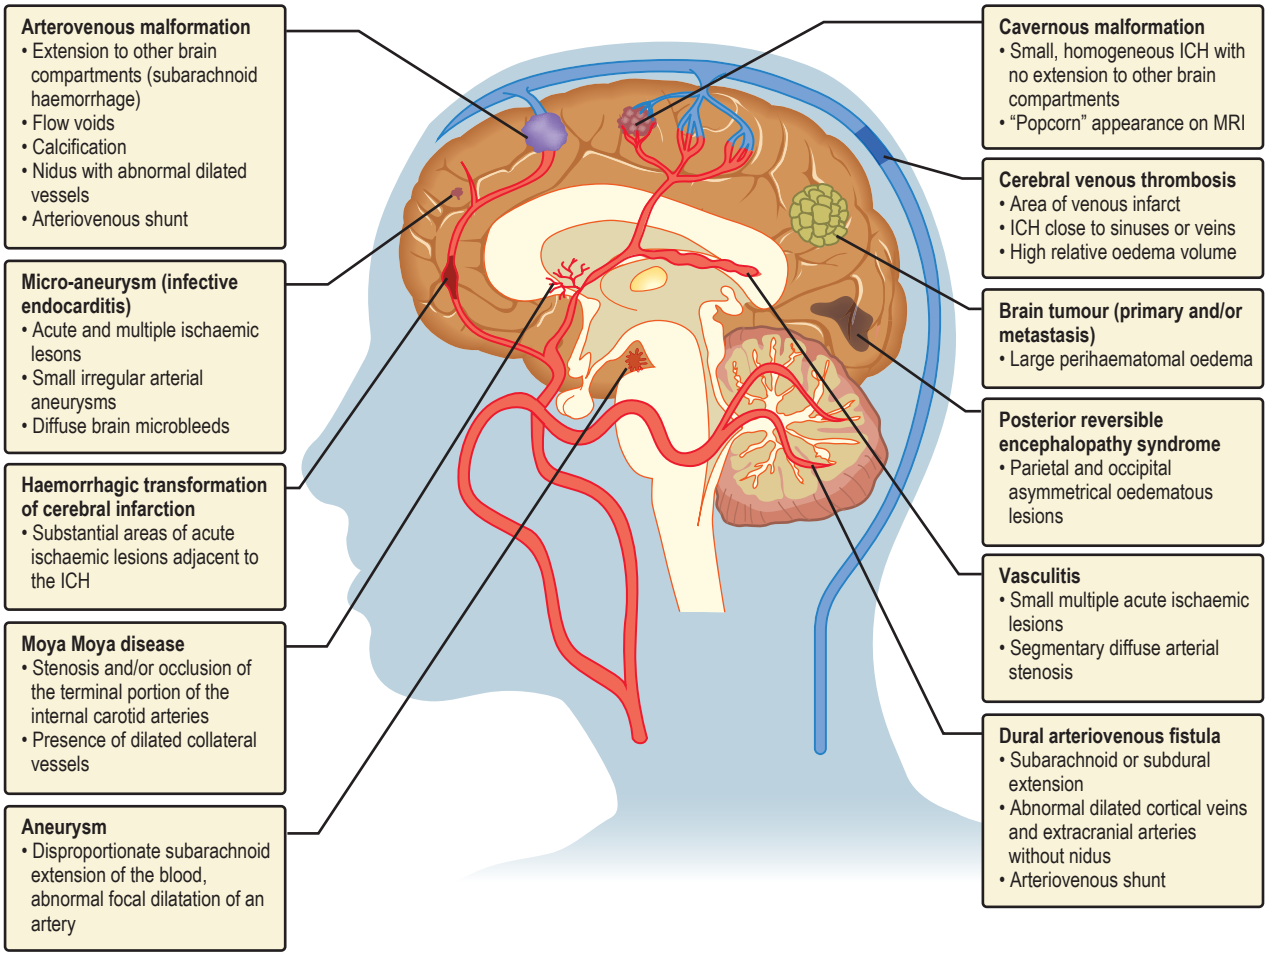

Fig. 29.16 Clues to treatable causes of ICH. *(https://www.nature.com/articles/s41572-023-00424-7.)*

Structural/vascular malformations

Brain neoplasms, arteriovenous malformations, cavernomas, and aneurysms cause approximately 20% of ICHs.

Haemostatic causes

Several studies have shown that anticoagulants increase the risk of ICH 8- to 11-fold. In comparison to vitamin K antagonists, DOACs are associated with a 50% reduction in ICH. Risk factors for anticoagulant-related ICH include older age, uncontrolled hypertension, diabetes, concomitant use of antiplatelet treatment, history of stroke or ICH as well as markers of cerebral small vessel disease (white matter hyperintensities, microbleeds, and lacunes). The use of dual antiplatelet treatment doubles the risk of ICH compared to monotherapy. Reperfusion therapies such as thrombolysis have been linked with an ICH risk between 1.7% and 8.8%.

Other aetiologies

- Sympathomimetic drugs (cocaine, amfetamines)
- Infective endocarditis
- Moyamoya
- Haemorrhagic transformation of a large ischaemic infarct may sometimes mimic a haemorrhage
- Venous sinus thrombosis or cortical vein thrombosis
- Chronic kidney disease is a risk factor.

Clinical features

At the bedside, there is no reliable way of distinguishing between cerebral haemorrhage and infarct. ICH is frequently associated with severe headache or decreased conscious level. Patients on oral anticoagulants should be assumed to have had a haemorrhage unless it is proven otherwise.

Investigations

Brain haemorrhage is seen on CT imaging immediately as intraparenchymal, intraventricular, or subarachnoid hyperdensity. This contrasts with CT brain imaging in the acute phase of an ischaemic stroke which may be normal or only show subtle signs of infarction. The CT scan is regarded as the reference standard for diagnosing ICH due to its rapidity, high sensitivity, and specificity for all forms of ICH, and widespread availability (Fig. 29.17).

Several non-contrast CT markers of expanding bleeds include the blend (blood-fluid level), black hole, island, and satellite signs. The spot sign (CT angiography) is an independent predictor of haematoma expansion, clinical deterioration, and mortality.

Structural causes must be suspected and investigated using CT/MRI angiography in those individuals without an explanation for the ICH, for example, those under age 45 years or those aged 45 to 70 years without a history of hypertension, malignancy, and anticoagulant use. Digital subtraction angiography is warranted in patients at high risk of macrovascular causes following negative CT/

Fig. 29.17 Non-contrast CT scan demonstrating a left basal ganglia bleed.

MRI angiography (**Box 29.7**). Additional imaging modalities including CT/MRI venography should be considered if venous sinus thrombosis is suspected. An interval MRI/MRA can be considered at 3 months where the aetiology has not been determined.

Baseline blood tests should include urgent coagulation studies, platelets, glucose, and toxicology where appropriate. For warfarin, point-of-care INR testing should be employed to minimize delays in reversal.

Medical management

ICH is a neurological emergency, and the treatment should be delivered in either a stroke unit or intensive care unit. Treatment is often provided as a bundle of care. Frequent monitoring of GCS and neurological signs is essential, and neurosurgery may be required. Anticoagulation should be rapidly reversed where possible (see Chapter 40).

Acute blood pressure management in ICH is recommended for people with ICH symptom onset within the last 6 hours, aimed to achieve a target of SBP 130–140 mmHg in those with SBP ranging between 150 and 220 mmHg. BP lowering should be achieved within 1 hour if possible and maintained for 7 days minimizing variability. For SBP > 220 mmHg, or GCS < 6 (elevated ICP suspected), caution should be exercised.

The third Intensive Care Bundle with Blood Pressure Reduction in Acute Cerebral Haemorrhage Trial (INTERACT3) demonstrated that implementing the care bundle—targeting SBP 140 to 130 mmHg within 1 hour of treatment initiation, intensively controlling elevated blood glucose (6.1–7.8 mmol/L for non-diabetic patients, 7.8–10.0 mmol/L for diabetic patients) as soon as possible, treating pyrexia to maintain a body temperature below 37.5°C within 1 hour, and reversing abnormal anticoagulation—resulted in better functional outcomes (measured on the modified Rankin Scale) at 6 months post-treatment compared to usual care. This included favourable effects on survival and health-related quality of life.

Mechanical ventilation may be required for individuals with a low GCS. Corticosteroids provide no benefit and should be avoided. Normoglycemia should be maintained. Prophylactic epileptic drugs are not recommended.

Surgical management

Posterior fossa haematoma may cause obstructive hydrocephalus or coma due to brainstem compression; urgent neurosurgical clot evacuation is lifesaving (and is required where the haematoma is >3 cm, shows mass effect, or the patient has a low GCS). The role of surgical decompression for non-cerebellar bleeds is less clear-cut and liaison with neurosurgeons is vital. Use of minimally invasive surgical techniques to evacuate haematomas is an area of active research. The Trial of Early Minimally Invasive Removal of Intracerebral Hemorrhage (ENRICH), predominantly recruiting patients with lobar haemorrhage with a hematoma volume of 30 to 80 mL, demonstrated that minimally invasive hematoma evacuation within 24 hours resulted in better functional outcomes at 180 days compared to best medical management alone in lobar haemorrhage. The SWITCH trial provided weak evidence that decompressive craniectomy plus best medical treatment might be superior to best medical treatment alone in people with severe deep ICH (volume 30–80 mL), but survival was associated with severe disability in both groups (mRS 4–6). An external ventricular drain may be required for obstructive hydrocephalus as seen with intraventricular haemorrhage or cerebellar mass effect.

Secondary prevention

Identifying the underlying aetiology is key to appropriate secondary prevention. Control of hypertension is central for many individuals with a target blood pressure goal of <130/80. It may be appropriate to resume anticoagulation if reversible risk factors for bleeding are identified however the optimal timing is not well established.

CORE SKILLS AND KNOWLEDGE

Psychiatry is a branch of medicine, and liaison psychiatry (LP) is a subspecialty of psychiatry that is based in the general hospital. LP sees patients on a consultation basis to bridge between general hospital colleagues and mental health clinicians, most of whom are community-based. The LP team assesses and treats emergencies (self-harm and suicide attempts, acute confusion, psychosis, etc.), as well as provides advice on patients with physical conditions who have related or unrelated psychological morbidity.

Key skills include:

- Taking a psychologically informed history
- Recording a mental state examination
- Assessing decision-making capacity and how this informs consent
- Making a formulation (complex understanding of interacting factors)
- Assessing risk to self or others
- Assessing the effects of alcohol, cannabis, other misused substances and psychiatric medication.

These skills can be developed by shadowing members of a liaison psychiatry team (including psychiatrists, psychiatric liaison nurses, and psychologists) as they review new cases. This can be supplemented by spending time in inpatient psychiatric units and shadowing community mental health teams—where mental health can be assessed in the broader context of the patient's home situation and community relationships.

CLINICAL SKILLS

Approach to the patient

There are several steps to follow when assessing patients in psychiatry:

- the psychiatric history (Boxes 30.1–30.3)
- the mental state examination (MSE; e.g., following the 'ASEPTIC' structure set out in Box 30.4); detailed assessment of cognition is set out in Box 30.5
- obtaining a collateral history, which is always worth the effort if possible (Box 30.6)
- physical examination and investigations for signs of physical illness that might be affecting mental state (Boxes 30.7 and 30.8).

Information from these different sources are combined to produce a 'formulation' which places a patient's likely mental health diagnosis in the wider context of their physical, psychological, and social context, and has far greater utility than a simpler model of 'diagnosis'.

Box 30.1 sets out the circumstances of a psychiatric interview. Taking a psychiatric history is quite different from history-taking in other areas of medicine, and developing these skills is a steep learning curve. The experience may be exhausting for both patient and interviewer.

Box 30.1 Preparation for psychiatric interviewing

Decisions about the circumstances of the interview

How much time have you got? Do you have time to read old notes?

Will you interview on your own? Might the patient bring a relative?

Which location is best, providing adequate privacy for patient and adequate safety for you?

Do you need an interpreter? Are there other communication difficulties (e.g., autism, deafness)?

How will you record key information (you may forget dates, medication doses)?

Good beginnings

After introductions, explain what your role is: student, doctor, psychiatrist

Explain that you will try not to trigger/retraumatize, but you will ask personal questions

Define the limits of confidentiality and with whom you will share information

Record if your patient is detained under legislation, or any special circumstances

Additional diagnostic information

Even with a thorough history from the patient and MSE, a collateral history will clarify many aspects of the diagnoses (Box 30.6). The key findings of the MSE determine the formulation and management plan.

Box 30.2 Key sections of psychiatric history

History of presenting complaint

- What is the problem? When did it start? How did it develop: onset/progress/severity/social impairment (e.g., unable to work)?
- What makes it better or worse?
- Past psychiatric history
- Age of onset of symptoms and first contact with services (there is always a time gap); nature and progression of difficulties; diagnoses
- Hospital admissions: when, approximate length; voluntary or under legal section
- Past treatments—medication, psychological therapy, electroconvulsive therapy (ECT): what has helped in the past, what has not, medication type, doses prescribed, and actual doses taken (i.e., concordance with prescription); list side-effects

Medical history

- Past and current physical illness and treatments
- Current medication, including any over-the-counter drugs taken regularly; any drug can be purchased online or acquired.
- See Box 30.3
- Drug allergy: list what happened (rash, anaphylaxis, other symptoms) with what substance

Family history and living conditions

- Who's at home with you now?
- Housing type: adequacy for needs of patient/others. Income, work details, debts
- Parents: biological/adoptive/step-parents and siblings: age, state of health or cause and age of death, quality of relationships, then and now? Currently, who supports the patient and who exacerbates their problems?
- Family history of mental disorder includes substance misuse and suicide

Premorbid personality

- How would they describe themselves, how would others describe them? (use quotation marks)
- Prevailing mood and stability of mood; impulse control
- Nature of relationships with others: partners, friends, colleagues (e.g., close and confiding, casual only)
- Leisure interests (hobbies)
- Tolerance of stress and coping style, use of substances to manage stress, modify mood or social interaction

Personal history

- Obstetric and birth: planned/unplanned conception, maternal physical and mental health during pregnancy; birth full-term/premature, obstetric events and complications, low birth weight, congenital abnormalities, neonatal illness, maternal separation, and bonding
- Development and milestones: delays in interaction with others, speech; motor control, walking, toilet training; sleep difficulties; emotional or behavioural difficulties, hyperactivity; physical illness
- Family atmosphere and stability: abuse?
- Were there periods of separation from caregivers (e.g., in hospital due to childhood illness; in foster care due to parental difficulties)?
- Social development: key friendships, experience of bullying, any juvenile delinquency
- Educational attainment: specific learning difficulties, school refusal, age left education and qualifications
- Occupation: periods of employment, nature of work/skills
- Psychosexual: age of first sexual experience, sexual orientation, number, length and quality of significant relationships, marriage(s), children from previous relationships

Risk history

- Risk episodes: previous self-harm and suicide attempts; self-neglect and exploitation by others (financial, sexual), thoughts of and actual harm to others
- Forensic history (always try for collateral): arrests, charges, and convictions: nature of offences, outcome (custodial sentence, community service, probation); always ask about violent actions
- Include criminal activities where patient was not arrested, crime not detected

Substance misuse history

- Alcohol use, amounts (in units) (Fig. 30.7)
- Illicit substance use: type, pattern of use including frequency, dependency; associated problems—occupational, social, relationship, health, and criminal activity

Collateral history from informants (e.g., friends, family, GP, work colleagues). Any contradictions from patient's account? See Box 30.6

Part of every first encounter is an additional, bespoke physical examination. This may reveal evidence of substance misuse (Box 30.9) or of physical co-morbidities which are common in patients with psychiatric disease (Box 30.10). All hospitals have protocols for routine physical examinations. This process is guided by current symptoms, likely disease processes (given this presentation, patient's age, sex, risk factors, etc.) and the speciality where that patient is being admitted. Psychiatry has its own priorities when a patient is admitted to hospital—even if a recent physical exam by others looks complete: Box 30.7.

The history (physical symptoms, medical history, medications, etc.), MSE, and physical exam determine routine then bespoke investigations (Box 30.8). Abnormal findings need discussion that day (sometimes urgently) with other members of the mental health team. For example, patients may present with what is thought to be a behavioural or 'psychiatric' presentation who have actually suffered and intracranial bleed (picked up on neuroimaging, Fig. 8.39), or may have acute encephalitis or an unusual epilepsy syndrome (evidenced by abnormal electroencephalography; Fig. 28.19). Acute disease processes that will likely deteriorate on a psychiatric ward merit urgent discussions with medical colleagues.

Formulation

Given the multifactorial nature of psychiatric disorders, many clinicians synthesize findings from their assessments using the four categories below as a 'formulation':

- **Predisposing factors** render someone vulnerable to developing a psychiatric disorder across their life course. These may include genetics, *in utero* environment, early development, adverse childhood experiences (ACEs), and personality, among others.
- **Precipitating factors** predate the onset of the disorder and are usually considered triggers that again can be divided into the categories of the biopsychosocial model. These interact with the predisposing factors and may at times lead to mental disorder. Biological examples include dysphoric medications (Box 30.3) and the strongest legal depressant, alcohol. Common psychological precipitants are losses (bereavement, relationship breakup), and social precipitants include 'exit events' such as loss of employment, moving home, or moving country (migrants).
- **Perpetuating factors**, also called maintaining factors, are highly relevant to clinical practice as identifying and managing these is key to successful treatment of a disorder. In general hospitals, biological examples include pain from physical disease processes, complications from medical procedures, and anxiety arising from uncertainty about medical outcomes. Psychological factors that prolong distress might be personality types that adjust badly to change. Social factors include unsuitable and insecure housing, other financial concerns, and life-changing injuries/symptoms that interfere with life goals.
- **Protective factors** predict the duration and severity of episodes. These include mature coping skills (gentle exercise, mindfulness, avoiding excess alcohol to reduce stress), a good support network, strong identity, and a high sense of belonging in a community, spirituality/religion, among others.

Risk assessment

Risk is defined as the likelihood of a negative event occurring, and its assessment is one of the most important outcomes of a clinical interview. While every healthcare professional should be proficient in determining risk for their patients, it is especially important for mental health professionals, as patients with mental disorders have a higher risk of self-harm. Risk assessments are dynamic,

Box 30.4 Mental State Exam details (ASEPTIC)

A—Appearance and behaviour

General appearance, physical state, abnormal movements, and behaviour

- Style and manner of dress, hygiene: self-neglect
- Physical state: any signs of distress or physical illness, drug/alcohol withdrawal, self-harm scars
- Quality of eye contact (e.g., fixed stare, avoidant)
- Manner of engagement during interview (e.g., suspicious/guarded/relaxed): comment on rapport
- Distractibility and preoccupation with internal world (e.g., appearing to respond to auditory hallucinations)
- Hyper-/hypoactivity: relevant in delirium and mood states
- Abnormalities of movement: mannerisms are idiosyncratic goal-directed behaviours (e.g., style of walking); motor stereotypes are regular repetitive non-goal directed movements (e.g., rocking)

S—Speech

Rate, amount, volume, form, and coherence

- Increased (mania)/decreased (depression); fast (pressure of speech—mania)/slow; loud (agitation, anxiety)/soft (depression)
- Verbal stereotypy: repetition of irrelevant words or phrases
- Formal thought disorder disruption to the continuity of thought

Answers may be initially appropriate but quote speech in full (inverted commas).

Common patterns of abnormality affecting the content of speech include:

- circumstantial speech, straying far from the topic before returning to the point of the question;
- tangential speech, where they do not return to answer the question or the conversation in hand, the latter represents mild derailment.

- Loosening of associations, the juxtaposition of completely irrelevant ideas. The most extreme form of thought disorder is known as word salad where meaning is indecipherable.
- Flight of ideas in hypomanic/manic states is the rapid transition between topics via internal links: connected words, themes, rhyming, puns, alliteration, e.g., 'Black bears scare me, I've a black bag'), or the inclusion of external distractions into the train of thought (e.g., subsequent comments on interviewer's black shoes)
  - Poverty of thought describes insubstantial speech that conveys little meaning
  - Neologisms: words or phrases invented or used idiosyncratically to denote new meaning ('I don't like my boss: he's a bosstard')

E—Emotion, meaning mood and affect

Mood, subjectively—according to the patient

Affect, objectively—as assessed by an external observer. Try to record a score

Suicidality: subjective + objective assessment (this is essential to every mental state examination)

- Subjectively patient's description of their current mood: rated out of 10, with 0 lowest they can imagine; it is useful to rate 'usual' mood as 8/10 (tell them 10/10 is the 'happiest day of their lives') and do NOT accept a negative number for worst mood.
- Objectively interviewers appraise their affect (external manifestation of emotional state) and emotional range during interview. The term euthymic describes an emotional state within the normal range and with normal reactivity. Abnormal states show incongruous affect. Emotional responses may be perplexed, blunted, or flat (lacking emotional reactions) in depression and some psychosis states. Affect can also be labile (extremely changeable range of emotions).
- Presence or absence of thoughts of self-harm: state any plans and degree of intent.
- Further enquiry about suicidal ideas. Record the spectrum from passive death wish (e.g., going to sleep and wishing s/he would not wake up), through suicidal ideation and suicidal intent, to suicide plan, and actions **(if you have not asked about suicide, you have not completed an MSE).**

P—Perception

Sensory distortions, sensory deceptions (illusions, hallucinations). Auditory hallucinations include noises and voices. Other hallucinations include visual, somatic, olfactory, taste, sexual, and touch. Some hallucinations (e.g., hypnopompic hallucinations) are part of normal experience.

- Distortions are changes in intensity or quality of real sensory phenomena (e.g., micropsia in a temporal lobe seizure).
- Deceptions are either illusions (misinterpretations of real stimuli), often in altered mood states or consciousness (e.g., hearing an innocuous noise as a sinister footstep when anxious) or hallucinations, which are internally generated perceptions in the absence of an external stimulus.
- Pseudohallucinations are experienced as arising from within the patient (e.g., 'voices in my head') rather than the external world, but they are beyond conscious control. In contrast to hallucinations, they are not experienced as having a material reality. They occur in normal grief (seeing or hearing the deceased) as well as a range of disorders including post-traumatic stress ('flashbacks') and emotionally unstable personality disorder.

T—Thought content

Morbid preoccupations (i.e., ruminations), obsessions, overvalued ideas, and delusions

- Obsessions: repetitive, intrusive, unwanted, stereotyped thoughts or images.
- Overvalued ideas: those held with a morbid intensity, but without fulfilling the criteria for a delusion. They are not argued beyond the bounds of reason (e.g., patients with anorexia nervosa are not deluded but have overvalued ideas about their weight).
- Delusions are fixed (usually false) beliefs held without evidence that is out of keeping with an individual's sociocultural background. Delusions may be primary or secondary. There are many subtypes of delusion, and these are key to differentiating the type of psychosis, for example, schizophrenia versus a depressive psychosis.
- Delusions of passivity describe the experience that one's mind (thought passivity), emotions, actions, will, or body (somatic passivity) is not under one's control. Passivity is usually linked with a delusional explanation (e.g., thoughts removed by the government), including: thought insertion—someone is inserting thoughts into one's head; thought withdrawal—someone is removing thoughts from one's head; thought broadcasting—loss of the sense of barrier between one's mind and external world: a delusion that others can hear or know what we are thinking

I—Insight

Understanding of illness and its treatment. We use the 3 'A's':

- Awareness: Do they think there is anything wrong with them?
- Attribution: If something is wrong, do they think it is a physical or psychological problem, or both? How do they describe the problem and what caused it?
- Acceptance: Do they think they need treatment, if so what? What do they think of treatment offered? Is psychiatric treatment acceptable to them?

C—Cognition

Perform detailed cognitive assessment (**Box 30.5**) if you suspect cognitive impairment.

For most patients, use the headings COMIC:

Consciousness level: describe in one word, usually alert; if impaired consider Glasgow Coma Scale or similar.

Orientation by person, place (the ward, floor level, and the hospital) day, month, and year.

Memory: a quick bedside test of short-term memory uses three unrelated words (a colour, a flower (that is not usually associated with that colour) and a place (perhaps a city). Get patient to register the three words, move on to something else, then test recall at 2 minutes. If the score is below 3/3 recall, give a hint: the word is a colour or flower or city, but record that you gave a prompt.

Intelligence quotient: only people with high IQ will give you a number; focus on levels of intelligence you observe (not language sophistication) in the light of patient's educational attainment.

Concentration: subtract serial 7s from 100, list the months of the year backwards; both can be established (time to answer, numbers of mistakes) with interpreters; in patients whose first language is not English, try days of the week backwards.

Box 30.5 Details of cognitive exam

Global	Dominant hemisphere tests	Non-dominant hemisphere tests	Frontal lobes tests
Level of consciousness (if abnormal, use the Glasgow Coma Scale), orientation in time, place, and person Attention and concentration (e.g., test naming months of the year backwards), memory Anterograde short-term ('working') memory tested by immediate recall of three given items Long-term tested by their recall 5 minutes later Retrograde memory includes public (e.g., 'Who is the prime minister?') and personal ('Where were you born?') information, semantic (e.g., how to use a fork) and episodic memory (e.g., 'What happened yesterday?') Global cognition includes IQ (usually estimated rather than formally tested; e.g., 'high', 'low normal')	Language (naming of objects, repetition of a phrase, comprehension of commands, reading and writing) Calculation (simple mathematical tests) Praxis (limb apraxia, e.g., 'Show how you wave goodbye') Finger agnosia, e.g., put a pen in their hand with eyes closed—'What's this?' Conceptual apraxia, e.g., show toothbrush—'What's this used for?') and awareness of details	Neglect (hemi spatial rather than sensory) Construction and visuospatial ability (e.g., 'draw a clock at 3:45'	Verbal fluency (e.g., 'Name as many animals as you can in a minute': tests fluency plus strategy, e.g., listing farm animals first) Similarities (e.g., 'What do a table and chair have in common?'; 'What is the difference between a mistake and a lie?') Estimates (e.g., 'How fast can a leopard run?': patients with frontal lobe lesions typically grossly overestimate) Alternating sequences (copying of alternating hand sequence, which tests sequential motor activity dependent on dorsolateral prefrontal cortex function)

Box 30.6 Collateral history: getting information from others to make/confirm the diagnosis

Index event(s)	Responses, adaptations	Possible psychiatric diagnosis (based on limited examples)
Early experiences of frequent separations, deaths in family, family breakdown	Insecure attachment styles: see Box 30.38	Personality difficulties characterized by problematic relationships; depression
Neurodevelopmental milestones: delayed or never attained; loss of milestones is unusual	Struggles with school readiness, problems learning at school	Intellectual disability (ID) is not a mental disorder but psychological co-morbidities are high in people with ID
Speech delay/difficulties (no single words by aged 2), deficits in social interactions, narrow interests and hobbies	Struggles with social imitative play, making friendships, coping with change at school/home	Autism spectrum disorder
Adverse childhood experiences (ACEs)	Effects of most ACEs can be mitigated with support from one trusted adult	Increased mental disorders—affective, anxiety, psychosis, and borderline traits (see Box 30.40)
School refusal or 'truancy'	Anxiety leading to avoidance behaviours	Anxiety disorders and/or state anxiety
School-based concentration difficulties: poor academic performance despite ability	Symptoms of conduct and emotional disorders; associated hyperactivity	Increased mental disorders—affective, anxiety, and attention deficit hyperactivity disorder (ADHD)
Failure to progress in social learning: empathy, adapting behaviour with age	Disruptive behaviours at school and home, trouble with police, violence	Personality difficulty on the dissocial domain (see Box 30.40)
Early life isolation: imposed on the child or self-imposed	Avoids new situations, favours solitary pursuits	Personality difficulty on the Detachment domain (see Box 30.40)
Late adolescence changes in social functioning: previously outgoing person withdraws over weeks then months	Prodrome symptoms: anxiety, mood changes, sleep and concentration deteriorate	Possible schizophrenia diagnosis
Adult changes in sleep and/or mood	Clarify any increase in alcohol/substances	If no alcohol/substances making things worse, likely depression
Act(s) of self-harm in all age groups	Changes observed before event that are indicative of suicidal intent; increasing isolation, completion of affairs (cancelled holidays, wrote a will), talked of being a 'burden' to others	Some people understate the extent of their difficulties and suicidal intent. Post self-harm, they are safe in hospital and may experience a 'flight into health', saying everything is just fine. Collateral history saves lives
New drug is prescribed: see Box 30.3	Changes in behaviour observed: new insomnia, new responding to voices, rising confusion or paranoia	Likely a transient mood, confusion, or psychotic state (stop the new medication) but remember the medication may have 'brought out' this change in mental state
Missing important events, new irritability due to concentration or subjective memory problems	Memory loss for recent events but intact long-term memories	Dementia—see Chapter 49

Box 30.7 Priorities in physical examination when admitting patients with mental disorders

Signs of acute medical illness: record abnormalities of vital signs (pulse and respiratory rates, blood pressure, temperature, and oximetry).

Any compromise of consciousness level—indicative of brain-based or systemic illness, or related to intoxication/withdrawal of alcohol or substances.

Signs of the effects of self-harm: cuts to limbs or body, bruises (self-harm and/or domestic violence), neck ligature marks (attempted hanging), other injuries including burns, and trichotillomania (hair pulling).

Signs of alcohol or substance misuse (**Box 30.9**).

Medical conditions that can cause/exacerbate affective, anxiety, or psychotic disorders (see **Box 30.8** for investigations).

Co-morbid medical conditions: these are the rule not the exception in people with psychosis/bipolar affective disorder over aged 30. They principally include cardiovascular and chest diseases and diabetes. Detecting these or their proximal risk factors (smoking, obesity, sedentary lifestyle) will prevent future physical morbidity and premature mortality.

Coincidental physical pathology: psychiatric patients do not get more cancers than other people (with the exception of lung cancer due to 40% smoking rates in people with psychosis) but their cancers are detected late and they are less likely to be offered treatments than the general population.

time-sensitive, and therefore require regular updating. Comprehensive risk formulations should include risk to self, risk to others (e.g., children), and risk *from* others. Each category should consider historic, present, and anticipated risk, taking into account protective factors (**Fig. 30.1**). Collateral information (**Box 30.6**) should be obtained, and neglecting this will undermine a full risk assessment. The whole process needs to be collaborative in nature and can have therapeutic potential. Risk assessments would ideally conclude with a comprehensive risk management plan and safety planning. Structured tools may be used, though these have not been shown to be useful in predicting suicide risk; they are most commonly used in forensic settings.

Treatment approaches in psychiatry

A wide range of evidence-based treatments are available for mental disorders. Most of these are delivered outside the general hospital, with many positive actions within the control of most patients. It is simplistic to consider psychiatric interventions as medications and talking therapy: for most conditions, a stepped approach to treatment is adopted of which medications are one part, having

Box 30.8 Investigations of a new patient for psychiatric admission, or at clinic

These routine tests should be performed on all or most patients being assessed in the context of a new or acute mental health problem, to screen for physical illness that might be undiagnosed or disease contributing to the disturbance of mental state

	Abnormality	Potential causes in patients with mental illness
Full blood count	Anaemia	Dietary deficiency, malabsorption or blood loss from any source e.g., gastrointestinal bleed
	Infection	Urine, chest, blood-borne–virus infection in intravenous drug users, opportunistic infection in those with HIV
	Neutropenia	Clozapine side-effect
	Thrombocytopenia	Alcohol excess
Urea and electrolytes	Acute kidney injury	Dehydration through self-neglect, nephrotoxic drug overdose
	Hypokalaemia	Vomiting or diuretic/laxative abuse in eating disorders
	Chronic kidney disease	Lithium Poorly treated medical co-morbidities, e.g., diabetes
Thyroid function	Hypothyroidism and hyperthyroidism	Thyrotoxicosis may mimic mania or psychosis Hypothyroidism is a differential diagnosis for depression
Random glucose, HbA_{1C}	Hyperglycaemia	Undiagnosed or poorly controlled diabetes
Liver profile	Raised transaminases	Alcohol excess, paracetamol overdose, medications, hepatitis
Urinalysis	Nitrites and leucocytes	Urinary tract infection causing sepsis and delirium in older adults
	Blood, protein, or glucose	Undiagnosed chronic kidney disease or diabetes
	Pregnancy test	Unknown/undisclosed pregnancy
Urine drug screen	Undisclosed substances (benzodiazepines, cannabis, methadone)	Extent of substance misuse (if minimized) may lead to reformulation of diagnosis
Electrocardiogram	Features of ischaemia	Undiagnosed ischaemic heart disease
	Prolonged QT interval	Urgently review psychiatric medications + medical referral

Additional tests may be indicated in some patients undergoing psychiatric evaluation as directed by specific features of the history and mental state examination

	Screening for	Actions
Lithium level	Low in non-adherence, high in toxicity e.g., renal failure	Review lithium dose, consider need for emergency treatment if toxicity
Drug levels for toxicity	Clozapine, other mood stabilizers, paracetamol (in overdose)	Keep within therapeutic ranges, specific treatments for toxicity

Box 30.8 Investigations of a new patient for psychiatric admission, or at clinic—cont'd

	Screening for	Actions
Cortisol	Cushing's disease	Refer to endocrinologist
Calcium	Hypercalcaemia: can disturb mental state	Consult endocrinology for parathyroid tests; rule out malignancy and myeloma
Phosphate, magnesium, calcium, vitamins, folate	Nutritional deficiencies in eating disorders, severe depression and dementia	Eating disorders emergencies are managed in general hospital then under the care of a specialist eating disorders service
Blood-borne viruses	Curable hepatitis C; treatable hepatitis B and HIV infections	Refer to hepatology, HIV, or general services
Creatinine kinase	Neuroleptic malignant syndrome: rise is CK is usually mirrored by a parallel rise in neutrophils	Refer to specialist medical/intensive care specialists for treatment
Chest X-ray	Cancer, lower respiratory tract infection, especially in smokers	Specialist respiratory referral
Brain scanning (CT and MRI)	Intracranial bleeds, trauma, CNS infection including abscess, neoplasm	Specialist neurology/neurosurgical referral
Lumbar puncture	Infection, encephalitis (see Chapter 28, 'Encephalitis' section)	Seek specialist neurological advice
Electroencephalogram	Episodes of abnormal mental state, e.g., psychosis of temporal lobe epilepsy or delirium	Specialist neurology referral. Prescribing antipsychotics will raise the seizure threshold

Box 30.9 Physical examination and signs of alcohol and substance misuse

Features of alcohol misuse
- Altered consciousness (intoxication withdrawals, hepatic encephalopathy)
- Smell of alcohol on breath
- Plethoric facies, jaundice, anaemia
- Chest diseases: tuberculosis, aspiration pneumonia
- Hand tremor, palmar erythema, spider naevi, irregular or fast pulse, high blood pressure, peripheral neuropathy
- Abdominal tenderness (gastritis, pancreatitis, hepatitis)
- Liver: tender and enlarged (alcoholic hepatitis), distended abdomen of ascites
- Lower limbs: check for balance (ataxia of cerebellar damage), muscle weakness and peripheral neuropathy

Features of substance misuse
- Altered consciousness level: depressed (opiates), increased (amfetamines and stimulants)
- Opiate/opioid withdrawal: lacrimation, rhinorrhoea, sweating
- Abnormal pupils (pinpoint in opiate intoxication, dilated in withdrawal)
- Damage to nasal passages or septum from 'snorting' cocaine
- Poor dentition
- Lymphadenopathy (opportunistic infection including HIV)
- Track marks of intravenous drug use (**Fig. 30.8**)
- Chest diseases: emphysema (tobacco/cannabis use), lung abscess (smoking heroin)
- Liver tenderness, enlarged (hepatitis)
- Groin: track marks of intravenous drug use, abscess, and sinus formation
- Proximal muscle weakness

Box 30.10 Common physical morbidities in patients with mental disorders excluding the effects of alcohol, substances, and self-harm

- Cognitive impairment: apparent (negative symptoms of psychosis, depression) or objective, e.g., dementia
- Anaemia, poor dentition, eye damage from diabetes
- Chest diseases: chronic obstructive pulmonary disease (COPD), pneumonia, tuberculosis—all three are increased in smokers
- Irregular or fast pulse (atrial fibrillation), high blood pressure, increased limb tone of high neuroleptic doses
- Obesity: compare weight with previous records, record silent effects on liver (obesity is 'diabetes in the liver') and the locomotor system (osteoarthritis); look for signs of recent weight loss (skin flaps, reduced muscle mass)
- Constipation: clozapine, opioids, anticholinergic medications
- Lower limbs: check peripheral pulses and for peripheral neuropathy and skin diseases of diabetes; signs of venous thromboembolism (hospital admission)

instituted other measures. **Box 30.11** sets out early universal interventions (steps 1–3) available to community teams, followed by more specialist treatments provided by experts (steps 4–7). Psychotherapy choice often depends on what is available locally, waiting lists, and whether the patient can commit time and money. In the UK, other than cognitive behavioural therapy (CBT), most therapies are not provided free.

It is good practice to communicate with the therapist about the modality of therapy: neither CBT nor psychodynamic approaches (involving long treatment times, examining past patterns, with less direct 'advice' than CBT) will suit all patients. Getting therapy right can be life changing for patients.

Prescribing in psychiatry

General principles of prescribing in psychiatry are covered in **Boxes 30.12 and 30.13**, with prescribing in the major psychiatric diagnoses covered in detail in the relevant sections later in the chapter.

Common classes of psychotropic medications include antidepressants, antipsychotics, and anxiolytics, although there is considerable overlap between classes and drugs formerly licensed for one indication sometimes prove effective in other contexts, for instance selective serotonin reuptake inhibitors, originally intended as antidepressants, are now commonly used to treat severe post-traumatic stress disorder and obsessive–compulsive disorder. Some medications prescribed for physical health indications (e.g., analgesics, antiepileptics, and some antiemetics) have psychotropic effects which can sometimes be used therapeutically—though they may have unwanted side-effects (**Box 30.3**).

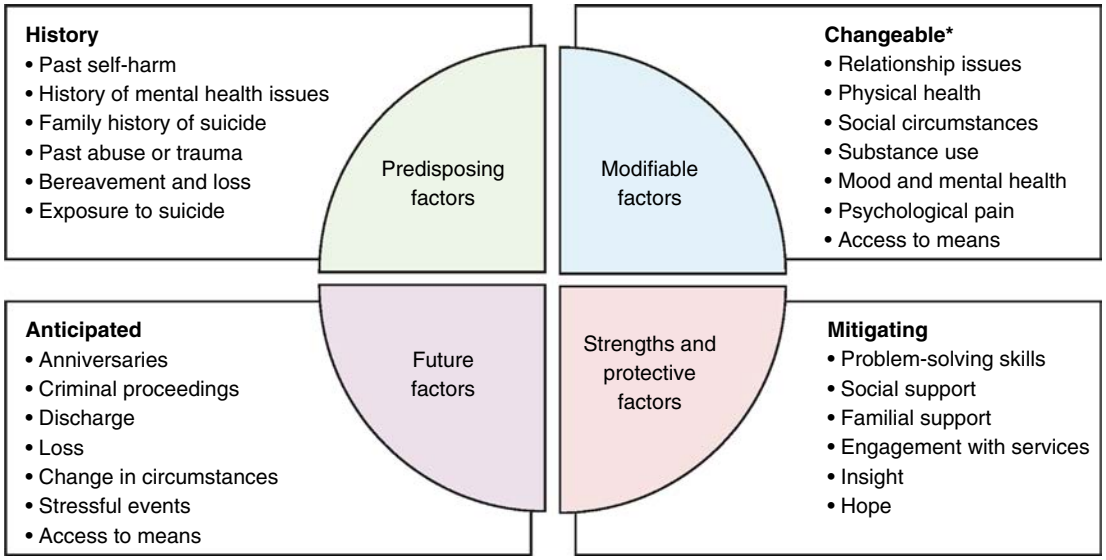

Fig. 30.1 Interactive components of risk assessment that can inform risk formulation and therapeutic management. *Acute exacerbation of any of these factors may constitute warning signs. (*From S2215036622002322/gr1.*)

Box 30.11 Treatment strategies in managing mental health conditions and other mental distress

Approach	Description	Examples within mental disorders
1	Therapeutic assessment: communication of formulation (verbally and by letter to professionals who need to know with a copy to the patient) in a useful and culturally sensitive way; plus agreed treatment plan to reduce symptoms	Diagnosing an anxiety disorder as the cause of symptoms, leading to simple advice on sleep hygiene, reducing caffeine and alcohol, gentle exercise, and renewing social networks Explaining distressing symptoms: feeling of guilt in depression; hallucinations as 'dreaming while you are awake' Diagnosing and explaining functional gastrointestinal disorders and offering diet and lifestyle advice
2	Self-management: making changes that will persist over time; engaging the patient by linking goals to their values (family life, health)	Stopping medications ('deprescribing') that are causing distressing symptoms Encouraging patients to stop behaviours that make them ill: quitting cigarettes/substances, avoiding unhealthy foods, finding alternatives to self-harm Specific advice on benefits/housing, signposting to other agencies; for some, a change of environment or meaningful work/study will drive recovery
3	Social prescribing: this requires understanding of what matters most to the patient (not 'what's the matter with that patient?') to empower them to take positive action; it requires local knowledge of what is available	Non-health interventions that will enhance the quality of life of people with mental disorders include walking groups, clubs, joining a choir, community projects, and volunteering; green social prescribing combines outdoor exercise/activity with climate action (this may be a core value in some patients) Mindfulness is a powerful anti-anxiety activity Such non-pharmaceutical interventions enhance patient experience, improve population health, reduce costs, and improve the work life of healthcare clinicians and staff
4	Psychotherapy: any intervention between patient and therapist (including non-verbal therapies such as music, art, and dance therapy) to explore the context of their distress. There are more elaborate models in better-resourced areas: hypnosis, or dialectical behavioural therapy (DBT) for borderline PD	Individual includes CBT, interpersonal therapy, psychodynamic therapy, or the third wave of therapies which combine components of these approaches, such as acceptance and commitment therapy (ACT) Modified therapies exist for specific disorders, such as focussed CBT in eating disorders (CBT-ED) Group includes family therapy, couples counselling, psychodynamic groups, or peer-led for addictions including Alcoholics and Narcotics Anonymous Less common are therapeutic communities where communal living is supported with therapies
5	Medication prescribing	These are covered within individual subsections of this chapter: prescribing is not the first step in treatment

Box 30.11 Treatment strategies in managing mental health conditions and other mental distress—cont'd

Approach	Description	Examples within mental disorders
6	Psychosocial treatments, and other treatments difficult to classify	For traumatized patients, there is eye movement desensitization and reprocessing (EMDR): patients move their eyes in a specific way while processing their traumatic memories Graded exercise therapy (GET) is delivered by physiotherapists with a proven value in chronic fatigue syndrome in the PACE trial
7	Collaborative care (a model where prescriber, therapist, and care coordinator work together to treat one patient) and integrated care (physical and mental healthcare are combined with social care)	Depression may become a long-term relapsing disorder, and collaborative care models show the best results for the reduction of symptoms, prevention of relapse and promotion of positive long-term outcomes; most community mental health teams have care coordinator models. How psychiatric services are organized varies across regions
8	Physical treatments other than medication: by nature, these are expensive, so higher up the stepped care model	Electroconvulsive therapy (ECT) has the best evidence base, and has been shown to be effective in depression, catatonia, and treatment-resistant psychoses, for example in Parkinson's disease or postpartum psychosis Transcranial magnetic stimulation (TMS) and deep brain stimulation (DBS) both have an emerging evidence base
9	Last resort: psychosurgery. This has an undistinguished history in psychosis	In severe OCD, controlled trials (randomized due to small numbers) show a modest evidence base for stereotactic ablative procedures of the subcaudate nucleus and associated areas

Box 30.12 Considerations when prescribing psychotropic medication

- Allergies: always check patient records for documented allergical reactions
- Age: adjust dose downwards, particularly in young and old, intellectual disability
- Adherence: special caution in patients with limited insight and/or cognitive impairment
- Formulation/preparation: (from preferred) liquid, orodispersible tablets, capsules, (to novel) inhalers and (least preferred) injection, depot, and suppositories: consider patient's needs/preferences
- Route of administration: oral, nasal, intramuscular, intravenous routes usually all available. Review impact on absorption and severity of side-effects
- Side-effect profile: take into consideration personal preferences and circumstances, as well as other co-morbidities (e.g., potential to lower seizure threshold in people with epilepsy or increased risk of bleeding [SSRIs] in people undergoing surgery)
- Therapeutic range: when possible, monitor drug levels to avoid under- or over-medicating and potential toxicity
- Fertility and reproduction: consider teratogenic effect of certain medications (sodium valproate, lithium)
- Pharmacodynamic and pharmacokinetic interactions: ask for a comprehensive list of prescribed, over-the-counter medication and acquired medications
- Co-morbid substance misuse: impact of recreational drugs on mental state, efficacy, and side-effect profile of medication. Consider street value and abuse potential of prescribed medication (pregabalin, quetiapine)
- Suicidality: supply only necessary amount of medication and consider supervised administration by family

Box 30.13 Potential adverse events from rapid tranquilization

- Oversedation (if severe, fatal respiratory arrest)
- Loss of consciousness
- Arrhythmias
- Cardiac arrest
- Aspiration
- Confusion
- Ataxia
- Falls
- Extrapyramidal side-effects
- Hypotension
- Seizure
- Psychological impact of restraint and forced medication

BACKGROUND

Mental health conditions are common, affecting one in four people in the general population over a lifetime and an even higher proportion of hospital inpatients. They coexist with medical or surgical problems, and often complicate treatment. Suicide remains the leading cause of death in young people, and over a life course, poor mental health drives higher mortality and morbidity, much of which is preventable with effective care.

LIAISON PSYCHIATRY

Mental health professionals can become involved at every stage of a patient's journey within the hospital, from the emergency department to inpatient wards and beyond. Liaison psychiatry (LP) is a subspecialty within psychiatry which is dedicated to the interface between physical and mental health, addressing the psychosocial needs of patients during and around inpatient admissions. Sometimes LP services will remain involved in a person's care through

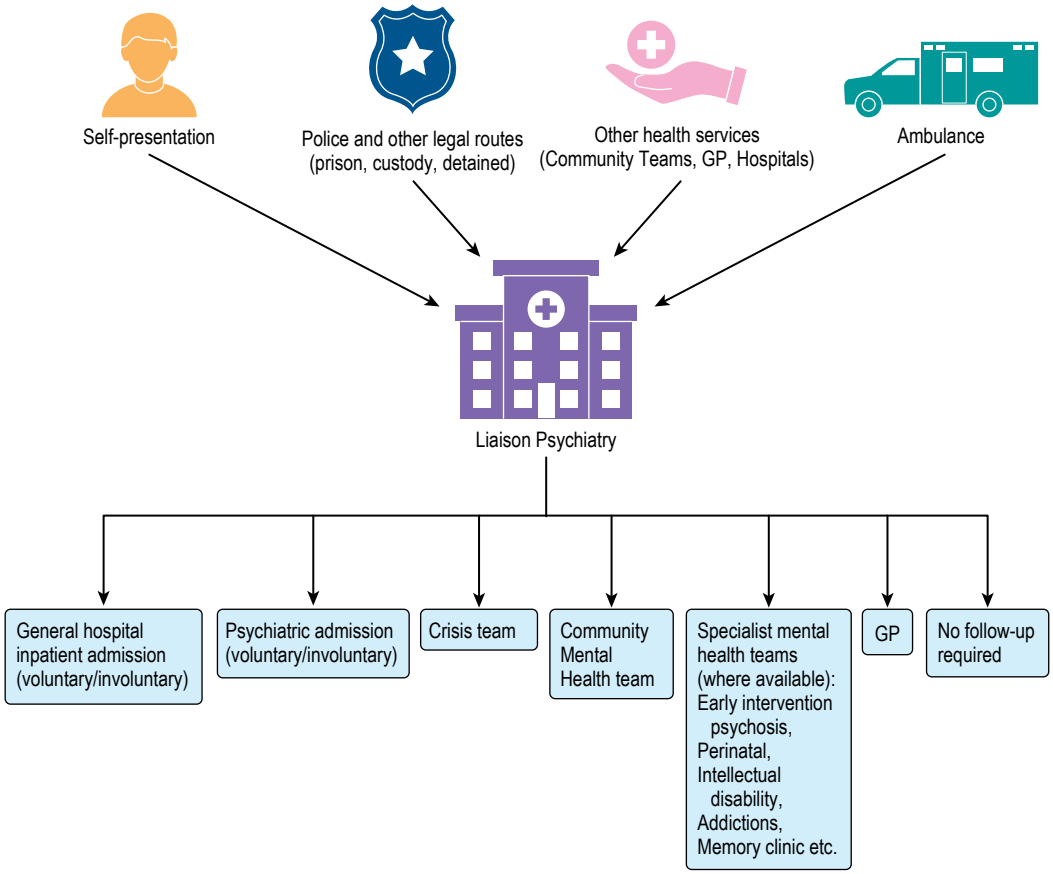

Fig. 30.2 **Liaison psychiatry and its place within other mental health services.**

outpatient clinics—perhaps run jointly with medical specialties—after discharge from hospital, or to provide alternatives to admission.

Given the time-limited nature of LP's involvement in a patient's care, it is important for these teams to establish communication channels with treating teams in the community early on in a patient's admission. This ensures all pertinent clinical information is available, so that treating clinicians can make safe decisions (Fig. 30.2). This form of collaborative approach ensures smooth transition and handover to community services when patients are ready for discharge from inpatient medical care.

The liaison psychiatry team

LP teams follow a multidisciplinary clinical model. While most teams are comprised of medical professionals specializing in psychiatry and nurses specializing in mental health, better-resourced teams have specialist psychologists, pharmacists, social workers, occupational therapists and addiction specialists working in the same team. There is a systematic under-recognition and undertreatment of the health needs of people with mental illness, and they tend to receive lower quality treatment for various other physical illnesses including cardiovascular disease, diabetes, and cancer than do people without mental illness. LP teams are therefore an essential part of a general hospital, as they ensure equal, equitable access to healthcare and provide safe, evidence-based care for all patients with psychiatric needs.

Special skillsets are required when assessing/managing patients with learning difficulties or other neurodevelopmental disorders, patients with cognitive impairment, as well as those under forensic services. LP teams might then seek the assistance/opinion of specialist mental health teams (Fig. 30.2) who might assess patients in the general hospital. The liaison component of LP teams is about learning from referrers (clinicians working in medical or surgical specialties who understand the context of their patient's physical illness), talking to community teams, perhaps their family doctor, and giving verbal feedback to referrers after interventions.

LP manages a wide range of mental disorders at any one time. People with schizophrenia are more likely to be admitted to a general hospital than a psychiatric one, with cardiorespiratory and metabolic diseases over-represented in this population. Two-thirds of people over 65 in a general hospital will have depression and/or dementia. One in five of the general population will have symptoms of depression or anxiety in any given year, and while most will never seek or receive treatment for this, they are likely to seek medical attention for related physical symptoms. Anxiety often co-occurs with low mood. Identifying how high stress levels impact on function, decision-making, and overall health is one of the core skills of every practising doctor and cannot be delegated to mental health specialists.

ETHICAL AND LEGAL ISSUES IN PSYCHIATRY

Consent and confidentiality

These key concepts underpinning the ethical and legal practice of medicine are discussed more generally in Chapter 3. In the context of mental illness and/or physical disease affecting the brain, there may be additional considerations: such illness may affect capacity to consent to treatment, and maintaining confidentiality may cause risk to the patient or others. A clinician should assure patients of confidentiality, but may tell a patient with a mental health condition, '*if, you were to tell me you have a plan to harm yourself or someone else, I could*

not keep that a secret and would have to talk to your doctors and others about how we could help prevent this'. That clinician records: 'I chose this course of action (to disclose my findings) because…'

As elsewhere in medicine, mental capacity to consent to treatment rests on the patient being able to **understand** what is said to them, recalling and **repeating back** this information, demonstrating that they are **weighing** key information, and **communicating** their decision to those around them. Capacity assessments can be carried by anyone familiar with the local code of practice, though these are usually carried out by professionals working in the health and social care services. LP teams are sometimes asked to advise in complex cases, for example, where there is uncertainty about whether a mental health condition is compromising a patient's capacity to consent to treatment for a physical health problem. In some patients with severe mental illness who are detained under legislation for the protection of themselves or others, mental capacity may be present for some interventions, but absent for others: for example, they may lack capacity to refuse a mental health assessment.

Confused patients usually understand the context of a hospital doctor who asks questions and performs a limited physical exam. A *best interest's decision* (where risks of no assessment outweigh the right to privacy in context of current situation) can be made in these circumstances. Clinicians should document *why* they chose to act, and if uncertain, talk to colleagues (and perhaps the patient's family)—always recording their reasons. Clinicians sometimes defer aspects of the physical examination in a refusing patient who lacks capacity; this is risky in an unknown patient and may lead to harm. Clinicians must document *why* they went ahead with inspection (e.g., for concealed substances or weapons) or examination (looking for injuries from self-harm, assessing vital signs) in these instances.

In most jurisdictions, mental capacity legislation exists to protect patients who lack capacity from potential abuse. For this legislation to be enacted, treating clinicians should document the disorder of brain (e.g., delirium) and/or of mind (mental disorder) that is believed to be causing impairment of capacity. For example, a depressed patient might decline lifesaving interventions, and disclose to a junior member of the team that this is because they believe they do not deserve to live. Most clinicians would judge that depression (which is treatable) has led to a temporary loss of capacity, and proceed with treatment. When assessing patients in a general hospital or clinic, it is prudent always to make clear as you begin that aspects of the assessment may be shared with other staff, starting with those who made the referral. Capacity assessments are decision specific, time-sensitive, and should take the patient's best interests into account.

Patients wanting to leave hospital

Patients sometimes change their minds about staying in hospital—choosing to leave the emergency department, declining admission to hospital, or attempting to self-discharge from the ward. It can be challenging for responsible clinicians to decide whether patients have mental capacity to decide this, especially in the context of an underlying mental disorder.

A comprehensive approach will consider the many factors potentially at play:

- Why did the patient attend this time (symptoms, diagnosis)?
- Have there been previous similar admissions?
- Might there be factors in the environment (noisy, lack of privacy, loss of autonomy) that provoked this change?
- Was it a procedure (blood test, lumbar puncture) that changed things?
- Could there be unpleasant physical symptoms (withdrawal from alcohol or substances; agitation from confusion) that escalated non-cooperation?

Patients may experience strong emotions ranging from anxiety, through agitation to outright hostility and even violence. Patients who have self-harmed may have been brought to hospital by others' decisions, or attended only for relief from a physical symptom (headache following overdose, bleeding from cuts to arms) and not for 'treatment' of self-harm: proper treatment is both to treat the physical effects of self-harm *and* address the psychosocial factors that led to it.

There are three essential areas to consider in patients who wish to self-discharge:

- **What is their mental state?** Perform a mental state exam (see later in chapter) to assess for confusion/cognitive impairment; significant anxiety; low or high mood; suicidality (thoughts, intent, and plans); psychotic symptoms; and insight into physical and mental disorders.
- **Do they have capacity to make this decision?** Can they understand what treatments are on offer, the consequences of refusing these, and the implications of self-discharge? Are they a risk to themselves (self-harm, neglect, exploitation by others) or a risk to others (children, partner, others)?
- **Who needs to know?** Which other professionals need to know about the presentation, the consequences of self-discharge, and the backup plan? It may be necessary to call the patient's relative or partner. It does not break confidentiality to seek information about a patient, even if permission to contact others is declined. The minimum output is to talk to the overall doctor in charge and write to the patient's general practitioner, usually copied to the patient.

All of the scenarios above (consent, capacity, refusing treatment, etc.) are core skills of every doctor, and cannot be delegated to LP teams given how often they arise.

The legal framework for mental health treatment

Autonomy is one of the four principles of biomedical ethics, alongside non-maleficence, beneficence, and justice (see Chapter 3). In practice, it means that patients cannot be forced or manipulated to make a treatment-relevant decision. The good intentions of clinicians are no defence in law and it is only in exceptional circumstances that treatment may be imposed—always under a strict and well-defined code of conduct.

The United Nations and the European Union have set out relevant international legal frameworks, and these helped shape and influence mental health legislation in various countries around the world, although national frameworks may have significant differences in their definitions and applications. Many countries distinguish consent to psychiatric treatment from other medical treatments. Capacity is a threshold concept: it is present or it is not. There are instances where clinicians can override decisions even in cases where capacity is maintained (e.g., in the UK a patient with depression may be deemed to have capacity to refuse admission to hospital, but still be detained under the Mental Health Act because suicidal behaviour is thought to represent a significant threat to their life).

An involuntary admission to a psychiatric hospital may be indicated, against a patient's wishes but in the interest of their health, in order to protect their safety and the safety of others (**Fig. 30.1**

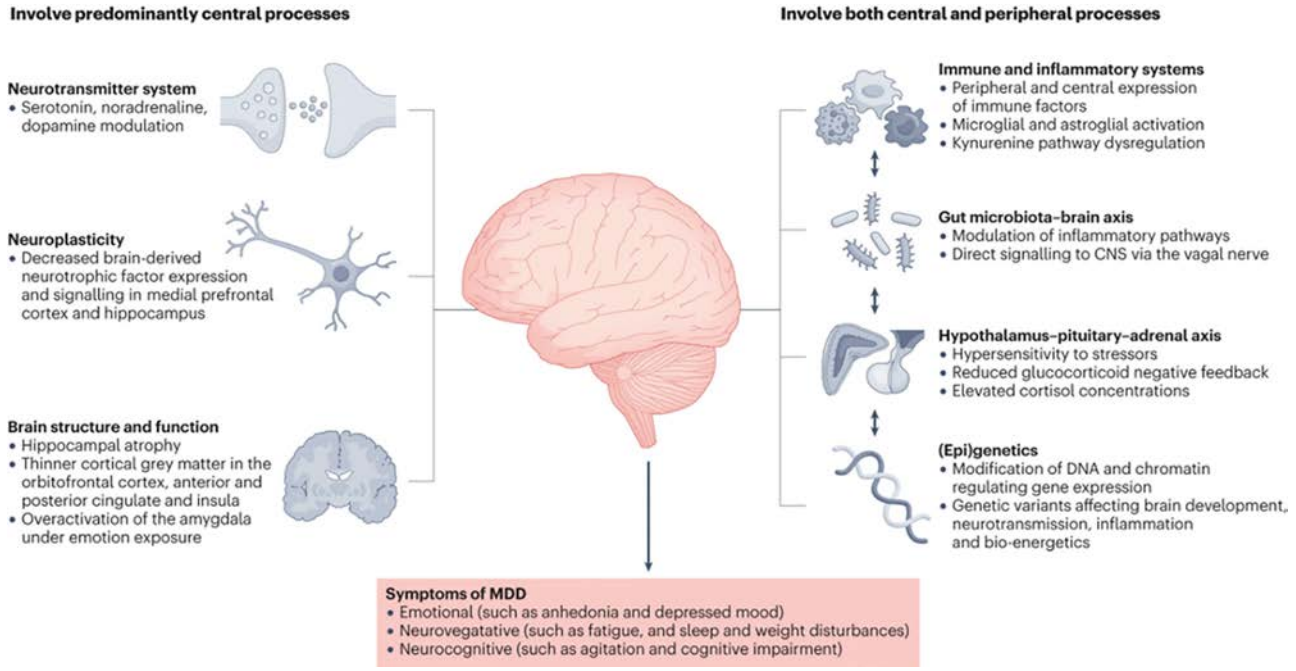

Fig. 30.3 Aetiology of depression. (*W Marx, B Penninx, M Solmi et al. (2023) Major depressive disorder.* Nature Reviews disease primers *9, 44*.)

and detailed in the 'Managing suicidal patients in healthcare settings' section). These difficult decisions are based on actual behaviours and measures (e.g., dangerous to others), and not merely on diagnosis. Legal protections incorporate the right to independent review, the right to appeal decisions, the right to an advocate, and equality before the law: that someone without this mental disorder would be treated the same.

AETIOLOGY OF MENTAL DISORDERS

The aetiology of psychiatric disorders is multifactorial, transcending the now discredited mind–body divide. Understanding the underlying factors is crucial in devising a safe and effective management plan, as most commonly patients present with multiple co-morbidities. Failing to identify and treat these leads to poorer outcomes and perpetuates longstanding health inequalities with detrimental consequences for patients.

First proposed by George Engels five decades ago, the biopsychosocial model remains a useful way of understanding mental illness, though it has its challengers. According to the biopsychosocial model, mental illness can be perceived as the combined effect of biology (genetics, neurotransmitters, hormones, substances, physical diseases), psychological factors (emotions, attitudes, perceptions, personality type), and social components (income, relationships, family, culture, subculture, society). Another emerging aspect tightly linked with the social aspect of the model is environment, including social media and other influences on identity. These overlap, compound/reinforce each other, and are interlinked.

Biological mechanisms

The brain is what makes us sentient and self-aware: its processes and external influences are limitless. Depression is the most common mental health disorder encountered in primary care, and modern concepts of brain abnormalities in depression describe both central and peripheral mechanisms (**Fig. 30.3**). One of the challenges of biological psychiatry is that these changes are difficult to quantify, vary over time and vary between individuals. While some present targets for pharmacological treatment (e.g., abnormal serotonin signalling that underlies use of selective serotonin reuptake inhibitors), there is no support for the proposition that depression is a serotonin deficiency state. Such changes in biomarkers may equally be the *effects* of depression, especially if prolonged. Many researchers argue that dopamine changes are as important in depression as they are in psychosis, and that serotonin pathways are even more abnormal in obsessive–compulsive disorder.

The wider context of mental illness

Looking beyond narrow diagnostic categories, the *Perspectives of Psychiatry* approach considers patients from four perspectives: disease, dimensional, behaviour, and life story (**Box 30.14**). Many environmental factors have been identified that drive physical illnesses, and these may play an even stronger role in the development of mental disorders. Most determinants of health, both good and bad health, are outside the scope of patients' interactions with hospital services (**Box 30.15**).

Epidemiology of mental illness

Mental disorders were rising in prevalence before COVID-19, and the inequalities of the pandemic increased that rate further, disproportionately affecting the poorest in society. Preventing the onset of mental disorders across the lifespan and reducing their severity, duration, and associated harms are considered essential to a worldwide drive for sustainability (see 'Prevention of mental illness: public mental health' section).

Box 30.14 Dimensions of mental illness

The HIDE paradigm	Perspectives of	Examples
What the patient **H**as	Diseases	Medical diagnoses
Who the patient **I**s	Dimensions	Character, personality
What the patient **D**oes	Behaviours	Health + risk behaviours
What the patient has **E**ncountered in life	Life stories	Individual trauma, losses; family stories of doctors

Dimensions of illness from PR McHugh and PR Slavney (1998) The Perspectives of Psychiatry. *Baltimore MD: John Hopkins University Press.*

Box 30.15 Social determinants of health

Health determinants →	↑↑ mental illness
○ Income, social status	○ Poverty, high crime area
○ Social support networks	○ Isolation (lonely)
○ Education + literacy	○ Lower education level
○ Employment/working conds	○ Low/no employment
○ Physical environments	○ Urban birth, residence
○ Social environments	○ Lack of social support
○ Personal health practices, coping skills	○ Sedentary, substance misuse
○ Healthy child development	○ Low birth weight, parents with mental health conditions or substance misuse
○ Biological, genetic factors	○ Inherited physical conditions
○ Health services	○ Problems with access to and discrimination within health services
○ Gender; culture/subculture	○ Example: double the rates of depression in postmenarche girls and women

COPMI, Children of parents with mental illness—where environmental factors usually exceed genetic aetiology (and are therefore points of intervention to prevent mental disorders in the children).

Physical health in patients with mental illness

Despite significant health spending, many US citizens with mental disorders get no treatment for them, and people with schizophrenia there frequently end up homeless, at-best accessing emergency care only. Inequalities (differences in a society between the very rich and its poorest citizens) explain much about the clustering of diseases and the large differences in outcomes between rich and poor.

One study of the 1.14 million people in the USA diagnosed with schizophrenia (patients engaged in health services) found that a diagnosis of schizophrenia increased mortality 3.5 times compared to the general population. People with schizophrenia mostly died young, with each death reflecting significant number of *years of potential life lost* had they survived to normal life expectancy:

- 38.3 potential life years for each death from suicide (more likely in first 5 years of psychotic illness—young adults who die by suicide lose many years of life)
- 29 years in deaths from liver diseases
- 27.3 years in deaths from diabetes
- 25.6 years in deaths from ischaemic heart disease
- 24.9 years in deaths from stroke, and
- 24 years each in deaths from COPD (see Chapter 20) and lung cancer.

Health inequalities (see Chapter 9) are high in the USA but rising fastest (among Western countries) in the UK. Since the 1990s, these two countries have also described the largest increases in preventable deaths in people with severe mental illness. Within individuals, poorer physical and mental health exert synergistic effects. Children living in poor families are more likely to experience adverse childhood experiences (ACEs), and these compound pre-existing inequalities and increase the risks of future smoking, harmful alcohol use, substance misuse, unhealthy diet, sedentary lifestyle, mental disorders, suicide and self-harm, and ultimately preventable deaths.

COMMON PSYCHIATRIC EMERGENCIES

Mental disorders can precipitate various emergency presentations leading to physical illness and risk to the patient and others. A clinical approach to patients presenting with a mental health emergency involves gathering information, assessing mental state, arriving at a formulation (why is this patient presenting, right now?), and investigating physical health to clarify what risks are present, and which ones need immediate attention. Of the five emergency presentations considered in more detail below, while suicidal patients who do not require medical treatments are managed in psychiatric settings, many presentations are medical emergencies requiring immediate medical care in a general hospital alongside management by mental health professionals. What doctors do, especially prescribing (**Boxes 30.3 and 30.12**), sometimes *causes* some of these emergencies—and merits careful consideration of proximal events.

Self-harm and suicide

Self-harm refers to an intentional act of self-poisoning or self-injury and is a clear sign of emotional distress. It includes both suicidal and non-suicidal attempts with behaviours such as cutting, burning, hanging, stabbing, drowning, and jumping from heights, among others. The Office for National Statistics in England estimated the male suicide rate to be 15.8 per 100 000 in 2021, compared to a female suicide rate of 5.5 per 100 000; globally suicide rates are higher in men than women. It is thought that the overall higher rate of suicide in men—despite the higher rate of self-harm in women—may be due to the choice of more lethal methods: firearms and hanging in men versus cutting and overdose in women.

Suicide remains a major public health concern, with 817 000 deaths by suicide reported internationally in 2016. The Global Burden of Disease Study estimated it to be the 15th leading cause of years of life lost, alerting the World Health Organization to make suicide reduction one of its main aims, aspiring to reduce suicide mortality by one-third by 2030. In 2021, a nationally representative

survey of adults in the USA showed that people identifying as LGBTQ+ (lesbian, gay, bisexual, trans, and queer) are more likely to report suicide-related thoughts, plans, and attempts within the past 12 months compared with those identifying as heterosexual. While all age groups are affected, suicide is the fourth leading cause of the death in 15–29 year olds. Epidemiological studies suggest that a significant proportion of people dying of suicide have a psychiatric disorder, with affective and psychotic illnesses being the most frequent. The suicide rate for people with schizophrenia spectrum disorders is over 20 times higher than the general population. Other co-morbid medical conditions, including chronic pain, stroke, epilepsy, and head injury, also increase suicide risk.

Managing suicidal patients in healthcare settings

Emergency department (ED) clinicians are crucial in the management of patients at high suicide risk, as suicide attempts and self-harm are most often first treated in a hospital's ED. In the USA, it was reported that for every death by suicide, there were eight preceding ED visits. The risk of death is highest within 30 days of discharge from an ED or from psychiatric inpatient care.

LP teams are best placed to provide detailed mental health and risk assessments (Fig. 30.1) that determine the next steps in a patient's management. This can include crisis interventions delivered in the community (Home Treatment or Mental Health Crisis Teams; or urgent follow-ups with Community Mental Health Teams; Fig. 30.2); alternatively, psychiatric inpatient admission may be required for patients at increased risk of completing suicide. Sometimes, admission to a medical or surgical ward is required, for example, in patients requiring an acetylcysteine infusion following paracetamol overdose, and close working between LP teams and other specialties is required to support people presenting with self-harm. The decision to detain non-consenting patients under appropriate legal framework is difficult, and its timing (in relation to medical treatments) is part of this.

A good practice point in treating people from at-risk groups is to explore suicide options with open questions (be careful not to introduce a novel suicide method into the conversation) when a crisis is lifting. *What might they do in the future if overwhelmed by thoughts to end their lives?* Encourage positive strategies (phone a friend, be with people, attend a doctor or ED), and suggest other 24/7 supports: national suicide prevention lines, local resources, and bespoke services (e.g., those run by the LGBTQ+ community). Encourage them to save these numbers on their phones.

Acute disturbance

Acute disturbance (AD) is an encompassing term describing escalating behaviours secondary to a change in mental state, including restlessness, agitation, aggression, and violence as well as verbal or non-verbal threats. Its aetiology is complex and includes psychiatric or other physical disorders including, yet not limited to, delirium and dementia, psychosis, stroke, and drug-induced states. A 2015 survey indicated that up to 80% of emergency department (ED) staff experienced workplace violence in the past year, with the majority of these incidents perpetrated by patients. A meta-analysis found up to 1 in 5 psychiatric inpatients (over a lifetime) may commit a violent act by causing harm or attempting to cause harm to another person. Violence and aggression in healthcare settings risk physical and psychological harm to the patient, staff, other patients, as well as to families. This applies to a range of disciplines and while emergency medicine and psychiatry are most heavily impacted, evidence suggests its effect is widespread, including renal units and geriatric and neurosurgery wards, among others.

In the first instance, if clinically appropriate, de-escalation should be used and this includes both verbal and non-verbal techniques. Building a personal connection with the patient, gently repeating their preferred name, actively listening, using non-threatening language, attempting to understand their circumstances, and offering choices may all help avert escalation to aggression or violence. Acknowledge they are upset even if you do not need to agree with their stated reasons for this. At times, involvement of others (colleagues or security staff) may be required to ensure that safety is maintained. Medical evaluation should not be side-lined even in an escalating AD patient, as several life-threatening conditions (intracerebral bleed, head injury, hypoglycaemia, adverse medication reactions, etc.) may be the root cause of AD.

Pharmacological management

Oral treatment should be offered first, and many will take up the offer of a sedative (tablet or liquid) to relieve their subjective distress; there are parenteral options in the uncooperative or violent patient or when oral route is not possible. Rapid tranquilization (RT) involves administration of medication through a parenteral route (intramuscular or intravenous), and aims to achieve a state of calmness for the patient, yet there may be instances where full sedation (induced by an anaesthetist) is required. RT is usually linked with the use of restraint; although in the UK, this is physical (by trained staff who ensure the full protecting of the patient's airway and chest), mechanical restraint is not uncommon around the world. There is a wide range of evidence-based interventions (Fig. 30.4). Although RT practice guidelines may differ in their details, benzodiazepines and second-generation (atypical) antipsychotics are generally preferred. Ketamine and dexmedetomidine are established alternatives. Regardless of the medication used, any RT requires careful monitoring of temperature, pulse, blood pressure, and respiratory rate and awareness of the medical risks involved (Box 30.13, Potential adverse events from RT).

Alcohol withdrawal

Substance-related presentations in the ED are extremely common and relevant to a wide range of substances, including opioids, stimulants, and gamma-hydroxybutyrate (GHB), among others, but alcohol is the most prevalent by far. The number of alcohol-intoxicated patients attending the ED varies significantly between countries, approaching 15% in the UK and is associated with disruptive behaviour. In 2018/19, there were almost 1.3 million estimated hospital admissions in the UK where the primary reason for admission or a secondary diagnosis was linked to alcohol. This represents 7.4% of all hospital admissions, with two-thirds of patients being male. Although this places a significant burden on EDs, it is an opportunity for screening, detection, and intervention for alcohol-related problems, including alcohol withdrawal.

Any alcohol-dependent patient can present with symptoms indicative of alcohol withdrawal as early as three hours after their last drink. These symptoms lie on a spectrum from mild (anxiety, irritability, tremor, sweating, nausea, tachycardia) to severe (seizures,

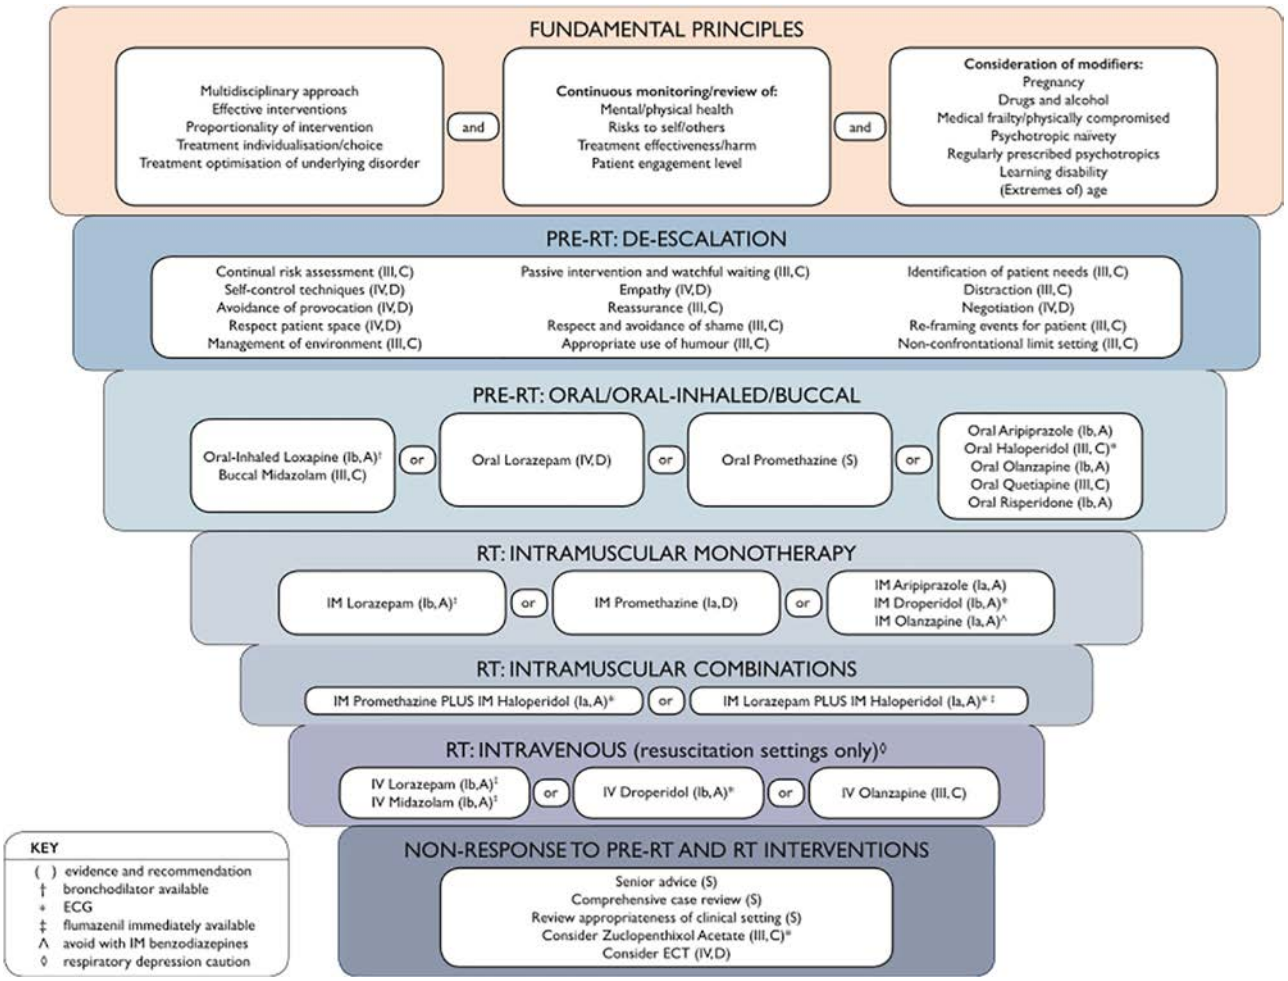

Fig. 30.4 Rapid tranquilization (RT). *(J Psychopharmacol. 2018 Jun;32(6):601-640.)*

delirium tremens). While pharmacologically assisted withdrawal (alcohol detoxification) can sometimes take place in the community, inpatient detoxification is likely to be required in all but mild withdrawals, and we should admit people with a history of severe withdrawals.

There are several detoxification regimen, all using one of the various benzodiazepines; chlordiazepoxide is most commonly used in the UK. Concurrent intravenous vitamin replacement in the form of parenteral thiamine is also recommended in at-risk patients to prevent Wernicke's encephalopathy. Patients at risk include those not eating properly for whatever reason (salience of alcohol, homelessness, crisis), those with vomiting or diarrhoea, those with other medical conditions such as diabetes, and all withdrawing patients with impaired consciousness or confusion. Early identification and treatment is paramount as severe alcohol withdrawal can be life-threatening.

Delirium tremens

This is an emergency present in about 3%–5% of those admitted to hospital for alcohol withdrawal, at times requiring ICU admission. It develops 2–4 days after the first signs of alcohol withdrawal and can be fatal in up to 4% of patients. It usually manifests as fluctuating cognitive disturbance, clouding of consciousness, and vivid visual hallucinations. Marked tremor, agitation, sleep disturbance, and autonomic dysfunction may also be present. Management requires a multidisciplinary approach that aims to safely manage severe agitation, replace B vitamins and other deficiencies, and use benzodiazepines to prevent and treat seizures. Alcohol detoxification with benzodiazepines does not cure alcohol misuse and dependence.

Wernicke-Korsakoff syndrome

This most commonly occurs in alcohol-dependent patients who stop drinking suddenly. Often, there is a physically traumatic event: surgery, road traffic collision, or myocardial infarct that increases demand on vulnerable brains. Wernicke's encephalopathy is an acute emergency with a triad of confusion, nystagmus, and ataxia. Waiting to see this triad misses the window of intervention to prevent permanent brain damage. Brain cells are continuously active and require energy generated from oxygen and glucose. Thiamine (B_1) acts as a co-factor in energy production as part of the Krebs cycle. Where dietary thiamine deficiency is followed by high glucose intake (admission to hospital and an offer of food, even sweet tea), disrupted metabolic activity results in a cellular energy deficits that can lead to neuronal loss in the mammillary body and other structures around the hypothalamus. Without B_1, transient Wernicke's encephalopathy can lead to permanent Korsakoff's psychosis (not technically a psychosis), characterized by extensive anterograde amnesia, permanent memory loss, and confabulation, where patients generate false memories to fill in gaps—potentially for the rest of their lives (Fig. 30.5). Prevention is based on rapid administration of parental vitamin preparations in at-risk individuals, before symptoms emerge.

Neuroleptic malignant syndrome and serotonin syndrome

Neuroleptic malignant syndrome (NMS) is a rare, adverse reaction to psychotropic medication that has the potential to become fatal, if untreated. Although mostly linked to antipsychotic medication and dopamine blockade, it has been reported with other psychiatric medications including SSRIs, lithium, valproate, and abrupt withdrawal of dopaminergic drugs.

The clinical presentation is highly variable, including autonomic instability, hyperthermia, altered consciousness, and muscle rigidity. Elevated serum creatine kinase is common, and repeated blood investigations are needed on suspicion of the disorder, alongside liver function tests. Risk factors include exposure to high-potency first-generation antipsychotics (haloperidol), being male and being young. Mortality varies, with mortality higher in older people.

Priority should be given to discontinuing antipsychotic medication, monitoring vital signs, and providing specialist medical intensive care support. Almost all cases will need intravenous fluids to protect renal function. There is a role for benzodiazepines, bromocriptine, and dantrolene, as well as electroconvulsive therapy (ECT). Restarting antipsychotic medication will probably be required in many cases, ideally at least 5 days later, but under close supervision. First-generation antipsychotics and depot medication should then be avoided.

Serotonin syndrome

A second medication-induced challenge is the lesser recognized, but likely more prevalent, serotonin syndrome. History guides the diagnosis: patients have taken high doses of serotonergic drugs, especially in overdose or polypharmacy. An additional group may have misused (often synthetic) substances that are serotonergic. Patients are confused with high temperatures, tremors and muscle twitching, even seizures in severe cases. Muscle tone is usually normal (unlike NMS), and although creatine kinase can be elevated (as in NMS), this is unusual, and the rise is modest. Management on the intensive care unit may be indicated, all serotonergic medications should be stopped (even lithium and some antibiotics), and serotonin antagonists are administered.

Box 30.16 Catatonia signs and symptoms

- Stupor
- Cataplexy
- Waxy-flexibility
- Mutism
- Negativism
- Posturing
- Mannerism
- Stereotypy

Catatonia

Catatonia is a neuropsychiatric syndrome first described in 1874. While originally considered part of psychotic and affective disorders, it is now known to be present in several other medical conditions including brain tumours, encephalitis, and autoimmune and metabolic disease. Observation, interview, and clinical examination are all necessary in uncovering the wide array of signs with which catatonia can present (see **Box 30.16**); two or more of these signs are considered adequate to consider catatonia in the differential diagnosis. Presence of autonomic instability is considered a complicating factor that significantly increases mortality.

There is no universal agreement on required investigations, and these are usually ordered to help exclude alternative diagnoses; neuroimaging and EEG are commonly requested. Given the similar presentation of catatonia and various encephalitides (see Chapter 28), in particular anti-*N*-methyl-D-aspartate (NMDA) receptor encephalitis, lumbar puncture may be considered. Administration of parenteral lorazepam can also be used as a catatonia challenge test to clarify diagnosis or predict future responses to treatment. Symptoms reduce with this disinhibitory challenge—even if there is a medical cause (brain tumour, CNS infection, etc.). For the challenge, the patient is given 1–2 mg lorazepam (ideally intravenously) while being monitored for response. The test is considered positive if there is a 50% reduction in catatonic signs. Benzodiazepines and ECT are considered the mainstay of treatment; followed by treatment of the underlying medical or mental disorder.

COMMON PSYCHIATRIC DISORDERS

The term 'affective disorders' covers those psychiatric disorders where the primary presentation is of abnormal mood. Diagnosis is based first on recognizing mood episodes (depressive, manic, or hypomanic), and then ascribing these to different disorders based on the pattern of mood episodes over time, along with associated psychiatric features. The common mood disorders are depression, bipolar disease (types I and II), and schizoaffective disorder (see **Fig. 30.6**).

DEPRESSION

Affective (mood) disorders are very common, affecting women more than men. One in four women will have at least one depressive episode in a lifetime, with 1 in 10 of the population reaching clinical thresholds for mild depression over a 12-month period. There is a mood spectrum from normal to acute crisis/turmoil (e.g., due to sudden loss), through to a longer period of being unhappy (perhaps with sleep disturbance) or persistent low mood symptoms. Even in Western countries with universal healthcare, only 1 in 4 depressed people get any treatment.

Aetiology

Depression is unlikely a single disorder, and it has proved difficult to agree a unifying aetiological model (**Fig. 30.3**), despite a good understanding about who gets depression and factors likely to drive prolonged symptoms and relapse. **Box 30.17** sets out risk factors and profiles of people likely to experience their first and further episodes of depression.

Targeted national policy and public health interventions could prevent many depressive episodes by promoting basic income, providing safety nets, and encouraging local meaningful work. Abuse and violence can also be prevented, and evidence shows the benefit of early intervention to mitigate the effects of these. Clinicians can address several major risk factors for depression by optimizing physical health through multidisciplinary working and supporting patients to make positive changes to how they live.

Most depressive episodes do not have a single cause though many patients identify a precipitant ('last straw'). ICD11 includes seasonal depressive (affective) disorder as part of recurrent depression. Postnatal depression is covered elsewhere (see Chapter 48).

Genetic factors

Parents with a history of depression have a risk of up to 30% that their children will develop depression. Researchers describe 'activation of phenotype' with evidence that inherited abnormalities of the neuroendocrine and immune systems are activated by ACEs.

Box 30.17 Risk factors for depression

Factors increasing the risk of developing moderate to severe depression	
Sex	Female
Age	Median age of diagnosed depression varies across countries: Germany 19; France 24; UK 55
Marital status	Married < single < separated/divorced < widowed
Socioeconomic status	Poorer people and those with lower educational attainment—a proxy for lower socioeconomic group
Employment	Unemployment, shift workers (disrupted sleep), insecure employment
Abuse	Childhood abuse (emotional less than sexual), domestic violence, and other victims of violent crime
Physical illnesses	Diabetes; migraine; asthma; obesity in women
Mental disorders	A history of one or more episodes of depression predicts more episodes
Health behaviours	Smoking; inconsistent or unhealthy diet
Sleep	Daytime naps for more than 30 minutes: strongest association
Sedentary behaviour	TV, excessive mobile phone use, excessive computer use including computer gaming
Factors reducing the risk of chances of incident depression	
Physical activity	Walking for pleasure, faster walking pace, cycling, swimming, any heavy physical activity, e.g., home repairs
Sleep	Normal hours of night-time sleep
Interpersonal	Frequency of visiting or confiding in others, membership of gym/club/other social activity

Clinicians note early experiences within the context of attachment to parent or carer: attachment styles may determine childhood and adult depression.

Sex differences in the incidence of depression (from puberty, women have twice the rates of depression as men) are partly explained by evidence that female adolescents experience more adverse life events than boys and men. Later on, intimate partner violence (domestic violence) and economic inequalities (women often entering lower-paid jobs than men or earning less for the same work as men) may also drive increased depression. Bipolar disorder (and related schizoaffective disorder) has a stronger heritability than depression: 30% of one parent has bipolar, rising to 50%–60% if both parents have the diagnosis.

Clinical features

For most people, the natural history of a depression episode is around 9 months. Within this period, patients will experience lower quality of life and complications of depression. Health harm from depression might be conceptualized as *depth of low mood multiplied by time* just as adverse outcomes in diabetes are predicted by *raised glucose multiplied by time*. Lower mood is associated with 'negative outlets' meaning increased unhealthy behaviours: comfort eating, smoking, excess alcohol, substance misuse, unfocussed online time, gambling, etc., but also (as effect or cause) there will be increased isolation, loneliness, work days lost and presenteeism (attending work with low mood but with lower productivity). All of these in turn worsen depression.

Untreated depression leads to increased co-morbidity, self-harm, and suicide. For the individual, untreated depression raises lifetime risk of cardiovascular diseases and dementia, and has adverse effects on the immune system. Additional motivation to treat depressed patients includes social effects on others (children, relationships) and the wider community—they will not reach their full potential in education or work.

Diagnosis

Even if diagnostic criteria are fully met, people are excluded from a diagnosis of depression if their symptoms are 'better accounted for' by drug withdrawals, intoxication or side-effects, medical conditions with high symptom burden (pain, weight loss), or bereavement. Co-morbidity is common, especially when low mood brings out anxiety (as trait or state): mood and anxiety disorders potentiate each other. The *International Classification of Diseases 11* (ICD11) defines three clusters of symptoms which may be present in addition to low mood, for at least 2 weeks):

i. **Affective:**
   - loss of full interest and pleasure in life—as Shakespeare writes 'with what I most enjoy contented least'

ii. **Cognitive-behavioural:**
   - impaired concentration, even indecision
   - beliefs of low self-worth, including excess guilt
   - loss of hope and negative appraisals of the future
   - thoughts of death including by suicide

iii. **Neurovegetative:**
   - low energy/fatigue with minimal effort
   - appetite disturbance: this usually reduces in depressed people but can increase in a minority
   - sleep disturbance: these include difficulties getting to sleep (initial insomnia), broken sleep (middle insomnia), and/or early morning wakening (late insomnia). In severe depression, there may be the clinical signs of psychomotor retardation (like looking at a slow motion version of someone) or psychomotor agitation (extreme restlessness) in the absence of mania.

To make the diagnosis, ICD11 expects at least 5 of the 8 core symptoms above. Some depressed patients will fail to disclose suicidal thoughts, perhaps related to guilt; many will minimize their symptoms as 'too much going on' or 'everyone gets insomnia'. Suicidality must be documented in any history of depression, as well as any two additional markers of severity that may become intolerable for the patient, and thereby increase the immediate risk of suicide. **Guilt** might focus on their past acts and omissions: the depressed person's cognitive distortions make these negative, and fuel lower self-worth and loss of hope for the future.

Depressed people may also exhibit **psychotic features**—usually indicative of a severe depressive episode. Their guilt or other beliefs become delusional, and they hear (typically second person) auditory hallucinations: 'you're a bad person… you harmed people'.

After completing a history and MSE for a person with depression, it is important to document the key findings and act: to make a safety plan for the patient. If they are safe to go home now, what will they do when next they feel overwhelmed by low mood or intolerable symptoms? They will need details of local emergency mental health services and national crisis lines.

Treatment and prognosis

Because depression is very common, most patients are treated in primary care rather than specialist psychiatry services. The most common evidenced interventions are listed in Box 30.18, and many of the

Box 30.18 Treatment of affective disorders

Diagnosis/setting	Recommended treatments
New episode of less severe depression: patient declines therapy	Check capacity to refuse, give information, arrange follow-up, make sure they know they can change their mind in the future
New episode of less severe depression: patient agrees to therapy	Individual or group cognitive behavioural therapy (CBT) or behavioural activation; group exercise; interpersonal therapy or counselling; medication such as SSRIs if physical illness
New episode of more severe depression	Combination of CBT or behavioural activation plus an antidepressant: agree regular reviews to monitor for side-effects and suicidality
Prevention of relapse	Remain on medication and/or mindfulness-based CBT
Treatment-resistant depression	Check adherence to treatment, reassess co-morbidities or ongoing stress, consider second-line antidepressant (e.g., venlafaxine) and the addition of low-dose antipsychotic medication, last line: ECT
Chronic depression	Moclobemide, older agents: tricyclics, MAOIs
Depression with co-morbid personality disorder (PD)	There is no evidence that medications will improve outcome with PD: manage in multidisciplinary team, refer to specialist PD service
Psychotic depression	Combined antidepressant and antipsychotic

interventions of **Boxes 30.11 and 30.19** apply here too. In all affective disorders, the patient should be actively engaged with both the diagnosis and its treatments. Self-management is essential: recognizing changes to mood (perhaps by recording a regular mood score out of 10 in a diary or smartphone, where 0/10 is lowest possible mood, 8/10 is average good mood, and 10/10 is the happiest day of one's life). These scores can be communicated to others as necessary. This scoring system is particularly useful for patients whose mood changes with the seasons or in cycles (cyclothymia: see **Fig. 30.6**). Self-management goes beyond asking for help when needed. It includes understanding individual protective factors, innate and therapy-acquired coping skills, and positive interdependent relationships.

Primary care may need to enlist other professionals' help with more complex mood disorders in a 'stepped care' approach: see **Box 30.19**. Collaborative care requires a general physician, a care manager (who acts as a point of contact for patients, and monitors adherence, mood scores, etc.), and a mental health professional (a therapist, or in some cases a psychiatrist). The decision to prescribe is made in the context of severity, sometimes urgency, and failure to improve with other interventions (**Box 30.19**): there are additional patient issues to consider in the choice of antidepressant (**Box 30.20**).

In some patients, small or no relief of mood symptoms means chronic depression. Historical studies found that 10%–25% of patients have a bad outcome with either chronic low mood or recurrent depressive episodes despite treatments. This group may then require more complex treatments under specialist care. The majority of patients have positive outcomes—even though the risks of recurrent depression remain throughout their lives.

In recovered patients, the decision to maintain or gradually withdraw an antidepressant is made jointly with the patient, based on an informed risk-benefit analysis. Antidepressant discontinuation

Box 30.19 Stepped care model of treatment

Focus of the intervention	Nature of the intervention
STEP 4: Severe and complex depression; risk to life; severe self-neglect	Medication, high-intensity psychological interventions, electroconvulsive therapy, crisis service, combined treatments, multiprofessional and inpatient care
STEP 3: Persistent subthreshold depressive symptoms or mild to moderate depression with inadequate response to initial interventions; moderate and severe depression	Medication, high-intensity psychological interventions, combined treatments, collaborative care, and referral for further assessment and interventions
STEP 2: Persistent subthreshold depressive symptoms; mild to moderate depression	Low-intensity psychosocial interventions, psychological interventions, medication, and referral for further assessment and interventions
STEP 1: All known and suspected presentations of depression	Assessment, support, psychoeducation, active monitoring, and referral for further assessment and interventions

syndromes are well-described: typically in people on long-term treatments at higher doses using shorter-acting agents such as paroxetine. Sometimes, it is difficult to separate relapse of anxiety or mood symptoms from multiple physical symptoms, made more memorable by the FINISH mnemonic: **Box 30.21**.

Not including in **Box 30.20** are agents that have fallen out of favour for treatment of depression, including benzodiazepines and other sedatives (which lead to dependence), paroxetine (the shortest-acting SSRI, more associated with discontinuation syndromes), amitriptyline (more sedation and anti-cholinergic symptoms than duloxetine), and monoamine oxidase inhibitors (which require a restrictive tyramine-free diet, and have other significant side-effects).

BIPOLAR AFFECTIVE DISORDER

Bipolar affective disorder describes an intermittent or cycling disorder of mood, with diagnosis being based on at least one episode of depression *plus* one episode of mania (bipolar type I) or hypomania (bipolar type II). Bipolar disorder is less common than depression

Box 30.20 Antidepressants, many of which are also licensed to treat anxiety disorders such as obsessive–compulsive disorder (OCD) and post-traumatic stress disorder (PTSD)

Drug name, start dose	Class	Positives	Negatives	Caution in
First line: prescribed in primary care for mild depression only if accompanied by physical symptoms in addition to CBT and social prescribing (Box 30.44); in moderate-severe depression, always prescribed in combination with CBT				
Fluoxetine 20 mg mornings up to maximum dose 80 mg	SSRI	Long acting: fewer discontinuation effects; weight neutral	Nausea for first few days; sexual dysfunction; rarely hyponatraemia and GI bleeds (especially in older people)	Liver failure, epilepsy, mania, and avoid in pregnancy and lactation; use lower doses in older patients
Sertraline 50 mg mornings up to maximum dose 200 mg	SSRI	Better tolerated, first choice if co-morbid cardiac disease	As for fluoxetine plus moderate weight gain; discontinuation problems (Box 30.21)	As fluoxetine
Citalopram 20 mg mornings to a maximum of 30 mg	SSRI	Less nausea than fluoxetine, but not as well tolerated as sertraline; available as drops for patients unable to take tablets	As for fluoxetine plus moderate weight gain; discontinuation problems	As fluoxetine; citalopram is the safest SSRI for patients with liver disease
Mirtazapine 15 mg night-time increasing to 45 mg daily—at night only	NaSSA	Sedative (promotes sleep), fast anti-anxiety effect, anti-nausea	Promotes appetite and significant weight gain often later in course; dry mouth, discontinuation effects	Liver and renal failure, epilepsy, mania; limited pregnancy data; avoid in glaucoma
Duloxetine 30 mg BD then up to 60 mg twice daily	SNRI	Good anti-anxiety effect and independent anti-pain actions	May reduce appetite and sleep, sexual dysfunction	Liver failure, epilepsy, mania, and hypertension; not safe in pregnancy
Second line: psychiatrist-led treatment; used in most severe cases (depression leading to weight loss, risks of suicide), a psychiatrist might add antipsychotic or consider ECT				
Venlafaxine 37.5 mg BD increasing to 375 mg max	SNRI	With titration, well tolerated and effective; has modified-release formulations	Blood pressure and prolactin elevation; sexual dysfunction	Liver and renal failure, epilepsy, and mania; never used in cardiac disease
Lofepramine 70 mg up to a maximum of 70 mg TDS	Tricyclic	Best tolerated tricyclic, the safest tricyclic taken in overdose	Some experience sedation by day; constipation common	Liver failure, epilepsy, mania, not used in porphyrias or cardiac disease
Moclobemide 150 mg BD up to max 300 mg BD	RIMA	Good anti-anxiety effect, even in social anxiety	Dietary consumption of tyramine-rich foods should be reduced; discontinuation more likely	Liver failure, epilepsy, mania, and avoid in pregnancy and lactation
Vortioxetine 10 mg daily, increasing to 20 mg once daily	Multimodal serotonin actions	NICE approved as second-line following two antidepressants; minimal sexual dysfunction	Skin reactions, abnormal dreams, and (as with all serotonin drugs) diarrhoea or constipation	Liver and renal failure, epilepsy, mania, and hypertension; never used in pregnancy or lactation

NaSSA, Noradrenaline and specific serotonin antidepressant; *RIMA,* reversible inhibitors of monoamine oxidase A; *SNRI,* serotonin and noradrenaline reuptake inhibitors; *SSRI,* selective serotonin reuptake inhibitors.

Box 30.21 Antidepressant discontinuation syndrome, FINISH

Flu-like symptoms (lethargy, fatigue, headache, achiness, sweating)
Insomnia (with vivid dreams or nightmares)
Nausea (sometimes vomiting)
Imbalance (dizziness, vertigo, light-headedness)
Sensory disturbances ('burning', 'tingling', 'electric-like', or 'shock-like' sensations)
Hyperarousal (anxiety, irritability, agitation, aggression, mania, jerkiness)

Source: Gabriel M, Sharma V. Antidepressant discontinuation syndrome. CMAJ. *2017 May 29;189(21):E747.*

(the lifetime prevalence of depression is 25% vs. 2.5% for mania, but while depression is commonly dealt with by primary care services, most patients with bipolar disorder require specialist psychiatric care. It is important to ask patients presenting with a depressive episode about previous episodes of elevated mood (mania or hypomania) as treatment differs considerably—mood stabilizers usually allow full restoration of social and vocational functioning.

Diagnosing elevated mood

Only some manic presentations have infectious good mood, where the patient laughs excessively or sings. To diagnose mania, it is important to identify *elevations* in **energy**, **mood**, and **interest**.

Box 30.22 Features of elevated mood: mania and hypomania

- Increased talkativeness or pressured speech (a feeling of internal pressure to be more talkative).
- Flight of ideas or experience of rapid or racing thoughts (e.g., thoughts flow rapidly and, in some cases, illogically from one idea to the next; the person reports that their thoughts are rapid or even racing and has difficulty remaining on topic).
- Increased self-esteem or grandiosity (the individual believes that he can accomplish tasks well beyond his skill level, or that they are about to become famous). In psychotic presentations of mania, this may be manifested as grandiose delusions.
- Decreased need for sleep (the person reports being able to function with only 2 or 3 hours of sleep), as distinct from insomnia, in which an individual wants to sleep but cannot.
- Distractibility (e.g., the person cannot stay on task, because attention is drawn to irrelevant or minor environmental stimuli, such as being overly distracted by outside noise during a conversation).
- Impulsive or reckless behaviour (e.g., the individual impulsively pursues pleasurable activities without regard to their potential for negative consequences, or impulsively makes major decisions in the absence of adequate planning).
- An increase in sexual drive, sociability, or goal-directed activity.

(Source: ICD11)

- The patient thinks and says they have more (even infinite) energy, with no need for rest or sleep.
- Mood may not be subjectively high (euphoric) but labile, and objectively irritable: people who know them notice a change for the worse.
- They are interested in everything, but intrusive (to other people) and ignoring all expertise but their own.

The diagnosis of bipolar is often a long time coming: on average 15 years after first presentation. So in all patients presenting with a mood disorder, we document the presence or absence of key features of mania in the clinical notes (see **Box 30.22**). Always note any significant change from the individual's usual behaviour or subjective state.

Hypomania describes elevated mood *without* psychotic features: by definition the symptoms are less severe, of shorter duration, and the patient usually has insight. Once a patient has been diagnosed with mania, they have achieved a diagnosis of **bipolar type 1** and will require long-term surveillance and medications; **Box 30.23** describes evidenced approaches. **Bipolar type 2** is an intermittent mood disorder with at least one *hypomanic* and one depressive episode. Lithium is an effective mood stabilizer but has a narrow therapeutic range and requires regular monitoring of drug concentrations to prevent toxicity (most importantly latent kidney disease).

A minority of bipolar patients can develop **rapid cycling of mood**, which presents one of the most challenging diagnostic and therapeutic scenarios in psychiatry. Rapid cyclers experience 4 or more episodes of mood disturbance (high or low) over one year—with full or partial remission to normal mood. The diagnosis cannot be made if there is substance misuse; many, however 'self-medicate' with alcohol excess, and alcohol makes rapid cycling episodes more likely. Risk factors include long-term antidepressant use and hypothyroidism; lithium remains preferred acute treatment, though it is also implicated in rapid cycling—if it is deemed unhelpful in rapid cyclers, it should be withdrawn slowly over months.

Bipolar disorder has a significantly better outcome than schizoaffective disorder (SZA) and a longer but not normal life expectancy.

Box 30.23 Treatment approaches in bipolar disorder

First episode of hypomania or mania	Consider stopping antidepressant (AD) and offer an antipsychotic (AP) regardless of whether AD had been stopped; haloperidol, quetiapine, or risperidone are first-line agents
Hypomania/mania where first AP is not tolerated	If an alternative AP is not effective, consider adding lithium or (in men with advice towards barrier contraception, and in women over 55 years old) valproate
Hypomania/mania: patient already taking lithium	Check lithium levels and adjust dose; add AP: haloperidol, olanzapine, quetiapine, or risperidone. No evidence for lamotrigine
Mania non-responsive to medication	Electroconvulsive therapy (ECT)
Bipolar in long term	Offer family therapy, individual or group therapy; lithium remains first-line medication: if ineffective, add valproate (in men with advice on barrier contraception, only in women over 55); if lithium is not tolerated, use olanzapine but watch for weight increases
Rapid cycling in long term	Carbamazepine, valproate (if safe), thyroid hormone

We diagnose SZA if there are features of schizophrenia at the same time or within a few days of the mood (depressed or manic) presentation.

ANXIETY DISORDERS

Anxiety is a feeling of uneasiness and worry that is a normal adaptive response to a threat. However, in some individuals, this can become maladaptive, excessive, or pathological causing impairment in the socio-occupational functioning of that person. Anxiety disorders are common but often not formally diagnosed even in medical settings, and therefore unlikely to receive any treatment. Patients with panic disorder frequently present to ED when they believe that they have a medical rather than a psychiatric condition.

When patients present to physicians in any medical setting with predominant psychological symptoms, these are often recognized and managed appropriately. However, when patients present with physical symptoms related to a primary anxiety disorder (see **Box 30.24**), if unrecognized, patients undergo extensive investigations for physical disease—increasing anxiety symptoms and health services costs. Patients then receive delayed or no mental health interventions.

Despite anxiety disorders being some of the most common medical conditions, hospitals do not often confer a formal mental disorder diagnosis for anxiety unless it is overwhelming for a patient (or staff), or crosses over with other conditions. Nevertheless, pathological anxiety is an important aspect of care to consider in hospital inpatients, for example:

Box 30.24 Types of anxiety symptoms

Physical symptoms	Cognitive symptoms	Affective symptoms	Behavioural symptoms
Increased heart rate Muscle tension Sweating Feeling light-headed Fatigue Hyperventilation/choking sensation/tightness in the chest Insomnia/hypersomnia Eating and weight changes Urge to pass urine Dry mouth GI symptoms: nausea, vomiting, diarrhoea Nightmares and night terrors Tremors Syncope Numbness or tingling in hands and/or feet	Difficulty concentrating/distractibility Mind often going blank/forgetfulness Irrational fears and dread Feeling as though one is going crazy Indecisiveness Feeling in danger Flashbacks Feelings of dissociation	Feeling of fear/worry/panic/uneasiness Persistent feeling of dread/anticipating the worst outcome Fear of dying/sense of impending doom Low mood Tearfulness or anger	Avoidance Decreased performance associated with anxiety Startle response/hypervigilance

i. a primary anxiety disorder (such as generalized anxiety disorder or panic disorder) causing significant anxiety symptoms and related symptoms (e.g., poorer pain control) in a hospital inpatient
ii. medical illness mimicking anxiety disorders (e.g., endocrine: hyperthyroidism, Cushing's disease, and the rare pheochromocytoma)
iii. stressful hospital events triggering anxiety symptoms—situational anxiety when awaiting tests/results/surgery, worse when procedures are cancelled; stress when changing ward or teams, perhaps requesting a second opinion
iv. stressors triggering/worsening the symptoms of pre-existing anxiety where there are other psychiatric or neurodevelopmental conditions present, for example, agitation in a patient with autism in an unfamiliar hospital setting.

Epidemiology

Anxiety disorders are common in the general population with a point prevalence of around 6%: see **Box 30.25**. They usually start in adolescence or early adulthood usually reaching peak during middle age and then decreasing with the elderly, and are more common in women than men.

Aetiology of anxiety syndromes

The exact aetiology of anxiety disorders is unknown but it is likely to be a combination of stress, genetic and environmental factors. Anxiety disorders often run in families, suggesting that a combination of genetic and environmental stresses is responsible.

Three neurotransmitters have been implicated in anxiety disorders:

- serotonin (levels associated with happiness; exaggerated postsynaptic receptor sensitivity to serotonin has been described in anxiety disorders)
- noradrenaline (increased 'fight or flight' adrenergic activity is seen in anxiety disorders, with increased presynaptic alpha 2-receptors)
- GABA (it is thought that reduced inhibitory receptor sensitivity with low levels of GABA also results in anxiety).

In panic attacks and in PTSD, there is increased activation in the amygdala, hippocampus, locus coeruleus, thalamus, and orbitofrontal areas.

Semple D, Smyth R. *Oxford Handbook of Psychiatry*, 4 edn. Oxford Medical Handbooks (Oxford, 2019; online edn, Oxford Academic, 1 June 2019).

In ICD11, anxiety disorders are grouped under the category of anxiety and fear-related disorders which also include specific phobias, social anxiety disorder, separation anxiety disorder, and selective mutism.

Panic disorders

In panic attacks, patients have spontaneous, unprovoked discrete intense episodes of severe anxiety that develop rapidly reaching a peak in 10 minutes and usually do not last longer than 20 minutes. Patients have a range of anxiety symptoms as described in **Box 30.24**. Patients can present frequently to medical care with a range of severity from mild (occasional, self-limited attacks) to severe attacks (patients describe unpleasant 'I'm going to die' experiences, with a fear of losing control).

Anxiety syndromes

Generalized anxiety disorder

In generalized anxiety disorder (GAD), patients have 'excessive worry': mild to moderate levels of anxiety, present for several months, at most of the time throughout the day about multiple everyday events or difficulties. Collateral history from a parent is often necessary to identify childhood/adolescent GAD symptoms. What people do (and avoid) often makes the diagnosis: school refusal, refusal to play school sports, self-isolation, and more. Patients may describe general apprehension (as free-floating anxiety), unfocussed 'worrying about worrying', or excessive worry focussed on multiple everyday events, along with the physical symptoms of anxiety (**Box 30.24**). Taken together, these cause significant impairments in socio-occupational functioning.

Agoraphobia

Agoraphobia is marked and excessive fear of public spaces or situations, for example, fear of public places (the Greek word for marketplace is *agora*) and busy shops/restaurants where escape is perceived to be difficult. Symptoms must be present for at least several months.

Box 30.25 Types of anxiety disorder

Anxiety disorder	Prevalence	Sex differences	Mean age at onset
Panic disorder	Lifetime prevalence 1.5%–3.7% (panic disorder) vs. 7%–9% for panic attacks Rates are higher in medical settings: 15% in dizziness clinics, 16%–65% in cardiac clinics, 25%–35% in HIV clinics	Women are 3 times more likely to be affected than men	Bimodal distribution Peak at 15–24 years Another peak at 45–54 years Rare after 65 years (0.1%)
Agoraphobia	6 months 2.8%–5.8%	M:F=1:3 (as panic disorder)	Bimodal distribution First peak 15–35 years Later life onset is associated with physical frailty and underlying medical problems
Simple phobia	Lifetime 12.5% 12 months 8.7% 6 months 4.5%–11.9%	M:F=1:3 Animal/situation phobias more common in women	Mean age of onset is 15 years Onset for animal phobia 7 years Situational phobias—around 20 years
Social phobia	Lifetime prevalence vary 2.4%–12.1% 12-month prevalence 6.8%	Community survey M>F Those seeking treatment F=M	Bimodal distribution with peaks at 5 years and 11–15 years Patients often do not present until they are in their 30s
Generalized anxiety disorder	6 months 2.5%–6.4% 12 months 3.1% Lifetime 5.7%	F>M	Lowest in 18–29 years—4.9% Highest 45–59 years 7.7% 60+ years 3.7% Early onset associated with childhood fears and marital/sexual difficulties Late onset is associated with stressful events, being single or being unemployed
Obsessive–compulsive disorder	0%–3%	M>F	70% onset before 25 years of age 15% after 35 years
Post-traumatic stress disorder	Lifetime 7.8%	M:F=1:2	Risk of PTSD after traumatic event 8%–13% men, 20%–30% for women Higher rates in some types of stressors, e.g., rape, torture, being prisoners of war

Phobic disorders

These are simple phobias with recurrent, intense, and excessive fear on exposure to specific objects or situations other than those covered in agoraphobia or social phobia. Symptoms persist for months/years, and patients usually avoid those situations. Examples of phobias include:

- Claustrophobia—fear of enclosed space (such as entering into an MRI scanner)
- Aerophobia—fear of flying
- Arachnophobia—fear of spiders
- Needle phobia—this is common in hospitals, and treated with reassurance, distraction, presence during venesection of a familiar family member or nurse, or occasionally, mild sedation.

Social anxiety disorder

This can be understood as a complex phobia. There is excessive anxiety restricted to social situations (meeting new people, unfamiliar situations, etc.) and the primary focus is the scrutiny by others or fear of being negatively evaluated by others. Fear of public speaking is universal (and not a disorder) but a recent change in a patient (perhaps starting University) may alert to a return of this aspect of social anxiety. Anecdotally, social anxiety increased during and after the COVID-19 pandemic, especially in younger people—who later withdrew from social activities onto their phones and online.

Disorders specifically associated with stress

In ICD11 the disorders specifically associated with stress are related to either short-term or long-term exposure to stressors or adverse events. These include acute stress reaction, adjustment disorder, post-traumatic stress disorder (PTSD), complex post-traumatic stress disorder, and prolonged grief disorder.

Core symptoms of these disorders comprise:

1. preoccupation with the stressor or its consequences, including excessive worry, recurrent and distressing thoughts about the stressor, or constant rumination about its implications; and
2. failure to adapt to the stressor with significant impairment in personal, family, social, and occupational functioning.

Acute stress reaction

The onset of symptoms of acute stress reaction are transient that can occur after a traumatic event. Symptoms usually resolve within 3 days.

Adjustment disorder

This describes a maladaptive reaction to an identifiable psychosocial stressor or multiple stressors (e.g., divorce, loss of a job, diagnosis of an illness, or recent onset of disability). The onset of symptoms is related to the adverse life event(s). Symptoms usually

emerge within a month after exposure to the stressful event but sometimes onset can occur after a longer delay, for example, 3 months after the exposure. Adjustment disorder lasts less than 6 months and diagnosis is excluded if patients meet the criteria for ICD11 criteria for (other) anxiety disorders or depression.

Post-traumatic stress disorder (PTSD)

This is a syndrome with onset following a traumatic, usually life-threatening, event. Symptoms persist for more than a month and include

i. re-experience of the traumatic events in the form of nightmares, flashbacks, or vivid intrusive memories (by day) accompanied by strong emotions such as fear
ii. avoidance of reminders of the traumatic event
iii. hypervigilance: patients describe being 'on edge', waiting for something bad to happen to them.

Complex post-traumatic stress disorder (CPTSD)

CPTSD consists of six symptom clusters: the three PTSD criteria (re-experiencing, avoidance, and hypervigilance) plus three disturbances of self-organization symptoms:

iv. emotional deregulation (heightened emotional reactivity, dissociative experiences, or emotional numbing)
v. disturbance in interpersonal relationships, and
vi. negative self-concept (feelings of guilt, shame, or worthlessness).

Normal and abnormal grief reactions

The pain of losing close family members, friends, and others is a universal human experience. A normal bereavement period is usually culturally determined but with wide variations. Anxiety (provoked by anger, denial of the loss, yearning for the deceased, sleep disturbances, etc.) is part of normal grief, and support with reassurance ('this too will pass; time heals') is the best management.

In general, if there remains continued subjective longing for the person and/or an (objective) excessive preoccupation with them six months after the bereavement (excluding the anniversary of the death), then a prolonged grief disorder, sometimes referred to as complex grief, might be present. Additional symptoms relate to cognitive distortions: patients believe they can no longer function in their post-bereavement role, with ongoing anger, even numbness, and speak of being 'unable to move on'. Assessment shows impairment of current social functions. This is a grey area of diagnosis with a significant overlap with normal experience and (sub)cultural factors, but complex grief probably affects between 4% and 10% of bereavements. A useful clinical approach involves promoting alcohol abstinence, treating co-morbid depression, offering bereavement counselling, and general supportive measures (**Box 30.11**) to prevent their loss becoming a life-changing bereavement.

Obsessive–compulsive disorder

Obsessive–compulsive disorder (OCD) is not based on a specific stress but is an episodic anxiety syndrome characterized by **obsessions** (e.g., of contamination, order or symmetry of objects, intrusive doubts) and **compulsions** (e.g., body washing, cleaning, checking, counting). Patients have recurrent intrusive, unwanted, unpleasant thoughts or images, and often a strong wish to carry out compulsive behaviours, known as rituals. Their rituals reflect their primary obsession. If their thoughts relate to hygiene or germs, there will be cleaning rituals—patients may clean their homes or hospital bedside areas 10–50 times daily, and the skin of their hands may be red or broken from handwashing. For others with OCD, their rituals are checking ('I must have left the gas cooker on'), counting (so called 'magical thinking'—'if I count to X, nothing bad will happen to my family') or other sequenced rituals that they know are unnecessary to perform, but which they feel compelled to complete. OCD patients have high co-morbidities with depression (when the thoughts and rituals recur) and other anxiety disorders. OCD diagnosis is relatively easy but there are differential diagnoses (**Box 30.26**).

Assessment of anxiety disorders

Establish onset, triggers, severity, duration, and the impact of symptoms on functioning through a careful history and MSE. Consider other co-morbid mental health diagnoses such as depression, substance misuse, or personality disorder; note coping mechanisms and previous responses to treatment. In acute hospital medical settings, consider whether the anxiety is triggered by ongoing hospital procedures or treatment. Screening anxiety scales (such as the Beck Anxiety Inventory [BAI] or Hospital Anxiety and Depression Scale [HADS]) can be used to diagnose and monitor progress.

If the age of onset of first anxiety symptoms is more than 35 years, recent onset depression is the more likely psychiatric diagnosis. However, in this over-35 group, when there is no significant past psychiatric history or family history of anxiety disorders, no significant life events for the onset of the symptoms, and no prior avoidance behaviours, then an organic cause of anxiety must be ruled out. New onset anxiety in an older person might herald dementia. Part of physical examination is to think through the possibility of a primary (treatable) medical cause for the anxiety recorded in history. Consider investigations such as full blood count, blood glucose, liver and renal profile, thyroid function, urine test for pregnancy, and drug screen (illegal drugs), then (rare) high urine catecholamines (**Box 30.8**). If there is prominent chest pain or dyspnoea, it may be necessary to rule out pulmonary embolus or acute coronary syndrome. Normal findings should reassure here.

Treatment of anxiety disorders in medical settings

Treating anxiety is part of managing all medical conditions. Identifying anxiety symptoms and behaviours (for instance, a patient repeatedly asking '*will I be alright doctor?*') and discussing them with patients can lead to direct improvement of symptoms and improves patient adherence to all treatments. It is important to intervene if a positive diagnosis of anxiety is made. Without treatment, anxiety is associated with increased disability, increased use of health service resources, poorer outcomes, and impaired quality of

Box 30.26 Differential diagnosis for OCD

Anankastic ('obsessive compulsive') personality disorder
Eating disorder—patients have overvalued ideas about eating and a morbid fear of fatness
Depression—patient may have obsessive ruminations that they are worthless or dirty: these resolve when depression is treated
Hypochondriasis—patient has excessive preoccupation of having a serious disease
Psychosis—patient may believe that someone is inserting unpleasant thoughts into their mind, or making them act in certain ways
Tourette's syndrome—characterized by motor and vocal tics, echolalia, and coprolalia (using offensive words without losing one's temper or the intent to shock)

life. Ideally, patients are best managed by involving LP in a hospital setting, but this may not always be possible as most hospitals may not have a full LP team with psychologists and occupational therapists. Therefore, all physicians must be aware of basic principles on managing anxiety in their patients.

Psychoeducation ('*your unpleasant symptoms are not a medical disease but are driven by a treatable mental health condition*') is the first step as patient feel reassured and this builds trust. Effective communication (listen, acknowledge, advise) is central to the consultation. Physicians should use open and closed questions to allow full disclosure of personal information. There may be undeclared stressors at home (marital problems, aggressive neighbours)—that cannot be easily 'fixed', but clinicians can support the person to problem solve after their discharge.

Depression, other anxiety disorders, and substance misuse need to be addressed—any improvement in these will lower the current anxiety burden. Discuss in your team how their anxiety might be provoked by (say) waiting for tests or surgery—can this be mitigated? If staff reassurance is making patients *more* anxious, then ration this.

Anxiety lowers the pain threshold. Opioids are **not** an anxiety treatment: they should be used in end-of-life care and prescribed, *short term*, for other pain if indicated. Even in a busy ward, patients can practice mindfulness as a distraction from their stresses. Visualization of unpleasant medical procedures (claustrophobic symptoms in MRI scanner) can reduce the discomfort. Benzodiazepines might be prescribed as a **once-off** to provide temporary relief from anxiety symptoms, but regular use promotes dependence and failure to develop positive coping mechanisms. While it is useful to refer to psychiatrists or psychologists for appropriate treatment options, most anxiety is treated in primary care. Consider referral to LP in hospitals or community mental health services if patients with an anxiety disorder also have:

- Thoughts/acts of self-harm or suicide
- Co-morbid severe depression or substance misuse
- Risk of self-neglect: this can be subtle, for example, anxiously avoiding a life-changing treatment if subjectively overwhelmed
- Complex medical conditions
- Treatment non-response or resistance: the anxious, stuck patient.

Psychological treatments

Cognitive-Behavioural Therapy (CBT) is the most effective treatment for anxiety disorders. Many patients avoid activities in response to anxiety, which worsens their anxiety and further worsens their functioning. The principle of treatment is that controlled exposure to the anxiety-producing stimulus will eventually lead to reduction in symptoms. Other techniques used in CBT are cognitive restructuring to change negative thoughts associated with anxiety, and behavioural modification (response prevention in OCD rituals). Single-session intensive debrief is not beneficial for patients who have experienced recent trauma. There are plentiful 'new' treatments that complement CBT: for example, guided relaxation and eye movement desensitization and reprocessing (EMDR)—described in **Box 30.11**.

Pharmacological treatments

SSRIs (**Box 30.20**) have become first-line medications for the treatment of anxiety disorders. In some patients, SSRIs can worsen anxiety in the first few days after commencing the treatment. To maximize the anxiogenic side-effect, treatment should be commenced at half or less of the usual starting dosage for depression. The dose could be titrated gradually after a week depending on the response and tolerability. SSRIs usually cause symptomatic improvement after 2 to 4 weeks of treatment.

Sertraline is often used as the first line of treatment, but if patients do not tolerate this, then another SSRI can be tried. Patients should be monitored for side-effects (GI disturbance, headache, sexual dysfunction) and drug interactions. Monitor younger patients (less than 30 years age) within a week of prescribing SSRI as there is increased risk of suicidal or self-harm ideas. Venlafaxine, mirtazapine (especially in PTSD), and pregabalin are used as alternatives.

Tricyclic antidepressants (imipramine and amitriptyline) can be used to treat anxiety disorders, and their sedation is usually welcomed by patients, but with caution in older people and vulnerable medical patients as they are associated with anticholinergic side-effects (dry mouth, constipation, urinary retention, and orthostatic hypotension) and can be dangerous if taken overdose. Beta-blockers such as propranolol can be helpful in reducing the peripheral autonomic symptoms of anxiety (tremor and tachycardia). Benzodiazepines are licenced for the temporary relief of acute anxiety but they should not be used for more than 2–4 weeks due to risk of dependence.

PSYCHOSIS

Psychosis is a syndrome comprising symptoms affecting thoughts, perception, and cognition (all three are essential to a healthy mental state), ultimately affecting behaviour. Psychosis can run a chronic course and has the potential to severely impact social functioning, wellbeing, and physical health.

While historically linked with schizophrenia, there has been a gradual shift in modern concepts of psychotic disorders. This includes the introduction of the Psychosis Clinical High Risk State (CHR, see below) and the realization that 70%–80% of people defined as CHR will in fact never develop psychosis. Many physical conditions may present with psychotic features, such as Parkinson's disease, epilepsy, and a wide range of encephalitides, that shed light on the role of the immune system in psychopathogenesis. Taking into account methodological issues and significant heterogeneity between the definitions of psychosis, median global prevalence of psychotic disorders is estimated to be 4.6 per 1000 persons. However, this relatively rare disorder accounts for over 90% of psychiatric admissions.

Clinical features

The prevalence of symptoms varies between the various manifestations of psychosis. The severity and frequency with which they

appear vary within the same population. MSE findings (Box 30.4) comprise the following:

- *Appearance and Behaviour:* there is no one way someone presents/behaves during a psychotic episode. Some may be dressed appropriately and others may have signs of self-neglect/look dishevelled. Patients may be restless, agitated and occasionally engage aberrant behaviour, posing a risk to themselves and occasionally to others. Someone responding to unseen stimuli may come across as being easily distracted as if 'on drugs' when seen talking to themselves. Bizarre behaviour may also be present with patients exhibiting mannerisms or stereotypies (Box 30.4), or on the other end of the spectrum, there may be a complete absence of goal-directed movements with someone in a catatonic state.
- *Speech* can be disorganized with significant variations in rate, tone, and volume. Syntax and grammar may be affected, making comprehension difficult for the listener. Idiosyncratic use of language (e.g., neologisms: Box 30.4) is noteworthy, while in others, near poverty of speech may be present with severe 'negative symptoms'.
- *Mood* can be low or irritable, even angry. Patients may describe a delusional mood or atmosphere ('something (strange) is going on'. On other occasions, people with psychosis lack the emotional reactivity one would expect in particular settings (blunting/flattening of affect), or their emotional reactions might be inappropriate (incongruent).
- *Thoughts:* both form and content of thoughts can be affected. This may appear as loosening of associations or even tangential thoughts, and in severe cases, thoughts may be totally unintelligible. Delusional content may be present, the main theme of which varies (Box 30.27). One word can usually describe thought content: religious, persecutory (paranoid), somatic, or bizarre.
- *Perception:* many types of perceptual abnormalities are commonly present, though their prevalence tends to vary between the different subtypes of psychosis. Auditory hallucinations (Box 30.28) are colloquially referred to as 'voices' that may be commenting on someone's actions or even commanding them to do a specific action. Visual hallucinations are more frequent in patients with Parkinson's psychosis (and other organic psychoses)—these can be very vivid and detailed.
- *Cognition:* although orientation to self, time, and place appears intact in the vast majority of psychosis, other cognitive domains appear to be affected. Processing speed, working memory, executive function, and verbal learning are some of the affected domains and these are linked to poor functional outcomes.
- *Insight:* usually linked with the severity of the psychotic episode, insight may fluctuate, and is often intermediate between total absence and full presence.

Psychotic disorders

Clinical High Risk for Psychosis (CHR)

The majority of patients that go on to develop schizophrenia experience a prodromal phase (otherwise known as 'at-risk mental state'), characterized by attenuated forms of typical psychotic symptoms (such as delusions and hallucinations) that may impact on their function. They may also carry several risk factors for psychosis. The CHR group is highly heterogeneous and is identified through well-validated assessment tools, like the CAARMS (Comprehensive Assessment of At-Risk Mental States) and the SIPS (Structured Interview for Psychosis-Risk Syndromes). Being able to accurately

Box 30.27 Types of delusions

Primary delusions occur out of the blue (i.e., without prior morbid experience).	
Delusional mood	Unpleasant sense that surrounding events refer to oneself. As the mind abhors a vacuum, delusional mood is usually resolved by the formation of an explanatory sudden delusional idea (an 'autochthonous' delusion): delusional mood is unlikely in a current MSE but may be recalled retrospectively
Delusional perception	Sudden attribution of delusional meaning to a normal perception, e.g., 'the position of that cup on the table means I will be famous'
Secondary delusions (usually) evolve from pre-existing morbid psychological processes (altered mood, hallucinations, other delusions)	
Persecutory	Someone is trying to discredit, harm or kill them
Of reference	Utterances or gestures of people, such as the media, are referring to the person, e.g., 'people on this TV programme are looking at me/seem to know about me/are talking about me'
Grandiose	Being famous, having a special ability or mission
Nihilistic	Extreme negation of self or world, e.g., believing part of the body has died
Shared delusion	A false fixed belief can be acquired from a close relationship (usually a relative or partner who tends to be more dominant, perhaps more intelligent than the receiver of the secondary delusion): this is a folie à deux (2); very rarely, more than two people share the delusion: folie à trois (3) or à eux (many)

Box 30.28 Types of auditory hallucinations

Type of hallucinations	Explanation with examples
Thought echo	Hearing one's thoughts repeated aloud after one thinks them
Second person	Voices talk directly to the patient, sometime addressing using their name, including giving commands
Third person	Hallucinations discuss the patient sometimes giving a running commentary
Reflex	Normal sensory modality triggers hallucination in another modality, e.g., seeing a bus triggers somatic hallucination of electric shock
Functional	Normal sensory modality triggers hallucination in the same modality, e.g., auditory hallucinations are associated with the sound of running water
Extracampine	Hallucinations experienced as outside of sensory field, e.g., voices heard from far away, even another country
Hypnogogic	Hallucinations as the person is going to sleep; normal experience
Hypnopompic	Hallucinations after or as person wakes up; normal experience
Formication	Hallucinations of touch, e.g., small animals/insects are felt to be crawling all over the body, classically seen in organic disorders such as cocaine psychosis

predict who will develop psychosis helps develop targeted prevention strategies and treatments, but staging of psychosis remains a work in progress, reflecting the high heterogeneity of the CHR group.

The prevalence of CHR differs significantly between the general population (1.7%) and people making their first contact with mental health services (19.2%). Some CHR referrals (to services) will develop other non-psychotic disorders. Meta-analytical data suggest that only around 1 in 5 people identified as being at CHR will transition to psychosis over one year.

Schizophrenia

Schizophrenia is a chronic, heritable form of psychosis of relapsing-remitting nature. While prevalence rates may vary by geographic location, the average lifetime prevalence of schizophrenia is close to 1%. Several risk factors have been identified over the years, including sex (incidence risk ratio of 1 to 1.4 for women to men), ethnicity (higher prevalence in minority ethnic groups), urban environment, childhood and social adversity, and substance misuse (especially cannabis).

Aetiology

The pathophysiology underlying schizophrenia is considered complex, and despite advances in research methodology and relevant investigations, many questions remain unanswered. Considered a neurodevelopmental disorder borne out of the complex interplay between genetic and environmental factors, people with schizophrenia display distinct differences in multiple neurotransmitter systems (dopamine, glutamate, GABA, and more), reductions in total grey and white matter volumes, ventricular enlargement, as well as altered activation patterns as displayed using functional neuroimaging. Genome-wide association studies have identified more than 100 chromosomal loci associated with the disorder, illustrating the polygenic, complex nature of schizophrenia in which both genetic and environmental factors are relevant. Given the lack of biomarkers that can be used in a clinical setting, diagnosis remains clinical, based on operational criteria, though even these differ between the various classification and diagnostic systems.

Psychotic disorders due to other medical conditions

Autoimmune encephalitis (AE) is a debilitating brain disorder caused by aberrations of the healthy immunological and inflammatory response (see Chapter 28), caused by with a wide range of antibodies (NMDA, AMPA, GABA, LGI1, CASPR2). NMDA receptor encephalitis is the most common antibody-mediated encephalitis, and commonly presents with features of psychosis. It should be considered in any patient (especially young females) first presenting with psychotic symptoms of acute/subacute onset, particularly when accompanied by neurological signs and symptoms such as cognitive dysfunction, movement disorders, autonomic dysfunction, and seizures, among others. A significant proportion of patients present with psychiatric symptoms, even before recognition of any neurological ones. Patients may present disorientated, with extremely disorganized behaviour and bouts of aggression, at times requiring an ICU admission. Prompt treatment is associated with good outcomes, but with long hospital admissions. Protracted recovery and persistent neuropsychiatric symptoms are common, and relapse remains a possibility.

Epilepsy: the link between epilepsy and psychosis is complex and potentially bidirectional. Meta-analytical studies estimate the prevalence of psychosis in people with epilepsy to be 5.6%, with a higher risk in people with temporal lobe epilepsy. Risk factors include a family history of mental illness, young onset epilepsy, hippocampal sclerosis, structural brain lesions, and poorly controlled disease. Depending on the temporal association with ictal events, psychosis can be classified as inter-ictal, pre-ictal, ictal, and post-ictal, with the latter being by far the most common. Post-ictal psychosis may present hours to days following a seizure and presents mainly with delusional thought content, hallucinations, and potentially challenging behaviour, for example automatisms. The course of the episode is usually short with an average of 10 days. Pharmacological management needs to take into account pharmacokinetic interactions between anticonvulsants and antipsychotics, as well as the propensity of certain antipsychotics to lower seizure threshold; safer options here are amisulpride and aripiprazole.

Parkinson's disease is the second most common neurodegenerative disorder. While initially perceived as a movement disorder, it is now well-established that in addition to the classic motor symptoms (tremor, stiffness, and slowness among others), people with Parkinson's present with a wide array of non-motor symptoms, affecting cognition, mood, anxiety, sleep, bowel function, and more. Parkinson's psychosis refers to a range of psychotic symptoms commonly encountered in people with Parkinson's, ranging from low level hallucinations to a presence (a feeling that someone is near you) and passage (seeing someone crossing your peripheral field), all the way to well-formed, vivid visual hallucinations with a varying degree of insight. Delusions can be present at a later stage. Not to be conflated with delirium, the incidence of Parkinson's psychosis is estimated at around 30% in patients with Parkinson's and has been closely associated with the use of dopaminergic medication: adjustment of their dose should be considered as a first point of action. Psychosis is a poor prognostic factor and leads to increased caregiver burden. As most antipsychotics have the tendency to worsen motor function, these should be used only when other options failed. Most evidence for efficacy with minimal impact on movements lies with clozapine and pimavanserin, a novel antagonist/inverse agonist at serotonin 2A receptors.

Stroke: neuropsychiatric symptoms after a stroke are common, affecting more than 1 in 3 survivors: (for understandable reasons) anxiety is common (**Box 30.24**) and over one-third of stroke survivors become depressed. Post-stroke psychosis affects up to 5% of stroke patients, and may present a long time after a stroke has occurred (or in minor or clinically silent strokes), especially in those affecting the right (non-dominant) hemisphere. The commonest presentation is with delusions, and the disorder has been linked with poor functional outcomes and increased caregiver burden.

Traumatic brain injury (TBI): following a TBI, psychosis is 2–3 times higher than the general population, though exact prevalence estimates vary between 1% and 10%. Presentation is dominated by positive symptoms (delusions and hallucinations), whereas majority of negative/cognitive symptoms are attributed to neuronal damage from the TBI. It is important to differentiate TBI psychosis from the phenomenon of post-traumatic amnesia (PTA), common in TBI survivors, which is characterized by anterograde amnesia, agitation, and disorientation.

Drug-induced psychosis: this can occur during or soon after intoxication and/or withdrawal from a series of substances

including alcohol, cannabis, synthetic cannabinoids, opioids, sedative-hypnotics, anxiolytics, cocaine, stimulants (including amfetamines, khat, methamfetamine or methcathinone), synthetic cathinone, hallucinogens, volatile inhalants, MDMA, dissociative drugs (including ketamine or phenylcyclohexyl piperidine, PCP, often known as angel dust). Prescribed medications can also provoke psychosis (Box 30.3).

Management

Psychology

There is increased recognition of the central role psychological therapies can play in the effective management of psychosis. Psychoeducation helps patients and their carers enhance their understanding of the condition, and has been linked with reduced relapse rates in schizophrenia, with a specific place in supporting young people at high risk for psychosis. CBT, cognitive remediation therapy, and family interventions have been extensively studied, all with positive outcomes.

Social

The impact of psychosis on functioning is considerable, affecting every aspect of daily living, including life skills, personal relationships, and employability. Devising a holistic care plan that considers these aspects will improve prognosis and potentially prevent further episodes, while at the same time allowing every individual to live a fulfilling life. Social skills training, case management/care coordination, open dialogue, peer support workers, and therapeutic communities are all interventions that can boost social relationships and have been credited as beneficial in relevant research. A multidisciplinary mode of co-working with patients with psychosis improves functional outcomes; occupational therapists and social workers work alongside mental health nurses, psychologists, and psychiatrists.

Medication

First generation antipsychotics

Advances in psychopharmacology led to the manufacture of the first antipsychotic medication, chlorpromazine, in 1951. This transformed the management of people with schizophrenia, as being on an effective medication allowed patients to integrate and function within society, eventually leading to the gradual closure of most mental asylums. Other drugs of this first era of antipsychotics are collectively known as 'conventional', 'first generation', or 'typical' antipsychotics, that followed chlorpromazine (Box 30.29). Acting mainly by excessively blocking dopamine D_2 receptors, they have been linked with a series of side-effects that can become debilitating, including akathisia, dystonia, and parkinsonism; and, in chronic use, tardive dyskinesia (Box 30.29).

Second generation antipsychotics

Second-generation antipsychotics have unique additional properties that render them efficacious with a relatively more favourable side-effect profile. Examples are olanzapine, risperidone, quetiapine (all acting as serotonin 2A and dopamine 2 antagonists), aripiprazole, lurasidone, and newer agents such as cariprazine (a combined dopamine D_2, dopamine D_3, and serotonin 1A partial agonist and serotonin 2A antagonist). These 'atypical antipsychotics' are now considered to be the first-line medication option for the treatment of psychosis, and have also been used in disorders such as mania and augmenting antidepressants. Many can be given in long-acting intramuscular forms ('depot') which allows scheduled administration by community mental health teams, assuring adherence with treatment in patients with limited insight into their condition. Their side-effect profile is diverse (Box 30.29), including metabolic, endocrine and neurocognitive effects, and merits regular clinician review.

Box 30.29 Antipsychotic medications

Drug	Side-effects	Monitoring	Depot	Additional notes
Amisulpride	Hyperprolactinaemia	Renal excretion: eGFR monitoring is required when kidney function is impaired	NO	Safe for post-ictal psychosis
Aripiprazole	Akathisia described, less than first-generation APs	No specific requirements	YES	Preferred for first-episode psychosis
Cariprazine	Akathisia	No specific requirements	NO	Advantages in bipolar
Clozapine	Sedation, weight gain, hypersalivation, constipation, hypotension, neutropenia	FBC, lipids, weight, plasma glucose	NO	Best for treatment resistant-schizophrenia. Most effective in Parkinson's psychosis. Plasma levels require monitoring
Haloperidol	Akathisia, parkinsonism	Mandatory ECG	YES	Avoid in antipsychotic naïve patients. If used for rapid tranquilization, give alongside promethazine
Lurasidone	Sedation, akathisia	No specific requirements	NO	Can be effective with managing patients with a strong affective component
Olanzapine	Sedation, weight gain (worst of all APs)	Lipids, weight, plasma glucose	YES	Commonly used in rapid tranquillization
Quetiapine	Sedation; weight gain, hypotension	QTc Monitoring	NO	Preferred when opting for lighter dopamine blockade, twice daily dosing
Risperidone	Weight gain, hypotension, hyperprolactinaemia	Prolactin	YES	Can be considered for post-stroke psychosis

Clozapine

Clozapine remains a third-line medication for treatment-resistant schizophrenia (when there has been treatment failure with two other antipsychotic medications). This approach has been challenged, with research suggesting clozapine should be introduced earlier in patients in whom it is safe to prescribe. Side-effects linked to clozapine include myocarditis, constipation, and hypersalivation, among others. Agranulocytosis is a rare (0.8% of patients over a treatment lifetime), life-threatening complication. While mortality rates in schizophrenia are lower in the clozapine group, all patients on clozapine require frequent mandatory blood count and clinical monitoring.

Approach to pharmacological treatment

Predicting response to pharmacological treatment is a constant work in progress. Male sex, longer duration of untreated psychosis, severe symptoms at presentation, non-adherence, and co-morbid substance misuse disorders all predict poor response. Lower doses are preferred in first-episode patients, and these can be stopped (gradually) after 2 years under clinical supervision. All evidence points towards significant benefits for patients on antipsychotics compared to placebo, with significant reductions in the risk of relapse, inpatient admissions, and improvements in overall life expectancy. Despite this, adherence remains an issue for more than half of patients diagnosed with schizophrenia. One potential solution is the administration of the antipsychotic medication in a depot formulation; some countries use compulsory community treatment orders.

Other physical treatments: further to established pharmacological and psychosocial treatment options, there is evidence for the benefits of:

- Electroconvulsive therapy (ECT) which may be of some benefit in the medium term for psychotic symptoms resistant to medication.
- Transcranial magnetic stimulation (TMS) is a non-invasive neuromodulation technique that has been beneficial in emergent research for the negative symptoms of schizophrenia.
- Deep brain stimulation (DBS), a minimally invasive neurosurgical technique is also being considered for treatment-resistant patients in clinical research settings, though evidence is still scarce.

Major clinical trials are presently underway to test the safety and efficacy of medical cannabidiol (CBD) in treating people with psychosis. This presents a paradox: inhaled cannabis (especially high frequency, high potency in early teens) makes psychosis *more* likely, as well as being associated with other unwanted effects: lung damage, apathy, nausea and vomiting, subfertility, and cancer.

MEDICALLY UNEXPLAINED SYMPTOMS AND FUNCTIONAL NEUROLOGICAL DISORDERS

Persistent physical symptoms that are *not* clearly linked to an identifiable pathophysiological disease are common. Patients may experience debilitating symptoms of any system (back pain, tiredness, chest pain, palpitations, bowel problems, seizures, weakness, tremor) or behaviours noticed by others (frequent use of the bathroom, weak voice, difficulties with any physiological function). One in five presentations in primary care and one in two new neurology consultations are believed to be due to medically unexplained symptoms (MUS) and functional neurological disorders (FND), respectively.

The personal, social, and financial impacts of these conditions are significant, with patients sometimes experiencing negative attitudes and stigma. Despite the high use of healthcare services, correct diagnosis and appropriate treatments are often delayed, with negative consequences on prognosis and detrimental impact on patients' functioning.

Classification and terminology

Various terms have been used to describe MUS, and some classifications have proved controversial. In the latest ICD11 classification, a new term, ***bodily distress disorder***, has been introduced under 'Mental, behavioural or neurodevelopmental disorders' to describe 'the presence of bodily symptoms that are distressing to the individual and excessive attention directed towards the symptoms, which may be manifest by repeated contact with healthcare providers. This may not replace the American term 'somatiform disorders' or 'functional somatic syndromes'.

Other conditions historically considered under the category MUS include:

- **functional gastrointestinal disorders:** often called ***irritable bowel disorder***, or latterly disorders of gut-brain interaction, and included under 'Diseases of the digestive system'
- **functional neurological disorders:** now referred to as ***dissociative disorders*** under 'Mental, behavioural or neurodevelopmental disorders' (see Chapter 11, 'Functional neurological disorder' section)
- ***fibromyalgia*** (see Chapter 32): is classified as a chronic pain disorder under the broad category 'Symptoms, signs or clinical findings, not elsewhere classified'
- ***chronic fatigue syndrome/myalgic encephalopathy*** is included in ICD11 under 'post-viral fatigue syndrome' within the broader category of 'Diseases of the nervous system'.

Chronic fatigue syndrome/myalgic encephalopathy

Although several studies have demonstrated abnormalities in endocrine, neurological, and immunological parameters in patients with CFS, understanding of potential biological mechanisms underlying the condition remains poor. Historical approaches that have suggested that the disorder is 'all in the mind' are unhelpful and stigmatizing, and prevent the development of a beneficial therapeutic relationship between doctors and patients. A more helpful approach acknowledges the presence of both physical *and* psychological symptoms, with no assumptions about the underlying aetiology.

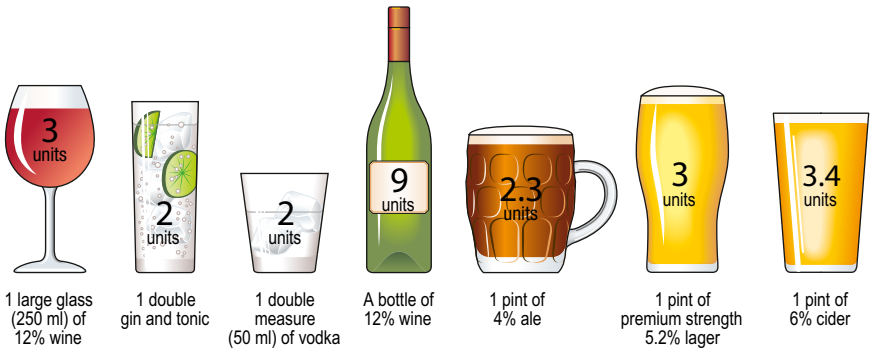

Fig. 30.7 Alcohol units.

Clinical approach to MUS/FND

While earlier theories placed disproportionate emphasis on psychological factors and life experiences, current understanding incorporates physiological processes with careful examination to uncover positive clinical features specific to MUS/FND before reaching a diagnosis. Identifying MUS/FND does not preclude other co-morbidities; for example a patient experiencing dissociative seizures (Chapter 28, 'Dissociative [non-epileptic] attacks' section) may also have epilepsy. Investigations may be required (video-EEG telemetry for seizure activity), and a rush to diagnose MUS/FND in the absence of positive investigation findings should be avoided.

Delivering and explaining a positive diagnosis of MUS/FND is the stepping stone towards a successful management plan that may include guided self-help, CBT, and input by several other members of a multidisciplinary team (e.g., physiotherapy or speech and language therapy, depending on the nature of the FND symptoms). Recovery depends on positive patient engagement with the process.

Communication of a diagnosis on MUS/FND

Patients with MUS/FND may experience symptoms which are considered 'red flags' for cancer or other serious health conditions, and anxiety about this may persist even when medical investigation has ruled these out. From a doctor's perspective, it might be regarded as good news that no more tests are indicated, but patients may continue to feel that their symptoms need an explanation. For example, a patient experiencing low back pain in the absence of physical trauma or radiological abnormality may be disappointed simply to be given medical advice on posture and gentle exercise. Although it would be wrong to decree that such back pain has a purely 'psychological' aetiology, psychological treatments (such as CBT) are proven to reduce symptom burden—likely by ameliorating the secondary effects of pain and loss of opportunities, combined with achieving behavioural changes to reduce avoidance.

Approaches to treatment

The spectrum of MUS disorders is broad, but many have the potential to become chronic and disabling and are unified by the absence of an effective biological cure. Treatment plans aim to lessen distress and disability, improve quality of life, promote effective coping strategies for symptom management, and facilitate recovery, and often require multiprofessional input organized via specialist clinics or services. Personalized integrated care plans may incorporate psychological therapies (e.g., CBT), psychosocial interventions (e.g., pragmatic active rehabilitation programmes), and drug therapies (e.g., antidepressant medications).

ADDICTIONS

Worldwide, alcohol is one of the leading causes of disease and disability. Even at the peak of the COVID-19 pandemic, alcohol and substances had a greater combined mortality than COVID deaths. There are no safe levels of alcohol consumption and the medical recommendation is to consume less than 14 units (**Fig. 30.7**) over 7 days, spread out over 3 or more days. ICD11 classifies several disorders related to alcohol (**Box 30.30**).

Alcohol dependence

There are wide sex, age, and ethnic variations in how people metabolize alcohol. It is important to record the amounts consumed (**Fig. 30.7**) and the settings where excess is more likely. Most people underestimate and under-disclose their actual consumption; the alcohol and hospitality industries may obfuscate the total units in their products from the public. ICD11 defines alcohol misuse as a disorder of regulation of alcohol use arising from repeated or continuous use of alcohol. The characteristic feature of dependence is a strong internal drive to use alcohol (craving) plus impaired control. The diagnosis requires two or more of the three central features (see **Box 30.31**) to be evident over a period of at least 12 months but the diagnosis may be made if alcohol use is continuous for at least 1 month. Impaired control over alcohol use may describe a subjective sensation of urge or craving to use alcohol, or lack of ability to regulate the onset, level, circumstances, or termination of use. Patients admitted to hospital who meet some of these criteria should have a plan made to address potential alcohol withdrawal before it develops (generally comprising benzodiazepines and intravenous B vitamins) rather than wait for the consequences to become evident.

Box 30.30 Disorders caused by harmful use of alcohol and substances

I. Single episode of harmful use
II. Disorders due to substance use
- Harmful pattern of use (causing damage to physical/mental health or to others)
- Dependence (see definition of physiological effects, physical tolerance, withdrawal, etc. below; **Box 30.31**)
- Intoxication (this is not usually a diagnosis but a frequent part of the workload of emergency medicine departments, with acute intoxication being a temporary condition that happens due to ingestion of a large amount of the substance)
- Substance-induced delirium
- Substance-induced psychotic disorder
- Certain specified substance-induced mental or behavioural disorders
- Withdrawal states: where patients have physical and physiological symptoms after cessation of a substance; they have been using the substance for a prolonged period of time and are likely dependent on that substance

Box 30.31 Features of alcohol dependence

Note that the criteria to diagnose dependence on other substances are identical

Central features (2/3 present for 12 months is necessary to make the diagnosis)
- Compulsion (craving) to drink alcohol with stereotyped drinking pattern
- Tolerance to alcohol increases (less intoxicated on greater units)
- Stopping drinking leads to withdrawal symptoms

Other features
- Awareness of physical/psychological/other harms but continues to drink
- Neglect of other pleasurable activities, e.g., self-care, hobbies, social, occupational
- Time preoccupied with alcohol increases over time: 'salience'
- Out of control use of alcohol
- Persistent, failed attempts to cut down alcohol

For people with alcohol dependence, alcohol use becomes an increasing priority in life such that its use takes precedence over other interests or enjoyments, daily activities, responsibilities, diet, health, or personal care. Other areas of life are relegated to the periphery, a pattern that continues despite the occurrence of problems.

Withdrawal symptoms must be characteristic for the withdrawal syndrome for alcohol and must not simply reflect a hangover ('morning after' dysphoria, headache, and dehydration that follow an alcohol binge). Dependent drinkers frequently have neuropsychiatric damage from alcohol (**Box 30.32**): admission is an opportunity to identify these and discuss them with patients to enable them to make an informed decision about future drinking.

Assessment

A thorough history clarifies the age of starting to drink, drinking pattern, beverages used, quantity, duration, and the impact of alcohol on family, physical and mental health. Screening instruments like AUDIT (Alcohol Use Disorders Identification Test) are useful to detect alcohol dependence (https://auditscreen.org/). Unlike other tools, high AUDIT scores point to dependence—prompting clinicians to act to prevent withdrawal. Check for dependence and withdrawal symptoms, previous treatment, detoxification treatment, periods of abstinence, and the context of relapses.

Box 30.32 Neuropsychiatric complications of alcohol use include

- Pathological intoxication
- Dependence
- Amnesia (blackouts)
- Alcoholic hallucinosis (visual or auditory; this may occur at different times to alcohol intoxication)
- Delirium tremens
- Wernicke-Korsakoff syndrome
- Confusion
- Alcohol-related brain damage (ARBD): the most common treatable form of dementia—cognitive decline can be partially reversed with abstinence
- Cerebellar damage
- Impotence and impairment of libido
- Peripheral neuropathy (in its early stages, this is reversible with abstinence—unlike most manifestations listed here)
- Pathological or morbid jealousy—a person develops a delusion that their partner is unfaithful. This delusion is notorious for the delusional content upon which the person is most likely to take action, including violence/homicide.
- Exacerbation of existing disorder, e.g., anxiety, depression, psychosis, bulimia
- Marchiafava-Bignami disease (rare): primary degeneration of the corpus callosum associated with long-term alcohol excess

Box 30.33 FRAMES—brief intervention counselling approach for harmful alcohol consumption (and other behaviours that damage health)

Key elements of FRAMES are:

Feedback of personal risks or impairment:
Many people are usually unaware of harmful effects of the alcohol/substances that they are using. The counsellor provides feedback from the screening tools or blood results on how alcohol is affecting the person or their personal relationships, work, health, etc.

Responsibility:
The counsellor emphasizes that only the individual is responsible to change drinking pattern or behaviour change.

Advice:
Clear advice is given to reduce the harm associated with alcohol by reducing the pattern or behaviour.

Menu:
Provide information about different strategies to change drinking pattern, e.g., setting goals to limit alcohol consumption, referral to specialist teams, strategies to avoid high-risk situations, and people who can provide support.

Empathy:
Provide emotional support by engaging in a collaborative, understanding, reflective, and empathetic approach. A confrontational direct authoritative approach will not be successful in supporting patients.

Self-efficacy:
Fostering confidence and optimism in patient ability to make changes to alcohol consumption.

Identify elements of the presentation indicating risk to self or others: separation from partner, loss of job, relationships, domestic abuse, significant physical ill-health, financial problems, drunk driving, criminal charges, etc. Recording insight on MSE is a good place to check motivation for drinking, and any motivation to stop drinking. You might use the FRAMES approach within this (**Box 30.33**). Physical examination looks for signs of intoxication or withdrawal and long-term complications of alcohol (**Box 30.32**). Investigation results (**Box 30.8**) suggesting significant, harmful alcohol misuse include macrocytosis, deranged liver function, abnormal clotting

Box 30.34 The stages of change model

Stage of change	Description with worked example in relation to alcohol misuse
Precontemplation (Not ready to change)	Does not understand there is a problem with the behaviour, and not thinking about making any change
Contemplation (Getting ready)	May be ambivalent and is thinking about the change, e.g., thinking about cutting down amount of alcohol
Preparation (Ready)	Decided to make changes, and takes active steps to change
Action	Implementing smaller changes towards goals, e.g., drinking only in company, seeing a counsellor in a treatment centre
Maintenance	Avoids former unhealthy behaviours to prevent relapse
Relapse	Returns to unhealthy/harmful patterns or behaviours

times, and evidence of steatohepatitis on ultrasound or fibroscan. People who have injected drugs, even once, should be screened for (treatable) blood-borne viruses (**Box 30.8**).

Management

For heavy drinkers and those who are beginning to use health services as a result of drinking, intervention and brief advice (IBA) has demonstrated efficacy in reducing drinking, health harms, and ED attendances. Brief interventions could be of 5 to 10 minutes across 1–4 sessions based on motivational interviewing principles (**Box 30.33**). Alcohol misuse is often subculture-driven (celebrations when a sports team wins or drinks to commiserate a loss), but for many patients with alcohol dependence, their alcohol misuse loses any social connections and becomes secret, solitary drinking. Supporting people to cut down is challenging.

FRAMES (**Box 30.33**) is a model of motivational interviewing (MI) ideal for alcohol excess, substance misuse, problem gambling, and other health-harming behaviours. When working with patients with alcohol use, direct challenging may not be helpful as many are ambivalent to change. Expecting and accepting a patient's resistance to change are key concepts in MI. The clinician/counsellor identifies where the patient stands in the cycle of change and then designs sessions to support the specific issues related to the patient's goals of cutting down or abstinence. Prochaska and DiClemente proposed *readiness for change* as a dynamic process which is a vital mediator of behavioural change. This can be used for any unhealthy behaviours to drive change (**Box 30.34**).

Relapse prevention is achieved with medication, support, and contingency planning. Acamprosate and naltrexone are anti-craving medications which help in relapse prevention.

Disulfiram ('Antabuse') is less commonly used—this is an acetaldehyde dehydrogenase inhibitor, causing accumulation of acetaldehyde which causes flushing and vomiting sensations when patients drink alcohol. The intention is to link alcohol with aversive sensations, and to de-programme drinking behaviours, however, many doctors do not wish to prescribe something that they know (if their patient consumes alcohol) will make their patient very unwell, if temporarily.

Support is achieved by referral to a community additions centre or, in some cases, a residential rehabilitation unit. The mainstay of relapse prevention for 7 decades is the peer support group Alcoholic Anonymous (AA). AA, with regular meetings and its 12-step programme, has the strongest evidence for long-term abstinence. Some areas offer family therapy, but many families seek their own support in the parallel peer-run Al-Anon groups for families of alcoholics.

Box 30.35 Symptomatic treatment of opioid withdrawal symptoms

Symptom	Medication
Pain	Use non-opioid analgesics, e.g., non-steroidal anti-inflammatory drugs (NSAIDs) or paracetamol
Stomach cramps	Hyoscine butylbromide: 10–20 mg orally every 8 h
Diarrhoea	Loperamide: 4 mg orally initially, plus additional 2 mg after each loose stool up to 16 mg in 24 h
Nausea and vomiting	Metoclopramide: 10 mg 4–6 h up to three times a day
Use with caution—it can help with many of the opioid withdrawal symptoms	Clonidine, alpha-2-adrenergic agonist: as per local protocols

Further reading

Alcohol-use disorders: diagnosis, assessment and management of harmful drinking and alcohol dependence NICE clinical guideline 115 published 23/02/2011. www.nice.org.uk/guidance/CG115.

Opioid addiction

Worldwide, opioids are the second most harmful substance (after alcohol) with significant death rates from respiratory depression in accidental overdose. In 2021, the USA reported over 100 000 preventable opioid deaths, and drug-related deaths from opioids in the UK are currently the worst in Europe. Deaths are mostly from respiratory depression, when excessive doses overwhelm even highly dependent patients; by contrast with alcohol withdrawal, opioid withdrawal state is uncomfortable for patients, but not life-threatening. When patients use street opiates (heroin, morphine) and opioids (methadone, mostly illegal fentanyl), they are at a high risk of overdose, as the doses of what they buy are unpredictable. Street drugs are also riskier due to harmful contaminants, or substitution with another (unknown) agent when stocks are low. Patients may request opioids to reduce their withdrawal symptoms even when they might probably be still under the influence of opioids. A thorough assessment is required before prescribing to avoid iatrogenic respiratory depression. When in doubt, provide symptomatic treatment (**Box 30.35**) to manage objective withdrawal symptoms based on direct examination (**Box 30.9** and **Fig. 30.8**): see **Box 30.36**.

Commence opioid replacement therapy only after getting advice from specialists. The Clinical Opioid Withdrawal Scale (COWS) can be used to assess the severity of opioid withdrawal symptoms in patients. If patients are started on opioids in ICU or other medical settings for pain management, doses should be tapered slowly over several days

Acute medical management can be challenging, but the next steps to signpost patients to addiction treatment are often lifesaving (**Boxes 30.33 and 30.37**).

Opioid substitution therapy (OST) with methadone or buprenorphine is the mainstay of harm minimization in chronic opioid misuse. If someone is already on methadone substitution treatment, the correct dose should be prescribed throughout a

Fig. 30.8 Injection sites ('skin tracks') in an intravenous drug user. There is overlying hyperpigmentation and scarring of veins due to inflammation from repeated non-sterile injections as well as injections of irritating drugs and adulterants'.

Box 30.36 Opioid withdrawal—more objective features are underlined

At 8–12 h:
- Sweating, lacrimation
- Yawning, rhinorrhoea
- Dilated pupils, irritable mood
- Tremor, restless, ↑heart rate

Methadone and buprenorphine withdrawal:
- Starts after 24 hours
- Can last for 2–4 weeks

From 24 to 36 h:
- Nausea + vomiting
- ↑blood pressure and ↑heart rate
- Muscle and abdominal cramps
- Insomnia, nightmares

hospital admission. Always check—with GP or pharmacy if necessary—both the total dose and when the patient had their last dose: many have a home supply, and some may take it all if anticipating hospital admission. Most general hospitals have specialist substance misuse teams who can guide therapy. Often the total methadone dose is split into two in hospitals (given at 8 AM and 8 PM), even though methadone's half-life is 36 hours. This is because a minority of patients might decide to leave hospital after their full morning dose and obtain 'top up' heroin resulting in a high risk of respiratory depression. If someone misses methadone for more than 48 hours, then they may have reduced opioid tolerance, and it may be necessary to consider restarting dose titration.

Only senior doctors and specialists in addictions should prescribe methadone or buprenorphine (and never both in the same patient), given the risks of overdose and other harms. Just as benzodiazepines do not cure alcohol addiction, neither does OST provide a cure here. Psychoeducation is provided to patients about the risks of opioids use and treatment options available. Patients may be referred to specialist addiction services, perhaps to an inpatient rehabilitation unit. The uptake of Narcotics Anonymous is lower than AA, though it is effective, and people with cross addictions may attend both.

Other harm reduction strategies include needle exchange programmes to avoid sharing needles and prevent blood-borne infections, advice on barrier contraception, supervised 'shooting up rooms' to inject drugs with medical support but no police enforcement, and provision of home naloxone to reverse accidental overdose.

Novel psychoactive substances

These are synthetic compounds that produce similar effects to recreational drugs. There is limited data available, and the nature of the market makes it difficult to keep pace with the newest agents. Clinicians may look up the names online and try to match to known compounds. Most of them are not detected in urine/blood tests done for recreational drugs and this makes management more challenging. Novel psychoactive substances (NPSs) can be divided into stimulants, cannabinoids, hallucinogens, and depressants. Hallucinogens can be further divided into two categories as dissociative and psychedelics. Dissociative NPSs produce a 'dissociate' state—temporally altering a person's mood, thoughts, and perception. Patients frequently present to hospital emergency departments with dysphoric mood crashes or associated self-harm. Management is expectant, to treat withdrawal and keep the patient safe.

PERSONALITY DISORDER

The term personality describes a person's unique character (traits) and ways of behaving. When taking a psychiatric history, it is important to ask about childhood temperament, and perhaps to which person in the family they are most alike, but there are no specific personality questions on the MSE. In treating anxiety, we try to define 'state anxiety' (episodic, often situational) as separate from 'trait anxiety' (habitual, and part of their usual personality). The same holds for people who have a constitutional mistrust of others: when might this become (if ever) a discrete episode of paranoia (by definition, a delusional belief system)? Personality dysfunction may become more obvious during physical and mental illness episodes: in a relapse of OCD, perfectionistic traits become obsessional behaviours such as rituals, while most aspects of character are exaggerated in mania. By their nature, personality disorders are fixed over an adult lifetime, though the behaviours and potential crises are modifiable with psychological treatments.

Box 30.37 The range of substances, taken by various means, and their harms

	Opiates	Cannabis	Stimulants	Hallucinogens	CNS depressants
Substances	Morphine, heroin Methadone Pethidine Codeine Dihydrocodeine NPS AH-7921, MT-45, novel fentanyl	Hash. Grass, Skunk, ganja, marijuana Main psychoactive contents are tetrahydrocannabinoid (THC) and cannabidiol (CBD) NPS: synthetic cannabinoid receptor agonists (SCRAs)	Cocaine, amfetamines Ecstasy (MDMA) NPS: Mephedrone, NBOMe, 2C-series	Two categories (1) dissociative, including ketamine, phencyclidine (PCP or 'angel dust') NPS: methoxetamine (2) Psychedelics, including lysergic acid diethylamide (LSD), gammahydroxybutyrate (GHB), psilocybin NPS: 5-MeO-DALT and the NBOMe- or 2C-series	Benzodiazepines Alcohol Barbiturates Sedatives Novel psychoactive substances: benzodiazepines—diclazepam, flubromazepam
Route	Smoking, snorted Tablets like codeine can be swallowed	Oral (cakes). Smoked (spliffs/joints) Inhaled (water pipe or 'bong') SCRAs sprayed on to herbal mixtures—called spice	Snorted, i.v. injection Amfetamines—oral Mephedrone (bombing—swallowed in wrapped paper)	Smoking Inhaled, swallowed, injected	Oral, i.v.
Intoxication	Rush is a brief intense pleasurable sensation, euphoria Other symptoms include pinpoint pupils, sedation, respiratory depression, analgesic effect	Euphoria, relaxation, distortion of time, disinhibition Psychiatric effect: Paranoia, over talkative giggling, anxiety Physical signs Tachycardia, conjunctival injection (red shot eye), dry mouth, poor coordination memory impairment	Abnormal excessive cheerfulness, over talkative, reduced appetite, increased frequency of micturition, poor concentration	Dissociative type—produce euphoric 'dissociated', state, catatonic state Psychedelics—perceptual alterations, quasi-mystical experiences MDMA can induce psychosis PCP ('angel dust')—can be fatal and cause violent reactions and brain damage LSD—exited, giggly. Euphoric, hallucinations, 'bad trip', flashback, visual distortions Tachycardia, hypertension, arrhythmias, fever, convulsions Formication—insects crawling under the skin (cocaine)	Lethargy Lack of concertation excessive sleepiness Fatal in high doses
Withdrawal symptoms	High resting pulse rate Sweating Restlessness Dilated pupils Bone and joint aches GI upset such as nausea, vomiting, loose stool Tremor Excessive yawning Anxiety or irritability Piloerection of skin Rhinorrhoea (runny nose) or lacrimation (tear production)	It may not cause physiological dependence Some people may experience irritability, anger, insomnia, vivid dreams, reduced appetite, weight loss, headache. Poor concentration, depression, stomach pan, sweating, chills	Drowsiness, fatigue, lack of interest, increased hunger		Withdrawal from barbiturates can lead to 'cold turkey' that can be fatal Benzodiazepines withdrawal symptoms include abdominal cramps, panic attacks, hallucinations, convulsions, and death
Complication	Overdose can cause respiratory depression Naloxone can reverse opioid overdose effects				Flumazenil can be used in benzodiazepine overdose
Management	Psychoeducation Methadone or buprenorphine substitution Harm reduction (avoid sharing needle, safe sex)				For benzodiazepine withdrawal—patient will need switching over from short-acting to long-acting benzodiazepines and then will slow tapering and stop

NPS, Novel psychoactive substances.

Box 30.38 Attachment styles in children and how these relate to adult attachment

Childhood attachment styles (prevalence)	Description of childhood behaviours observed in play rooms	Adult attachment
Secure attachment (60%–70%)	Upset when mother (carer) leaves their company, and play decreases. They settle, greet her on her return, and continue to explore their environment.	Autonomous
Insecure—avoidant (20%)	Infant appears independent when mother is present, and does not appear upset with separation; on her return seeks closeness but avoids gaze if picked up.	Dismissing
Insecure—ambivalent (10%)	Tend not to explore, preoccupied with mother and 'clingy'; upset by separation—may greet carer with ambivalence, e.g., reach out and push away at once.	Preoccupied
Unresolved (10%–15%)	No specific attachment style identified.	Disorganized

Box 30.39 ICD11 description of emotional, cognitive, and behavioural dysfunction in personality disorder

Emotional manifestations:
- Range and appropriateness of emotional experience and expression.
- Tendency to be emotionally over- or under-reactive.
- Ability to recognize and acknowledge emotions that are difficult or unwanted by the individual (e.g., anger, sadness).

Cognitive manifestations:
- Accuracy of situational and interpersonal appraisals, especially under stress.
- Ability to make appropriate decisions in situations of uncertainty.
- Appropriate stability and flexibility of belief systems.

Behavioural manifestations:
- Flexibility in controlling impulses and modulating behaviour based on the situation and consideration of the consequences.
- Appropriateness of behavioural responses to intense emotions and stressful circumstances (e.g., propensity to self-harm or violence).

Theoretical approaches

There are a multitude of personality theories, and many remain relevant to psychiatry (especially child psychiatry). Jean Piaget devised stages for each of cognitive and moral development. Social learning theorists point to the process of imitation of others (typically parents) as central to the development of personality, as it is in language development. Psychoanalysts (beginning with Sigmund Freud) have focussed on feelings and impulses (drives), for example, Erik Erikson's *Eight Stages of Man* as binary oppositions.

Building on many of these theories and drawing on anthropology, John Bowlby directly studied infant/child behaviour to devise *attachment theory* (see **Box 30.38**). According to attachment theory, around two-thirds of individuals were securely attached in childhood and are autonomous in relationships as adults. Adults in the 'insecure avoidant' group idealize their childhood, and tend to minimize ('dismiss') their own adverse, even traumatic, childhood events. Though the smallest proportion, the 'insecure ambivalent' or 'pre-occupied' group, is over-represented in psychiatric presentations: as adults, they often remain angry at their parents, wanting answers for their current unpleasant feelings.

The best definition of any psychotherapeutic intervention is that the therapist (who can never replace a parent or become the patient's friend) provides a *safe space from which to explore*. Once a person begins to understand variations in attachment, they can begin to imagine the effects of disrupted childhood development, and the multiple negative consequences of ACEs. In assessing patients with complex psychological symptoms, their early history (**Box 30.2**) can be a catalogue of childhood separation, loss, and uncertainty—even if there was no abuse.

Diagnosis

To establish this diagnosis, we must identify both the nature and degree (severity) of dysfunction in **functioning of aspects of the self** (identity, self-worth, capacity for self-direction) and/or problems in **interpersonal functioning** (developing and maintaining close and mutually satisfying relationships, understanding others' perspectives, managing conflict in relationships): see **Box 30.35**. There is a spectrum from 'normal' (poorly defined and subculture-dependent) to personality difficulty (traits present, but not a disorder) and then mild, moderate, and severe personality disorder [PD]). Just as Bowlby's prevalence rates (**Box 30.38**) are approximations, differences in measurement and standardization yield 'ball park' figures for personality difficulties (7%, but more prevalent in people in general hospitals due to the stress of being ill) and severe PD (4%).

Within psychiatric services, PD rates are higher still and greater levels of impact on others make the diagnosis more likely; PD can be context and culture specific, often manifesting at a time of crisis. Exclusions from diagnosing PD are ongoing substance misuse, effects of medications or medical illness (e.g., head injury causing enduring personality change), another active mental disorder, or specific developmental stages: for example, abnormal adolescent self-identity (of which, one example is gender incongruence). All five exclusions are also recognized co-morbidities in patients with established PD diagnoses. Severity and pervasiveness of core PD features (consistently present in adults for at least 2 years) merit documentation (**Box 30.39**). High scores in just one of five domains (**Box 30.40**) are unusual, but of itself, this is enough to confirm a PD diagnosis.

There is one clinical diagnosis of PD, but there are 93 separate ICD11 diagnostic possibilities from three levels of severity, five domains (plus a borderline identifier), and an additional 'unspecified PD' category: **Box 30.40**. Overlap is considerable, even before co-morbidities intervene. Approaches to managing an individual patient's difficulties differ widely: two people with *negative affectivity* may have either detachment (common in primary care) or dissociality (common in those in the criminal justice system). The former person is unhappy with self-blame and internalized anger; the latter may be of variable subjective mood but blaming of and angry at others.

Making a PD diagnosis relies on collateral history (**Box 30.6**): even with modern classifications, many of the words used *(fussy, rigid, manipulative)* are pejorative. We evaluate the behaviours (we might list instances of harm to others in dissociality; carefully noting the person's remorse for past actions) without judging the person as good or bad. For example, in the case of narcissistic PD (a 'cluster

B' diagnosis in the American DSM classification but not now part of ICD11), traits are predominantly viewed negatively by society: sense of entitlement, arrogance, displays of contempt to others, and more. Modern understandings of narcissistic traits lead us to see these patients (who ask for help) as insecure and having low self-esteem despite these traits. If that person engages in therapy, the focus might be to shift belief systems to the rewards of being a team player, that superiority to others is their value judgement or that we can be happy without needing affirmation and admiration by others.

Management

Only a minority will request treatment for PD of itself. Patients are more likely to present with a mood or anxiety disorder, perhaps where relationship difficulties dominate. Co-morbidities are treated in the usual ways, and changes in PD features as the crisis resolves are noted. Core treatment recommendations are structured assessments, engaging with carers, offering individual psychotherapy (or group-based for dissociality), and negotiating long-term goals. Medication is reserved for crises, and not given long term unless treating a key co-morbidity like depression. There is efficacy evidence for a specialist PD service within mental health services, providing therapies and multidisciplinary support for people with severe PD. Specific techniques showing promise include mentalization and dialectical behavioural therapy. The key is consistent support from a mental health professional within a team, with regular healthcare follow-up, and agreed 'safety net' plans in times of crisis.

EATING AND FEEDING DISORDERS

In ICD11 eating disorders are classified under 'feeding or eating disorders', and include anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder, avoidant or restrictive food intake disorder (ARFID), pica and ruminations—regurgitation disorders. Of these, AN is a severe mental illness with a high mortality and physical morbidity and is discussed in detail here.

Epidemiology

Eating disorders predominantly affect women but the prevalence rates are increasing in men too (in the USA, the lifetime prevalence for AN is 0.9% in women and 0.3% in men). Age at onset for AN for females is around 16–17 years (though more severe cases can start before or at puberty) and for males is around 12 years. Age at onset for BN is in females in mid-adolescent age. First-degree relatives of those with AN and BN have tenfold higher risk of developing eating disorders indicating they share similar genetic abnormalities.

Anorexia nervosa

The clinical features of AN are set out (**Box 30.41**). There are too many medical causes of unintentional weight loss to list here, and given the late presentations of AN, general hospitals are mostly the right setting to rule out medical illness as treatment begins. In BN there may be a similar concern about weight and body shape, with cycles of binge eating followed by purging, although body mass index (BMI) is often normal.

History

Patients with eating disorders are at various stages of motivation as described by Prochaska and DiClemente's transtheoretical model of change (**Box 30.34**). They may be reluctant to provide full history or may be ambivalent to engage in assessment. A collaborative, non-confrontational, and empathetic approach gathers a better history. If a patient says they have had three meals per day, then enquire in detail about the portion size and food contents to get an approximate idea about how many calories they are consuming. Record their explanations for weight loss and physical symptoms: these relate to insight and motivation. When asking about a

Box 30.40 ICD11 five personality domains, with additional specifier of borderline

Domains	Five-factor model	Description	Likely behaviours
Negative affectivity	High neuroticism	Lower self-esteem and self-confidence; tend to worry more/be more anxious; expect the worst	Avoid others and activities, at times become overdependent on others to regulate emotion
Detachment	Low extraversion	Low on trust for others, aloof; eccentric	No/few close relationships, tend to keep to themselves
Dissociality	Low agreeableness	Belief that rules are for other people, no care for consequences of their behaviours	Antagonistic, manipulative, or exploitative of other people; may become known to police
Disinhibition	Low conscientiousness	Cannot control emotions or temper	Impulsive, regret acts later; may be known for angry or unpredictable behaviours
Anankastic	High conscientiousness	Perfectionistic, high standards, obsessional by nature	Fixed routines, described by others as fussy or rigid
Borderline (also known as emotionally unstable PD)	Its name derives from the borderline of neurosis and psychosis: e.g., 'brief pseudo- or full hallucinations, paranoia in situations of high affective arousal'. PD with cycles of negative affectivity, high impulsivity (self-harm), instability of self-concept (emptiness), and relationships (fear of abandonment, lack of trust in others)		Long-term difficulties in work and relationships; shorter, intense relationships with denigration of person after; self-harm is common, and does not always present

patient's weight, now and over time, use open questions to check if there is any target weight (often pathological low weights) that the patient is aiming for.

Physical examination

Immediate physical examination is required in AN—do it systematically from head to toe, involving all the systems as included in **Box 30.10**. Patients can have signs of malnutrition (lanugo on arms), slow capillary filling, or proximal myopathy (**Box 30.42**). Check weight, height, BMI, pulse rate, and blood pressure, and check too for postural hypotension. You might use a squat test, asking the patient to stand and go low with fully bent knees before standing. When performing this test, support the patient as they may fall. Due to proximal myopathy, patients with AN are unable to rise from squatting position without supporting their upper limbs.

Box 30.41 ICD 11 criteria for anorexia nervosa

Extreme fear of weight gain
A persistent pattern of restrictive eating or other behaviours aimed at establishing or maintaining abnormally low body weight (reduced calorie intake, excessive exercise, or use of medications or laxatives)
Low body weight with a body mass index (BMI) less than 18.5 kg/m^2
Excessive preoccupation with body weight or shape/distorted body image
Endocrine disturbances (e.g., of the hypothalamic–pituitary–gonadal axis, which may result in amenorrhoea)

Investigations

Obtain an urgent ECG to confirm bradycardia or detect arrhythmias. Blood tests include nutritional markers (albumin, phosphate, magnesium). A DXA scan may be requested to assess bone density. Although rare in AN because of impaired physiology, always rule out pregnancy.

Management

Patients with AN may engage with medical services because they want a problem fixed (e.g., fainting, insomnia, secondary infections, etc.), and are usually ambivalent to engage in AN treatment that leads with weight gain. Initial assessment builds a therapeutic alliance: be empathetic (never blame them for not eating or overexercising) and use motivational interviewing techniques (**Box 30.33**) to work collaboratively with each patient. Medical Emergencies in Eating Disorders (MEED) is a new guideline to manage patients with eating disorders (**Box 30.43**). It provides a traffic light assessment tool based on a number of clinical features allowing clinicians to stratify clinical risk. In profoundly malnourished AN patients, the risk of refeeding syndrome should be considered and managed (see Chapter 25).

At an appropriate time, provide psychoeducation about healthy eating, health risks associated with starvation, exercise, and laxative use. Be sensitive with family members as they may be in a lot of

Box 30.42 Signs, symptoms, and medical complications of eating disorder

History/System	Starvation	Purging, laxative misuse, 'slimming pills' bought online
Hair	Thinning of hair, brittle hair, hair loss	
Central nervous system	Depression, insomnia, memory problems, fainting episodes, hypothermia	Generalized seizures EEG abnormalities Peripheral neuropathy
Haematological and Biochemical	Anaemia, pancytopenia Reduced ESR Compromised immune system Low magnesium, phosphates and more	Low potassium
Musculoskeletal	Proximal myopathy (Squat test) Reduced bone density leading to osteoporosis Joint pains Delayed growth	Worn upper teeth and marks on knuckles from purging Diarrhea may cause anal damage including rectal prolapse
Cardiovascular system	Bradycardia Low BP Reduced capillary filling Postural hypotension Symptoms of cardiac failure Mitral valve prolapse	Arrhythmia Cardiac failure Sudden death
Gastrointestinal	Dysphagia Delayed gastric emptying Acute gastric dilatation (superior mesenteric artery syndrome) Re-feeding pancreatitis Constipation, ileus	Parotid swelling Dental erosion Oesophageal erosion Gastric/duodenal ulcers
Endocrine and renal	Amenorrhoea Thyroid abnormalities Infertility Low glucose and phosphate Neurogenic diabetes insipidus Low sodium Renal stones	
Respiratory	Aspiration pneumonia Pneumothorax	

Box 30.43 MEED instrument to identify risk in eating disorders

MEED score example (Version 2)

	Red	Amber	Green
Weight loss	☐ Recent loss of weight of ≥1kg/week for 2 weeks (consecutive) in an undernourished patient 34 Rapid weight loss at any weight, e.g., in obesity or ARFID	☑ Recent loss of weight of 500-999g/week for 2 consecutive weeks in an undernourished patient	☐ Recent weight loss of <500g/week or fluctuating weight
BMI and weight	☐ Under 18 years: WFH <70%, Over 18: BMI <13	☑ Under 18 years: WFH 70%-80%, Over 18: BMI 13-14.9	☐ Under 18 years: WFH>80% Over 18: BMI >15
HR (awake)	☐ <40	☐ 40-50	☑ >50
Cardiovascular health click for blood pressure centile calculator	☑ Standing systolic BP below 0.4th centile for age or less than 90 if 18+, associated with recurrent syncope and postural drop in systolic BP of >20mmHg or increase in HR of over 30bpm (35bpm in <16 years)	☐ Standing systolic BP <0.4th centile or <90 if 18+ associated with occasional syncope; postrual drop in systolic BP of >15mmHg or increase in HR of up to 30bpm (35bpm in <16 years)	☐ Normal standing systolic BP for age and gender with reference to centile charts normal orthostatic cardiovascular changes, normal heart rhythm
Assessment of hydration status	☐ Fluid refusal, severe dehydration (10%): reduced urine output, dry mouth, postrual BP drop, decreased skin turgor, Sunken eyes, tachypnoea, tachycardia	☑ Severe fluid restriction, moderate dehydation (5-10%): reduced urine output, dry mouth, BP drop, normal skin turgor, some tachypnoea, some tachycardia, peripheral oedema	☐ Minimal fluid restriction, No more than mild dehydration (<5%): may have dry mouth or concerns about risk of dehydration with negative fluid balance
Temperature	☐ <35.5°C tympanic or 35.0°C axillary	☐ <36°C	☑ >36°C
Muscular function: Hand grip strength AND Muscular function: MUAC	☐ Male <30.5kg Female <17.5kg (3rd percentile) AND <18cm (approx BMI <13)	☑ Male <38kg Female <23kg (5th percentile) AND 18-20 cm (approx BMI <15.5)	☐ Male >38kg Female >23kg - AND >20 cm (approx BMI >15.5)
Other clinical state	☐ Life-threatening medical condition, e.g., severe haematemesis, acute confusion, severe cognitive slowing, diabetic ketoacidosis, upper gastrointestinal perforation, significant alcohol consumption	☐ Non-life-threatening physical compromise, e.g., mild haematemesis, pressure sores	☑ Evidence of physical compromise, e.g., poor cognitive flexibility, poor concentration
Activity and exercise	☐ High levels of dysfunctional exercise in the context of malnutrition (>2h/day)	☐ Moderate levels of dysfunctional exercise in the context of malnutrition (>1h/day)	☑ Mild levels of or no dysfunctional exercise in the context of malnutrition (<1h/day)
Purging behaviours	☑ Multiple daily episodes of vomiting and/or laxative abuse	☐ Regular (=>3x per week) vomiting and/or laxative abuse	
Self-harm and suicide	☐ Self-poisoning, suicidal ideas with moderate to high risk of completed suicide	☐ Cutting or similar behaviours, suicidal ideas with low risk of completed suicide	

Box 30.44 ICD11 criteria for bulimia nervosa

Frequent, recurrent episodes of binge eating (defined as a discrete period of time, e.g., 2 hours, during which the individual experiences a loss of control over their eating behaviour and eats notably more or differently than usual)
Extreme fear of weight gain
Excessive preoccupation with body weight or shape
Repeated inappropriate compensatory behaviours to prevent weight gain (excessive exercise, self-induced vomiting, use of laxatives or diuretics, omitting insulin if diabetic)

distress. Enteral (nasogastric) feeding is used as emergency rescue treatment—however, patients benefit from a *food first* approach as there is no physical reason they should not achieve nutrition by eating. A multidisciplinary approach including the medical team, LP, an eating disorders psychologist, and dietician helps support patients through difficult initial stages of treatment. Once they achieve a safe weight (note patients may employ bargaining strategies around weight targets, an indication of the severity of their AN), LP plans discharge with local eating disorders services.

Bulimia nervosa

Bulimia nervosa (BN) is a more common eating disorder than AN, but with lower morbidity and mortality. Diagnosis is by history (binges leading to self-induced vomiting, see **Box 30.44**), and there are commonalities with AN. If there is low BMI, physical examination and investigations are the same for AN. Differential diagnoses include rare medical diseases causing vomiting (upper gastrointestinal obstruction, raised intracranial pressure) and other psychiatric disorders (depression, PD, OCD).

Most patients with BN can be managed in the community as they are more forthcoming with their symptoms/cognitive distortions and more motivated to engage in treatment than low-weight AN patients. Treatment includes psychoeducation and treating any medical or nutritional complications. Psychological treatment comprises individual or group CBT adapted for eating disorders, or interpersonal therapy models. Family therapy is helpful in younger people. SSRIs in higher doses can be beneficial when patients have binging and purging episodes. BN has a better prognosis compared to AN, with a 30% remission rate with CBT.

Avoidant/restrictive food intake disorder

ARFID is an eating disorder, perhaps better described as disordered eating, where children/adults do not eat enough food (or do not eat a wide enough variety of foods), leading to periodic loss of weight. Children developing the condition before puberty develop significant, sometimes severe, nutritional deficiencies and/or growth problems. ARFID can happen at any age but is more common in younger children, more boys than girls. Children might present with history of food avoidance, reduced appetite, restrictive diet, dislike of the sensory aspects of hated foods, abdominal pains, or fear of vomiting. Children with ARFID are more likely to have coexisting difficulties such as anxiety, OCD, autism spectrum disorders, and attention deficit disorder. ARFID is different from AN and BN in that patients do not have body image disturbances, nor do they deliberately lose weight; induced vomiting is uncommon unless there is a severe aversion to a food type or its texture.

There are considerable overlaps between ARFID and both neurodevelopmental disorders (autism) and medical diagnoses (principally irritable bowel syndrome, now described as disorders of brain–gut interaction). To make the diagnosis, the restricted food intake and consequent weight loss must not be due to unavailability of food, or be a manifestation of another medical condition (e.g., food allergies, hyperthyroidism), must not be due to the effect of a substance or medication (e.g., amfetamines), including withdrawal, and not due to another mental disorder.

ARFID is best managed in an MDT outpatient setting consisting of a doctor, dietician, psychologist, and other professionals such as speech and language therapist (to address swallowing difficulties for certain foods). The main goals of treatment are to treat underlying nutritional deficiencies, to understand the reasons for avoiding certain type of food, and to provide psychoeducation with support towards healthy eating. Psychological treatment is based on CBT models where graded exposure can help patients to manage anxiety associated with food: increasing 'safe' foods and portion sizes are a good start. Family therapy can also help anxious or angry parents to support their children towards 'food first' healthy eating, create a healthy environment/routine around mealtimes, and thereby reduce anxiety associated with food. As ARFID is a relatively new diagnosis, it is unwise to speculate on prognosis.

ADDITIONAL CONSIDERATIONS IN SELECTED PATIENT GROUPS

Box 30.45 sets out additional challenges in assessing a variety of other patient groups.

Neurodiversity and learning disability

Individuals with intellectual disability and/or neurodiversity are often treated by specialist mental health teams. If they are admitted to hospital, their developmental stage and communication differences impact on the investigation and treatment of medical and surgical conditions. Just as when there are specific physical barriers (e.g., in individuals with visual or hearing impairment or a language barrier), it is important to make *reasonable adjustments* to reduce uncertainties about diagnosis and treatment over the course of admission. Finding old notes *(what worked before)* and engaging carers are essential preparations, and although LP does not need to be involved in every case, the treating team benefit from direct contact with the community teams including general practitioner who knows them best. Many hospitals have specialist learning disability teams to promote equitable care for these individuals: this is necessary to support people with these conditions and to establish new diagnoses.

Box 30.45 Communication with specific patient populations

For all groups:
- be flexible in your interview style
- consider shorter interviews (come back later)
- is there a staff member who already gets on well with this patient? Consider a joint assessment
- think through the (potentially negative) consequences of giving your formulation/diagnosis there and then

Category	Challenges for clinician	How to approach interviews
Visually impaired or hearing-impaired patients, or those with a language barrier	Bias towards finding other deficits, assumptions that delayed responses indicate psychopathology; premature use of closed questions.	Check old notes, collateral history before interview, lower threshold to have friend or relative in the room, well-lit and quiet room, communication aids (hearing loop, cue picture cards), in-person interpreter; chaperone for physical exam.
Young adults (see Chapter 46)	Assessment must be appropriate to their developmental age; transitions (from paediatric to adult services) are difficult for all.	Trauma-informed approach, if possible embed mental health services within a clinical environment designed for young adults.
People with intellectual disability and/or autism spectrum disorder	Evaluate capacity to consent to assessment and treatment. Interview must be appropriate to developmental age. Consider IQ (intelligence quotient) testing; in autism, there may be a double empathy challenge contributing to patient–doctor misunderstandings: doctors assume the patient lacks empathy, and reduces their empathy towards that patient.	Check old notes, obtain collateral history. Consider locating the assessment in patient's home. Know the prevalence: 2% of the population have intellectual disability, only some of whom have mental disorders (although with 5 times the prevalence as in the general population); autism spectrum has a 1%–2% prevalence, though it is higher in females than previously thought. Seventy percent on the autistic spectrum have intellectual disability; autism has standardized assessment tools.
Attention deficit hyperactivity disorder (ADHD)	Patients present with long-term concentration and attention difficulties: key collateral comes from parents, employers and teachers/school records. ADHD is a collection of neurodevelopmental disorders: likely overdiagnosed in the USA, and underdiagnosed in UK adolescent and young adult populations.	ADHD diagnosis is specialist based and there are a number of validated instruments to support this. Amfetamine prescription is also best left to specialist clinics: there are risks of addiction and long-term use but clear benefits if the ADHD diagnosis is correct. A specialist ADHD clinic must then monitor progress closely.
Cognitive impairment	Capacity may be absent for the interview: consider safeguards for the patient; in traumatic brain injury, (post-traumatic) memory loss can be temporary; variation is also expected in delirium and post-ictal patients.	Check old notes for risk factors (smoking, hypertension, arrhythmias etc.), collateral history, and consider MOCA (Montreal Cognitive Assessment) before interview. Look for treatable pathology: depression is present in 50% of stroke patients and is common in Alzheimer's disease.
Forensic populations: people charged with or convicted of a crime	Think about consent: the role of medical practitioners is not to gather evidence of a crime, however, such details may arise in the interview. Criminal intent to harm others should be reported to the police, breaking confidentiality; potential risks to other patients or staff (e.g., from Impulsivity) should be recorded and mitigated. Previous violence to others predicts future violence: devise containment and contingencies plan.	Apply the same standards and ethics as to other patients; focus on the patient's symptoms. Mood, hope, and suicidality are key questions: suicide in prisoners on remand (not yet charged with a crime) is relatively high—especially in people who are innocent, or if the person has no one to advocate for them. Doctors have a role in advocating for patients' needs.

Attention deficit hyperactivity disorder

Currently one of the most frequent medical queries from adolescents and young adults at psychiatric clinics is '*do I have attention deficit hyperactivity disorder (ADHD)*?' Psychiatric co-morbidities are almost universal in ADHD, but patients may prefer ADHD medication (amfetamines) to treatments for depression, anxiety, eating disorder, addiction, trauma, etc. LP teams are not likely to start these but may continue their prescription in hospital if the patient has a plausible ADHD diagnosis.

Mental health problems in older people

Across the world, most hospital beds are occupied by people over 65. The community prevalence of dementia in this age group is 7% (with significant numbers undiagnosed); rates are higher in hospital due to multimorbidity. Most will be managed by geriatric medicine teams (see Chapter 49), though LP may be consulted for advice on management of *acute on chronic* confusion, specifically delirium. Depression may coexist with dementia and a specialist LP assessment may make a major difference to that person's quality of life in hospital and beyond.

Patients in the criminal justice system

Someone convicted or charged with a violent crime *may* pose risks to other patients or staff if they are admitted to hospital, and so this information should be communicated as necessary to staff in order to keep the ward safe. This should be done without discriminating against the patient, who has a right in law to equal treatment in healthcare settings. It is for the courts and prison systems to deal with offenses and punishment, not doctors. Mental capacity to consent to or refuse treatment is almost always present, and the limits of confidentiality should be discussed with patients, including in circumstances where reports on medical or psychiatric conditions might later be requested by judicial authorities. If the person's criminal offences have been linked to mental disorders, they are best managed by a specialist forensic psychiatry team, and agreeing adjustments to management between teams is an important part of care. The patient might be subject to prescribed restrictions to their liberty, and Court Orders take precedence over routine capacity decisions.

DIAGNOSES OF EXCLUSION: FACTITIOUS DISORDER AND FACTITIOUS DISORDER INDUCED BY ANOTHER

Sometimes patients do not fit neatly into the diagnostic categories of psychiatry and other medical specialties. Patients may continue to have high symptom levels, be unresponsive to treatments, or be assigned diagnoses that fluctuate as one is disproven over another.

Where there is concern about diagnosis, patients should be reassessed with colleagues in joint/interdisciplinary assessments, perhaps in a different setting than before. Information may be sought from additional sources, including historical notes and documentation from other hospitals. Contradictory investigations should be reviewed and alternative explanations considered. These patients take time and they often need the additional time investment by a multidisciplinary panel to collate findings.

There are three broad explanations when findings do not conform readily to recognized diagnostic categories:

- ***Wrong diagnosis:*** doctors don't always get it right. Perhaps a patient felt pressured to answer questions to give positive responses to closed questions, deny a key symptom 'in the moment', or the wrong assumptions, even bias, led the team in the wrong direction. Overlooking an outlier investigation which challenges a working assumption (usually a negative result) is readily done, though some critics have called this 'diagnostic greed'. If it is clear a mistake was made, there is a duty of candour to the patient to disclose this and formulate a new treatment plan. This is a variant of breaking bad news, although the patient may extract a positive from the exchange, as the wrong treatments will be stopped, with the hope of better alternatives. A good example of this is the late diagnosis of bipolar disease (**Box 30.22**) in a patient previously diagnosed with recurrent depression. The average time to diagnosis of bipolar remains 10–15 years; patience and an open mind reduce this.
- ***Lack of honesty during the medical or psychiatric evaluation.*** First impressions ('*the doctor was busy, they didn't listen or care*') impair the development of a trusting doctor-patient relationship. Disengagement is common in clinical practice, and sometimes dishonesty plays a role in the process, generally higher in that small proportion of patients who are dissatisfied with their medical care. In retrospect, it may be possible to explain inconsistencies in patients' histories: some might have felt they needed to exaggerate some symptoms to achieve faster or better help. *Primary gain* is the relief of symptoms; *secondary gain* refers to the indirect benefits of help-seeking behaviours, and does not result from a conscious process. Just as the sick child may get extra treats or get to skip school, so (rarely) there may be income generation from sickness in adults, such as a legal payout or access to income benefits. Studies of medical interviews have highlighted 'inconsistencies' in both what patients report, and what doctors say in response. In the same clinical scenario, one doctor may promise unrealistic cure, and a second might declare there is no hope for any recovery.

  With thought and time, these relationships are usually salvable—even when the patient has elaborated for the purposes of secondary gain. The best approach is *acknowledgement* (we now agree your symptoms are limited to X) then *action* (agreed treatment plan for X). If there are grains of truth within primary symptoms, these scenarios are not without hope and can usually be rescued in a redefined, open, and honest doctor–patient relationship, so that the patient's care remains within the treating hospital system. The key breakdown of the therapeutic relationship is when a patient has had a supportive challenge but continues to overstate or lie about symptoms.
- **Diagnoses of exclusion: malingering or factitious disorder (FD).** A malinger wants to miss work, an exam, or a court case, and consciously plans to achieve this. Perhaps they are bringing a legal case for compensation against a person or system, and think through what to say to actively simulate and dissimulate towards a payout. Malingering prevalence is thought to be less than 1% of all medical presentations, but up to 8% of people referred to occupational health programmes. Clinicians have duties to be honest (and not join a 'scam' to mislead), duties to their patients (to advise them not to risk reputation, health, and more by pursuing a false claim), and duties to the services that employ them. Confronting malingerers is difficult, and might end professional relationships with them.

  The (even) more challenging diagnosis FD describes simulation of physical and/or mental symptoms that are ***not*** present. There is no *apparent* gain for FD patients, unlike in those who are malingering. **Box 30.46** sets out common features from the literature. The 'gains' (why they do this) often relate to poor relationships with clinicians, grievances against others/institutions, and feeling 'special' as a patient.

Management of factitious disorder

Even with 'supportive confrontation', FD patients usually self-discharge and do not attend follow-up with that service. The risks to themselves are manifest; they consume considerable resources and may disrupt medical systems. Because there is no identifiable, treatable mental disorder, psychiatric treatment should not be forced on them. In some cases, there is a duty to share information with other hospitals—with both a best interest and a public interest defence. If a patient with a diagnosis of FD seeks to work

Box 30.46 Features of factitious disorder

Has attended many previous clinics/hospitals over a wide area, and (importantly) resists requests for shared information from these: they may appear cooperative but give wrong clinician contact details, etc.	History has inconsistencies in dates or severity of symptoms Physical examination/observations mismatch reported symptoms MSE: no findings, no disorder obviously explains symptoms	Illness course does not follow expected pattern: too many 'relapses' following brief responses to treatment. Sometimes a routine test, previously normal on many readings, comes back as abnormal—in this patient, in the absence of other causes, might s/he have interfered with the test?
Connections with health professionals: family members, medical/nursing students Up to 50% of FD cases in some series are in health professionals or students	Hospital admission reveals different patient accounts to different staff Nurses (mostly outside office hours) observe secretive/odd behaviours Patients try to read their notes or access forbidden hospital areas	Evidence emerges that some abnormal findings have been manipulated by the patient; i.v. lines/wounds might be wilfully contaminated Patients may have their own medication/insulin supply
May seek procedures that have been declined (for good medical reasons) by other hospitals: enteral feeding tubes, parenteral nutrition, etc.	Hospital admission also defined by arguments with staff and patients: disruptive of ward activity with 'self-aggrandizing behaviours'	Evidence of covert treatment refusal: supplies of tablets found hidden, medications/ parenteral nutrition flushed down the toilet
May seek euphoria-inducing drugs as part of complex sick role behaviours: opioids, benzodiazepines, cyclizine	May even interfere with other patients' medical care: 'I am only the one who can help—not these (bad) doctors and nurses'	Resist psychiatric evaluation. Inconsistencies when assessed Don't engage with support; don't attend follow-up

in a medical or nursing setting, objective evidence of dishonesty should be shared with their university and professional registration authorities.

Factitious disorder imposed on another

Factitious disorder imposed on another (FDIA) is a term assigned to an individual who is feigning, falsifying, or inducing the symptoms *in another person*, not to the person who is presented as having the symptoms. The term replaces the older much litigated diagnosis of 'Munchausen's syndrome by proxy'. The ill person is invariably unaware of subterfuge, and FDIA might be seen as a variant of *gaslighting*—where a more powerful (controlling) person convinces another that they are the one who is abnormal in some way. Occasionally the individual induces or falsifies symptoms in a pet rather than in another person. The commonest setting is on paediatric clinics and wards, where FDIA does happen (though it is thankfully rare). A parent, for whatever reason (often none can be found), *actively* makes their child sick, inviting more harmful investigations and treatments. Some parents seem validated by dramatic medical interactions or crises that most parents would dread.

Child protection procedures should be initiated: this process will gather evidence and get together as many professionals as possible (teachers, clinicians, social workers, and more) into the same case conference to decide how best to keep the child safe. Raising a tentative diagnosis of FDIA will involve conflict with the parent; however, professionals cannot be faulted for requesting a child protection conference if something does not seem right. By contrast, failing to act on a 'red flag' of unexplained injuries and/or harms to a child will have longstanding consequences for them (and the clinician involved). Doctors and other health professionals do not wilfully cause harm to their patients, but FDIA is an exception. If an FDIA diagnosis is proven in a healthcare professional, they cannot work again in a clinical setting, supervised or not.

PREVENTION OF MENTAL ILLNESS: PUBLIC MENTAL HEALTH

Rates of referral to psychiatry services are rising globally, and only a fraction of these are explained by increased mental health awareness, lower referral thresholds, and over-medicalization. Rather, there is evidence for a global mental health crisis, fuelled by worsening social and economic determinants of mental illness (**Box 30.15**) and a fall in protective factors. System reform of health services to make care more appropriate and accessible to people who need it is only part of the solution.

Public mental health applies a multisystem public health approach to the prevention of mental disorders, and advocates to reduce the mental health treatment gap (the proportion of people with mental disorders who get no treatment, currently 3 in 4). The alternative to adopting a more proactive, preventative approach to mental illness is unthinkable: a rising proportion of the population who are economically inactive due to illness and overwhelmed health services.

Prevention can be applied at three levels:

- *Tertiary prevention* is treating the symptoms of mental illness to restore good levels of function and prevent relapse, including much of the work traditionally carried out by specialist psychiatry services.
- *Secondary prevention* involves actively looking for illness and working with patients to remediate early ***(don't just screen, intervene).*** Early intervention (EI) teams in psychosis are a good

example of how providing rapid assessment, support, and treatment can avert a prolonged period of mental illness.

- *Primary prevention* involves actions to prevent onset of mental health disorders. **Box 30.15** illustrates how an evidence-based understanding of the social determinants of mental illness guides universal and selected interventions to support individuals to maintain good mental health.

Investment in public mental health programmes pays off in multiple domains, but political pressures that resist income distribution and commercial interests that benefit from activities that damage health provide challenges to implementation. Falling life expectancy in Western countries (despite medical advances and health spending) is frequently mediated by poor mental health. Future generations of doctors, working collaboratively, have a chance to change this.

CORE SKILLS AND KNOWLEDGE

Ophthalmology often gains limited exposure during medical training. It remains the busiest specialty in medicine and although many diseases are minor and self-limiting, destructive diseases can lead to serious disability and may be caused by a range of systemic inflammatory disorders.

All doctors, especially those working in primary care, require a basic understanding of eye function and health. Key to this is the approach to the common symptoms and signs that may result in visual loss in both the short and long term. Care for more serious conditions is generally carried out in specialist ophthalmology centres.

Key knowledge and skills to obtain in ophthalmology include:

- Developing an appropriate diagnostic approach to examining the eye appropriately
- Identifying sight-threatening eye emergencies and understanding their urgent management
- Identifying urgent eye diseases that may be life-threatening and managing appropriately.

Learning opportunities include attending ophthalmology outpatient clinics and surgical lists as well as practising clinical skills including slit lamp examination and fundoscopy.

BACKGROUND

Ophthalmology is one of the busiest specialities in medicine. In the NHS, it accounted for 10% of all outpatient activity (nearly 8 million appointments) in 2019–2020, as well as 6% of all surgical interventions, mostly carried out as outpatient, day-case procedures. Cataract surgery is the most common operation offered on the NHS, and the second commonest worldwide after Caesarean section.

Most ophthalmologists are 'surgical ophthalmologists', who perform a range of surgical procedures including cataract surgery, squint and glaucoma surgery, retinal surgery, corneal transplantation, orbital surgery, nasolacrimal surgery, and oculoplastic surgery, often with the help of an operating microscope and with or without lasers.

However, over 50% of initial presentations of ophthalmic conditions are associated with underlying systemic disorders, requiring ophthalmologists to have a broad awareness of general medicine.

Medical ophthalmology is a growing medical subspecialty treating vascular, inflammatory, and neurological disorders of vision, including diabetic nephropathy, uveitis, eye disease in systemic conditions such as vasculitis or thyroid disorders, and neuroinflammatory conditions such as optic neuritis. Such '**ophthalmic physicians**' may deliver procedures such as laser therapy or intraocular injection, or may be involved in public health interventions such as retinal screening.

Most major types of eye disease are covered in this chapter; however, diabetic eye disease (Chapter 35) and hypertensive eye disease (Chapter 18) are discussed elsewhere.

APPLIED ANATOMY AND PHYSIOLOGY

The average length of the human eye is 24 mm. It is essentially made up of two segments:

- The smaller anterior segment is composed of the conjunctiva, anterior chamber, and iris and is coated by the transparent cornea, and measures approximately 4 mm in depth
- The larger posterior segment is composed of the vitreous, retina, choroid, optic nerve head and is coated by the opaque sclera, and measures approximately 20 mm in depth.

It is the cornea and the sclera that give the mechanical strength and shape to the exposed surface of the eye.

The cornea occupies the central aspect of the globe and is one of the most richly innervated tissues in the body. This clear, transparent, avascular structure, measuring 12 mm horizontally and 11 mm vertically, and provides 78% of the focusing power of the eye. The eyelids prevent the cornea from drying and becoming an irregular surface by distributing the tear film over the surface of the globe with each blink.

Anatomically, the cornea is made up of five layers:

- epithelium
- Bowman's layer (membrane)
- stroma
- Descemet's membrane
- endothelium.

The endothelial cells lining the inner surface of the cornea are responsible for maintaining the clarity of the cornea by continuously pumping fluid out of the tissue. Any factor that alters the function of these cells will result in corneal oedema and cause blurred vision.

The sclera is an opaque white structure covering four-fifths of the globe and is continuous with the cornea at the limbus. The six extraocular muscles responsible for eye movements are attached to the sclera, and the optic nerve perforates it posteriorly.

The conjunctiva covers the anterior surface of the sclera. This richly vascularized and innervated mucous membrane stretches from the limbus over the anterior sclera (where it is called the bulbar conjunctiva) and is then reflected on to the undersurface of the upper and lower lids (the tarsal conjunctiva). The area of conjunctival reflection under the lids makes up the upper and lower fornix.

The anterior chamber is the space between the cornea and the iris, and is filled with aqueous humour (Fig. 31.1). This fluid is produced by the ciliary body (2 μL/min) and provides nutrients and oxygen to the avascular cornea. The outflow of aqueous humour is through the trabecular meshwork and canal of Schlemm adjacent to the limbus. Any factor that impedes its outflow will increase the intraocular pressure (IOP). The upper range of normal for IOP is 21 mmHg.

The uveal tract is made up of the iris anteriorly, the ciliary body, and the choroid. The ***iris*** is the coloured part of the eye under the transparent cornea. The muscles of the iris diaphragm regulate the size of the pupil, thereby controlling the amount of light entering the eye. The muscles of the ***ciliary body*** control the accommodation of the lens, and the secretory epithelium produces the aqueous humour (see above). The highly vascular ***choroid*** lines the inner aspect of the sclera and upon this lies the retina.

The lens lies immediately posterior to the pupil and anterior to the vitreous humour. It is a transparent biconvex structure and is responsible for 22% of the refractive power of the eye. By changing its shape, it can alter its refractive power and help to focus objects at different distances from the eye. By the fourth decade of life, this ability to change shape starts to decline and, with time, the lens starts to become less transparent and cataracts begin to develop.

The vitreous humour fills the cavity between the retina and the lens.

The retina is a multilayered structure. The metabolically active region of the retina is represented in Fig. 31.2. There are two types of photoreceptors in the retina: rods and cones. There are approximately 6 million cones, mainly confined to the ***macula***, and these are responsible for detailed central vision and colour vision. The peripheral retina has around 125 million rods that are responsible for peripheral vision. The axons of the ganglion cells form the optic nerve (or disc) of the eye (Fig. 31.3).

The blood supply to the eye is via the ophthalmic artery; in particular, the central retinal artery is responsible for supplying the inner retinal layers. Venous return is through the central retinal and ophthalmic veins. Local lymphatic drainage is to the pre-auricular and submental nodes.

The sensory innervation of the eye is through the trigeminal (Vth) nerve. The six extraocular muscles are supplied by different nerves (see Chapter 28):

- oculomotor (IIIrd) nerve: medial, superior, inferior rectus, and inferior oblique
- trochlear (IVth) nerve: superior oblique
- abducens (VIth) nerve: lateral rectus.

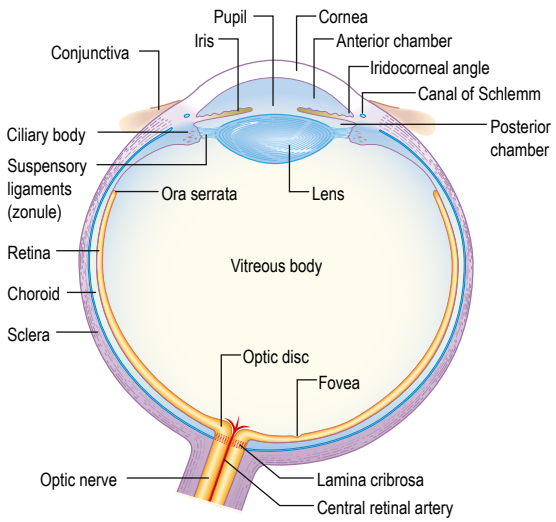

Fig. 31.1 **Cross-section of the eyeball.**

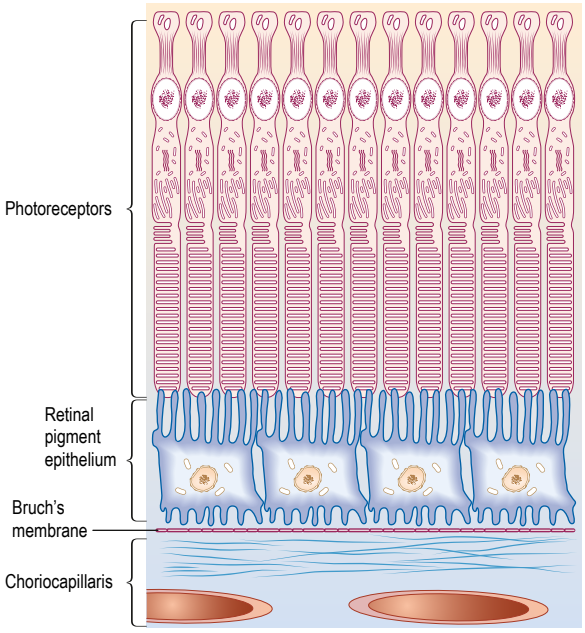

Fig. 31.2 **Schematic diagram of the retina.**

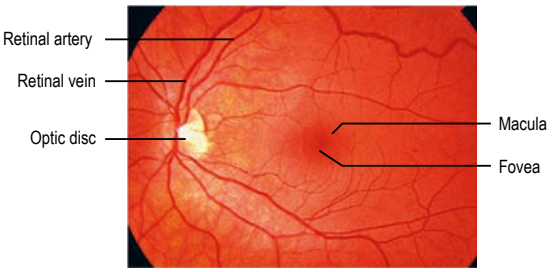

Fig. 31.3 **Fundus photograph of the left eye.**

The oculomotor (IIIrd) nerve also supplies the upper lid and, indirectly, the pupil (parasympathetic fibres are attached to it). The facial (VIIth) nerve supplies the orbicularis and other muscles of facial expression.

CLINICAL APPROACH TO THE PATIENT WITH A DISORDER OF THE EYE

History

A detailed history gives most of the facts needed to make a working diagnosis. The eye has limited mechanisms by which it can convey a diseased state.

In general, the following questions are basic guidelines to ophthalmic history taking:

- onset and duration of symptoms
- previous ocular history
- use of contact lenses
- red eye (see **Box 31.1**)
- photophobia
- eye pain (nature and character of the pain, association with eye movements)
- compromise of vision (onset of loss of vision: acute or gradual, permanent or transient, peripheral, altitudinal or central vision loss, abnormal colour vision)
- trauma—determine the involvement of foreign objects, type of objects (metallic or vegetation), and the mechanism of injury. Small, sharp, and high-velocity objects (e.g., from hammering metal or through the use of a grinder) can often lead to penetrating injuries
- diplopia (binocular diplopia resolves when one eye is covered; monocular diplopia, which is much rarer, persists with only one open)
- floaters
- loss of visual fields or scotomas.

A past medical and family history should be taken to identify autoimmune diseases, diabetes mellitus, hypertension, hypercoagulopathies, or thyroid disease. Symptoms in the history may point towards a wide range of systemic diseases with ophthalmic manifestations, as described in **Box 31.2**.

Examination

It is essential to adopt a systematic approach to the examination of the eye. Different approaches and instruments (including direct ophthalmoscope, slit lamp with or without Goldman or Volk lens) are necessary for examination of the lids and anterior and posterior segments, as well as extraocular movements. A slit lamp is a device combining a biomicroscope and a light source focused to produce a thin sheet of light, that can be adjusted to examine various features of the eye (**Fig. 31.4**). The sequence used for a full examination of the eye is described in **Box 31.3** (including the content below).

Box 31.1 Red flags for a red eye

The following symptoms require urgent referral:

- Severe pain
- Photophobia
- Reduced vision, particularly if sudden
- Coloured halos around point of light in a patient's vision
- Proptosis
- Smaller pupil in affected eye

Plus on medical assessment:

- High intraocular pressure
- Corneal epithelial disruption
- Shallow anterior chamber depth
- Ciliary flush

Clinical examination

Ophthalmic clinical examination involves using a vision chart and slit-lamp bio-microscope. An ophthalmic examination may include:

- Inspection of the eyes and surrounding structures:
  - Inspection for evidence of eye redness: generalized or localized, conjunctiva, episclera, or sclera. Causes of red eye are listed in **Box 31.1**
  - Inspection for evidence of thyroid eye disease: exophthalmos, lid lag, lid retraction, proptosis.
- Inspection of the cornea:
  - Keratic precipitates ('mutton fat' keratic precipitates with uveitis are seen in sarcoidosis or tuberculosis)
  - Loss of corneal sensation (herpetic eye disease)
  - Dry cornea or ulcers (exposure keratopathy)

Box 31.2 Symptoms and signs of systemic diseases associated with inflammatory eye conditions

Associated symptoms	Associated disease
Cardiac	
Chest pain	TB, RA, SLE, syphilis
Palpitations	Sarcoidosis, syphilis, RA, SLE, HIV
Respiratory	
Cough	TB, sarcoidosis, AAV, HIV, toxocariasis
Haemoptysis	TB, AAV, HIV, RA, SLE, sarcoidosis
Pleuritic chest pain	Sarcoidosis, TB, AAV, SLE, RA, HIV
Shortness of breath	Sarcoidosis, TB, AAV, SLE, RA, HIV
Gastrointestinal	
Diarrhoea	IBD, Behcet's, HIV
Blood in stool	IBD, Behcet's, HIV
Jaundice	IBD, HIV
Genitourinary	
Dysuria/discharge	Reiter's, syphilis, TB
Genital ulcers	Behcet's, syphilis, HLA-B27–related diseases
Haematuria	AAV, SLE, TB
Ear-nose-throat	
Oral ulcers	Behcet's, herpes, SLE
Deafness/tinnitus	VKH, AAV
Recurrent epistaxis	AAV
Musculoskeletal	
Joint pain and swelling	HLA B27 arthropathies, JIA, sarcoidosis, RA, SLE, Behcet's, AAV, Lyme
Lower back stiffness	HLA-B27, arthropathies, TB
Skin	
Rash	Sarcoidosis, Behcet's, TB, IBO, Herpes, syphilis, Lyme
Photosensitivity	SLE
Vitiligo	SLE, VKH, leprosy
Central nervous system	
Headache	Sarcoidosis, VKH, Behcet's TB, SLE, lymphoma
Weakness	Multiple sclerosis, sarcoidosis, Behcet's, HIV, leprosy, syphilis, lymphoma
Numbness/tingling	Multiple sclerosis, sarcoidosis, Behcet's, HIV, leprosy, syphilis, lymphoma
Behavioural change	VKH, sarcoidosis, Behcet's, SLE, AAV, HIV, TB, syphilis, lymphoma

AAV, ANCA-associated vasculitis; *IBO,* inflammatory bowel disease; *JIA,* juvenile idiopathic arthropathy; *RA,* rheumatoid arthritis; *SLE,* systemic lupus erythematosus; *TB,* tuberculosis; *VKH,* Vogt-Koyanagi-Harada syndrome.

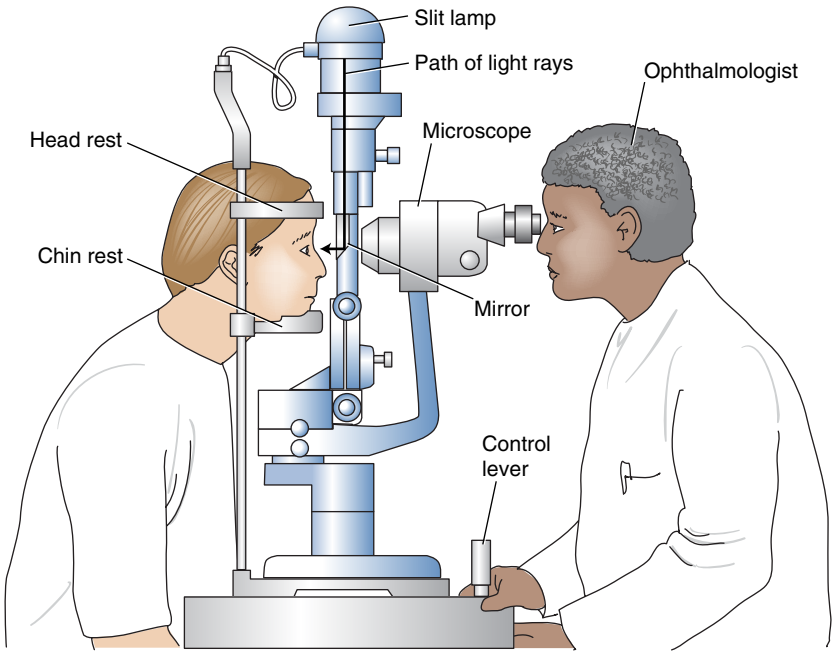

Fig. 31.4 Slit lamp. A slit lamp is a microscope with a light attached. The name is derived from the adjustable light beam.

Box 31.3 Differential diagnosis of the acute red eye

Cause	Conjunctival injection	Unilateral or bilateral	Pain	Photophobia	Vision	Pupil	Intraocular pressure
Conjunctivitis	Diffuse	Bilateral (often unilateral initially)	Gritty	Occasionally with adenovirus	Normal	Normal	Normal
Keratitis	Diffuse	Unilateral	Gritty	Yes	Reduced	Normal	Normal
Anterior uveitis	Circumcorneal	Unilateral	Painful	Yes	Reduced	Constricted	Normal or raised
Acute glaucoma	Diffuse	Unilateral	Severe pain	Mild	Reduced	Mid-dilated	Raised

  - Fluorescein staining and examination under a blue light to determine cornea epithelium integrity
  - Leak of aqueous humour (Seidel test) may be seen in cases of trauma, if full-thickness corneal injury is present.
- Inspection of the anterior chamber:
  - Anterior chamber: flare and inflammatory cells are seen in anterior uveitis, and in severe disease, hypopyon (pus in the anterior chamber) may be seen
  - Presence of blood (hyphaema) suggests trauma or a bleeding disorder, or pus (hypopyon) in the anterior chamber of the eye.
    - Integrity of eyelids, including any lumps and bumps or lacerations (partial or full thickness, involvement of canaliculi) in cases of trauma
    - Inspection for periorbital redness and swelling (periorbital cellulitis): if present, temperature measurement must be documented.
- Assessment of vision using a Snellen (or LogMAR) chart at 6 m
- Pupil examination, which involves useful objective tests to determine the afferent and efferent pathways:
  - Size of pupil
  - Pupil reactivity
  - Relative afferent pupillary defect.
- Fundal examination using cycloplegic eye drops such as tropicamide 1% or cyclopentolate 0.5% or 1%:
  - Vitreous examination: presence of vitritis in intermediate or posterior uveitis
  - Retinal examination:
    - dot/blot/flame-shaped haemorrhages in vascular diseases
    - perivascular sheathing, intraretinal infiltrates, cotton wool spots (microinfarcts of the retinal nerve fibre layer) in vasculitis and posterior uveitis
    - whitening of the retina with a cherry red spot in acute artery occlusion
    - presence of cholesterol or calcific embolus may be noted in the vessels.
  - Optic nerve swelling
- Visual field examination by confrontation or an automated visual fields (Humphreys) test
  - Enlarged blind spots in papilloedema
  - Bitemporal visual field loss in pituitary diseases
  - Visual field compromise involving the vertical midlines in various types of cerebrovascular disease.

Visual acuity

It is vital for an accurate assessment of visual acuity to be recorded in all people with an eye problem. The visual acuity of each eye is recorded in two ways: distance visual acuity and near visual acuity.

The Snellen visual acuity chart (Fig. 31.5) is most commonly employed to assess distance visual acuity, but use of the LogMAR

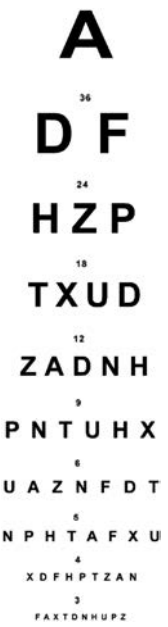

Fig. 31.5 Snellen chart.

Fig. 31.6 LogMAR chart (logarithm of the *M*inimum *A*ngle of *R*esolution).

chart (*log*arithm of the *M*inimum *A*ngle of *R*esolution; Fig. 31.6) is increasing, largely due to its necessity in studies or research, since it allows better statistical analysis of results. Unlike the Snellen and other visual acuity charts, the LogMAR chart has equal graduation between the letters on a line, as well as the space between lines. There is also a fixed number of letters—five—on each line. Research conducted using a logarithmic progression in size of letters on a test chart provides the most accurate visual acuity measurement. Snellen equivalents can be calculated from the LogMAR charts if necessary (Fig. 31.7).

The recording is given as an expression of the line of letters that can be discerned at a particular distance, usually 6 metres (20 feet): for example, 6/60, where 6 equals the distance of the chart from the eye in metres and 60 equals the distance at which the letter subtends 5′ at the nodal point.

OPHTHALMIC EMERGENCIES

The three main ophthalmic emergencies are:

- Eye trauma
- The painful red eye
- Sudden loss of vision.

An approach to these emergencies and the urgency of referral to specialist ophthalmological assessment is given in Fig. 31.8. The emergency assessment of these conditions is given below.

Eye trauma

Corneal abrasions

Trauma resulting in the removal of a focal area of epithelium on the cornea is very common. Abrasions usually occur when the eye is accidentally poked with a finger, a foreign body flies into the eye, or something brushes against the eye.

Symptoms include severe pain, due to exposure of the corneal nerve endings, lacrimation, and inability to open the eye (blepharospasm). Blinking and eye movement can aggravate the pain and foreign body sensation. The visual acuity is usually reduced. Most cases will need topical anaesthetic drops such as oxybuprocaine or tetracaine to be administered before it is possible to examine the eye. The cornea should be inspected with a blue light after instillation of fluorescein drops. The orange dye will stain the area of the abrasion. Under blue light, the abrasion lights up as green. Occasionally, foreign bodies can lodge on the undersurface of the upper lid and give rise to linear vertical abrasions. Eversion of the upper lid is necessary in all cases of abrasions (Fig. 31.9).

Treatment consists of a broad-spectrum topical antibiotic, such as chloramphenicol drops or ointment, four times a day for 5 days. The role of padding is controversial but common practice is to pad the affected eye for 24 hours once chloramphenicol ointment has been applied to the eye.

Corneal foreign body

Occasionally, when something flies into the eye, it sticks on the cornea (Fig. 31.10A). It may be associated with lacrimation and photophobia. Examination is best attempted following instillation of a topical anaesthetic and should include eversion of the upper lid (see Fig. 31.10B). Corneal foreign bodies can usually be seen directly with a white light.

The corneal foreign body should be removed. ***Treatment*** involves a topical antibiotic, such as chloramphenicol four times a day for 5 days, or fusidic acid twice a day for 5 days.

High-velocity trauma

In cases of high-velocity trauma, corneal perforation or an intraocular foreign body should be suspected. Examination may show a corneal laceration and a foreign body may also be embedded in the cornea. The foreign body may be present on the iris or in the lens or vitreous. Other clues pointing towards a penetrating injury include a large subconjunctival haemorrhage, a flat anterior chamber with low IOP, and the presence of blood in the anterior chamber (hyphaema). Urgent referral to the ophthalmologist is mandatory, ensuring that no drops are instilled into the eye and that a plastic shield is placed over the eye to minimize further risk of trauma.

Blunt trauma usually results in periorbital bruising and gross lid oedema, which can make examination to exclude perforating injury difficult. These patients should be referred to the ophthalmologist for a detailed ocular examination to exclude a perforation, retinal detachment, or a traumatic hyphaema (Fig. 31.11).

20 feet (Snellen)	6 metres (Snellen)	Decimal	4 metres	log MAR
20/200	6/60	0.1	4/40	+1.0

Fig. 31.7 Snellen equivalents can be calculated from the LogMAR charts if necessary. Vision is often recorded at 4 metres in studies, and logMAR equivalents or decimals are used in statistics.

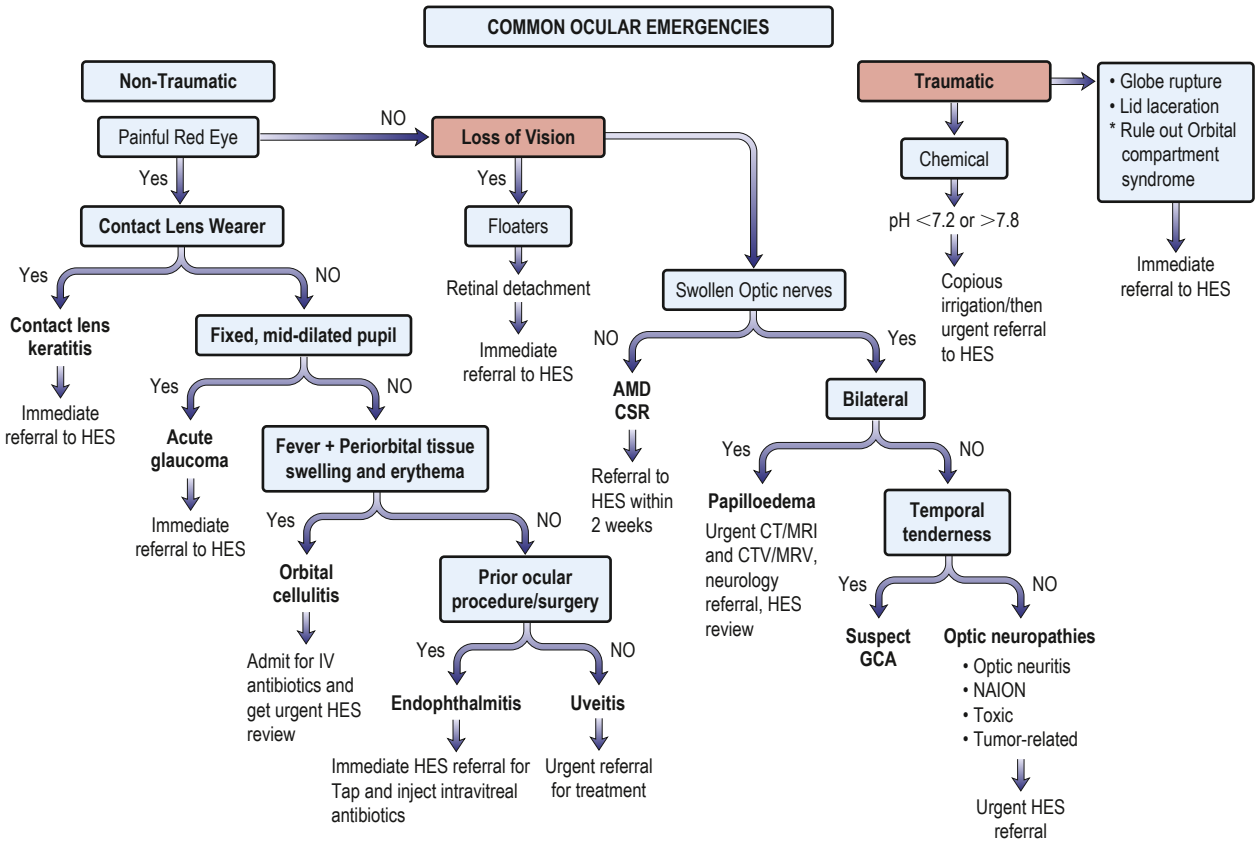

Fig. 31.8 Pathways and timing of referral for investigation and treatment in eye emergencies. *AMD,* Age-related macular degeneration; *CSR,* central serous retinopathy; *GCA,* giant cell arteritis; *HES,* hospital eye service; *NAION,* non-arteritic anterior ischaemic optic neuropathy.

Acute red eye

Patients may present complaining of acute red eyes with simple and self-limiting conditions (such as viral conjunctivitis or subconjunctival haemorrhage), or severe and sight-threatening ones. General doctors need to be adept in identifying 'red flag' features that suggest a serious diagnosis and require urgent specialist review (**Box 31.1**).

Featured suggestive of other causes of red eye are listed in **Box 31.3**.

Sudden onset sight loss

This is always a medical emergency, with a wide range of potential causes. Some of these require urgent specialist ophthalmology care (such as acute angle closure glaucoma), whilst others require urgent care by general medical or neurology teams (such as amaurosis fugax or optic neuritis).

The traditional divide is used to begin diagnostic evaluation based on whether or not the visual loss is associated with eye pain

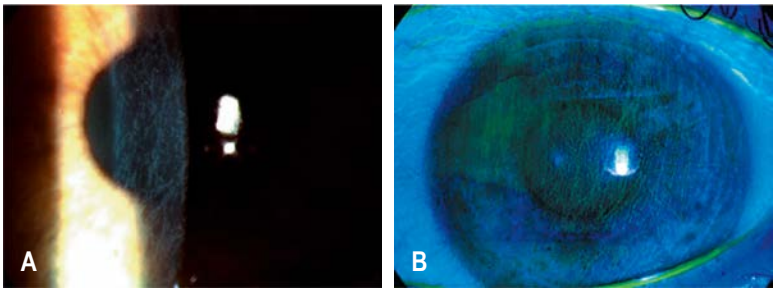

Fig. 31.9 Linear corneal abrasion. **(A)** Stained with fluorescein. **(B)** Stained with fluorescein and viewed with blue light.

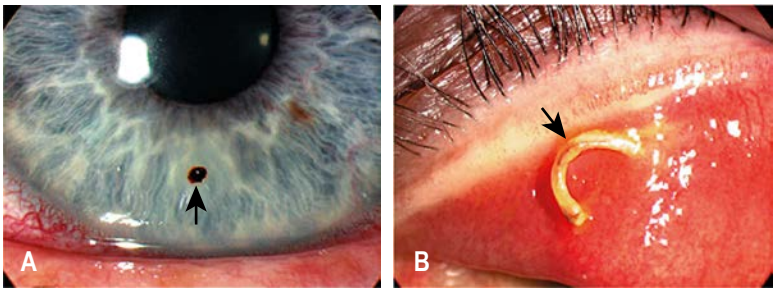

Fig. 31.10 Foreign bodies *(arrowed)*. **(A)** Corneal. **(B)** Subtarsal.

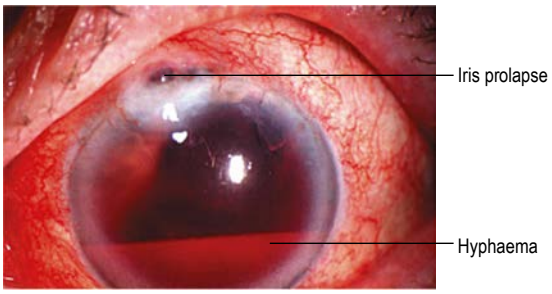

Fig. 31.11 Blunt trauma. Hyphaema and globe rupture with iris prolapse.

(Box 31.4). A guide to suggestive findings on history and examination is given in Box 31.5 and should be used to ensure patients are directly down appropriate emergency pathways.

COMMON DISORDERS OF THE EYE

Refractive errors

The eye projects a sharp and focused image on to the retina. Refractive errors refer to any abnormality in the focusing mechanism of the eye and not to any opacity in the system, such as a corneal or retinal scar.

The refraction of light in emmetropic (normal), myopic (short-sighted; negative lenses will correct), and hypermetropic (long-sighted; positive lenses will correct) eyes is shown in Fig. 31.12.

Astigmatism is a refractive error of the eye in which there is a different degree of refraction in the different meridians of curvature. It may be myopic in one plane and hypermetropic or emmetropic in the other plane. In this situation, the front surface of the eye is shaped more like a rugby ball than a football.

Presbyopia is the term used to describe the normal ageing of the lens, which leads to a change in the refractive state of the eye. As the lens ages, it becomes less able to alter its curvature and this causes difficulty with near vision, especially reading.

Management

Errors of refraction can be corrected by using spectacles or contact lenses. The latter often result in better-quality vision but carry the risk of infection. They may be the only option in some refractive states such as keratoconus, a degenerative disorder of the eye in which structural changes within the cornea cause it to thin and to take on a more conical shape than its normal gradual curve. A number of surgical techniques can correct these errors of refraction, with varying degrees of accuracy. Phakic intraocular lenses may be used to treat high degrees of myopia but the most popular method remains the excimer laser to re-profile the corneal curvature (using PRK, LASIK, and LASEK techniques). The laser either removes corneal tissue centrally to flatten the cornea in myopia or it removes tissue from the peripheral cornea to steepen it in hypermetropia.

Disorders of the lids

The lids afford protection to the eyes and help to distribute the tear film over the front surface of the globe. Excess tears are drained via the puncta and lacrimal system to the nose (Fig. 31.13). Malposition of the lids, factors that affect blinking and lacrimal drainage can all cause problems.

Entropion

The lid margin rolls inwards so that the lashes are against the globe (Fig. 31.14A). The lashes act as a foreign body and cause irritation, leading to a red eye that can mimic conjunctivitis. Occasionally, the constant rubbing of lashes against the cornea causes an abrasion. The most common cause is ageing and surgery is usually required.

Box 31.4 Causes of loss of vision

Painless loss of vision

- Cataract
- Open-angle glaucoma
- Retinal detachment
- Central retinal vein occlusion
- Central retinal artery occlusion
- Diabetic retinopathy
- Vitreous haemorrhage
- Posterior uveitis
- Age-related macular degeneration
- Optic nerve compression
- Cerebral vascular disease

Painful loss of vision

- Acute angle-closure glaucoma
- Giant cell arteritis
- Optic neuritis
- Uveitis
- Scleritis
- Keratitis
- Shingles
- Orbital cellulitis
- Trauma

Ectropion

The lid margin rolls outwards and is not apposed to the globe. As a result, the lacrimal punctum is not in the correct anatomical position to drain tears and patients usually complain of a watery eye. Underlying factors include age, VIIth nerve palsy, and cicatricial skin conditions. Surgery is usually required.

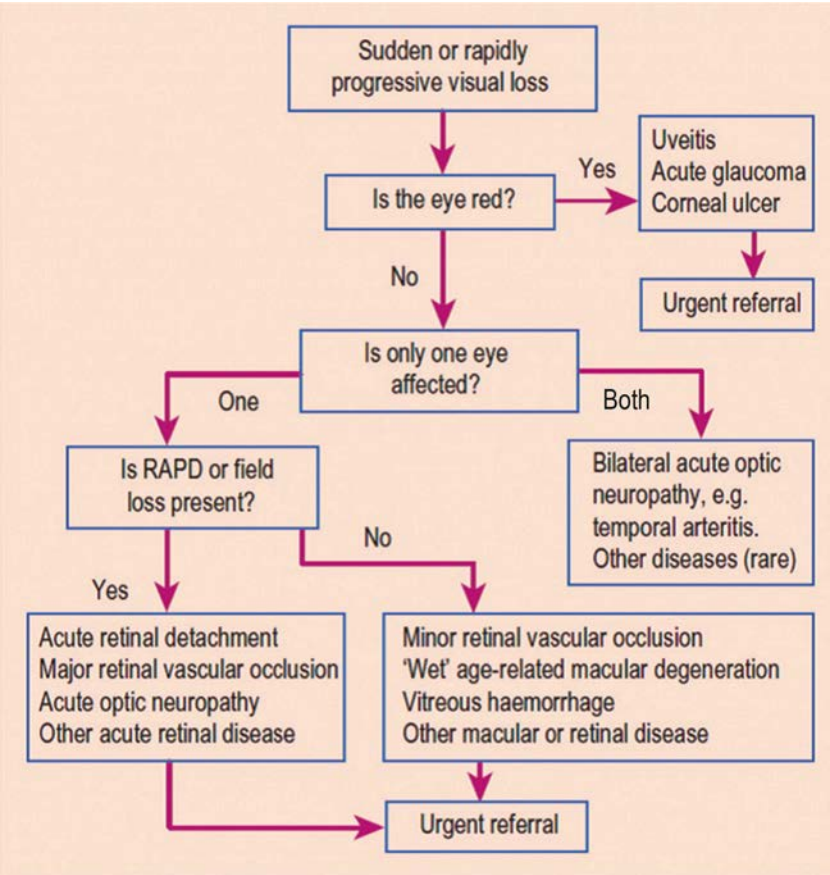
Dacryocystitis

Patients who have inflammation of the lacrimal sac usually present with a painful lump at the side of the nose adjacent to the lower lid (see Fig. 31.14B). This should be treated with oral broad-spectrum antibiotics such as a cephalosporin, and patients should be watched carefully for signs of cellulitis. All patients should be referred to the ophthalmologist, as some have an underlying mucocele or dilated sac, and will require surgery.

Blepharitis

This is an extremely common condition in which inflammation of the lid margins may involve the lashes and lash follicles (Fig. 31.15A), resulting in styes, or inflammation and blockage of meibomian glands (see Fig. 31.15B) leading to chalazion (see Fig. 31.15C). Common underlying causes of blepharitis include meibomian

Box 31.5 Initial history and examination in sudden loss of vision



RAPD, Relative afferent papillary defect.
(After Pane A, Simcock P. Practical Ophthalmology. *Edinburgh: Churchill Livingstone; 2005.)*

gland dysfunction, seborrhoea, and *Staphylococcus aureus* infection. Patients can be asymptomatic or complain of itchy, burning eyes because of tear film instability resulting from meibomian gland dysfunction. *S. aureus* is frequently responsible for chronic blepharoconjunctivitis and some patients may develop keratitis in the cornea (Fig. 31.16).

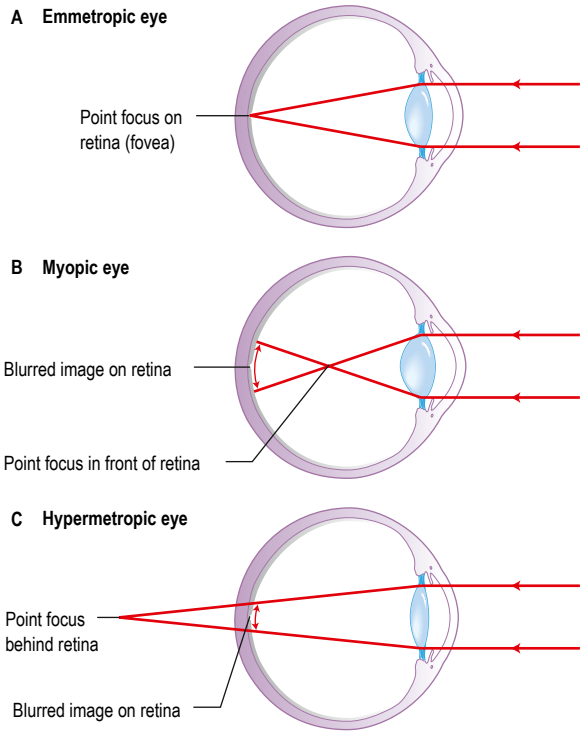


Fig. 31.12 Refraction. **(A)** Emmetropic (normal). **(B)** Myopic (short-sighted). **(C)** Hypermetropic (long-sighted).

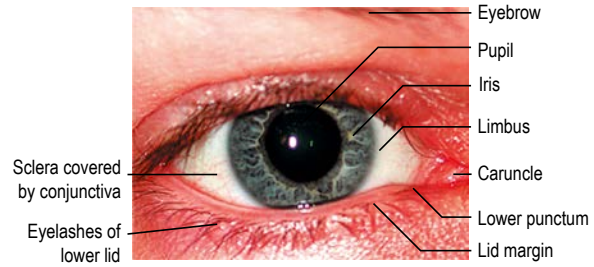

Fig. 31.13 The right eye.

Management

Lid hygiene is the mainstay of treatment for blepharitis, as it helps to reduce the bacterial load and unblock meibomian glands. A short course of topical chloramphenicol or fusidic acid is useful in chronic cases, but in severe cases or cases where acne rosacea is suspected, oral doxycycline is used. Some patients are left with a lump once the acute inflammatory phase has subsided. Most of these patients find the lump, or chalazion, cosmetically unacceptable and require incision and curettage. People with keratitis should be referred to the ophthalmologist for topical steroids.

Conjunctivitis

The most common cause of a red eye, inflammation of the conjunctiva can arise from a number of causes, viral, bacterial, and allergic being the most frequently encountered. Common features in all types include soreness, redness, and discharge; in general, the visual acuity is good. History should include the speed of onset of the inflammation, the colour and consistency of the discharge, whether the eye is itchy, and if there has been a recent history of a cold or sore throat. The differential diagnosis of conjunctivitis is shown in Box 31.6.

Bacterial conjunctivitis

Bacterial conjunctivitis is uncommon, making up 5% of all cases of conjunctivitis. In the vast majority of patients, it causes a sore or gritty eye in the presence of good vision. Bacterial conjunctivitis is invariably bilateral and should be suspected when conjunctival inflammation is associated with a purulent discharge.

Gonococcal conjunctivitis

This should be suspected when the onset of symptoms is rapid, the discharge is copious, and ocular inflammation includes chemosis (conjunctival oedema) and lid oedema. There may be a palpable pre-auricular node.

Less acute or subacute purulent conjunctivitis with moderate discharge can be attributed to organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Chronic conjunctivitis is usually associated with mild conjunctival injection and scant purulent discharge. Common organisms include *S. aureus* and *Moraxella lacunata*.

Management

Prompt treatment with oral and topical penicillin is given in gonococcal conjunctivitis to ensure a reduced rate of corneal perforation. A Gram-stain of the conjunctival swab can quickly confirm the

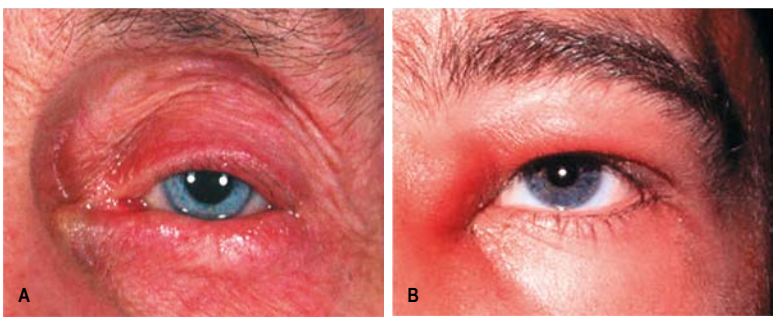

Fig. 31.14 Disorders of the eyelid. **(A)** Lid entropion. The lower lid appears inverted. **(B)** Acute dacryocystitis, showing a lump on the side of the nose.

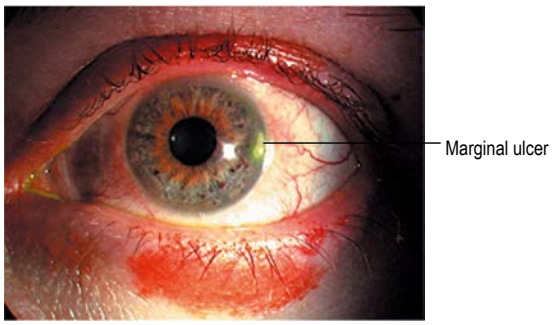

Fig. 31.16 Marginal keratitis.

presence of diplococci. Gonococcal conjunctivitis is a notifiable disease in the UK. Empirical treatment for both subacute and chronic conjunctivitis involves a topical broad-spectrum antibiotic, such as chloramphenicol. Swabs should be taken if these cases do not respond to this initial treatment. Antibiotic resistance is increasing.

Chlamydial conjunctivitis

Chlamydia trachomatis (see Chapter 43) in high-income countries causes a sexually transmitted infection that is most prevalent in sexually active adolescents and young adults. Direct or indirect contact with genital secretions is the usual route of infections but shared eye cosmetics can also be involved.

The onset of symptoms is slow, and patients may complain of mild discomfort for weeks. In these cases, the red eye is associated with a scanty mucopurulent discharge and a palpable pre-auricular lymph node. In chronic cases, it is not unusual to see superior corneal vascularization. Conjunctival swabs should be taken and a nucleic acid amplification test (NAAT; see Chapter 43) performed prior to commencement of treatment.

Management

Topical erythromycin twice daily is commenced and patients referred to the sexual health clinic.

Trachoma

This is a major cause of blindness worldwide. Clinical features are described in **Box 31.7**.

Viral conjunctivitis

Adenoviral conjunctivitis

This is highly contagious and can cause epidemics in communities. Transmission is through direct or indirect contact with infected individuals. The onset of symptoms may be preceded by a cold or influenza-like symptoms. Inflammation is commonly associated with chemosis, lid oedema, and a palpable pre-auricular lymph node. Some patients develop a membrane on the tarsal conjunctiva (**Fig. 31.17**) and haemorrhage on the bulbar conjunctiva. Viral conjunctivitis can cause deterioration in visual acuity owing to corneal involvement (focal areas of inflammation). In 50% of these patients, the conjunctivitis is unilateral.

The condition is largely self-limiting in the majority of cases. Lubricants, together with a cold compress, can be a soothing element of ***management*** for patients. Adhering to strict hygiene and keeping towels separate from those of the rest of the household go a long way towards reducing the spread of the infection. In people with corneal involvement or intense conjunctival inflammation, topical steroids are indicated.

Herpes simplex conjunctivitis

Primary ocular herpes simplex conjunctivitis is typically unilateral. It usually causes a palpable pre-auricular lymph node, and cutaneous vesicles develop on the eyelids and the skin around the eyes in the majority. Over 50% of these patients develop a dendritic corneal ulcer (**Fig. 31.18**). The organism responsible for this condition is the herpes simplex virus (HSV), usually HSV-1, although HSV-2 can give rise to ocular infection.

Primary ocular HSV infection is self-limiting but most clinicians choose ***treatment*** with topical aciclovir in order to limit the risk of corneal epithelial involvement.

Molluscum contagiosum conjunctivitis

This is typically unilateral; it produces a red eye that generally goes unrecognized and comes to the forefront because patients fail to improve and the cornea starts to become involved. On close inspection, pearly, umbilicated nodules, filled with the DNA poxvirus, can be seen on the lid margin.

Management includes curetting the central portion of the lesion, freezing the centre, or completely excising the lesion. If the corneal involvement is severe or the eye is very inflamed, a short course of topical steroids, such as prednisolone 0.5% or dexamethasone 0.1%, is helpful.

Phthiriasis palpebrarum

Phthiriasis palpebrarum (**Fig. 31.19**) is an eyelid infestation caused by *Phthirus pubis*, or the crab louse. Infestation of the cilia and eyelid is rare. It leads to blepharitis with marked conjunctival inflammation, pre-auricular lymphadenopathy and, rarely, secondary infection at the site of louse bite.

Management

Mechanical removal of the lice with fine forceps, physostigmine 1.25%, and pilocarpine gel 4% are all effective treatments.

Box 31.6 Conjunctivitis

Chlamydial	Watery	+ve	+ve	Genitourinary discharge
Allergic	Stringy	–ve	+ve	Itchiness

Box 31.7 Trachoma

- A very common cause of blindness worldwide (see Chapter 42)
- Found mainly in the tropics and the Middle East
- Caused by *Chlamydia trachomatis* but not usually sexually transmitted
- Chronic conjunctival inflammation causes progressive scarring, trichiasis, entropion, and subsequent corneal scarring
- The result may be severe visual impairment or blindness from corneal opacification or ulceration

Allergic conjunctivitis

There are five main types of allergic conjunctivitis: seasonal, perennial, vernal, atopic, and giant papillary. The last three are difficult to treat; they are chronic and can be sight-threatening, so should be referred to an ophthalmologist.

Seasonal/perennial conjunctivitis

Seasonal allergic conjunctivitis and perennial conjunctivitis, affecting 20% of the general population in the UK, are allergic reactions to grass and tree pollen and fungal spores. Seasonal allergic conjunctivitis occurs mainly in spring and summer. Perennial allergic conjunctivitis occurs all year round but peaks in the autumn; causes include allergens, such as house dust mites.

The main symptoms include itching, redness, soreness, watering, and a stringy discharge. Occasionally, the conjunctiva may become so hyperaemic that chemosis results. This is usually associated with swollen lids.

Lowering the allergen load (reducing dust) is helpful. Medical ***treatment*** includes the use of antihistamine drops such as azelastine and emedastine, together with topical mast-cell-stabilizing agents such as sodium cromoglicate and nedocromil. Olopatadine (twice daily) has dual action and is very effective. Corticosteroid drops should be avoided. Oral antihistamines and cold compresses help the itching.

Corneal disorders

Keratitis

This is a general term used to describe corneal inflammation. Common causes include HSV, contact lens-associated infection, and blepharitis. Symptoms include the sensation of a foreign body or pain (depending on the size and depth of the ulcer), photophobia, and lacrimation. Vision is reduced if the ulcer affects the visual axis.

Herpes simplex keratitis

Corneal epithelial cells infected with the virus eventually undergo lysis and form an ulcer, which is typically dendritic in shape (see Fig. 31.18). The ulcer stains with fluorescein and can be observed easily with a blue light. Topical immunosuppression, such as with steroid drops, or systemic immunosuppression, such as in AIDS, can lead to the centrifugal spread of the virus, such that the ulcer increases in area and is referred to as a geographic ulcer. Recurrent attacks of HSV keratitis can be triggered by ultraviolet light, stress, and menstruation. All these factors are responsible for activating the virus, which normally lies dormant in the ganglion of the Vth nerve.

Treatment consists of aciclovir ointment five times a day for 2 weeks; this is usually very effective.

Contact lens-related keratitis

A small number of contact lens wearers develop infective corneal ulcers, which are potentially sight-threatening (Fig. 31.20). The organisms usually responsible include Gram-positive and Gram-negative bacteria. Patients should be referred to an ophthalmologist for scraping of the ulcer and commencement of antibiotic treatment.

Keratoconus

Keratoconus is an eye condition in which the normally round, dome-shaped cornea progressively thins and causes a cone-shaped bulge to develop. Aetiology is uncertain but genetic factors play a role, and the condition is more common in people with allergic diseases such as asthma, in Down's syndrome and in some disorders of collagen such as Marfan's disease. Keratoconus affects up to 1 in 1000 people and is more common in individuals of Asian heritage. It is usually diagnosed in teenagers and young people.

Management

In the early stages, spectacles or soft contact lenses may be used to correct vision. As the cornea becomes thinner and steeper, rigid gas-permeable contact lenses may be necessary.

Corneal cross-linking is a new treatment that can stop keratoconus becoming worse. It is effective in more than 9 out of 10 patients, with a single 30-minute day-case procedure, but is only suitable when the corneal shape is continuing to deteriorate. In very advanced cases, where contact lenses fail to improve vision, a corneal transplant may be needed.

Corneal dystrophy

Corneal dystrophies may be classified anatomically as comprising:

- epithelial and subepithelial dystrophies
- epithelial–stromal *TGFBI* corneal dystrophies
- stromal dystrophies
- endothelial dystrophies.

The most common endothelial dystrophy, Fuchs' corneal dystrophy, is a genetically associated degenerative disorder leading to corneal oedema and vision loss. The gene involved is *TCF4*. The condition affects both eyes; it is more common in females and is of gradual onset, leading to blindness in the 40 to 60 age group. There is an accumulation of deposits (guttae) in the cornea with thickening of Descemet's membrane. Treatment is by corneal transplantation.

Corneal transplantation

A corneal transplant, often described as a graft or keratoplasty, is an operation to remove part or all of a damaged cornea and replace it with donor tissue. The type of keratoplasty depends on what part of the cornea is damaged:

- Penetrating keratoplasty—this is a full-thickness transplant, often used in patients with significant keratoconus or trauma.

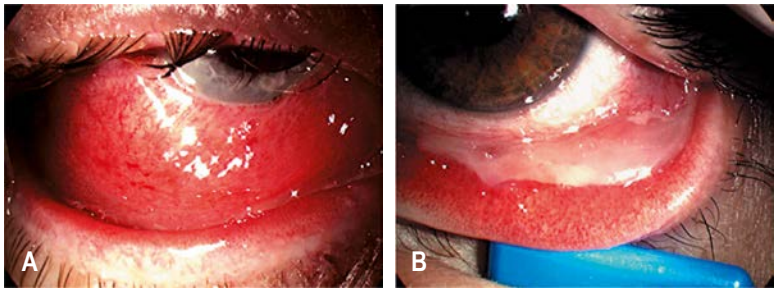

Fig. 31.17 Viral conjunctivitis. **(A)** Conjunctival chemosis. **(B)** Pseudomembrane on lower lid.

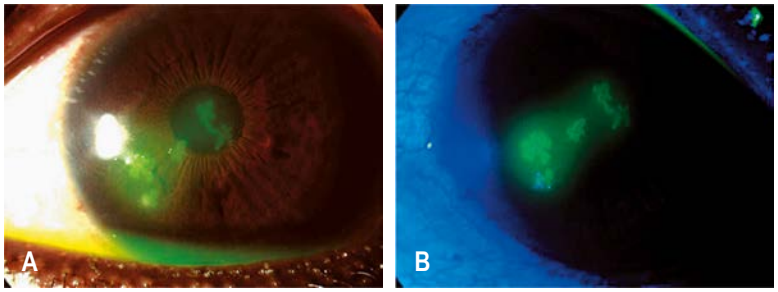

Fig. 31.18 Dendritic ulcers on the cornea. **(A)** Stained with fluorescein. **(B)** Stained with fluorescein and viewed with blue light.

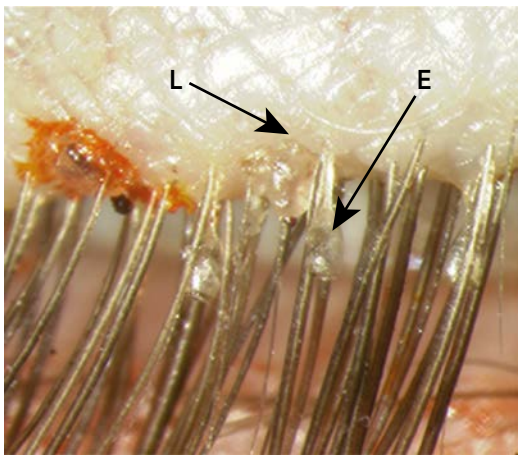

Fig. 31.19 Phthiriasis palpebrarum. The lice *(L)* and the nits (eggs) can be seen on the lid margins. *E,* Empty egg.

- Deep anterior lamellar keratoplasty (DALK)—this replaces or reshapes the outer (front) and middle layers of the cornea.
- Endothelial keratoplasty—this replaces the deeper (back) layers of the cornea.

Cataracts

Cataract (Fig. 31.21) is by far the most common cause of preventable blindness in the world, having an effective surgical treatment.

Aetiology

Age-related opacification of the lens (cataract) is the commonest cause of visual impairment, with 30% of people over 65 years having visual acuities below that required for driving (Snellen acuity less than 6/12). The common causes of cataracts are summarized in Box 31.8.

In young patients, familial or congenital causes should be excluded. Any history of ocular inflammation is noted.

Clinical features

Gradual painless deterioration of vision is the most common symptom. Other symptoms are dependent on the type of cataract: for example, a posterior capsular type would lead to glare and problems with night driving. Early changes in the lens are correctable by spectacles but eventually the opacification needs surgical intervention.

Investigations

Blood glucose, serum calcium, and liver biochemistry should be measured to diagnose metabolic disorders.

Management

Small-incision extracapsular or phacoemulsification cataract extraction with the insertion of an intraocular lens is the treatment of choice (see Fig. 31.20C). Recent advances have enabled surgeons to perform multiple steps in the surgical process with the excimer laser to enhance visual outcomes. Lens technology has also improved and toric lenses are available to treat astigmatism, and multifocal or accommodative lenses to overcome intraocular lens-induced presbyopia.

Glaucoma

Glaucoma is due to increased pressure inside the eye, which is sufficiently elevated to cause optic nerve damage and result in visual field defects, with loss of sight (Fig. 31.22). Normal IOP is 10 to 21 mmHg. Some types of glaucoma can result in an IOP exceeding 70 mmHg. Glaucoma is the second most common cause of blindness worldwide.

Primary open-angle glaucoma

Primary open-angle glaucoma (POAG) is the most common form of glaucoma. High IOPs result from reduced outflow of aqueous humour through the trabecular meshwork (Fig. 31.23A). Common risk factors include age (0.02% of 40 year olds vs. 10% of 80 year olds),

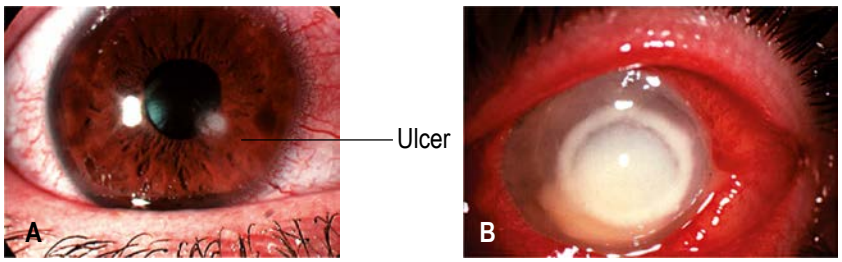

Fig. 31.20 Contact lens-related keratitis. **(A)** Corneal ulcer. **(B)** Severe keratitis with a corneal abscess and a hypopyon.

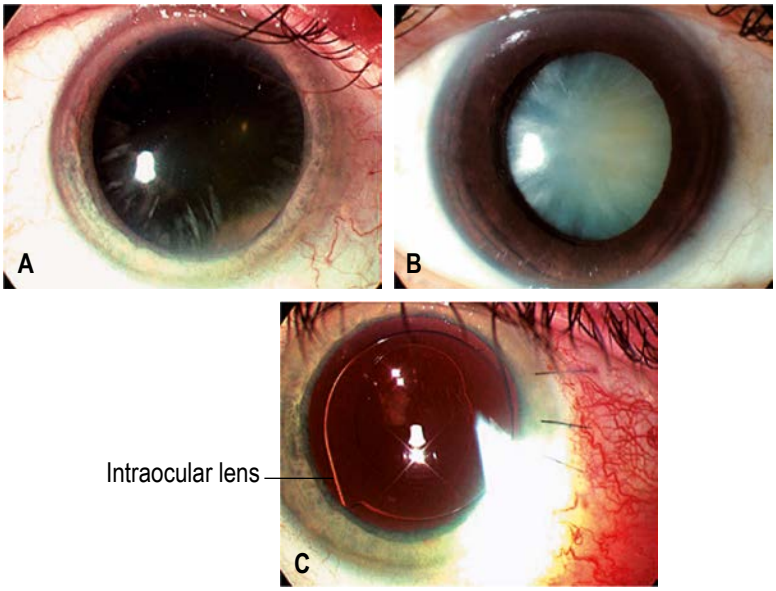

Fig. 31.21 Cataracts. **(A)** Early cataract. **(B)** White mature cataract. **(C)** Artificial intraocular lens following phacoemulsification.

race (black African patients are at five times greater risk than white patients), positive family history, and myopia.

Clinical features

POAG causes a gradual, insidious, painless loss of peripheral visual field, causing loss of vision. It is initially asymptomatic and the central vision remains good until the end-stage of the disease. Usually, glaucoma is identified during a routine ophthalmic examination. Diagnosis is only made if the IOP is measured. The optic disc is inspected and shows an enlarged cup with a thin neuroretinal rim. Visual fields are assessed and show a normal blind spot with scotomas.

Management

Treatment aims to reduce the IOP, either by reducing aqueous production or by increasing aqueous drainage:

- ***Beta-blockers***, such as timolol, carteolol, and levobunolol, reduce aqueous production and are the most commonly prescribed topical agents.
- ***Prostaglandin analogues***, such as latanoprost, bimatoprost, and travoprost, increase aqueous outflow and are also used (alone or in combination with beta-blockers) for POAG, as they can reduce IOP by 30%.
- ***Carbonic anhydrase inhibitors***, such as dorzolamide and acetazolamide, reduce aqueous production and are available in

topical preparations. Acetazolamide is also available orally and, in this form, is the most potent drug for reducing IOP.

- ***Selective laser trabeculoplasty (SLT)*** is a form of laser surgery that can lower the IOP by about 30% when used as initial therapy. It is useful when eye-drop medications are not lowering the eye pressure enough or are causing significant side-effects. It may sometimes be used as initial treatment in glaucoma, although effects commonly last 1 to 5 years only.
- ***Surgical intervention*, such as trabeculectomy**, is designed to bypass the trabecular meshwork and create an alternative passage for aqueous drainage. This procedure has been largely superseded by the use of tube shunt surgery. More recent advances include minimally invasive glaucoma surgery, which involves the use of microstents to bypass the trabecular meshwork.

Acute angle-closure glaucoma

Acute angle-closure glaucoma (AACG) is an ophthalmic emergency. There is a sudden rise in IOP to levels over 50 mmHg. This occurs due to reduced aqueous drainage when the ageing lens pushes the iris forwards against the trabecular meshwork (see Fig. 31.23B). People most at risk of developing AACG are those with shallow anterior chambers, including women and hypermetropes. The attack is more likely to occur under reduced light conditions when the pupil is dilated.

Clinical features

AACG causes sudden onset of a red, painful eye and blurred vision. Patients become unwell, with nausea and vomiting, and complain of headache and severe ocular pain. The eye is injected and tender, and feels hard. The cornea is hazy and the pupil is semi-dilated (Fig. 31.24). Box 31.3 shows the differential diagnosis of the acute red eye. Box 31.1 shows features that require ***urgent referral*** to an ophthalmologist.

Management

Prompt treatment is required to preserve sight and includes:

- i.v. acetazolamide 500 mg (provided there are no contraindications) to reduce IOP, *and*
- instillation of pilocarpine 4% drops to constrict the pupil to improve aqueous outflow and prevent iris adhesion to the trabecular meshwork.

Other topical drops, such as beta-blockers and prostaglandin analogues, can also be instilled if available, provided there are no contraindications. Analgesia and antiemetics are given as required.

Patients must be referred to an ophthalmologist immediately so that reduction in IOP can be monitored and other agents, such as oral glycerol or i.v. mannitol, can be administered to non-responding patients. Definitive treatment involves making a hole in the periphery of the iris of both eyes either by laser or by surgical means.

Uveitis

Uveitis is inflammation of the uveal tract, which includes the iris, ciliary body, and choroid. It is classified according to the part of the uveal tract that the inflammation affects:

- ***Anterior uveitis*** is inflammation that affects the anterior part of the uveal tract. This can include the iris (iritis), or both the iris and the ciliary body (iridocyclitis). It is the most common type of uveitis.
- ***Intermediate uveitis*** is inflammation that affects the middle part of the uveal tract or eye, mainly the vitreous. It can also affect the underlying retina.
- ***Posterior uveitis*** is inflammation that affects the posterior part of the eye. It can affect the choroid, optic nerve head, and the retina (or any combination of these structures). It includes chorioretinitis, retinitis, and neuroretinitis.

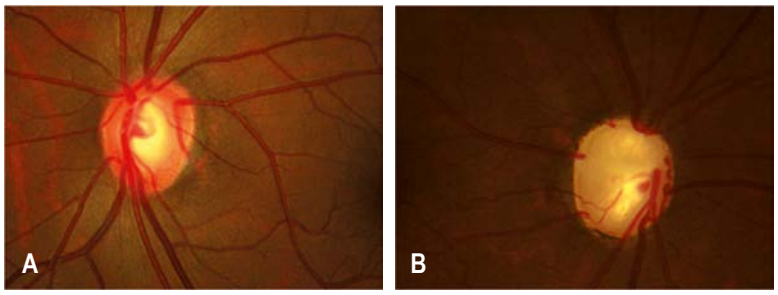

Fig. 31.22 The optic disc. **(A)** Normal optic disc. **(B)** Glaucomatous optic disc. The central cup is enlarged and deepened.

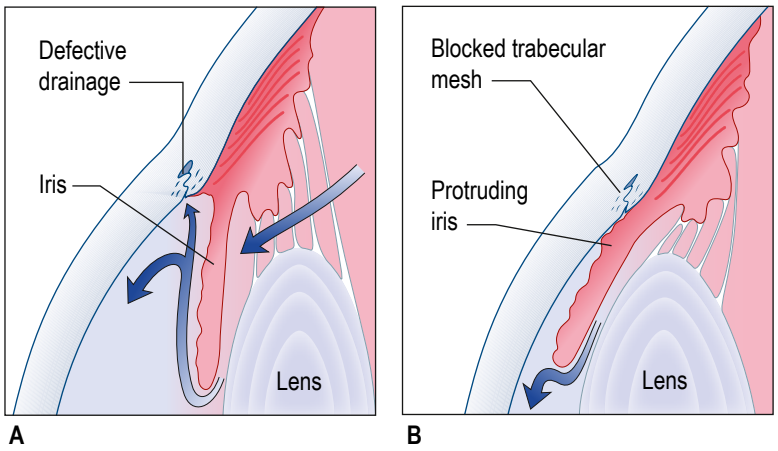

Fig. 31.23 Glaucoma. **(A)** Primary open-angle glaucoma. **(B)** Angle-closure glaucoma.

- ***Panuveitis*** is inflammation affecting the whole of the uveal tract.

The most common symptoms of uveitis are blurred vision, pain, redness, photophobia, and floaters. Each symptom is determined by the location of the inflammation, such that photophobia and pain are common features of iritis while floaters are commonly seen with posterior uveitis.

Anterior uveitis (iritis)

The classic presentation entails a triad of eye symptoms: redness, pain, and photophobia. Vision can be normal or blurred, depending on the degree of inflammation. The eye can be generally red or the injection can be localized to the limbus. The anterior chamber shows features consistent with inflammation, including cells, keratic precipitates on the corneal endothelium, fibrin or hypopyon (pus), and the pupil may have adhered to the lens (posterior synechiae) (Fig. 31.25). The IOP may be normal or raised, either due to cells clogging up the trabecular meshwork, or due to posterior synechiae causing aqueous humour to build up behind the iris and force the iris against the trabecular meshwork and so reduce aqueous drainage.

Management

This consists of reducing inflammation with the use of topical steroids such as dexamethasone 0.1% and dilating the pupil with cyclopentolate 1% to prevent formation of posterior synechiae. Dilation also allows fundoscopy to exclude posterior segment involvement. If the IOP is raised, this is treated with topical beta-blockers, prostaglandin analogues, or oral or i.v. acetazolamide. Referral should be made to the ophthalmologist.

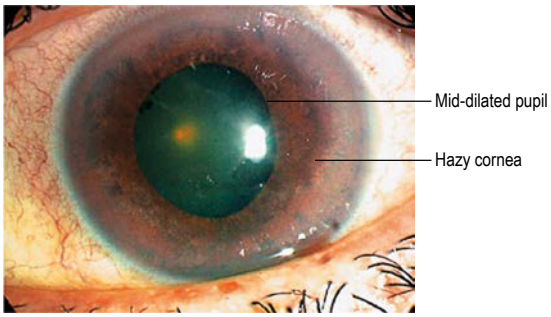

Fig. 31.24 Acute angle-closure glaucoma.

Intermediate uveitis

This usually causes painless blurred vision, most commonly associated with floaters. It is unusual to experience photophobia and redness. Both eyes are commonly affected in intermediate uveitis.

Management

This consists of a combination of treatment for anterior and posterior uveitis depending on the degree of anterior and posterior involvement.

Posterior uveitis

This commonly causes painless, blurred vision and can progress to severe visual loss. It is commonly associated with floaters and scotomata, or blind spots in the visual field.

Posterior uveitis is often found with systemic autoimmune diseases or infections; appropriate investigations should be performed and treatment given that is aimed at the cause.

Autoimmune diseases associated with uveitis include rheumatoid arthritis and Behçet's disease, ankylosing spondylitis and positive HLA-B27 (see Chapter 32, 'Ankylosing spondylitis' section), reactive arthritis, sarcoidosis, psoriasis and inflammatory bowel disease (Crohn's disease and ulcerative colitis; see Chapter 22). Infections, a rare cause of uveitis, include herpes simplex, herpes zoster, toxoplasmosis, cytomegalovirus, syphilis, tuberculosis, HIV infection, and Lyme disease. In a number of patients, no cause is found (idiopathic uveitis).

Management

Steroids are commonly given orally, or more locally by injection into or around the eye. If steroid treatment is needed to treat uveitis in the longer term, second-line immunosuppressive drugs, such as mycophenolate mofetil, ciclosporin, or azathioprine, are used. Biological agents, such as rituximab or adalimumab, are used in more severe cases, alongside treatment of any underlying systemic inflammatory disorder.

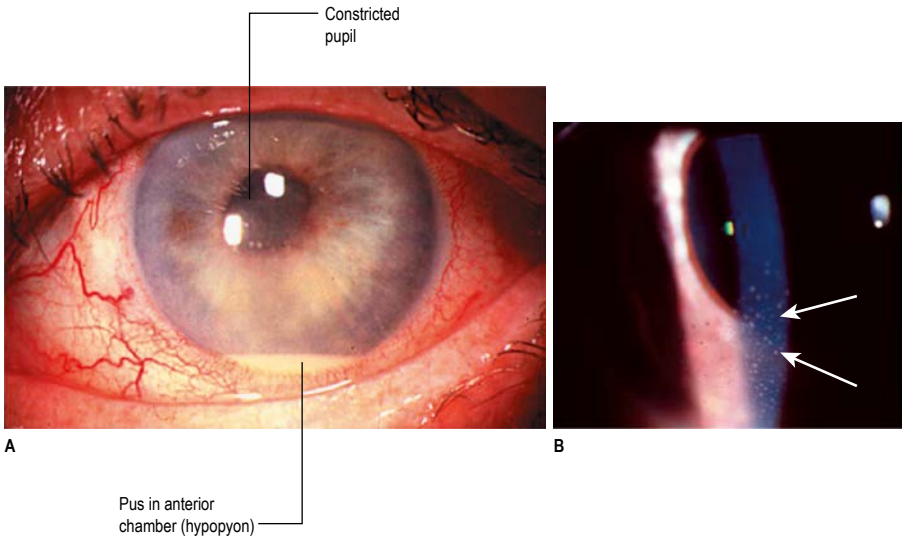

Fig. 31.25 Anterior uveitis. (A) Acute uveitis with hypopyon. **(B)** Keratic precipitates *(arrowed)* on the corneal endothelium.

Disorders of the retina

Central retinal vein occlusion

Central retinal vein occlusion (CRVO) usually leads to profound, sudden, painless loss of vision with thrombosis of the central retinal vein at or posterior to the lamina cribrosa, where the optic nerve exits the globe. The thrombus causes obstruction to the outflow of blood, leading to a rise in intravascular pressure. This results in dilated veins, retinal haemorrhage, cotton wool spots, and abnormal leakage of fluid from vessels, causing retinal oedema (**Fig. 31.26**). In severe cases, an afferent papillary defect (Chapter 28) is present and this suggests the ischaemic variant.

Predisposing factors include increasing age, hypertension and cardiovascular disease, diabetes, glaucoma and, in the younger age group, blood dyscrasias, and vasculitis.

Management

Treatment of any underlying medical condition is mandatory. Referral to an ophthalmologist is essential to monitor the eye, as some patients can develop retinal ischaemia with resulting neovascularization of the retina and iris. Panretinal photocoagulation should be commenced if there is neovascularization, and intravitreal steroid or anti-vascular endothelial growth factor (anti-VEGF) therapy is also used if there is macular oedema. Patients who develop iris neovascularization—rubeosis—where these new blood vessels block the drainage angle are at risk of developing rubeotic glaucoma.

Central retinal artery occlusion

Central retinal artery occlusion (CRAO) results in sudden, painless, severe loss of vision. Some patients may present with transient loss of vision or amaurosis fugax (see Chapter 29). Unrelieved retinal arterial occlusion results in infarction of the inner two-thirds of the retina. The arteries become narrow and the retina becomes opaque and oedematous. A cherry-red spot is seen at the fovea because the choroidal vasculature shows up through the thinnest part of the retina (**Fig. 31.27**). An afferent papillary defect is usually present.

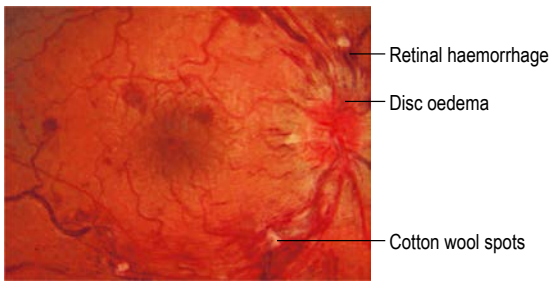

Fig. 31.26 **Central retinal vein occlusion.**

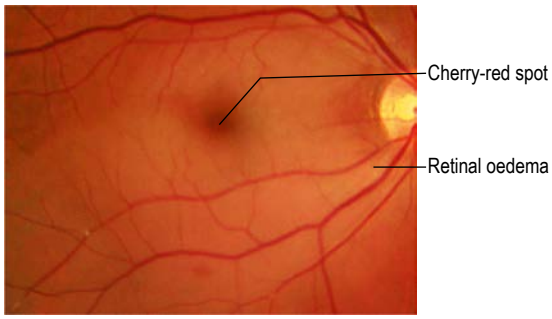

Fig. 31.27 **Central retinal artery occlusion.**

Arteriosclerosis-related thrombosis is the most common cause of CRAO. Emboli from carotid atheroma and diseased heart valves are other causes. Giant cell arteritis (see Chapter 32) must be excluded.

Management

CRAO is an ophthalmic emergency since studies have shown that irreversible retinal damage occurs *within 90 minutes of onset*. Ocular massage and 500 mg i.v. acetazolamide help to reduce ocular pressure and may assist in dislodging the emboli. Breathing into a paper bag allows a build-up of carbon dioxide, which acts as a vasodilator and so helps dislodge the emboli. Other options include making a corneal paracentesis to drain off some aqueous humour, thereby reducing the IOP.

People with CRAO should be referred for urgent investigation under stroke services to determine the aetiology of the emboli or thrombus (Chapter 29). All people with CRAO and amaurosis fugax should be started on oral aspirin if it is not medically contraindicated.

Retinal detachment

This causes a painless, progressive visual field loss. The visual 'shadow' corresponds to the area of detached retina. If the detachment affects the macula, central vision will be lost. Following a tear in the retina, fluid collects in the potential space between the sensory retina and the pigment epithelium (**Fig. 31.28**). Patients usually report a sudden onset of floaters, often associated with flashes of light (photopsia) prior to the detachment. These individuals should be referred to an ophthalmologist for a detailed fundal examination. Surgical treatments including vitrectomy (removal and replacement of vitreous humour) can prevent progressive visual loss.

Retinitis pigmentosa

This is a common chronic, inherited, degenerative disease of the retina, which can be primary or part of a syndrome, and leads to blindness. There is constriction of the peripheral vision, leading to tunnel vision and progressive loss of night vision.

Ophthalmoscopy shows bone spicule deposits and attenuated retinal vessels. Several genes are implicated.

There is no treatment but high-dose vitamin A supplementation may slow progression. Gene therapy is being investigated.

Fig. 31.28 **Retinal tear leading to detachment.**

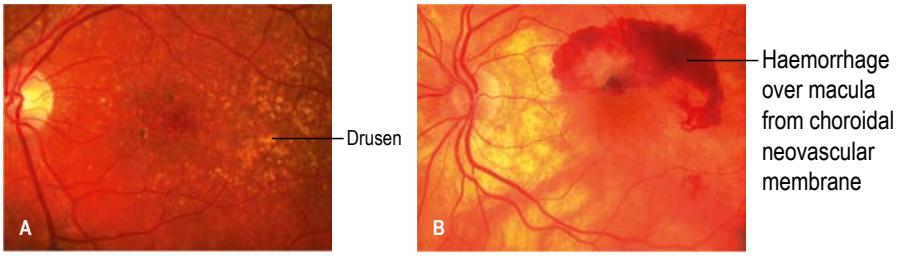

Fig. 31.29 Age-related macular degeneration. **(A)** With deposition of material (drusen) over the macula. **(B)** With choroidal neovascularization.

Age-related macular degeneration

Age-related macular degeneration (AMD) is the most common cause of visual impairment in patients over 50 years in the Western world, and the most common cause of blind registration in this age group. It affects 10% of people over 65 years and 30% over 80 years. Mutations in various genes have been reported: fibulin 5, complement factor H, and the Arg 80 Gly variant of complement C3.

The cause is unknown but suggested risk factors include increasing age, smoking, hypertension, hypercholesterolaemia and ultraviolet exposure.

There are two types:

- ***Non-exudative (dry) macular degeneration*** describes a painless and progressive loss of central vision. With age, lipofuscin deposits (drusen) are found between the retinal pigment epithelium (RPE) and Bruch's membrane (**Fig. 31.29A**; see **Fig. 31.2**). Drusen may be hard or soft, and there may be focal RPE detachment. Not all people with these changes will be affected visually but some develop distortion and blurring of their central vision. Extensive atrophy of RPE can occur (geographic atrophy).
- ***Exudative (wet) AMD*** (10% of cases) occurs with the development of abnormal subfoveal choroidal neovascularization in the region of the macula and causes severe central visual loss (see **Fig. 31.29B**).

Management

People with central distortion or with frank macular pathology should be referred *urgently* to the ophthalmologist for assessment of treatment. Anti-VEGF treatments, such as ranibizumab, aflibercept, and bevacizumab, are given by intravitreal injections with great success in wet AMD. The treatment course should be commenced *as a matter of urgency*, as vision is maintained in up to 95% of patients and improves in approximately one-third. Initial monthly monitoring with optical coherence tomography (OCT) is recommended (**Fig. 31.30**). Laser treatment and photodynamic therapy with verteporfin may also be used where there is extensive neovascularization.

There is no specific treatment for dry AMD. Severe visual loss is possible and low-vision aids, such as magnifying glasses, may help to improve a patient's independence.

The Age-Related Eye Disease Study (AREDS) has shown that vitamin supplementation containing vitamins C and E, β-carotene, zinc, and copper slow the progression of the disease, probably through their antioxidant effects, and may be used in selected cases.

Visual loss

The common causes of blindness are similar across the world (**Box 31.4**). In low- and middle-income countries, trachoma due to *C. trachomatis* (see Chapter 43) is also a major cause, accounting for 10% of global blindness; onchocerciasis (river blindness, due to *Onchocerca volvulus*; see Chapter 42) accounts for blindness in about 1 million people, although this figure is decreasing with community treatment programmes. In leprosy, 70% of patients have ocular involvement, and blindness occurs in 5% to 10% of these. Ocular involvement is common in cerebral malaria (see Chapter 42), although loss of vision is rare.

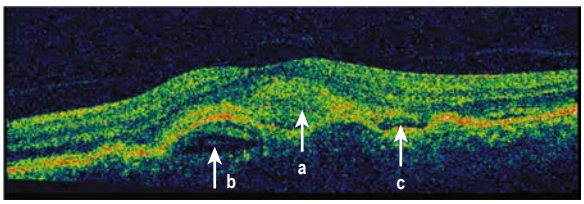

Fig. 31.30 Age-related macular degeneration seen by optical coherence tomography. **(a)** Area of thickened retina. **(b)** Pigment epithelial detachment. **(c)** Subretinal fluid.

HIV infection can produce uveitis but the major problem is severe opportunistic infection of the eye (e.g., with cytomegalovirus) in patients not of effective anti-retroviral treatment whose CD4 count is low.

Vitamin A deficiency and xerophthalmia affect millions each year; the World Health Organization (WHO) classification of xerophthalmia by ocular signs is shown in **Box 25.10**.

The WHO lists the most common causes of blindness across the world as cataract, glaucoma, acute macular degeneration, corneal opacity, diabetic retinopathy, and infections from bacteria or parasites.

CORE SKILLS AND KNOWLEDGE

Musculoskeletal complaints are very common, comprising 25%–30% of consultations in primary care. The majority of patients have soft tissue complaints or osteoarthritis, with inflammatory arthritis and autoimmune rheumatic diseases having a much lower prevalence, of between 0.01% and 1% of the population.

Rheumatology is mainly an outpatient specialty, with care being delivered by multidisciplinary teams including nurse specialists, physiotherapists, and other allied health professionals. Apart from general rheumatology clinics, specialist clinics often exist (sometimes in tertiary referral centres) for patients with inflammatory conditions such as rheumatoid arthritis or systemic lupus erythematosus. Few patients require admission to hospital but many receive day-case infusions of biological disease-modifying drugs.

Key learning outcomes in musculoskeletal disease include:

- Learning to distinguish mechanical from inflammatory problems, and then identifying the number and pattern of joint involvement as well any extra-articular features in patients with inflammatory multisystem disease
- Becoming familiar with the main drug categories of analgesics and medication that alter the immune response
- Learning how to examine joints, and when to order autoantibody tests.

Opportunities for learning include sitting in general and specialist rheumatology clinics, observing musculoskeletal and joint injection lists, talking with and examining patients attending day units for infusions of medication, and attending imaging meetings.

The authors would like to dedicate this chapter to the memory of Dr Michael Shipley, who wrote the Rheumatology section of this textbook for many years and whose voice is still present in many of the sections below. He was a wonderful clinician and mentor and is greatly missed.

CLINICAL SKILLS

Taking a musculoskeletal history

In most rheumatological disorders (Box 32.1), the diagnosis is ***clinical:*** that is, made on the history and examination, and then supported by investigations. Taking a thorough history is therefore crucial, and the main points to consider are:

1. **Who is the patient?**
- ***Age:*** osteoarthritis, polymyalgia rheumatica, and giant cell arteritis present mainly in patients over the age of 50. Autoimmune rheumatic diseases and inflammatory arthritis frequently present in people under 50.
- ***Sex:*** rheumatoid arthritis (RA), Sjögren's syndrome, systemic lupus erythematosus (SLE), and systemic sclerosis are more common in females, whereas gout and ankylosing spondylitis are more common in males.
- ***Ethnicity:*** SLE is more common in people of black African or Caribbean background than in other ethnicities.
- ***Occupation:*** jobs that involve heavy use of one part of the body can lead to soft tissue pain and/or OA; for example, in the low back, hips, and knees of people who do a lot of heavy lifting. Musculoskeletal pain may also affect people's ability to do their job, or care for children or dependents. The effects of these on quality of life should be assessed.

2. **Has something happened to the patient?**
- ***Physical trauma:*** trauma to a particular region of the body may cause pain there and/or in related regions.
- ***Psychosocial stress and depression:*** physical, psychological, and social factors interact to contribute to symptoms. In musculoskeletal disorders, pain may cause distress and poor sleep, which in turn build up muscle tension and worsen the pain (see 'Chronic pain syndromes' section). Acute stressful events, such as bereavement, bullying, abuse, and redundancy, may exacerbate these symptoms.

3. **What are the symptoms?**
- **Pain:**
  - ***Where is it?*** The pattern of joint involvement is a useful clue to the diagnosis (Box 32.2).
  - ***Is it arising from joints, spine, muscles, or bone, with local tenderness?***
  - ***Could it be referred from another site?*** Joint pain is localized but may radiate distally—shoulder to upper arm; hip to thigh and knee.
  - ***Is it constant, intermittent, or episodic?***
  - ***Are there aggravating or precipitating factors?*** Is it made worse by activity and eased by rest (mechanical), or worse after rest (inflammatory)?
  - ***Are there any associated neurological features?*** Numbness, pins and needles, and/or loss of power suggest 'nerve' involvement.
- **Stiffness:**
  - Is it generalized or localized?
  - Does it affect the limb girdles or periphery?
  - Is it worse in the morning and relieved by activity?

  Joint stiffness for more than 30 minutes each morning—think of inflammatory arthritis. Morning spinal stiffness in younger adults—think of axial spondyloarthritis (e.g., ankylosing spondylitis) (see 'Axial spondyloarthritis' section). Shoulder and pelvic girdle stiffness and pain in a patient over 55 years may be polymyalgia rheumatica (see 'Polymyalgia rheumatica' section).
- **Swelling**
  - ***Does it affect one joint or several?*** Look for symmetry or asymmetry, and/or a peripheral or proximal pattern. An acute monoarthritis may be due to trauma, gout, pseudogout, or sepsis (fever or immunosuppression). A polyarthritis is more likely to be due to OA or RA.
  - ***Is it constant or does it come in short-lived or longer episodes?***
  - ***Is there associated inflammation*** (redness and warmth)?
- **Extra-articular symptoms:**
  - Osteoarthritis and soft tissue problems are not usually associated with symptoms outside the joints.
  - Features such as rash, breathlessness, neurological symptoms, or blood disorders suggest that the locomotor problems may be one facet of a more systemic disorder, such as RA, psoriatic arthritis, or SLE.

4. **What medication is the patient taking?**
- ***Could a drug be a cause?*** Diuretics may precipitate gout in men and older women. Steroids can cause avascular necrosis.
- ***Have the symptoms responded to medication?*** A good response to a trial of oral or intramuscular corticosteroid suggests an inflammatory or autoimmune problem.

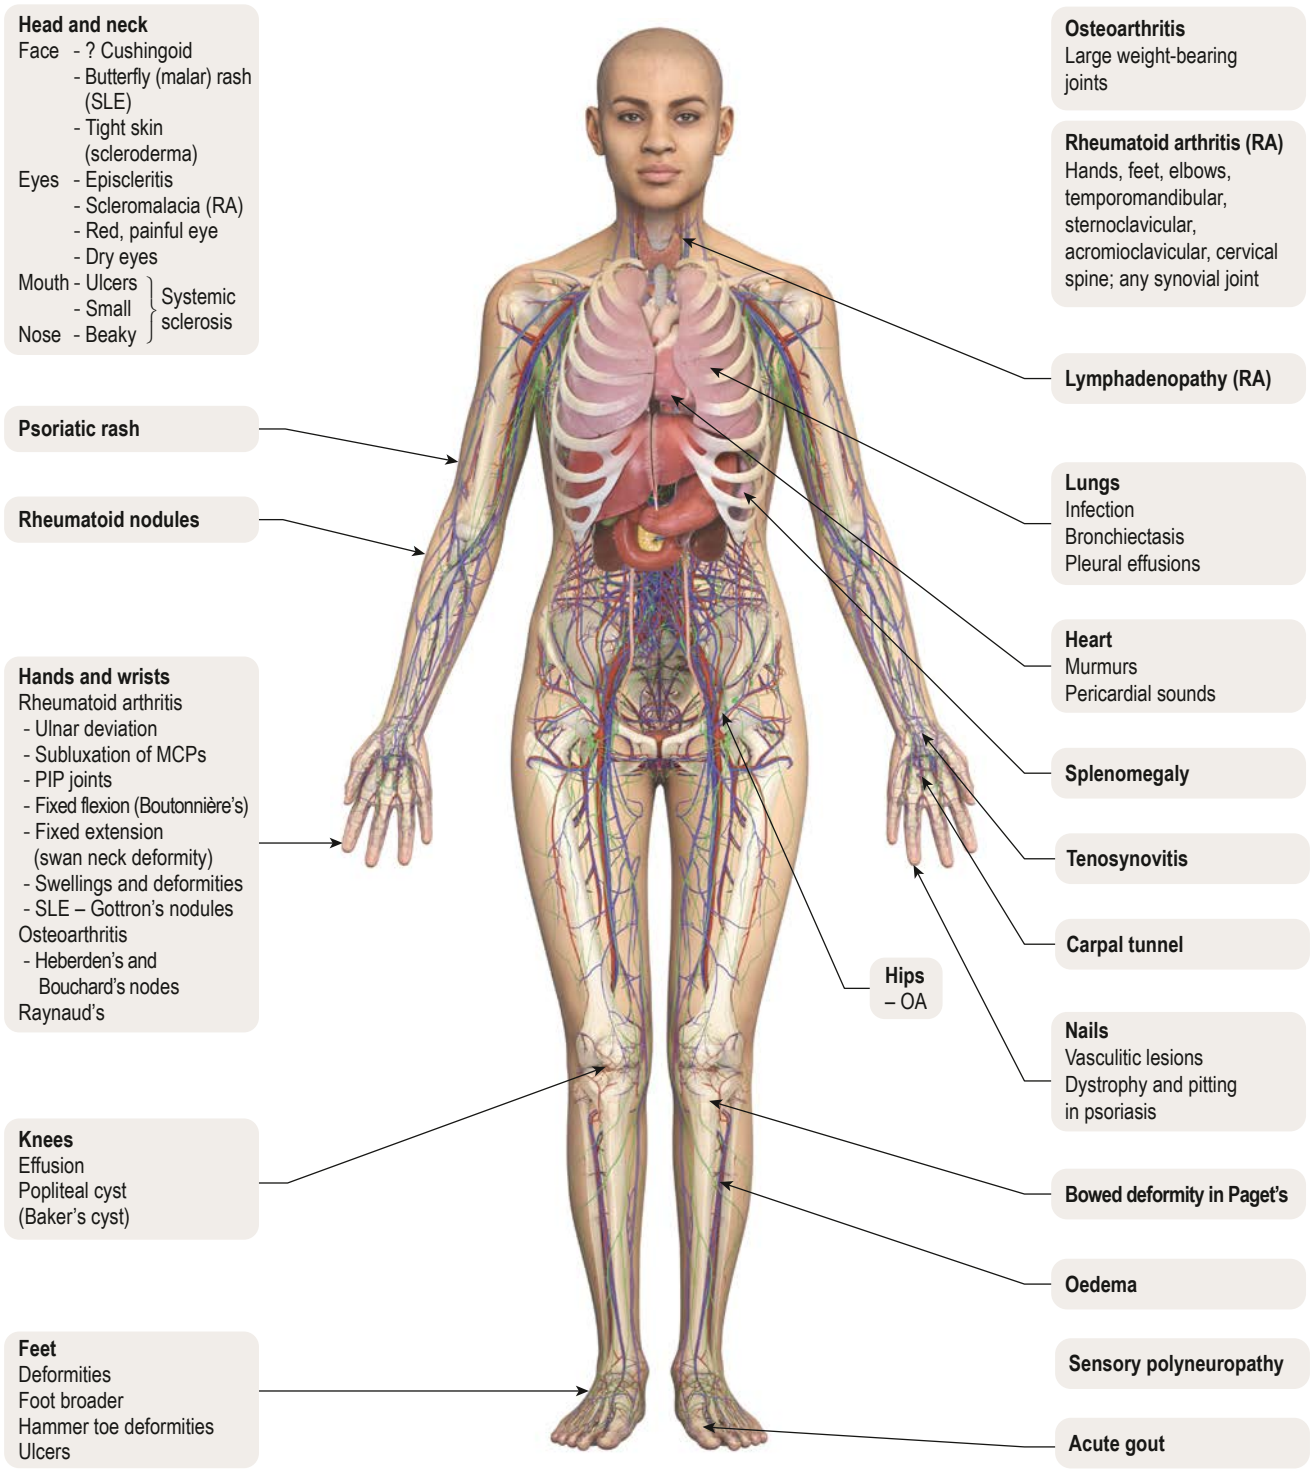
5. **What is the family history?**

i Box 32.1 The 'top 10' rheumatic conditions that students should understand

- Regional musculoskeletal conditions
- Chronic pain syndromes
- Osteoarthritis
- Rheumatoid arthritis
- Spondyloarthropathies
- Crystal arthropathies
- Infection-related arthritis
- Autoimmune rheumatic diseases
- Systemic vasculitides
- Juvenile idiopathic arthritis

? Box 32.2 Distinguishing patterns of rheumatic disease

Regional	Inflammatory	Multisystem
• Localized joint pain • Increased pain with activity • Short-lived stiffness • Distal radiation • Joint swelling • Functional limitation • Localized joint abnormalities on examination	• Widespread joint pain • Reduced pain with activity • Prolonged early morning stiffness • Multiple joint swelling • Functional limitation • Widespread joint abnormalities on examination	• Fever • Fatigue • Rash • Alopecia • Raynaud's phenomenon • Positive systems enquiry • Systems abnormalities on examination



Examination

Always observe patients, looking for disabilities, as they walk into the room and sit down. General and neurological examinations are often necessary, and may reveal some of the signs described in the figure above. Guidelines for rapid examinations of the limbs and spine are shown in **Box 32.3**.

Examining an individual joint involves three stages: looking, feeling, and moving (**Box 32.4**). A screening examination of the locomotor system, known by the acronym GALS (Gait, Arms, Legs, Spine), has been devised. Video demonstrations are available (see 'Further reading').

Further reading

https://www.versusarthritis.org/about-arthritis/healthcare-professionals/training-and-education-resources/clinical-assessment-of-patients-with-musculoskeletal-conditions/the-musculoskeletal-examination-gals/.

Box 32.3 Rapid examinations of the limbs and spine

Upper limbs

- Raise the arms sideways to the ears (abduction). Reach behind the neck and back. Difficulties with these movements indicate a shoulder or rotator cuff problem.
- Hold the arms forwards, with elbows straight and fingers apart, palm up and palm down. Fixed flexion at the elbow indicates an elbow problem. Examine the hands for swelling, wasting, and deformity.
- Place the hands in the 'prayer' position with the elbows apart. Flexion deformities of the fingers may be due to arthritis, flexor tenosynovitis, or skin disease. Painful restriction of the wrist limits the person's ability to move the elbows out with the hands held together.
- Make a tight fist. Difficulty with this indicates a loss of flexion or grip. Grip strength can be measured.

Lower limbs

- Ask the patient to walk a short distance away from and towards you, and to stand still. Look for abnormal posture or stance.
- Ask the patient to stand on each leg. Severe hip disease causes the pelvis on the non-weight-bearing side to sag (positive Trendelenburg test).
- Watch the patient stand and sit, looking for hip and/or knee problems.
- Ask the patient to straighten and flex each knee.
- Ask the patient to place each foot in turn on the opposite knee with the hip externally rotated. This tests for painful restriction of the hip or knee. Abnormal hips or knees must be examined with the patient lying down.
- Move each ankle up and down. Examine the ankle joint and tendons, medial arch, and toes while the patient is standing.

Spine

Stand behind the patient

- Ask the patient to (a) bend forwards to touch the toes with straight knees, (b) extend backwards, (c) flex sideways, and (d) look over each shoulder, flexing and extending and side-flexing the neck. Observe abnormal spinal curves—scoliosis (lateral curve), kyphosis (forward bending), or lordosis (backward bending). A cervical and lumbar lordosis and a thoracic kyphosis are normal. Muscle spasm is worse while standing and bending. Leg length inequality leads to a scoliosis that decreases on sitting or lying (the lengths are measured with the patient lying down).
- Ask the patient to lie supine. Examine any restriction of straight-leg raising (see disc prolapse, below).
- Ask the patient to lie prone. Examine for anterior thigh pain during a femoral stretch test (flexing knee while prone), which indicates a high lumbar disc problem.
- Palpate the spine and buttocks for tender areas.

Box 32.4 Examination of the joint

Look at the appearance of the joint

- Swelling—could be bony, fluid, or synovial
- Deformity:
  - Valgus, where the distal bone is deviated laterally (e.g., knock-knees or genu valgum)
  - Varus, where the distal bone is deviated medially (bow-legs or genu varum)
  - Fixed flexion or hyperextension
- Rash—especially psoriasis
- Muscle wasting—easier to see in large muscles like the quadriceps
- Scars—from surgery or trauma
- Signs of inflammation
- Symmetry:
  - Are the right and left joints (e.g., hips, knees, any other paired joint) the same?
  - If not, which do you think is abnormal?

Feel

- Swelling:
  - Fluid swelling (effusion) usually represents increased synovial fluid in inflammatory arthritis, but can be due to blood or pus
  - Synovial swelling is rubbery or boggy and usually occurs in inflammatory arthritis
  - Bony swelling, such as Heberden's nodes in the fingers, is usually seen in osteoarthritis
- Warmth—a warm joint may be inflamed or infected
- Tenderness—may represent joint inflammation, but many people have chronic tenderness all over the body (e.g., in fibromyalgia)

Move

- Active movement:
  - Is the range full and pain free?
  - Is the movement fluid?
  - In the hands, can the patient perform fine movements?
  - In the legs, can the patient walk properly?
- Compare movements on the right and left sides—are they symmetrical?
- Is there crepitus when the joint is moved?
- If active movement is limited, try passive movement:
  - In a joint problem both will usually be affected.
  - In a muscle or nerve problem, passive movement may remain full.

ANATOMY AND PHYSIOLOGY OF THE NORMAL JOINT

A joint can be defined as a place where two or more bones meet. There are three types of joints: fibrous, fibrocartilaginous, and synovial.

Fibrous and fibrocartilaginous joints

These include the intervertebral discs, the sacroiliac joints, the pubic symphysis, and the costochondral joints. Skull sutures are fibrous joints. Little movement occurs at such joints.

Synovial joints

Synovial joints (Fig. 32.1) include the ball-and-socket joints (e.g., hip) and the hinge joints (e.g., interphalangeal). They are designed to allow movement, which is restricted to a required range, and stability is maintained during use. The load is distributed across the surface, thus preventing damage by overloading or disuse. Each structural component of a synovial joint plays a key functional role, and different components are affected in different disease processes.

Juxta-articular bone

Bone structure and physiology are discussed in Chapter 33. The bone that abuts a joint (juxta-articular bone) is highly vascular and comprises a light framework of mineralized collagen enclosed in a thin coating of tougher, cortical bone. It withstands pressure poorly if the normal intra-articular covering of hyaline cartilage is lost, as in osteoarthritis (OA; see 'Osteoarthritis' section). This process can lead to abnormalities of bone growth and remodelling.

Articular cartilage

The hyaline cartilage lining the bones within a joint is called articular cartilage. It is avascular and derives nourishment from synovial fluid. It is predominantly composed of type II collagen, encoded by

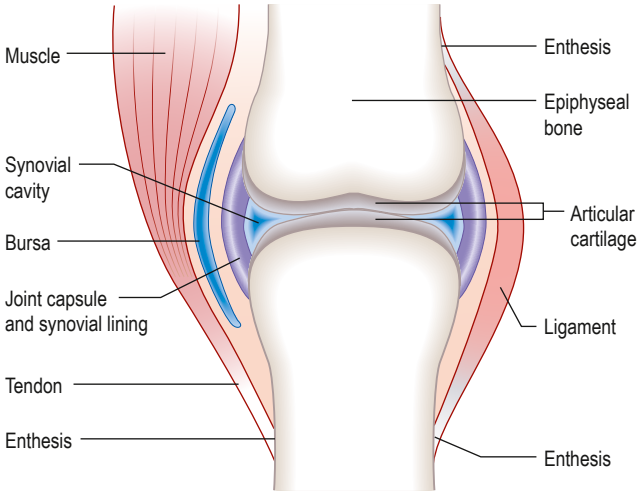


Fig. 32.1 Normal synovial joint.

the *COL2A1* gene, which forms a mesh-like network. Chondrocytes secrete collagen and proteoglycans, and are embedded in the cartilage. Defects in articular cartilage and underlying bone are features of ***osteoarthritis***.

Synovium and synovial fluid

The joint capsule, which is connected to the periosteum, is lined with synovium, which is a few cells thick and vascular. Its surface is smooth, non-adherent, and is permeable to proteins and crystalloids. Synovial fluid is a highly viscous fluid secreted by the synovial cells and has a similar consistency to plasma. Glycoproteins ensure a low coefficient of friction between the cartilaginous surfaces. Tendon sheaths and bursae are also lined by synovium. Inflammation of the synovium is a feature of ***inflammatory arthritis***.

Ligaments and tendons

These structures stabilize joints. Ligaments are variably elastic and this contributes to the stiffness or laxity of joints (see 'Hypermobile Ehlers-Danlos syndrome and hypermobility spectrum disorders' section). Tendons are inelastic and transmit muscle power to bones. The joint capsule is formed by intermeshing tendons and ligaments. The point where a tendon or ligament joins a bone is called an ***enthesis*** and may be the site of inflammation. Whereas most ligaments and tendons run outside the joints, some, like the supraspinatus tendon in the shoulder and the cruciate ligaments in the knee, run through the joint. Inflammation or trauma to these structures can cause severe joint symptoms.

Blood vessels and nerves

The ligaments, periosteum, synovial tissue, and capsule of the joint are richly supplied by blood vessels and nerves. Pain usually derives from inflammation of these sites because the synovial membrane is relatively insensitive.

Skeletal muscle

This tissue consists of bundles of myocytes containing actin and myosin molecules. These molecules interdigitate and form myofibrils, which cause muscle contraction in a similar way to myocardial muscle (see Chapter 17). Bundles of myofibrils (fasciculi) are covered by connective tissue, the perimysium, which merges with the epimysium (covering the muscle) and forms the tendon, which attaches to the bone surface (enthesis).

Though not strictly a component of the joint itself, muscles are so closely related to joints that strain and tension in muscles are commonly interpreted by patients as joint pain. Pain in muscles and ligaments (myofascial pain) is a very common cause of locomotor symptoms. Primary inflammatory disease of muscle (myositis) is far less common.

INVESTIGATION OF RHEUMATIC DISEASE

Investigations are unnecessary in many of the common musculoskeletal problems; the diagnosis is clear from the history and examination findings. Tests help to exclude another condition and to reassure the patient or their primary care physician.

Useful blood screening tests

- Full blood count:
  - ***Haemoglobin.*** Normochromic, normocytic anaemia suggests chronic inflammatory and autoimmune diseases. Hypochromic, microcytic anaemia indicates iron deficiency, sometimes due to non-steroidal anti-inflammatory drug (NSAID)-induced gastrointestinal bleeding.
  - ***White cell count.*** Neutrophilia is seen in bacterial infection (e.g., septic arthritis). It also occurs with corticosteroid treatment. Lymphopenia is found in viral illnesses or SLE. Neutropenia may reflect drug-induced bone marrow suppression. Eosinophilia is seen in eosinophilic granulomatosis with polyangiitis (EGPA) (see Chapter 20).
- ***Platelets.*** Raised platelets occur with any chronic inflammation. Thrombocytopenia is seen in drug-induced bone marrow suppression and may be a feature of SLE.
- ***Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).*** An increase in these reflects inflammation. Plasma viscosity is also raised in inflammatory disease.
- ***Bone and liver biochemistry.*** A raised serum alkaline phosphatase may indicate liver or bone disease. A rise in liver enzymes is often seen with drug-induced toxicity. For other investigations of bone, see Chapter 33.

Other blood and urine tests

- Protein electrophoresis (and/or immunofixation), serum-free light chain testing, and urinary Bence Jones protein—to exclude myeloma as a cause of a raised ESR.
- Serum uric acid—for gout.
- Antistreptolysin O titre—in rheumatic fever.

Serum autoantibody studies

- ***Rheumatoid factors (RFs)*** (see also 'Rheumatoid arthritis' section). RFs are detected by enzyme-linked immunosorbent assay (ELISA). RFs are antibodies (usually immunoglobulin (Ig) M, but also IgG or IgA) against the Fc portion of IgG. They are detected in 70% of people with RA but are not diagnostic. RFs are detected in many autoimmune rheumatic disorders (e.g., SLE), in chronic infections, and in asymptomatic older people (**Box 32.5**).
- ***Anti-citrullinated peptide antibodies (ACPA).*** These antibodies are directed against citrullinated antigens, vimentin, fibrinogen, alpha enolase, and type II collagen. They are measured by an ELISA technique and are present in up to 80% of people with RA. They have a high specificity for RA (90%, with a sensitivity of 60%–80%). They are helpful in early disease when the RF is negative, to distinguish it from acute transient synovitis (see **Box 32.28**). Positivity for RF and/or ACPA is associated with a worse prognosis and an increase in the likelihood of bony erosions in people with RA.

- ***Antinuclear antibodies (ANAs).*** The gold-standard method for ANA detection is indirect immunofluorescence on human epithelial (Hep-2) cells. Different patterns reflect a variety of antigenic specificities that occur with different clinical pictures, for example the anti-centromere pattern seen in samples from patients with limited cutaneous systemic sclerosis and the speckled pattern suggesting antibodies to extractable nuclear antigens (see below). ANA is used as a screening test for SLE and systemic sclerosis—a negative ANA makes either condition highly unlikely—but low titres occur in RA and chronic infections and in normal individuals, especially the elderly (Box 32.6).
- ***Anti-double-stranded DNA (dsDNA) antibodies.*** These are usually detected by a precipitation test (Farr assay), ELISA, or an immunofluorescent test using *Crithidia luciliae* (which contains dsDNA). Raised anti-dsDNA is highly specific for SLE; the levels usually rise and fall in parallel with disease activity so can be used to monitor the level of treatment required.
- ***Anti-extractable nuclear antigen (ENA) antibodies*** (see Box 32.38). These produce a speckled ANA fluorescent pattern, and can be identified by ELISA. The most commonly measured ENAs are:
  - ***anti-Ro and anti-La***, which occur in Sjögren's syndrome and SLE
  - ***anti-Sm***, which is highly specific for SLE
  - ***anti-Jo-1***, which is the most common of the anti-tRNA synthetase enzymes that occur in some people with dermatomyositis or polymyositis
  - ***anti-topoisomerase I (anti–Scl-70)***, which is specific for systemic sclerosis
  - ***anti-RNA polymerase I and III***, which occur in systemic sclerosis and are associated with pulmonary fibrosis.
- ***Anti-neutrophil cytoplasmic antibodies (ANCAs)*** (see 'Small-vessel vasculitis' section). These are predominantly IgG autoantibodies directed against the primary granules of neutrophil and macrophage lysosomes. They are strongly associated with small-vessel vasculitis. Two major clinically relevant ANCA patterns are recognized on ***immunofluorescence:***
  - ***proteinase 3 (PR3-ANCA)***, also called cytoplasmic or cANCA, producing a granular immunofluorescence and seen in granulomatosis with polyangiitis (GPA)
  - ***myeloperoxidase (MPO-ANCA)***, also called perinuclear or pANCA, producing a perinuclear staining pattern and seen in microscopic polyangiitis and EGPA.
- ***Antiphospholipid antibodies*** These are detected in the antiphospholipid syndrome (see 'Antiphospholipid syndrome' section).
- ***Complement.*** Low complement levels indicate consumption and suggest an active disease process in SLE.

Box 32.5 Conditions in which rheumatoid factor (RF) is found in the serum

Condition	RF (IgM) %
Autoimmune rheumatic diseases

Drug-induced lupus	>95
Myasthenia gravis	50
Idiopathic pulmonary fibrosis	30
Diabetes mellitus	25
Infectious mononucleosis	5–10
Normal population	8

Joint aspiration and examination of synovial fluid

Examination of joint (or bursa) fluid is used mainly to diagnose septic, reactive, or crystal arthritis. The appearance of the fluid is an indicator of the level of inflammation. The procedure is often undertaken in combination with injection of a corticosteroid. Aspiration alone is therapeutic in crystal arthritis (Fig. 32.2 and Box 32.7).

Aspiration and analysis of synovial fluid are always indicated when septic or crystal-induced arthritis is suspected, particularly a monoarthritis. Normal fluid is clear and straw-coloured, and contains fewer than 3000 white blood cells (WCC)/mm^3. Inflammatory fluid is cloudy and contains more than 3000 WCC/mm^3. Septic fluid is opaque and less viscous, and contains up to 75 000 WCC/mm^3. There is much overlap.

Polarized light microscopy is performed for crystals:

- ***gout:*** negatively bi-refringent, needle-shaped crystals of sodium urate
- ***calcium pyrophosphate deposition arthropathy:*** rhomboidal, weakly positively bi-refringent crystals of calcium pyrophosphate.

Gram-staining is essential if septic arthritis is suspected and may identify the organism immediately. Joint fluid should be cultured and antibiotic sensitivities requested.

Diagnostic imaging and visualization

- ***X-rays*** can be diagnostic in certain conditions (e.g., established RA) and are the first investigation in many cases of trauma. X-rays can detect joint space narrowing, erosions in RA, calcification in soft tissue, new bone formation, e.g., osteophytes, and

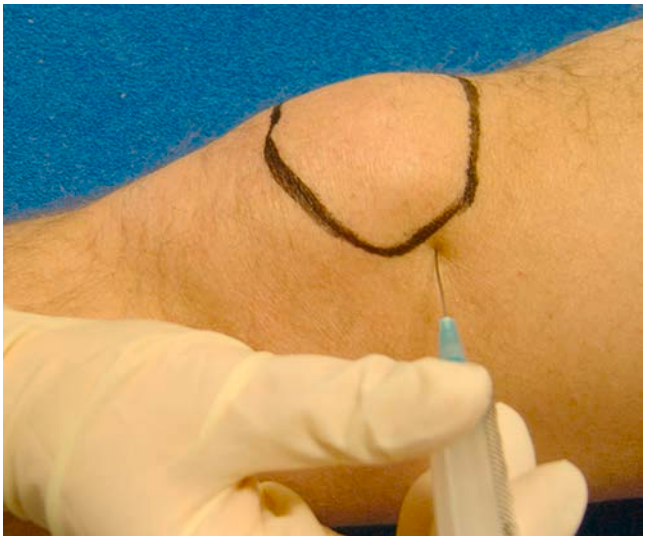

Fig. 32.2 Joint aspiration.

Box 32.7 Joint aspiration

This is a sterile procedure that should be carried out in a clean environment. Explain the procedure to the patient; obtain consent.

1. Decide on the site to insert the needle and mark it.
2. Clean the skin and your hands scrupulously.
3. Draw up local anaesthetic (and corticosteroid if it is being used).
4. Insert the needle, injecting local anaesthetic as it advances; if a joint effusion is suspected, attempt to aspirate as you advance it.
5. If fluid is obtained, change syringes and aspirate fully.
6. Examine the fluid in the syringe and decide whether or not to proceed with a corticosteroid injection (if fluid is clear or slightly cloudy) or send for microbiological tests.
7. Cover the injection site and advise the patient to rest the affected area for a few days. Warn the patient that the pain may increase initially but to report urgently if this persists beyond a few days, if the swelling worsens or if they become febrile, because this might indicate an infected joint.

Aspirated fluid is sent for microscopy, Gram-stain, and culture. Different types of crystals can be identified using polarized light microscopy. Fluid from septic arthritis is often excessively turbid.

decreased bone density (osteopenia) or increased bone density (osteosclerosis):

- In acute low back pain (see 'Pain in the lower back' section), X-rays are indicated only if the pain is persistent, recurrent, associated with neurological symptoms or signs, worse at night, or associated with symptoms such as fever or weight loss.
- Radiological changes are common in older people and may not indicate symptomatic OA or spondylosis, a term that implies OA within the spine.
- X-rays are of little diagnostic value in early inflammatory arthritis but are useful as a baseline from which to judge later change.

- ***Ultrasound*** is particularly useful for periarticular structures, soft tissue swellings, and tendons, and for detecting active synovitis in inflammatory arthritis. It is increasingly used to examine the shoulder and other structures during movement, e.g., shoulder impingement syndrome (see 'Pain in the shoulder' section). Doppler ultrasound measures blood flow and hence inflammation. Ultrasound may be used to guide local corticosteroid injections.
- ***Magnetic resonance imaging (MRI)*** shows bone changes and intra-articular structures in striking detail. Visualization of particular structures can be enhanced with different resonance sequences. T_1-weighted MRI is used for anatomical detail, T_2-weighted for fluid detection, and short tau inversion recovery (STIR) for the presence of bone marrow oedema. MRI is more sensitive than X-rays in the early detection of articular and periarticular disease. Gadolinium injection enhances inflamed tissue. MRI is especially useful for detection of damage to non-bony tissues in or near joints, e.g., meniscal tears in the knee and torn rotator cuff muscles in the shoulder; detection of nerve root compression in the spine; detection of inflamed muscle in myositis; and early detection of synovitis in inflammatory arthritis.
- ***Computerized axial tomography (CT)*** is useful for detecting changes in calcified structures but the dose of radiation is high.
- ***Bone scintigraphy*** utilizes radionuclides, usually ^{99m}Tc, and detects abnormal bone turnover and blood circulation; although non-specific, it helps in detecting areas of inflammation, infection, or malignancy. It is best used in combination with other anatomical imaging techniques.
- ***Dual-energy X-ray absorptiometry (DXA) scanning*** uses very low doses of X-irradiation to measure bone density and is used in the screening and monitoring of osteoporosis.
- ***Positron emission tomography (PET) scanning*** uses radionuclides, which decay by emission of positrons. ^{18}F-fluorodeoxyglucose uptake indicates areas of increased glucose metabolism. PET is used to locate tumours and demonstrate large-vessel vasculitis, e.g., Takayasu's arteritis (see Chapter 17). PET scans are combined with CT to improve anatomical details.

Other tests to investigate rheumatological disease

- ***Arthroscopy*** is a direct means of visualizing a joint, particularly the knee or shoulder. Biopsies can be taken, surgery performed in certain conditions (e.g., repair or trimming of meniscal tears), and loose bodies removed.
- ***Nerve conduction studies and electromyography*** are used to diagnose nerve entrapment syndromes (such as carpal or tarsal tunnel) and to distinguish myositis from neuropathies.

CLINICAL CONDITIONS IN RHEUMATOLOGY

These can be divided into three types:

- ***Pain arising from soft tissues around joints***, such as muscles and tendons. The joints themselves are normal. These are the most common locomotor problems, and are generally self-limiting or respond to simple analgesia, physiotherapy, or exercise.
- ***Diseases of the joints themselves.*** Osteoarthritis is more common than inflammatory arthritis, especially in the elderly.
- ***Autoimmune rheumatic diseases.*** These include disorders such as SLE, where the locomotor symptoms are just one manifestation of a systemic disorder.

COMMON REGIONAL MUSCULOSKELETAL PROBLEMS

See Fig. 32.3.

Pain in the neck and shoulder

See Box 32.8.

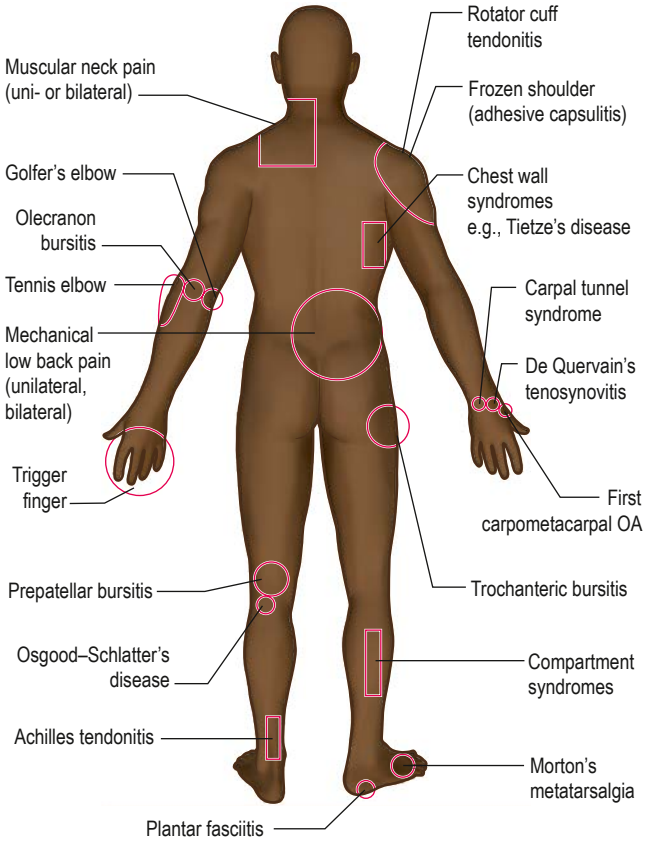

Fig. 32.3 Common regional musculoskeletal problems. *OA,* Osteoarthritis.

? Box 32.8 Pain in the neck and shoulder

- Trauma (e.g., a fall)
- Mechanical or muscular neck pain
- Whiplash injury
- Disc prolapse—nerve root entrapment
- Ankylosing spondylitis
- Shoulder lesions:
  - Rotator cuff tendonitis
  - Calcific tendonitis or bursitis
  - Impingement syndrome or rotator cuff tear
  - Adhesive capsulitis (true 'frozen' shoulder)
  - Inflammatory arthritis or osteoarthritis
- Polymyalgia rheumatica
- Fibromyalgia (chronic widespread pain)
- Chronic (work-related) upper-limb pain syndrome
- Tumour

Mechanical or muscular neck pain (shoulder girdle pain)

Unilateral or bilateral muscular-pattern neck pain is common and usually self-limiting. Chronic burning neck pain occurs because of muscle tension from anxiety and stress.

Spondylosis seen on X-ray increases after the age of 40 years but it is not always related to pain. Spondylosis can, however, cause stiffness and increases the risk of mechanical or muscular neck pain. Muscle spasm is palpable and tender, and may lead to abnormal neck posture (e.g., acute torticollis). Muscular-pattern neck pain is not localized but affects the trapezius muscle, the C7 spinous process, and the paracervical musculature (shoulder girdle pain). Pain often radiates upwards to the occiput and is commonly associated with tension headaches. These features are also seen in chronic widespread pain (see 'Chronic widespread pain' section).

i Box 32.9 Cervical nerve root entrapment: symptoms and signs

Nerve root	Sensory changes	Reflex loss	Weakness
C5	Lateral arm	Biceps	Shoulder abduction
			Elbow flexion
C6	Lateral forearm	Biceps	Elbow flexion
	Thumb and index finger	Supinator	Wrist extension
C7	Middle finger	Triceps	Elbow extension
C8	Medial forearm	None	Finger flexion
	Little and ring fingers		
T1	Medial upper arm	None	Finger abduction and adduction

Management

Patients are given short courses of analgesic therapy, along with reassurance and explanation. Physiotherapists can help to relieve spasm and pain, teach exercises and relaxation techniques, and improve posture. An occupational therapist can advise about the ergonomics of the workplace if the problem is work-related (see 'Chronic [work-related] upper-limb pain syndrome' section).

Nerve root entrapment

This is caused by an acute cervical disc prolapse or pressure on the root from spondylotic osteophytes narrowing the root canal.

Acute cervical disc prolapse presents with unilateral pain in the neck, radiating to the interscapular and shoulder regions. This diffuse, aching, dural pain is followed by sharp, electric shock-like pain down the arm, in a nerve root distribution, often with pins and needles, numbness, weakness, and loss of reflexes (**Box 32.9**).

Cervical spondylosis occurs in the older patient with posterolateral osteophytes compressing the nerve root and causing root pain (see **Fig. 28.43**, commonly at C5/C6 or C6/C7; it is seen on oblique radiographs of the neck. An MRI scan clearly distinguishes facet joint OA, root canal narrowing, and disc prolapse.

Management

A support collar, rest, analgesia, and sedation are used initially as necessary. Patients should be advised not to carry heavy items. They usually recover in 6–12 weeks. MRI is the investigation of choice if surgery is being considered or the diagnosis is uncertain (**Fig. 32.4**). A cervical root block, administered under direct vision by an experienced pain specialist, may relieve pain while the disc recovers. Neurosurgical referral is recommended if the pain persists or if the neurological signs of weakness or numbness are severe or bilateral. Bilateral root pain, with or without long tract symptoms or signs, is a neurosurgical emergency because a central disc prolapse may compress the cervical spinal cord. Posterior osteophytes may cause spinal claudication and cervical myelopathy.

Whiplash injury

Whiplash injury results from acceleration–deceleration forces applied to the neck, usually in a road traffic accident when the car of a person wearing a seat belt is struck from behind. A simple decision plan based on clinical criteria helps to distinguish those most

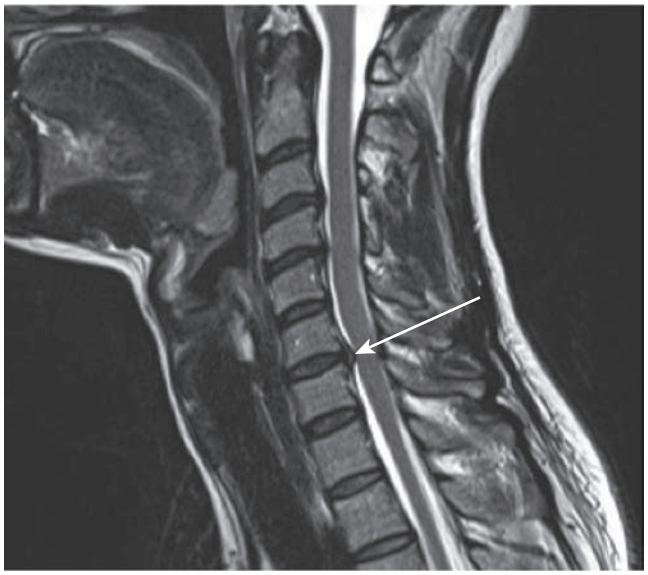

Fig. 32.4 Magnetic resonance image of the cervical spine. A large central disc prolapse *(arrowed)* is shown at the C6/7 level, and smaller disc bulges at C3/4 and C4/5.

at risk and who warrant radiography. There is a low probability of serious bony injury if there is:

- no midline cervical tenderness
- no focal neurological deficit
- normal alertness
- no intoxication
- no other painful distracting injury.

CT scans are reserved for those with bony injury. MRI scans occasionally show severe soft tissue injury. Whiplash injuries may lead to litigation or insurance claims.

Whiplash injury is a common cause of chronic neck pain, although most people recover within a few weeks or months. Delayed recovery depends, in part, on the severity of the initial injury. The pattern of chronic neck pain is often complex, involving pain in the neck, shoulder, and arm. It may be accompanied by subjective symptoms, such as headache, dizziness, and poor concentration. The subjective nature of these symptoms has led to controversy about their cause.

Management

Management is with reassurance (the patient is often distressed and anxious), analgesia, a short-term support collar and physiotherapy. Pain may take a few weeks or months to settle and the patient should be warned of this. Clinical trial evidence shows no benefit with prolonged physiotherapy.

Pain in the shoulder

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff, which is part of the joint capsule. It comprises the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly, and teres major and subscapularis anteriorly. The rotator cuff (particularly supraspinatus) prevents the humeral head from blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning movement, and the greater tuberosity glides under the acromion without impingement. Shoulder pathology restricts or is made worse by shoulder movement. Specific diagnoses are difficult to make clinically but may be clearer on imaging.

? Box 32.10 Differential diagnosis of 'shoulder' pain

- Rotator cuff tendonitis pain is worse at night and radiates to the upper arm.
- Painful shoulders produce secondary muscular neck pain.
- Muscular neck pain (also known as shoulder girdle pain) does not radiate to the upper arm.
- Cervical nerve root pain is usually associated with pins and needles or neurological signs in the arm.

Pain in the shoulder can sometimes be due to problems in the neck; the differential diagnosis is shown in **Box 32.10**. Early inflammatory arthritis and polymyalgia rheumatica (PMR) in the elderly may present with shoulder pain.

Rotator cuff (supraspinatus) tendonosis

This condition is a common cause of shoulder pain at all ages. It follows trauma in 30% of cases and is bilateral in under 5%. The pain radiates to the upper arm and is made worse by arm abduction and elevation, which are often limited. The pain is often worse during the middle of the range of abduction, reducing as the arm is raised fully; a so-called 'painful arc syndrome'. When examined from behind, the scapula rotates earlier than usual during elevation. Passive elevation reduces impingement and is less painful. Severe pain virtually immobilizes the joint, although some rotation is retained (compare adhesive capsulitis; see below). There is also painful spasm of the trapezius. There may be an associated subacromial bursitis. Isolated subacromial bursitis occurs after direct trauma, falling on to the outstretched arm or elbow. Acromioclavicular osteophytes increase the risk of impingement and may need to be removed surgically.

X-ray is often normal but ultrasound is very useful to distinguish bursitis, tendonitis, and partial or complete tendon tears. Corticosteroid injections can be guided by ultrasound.

Management

Analgesics, NSAIDs, and/or physiotherapy may suffice, but severe pain responds to an injection of corticosteroid into the subacromial bursa (see **Fig. 32.5**). Patients should be warned that 10% will develop worse pain for 24–48 hours after injection. Some 70% improve over 5–20 days and mobilize the joint themselves. Physiotherapy helps persistent stiffness. If injection in the clinic is unsuccessful ultrasound-guided corticosteroid injections may be more effective.

Torn rotator cuff

This condition is caused by trauma but also occurs spontaneously in the elderly and in RA. It prevents active abduction of the arm but patients learn to initiate elevation using the unaffected arm. Once elevated, the arm can be held in place by the deltoid muscle. In younger people, the tear is repaired surgically but this is rarely possible in the elderly or in RA. Some patients require arthroscopic surgery.

Calcific tendonosis and bursitis

Calcium pyrophosphate deposits in the tendon are visible on X-ray but they are not always symptomatic. The pathogenesis is unclear, although ischaemia may play a part. The deposit is usually just proximal to the greater tuberosity. It may lead to acute or chronic recurrent shoulder pain and restriction of movement. A local

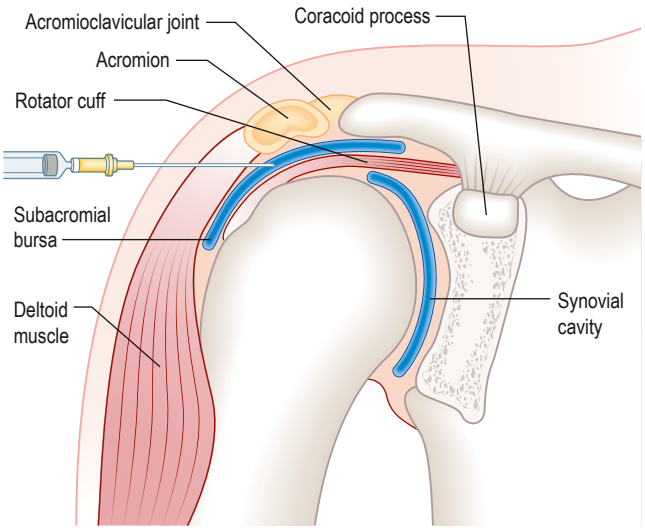

Fig. 32.5 The shoulder region, showing site of injection and subacromial space.

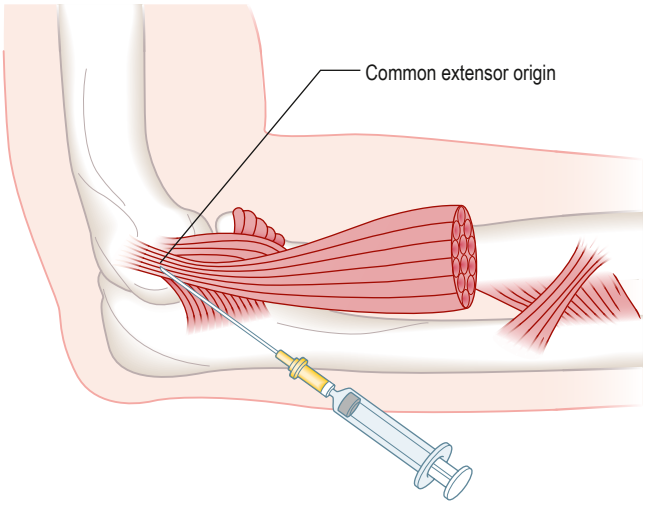

Fig. 32.6 Injection for tennis elbow.

corticosteroid injection may relieve the pain. The calcification may persist or resolve. Aspiration or breaking up of the deposit under ultrasound control may be required for persistent pain. Rarely, arthroscopic removal is necessary.

Shedding of crystals into the subacromial bursa causes a bursitis with severe pain and shoulder restriction. The shoulder feels hot and swollen, and an X-ray shows a diffuse opacity in the bursa. The differential diagnosis of calcific bursitis is gout, pseudogout, or septic arthritis. Aspiration and injection with corticosteroid can help.

Adhesive capsulitis (true 'frozen' shoulder)

This condition can develop with rotator cuff lesions, or following hemiplegia, chest or breast surgery, or myocardial infarction and in diabetics. Initially, it causes severe shoulder pain and a gradually reducing range of movement, leading to a 'frozen' phase where there is loss of all shoulder movements but little pain. NSAIDs and intra-articular injections of local anaesthetic and corticosteroids are helpful in the painful phase. Hydrodistension, where 20–30 mL of a mixture of saline, steroid, and local anaesthetic is injected into the shoulder to stretch the capsule, is effective and carried out under ultrasound guidance. Subsequently, there is usually a gradual improvement in function over weeks to months. Therapeutic exercises and physiotherapy help in later phases. Once the pain settles, arthroscopic release speeds functional recovery but is not necessary in most cases.

Pain in the elbow

Pain in the elbow can be due to epicondylitis, inflammatory arthritis, or, occasionally, OA.

Epicondylitis

Two common sites where the insertions of tendons into bone become inflamed (enthesitis) are the common wrist extensor origin at the lateral humeral epicondyle ('tennis elbow') and the common wrist flexor origin at the medial epicondyle ('golfer's elbow'). Despite the names, both conditions are usually unrelated to either sport!

There is local tenderness. Pain radiates into the forearm on using the affected muscles—typically, gripping or holding a heavy bag in tennis elbow or carrying a tray in golfer's elbow. Pain at rest also occurs.

Management

Advise rest and arrange review by a physiotherapist. A local injection of corticosteroid at the point of maximum tenderness is helpful when the pain is severe (Fig. 32.6) but needs physiotherapy follow-up to prevent recurrences. Avoid the ulnar nerve when injecting golfer's elbow. Both conditions settle spontaneously eventually, but occasionally persist and require surgical release.

Pain in the hand and wrist

See Box 32.11. Hand pain is commonly caused by injury or repetitive, work-related activities. When associated with pins and needles or numbness, it suggests a neurological cause arising at the wrist, elbow, or neck. Pain and stiffness that are worse in the morning are due to tenosynovitis or inflammatory arthritis. The distribution of hand pain often indicates the diagnosis.

Tenosynovitis

The finger flexor tendons run through synovial sheaths and under loops that hold them in place. Inflammation occurs with repeated or unaccustomed use, or in inflammatory arthritis. The thickened sheaths are often palpable.

Flexor tenosynovitis causes finger pain when gripping and stiffness of the fingers in the morning. Occasionally, a tendon causes a trigger finger, when the finger remains flexed in the morning or after gripping, and has to be pulled straight. A tender tendon nodule is palpable, usually in the distal palm. Trigger finger or thumb is more common in diabetic patients.

Dorsal tenosynovitis is less common, except in RA. The hourglass swelling extends from the back of the hand and under the extensor retinaculum.

De Quervain's tenosynovitis causes pain and swelling around the radial styloid, where the abductor pollicis longus tendon is held in place by a retaining band. There is local tenderness, and the pain at the styloid is worsened by flexing the thumb into the palm.

Management

Resting, splinting, and NSAIDs may help. Local corticosteroids injected alongside the tendon under low pressure (not into the

Box 32.11 Causes of pain in the hand and wrist

  - Tophaceous

tendon itself) are helpful. Occasionally, surgery is needed if symptoms persist.

Carpal tunnel syndrome

This condition arises due to median nerve compression in the limited space of the carpal tunnel. Thickened ligaments, tendon sheaths, or bone enlargement can cause it, but it is usually idiopathic. (Causes are discussed in Chapter 28.) The history is usually typical and diagnostic, with the patient waking with numbness, tingling, and pain in a median nerve distribution. The pain may radiate to the forearm. Wasting of the thenar eminence muscles develops with sensory loss in the radial three-and-a-half fingers. The pain may be produced by tapping the nerve in the carpal tunnel (Tinel's sign) or by holding the wrist in flexion (Phalen's test).

Management

Management is with a splint to hold the wrist in dorsiflexion overnight, which relieves the symptoms and is diagnostic; used nightly for several weeks, it may produce full recovery. If it does not, a corticosteroid injection into the carpal tunnel (avoid the nerve!) helps in about 70% of cases, although it may recur. Persistent symptoms or nerve damage produce prolonged latency across the carpal tunnel on nerve conduction studies and require surgical decompression.

Other conditions causing pain

Inflammatory arthritis

This may present with pain, swelling, and stiffness of the hands. In RA, the wrists, proximal interphalangeal (PIP) joints, and metacarpophalangeal (MCP) joints are affected symmetrically. In psoriatic arthritis and reactive arthritis, a finger may be swollen (dactylitis), or the distal interphalangeal (DIP) joints and nails are affected asymmetrically.

Nodal osteoarthritis

This affects the DIP and, less commonly, PIP joints, which are initially swollen and red. The inflammation and pain settle but bony swellings remain (see 'Nodal OA' section).

First carpometacarpal osteoarthritis

This causes pain at the base of the thumb when gripping, or painless stiffness at the base of the thumb, often in people with nodal OA.

Scaphoid fractures

These cause pain in the anatomical snuffbox. They are not seen immediately on X-ray; if there is clinical suspicion, a cast is necessary. Untreated scaphoid fractures can eventually cause pain because of failed union.

Ganglion

A ganglion is a jelly-filled, often painless swelling caused by a partial tear of the joint capsule or tendon sheath. The wrist is a common site. Treatment is not essential, as many resolve or cause little trouble; otherwise, surgical excision is the best option.

Dupuytren's contracture

This condition is a painless, palpable fibrosis of the palmar aponeurosis, with fibroblasts invading the dermis. It causes puckering of the skin and gradual fixed flexion, usually of the ring and little fingers. It is more common in males, white people, individuals with diabetes mellitus, and those who overuse alcohol. A similar fibrosis occurs in the feet and is often more aggressive. Intralesional steroid injections may help in early disease and some advocate transcutaneous needle aponeurotomy. Percutaneous collagenase injection into the lesion has been shown to be effective in several studies and is now first-line treatment used before surgery. Surgical release of the contracture is restricted to those with severe deformity of the fingers.

Pain in the lower back

Low back pain is a common symptom. It is often traumatic and work-related, although lifting apparatus, other mechanical devices, and improved office seating help to avoid it. Episodes are generally short-lived and self-limiting, and patients attend a physiotherapist or osteopath more often than a doctor. Chronic back pain is the cause of 14% of long-term disability in the UK. The causes are listed in **Box 32.12**.

The majority of cases (about 90%) of low back pain are uncomplicated and arise from mechanical causes. Management of this type of back pain is summarized in **Box 32.13**.

One should be alert to clues in the history and examination that could suggest more serious causes of low back pain. These ***'red flag'*** clues (summarized in **Fig. 32.7**) include the following:
- pain has persisted for more than 6 weeks
- is worse at night or in the morning, when an inflammatory arthritis (e.g., ankylosing spondylitis), infection, or a spinal tumour may be the cause
- is associated with a systemic illness, fever, or weight loss
- is associated with neurological symptoms or signs, especially new onset incontinence, which may suggest cauda equina compression.

Investigations

- ***Spinal X-rays*** are required only if the pain is associated with 'red flag' symptoms or signs.
- ***MRI*** (**Figs. 32.8 and 32.9**) is preferable to CT scanning when neurological signs and symptoms are present. CT scans demonstrate bony pathology better. Interpretation of the relevance of the findings may require a specialist opinion.
- ***Bone scans*** are useful in infective and malignant lesions but are also positive in degenerative lesions.
- ***Full blood count, ESR, and biochemical tests*** are required only when the pain is likely to be due to malignancy, infection, or a metabolic cause. Normal ESR and CRP distinguish mechanical back pain from PMR, a likely differential in the elderly.

Mechanical low back pain

Mechanical low back pain starts suddenly, may be recurrent and is helped by rest. It is often precipitated by an injury and may be unilateral or bilateral. It is usually short-lived.

Box 32.12 Causes of pain in the back (lumbar region)

Mechanical
- Trauma
- Muscular and ligamentous pain
- Lumbar spondylosis

- Osteoporotic spinal fractures
- Osteomalacia
- Paget's disease

Neoplastic (see Chapter 41)
- Metastases
- Multiple myeloma
- Primary tumours of bone

Referred pain

Box 32.13 Management of back pain

- Most back pain presenting to a primary care physician needs no investigation
- Mechanical back pain is managed with analgesia, brief rest if necessary, and physiotherapy
- Patients should stay active within the limits of their pain
- Early treatment of the acute episode, advice, and exercise programmes reduce long-term problems and prevent chronic pain syndromes
- Physical manipulation of uncomplicated back pain produces short-term relief and enjoys high patient satisfaction ratings
- Psychological and social factors may influence the time of presentation
- Appropriate early management reduces long-term disability

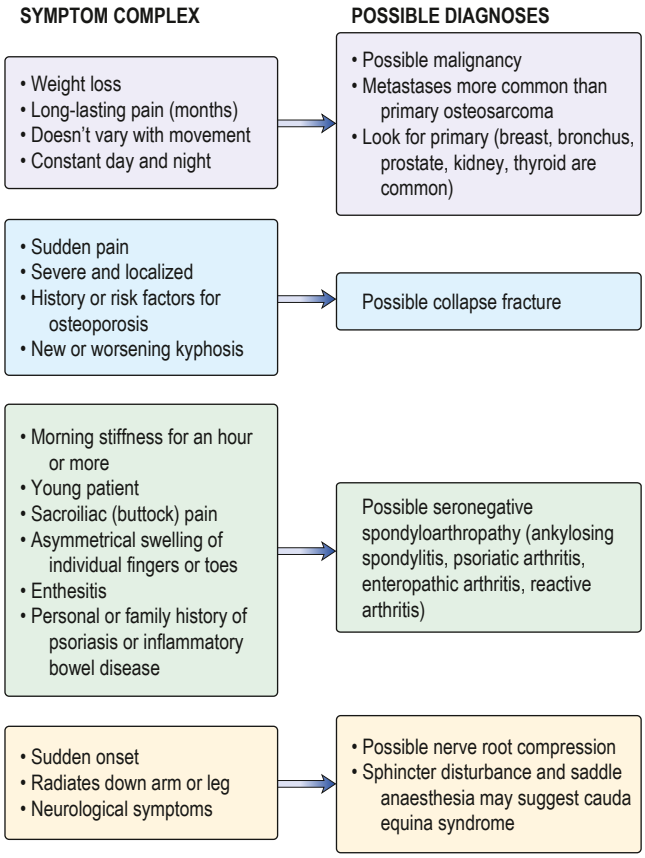

Fig. 32.7 Diagnoses for serious causes of back pain.

Examination

The back is stiff and a scoliosis may be present when the patient is standing. Muscular spasm is visible and palpable, and causes local pain and tenderness. It lessens when sitting or lying. Excessive rest should be avoided. Once a patient develops low back pain, although the episode itself is usually self-limiting, there is a significantly increased risk of further back pain episodes. Risk factors for recurrent back pain include:

- female sex
- increasing age
- pre-existing chronic widespread pain (fibromyalgia)
- psychosocial factors, such as high levels of psychological distress, poor self-rated health, and dissatisfaction with employment.

Chronic low back pain is a major cause of disability and time off work and is reduced by appropriate early management.

Spinal movement occurs at the disc and the posterior facet joints, and stability is normally achieved by a complex mechanism of spinal ligaments and muscles. Any of these structures may be a source of pain. An exact anatomical diagnosis is difficult but some typical syndromes are recognized (see below). They are often associated with, but not necessarily caused by, radiological spondylosis (see Chapter 28).

Postural back pain develops in individuals who sit in poorly designed, unsupportive chairs.

Lumbar spondylosis

The fundamental lesion in spondylosis occurs in an intervertebral disc, a fibrous structure whose tough capsule inserts into the rim of the adjacent vertebrae. This capsule encloses a fibrous outer zone and a gel-like inner zone. The disc allows rotation and bending.

Fig. 32.8 Spinal metastasis in L2. The patient had severe back pain and weight loss, and prior carcinoma of the breast.

Changes in the discs occasionally start in teenage years or early twenties and often increase with age. The gel changes chemically, breaks up, shrinks, and loses its compliance. The surrounding fibrous zones develop circumferential or radial fissures. In the majority, this

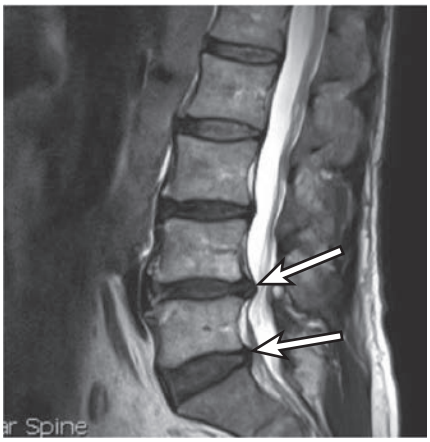

Fig. 32.9 Magnetic resonance image of the lumbar spine. A large disc prolapse is shown at the L4/L5 level and a smaller prolapse at L5/S1 *(arrowed)*. The signal from all the lumbar discs indicates dehydration.

is initially asymptomatic but visible on MRI as decreased hydration. Later, the discs become thinner and less compliant. These changes cause circumferential bulging of the intervertebral ligaments.

Reactive changes develop in adjacent vertebrae; the bone becomes sclerotic and osteophytes form around the rim of the vertebra (see Fig. 32.9). The most common sites of lumbar spondylosis are L5/S1 and L4/L5.

In young people, disc prolapse through an adjacent vertebral end-plate produces a Schmorl's node on X-ray. This process is painless but may accelerate disc degeneration.

Spondylosis may be symptomless but can cause:

- episodic mechanical spinal pain
- progressive spinal stiffening
- facet joint pain
- acute disc prolapse, with or without nerve root irritation
- spinal stenosis
- spondylolisthesis.

Facet joint syndrome

Lumbar spondylosis also causes secondary OA of the misaligned facet joints. Pain is typically worse on bending backwards and when straightening from flexion. It is lumbar in site, unilateral or bilateral, and radiates to the buttock. The facet joints are well seen on MRI and may show OA, an effusion, or a ganglion cyst. Direct corticosteroid injections into the joints under imaging may help but their long-term value is unclear. Physiotherapy to reduce hyperlordosis and weight reduction are helpful.

Management of mechanical back pain

Adequate analgesia to allow normal mobility and avoidance of bed rest is best, combined with physical treatments such as physiotherapy, back muscle training regimens, and manipulation. Manipulation produces more rapid pain relief in some patients. Acupuncture may help. Re-education in lifting and exercises helps to prevent recurrent attacks of pain. Most episodes recover, irrespective of the treatment given. A positive approach probably reduces the development of chronic pain. A comfortable sleeping position should be adopted using a mattress of medium (not hard) firmness.

Acute lumbar disc prolapse

The central disc gel may extrude into a fissure in the surrounding fibrous zone and cause acute pain and muscle spasm. These events are often self-limiting. A disc prolapse occurs when the extrusion extends beyond the limits of the fibrous zone (see Fig. 32.9). The weakest point is posterolateral, where the disc may impinge on emerging spinal nerve roots in the root canal.

Box 32.14 Lumbar nerve root entrapment: symptoms and signs

Nerve root	Sensory changes	Reflex loss	Weakness	Usual disc prolapse
L2	Front of thigh	None	Hip flexion/ adduction	L1/2
L3	Inner thigh and knee	Knee	Knee extension	L2/3
L4	Inner calf	Knee	Knee extension	L3/4
L5	Outer calf	None	Inversion of foot	L4/5
	Upper, inner foot		Dorsiflexion of toes	
S1	Posterior calf	Ankle	Plantar flexion of foot	L5/S1
	Lateral border of foot			

The episode often starts dramatically during lifting, twisting, or bending, and produces a typical combination of low back pain and muscle spasm, and severe, lancinating pains, paraesthesia, numbness, and neurological signs in one leg (rarely both). The back pain is diffuse and usually unilateral, and radiates into the buttock. The muscle spasm leads to a scoliosis that reduces when lying down. The nerve root pain develops with, or soon after, the onset. The site of the pain and other symptoms are determined by the root affected (Box 32.14). A central high lumbar disc prolapse may cause spinal cord compression and long tract signs (i.e., upper motor neurone). Below L2/L3, it produces lower motor neurone lesions.

Examination

On examination, the back often shows a marked scoliosis and muscle spasm. The straight-leg-raising test, while the patient is lying, is positive in a lower lumbar disc prolapse—raising the straight leg beyond 30 degrees produces pain radiating down the leg further than the knee. Slight limitation or pain in the back limiting this movement is seen with mechanical back pain. Pain in the affected leg produced by a straight raise of the other leg suggests a large or central disc prolapse. Look for perianal sensory loss and urinary retention or incontinence, which indicate a cauda equina lesion—a neurosurgical emergency (see Chapter 28). An upper lumbar disc prolapse produces a positive femoral stretch test: pain in the anterior thigh when the knee is flexed in the prone position.

Management

Advise a short period (2–3 days) of bed rest, lying flat for a lower disc but semi-reclining for a high lumbar disc, and prescribe analgesia and muscle relaxants. Once the pain is tolerable, encourage the patient to mobilize and refer them to a physiotherapist for exercises and preventative advice. The investigation of choice is MRI, which identifies the abnormal disc and any compressed nerves. An imaging-guided epidural or nerve root canal injection reduces pain rapidly, although the evidence that it speeds resolution or prevents surgery is unclear. Caudal epidural injections are less effective than lumbar ones. Resuscitation equipment must be available for these procedures. Referral to a surgeon for possible microdiscectomy or hemi-laminectomy is necessary if the neurological signs are severe,

if the pain persists and is severe for more than 6–10 weeks, or if the disc is central. If bladder or anal sphincter tone is affected, it becomes a neurosurgical emergency.

Spinal and root canal stenosis

Progressive loss of disc height, OA of the facet joints, posterolateral osteophytes, and buckling of the ligamentum flavum all contribute to root canal stenosis. These changes cause nerve root pain or spinal root claudication—pain and paraesthesiae in a root distribution brought on by walking and relieved slowly by rest. The associated sensory symptoms, slower recovery when the patient rests, and presence of normal foot pulses distinguish this from peripheral arterial claudication. Severe cervical spondylosis may also produce spinal claudication, often with arm symptoms and signs.

The investigation of choice to identify the location and extent of stenosis is MRI. Spinal canal stenosis at more than one level is often associated with severe spondylosis and/or a congenitally narrow spinal canal. It causes buttock and bilateral leg pain, 'heaviness', paraesthesiae, and numbness when walking. Rest helps, as does bending forwards, a manoeuvre that opens the spinal canal. Specialist surgical advice is necessary.

Spondylolisthesis

This condition occurs in adolescents and young adults when bilateral congenital pars interarticularis defects cause instability and permit a vertebra to slip, with or without preceding injury. Rarely, a cauda equina syndrome develops, with loss of bladder and anal sphincter control, and saddle-distribution anaesthesia. It is diagnosed radiologically and can be seen on plain radiographs, though MRI may be necessary if entrapment of nerve roots or cauda equina syndrome is suspected. Low back pain in adolescents warrants investigation, and spondylolisthesis requires orthopaedic assessment. It needs monitoring during the growth spurt.

A degenerative spondylolisthesis may also develop in older people with lumbar spondylosis and OA of the facet joints.

Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH, or Forestier's disease) affects the spine and extraspinal locations. It causes bony overgrowths and ligamentous ossification, and is characterized by flowing calcification over the anterolateral aspects of the vertebrae. The spine is stiff but not always painful, despite the dramatic changes seen on plain radiographs, which are the imaging investigation of choice. Ossification at muscle insertions around the pelvis produces radiological 'whiskering'. Similar changes occur at the patella and in the feet. It is more common in people with metabolic syndrome (high body mass index [BMI]), diabetes mellitus, hypertension, and dyslipidaemia; see Chapter 37).

Management is with analgesics or NSAIDs for pain, and exercise to retain movement and muscle strength.

Osteoporotic crush fracture of the spine

Osteoporosis is asymptomatic but leads to an increased risk of fracture of peripheral bones, particularly neck of femur and wrist, and thoracic or lumbar vertebral crush fractures. Such vertebral fractures may develop with no or minimal trauma. They may develop painlessly or cause agonizing localized pain that radiates around the ribs and abdomen. Multiple fractures lead to an increased thoracic kyphosis. They cause disability and reduced quality of life. The diagnosis is confirmed by X-rays, showing loss of anterior vertebral body height and wedging, with sparing of the vertebral endplates and pedicles. Bone oedema on MRI indicates that a fracture is recent. An underlying tumour and pathological fracture need to be excluded.

Management

Advise bed rest and analgesia until the severe pain subsides over a few weeks, then gradual mobilization. It may warrant hospitalization, and the prescription of intravenous bisphosphonates or subcutaneous or nasal calcitonin to relieve pain. There may be some residual pain and deformity.

The role of percutaneous vertebroplasty and balloon kyphoplasty remains unclear. Both involve inserting a needle through a pedicle into the affected vertebral body under CT guidance with the aim of stabilizing the fracture. Kyphoplasty involves inflating a balloon filled with methyl methacrylate cement in order to restore vertebral shape. Vertebroplasty is the injection of cement alone, without restoring vertebral shape. Pain relief is usual with both but the risks are higher with vertebroplasty.

Bone density measurement and preventative treatment of osteoporosis are essential (see Chapter 33).

Septic discitis

Septic discitis may cause severe pain and rapid adjacent vertebral destruction. It is seen on MRI and requires urgent neurosurgical referral.

Ankylosing spondylitis

Buttock pain and low back stiffness in a young adult suggest axial spondyloarthritis (e.g., ankylosing spondylitis) (see 'Axial spondyloarthritis' section), especially if they are worse at night and in the morning.

Pain in the hip

'Hip' refers to a wide area between the upper buttock, trochanter, and groin. It is useful to ask the patient to point to the site of pain and its field of radiation (**Box 32.15**).

Osteoarthritis of the hip

OA (see 'Osteoarthritis' section) is the most common cause of hip joint pain in a person over the age of 50 years. It gives rise to pain in the buttock and groin on standing and walking. Stiff hip movements cause difficulty in putting on a sock and may produce a limp. Sudden-onset pain may be associated with an effusion on

? Box 32.15 Pain in the hip: causes

Hip region problems	Main sites of pain
Osteoarthritis of hip	Groin, buttock, front of thigh to knee
Trochanteric bursitis (or gluteus medius tendinopathy)	Lateral thigh to knee
Meralgia paraesthetica	Anterolateral thigh to knee
Referred from back	Buttock
Facet joint pain	Buttock and posterior thigh
Fracture of neck of femur	Groin and buttock
Inflammatory arthritis	Groin, buttock, front of thigh to knee
Sacroiliitis (ankylosing spondylitis)	Buttock(s)
Avascular necrosis	Groin and buttocks
Polymyalgia rheumatica	Lumbar spine, buttocks, and thighs

MRI and can be treated by an ultrasound-guided steroid injection. Severe hip OA is characterized by pain and limitation even at rest and abnormal gait. In severe cases, total hip replacement is the only successful therapy.

Lateral hip pain syndrome: trochanteric bursitis and gluteus medius tendinopathy

This syndrome may be due to trochanteric bursitis and caused by trauma or unaccustomed exercise. It also occurs in inflammatory arthritis. The pain over the trochanter is worse on going up stairs, lying on that side in bed, and crossing the legs. The best management is unclear but exercises help, as may a local corticosteroid injection, although the evidence base for treatment is poor. Surgery is rarely necessary. Lateral hip pain may be referred from the upper lumbar spine. A tear of the gluteus medius tendon at its insertion into the trochanter causes a similar syndrome but does not respond to injection.

Meralgia paraesthetica

This condition causes numbness and burning dysaesthesia (increased sensitivity to light touch) over the anterolateral thigh, and may be precipitated by a sudden increase in weight, an injury, or pelvic surgery. It is usually self-limiting but can be helped by amitriptyline or gabapentin at night.

Fracture of the femoral neck

This fracture usually occurs after a fall, occasionally spontaneously. There is pain in the groin and thigh, weight-bearing is painful or impossible, and the leg is shortened and externally rotated. Occasionally, a fracture is not displaced and remains undetected. X-rays are diagnostic. Anyone with a hip fracture, especially after minimal trauma, should be reviewed for osteoporosis (see Chapter 33).

Avascular necrosis (osteonecrosis) of the femoral head

This condition is uncommon but occurs at any age. (Risk factors are discussed in Chapter 33.) There is severe hip pain. X-rays are diagnostic after a few weeks, when a well-demarcated area of increased bone density is visible at the upper pole of the femoral head. The affected bone may collapse. Early, the X-ray is normal but bone scintigraphy or MRI demonstrates the lesion and shows bone marrow oedema.

Inflammatory arthritis of the hip

Inflammatory arthritis produces pain in the groin and stiffness, which is worse in the morning. RA rarely presents with hip pain, although the hip is involved eventually in severe RA. Ankylosing spondylitis and other seronegative spondyloarthropathies cause inflammatory hip arthritis in younger people.

Polymyalgia rheumatica

Bilateral hip, buttock, and thigh pain and stiffness that are worse in the morning in an elderly patient may be attributable to PMR (see 'Polymyalgia rheumatica' section). Neck and shoulder pain and stiffness are usually also present.

Pain in the knee

The knee depends on ligaments and quadriceps muscle strength for stability. It is frequently injured, particularly during sports. Trauma or overuse of the knee leads to a variety of peri- and intra-articular problems. Some are self-limiting; others require physiotherapy, local corticosteroid injections, or surgery.

? Box 32.16 Pain in the knee: causes

Problems arising within the joint

- Quadriceps tendon enthesitis
- Osgood–Schlatter disease

Posterior
- Popliteal (Baker's) cyst

Other
- Hypermobility syndrome
- Referred from hip joint

Trauma and overuse

Painful knee problems can be divided into those that arise within the joint and those that arise in the soft tissues around the joint (Box 32.16). Only problems arising within the joint are likely to cause accumulation of fluid (effusion). Identification and aspiration of fluid from effusions are relevant diagnostic procedures.

Knee joint effusions

An effusion of the knee causes swelling, stiffness, and pain. The pain is more severe with an acute onset and with increasing inflammation because the capsule that contains the pain receptors is stretched. A full clinical history must include a past medical, family, and drug history.

Examination

A large and tense effusion is easily seen and felt on each side of the patella and in the suprapatellar pouch, and is fluctuant. The effusion delays the patella tapping against the femur when it is pressed firmly and quickly with the knee held straight and relaxed (the 'patellar tap' sign). Small effusions also demonstrate the 'bulge' sign when the patient is lying with the quadriceps relaxed. For this test, apply a gentle sweeping pressure, first to the medial side of the joint and then, watching the medial dimple, to the lateral side. Slightly delayed bulging of the medial dimple indicates fluid in the joint.

Investigations

These are:
- blood tests (urate, blood cultures)
- aspiration (see Fig. 32.2) and examination of the knee effusion.

The basic technique of aspiration is described in Box 32.7. If the fluid obtained is very cloudy, septic arthritis (or occasionally gout) is the likeliest diagnosis. Slightly cloudy or blood-stained fluid that does not clot is likely to indicate pseudogout. Frank blood that clots suggests a haemarthrosis. Fluid should be sent for Gram-stain and culture if sepsis is suspected. It should be sent for polarized light microscopy if looking for crystals (see 'Crystal arthritis' section).

Pain arising from within the knee

Osteoarthritis of the knee

Minor radiographic changes of OA (see Fig. 32.15) are very common in those aged over 50 years and do not usually cause pain, which is more likely to arise from surrounding soft tissues. X-ray appearances and the degree of pain felt in OA of the knee are not closely correlated. Marked valgus, varus, or fixed flexion deformities suggest severe OA. For severe cases, surgery, usually total knee

replacement, is the treatment of choice. In milder cases, pain relief, physiotherapy and, sometimes, intra-articular corticosteroid injections may help.

Inflammatory arthritis of the knee

Monoarthritis of the knee, associated with severe pain and marked redness, may be due to septic arthritis, gout, or pseudogout. A cool, clear, viscous effusion is seen in elderly people with moderate or severe symptomatic OA. RA rarely presents with knee involvement alone, though seronegative spondyloarthritis may do so.

Haemarthrosis of the knee

This condition is caused by:

- trauma: meniscal, cruciate, or synovial lining tear
- clotting or bleeding disorders, e.g., haemophilia, sickle cell disease, or von Willebrand's disease.

Torn meniscus

The menisci are partially attached fibrocartilages that stabilize the rounded femoral condyles on the flat tibial plateaux. In the young, they are resilient, but this decreases with age. They can be torn by an injury, commonly in sports that involve twisting and bending. The history is usually diagnostic. There is immediate medial or lateral knee pain and swelling within a few hours. The affected side is tender. If the tear is large, the knee may lock flexed. The immediate treatment is to apply ice. MRI demonstrates the tear (Fig. 32.10). In most circumstances, especially in active sportspeople, early arthroscopic repair or trimming of the torn meniscus is essential. Surgical intervention reduces recurrent pain, swelling, and locking but not the risk of secondary OA. In older patients with OA plus meniscal tear, surgery is no more effective than physiotherapy alone. The long-term benefit of early repair of tears is not yet known. Post-surgical quadriceps exercises aid a return to sport and other activities.

Torn cruciate ligaments

Torn cruciate ligaments account for around 70% of knee haemarthroses in young people. They often coexist with a meniscal tear. Partial cruciate tears are difficult to diagnose clinically. On flexing the knee to 90 degrees, a torn anterior cruciate allows the tibia to be pulled forwards on the femur. MRI is the investigation of choice. Such injuries need urgent orthopaedic referral, reconstructive surgery usually being necessary in young active adults. There is a significant incidence of secondary OA.

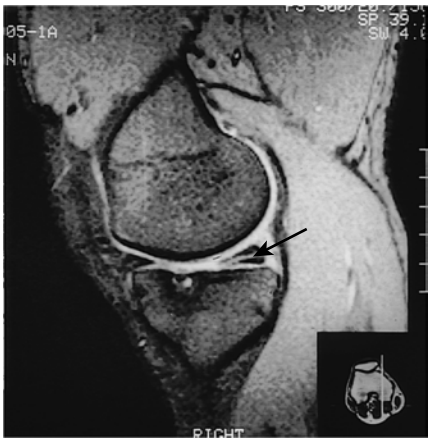

Fig. 32.10 Magnetic resonance image of a knee. A complete tear of the posterior horn of the medial meniscus is shown, extending to its lower surface *(arrowed)*.

Chondromalacia patellae

This diagnosis is made arthroscopically. The retropatellar cartilage is fibrillated. In most cases, the pain settles eventually. When there is patellar misalignment, it may need surgery, as does recurrent patellar dislocation in adolescent females.

Osteochondritis dissecans

This condition occasionally causes knee pain and swelling in adolescents and young adults, more commonly males. It is probably traumatic, possibly with hereditary predisposing factors. A fragment of bone and its attached cartilage detach by shearing, most commonly from the lateral aspect of the medial femoral condyle.

There is aching pain after activity and, if the fragment becomes loose, locking or 'giving way' occurs. The lesion is seen on a tunnel-view X-ray but MRI is more sensitive, especially if the fragment is undisplaced. Undisplaced lesions are treated with rest, then isometric quadriceps exercises. Loose fragments can be fixed arthroscopically or removed. A similar lesion affecting the lateral femoral condyle occurs in older people.

Spontaneous osteonecrosis of the knee

Osteonecrosis may occur spontaneously or after injury. There is local pain and there are marked bone marrow changes on MRI (Fig. 32.11A) or single-photon emission computed tomography (SPECT; Fig. 32.11B). In particular, weight-bearing must be avoided. Pamidronate by infusion is sometimes used. Spontaneous osteonecrosis of the knee (SONK) may progress to bone infarction and require replacement surgery.

Pain from structures around the knee

Medial knee pain

There may be medial or lateral ligament strain but the medial ligament is more commonly affected. There is pain at the ligament's insertion into the upper medial tibia, which is worsened by standing or stressing the affected ligament.

Anserine bursitis causes pain and localized tenderness 2–3 cm below the posteromedial joint line in the upper part of the tibia at the site of the bursa. It occurs in obese females, often with valgus deformities, and in breast-stroke swimmers.

Management is with physiotherapy and a local corticosteroid injection.

Anterior knee pain

Anterior knee pain is common in adolescence. In many cases, no specific cause is found, despite investigation. This is called 'anterior knee pain syndrome' and settles with time. Isometric quadriceps exercises and avoidance of high heels both help the condition. Patients and parents often need firm reassurance. Abnormal patellar tracking may be a cause and may need surgical treatment. Hypermobility of joints causes joint pain, maltracking and, rarely, recurrent patellar dislocation (see also 'Hypermobile Ehlers–Danlos syndrome and hypermobility spectrum disorders' section).

Pre- and infrapatellar bursitis

This can occur in patients whose jobs involve frequent kneeling ('housemaid's knee', 'clergyman's knee', 'carpet-layer's knee'). There is local pain, tenderness, and sometimes swelling. Avoidance of kneeling and a local corticosteroid injection are helpful. Septic bursitis can occur.

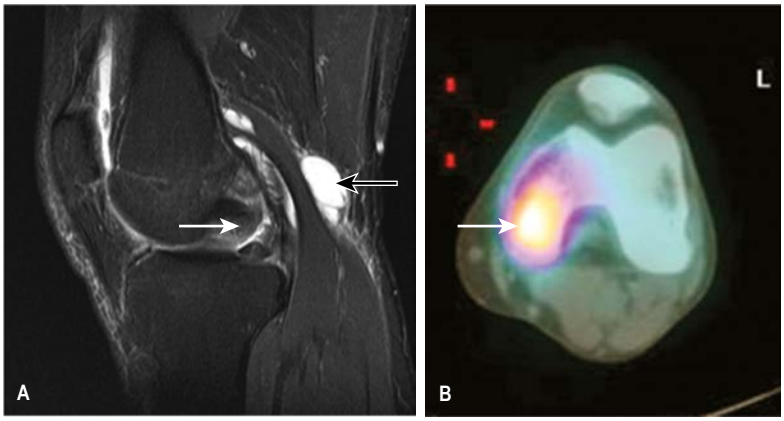

Fig. 32.11 Spontaneous osteonecrosis of the knee. **(A)** Magnetic resonance image showing a high signal in the posterior aspect of the femoral condyle *(white arrow)*, a small effusion and a popliteal cyst *(black arrow)*. **(B)** Single-photon emission computed tomography (SPECT) image showing a high signal in the posterior medial femoral condyle.

Osgood–Schlatter disease

Osgood–Schlatter disease causes pain and swelling over the tibial tubercle. It is a traction apophysitis of the patellar tendon and occurs particularly in teenage sports players.

Enthesitis

This may occur at the patellar end of the quadriceps tendon (jumper's knee).

Posterior knee pain

Popliteal cyst (Baker's cyst)

In approximately 5% of people with a knee effusion, a swollen, painful popliteal cyst develops. The semi-membranosus bursa in some individuals has a valve-like connection to the knee, allowing the effusion to flow into the bursa but not back. The cyst is best seen and felt in the popliteal fossa with the patient standing.

Ruptured popliteal cyst

Fluid escapes into the soft tissue of the popliteal fossa and upper calf, causing sudden and severe pain, swelling, and tenderness of the upper calf.

A history of previous knee problems and the sudden onset of pain and tenderness high in the calf suggest a ruptured cyst rather than a deep vein thrombosis (DVT). A diagnostic ultrasound examination distinguishes a ruptured cyst from a DVT (see Chapter 8), which can avoid inappropriate treatment with anticoagulants. Analgesics or NSAIDs, rest with the leg elevated, and aspiration and injection with corticosteroids into the knee joint are required.

Pain in the shin, calf, and ankle

Sever's disease

This is a traction apophysitis of the Achilles tendon in young people (compare Osgood–Schlatter disease, see above).

Pain at the insertion of the Achilles tendon into the calcaneum is an enthesitis. This is traumatic or it can complicate spondyloarthritis. Raising the shoe heel reduces pain. Occasionally, a low-pressure corticosteroid injection near the enthesis is necessary.

Achilles tendonosis

This causes a painful, tender swelling a few centimetres above the tendon's insertion. Advise against walking barefoot and jumping. Tendon damage or rupture can occur with quinolone, for example, ciprofloxacin therapy. Therapeutic ultrasound is helpful. (*Caution:* a local injection may cause the tendon to rupture.) Autologous platelet concentrates are used but evidence of efficacy is poor. Procedures to remove or sclerose new blood vessels in the inflamed areas may help.

Achilles bursitis

This lies clearly anterior to the tendon and can be safely injected with corticosteroid.

Compartment syndromes

The muscles of the lower leg are enclosed in fascial compartments, with little room for expansion to occur. Compartment syndromes can be acute and severe, such as following exercise.

In ***anterior tibial syndrome*** there is severe pain in the front of the shin, occasionally with foot drop. Immediate surgical decompression to prevent muscle necrosis is sometimes required.

Chronic compartment syndrome produces pain in the lower leg that is aggravated by exercise and may therefore be mistaken for a vascular or neurological disorder.

Pain in the foot

See **Box 32.17**. The feet are subjected to extreme pressures by weight-bearing and inappropriate shoes. They are commonly painful. Broad, deep, thick-soled shoes are essential for sporting activities, prolonged walking or standing, and in people with congenitally flat or arthritic feet.

There are two common types of foot deformity:

- ***Flat feet.*** These stress the ankle and throw the hindfoot into a valgus (everted) position. A flat foot is rigid and inflexible.
- ***High-arched feet.*** These place pressure on the lateral border and ball of the foot.

The foot is affected by a variety of inflammatory arthritic conditions. After the hand, the foot joints are the most commonly affected by RA. The diagnosis depends on assessment of the distribution of the joints affected, the pattern of other joint problems, or the finding of an associated condition (e.g., psoriasis; see Chapter 45).

Hallux valgus

The big toe migrates laterally. In the congenital form, the first metatarsal bone is displaced medially (metatarsus primus varus). The

Box 32.17 Pain in the foot and heel: causes

Foot pain
- Structural—flat (pronated) or high-arched (supinated)
- Hallux valgus/rigidus (± osteoarthritis)
- Metatarsalgia
- Morton's neuroma
- Stress fracture
- Inflammatory arthritis
- Acute, monoarticular—gout
- Chronic, polyarticular—rheumatoid arthritis
- Chronic, pauciarticular—spondyloarthritis
- Tarsal tunnel syndrome

Heel pain
- Plantar fasciitis: below heel
- Plantar spur: below heel
- Achilles tendonitis/bursitis: behind heel
- Sever's disease: behind heel
- Arthritis of ankle/subtaloid joints

shape of modern shoes causes later onset of hallux valgus. It is a common complication of RA.

Hallux rigidus

OA of the first metatarsophalangeal (MTP) joint in a normally aligned or valgus joint causes hallux rigidus: a stiff, dorsiflexed, and painful big toe. Careful choice of footwear and the help of a podiatrist suffice for most cases but some require surgery.

Metatarsalgia

This is common, especially in people who wear high-heeled shoes, after trauma and in those with hammer toes. The ball of the foot is painful to walk and stand on. Callosities and pressure-induced bursae develop under the metatarsal heads. RA causes misalignment of the metatarsal bones and severe metatarsalgia.

Management is with podiatry and the wearing of appropriate shoes. Surgery is occasionally needed, particularly in the rheumatoid forefoot.

Morton's neuroma

This usually occurs between the third and fourth metatarsal heads. It causes pain, burning, and numbness in the adjacent surfaces of the affected toes when walking. It is helped by wearing wider, cushion-soled shoes. Occasionally, a steroid injection under ultrasound guidance or excision is necessary.

Stress fractures of the metatarsals

These cause sudden, severe, weight-bearing pain in the distal shaft of the fractured metatarsal bone. They occur after unaccustomed walking or with new shoes. There is local tenderness and swelling, but initially X-rays are normal and diagnosis delayed (Fig. 32.12). A radioisotope bone scan or MRI reveals the fracture earlier than X-rays. Reduced weight-bearing for a few weeks usually suffices. Underlying osteoporosis may be a cause.

Tarsal tunnel syndrome

This is an entrapment neuropathy of the posterior tibial nerve at the medial malleolus. It produces burning, tingling, and numbness of the toes, sole and medial arch. The nerve is tender below the malleolus and, when tapped, produces a shock-like pain (Tinel's sign). A local steroid injection under the retinaculum, between the medial malleolus and calcaneum, is helpful.

Pain under the heel

See Box 32.17.

Fig. 32.12 Callus forming around a stress fracture. The image shows a stress fracture of the second metatarsal at 4 weeks. X-rays initially were normal.

Plantar fasciitis

This is an enthesitis at the insertion of the plantar fascia into the calcaneum. It produces localized pain under the heel when standing and walking, as well as local tenderness. It occurs alone or in spondyloarthritis. Obesity, particularly in flat-footed people who walk a lot, can predispose to plantar fasciitis.

Plantar spurs

These are traction lesions at the insertion of the plantar fascia in older people and are usually asymptomatic. They become painful after trauma.

Calcaneal bursitis

This is a pressure-induced (adventitious) bursa that produces diffuse pain and tenderness under the heel. Compression of the heel pad from the sides is painful, which distinguishes it from plantar fascia pain.

Clinical features and management of heel pain

Whatever the cause, heel pain is always worse in the morning as soon as weight is placed on the foot.

All these lesions are treated with heel pads, and reduced walking; they are often self-limiting. A dorsiflexion splint at night to stretch the plantar fascia is worth trying. When an injection is necessary, a medial approach is used, rather than advancing through the heel pad, often under ultrasound guidance.

Pain in the chest

Musculoskeletal conditions are sometimes a cause of chest pain. An example is Tietze's disease. In this condition, pain arises from the costosternal junctions. It is usually unilateral and affects one, two, or three ribs. There is local tenderness, which helps to make the diagnosis. The condition is benign and self-limiting. It often responds well to anti-inflammatory drugs. Other causes of chest wall pain include rib fractures due to trauma, osteoporosis, or a malignant deposit. Costochondral pain occurs in ankylosing spondylitis (see 'Ankylosing

spondylitis' section). In people with heart disease, costochondral pain may cause severe anxiety but it is not like angina and the patient should be reassured.

Pain associated with sport and the performing arts

Pain in muscles and soft tissues is common after sport or associated with performing arts, such as dancing or playing musical instruments. General advice, such as warming up properly and using appropriate supportive footwear for running, can help. However, in cases of prolonged pain or where the person suffering pain is a professional sportsperson or performer, referral to a sports medicine specialist is advisable.

CHRONIC PAIN SYNDROMES

Chronic pain is defined as pain lasting more than 3 months (the natural tissue-healing time). Many rheumatological illnesses (e.g., RA and OA) cause pain of such duration but are not considered as chronic pain syndromes. In chronic pain syndromes, the pain generally has no clear structural cause or curative treatment and is often combined with psychological distress, poor sleep, and altered use of the muscles due to the pain (called fear-avoidance behaviour or abnormal pain behaviour). This altered behaviour can lead to more stress and tension in the muscles, exacerbating the pain (Fig. 32.13).

The pain suffered by these patients is neither imaginary nor artefactual, even though there may be no structural abnormality in the painful area. There is a problem with the pain processing system in the nervous system, leading to amplification of pain signals. Psychological factors often contribute to this amplification, and the pain can make psychological distress worse, in a vicious circle. The combination of physical pain and psychological distress makes these syndromes difficult to manage.

Living with chronic pain is difficult. Patients may become anxious, depressed, or socially isolated, and their quality of life is reduced. There are often adverse effects on employment, personal relationships, and dependence on others. Consultations need to address these issues, as well as the pain itself, to be effective. In chronic pain syndromes, patients need help to lead a more normal life despite their pain, and are best referred to a specialist, multidisciplinary pain service. Medications alone are not the answer.

These syndromes can be conveniently subdivided into chronic widespread pain (above and below the waist and on both sides of the body) and chronic regional pain (any other distribution). Both are very common. Epidemiological studies show that the prevalence of chronic widespread pain is 10%–11% and that of chronic regional pain is 20%–30%.

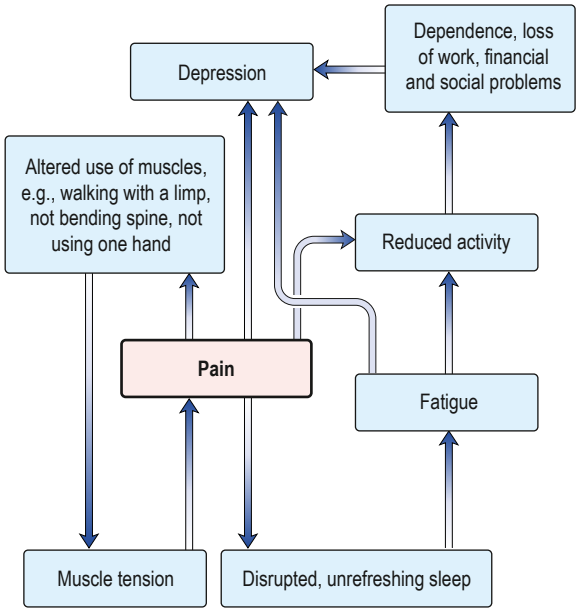

Fig. 32.13 Interaction of physical and psychological factors in chronic widespread pain.

Chronic widespread pain

Pain that starts in a single area can spread to other areas of the body, as more muscles become tense and tender. Conversely, patients with chronic widespread pain can develop new, localized causes of pain (e.g., appendicitis, OA) that can be treated successfully. It should not be assumed that every pain in these patients is always due to the same chronic problem.

Two of the main causes of chronic widespread pain are fibromyalgia and hypermobility spectrum disorders (HSDs; see 'Hypermobile Ehlers–Danlos syndrome and hypermobility spectrum disorders' section).

Fibromyalgia

Fibromyalgia is not a diagnosis of exclusion. It can occur in patients who have other illnesses like RA and SLE. Individuals suffer chronic widespread pain with disrupted and unrefreshing sleep, constant tiredness, and tender points detectable on pressing their muscles (Fig. 32.14). Multiple other symptoms, such as irritable bowel syndrome (IBS), tension headaches, dysmenorrhoea, atypical facial or chest pain, and forgetfulness, often coexist. It occurs in about 1 in 50 people, can develop at any age and affects females more than males (2:1). The diagnosis is clinical, and blood tests and imaging are normal. These tests may be requested to exclude other causes of pain.

Management

See also Chapter 30. A clear explanation of the diagnosis is vital. While being honest about the fact that there is no cure for fibromyalgia, it is also necessary to reassure the patient that it is not arthritis and that the pain is not causing damage to joints or muscles. Many patients have never had an explanation of the cause of their symptoms, which leads to fear and doubt. Treatment options that can be offered to help (not cure) are described below. Management guidelines stress use of non-drug measures instead of or alongside drugs.

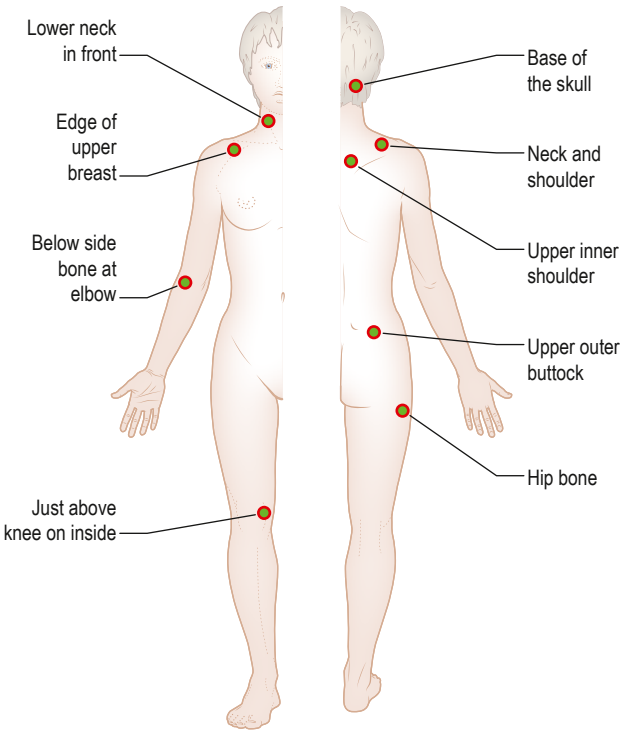

Fig. 32.14 **Trigger points in fibromyalgia.**

Drugs

There is evidence from clinical trials for use of analgesics, anticonvulsants, and antidepressants. Commonly used drugs include amitriptyline (which may also improve sleep), pregabalin, paracetamol, tramadol, duloxetine, and gabapentin. Benefits, however, are often short-term and adverse effects common.

Non-drug therapies

A sympathetic, psychosocial, multidisciplinary approach is appropriate. A graded, supervised aerobic exercise regimen over 3 months is safe and effective. When depression is present, it should be treated. Cognitive behavioural therapy can help the person to pace their life more effectively and to cope better. Pain management programmes, combining psychology with physiotherapy, are designed to improve physical function and quality of life but do not reduce pain intensity. Acupuncture can lessen pain in some cases but the effect is usually transient.

Chronic regional pain

Chronic (work-related) upper-limb pain syndrome

This term is preferred to 'repetitive strain injury' (RSI). The predominant symptoms are pain in all or part of one or both arms. A specific lesion, such as tennis elbow or carpal tunnel syndrome, or muscular-pattern neck pain often develops first, and early recognition and treatment may prevent chronicity. After a variable period, the pain becomes more diffuse and no longer simply work-related, and there is often severe distress. It is seen in keyboard workers and in musicians. When it arises at work, it is often at a time of stress, such as changing work practices, shortage of staff, or disharmony.

Management

If possible, there should be a brief period off work and a gradual return to activity as the pain settles. Use of analgesia and NSAIDs, with physiotherapy, is helpful during the initial phase to prevent a vicious circle developing. Amitriptyline or pregabalin is helpful for some patients.

A review of working practices and the positioning of screen, keyboard, and chair are essential, as is support of the patient by their manager. Musicians are helped by expert advice on playing technique and should reduce playing times temporarily, but not stop completely.

Temporomandibular pain dysfunction syndrome

This pain syndrome is a disorder of the temporomandibular joint that is associated with nocturnal tooth grinding or abnormalities of bite. It occurs most commonly in anxious people. It gives rise to pain in one or both temporomandibular joints.

Dental correction of the bite helps a few, but when no dental cause is found, low-dose tricyclic antidepressant therapy is used. Many patients are made worse by unnecessary dental treatment.

Complex regional pain syndrome

Complex regional pain syndrome (CRPS) is a rare condition (prevalence 20:100 000), in which regional neuropathic pain is associated with abnormal sensory, autonomic, motor, and/or trophic changes. There are two types. In CRPS type I, there is no identifiable overt nerve lesion, whereas such a lesion is identifiable in CRPS type II. CRPS usually occurs after trauma but the pain is disproportionate in time or intensity to that usually caused by such an injury. It may also develop after central nervous system (CNS) lesions (e.g., strokes) or without cause.

Its features are pain and other sensory abnormalities, including hyperaesthesia; and autonomic vasomotor dysfunction, leading to abnormal blood flow and sweating; and motor system abnormalities, leading to structural changes of superficial and deep tissues (trophic changes). Not all components need be present. The sensory, motor, and sympathetic nerve changes are not restricted to the distribution of a single nerve and may be remote from the site of injury. The early phase, with pain, swelling, and increased skin temperature, is difficult to diagnose but potentially reversible.

After a period of weeks or months, a second, still painful, dystrophic phase develops, characterized by articular stiffness, cold skin, and trophic changes, often with localized osteoporosis.

A late phase involves continued pain, skin and muscle atrophy, and muscle contractures, and is extremely disabling.

Diagnosis is clinical—a high index of suspicion and recognition of the unusual distribution of the pain. There are no specific or sensitive investigations, though demineralization may be seen on X-ray. Bone scan and MRI are not required to make the diagnosis.

Management

Management is difficult and the problem is often very disabling. The evidence base for treatment is poor. Early diagnosis, effective pain relief, and general care of the patient are essential. NSAIDs, tricyclic antidepressants, serotonin–norepinephrine reuptake inhibitors, and pregabalin or gabapentin are used in the early phase, together with active exercise of the limb, encouraged by a physiotherapist. Intravenous bisphosphonates can also be effective. Referral to a specialist pain clinic is essential. Nerve blocks were used in the past but are less common now. Intravenous immunoglobulins have been used in clinical trials but are not yet an accepted therapy.

ANALGESIC AND ANTI-INFLAMMATORY DRUGS FOR MUSCULOSKELETAL PROBLEMS

The key to using drugs, particularly in chronic disorders and the elderly, is to balance risk and benefit and to review their appropriateness constantly. **Box 32.18** shows the main drugs available.

Simple and compound analgesic agents

Simple agents, such as paracetamol, aspirin, or codeine compounds (or combination preparations), used when necessary or regularly, relieve pain and improve function. Sleep may also be improved. Side-effects are relatively infrequent, although drowsiness and constipation occur with codeine preparations, especially in the elderly.

Stronger analgesics, such as dihydrocodeine, tramadol, or morphine derivatives, should be used only for severe pain.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) have anti-inflammatory and centrally acting analgesic properties. They inhibit cyclo-oxygenase (COX), a key enzyme in the formation of prostaglandins, prostacyclins, and thromboxanes). There are two specific COX enzymes:

- ***COX-1*** is the constitutive form present in many normal tissues.
- ***COX-2*** is the form mainly induced in response to pro-inflammatory cytokines and is not found in most normal tissues (except the kidney). It is associated with oedema and the nociceptive and pyretic effects of inflammation.

i Box 32.18 Analgesics and NSAIDs

Drug	Dose	Frequency
Analgesics[a]		
To be taken only if needed. Maximum doses are indicated.		
Paracetamol	500–1000 mg	6-hourly
Paracetamol (500 mg) and codeine (8–30 mg)	1–2 tablets	6-hourly
Dihydrocodeine	30–60 mg	Every 6–8 h
Paracetamol with dihydrocodeine (e.g., 'Co-dydramol' preparations)	1–2 tablets	Every 6–8 h
Non-steroidal anti-inflammatory drugs (NSAIDs)		
Always to be taken with food. Slow-release preparations are used in inflammatory conditions or if more regular pain control is needed. Examples are shown.		
Ibuprofen	200–400 mg	Every 6–8 h
Ibuprofen slow-release	600–800 mg	12-hourly
Diclofenac	25–50 mg	8-hourly
Diclofenac slow-release	75–100 mg	×1–2 daily
Naproxen	250 mg	×3–4 daily
Celecoxib[b]	100–200 mg	×2 daily

[a]In order of potency.
[b]COX-2-specific NSAID (coxib).

Effects and side-effects

Most of the older NSAIDs are non-specific and block both enzymes but with variable specificity ('non-specific NSAIDs', or nsNSAIDs). Their therapeutic effect depends on blocking COX-2 and their side-effects mainly on blocking COX-1. COX-1 protects the gastric mucosa and blocking it accounts for the majority of upper gastrointestinal side-effects.

The most common side-effects with non-specific NSAIDs are indigestion or skin rashes. More serious upper gastrointestinal side-effects are gastric erosions and peptic ulceration with perforation and bleeding. These occur more frequently in the elderly, in whom mortality is higher, in long-term use, and in those with high-risk factors: a history of ulcers, *Helicobacter pylori*, and concurrent corticosteroid or anticoagulant therapy. Ibuprofen, in combination with low-dose aspirin, significantly increases the risk of severe gastrointestinal bleeding. Practice guidelines recommend proton pump inhibitors in high-gastrointestinal-risk patients on non-specific NSAIDs. H_2 blockers are less effective as gastroprotective agents. Prostaglandin E_2 analogues, such as misoprostol, reduce ulcer complications and are popular, but may cause nausea and diarrhoea. Lower gastrointestinal side-effects of non-specific NSAIDs are becoming more common.

COX-2 inhibitors ('coxibs') produce fewer gastrointestinal side-effects but these still occur. Coxibs are used in patients who have a high risk of gastrointestinal disease but are avoided in patients with cardiovascular risks. In fact, all NSAIDs can cause an increase in risk of cardiovascular events, such as myocardial infarction or stroke. NSAIDs and coxibs also increase the risk of heart failure.

Coxibs and NSAIDs may reduce renal function, especially in the elderly (see **Box 26.21**).

Uses

- ***In musculoskeletal pain and in OA and spondylosis***, short courses of NSAIDs or coxibs are used but simple analgesia is often more appropriate.
- ***In crystal synovitis***, NSAIDs and coxibs have a true anti-inflammatory effect.
- ***In chronic inflammatory synovitis***, NSAIDs and coxibs do not alter the chronic inflammatory process or decrease the risk of joint damage, but they do reduce pain and stiffness.
- ***In inflammatory arthritis and situations where more constant pain control is needed***, slow-release preparations are useful.
- ***In chronic arthritis***, NSAID gels have some value.

The standard advice is to use NSAID in the lowest dose possible for the shortest time necessary to control pain. Be aware of the patient's gastrointestinal, renal, and cardiac risks before prescribing NSAIDs or coxibs.

Box 32.19 The major types of collagen

Collagen structure	Type number	Encoding gene	Associated conditions
Fibrillar	I, II, III, V, XI	*COL1A1–2, COL2A2, COL3, COL5, COL11*	Osteogenesis imperfecta, Ehlers–Danlos syndrome (subtypes)
Basement membrane	IV	*COL4A1–5*	Alport's syndrome (see Chapter 26)
Fibril-associated collagen with interrupted triple helix (FACIT)	IX, XII, XIV	*COL9, 12, 14*	
Filament-producing	VI	*COL6A1–3*	
Network-forming	VIII, X	*COL8A1, 10A1*	
Anchoring fibril	VII	*COL7A1*	Epidermolysis bullosa (see Chapter 45)

Box 32.20 Beighton hypermobility score[a] and diagnostic criteria for joint hypermobility syndrome

Joint	Finding	Score
Little (fifth) finger	Passive dorsiflexion >90 degrees	1 for each side
Thumb	Passive dorsiflexion to the flexor aspect of the forearm	1 for each side
Elbow	Hyperextends >10 degrees, extends ≤10 degrees	1 for each side
Knee	Hyperextends >10 degrees, extends ≤10 degrees	1 for each side
Forward flexion of trunk with the knees fully extended	Palms can rest flat on the floor	1

[a]In this 9-point system, the higher the score, the higher the laxity. Young adults can score 4–6. Diagnostic criteria for joint hypermobility syndrome: Beighton score ≥4; arthralgia for ≥3 months in ≥4 joints.

DISORDERS OF COLLAGEN

Collagen is responsible for many of the structural, tensile, and load-bearing properties in the various tissues where it is found. Thirty or more dispersed genes encode for more than 19 different types of collagens (**Box 32.19**).

Hypermobile Ehlers–Danlos syndrome and hypermobility spectrum disorders

Hypermobility is very common (15%–20% of adults); it may be demonstrated by showing increased flexibility in the thumbs, little fingers, elbows, knees, and lumbar spine, and quantified using the Beighton score (**Box 32.20**). The majority of hypermobile people suffer no adverse effects from the hypermobility but in some it can cause recurrent subluxations of individual joints and/or persistent widespread musculoskeletal pains. According to the 2017 classification, these people are classified into two groups; hypermobile Ehlers–Danlos syndrome (hEDS) for those who fulfil specific classification criteria and hypermobility spectrum disorder (HSD) for those who do not. Both groups may suffer other symptoms such as bowel disturbance, easy scarring, and faintness on standing (postural orthostatic tachycardia syndrome; POTS), and the combination can be very disruptive to normal life. Treatment of the musculoskeletal symptoms relies on specialist physiotherapy to advise on exercises that take the patient's hypermobility into account. Pain management programmes can be helpful in more severe cases. It is usually better to avoid surgery due to difficulties in healing.

Other forms of Ehlers–Danlos syndrome

Whereas hEDS is the most common form of EDS and has no known genetic basis, there are 12 rarer forms that have all been linked to particular genes encoding collagen or collagen modifiers. These rarer forms are named according to their clinical phenotype for example classical EDS, classical-like EDS, cardiac valvular EDS, vascular EDS, and kyphoscoliotic EDS. Classical, vascular, arthrochalasia, and periodontal EDS are autosomal dominant whereas the others are autosomal recessive (myopathic EDS can be either).

Vascular EDS can be particularly severe and the most common form is associated with an autosomal dominant mutation in the *COL3A1* gene. These patients may suffer rupture of arteries, the sigmoid colon, or the uterus and have hypermobility in small rather than large joints.

Marfan's syndrome

This condition is described in Chapter 17.

Osteogenesis imperfecta

This is a heterogeneous group of disorders inherited mainly in autosomal dominant fashion with mutations in *COL1A1* and *COL1A2* genes. There are four main types of osteogenesis imperfecta and clinical subtypes are also described (V, VI, and VII). The major clinical feature is bone fragility but other collagen-containing tissues are also involved, such as tendons, skin, and eyes.

- ***Type I:*** mild bony deformities, blue sclerae, defective dentine, early-onset deafness, hypermobility of joints and heart valve disorders
- ***Type II:*** death in the perinatal period
- ***Type III:*** severe bone deformity and blue sclerae
- ***Type IV:*** fewer fractures, normal sclerae, normal lifespan but can also be severe, as in type III.

Management with daily oral risedronate in children improves BMD and reduces fracture risk. Intravenous pamidronate is another option. Prognosis is variable, depending on the severity of the disease. Stem cell therapy is being used. Types I and IV are associated with normal lifespan and people with these forms continue to have increased fracture risk into adulthood.

Achondroplasia

Achondroplasia ('dwarfism') is diagnosed in the first years of life. The disease is inherited in an autosomal dominant manner and is caused by a defect in the fibroblast growth factor receptor-3 gene. The trunk is of normal length but the limbs are very short and broad due to abnormal endochondral ossification. The vault of the skull is enlarged, the face is small and the nose bridge is flat. Intelligence is normal.

OSTEOARTHRITIS

Osteoarthritis (OA) is the most common type of arthritis. It results from a loss of articular cartilage induced by an interaction of genetic, metabolic, and biomechanical factors, affecting cartilage, subchondral bone, ligaments, menisci, synovium, and capsule. Despite intense investigation, disease-modifying therapies remain elusive for this condition.

Epidemiology

Globally approximately 1 in 5 females and 1 in 10 males aged over 60 years have symptomatic OA, such that 80% have limitations in movement and 25% cannot perform major daily activities of life. Worldwide it has a variable pattern of presentation. For instance, hip OA is less common and knee OA is more common in Asians than in Europeans. Beyond 55 years of age, females are affected more commonly than males by nodal and primary generalized forms of OA, with strong familial predisposition. Resulting disabilities have major socioeconomic resource implications, particularly in the developed world where OA is one of the ten most disabling diseases in older adults.

Aetiology and pathogenesis

Cartilage is a matrix of water (>70%) and organic extracellular matrix components, mainly type II collagen and aggrecan or other proteoglycans; it has a smooth surface and shock-absorbing properties. OA is now considered a disease of the whole joint with alterations in subchondral bone, ligaments, capsule, synovial membrane as well as articular cartilage. Consequent structural changes include surface fibrillation and ulceration with loss of cartilage that exposes underlying bone to increased stress, producing microfractures and cysts leading to abnormal sclerotic subchondral bone and overgrowths at the joint margins, called osteophytes (Fig. 32.15). Inflammatory changes may also occur. This process produces a spectrum of OA, ranging from atrophic disease in which cartilage destruction occurs without any subchondral bone response, to hypertrophic disease with massive new bone formation at the joint margins.

Various mechanisms have been suggested:

- ***Abnormal stress and loading***, leading to mechanical cartilage damage.
- ***Obesity*** is a risk factor for developing OA of the hand and knee and thought to trigger metabolic inflammation via adipokines, released from adipose tissue, inducing pro-inflammatory cytokines that cause cartilage and bone damage.
- ***Matrix degradation*** by matrix metalloproteinase (MMP)-1, MMP-2, MMP-3, MMP-9, and MMP-13, which are secreted by chondrocytes in an inactive form. Extracellular activation then leads to the degradation of both collagen and proteoglycans around chondrocytes.
- ***Tissue inhibitors of metalloproteinases*** (TIMPs) regulate the MMPs. Disturbance of this regulation may lead to an increase in cartilage degradation over synthesis and contribute to the development of OA.

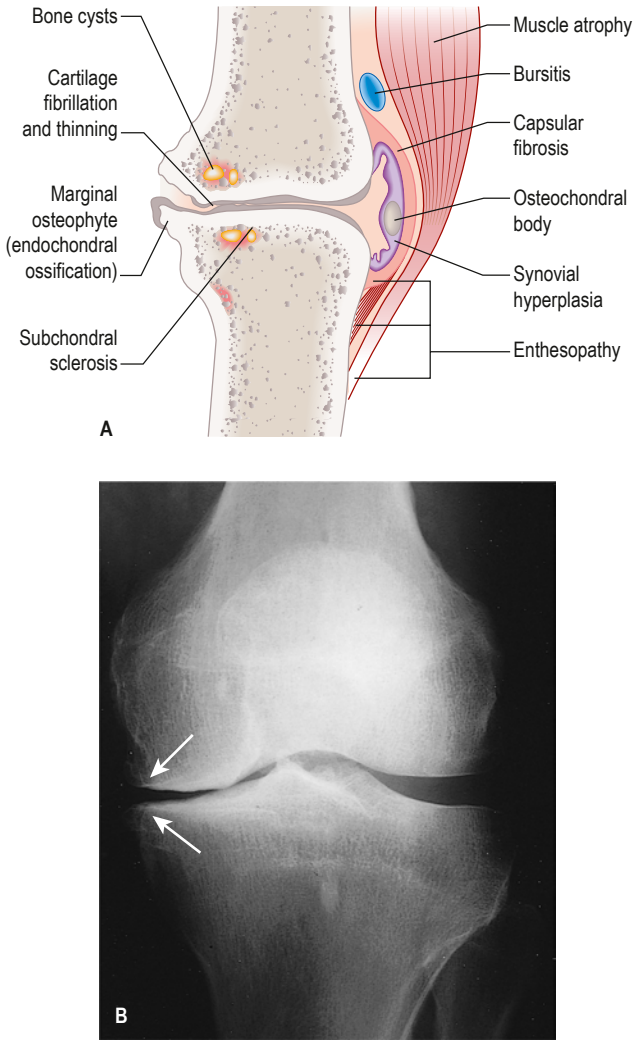

Fig. 32.15 Early osteoarthritis of a knee. (A) Pathology. (B) On the X-ray, there is medial compartment narrowing owing to cartilage thinning with subarticular sclerosis and marginal osteophyte formation *(arrowed)*.

- ***Osteoprotegerin (OPG), RANK, and RANK ligand (RANKL)*** control subchondral bone remodelling. Their levels are significantly different in OA chondrocytes.
- ***Aggrecanase*** production is stimulated by pro-inflammatory cytokines, and aggrecan (the major proteoglycan) levels fall.
- ***Inflammatory mediator release*** (including interleukin-1, IL-1 and tumour necrosis factor-alpha, TNF-α) stimulates metalloproteinase production, and IL-1 inhibits type II collagen production. IL-6 and IL-8 may also be involved. The production of cytokines by macrophages and that of MMPs by chondrocytes in OA are dependent on the transcription factor nuclear factor kappa B (NF-κB).
- ***Growth factors***, including insulin-like growth factor 1 (IGF-1) and transforming growth factor beta (TGF-β), are involved in collagen synthesis, and their deficiency may play a role in impairing matrix repair. Paradoxically, increased TGF-β may also cause increased subchondral bone density.
- ***Cell derived and/or cartilage breakdown products***, such as alarmins, fibronectin fragments, hyaluronic acid fragments, collagen fragments, proteoglycan fragments, and high mobility group box proteins, act to further deregulate chondrocyte function and contribute to cartilage degradation.

- ***Vascular endothelial growth factor (VEGF)*** from macrophages is a potent stimulator of angiogenesis and may contribute to inflammation and neovascularization in OA. Innervation can accompany vascularization of the articular cartilage.
- ***A strong hereditary element*** underlying OA is suggested by twin studies. The influence of genetic factors is estimated at 35%–65%. To date, genome-wide association studies (GWAS) have identified several common variants associated with knee or hip OA, although the individual risk alleles exert only moderate to small effects. Loci that are associated with OA include genes encoding components of the TGF-β and bone morphogenetic protein signalling pathways: growth/differentiation factor 5 (GDF5); type II iodothyronine deiodinase (DIO2), which regulates synthesis of triiodothyronine that is involved in cartilage maintenance and repair; proteins involved in apoptosis and mitochondrial damage; molecules that regulate the turnover of extracellular matrix components; and proteins that are associated with inflammation and immune responses.
- ***Sex.*** In females, weight-bearing sports produce a two- to threefold increase in risk of OA of the hip and knee. In males, there is an association between hip OA and certain occupations: farming and labouring. OA may flare after the female menopause or after cessation of hormone replacement therapy.
- ***Periarticular enthesitis*** is recognized in nodal generalized OA (NGOA) and may be difficult to distinguish from psoriatic arthritis at DIP joints.

The term ***primary OA*** may be used when various predisposing factors (**Box 32.21**), occur in the absence of other conditions that may cause secondary OA (**Box 32.22**).

Box 32.21 Factors predisposing to osteoarthritis (OA)

- Obesity: This predicts a later risk of radiological and symptomatic OA of the hip and hand in population studies
- Heredity: There is a familial tendency to develop nodal and generalized OA
- Gender: Polyarticular OA is more common in females; a higher prevalence after the menopause suggests a role for sex hormones
- Hypermobility (see 'Hypermobile Ehlers–Danlos syndrome and hypermobility spectrum disorders' section): Increased range of joint motion and reduced stability lead to OA
- Diseases: See **Box 32.22**
- Trauma: A fracture through any joint predisposes. Meniscal and cruciate ligament tears cause OA of the knee
- Congenital joint dysplasia: This alters joint biomechanics and leads to OA. Mild acetabular dysplasia is common and leads to earlier onset of hip OA
- Joint congruity: Congenital dislocation of the hip or a slipped femoral epiphysis or Perthes' disease predispose; osteonecrosis of the femoral head (see Chapter 33) in children and adolescents causes early-onset OA
- Occupation: Miners develop OA of the hip, knee and shoulder, cotton workers OA of the hand, and farmers OA of the hip
- Sport: Repetitive use and injury in some sports cause a high incidence of lower-limb OA

Box 32.22 Causes of osteoarthritis

Primary OA
- No known cause

Secondary OA

Pre-existing joint damage
- Rheumatoid arthritis
- Gout
- Spondyloarthritis
- Trauma
- Overuse/abnormal use, e.g., athletes
- Septic arthritis
- Paget's disease
- Avascular necrosis, e.g., corticosteroid therapy

Metabolic disease
- Cartilage calcification
- Hereditary haemochromatosis
- Acromegaly

Systemic disease
- Haemophilia—recurrent haemarthrosis
- Haemoglobinopathies, e.g., sickle cell disease
- Neuropathies

Clinical features

OA affects many joints, in diverse clinical patterns, typically causing mechanical pain with movement and/or loss of function (**Fig. 32.16**). Hip and knee OA are major causes of disability. Early OA is rarely symptomatic, however, unless accompanied by a joint effusion, while advanced radiological and pathological OA is not always symptomatic.

Symptoms are usually gradual in onset and progressive. Episodic disease flare-ups may be inflammatory in nature, although typically ESR and/or CRP are normal. Radiological OA is not inevitably progressive. Radiological improvement is uncommon but has been observed, suggesting that repair is possible.

Symptoms

- Joint pain with movement and/or weight-bearing
- Short-lived morning joint stiffness
- Functional limitation

Signs

- Crepitus
- Restricted movement
- Bony enlargement
- Joint effusion and variable levels of inflammation
- Bony instability and muscle wasting

Clinical subsets

Localized OA

Nodal OA

In nodal OA (**Box 32.23**), joints of the hand are usually affected one at a time over several years, with the DIPs more frequently involved than the PIPs. Nodal OA often begins around the female menopause, with inflammation causing painful, tender, swollen interphalangeal joints and impairment of hand function. At this stage, enthesitis can be seen on MRI. Intra-articular corticosteroid injections may be helpful at this stage. The inflammatory phase settles after some months or years, leaving painless bony swellings posterolaterally: ***Heberden's nodes (DIPs)*** and ***Bouchard's nodes (PIPs)***, along with stiffness and deformity (**Fig. 32.17**). Functional impairment is usually limited, although PIP OA restricts grip more than DIP involvement. On X-ray, the nodes are marginal osteophytes and there is joint space loss.

Thumb-base OA coexists with nodal OA causing pain and disability, which decrease as the joint stiffens. The 'squared' hand in OA (see **Fig. 32.17**) is caused by bony swelling of the first carpometacarpal joint and fixed adduction of the thumb. Function is rarely severely compromised.

Polyarticular hand OA is associated with a slightly increased frequency of OA at other sites.

Hip OA

Hip OA affects 7%–25% of adult white people but is significantly less common in black and Asian populations. There are two major subgroups defined by the radiological appearance. The most common is ***superior-pole hip OA***, where joint space narrowing and

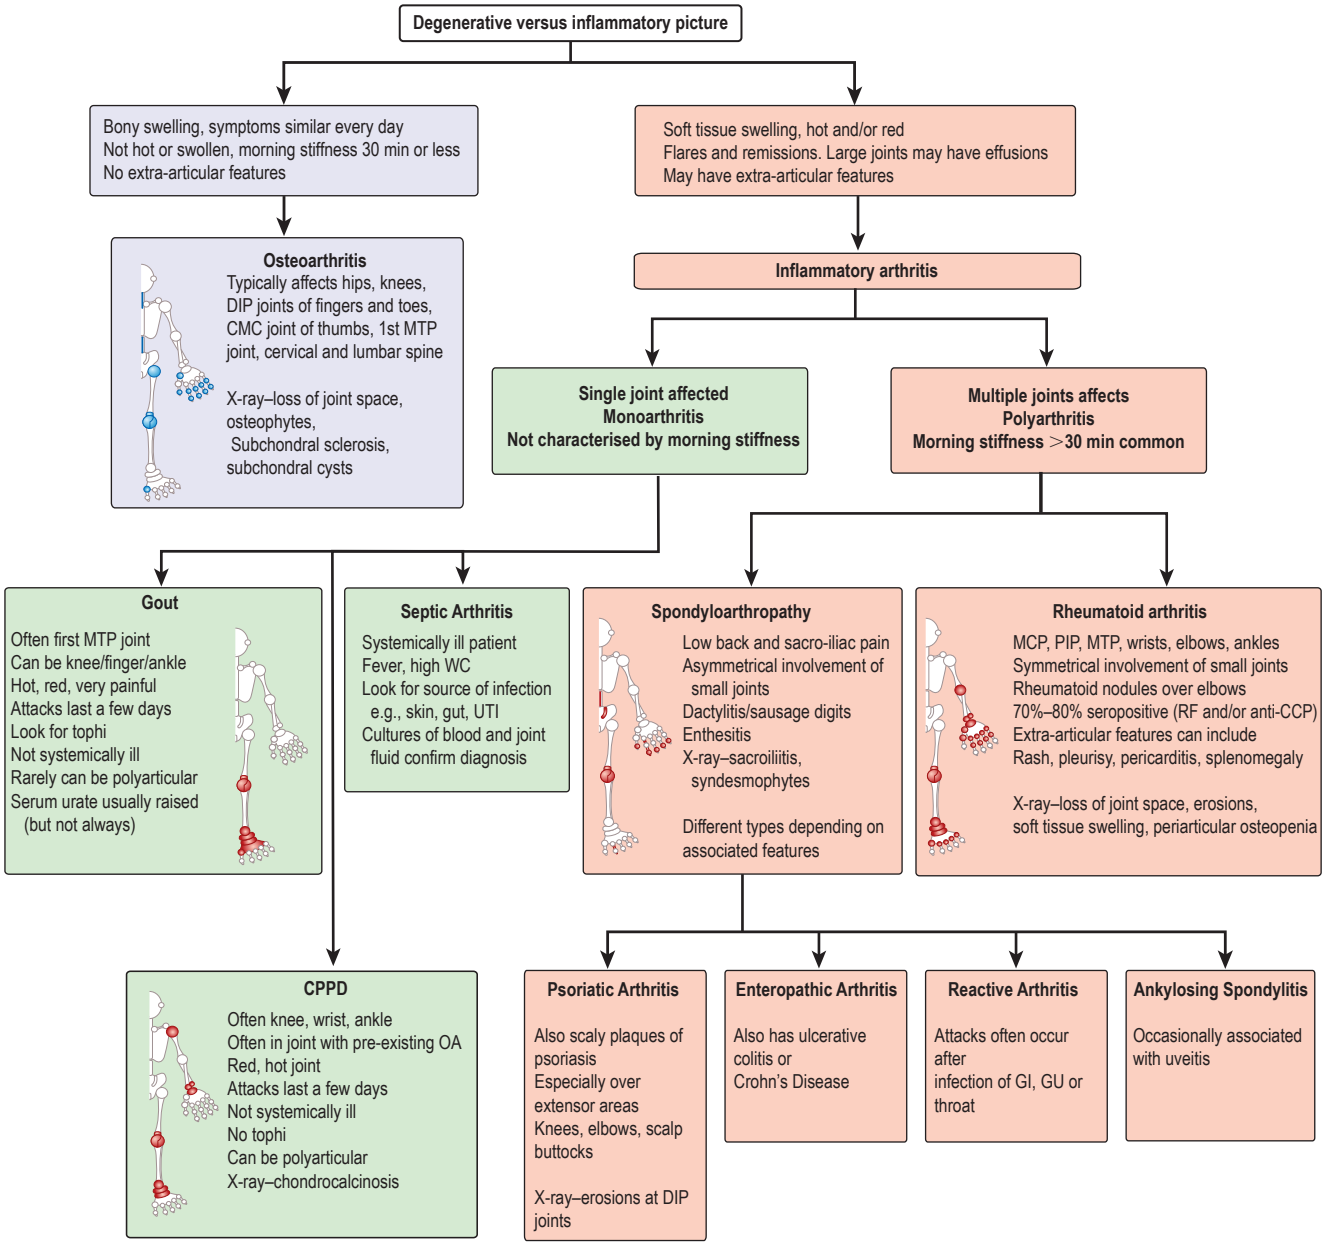

Fig. 32.16 Patterns of joint involvement in degenerative and inflammatory arthritis. *CMC,* Carpometacarpal; *CPPD,* calcium pyrophosphate deposition; *DIP,* distal interphalangeal; *MCP,* metacarpophalangeal; *MTP,* metatarsophalangeal; *PIP,* proximal interphalangeal; *RF,* rheumatoid factor; *WC,* white cell count.

i Box 32.23 Features of nodal osteoarthritis

- Demonstrates a familial nature
- Has a higher incidence in females
- Shows a typical pattern of polyarticular involvement of the hand joints
- Develops in late middle age and around female menopause
- Has a generally good long-term functional outcome
- Is associated with osteoarthritis of the knee, hip, and spine (nodal generalized osteoarthritis)

sclerosis predominantly affect the weight-bearing upper surface of the femoral head and adjacent acetabulum. This finding is most common in males and unilateral at presentation, although both hips may become involved in progressive disease. Early onset of hip OA is associated with acetabular dysplasia or labral tears. Less commonly, ***medial cartilage loss*** occurs. This appearance is seen most commonly in females and is associated with hand involvement (NGOA), and is usually bilateral. It is more rapidly disabling.

Knee OA

The prevalence of symptomatic knee OA is 40% in individuals over 75 years of age and is more common in females and black compared with white people. There is a strong relationship with obesity. The disease is generally bilateral and strongly associated with nodal OA of the hand in elderly females, or as part of generalized OA. The medial compartment is most commonly affected, leading to a varus (bow-legged) deformity. Often, retropatellar OA is also present. Previous trauma and meniscal and cruciate ligament tears are

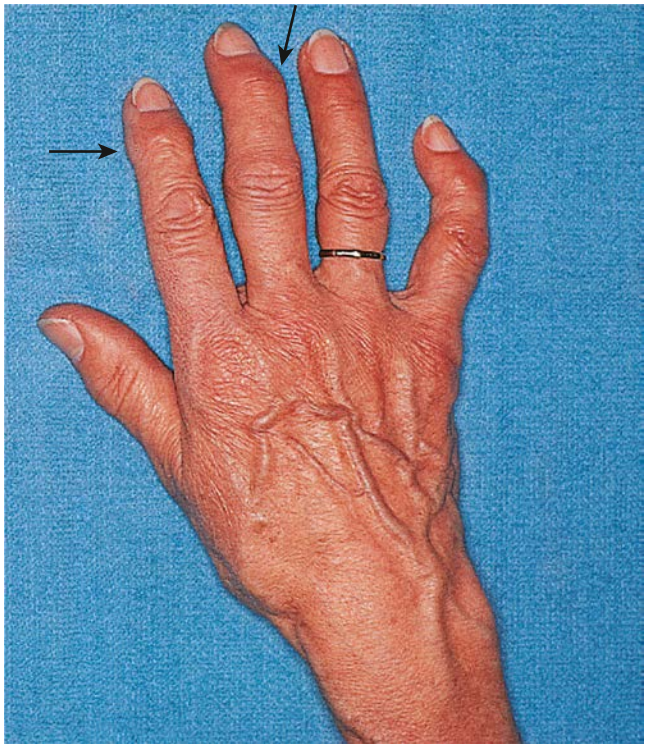

Fig. 32.17 Severe nodal osteoarthritis. The distal interphalangeal joints (DIPs) demonstrate Heberden's nodes *(arrowed)*. The middle finger DIP joint is deformed and unstable. The thumb is adducted and the bony swelling of the first carpometacarpal joint is clearly shown—'the squared hand of nodal osteoarthritis'.

risk factors for developing knee OA. Bone marrow lesions seen on MRI predict disease progression and eventual joint replacement.

Primary generalized OA

This condition is rare and usually seen in combination with NGOA. Other affected areas include the knees, first MTP, hip, and intervertebral (spondylosis) joints. Its onset is often sudden and severe. There is a female preponderance and a strong familial tendency. Periarticular ligamentous pathology may have an important role in the phenotypic expression of NGOA.

Erosive OA

In this rare subgroup, the DIPs and PIPs are inflamed and equally affected, with a poor functional outcome. Radiologically, there is marked osteolysis. Destructive phases are followed by phases of remodelling.

Crystal-associated OA

This condition most commonly occurs with calcium pyrophosphate deposition (CPPD) in the cartilage. It increases in frequency with age and causes cartilage calcification (CC) on over 40% of knee X-rays in the over-eighties, but is usually asymptomatic. The joints most frequently affected are the knees (hyaline cartilage and fibrocartilage) and wrists (triangular fibrocartilage); see Fig. 32.16. There is patchy linear CC on X-ray (Fig. 32.18).

A chronic arthropathy (pseudo-OA) occurs, predominantly in elderly females with severe CC. There is a florid inflammatory component and marked osteophyte and cyst formation visible on X-rays that predominantly affects the knees, then wrists and shoulders. CC is associated with CPPD crystal-induced arthritis (see 'Calcium pyrophosphate dihydrate deposition arthropathy' section).

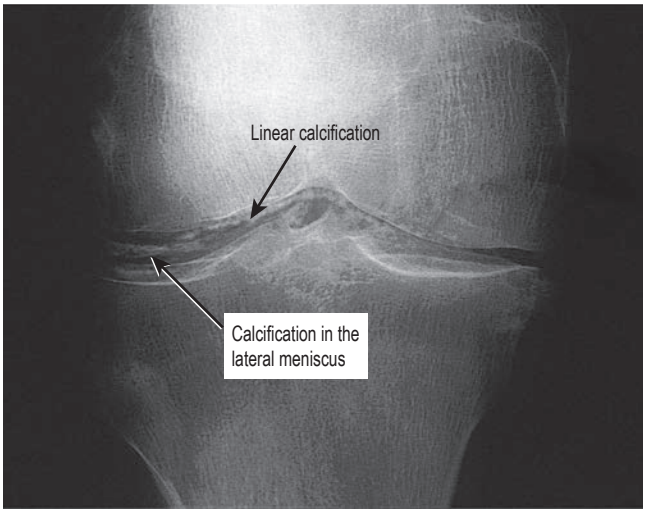

Fig. 32.18 Cartilage calcification of the knee. Note the linear calcification in the hyaline cartilage and calcification of the lateral meniscus (plus mild secondary osteoarthritis).

A rare, rapidly destructive arthritis in elderly females, affecting shoulders, hips, and knees, is associated with the finding of crystals of calcium apatite in a bloody joint effusion. The outlook is poor and joints require early surgical replacement.

Investigations

- ***Blood tests*** lack specificity; the ESR is usually normal, although high-sensitivity CRP may be slightly raised. RFs and antinuclear antibodies are negative.
- ***X-rays*** are abnormal only when the damage is advanced. They are useful in preoperative assessments. For knees, a standing X-ray (stressed) is used to assess cartilage loss, and 'skyline' views in flexion are used for patello-femoral OA.
- ***MRI*** demonstrates meniscal tears, early cartilage injury, and subchondral bone marrow changes (osteochondral lesions).
- ***Arthroscopy*** reveals early fissuring and surface erosion of the cartilage.
- ***Aspiration of synovial fluid*** if there is a painful effusion shows a viscous fluid with few leucocytes (see 'Joint aspiration and examination of synovial fluid' section).

Management

The guiding principle is to treat the symptoms and disability, not the radiological appearances; depression and poor quadriceps strength are better predictors of pain than radiological severity in OA of the knee. Patient education about the disease and its effects reduces pain, distress, and disability, and increases compliance with treatment. Psychological or social factors alter the impact of the disease.

Physical measures

Weight management is recognized to reduce the risk of development of OA and slow its progression. Females who lost an average of 5 kg decreased their risk for knee OA by 50% in the Framingham study. As little as 1% change in body weight in obese adults modifies the rate of knee cartilage loss. Overall, maintenance of muscle mass and reduction of adiposity is central to OA management. Exercises for strength and stability are useful and land-based exercise programmes for the hip and knee improve physical function and pain. Hydrotherapy helps, especially in lower-limb OA. Insoles for flat feet and a walking stick held on the contralateral side to the

affected lower limb joint are useful. Transcutaneous electrical nerve stimulation, acupuncture, and thermotherapy may be adjuncts for treating OA but are not universally recommended due to their limited evidence of efficacy.

Medication

Topical, oral, and injectable therapies are available and potential benefit must be balanced against potential side-effects, especially in the elderly. First-line therapies include topical or oral NSAIDs. Paracetamol has limited efficacy in OA (see **Box 32.18**). NSAIDs or coxibs should be used intermittently when possible due to their toxicities. Topical rubefacients, such as capsaicin, may be used as a supplementary analgesic. Opioids are a last resort and should be used cautiously in older patients.

Intra-articular corticosteroid injections may produce short-term (~6 weeks) improvement when there is a painful joint effusion in elderly patients unsuitable for joint replacement, but symptoms are likely to return. There are concerns of possible cartilage degradation and worsening symptoms with repeat injections over 2 years. Heterogeneity of relevant studies of intra-articular hyaluronan preparations displays limited efficacy.

Glucosamine and chondroitin (sold as food supplements) have no clinically relevant effect on joint pain or joint space narrowing.

There are no proven agents that halt or reverse OA, although they are greatly needed.

Surgery

Arthroscopy for knee OA is rarely beneficial. Replacement arthroplasty, however, has transformed the management of severe OA to reduce pain, improve function, restore quality of life, and regain independence. Increasing numbers of arthroplasties, particularly hip and knee, are being performed worldwide each year with shortened recovery times, improved durability and mortality. However, an increasing trend for hip or knee arthroplasty in patients less than 60 years of age is associated with an increased lifetime risk of revision surgery. Serious complications occur in less than 1%, with venous thromboembolism and infection being the most serious. These slight but definite risks make it essential for the patient to be certain that surgery is necessary. Resurfacing hip surgery has become popular but may have higher complication rates in women, particularly with metal-on-metal resurfacing. Uni-compartmental knee replacement is a less major procedure and may be appropriate in some cases.

Other surgical procedures include re-alignment osteotomy of the knee or hip, excision arthroplasty of the first MTP and base of the thumb, and fusion of a first MTP joint.

INFLAMMATORY ARTHRITIS

Inflammatory arthritis is characterized by synovial inflammation. The three main subgroups of inflammatory arthritis are rheumatoid arthritis (RA), spondyloarthritis, and crystal arthritis (**Box 32.24**). The diagnosis of these conditions is helped by distinguishing:

- the number and pattern of joint involvement (symmetrical or asymmetrical, large or small) (**Box 32.25** and **Fig. 32.16**)
- presence of any non-articular disease
- a past and family history
- periodicity of the arthritis (single acute, relapsing, chronic, and progressive).

Box 32.24 The three main subgroups of inflammatory arthritis

1. Rheumatoid arthritis (associated with antibodies)
2. Spondyloarthritis (associated with human leucocyte antigen (HLA)-B27)
3. Metabolic arthritis (e.g., associated with crystals)

Box 32.25 Pattern of joint involvement in inflammatory arthritis

Monoarthritis
- Crystal arthritis
- Septic arthritis

Oligoarthritis
- ReA
- Palindromic rheumatism
- Crystal arthritis
- Septic arthritis
- *PsA*
- *ReA*

Polyarthritis
- RA
- PsA, AxSpA
- ReA
- Postviral
- Lyme arthritis
- EA
- Arthritis associated with EN

AxSpA, Axial spondyloarthropathy; *EA*, enteropathic arthritis; *EN*, erythema nodosum; *PsA*, psoriatic arthritis; *RA*, rheumatoid arthritis; *ReA*, reactive arthritis. Italics indicate less common pattern of joint involvement.

Certain non-articular diseases, such as psoriasis, iritis, inflammatory bowel disease, non-specific urethritis, or recent dysentery, suggest spondyloarthritis. There may be evidence of recent viral illness (rubella, hepatitis B, or erythrovirus), rheumatic fever, or a tick bite and skin rash (Lyme disease). In early arthritis, it may not be possible to make a specific diagnosis until the disease has evolved from an undifferentiated arthritis into a chronic form.

There is a distinct genetic separation of rheumatoid-pattern synovitis and spondyloarthritis; RA (see below) is associated with a genetic marker in the class II major histocompatibility complex (MHC) genes, while spondyloarthritis shares certain alleles in the B locus of class I MHC genes, usually B27 (see 'Spondyloarthritis' section).

In general, the pain and stiffness of inflammatory arthritis are worse in the morning, often lasting for several hours and improving with activity, in contrast with the much shorter morning stiffness and mechanical pain with activity of OA. Inflammatory markers (ESR and CRP) are typically raised in inflammatory arthritis. Specific types of arthritis are discussed below.

Early inflammatory polyarthritis

Undifferentiated polyarthritis requires urgent referral to a rheumatologist for diagnosis and treatment, including the early introduction of disease-modifying agents when indicated (see 'Disease-modifying anti-rheumatic drugs' section). In persistent inflammatory arthritis, sustained remission depends on rapid diagnosis and intensive treatment. Poor prognostic features for undifferentiated polyarthritis are:

- polyarticular onset
- positive anti-citrullinated peptide antibodies (ACPAs)
- positive rheumatoid factor
- joint erosion on X-ray at presentation
- disease for longer than 3–6 months.

RHEUMATOID ARTHRITIS

RA is a chronic inflammatory rheumatic disease. It has a multifactorial pathogenesis, with various genetic and environmental factors being implicated, giving rise to immune dysregulation with consequent joint inflammation and tissue damage. Patients typically develop a chronic symmetrical polyarthritis with systemic inflammation.

Epidemiology

RA has a worldwide distribution affecting 0.5%–1% of the population (with a female preponderance of 3:1). The prevalence is low in black people of African background and Chinese people. The incidence is falling. RA is the 42nd highest contributor to global disability just below malaria and just above iodine deficiency. It presents from early childhood (when it is rare) to late old age. The most common age of onset is between 30 and 50 years.

Aetiology and pathogenesis

There has been a greater understanding of genetic and environmental factors in the last two decades.

- ***Genetic factors.*** There is an increased incidence in first-degree relatives and a high concordance among monozygotic twins of up to 15%. Over 100 loci are associated with disease risk and progression. There is a strong association between susceptibility to RA and certain human leucocyte antigen (HLA) haplotypes: HLA-DR4, which occurs in 50%–75% of patients and correlates with a poor prognosis, as does possession of certain shared alleles of HLA-DRB1*04. The possession of these shared epitope alleles in HLA-DRB1 (S2 and S3P) increases susceptibility to RA and may predispose to anti-cyclic citrullinated peptide antibody (ACPA) development against citrullinated antigens. Citrullination is a process that modifies antigens, allowing them to fit into the shared epitope on HLA alleles. A genome-wide association study in ACPA-positive RA found an association with loci near HLA-DRB1 and PTPN22 in people of European descent. These genes affect the presentation of autoantigens *(HLA-DRB1)*, T-cell receptor signal transduction *(PTPN22)*, and targets of ACPA *(PAD14)*.
- ***Environment.*** Smoking and other forms of bronchial stress increase the risk of RA with HLA-DR4 and act synergistically with HLA-DRB1 to increase the risk of having ACPA. Mucosal surfaces of the oral cavity, upper respiratory tract, and gut are colonized by commensal microorganisms; a population known as the microbiome. Alterations in the microbiome may facilitate developments in innate and adaptive immunity that predispose to RA, such as the association of periodontal disease and alterations in the gut microbiome with RA.
- ***Autoantibodies.*** Rheumatoid factor (RF), autoantibodies to the Fc portion of immunoglobulin G, are found in 75%–80% of RA patients and are relatively specific for diagnosis of RA compared with other forms of inflammatory arthritis but have little predictive value in the general population. In contrast, ACPA is more specific and sensitive to RA.

Immunology

RA is primarily a synovial disease, and synovitis occurs when chemoattractants produced in the joint recruit circulating inflammatory cells. Over-production of tumour necrosis factor-alpha (TNF-α) leads to synovitis and joint destruction. Interaction of macrophages and T and B lymphocytes drives this over-production. TNF-α stimulates over-production of IL-6, as well as other cytokines. The increased understanding of the immunopathogenesis of this disease has informed the development of targeted biological therapies (**Fig. 32.19**).

Dysfunction of certain cell types is significant in immunopathogenesis:

- ***Synovial cells*** in chronic rheumatoid synovitis are predominantly fibroblast-like synoviocytes and macrophage-like synoviocytes that produce pro-inflammatory cytokines.
- ***Osteoclasts*** cause bone and cartilage destruction.
- ***Synovial B cells***, activated by cytokine-activated macrophages and T cells, produce autoantibodies, of which IgM and IgA RF are the most typical in RA. As RFs bind the Fc portion of IgG, they have the potential for self-aggregation and immune complex formation in the synovium. These may then trigger macrophages via IgG Fc receptors to produce even more cytokines, including IL-1, IL-8, TNF-α, and granulocyte–macrophage colony-stimulating factor, and fibroblasts to produce IL-6.
- ***Synovial fibroblasts*** have high levels of the adhesion molecule, vascular cell adhesion molecule (VCAM-1, a molecule that supports B-lymphocyte survival and differentiation), decay accelerating factor (DAF, a factor that prevents complement-induced cell lysis), and cadherin II (which mediates cell-to-cell interactions). These molecules may facilitate the formation of ectopic lymphoid tissue in synovium.
- ***T cells*** can be a part of the destructive process. The pro-inflammatory cytokine IL-17 is produced by a specific subset, Th17 helper cells (see Chapter 6), which produce IL-17, 21 and 22, and TNF-α. The normal regulatory T cells are suppressed by TGF-β and interleukins (produced by macrophages and dendritic cells), allowing Th17 helper cells to increase.

The ***triggering antigen***, which leads to self-maintained inflammation in RA, remains unclear. Triggers for ACPA production include filaggrin, type II collagen, and vimentin. There is little evidence that type II collagen is the triggering antigen, although it is a cause of arthritis in animal models of RA. Smoking is a potential trigger, particularly in ACPA-positive RA.

Pathology

RA is typified by widespread, persistent synovitis of joints, tendon sheaths, or bursae. Normal synovium comprises a thin lining layer that contains fibroblast-like synoviocytes and macrophages overlying loose connective tissue. In RA, the synovium becomes greatly thickened, causing 'boggy' swelling around joints and tendons, with proliferation of the synovium into folds and fronds, and infiltration by a variety of inflammatory cells, including polymorphs, which transit through the tissue into the joint fluid, and lymphocytes and plasma cells. The normally sparse surface layer of lining cells becomes hyperplastic and thickened (**Fig. 32.20**). There is marked vascular proliferation. Increased permeability of blood vessels and the synovial lining layer leads to joint effusions containing lymphocytes and dying polymorphs.

The hyperplastic synovium spreads from the joint margins to the cartilage surface. This 'pannus' of inflamed synovium damages the underlying cartilage by blocking its normal route for nutrition and by the direct effects of cytokines on the chondrocytes. The cartilage becomes thinned and the underlying bone exposed. Local cytokine production and joint disuse combine to cause juxta-articular osteoporosis during active synovitis.

Fibroblasts from the proliferating synovium also grow along the course of blood vessels between the synovial margins and the epiphyseal bone cavity, and damage the bone. This process is

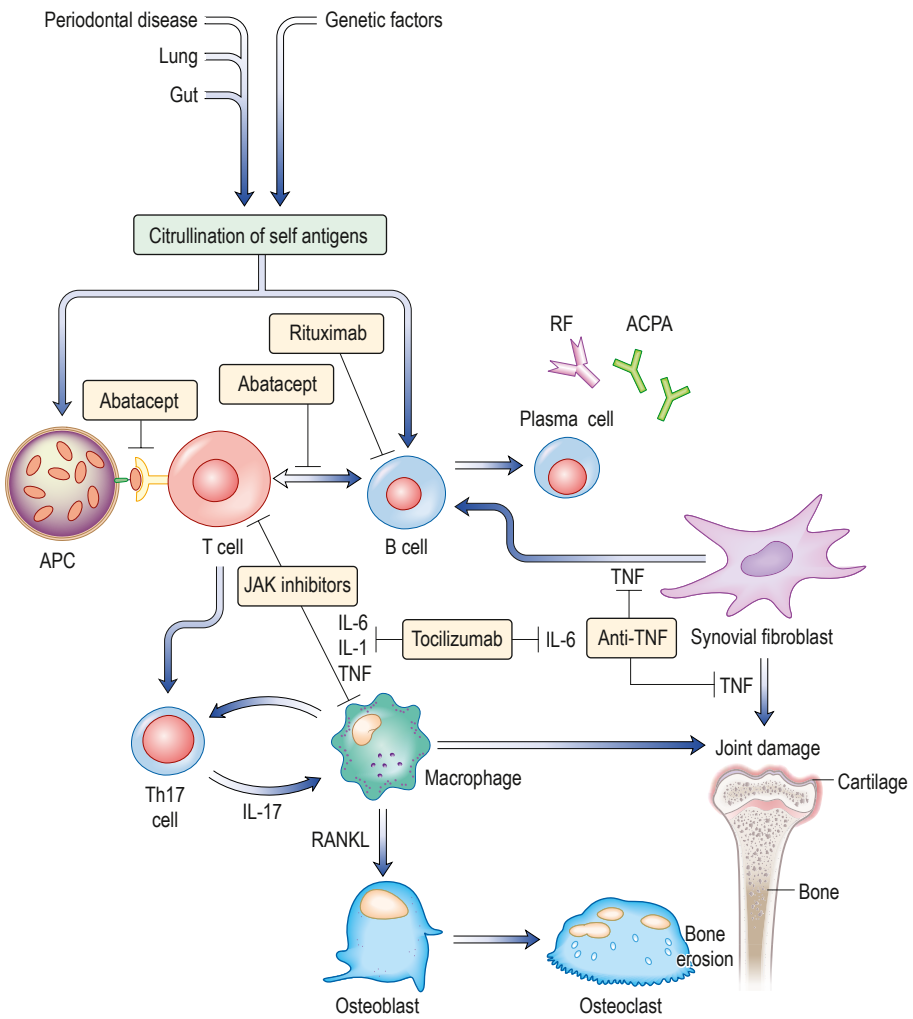

Fig. 32.19 Pathogenesis of rheumatoid arthritis. Environment–gene interactions promote citrullination of self-proteins, which can then be detected by T and B cells; this leads to a loss of tolerance and promotion of the inflammatory response, resulting in joint damage. Targeted therapy is shown in yellow. *ACPA,* Anti-citrullinated peptide antibody; *APC,* antigen-presenting cell; *IL,* interleukin; *RANKL,* receptor activator of nuclear factor kappa B ligand; *RF,* rheumatoid factor; *Th,* T helper; *TNF,* tumour necrosis factor.

shown by MRI (Fig. 32.21) to occur in the first 3–6 months following onset of the arthritis before the diagnostic, ill-defined, juxta-articular bony 'erosions' appear on X-ray (Fig. 32.22). This early damage justifies the use of disease-modifying anti-rheumatic drugs (DMARDs; see 'Disease-modifying anti-rheumatic drugs' section) within 3 months of onset of the arthritis to try to induce disease remission and prevent erosion formation. Erosions lead to a variety of deformities and contribute to long-term disability.

Rheumatoid factors and anti-citrullinated peptide antibodies (ACPAs)

RFs (see 'Serum autoantibody studies' section) are of any immunoglobulin class (IgM, IgG, or IgA), but the most common tests employed clinically detect IgM RF. The term 'seronegative RA' is used when the standard tests for IgM RF are persistently negative. These patients tend to have a more limited pattern of synovitis.

IgM RF is not diagnostic of RA and its absence does not rule the disease out; however, it is a useful predictor of prognosis. A persistently high titre in early disease implies more persistently active synovitis, more joint damage leading to greater disability, and thus justifies earlier use of DMARDs.

ACPAs (see 'Serum autoantibody studies' section) are usually present with RF in RA. They are better predictors of a transition from early transient inflammatory arthritis to persistent synovitis and early RA. RF and ACPA together are even more specific.

Clinical features

Typical presentation

RA typically presents (≈70%) as a progressive, symmetrical, peripheral polyarthritis, evolving over a period of a few weeks or months in patients between 30 and 50 years of age, although the disease can occur at any age (Fig. 32.16). Less commonly (≈15%), a rapid onset can occur over a few days (or explosively overnight), with a severe symmetrical, polyarticular involvement, especially in the elderly. Factors indicating a poor prognosis are listed in Box 32.26. The differential diagnosis of early RA is shown in Box 32.27.

Current classification criteria from 2010 are more suitable for assessing and diagnosing early arthritis than previous versions

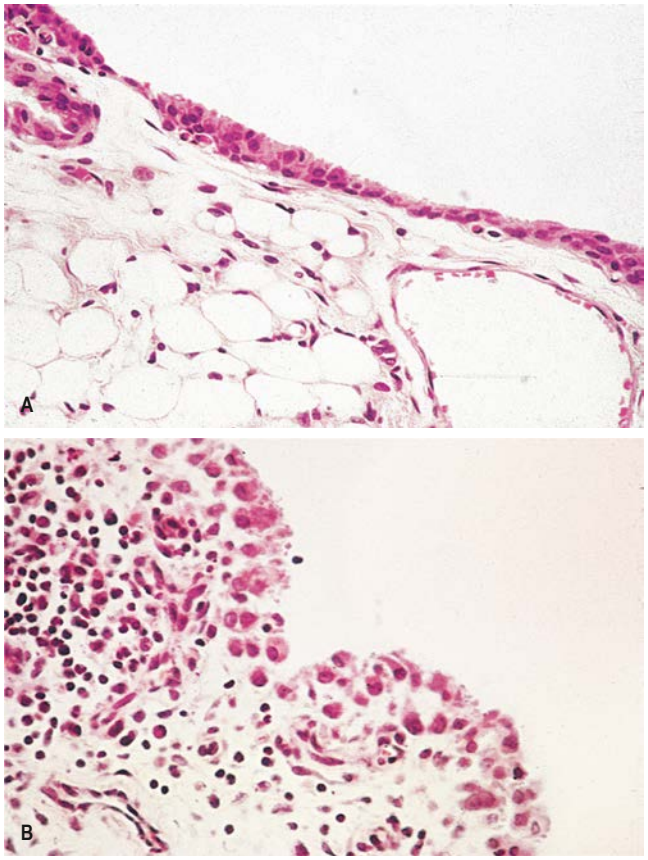

Fig. 32.20 Histological appearance of synovium in rheumatoid arthritis (RA). **(A)** Normal synovium. **(B)** Synovial appearances in established RA, showing marked hypertrophy of the tissues with infiltration by lymphocytes and plasma cells. Fig. 32.21 Magnetic resonance imaging of erosions at the wrist in rheumatoid arthritis. Typical erosions may be seen at the ulnar styloid, radial head *(white arrows)*, and carpal bones *(black arrows)*. (*From Elias-Jones C.* Crash Course Orthopaedics and Rheumatology, *3rd edn. Edinburgh: Elsevier, 2015.*)

Fig. 32.22 X-ray of early rheumatoid arthritis. Typical erosions may be seen at the thumb *(black and white arrows on the left)*, middle metacarpophalangeal joints *(central black arrow)*, and ulnar styloid *(white arrow on the right)*.

Box 32.26 Factors predicting a poor prognosis for progression in early rheumatoid arthritis

- Older age
- Female sex
- Symmetrical small joint involvement
- Morning stiffness >30 min
- >4 swollen joints
- Cigarette smoking
- Co-morbidity
- C-reactive protein >20 g/dL
- Positive rheumatoid factor and anti-citrullinated peptide antibodies

Box 32.27 Differential diagnosis of early rheumatoid arthritis

- Postviral arthritis: rubella, hepatitis B, or erythrovirus
- Seronegative spondyloarthropathies
- Polymyalgia rheumatica
- Acute nodal osteoarthritis (proximal and distal interphalangeal joints involved)

because they do not rely on later changes, such as erosions and extra-articular disease to distinguish RA (**Box 32.28**).

In early RA, the combination of at least one swollen joint for more than 6 weeks with no prior injury, no associated history or family history of spondyloarthritis or associated conditions such as psoriasis (see Chapter 45), and a positive ACPA test is the best way to select patients for earlier treatment to avoid joint damage. This

Box 32.28 ACR/EULAR 2010 criteria for rheumatoid arthritis[a]

Criteria	Points
1. Joint involvement	**0–5**
1 medium to large joint	0
2–10 medium to large joints	1
1–3 small joints (large joints not counted)	2
4–10 small joints (large joints not counted)	3
>10 joints; at least one small joint	5
2. Serology	**0–3**
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
3. Acute-phase reactants	**0–1**
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
4. Duration of symptoms	**0–1**
<6 weeks	0
≥6 weeks	1

[a]The cut-off point for RA is at ≥6 points. Patients can also be classified as having RA if they have both typical erosions and longstanding disease previously satisfying the classification criteria.
ACPA, Anticitrullinated peptide antibody; *ACR*, American College of Rheumatology; *CRP*, C-reactive protein; *EULAR*, European League Against Rh.

evidence-based approach has been shown to reduce the risk of the development of damage and permanent joint deformities.

Symptoms and signs of early RA

Most patients complain of pain and stiffness of the small joints of the hands (MCPs, PIPs) and feet (MTPs). The DIPs are usually spared. Wrists, elbows, shoulders, knees, and ankles are also affected. In most cases, multiple joints are involved, but 10% of patients present with a monoarthritis of the knee or shoulder or with carpal tunnel syndrome. The pain and stiffness are significantly worse in the morning. Sleep disturbance and fatigue are common complaints.

The joints are usually warm and tender with some joint swelling. There is limitation of movement and muscle wasting. Deformities and non-articular features develop if the disease cannot be controlled (see below).

RA in older patients may mimic PMR; the synovitis becomes apparent as the corticosteroid dose is reduced.

Other presentations

The variable presentations and progression of RA are shown in **Box 32.29**. Relapses and remissions occur either spontaneously or on drug therapy. Active disease, producing progressive joint damage, requires targeted treatment to induce remission.

Seronegative RA initially affects the wrists more often than the fingers and has a less symmetrical joint involvement. It has a better long-term prognosis but some cases progress to severe disability. This form can be confused with psoriatic arthropathy, which has a similar distribution (see 'Psoriatic arthritis' section).

Palindromic rheumatism is unusual (5%) and consists of 24–48-hour episodes of acute monoarthritis. The joint becomes acutely painful, swollen, and red but resolves completely. Further attacks occur in the same or other joints. About 50% of patients develop typical chronic rheumatoid synovitis after a delay of months

Box 32.29 Presentations of rheumatoid arthritis

- ***Palindromic.*** Palindromic monoarticular attacks last 24–48 h; 50% progress to other types of RA.
- ***Transient.*** Disease is self-limiting, lasting <12 months and leaving no permanent joint damage. It is usually seronegative for IgM RF and ACPA. Some of these patients may have undetected postviral arthritis.
- ***Remitting.*** There is a period of several years during which the arthritis is active but then remits, leaving minimal damage.
- ***Chronic, persistent.*** This is the most typical form; it may be seropositive or seronegative for IgM RF. The disease follows a relapsing and remitting course over many years. Seropositive (plus ACPA) patients tend to develop greater joint damage and long-term disability. They warrant earlier and more aggressive treatment with disease-modifying agents.
- ***Rapidly progressive.*** The disease progresses remorselessly over a few years and leads rapidly to severe joint damage and disability. It is usually seropositive (plus ACPA), has a high incidence of systemic complications, and is difficult to treat.

ACPA, Anti-citrullinated peptide antibody; *RF*, rheumatoid factor.

or years. The rest remit or continue with acute episodic arthritis. Detection of RF or ACPA predicts conversion to chronic, destructive synovitis.

Complications

Septic arthritis (see also Chapter 11)

This serious complication has significant morbidity and mortality. In immunosuppressed patients, affected joints may not display the typical signs of inflammation with accompanying fever found in patients with an intact immune system. Treatment is with systemic antibiotics and drainage.

Amyloidosis

Amyloidosis (see Chapter 26) is found in a very small number of people with uncontrolled RA. RA is the most common cause of secondary AA amyloidosis. AL amyloidosis causes a polyarthritis that resembles RA in distribution and is also often associated with carpal tunnel syndrome and subcutaneous nodules.

Joint involvement in RA

These changes are seen in established disease or when early drug treatment has been ineffective.

Hands and wrists

In early disease, the fingers are swollen, painful, and stiff. Inflamed flexor tendon sheaths increase functional impairment and may cause a carpal tunnel syndrome. Joint damage causes:

- ***A combination of ulnar drift and palmar subluxation of the MCPs.*** This change (**Fig. 32.23**) leads to unsightly deformity, but function may be preserved once the patient has learned to adapt and pain is controlled.
- ***Fixed flexion*** (buttonhole or boutonnière deformity) or ***fixed hyperextension*** (swan-neck deformity) of the PIP joints, which impairs hand function.
- ***Swelling and dorsal subluxation of the ulnar styloid***, which causes wrist pain. It may also cause rupture of the finger extensor tendons, leading to a sudden drop of the little and ring fingers that requires urgent surgical repair.

Shoulders

RA commonly affects the shoulders. Initially, the symptoms mimic rotator cuff tendonosis (see 'Rotator cuff [supraspinatus] tendonosis'

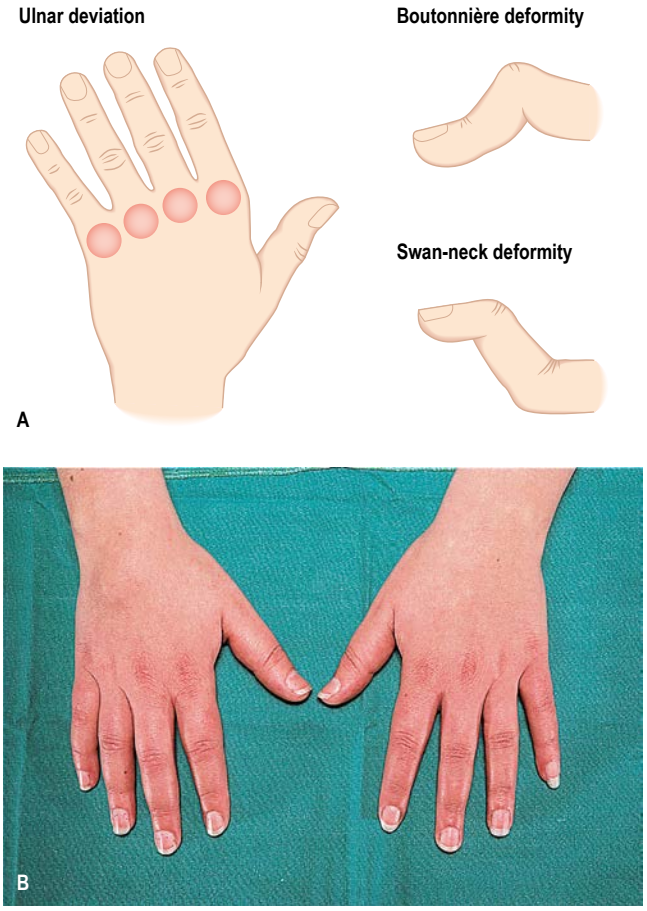

Fig. 32.23 Rheumatoid arthritis. (A) Characteristic hand deformities. (B) Early rheumatoid arthritis—dorsal tenosynovitis of the right wrist and small joints of both hands with spindling of the fingers.

section) with a painful arc syndrome and pain in the upper arms at night. Further joint damage leads to global stiffening; rotator cuff tears become more common and interfere with dressing, feeding, and personal toilet.

Elbows

Synovitis of the elbows causes swelling and a painful fixed flexion deformity. In late disease, flexion may be lost and severe difficulties with feeding result, especially combined with shoulder, hand, and wrist deformities.

Feet

One of the earliest manifestations of RA is painful swelling of the MTP joints.

- The foot becomes broader and a hammer-toe deformity develops.
- Exposure of the metatarsal heads to pressure by the forward migration of the protective fibrofatty pad (Fig. 32.24) causes pain.
- Ulcers or calluses may develop under the metatarsal heads and over the dorsum of the toes.
- Mid- and hindfoot RA causes a flat medial arch and loss of flexibility of the foot.
- The ankle often assumes a valgus position.

Appropriate broad, deep, cushioned shoes are essential but rarely wholly adequate, and walking is often painful and limited. Podiatry helps and surgery may be required.

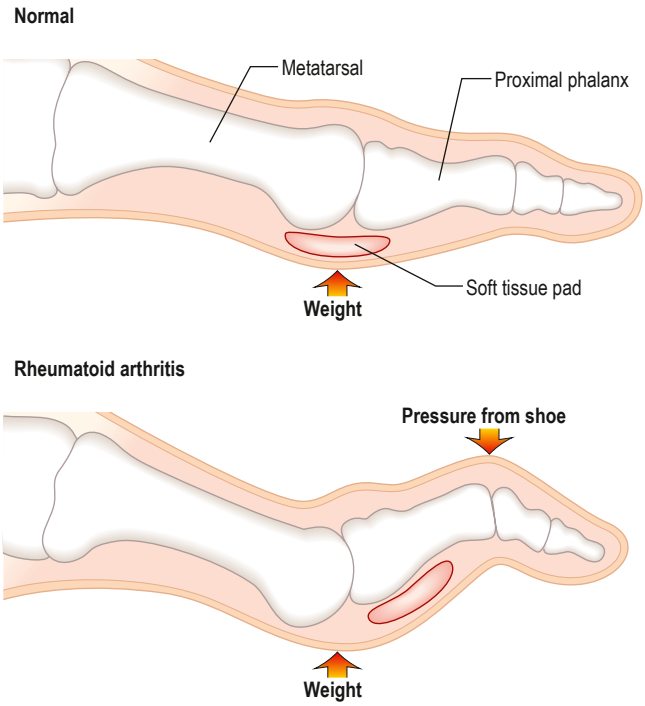

Fig. 32.24 The toes in rheumatoid arthritis. There is exposure of the metatarsal heads with forward migration of the soft tissue pad.

Knees

Massive synovitis and knee effusions occur but respond well to aspiration and steroid injection. A persistent effusion increases the risk of popliteal cyst formation and rupture (see 'Popliteal cyst [Baker's cyst]' section). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary OA follows. Total knee replacement may be required to restore mobility and relieve pain.

Hips

The hips are occasionally affected in early RA but less commonly so than the knees at all stages of the disease. Pain and stiffness are accompanied by radiological loss of joint space and juxta-articular osteoporosis. The latter may permit medial migration of the acetabulum (protrusio acetabulae). Later, secondary OA develops. Hip replacement may be necessary.

Cervical spine

Painful stiffness of the neck in RA is often muscular, but it may be due to rheumatoid synovitis affecting the synovial joints of the upper cervical spine and the bursae, which separate the odontoid peg from the anterior arch of the atlas and its retaining ligaments. This synovitis leads to bone destruction, damages the ligaments and causes atlantoaxial or upper cervical vertebral instability. Subluxation and local synovial swelling may damage the spinal cord, producing pyramidal and sensory signs. MRI is the imaging of choice, but lateral flexed and extended neck X-rays can demonstrate instability. In late RA, difficulty walking that cannot be explained by articular disease, weakness of the legs, or loss of control of bowel or bladder may be due to spinal cord compression and is a neurosurgical emergency.

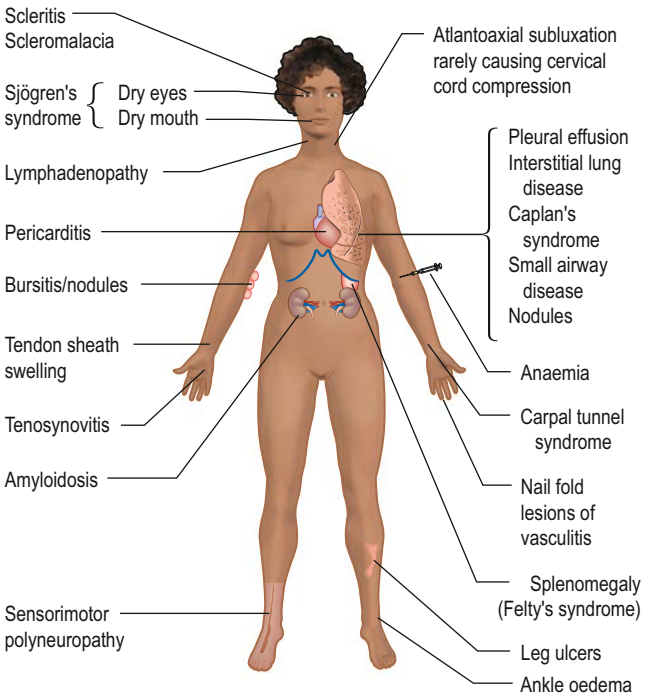

Fig. 32.25 Non-articular manifestations of rheumatoid arthritis.

Imaging of the cervical spine in flexion and extension is recommended in patients with RA before surgery or upper gastrointestinal endoscopy to check for instability and reduce the risk of cord injury during intubation.

Other joints

The temporomandibular, acromioclavicular, sternoclavicular, cricoarytenoid and any other synovial joint can be affected.

Non-articular manifestations

See Fig. 32.25.

Soft tissue surrounding joints

Subcutaneous nodules are firm and intradermal, generally occurring over pressure points: typically, the elbows, the finger joints, and the Achilles tendon in patients with seropositive erosive disease. They can be removed surgically but they tend to recur.

The olecranon and other bursae may be swollen (bursitis).

Tenosynovitis of flexor tendons in the hand can cause stiffness and occasionally a trigger finger. Swelling of the extensor tendon sheath over the dorsum of the wrist is common.

Muscle wasting around joints is common. Corticosteroid-induced myopathy occurs. Osteoporosis is more common in poorly controlled RA.

Less common non-articular manifestations

Non-articular complications are less common, probably because of more effective disease control.

Lungs

Findings in the lungs (see Chapter 20) include:

- airways disease: from predominant bronchiectasis (cough and daily sputum) to predominant obliterative bronchiolitis (progressive breathlessness)
- pleural disease: pleural effusion (asymptomatic to mildly breathless) and thickening
- interstitial lung disease: a combination of inflammation and basal lung fibrosis
- peripheral, intrapulmonary nodules: asymptomatic but may cavitate, especially with pneumoconiosis (Caplan's syndrome)
- infective lesions, e.g., tuberculosis in patients on biological DMARDs.

Vasculitis

Vasculitis (see 'Systemic inflammatory vasculitis' section) is uncommon. Risk factors include high titres of RF and active extra-articular disease elsewhere. Findings include:

- widespread cutaneous vasculitis with necrosis of the skin
- mononeuritis multiplex (see Chapter 28).

Heart and peripheral vessels

Poorly controlled RA with a persistently raised CRP and high cholesterol is a cardiovascular risk factor, independent of traditional risk factors (i.e., high cholesterol and hypertension). Other cardiovascular problems include:

- pericarditis, which is rarely symptomatic
- endocarditis and myocardial disease, rarely symptomatic, found at postmortem in approximately 20% of cases.

Nervous system

- Peripheral sensory neuropathies: mononeuritis multiplex or symmetrical peripheral neuropathy—due to vasculitis of the vasa nervorum.
- Compression neuropathies: carpal or tarsal tunnel syndrome—due to synovitis.
- Cord compression: due to atlantoaxial subluxation (see earlier).

Eyes

- Sicca syndrome causes dry mouth and eyes (see Sjögren's syndrome, 'Sjögren's syndrome' section).
- Scleritis and episcleritis occur in severe, seropositive disease, resulting in painful red eye.
- Scleromalacia perforans is a rare feature.

Kidneys

Amyloidosis causing proteinuria, nephrotic syndrome, and chronic kidney disease occurs rarely in severe, longstanding RA, due to the deposition of highly stable serum amyloid A protein (SAP) in the intercellular matrix of a variety of organs (see Chapter 26).

Spleen, lymph nodes, and blood

Felty's syndrome is splenomegaly and neutropenia in a patient with RA. Leg ulcers and sepsis are complications. HLA-DR4 is found in 95% of such patients, compared with 50%–75% of people with RA alone.

Anaemia is almost universal and is usually normochromic and normocytic. It may be iron-deficient owing to gastrointestinal blood loss from NSAID ingestion, or rarely haemolytic (Coombs-positive). There may be a pancytopenia due to hypersplenism in Felty's syndrome or as a complication of DMARD treatment. A high platelet count occurs with active disease.

Diagnosis and investigations

Diagnosis relies on the clinical features described earlier. The predictors of poor prognosis arthritis are listed in Box 32.26. Initial investigations include:

- ***Blood count*** may show a normochromic, normocytic anaemia.

Fig. 32.26 MRI of chronic rheumatoid arthritis of the knee. There is inflamed synovium throughout joint and spreading into the popliteal bursa *(white arrows)*.

- ***ESR and/or CRP*** are raised in proportion to the activity of the inflammatory process and are useful in monitoring treatment.
- ***Serology*** reveals ACPA positivity (see 'Serum autoantibody studies' section) that may be present early in the disease (and even predate it by many years), and in early inflammatory arthritis indicates the likelihood of progressing to RA. RF is present in approximately 75%–80% of cases and ANA at low titre in 30%.
- ***X-rays*** show soft tissue swelling in early disease, but ultrasound and MRI (**Fig. 32.26**) are useful to demonstrate synovitis and early erosions.
- ***Aspiration of the joint*** may be needed if an effusion is present. The aspirate looks cloudy owing to white cells. In a suddenly painful joint, septic arthritis should be suspected (see Chapter 11).
- ***Musculoskeletal ultrasound*** is a very effective way of demonstrating persistent synovitis when deciding on the need for DMARDs or assessing their efficacy.
- **MRI** can detect RA erosive change, particularly in early disease and allows direct visualization and assessment of synovitis and of bone oedema.

Other investigations will depend on the clinical picture, as outlined above. In severe disease, extensive imaging of joints may be required.

Management

See **Box 32.30**. The diagnosis of RA inevitably causes concern and fear in the patient and requires explanation and reassurance. Anyone with persistent arthritis should be referred urgently to a rheumatologist if small joints of hands or feet are affected, more than one joint is affected, or there has already been a delay of more than 3 months from symptom onset.

The doctor should have a positive approach and remind the patient that, with the help of drugs, most people continue to lead a more or less normal life, as the aim of therapy is disease remission. Furthermore, early therapy targeted at remission within 3 months of symptom onset is more likely to achieve sustained remission with subsequent drug tapering. People should be helped and encouraged to stay at work, as 30% lose their job within 2 years of diagnosis. Patients often adjust and cope remarkably with time and support from the specialist team in a rheumatology unit (including doctors, nurses, physiotherapists, podiatrists, and psychologists) and from leaflets, websites, and local patient groups.

Patients from socially deprived backgrounds and smokers have a worse prognosis. Due to the increased prevalence of cardiovascular risk in RA, aggressive management of traditional cardiac risk factors and suppression of disease are required.

Box 32.30 Management of rheumatoid arthritis

- Establish the diagnosis clinically.
- Use non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics to control symptoms.
- Consider intramuscular depot methylprednisolone 80–120 mg if synovitis persists beyond 6 weeks.
- Refer to a rheumatologist to start csDMARDs, typically beginning with methotrexate monotherapy; if lack of response consider switch to other csDMARD.
- Refer for physiotherapy and general advice through a specialist team.
- As improvement occurs, as measured by less pain, less morning stiffness and reduced acute-phase response, tail off steroids, and possibly reduce drugs.
- If no better after two csDMARDs use bDMARD or tsDMARD to induce remission/low disease activity.

bDMARD, Biologic DMARD; *csDMARD,* conventional synthetic DMARD; *DMARDs,* disease-modifying anti-rheumatic drugs; *tsDMARD,* targeted synthetic DMARD.

Drug therapy

No curative agent exists for RA but early recognition and an intensified treat to target (T2T) regimen, with regular review and escalation of therapy until remission occurs, improves outcomes. Less frequent review is then continued to assess disease activity, damage, function, and co-morbidities.

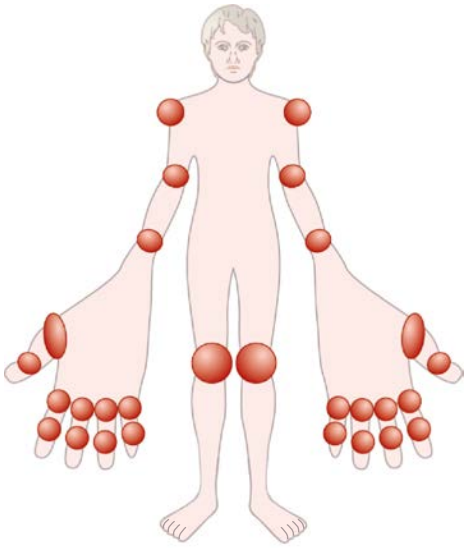
The disease activity score DAS28 is widely used to measure disease activity in RA by counting the number of tender and swollen joints in 28 joints in the upper limbs and knees, combining these values with the ESR and the patient's assessment of their general health on a visual analogue scale to generate a numerical score (**Fig. 32.27**). A DAS28 score of greater than 5.1 implies active disease, less than 3.2 low disease activity, and less than 2.6 remission.

For newly diagnosed patients, treatment begins with conventional synthetic (cs)DMARDs, typically methotrexate, at diagnosis, with consideration of short-term use of corticosteroids when initiating or changing csDMARD, with tapering and discontinuation as rapidly as clinically feasible to give benefit with minimal side-effects. With regular and frequent review, the T2T approach enables optimization and intensification of therapy with effective doses of csDMARDs, often in combination to prevent the long-term irreversible damaging effects of joint inflammation.

For patients who fail to achieve low disease activity or remission with serial csDMARDs, typically methotrexate and at least one other such as sulfasalazine or leflunomide, biological therapies (bDMARDS) are then used to achieve the desired target. If efficacy is not achieved, or subsequently lost, then switching to an alternative bDMARD is indicated. A new therapeutic class of DMARDs that inhibit intracellular Janus kinase (JAK) enzymes is now licensed in RA. These drugs, known as targeted synthetic (ts)DMARDs, have oral bioavailability, rapid onset of action, efficacy similar to bDMARDs and may be used with consideration of pertinent risk factors discussed below.

Non-steroidal anti-inflammatory drugs and coxibs

Most people with RA require an NSAID to relieve night pain and morning stiffness in addition to DMARDs. The individual response



Number of tender joints = t
Number of swollen joints = sw
Erythrocyte sedimentation rate in mm/h = ESR
Visual analogue scale of overall health in mm = GH

0 mm = Best — Worst = 100 mm

Calculate on online calculator (www.4s-dawn.com/DAS28)
or calculate on equation below:

DAS28 = 0.56*√(t) + 0.28*√(sw) + 0.70*Log(ESR) + 0.014*GH

Fig. 32.27 Calculation of disease activity score from 28 joints (DAS28).

to NSAIDs varies greatly, so several different drugs may have to be tried for at least a week to find the most effective (see **Box 32.18**). The major side-effects of NSAIDs and the use of coxibs are discussed earlier (see 'Non-steroidal anti-inflammatory drugs' section). If gastrointestinal side-effects are prominent, or the patient is over 65 years of age, add a proton pump inhibitor. For additional relief, a simple analgesic is taken as required (e.g., paracetamol or a combination of codeine or dihydrocodeine and paracetamol).

Corticosteroids

The early use of corticosteroids slows down the course of the disease but intensive short courses in very early arthritis do not appear to stop progressive disease. Recent guidelines recommend avoidance of long-term (≥3 months) corticosteroids due to their established toxicity profile and to increase focus on disease remission with escalation of DMARDs. Corticosteroids are a common cause of secondary osteoporosis; therefore, concomitant vitamin D and bisphosphonates are necessary to reduce fracture risk in patients who may require long-term (≥3 months) corticosteroid therapy.

Intra-articular injections with semi-crystalline steroid preparations have a powerful but sometimes only short-lived effect.

Intramuscular depot injections (40–120 mg depot methylprednisolone) are used to help induce remission while waiting for DMARDs to work and to control severe disease flares.

Oral corticosteroids are powerful disease-controlling drugs but cause a number of problems (**Box 32.31**; see also **Box 34.20**); so are not recommended long term because side-effects are inevitable. Short-term (<3 months) regimens may be considered to help induce remission. Corticosteroids are invaluable to people with severe disease who have extra-articular manifestations such as vasculitis.

Box 32.31 Problems associated with the use of corticosteroids

- Awareness of the potential side-effects of corticosteroids is increasing both among clinicians and patients. Guidelines recommend minimizing corticosteroid use and considering the risks posed by the drugs themselves.
- Patients should be advised to reduce consumption of sugars and saturated fats, and to be proactive in adjusting their diet to reduce the risk of weight gain.
- The skin becomes thin and easily damaged.
- Patients should be monitored for diabetes and hypertension.
- Cataract formation may be accelerated.
- Osteoporosis develops within 3 months on doses above 7.5 mg daily. Monitor with DXA scan and treat with calcium, vitamin D, and bisphosphonate (see Chapter 33).

DXA, Dual-energy absorptiometry.

Disease-modifying anti-rheumatic drugs

Various DMARDs are listed in **Box 32.32**. Their beneficial effect is not immediate, taking 2–3 months to become apparent. As monotherapy, conventional synthetic DMARDs (csDMARDs) often have only a partial effect, achieving between 20% and 50% improvement by ACR criteria for disease remission (**Box 32.33**), and are frequently used in combination.

Early intervention with csDMARDs within 3 months of disease onset improves the outcome. Although DMARD combinations (sulfasalazine, methotrexate, and/or hydroxychloroquine) may be used, a switch to bDMARDs is preferred when at least two csDMARDs have failed. Several DMARDs are contraindicated in pregnancy (see **Box 48.11**). Effective treatment with DMARDs including TNF-α blockers reduces the increased cardiovascular risk in RA.

Methotrexate

Methotrexate remains the anchor drug in RA therapy, although it should not be used in pregnancy. A screening history, chest X-ray, and an interferon-gamma release assay (IGRA) in high-risk patients are performed to exclude tuberculosis. Initial pneumococcal and annual influenza vaccinations are given. The starting *weekly* dose of 10 mg orally is increased up to 15–25 mg as necessary to T2T. It is well tolerated, although nausea or poor absorption may limit its efficacy, in which case it is given by subcutaneous injection. Oral folic acid reduces side-effects but may also lessen efficacy. Full blood counts and liver biochemistry should be monitored. Methotrexate usually works within 1–2 months. More patients remain on this agent than on most other DMARDs, indicating that it is effective and has relatively few side-effects.

Sulfasalazine

Sulfasalazine is well tolerated and can be used during pregnancy. The usual starting dose of 500 mg per day is increased to a maintenance dose of 2–3 g per day. Around 50% of patients respond in the first 3–6 months, but efficacy can be lost.

Hydroxychloroquine

A dose of 200–400 g daily is well tolerated. It is used alone in mild disease or commonly as an adjunct to other DMARDs. Due to the risk of irreversible retinopathy with increasing dose and duration of

Box 32.32 Disease-modifying anti-rheumatic drugs (DMARDs)

Drug	Dose	Side-effects	Monitoring
Sulfasalazine (enteric coated)	500 mg daily after food, increasing to 2–3 g daily	Nausea Skin rashes and mouth ulcers Neutropenia and/or thrombocytopenia Abnormal liver biochemistry	Baseline FBC, serum creatinine and electrolytes, LFTs, then at 2, 4, 6, and 10 weeks, then 3-monthly
Methotrexate[a]	7.5–10 mg increasing to max. 25 mg weekly, orally or s.c.	Nausea, mouth ulcers, and diarrhoea Abnormal liver biochemistry Neutropenia and/or thrombocytopenia Renal impairment Rare—pulmonary fibrosis	Baseline FBC, serum creatinine and electrolytes, LFTs, then at 2, 4, 6, and 10 weeks, then 3-monthly
Leflunomide[a]	10–20 mg daily, occasionally with initial loading dose	Diarrhoea Neutropenia and/or thrombocytopenia Abnormal liver biochemistry Alopecia Hypertension	Baseline FBC, serum creatinine and electrolytes, LFTs, then at 2, 4, 6, and 10 weeks, then 3-monthly
Biological drugs—TNF-α blockers[a]			
Etanercept (alone or with methotrexate)	s.c. 25 mg × 2-weekly or 50 mg weekly		Monitor as per concomitant DMARD; if monotherapy repeat FBC, serum creatinine and electrolytes, and LFTs 3–6 monthly
Adalimumab (with methotrexate)	s.c. 40 mg alternate weeks	Injection site reactions Heart failure Reversible lupus-like syndrome Infections Hypersensitivity reactions Rare—demyelination and autoimmune syndromes	As per etanercept
Infliximab (with methotrexate)	i.v. 3–10 mg/kg every 4–8 weeks		As per etanercept
Certolizumab pegol (alone or with methotrexate)	s.c. 400 mg in weeks 0, 2, 4, then 200 mg fortnightly		As per etanercept
Golimumab	s.c. monthly 50 mg		As per etanercept
Biological drugs—non-TNF-α blockers[a]			
Rituximab	i.v. 500–1000 mg	Hypo-/hypertension Pruritus and skin rash Back pain Hypogammaglobulinaemia Rare—toxic epidermal necrolysis	FBC, LFTs, and immunoglobulins at baseline and prior to each subsequent infusion
Abatacept	i.v. 10 mg/kg on days 1, 15, 30, and then monthly s.c. preparations available	Nausea, vomiting Headache Rare—hypersensitivity	Monitor as per concomitant DMARD; if monotherapy repeat FBC, serum creatinine and electrolytes, and LFTs 3–6 monthly
Tocilizumab	i.v. 8 mg/kg infusion every 4 weeks or s.c. 162 mg weekly	Upper respiratory tract infections, dyslipidaemia, neutropenia, increased liver enzymes, skin reactions	As per abatacept plus baseline and 3-month check of lipids with repeat at physician's discretion
Sarilumab	s.c. 200 mg alternate weeks	As per tocilizumab	As per tocilizumab
Ustekinumab	s.c. 45 mg (body weight <101 kg, or 90 mg ≥101 kg) on day 1 and 28 then every 12 weeks	Nasal congestion, sore throat, asthenia, nausea, skin reactions Rare—cutaneous lupus erythematosus, hypersensitivity vasculitis	As per abatacept
Guselkumab	s.c. 100 mg on day 1 and 28 then every 4–8 weeks	Arthralgia, diarrhoea, headache, increased risk of infection Uncommon—skin reactions	As per abatacept
Risankizumab	s.c. 150 mg on day 1 and 28 then every 12 weeks	As per guselkumab	As per abatacept
Secukinumab	s.c. 150 mg weekly for 5 doses then 150–300 mg every 4 weeks	Sore throat or dry cough, runny nose, fatigue, diarrhoea, skin reactions Rare—anaphylactic, hypersensitivity vasculitis	As per abatacept

Box 32.32 Disease-modifying anti-rheumatic drugs (DMARDs)—cont'd

Drug	Dose	Side-effects	Monitoring
Ixekizumab	s.c. 160 mg on day 1 then 80 mg 2 weekly for 6 doses then 80 mg every 4 weeks	Conjunctivitis, nausea, oropharyngeal pain, skin reactions Rare—anaphylactic reaction	As per abatacept
Targeted small-molecule inhibitors			
JAK inhibitors[a]			
Tofacitinib	5 mg oral twice daily	Anaemia, cough, neutropenia, diarrhoea, dyslipidaemia, dyspnoea, fatigue, gastritis, headache, hypertension, skin reactions Uncommon—decreased leucocytes, deep vein thrombosis, myocardial infarction, neoplasms, thromboembolism	Baseline as per etanercept, then monitor FBC, serum creatinine and electrolytes, and LFTs at 4 and 8 weeks then 3-monthly. Check lipids at baseline and after 8 weeks
Baricitinib	4 mg oral once daily in adults 18–74 years; 2 mg oral once daily in adults ≥75 years	Dyslipidaemia, herpes zoster, increased risk of infection, nausea, oropharyngeal pain, thrombocytosis, acne, neutropenia, weight gain	As per tofacitinib
Filgotinib	200 mg oral once daily in adults 18–74 years; 100 mg oral once daily in adults ≥75 years	Abdominal pain, anaemia, cough, dyslipidaemia, fever, headache Unknown frequency of embolism and thrombosis, malignancy, reactivation of infections	As per tofacitinib
Upadacitinib	15 mg oral once daily	As per filgotinib	As per tofacitinib
Phosphodiesterase type-4 (PDE4) inhibitor[a]			
Apremilast	10 mg oral once a day increasing to by 10 mg a day to maintenance 30 mg twice daily on day 6	Reduced appetite, back pain, cough, depression, diarrhoea, increased risk infection Rare—gastrointestinal haemorrhage, suicidal behaviours	No routine laboratory monitoring

All patients administered immunosuppressive medications (labelled[a]) should be given pneumococcal, COVID-19, and annual influenza vaccinations.
CD19, Cluster of differentiation 19; *FBC,* full blood count; *i.v.,* intravenous; *JAK,* Janus kinase inhibitor; *LFTs,* liver function tests; *s.c.,* subcutaneous; *TNF-α,* tumour necrosis factor-alpha.

Box 32.33 The 2011 ACR/EULAR definitions for disease remission in rheumatoid arthritis clinical trials

- Tender joint count (including feet and ankles) ≤1
- Swollen joint count (including feet and ankles) ≤1
- C-reactive protein ≤1 mg/L
- Patient global assessment ≤1 (on a 10-cm visual analogue scale)

ACR, American College of Rheumatology; *EULAR,* European League Against Rheumatism.

use, a dose ceiling of 5 mg/kg/day is recommended and current guidance is for annual eye assessment (ideally including optical coherence tomography) after 5 years of therapy are completed or earlier if patient has eGFR <60 mL/min, concomitant tamoxifen or dose >5 mg/kg/day.

Leflunomide

This csDMARD prevents pyrimidine production in proliferating lymphocytes through blockade of the enzyme dihydro-orotate dehydrogenase, thus blocking clonal expansion of T cells. It has a long half-life of 4–28 days. A dose of 20 mg daily (10 mg if diarrhoea is a problem) is used. Diarrhoea diminishes with time. Blood monitoring is obligatory (full blood count, platelets, liver biochemistry). The onset of action is 4 weeks with some further improvement sustained at 2 years. Leflunomide works in some patients who have failed to respond to methotrexate. Its long half-life means that it is best avoided in females planning a family.

Biological therapies (bDMARDs)

These drugs are more expensive than csDMARDs and rheumatologists should consider the cost of therapies that are being reduced by the introduction of biosimilar medicines. These medicines are highly similar to another (originator) drug and have been shown to have no clinically meaningful differences in quality, safety or efficacy from the originator compound.

TNF-α blockers

These agents are used after at least two csDMARDs (usually sulfasalazine and methotrexate) have failed. They are usually given in combination with methotrexate to reduce loss of efficacy due to anti-drug antibody (ADA) formation.

- ***Etanercept*** is a fully humanized p75 TNF-α receptor IgG1 fusion protein given by self-administered subcutaneous injection. Around 65% of patients respond well. Some develop an injection reaction.
- ***Adalimumab*** is a fully human monoclonal antibody against TNF-α, given along with methotrexate.
- ***Infliximab*** is a monoclonal antibody against TNF-α, given intravenously and co-prescribed with methotrexate to prevent loss of efficacy because of antibody formation.
- ***Certolizumab pegol*** is a Fab fragment of a humanized TNF-α inhibitor monoclonal antibody that has polyethylene glycol (PEG) groups attached to reduce immunogenicity and prolong half-life. The presence of PEG and lack of Fc portion ensure minimal transfer across the placenta and into breast milk. It is useful with or without methotrexate for severe active RA.

- ***Golimumab*** is a human IgG1-κ monoclonal antibody against TNF, which is given by subcutaneous injection once monthly for severe RA.

These products slow or halt erosion formation in up to 70% of people with RA and produce healing in a few. Malaise and tiredness improve in a manner that is not seen with csDMARDs. Secondary failure may occur with all in the first year; changing to another anti-TNF agent is justified and often regains control of the disease. Failure to respond to one does not predict failure to others. Currently, biosimilars exist for etanercept, infliximab, and adalimumab.

Safety data. Various national registries exist to study adverse events, long-term outcomes, and problems arising from biological therapies. To date, the results are reassuring. Infection rates are increased with TNF-α blockers, particularly in the first few months of treatment, but the rate then declines. There is a known association between RA and non-Hodgkin's lymphoma (NHL) but, overall, registers have not shown an increased risk of NHL in patients with RA treated with TNF-α blockers, to date. There is no convincing evidence of any increased risk of other cancers. Reactivation of old tuberculosis may occur but is probably less common with etanercept. A pre-treatment chest X-ray is recommended, with IGRA and specialist review for high-risk groups. Tuberculosis should be treated before these agents are prescribed, and a course of prophylaxis is used in latent disease. Hepatitis B and C infection requires risk analysis and regular aminotransferase monitoring if anti-TNF agents are prescribed. They should not be used in patients who have severe cardiac failure. To date, there is no evidence of an adverse effect on pregnancy outcome but care is essential (see **Box 48.11**).

Other biological agents

- ***Rituximab*** is a chimeric monoclonal antibody (see Chapter 6), directed against the CD20 receptor expressed on pre-B and mature B cells. Rituximab produces significant improvement in RF-positive RA for 8 months to several years when used alone or in combination with corticosteroids and/or methotrexate. This clinical improvement is associated with a 6–9-month B-cell lymphopenia. A re-flare is often accompanied by a return of peripheral B lymphocytes and rise in CRP. Repeated courses, with disease flare, are well tolerated and around 80% of RF-positive patients respond, with 50%–60% showing persistent disease control; however, immunoglobulin levels should be monitored, as they may fall with repeated treatments. Rituximab is mainly used in patients who have failed to respond to anti-TNF agents and a biosimilar exists.
- ***Abatacept*** is a recombinant fusion protein of CTLA4 and the Fc portion of IgG1, which selectively modulates T-cell activation by co-stimulation blockade. It may be used in patients who do not respond to anti-TNF regimens.
- ***Tocilizumab and sarilumab*** are monoclonal antibodies against the anti-IL-6 receptor that may be used with methotrexate for moderate to severe RA, usually after at least one other biologic has failed, but may also be considered as a first-line biological therapy.

Targeted synthetic DMARDs (tsDMARDs)

Baricitinib, filgotinib, tofacitinib, and upadacitinib are oral JAK inhibitors that may be used in combination with methotrexate, or as monotherapy in patients who cannot take methotrexate, instead of a bDMARD. An RCT studied patients with RA >50 years of age who had cardiovascular risk factors, comparing two groups: those on tofacitinib and those treated with TNF-α blockers. There was an increased risk of major adverse cardiovascular events and malignancy in the tofacitinib group. Therefore, all JAK inhibitors are considered with caution in patients >65 years and/or with risk factors for cardiovascular disease, thromboembolism, or malignancy.

Switching between DMARDs and tapering therapy

Patients who fail to respond initially (primary failure) or subsequently lose efficacy (secondary failure) to a bDMARD over time will usually be switched to another bDMARD. In patients who lose response to a TNF-α blocker, it is helpful to measure drug levels and for presence of neutralizing ADAs, where possible. If the drug level is therapeutic, then a non-TNF-α blocker is preferred. Alternatively, if the drug level is subtherapeutic, non-adherence or the presence of ADA are likely explanations and switching to another TNF-α blocker or a different class of bDMARD are viable alternatives. If primary or secondary failure occurs to a subsequent bDMARD the switching process may be repeated multiple times. Switching to tsDMARDs may now be considered.

In patients who achieve sustained remission (>1 year) it is now commonplace to attempt dose reduction of DMARDs by either dose reduction or prolongation of dosing interval. Potential biomarkers of responsiveness are being explored to ensure a precision medicine approach to each individual patient.

Physical measures

Input is required from the multidisciplinary team. Physiotherapists advise a combination of rest for active arthritis and exercises to maintain joint range and muscle power. Exercise in a hydrotherapy pool is popular and effective. Occupational therapists help to manage activities of daily living despite the arthritis and provide functional adaptations in the home or at work. Family and friends should be involved. Podiatry, footwear advice, and psychological support should also be offered to all people with RA.

Surgery

Surgery has a useful role in the long-term approach to patient management but is less frequently needed as therapeutic disease control becomes more effective. Its main objectives are prophylactic, to prevent joint destruction and deformity, and reconstructive, to restore function.

Surgical options in RA include: surgical synovectomy; tendon repair; osteotomy to realign weight-bearing surfaces; joint fusion to stabilize damaged joints that are not easily replaced; small joint implant arthroplasty, for example, MCP joints; excision arthroplasties of the metatarsal heads to reduce metatarsal pain; and total joint replacement arthroplasty of the shoulder, elbow, wrist, hip, knee, and ankle. The main aim of joint arthroplasty is to reduce pain and improve function, requiring careful planning with explanation of risks and outcomes to the patient.

Prognosis

A poor prognosis is indicated by:

- ***a clinical picture*** of an insidious rather than an explosive onset of RA, female sex, increasing number of peripheral joints involved, and the level of disability at the onset
- ***blood tests*** showing a high CRP/ESR, normochromic normocytic anaemia, and high titres of ACPA and of RF
- ***X-rays*** with early erosive damage (*Note:* ultrasound and MRI can show cartilage and bone damage prior to conventional X-rays).

Prognosis can be altered dramatically with early DMARD therapy and T2T regimen (see 'Drug therapy' section) under expert supervision.

SPONDYLOARTHRITIS

The term spondyloarthritis (SpA) describes a group of conditions affecting the spine and peripheral joints with familial clustering and a link to certain type 1 HLA antigens. These conditions share genetic factors and increasing implication of the IL-17 pathway in pathogenesis. Joint involvement differs from RA, with a different distribution and associated extra-articular features (**Fig. 32.16**). These diseases occasionally present in childhood.

They may also be categorized according to their predominant clinical manifestation of axial (sacroiliac and/or spine) or peripheral (arthritis, enthesitis, and/or dactylitis) disease with possible overlap. Distinct SpA conditions exist (see **Box 32.34**).

Histologically, synovitis is similar to that of RA, but there is no production of RF or ACPA. Inflammation of the enthesis (junction of ligament or tendon and bone) and joint ankylosis develop more commonly than in RA. All are associated with an increased frequency of sacroiliitis and HLA-B27.

Aetiology

These disorders have a striking association with HLA-B27, particularly ankylosing spondylitis (AS). HLA type B27 is present in more than 90% of Caucasians with AS but only 8% of controls. HLA-B27 exhibits a number of unusual characteristics, including a high tendency to misfold. The types of arthritis that follow a precipitating infection are called reactive arthritis (see 'Reactive arthritis' section).

Axial spondyloarthritis

Axial spondyloarthritis (AxSpA) occurs in 1% of the general population. It is an inflammatory disorder primarily affecting sacroiliac joints or fibrous and synovial joints of the spine that are detectable on MRI. When radiographic changes at the sacroiliac joints are present, the term ankylosing spondylitis (AS) is used.

Ankylosing spondylitis

It is now recognized that AS forms part of the spectrum of AxSpA. It presents with inflammatory back pain and sacroiliac inflammation. It is seen in 0.2%–0.5% of the population in Northern Europe and approximately 0.5% in the USA, affecting mainly young adults (late teens to early thirties) and occurring worldwide, with a male to female ratio of 3:1. Diagnostic delay remains a problem, particularly in females who are under-diagnosed. The frequency of AxSpA in different populations is roughly paralleled by the incidence of HLA-B27; Africans and Japanese have a low incidence of both HLA-B27 and AS, while the North American Haida Indians have a high incidence of both.

Aetiology

A combination of genetic and environmental features:

- Among white individuals with AS, 95% carry HLA-B27, in contrast to 8% of most white populations. Twin studies indicate a much higher disease concordance in HLA-B27-positive monozygotic twins (up to 70%) than in dizygotic twins (about 20%–25%).
- Other genes lying within the MHC (the *IL-1* gene cluster and *CYP2D6*) also influence susceptibility to AS but the disease is polygenic and GWAS have identified significant associations with the endoplasmic reticulum aminopeptidase *(ERAP)*-1 and *IL-23* genes.
- The association of *ERAP-1* with AxSpA may support the arthritogenic peptide hypothesis, whereby disease is triggered by presentation of peptide by HLA-B27 to CD8-positive T cells. Furthermore, misfolding of HLA-B27 leads to the production of IL-23, and T cells resident in entheses promote inflammation characteristic of SpA in response to IL-23.
- The finding of increased frequency of Th17 cells and various genetic association studies have implicated the IL-23-IL-17 axis in pathogenesis and this knowledge has been translated into therapies that target this pathway.
- Reports of dysbiosis in the gut microbiome of AS patients support previous work indicating a link between gut microbiota, intestinal inflammation, and AxSpA.
- Lymphocyte and plasma cell infiltration occurs with local erosion of bone at the attachments of the intervertebral and other ligaments (enthesitis), which heals with new bone (syndesmophyte) formation.

Clinical features

Initially, the diagnosis is often missed because the patient is asymptomatic between episodes and radiological abnormalities are absent.

- ***Back pain*** with episodic inflammation of the sacroiliac joints in the late teenage years or early twenties is the first manifestation of AxSpA.
- ***Pain in one or both buttocks*** and low back pain and stiffness are typically worse in the morning and relieved by exercise.
- ***Retention of the lumbar lordosis during spinal flexion*** is an early sign. Later, paraspinal muscle wasting develops.

Criteria for classifying inflammatory back pain as AxSpA are shown in **Box 32.35**. These criteria encompass the whole spectrum of disease, with evidence of sacroiliitis being based on radiographic or MRI evidence of disease. Spinal stiffness can be measured by Schober's test; skin over the midline of the spine is marked 5 cm below and 10 cm above the dimples of Venus and the increase in distance between those marks during flexion is recorded. An increase of less than 5 cm implies spinal stiffness.

Non-spinal complications (uveitis or costochondritis) suggest the diagnosis of SpA (**Box 32.36**):

- ***Costochondral junction inflammation*** causes anterior chest pain. Measurable reduction of chest expansion is due to costovertebral joint involvement.
- ***Peripheral joint involvement*** is asymmetrical and affects a few, predominantly large, joints. Hip involvement leads to fixed

Box 32.34 Spondyloarthritis

- Axial spondyloarthritis, including ankylosing spondylitis
- Psoriatic arthritis
- Reactive arthritis (sexually acquired)
- Post-dysenteric reactive arthritis
- Enteropathic arthritis (ulcerative colitis/Crohn's disease)

Box 32.35 Back pain criteria for diagnosing axial/ankylosing spondylitis

- Age of onset <45 years
- Insidious onset
- Improvement of back pain with exercise
- No improvement of back pain with rest
- Pain at night with improvement on getting up

The presence of four of the five criteria suggests ankylosing spondylitis with 80% sensitivity. All criteria have high sensitivity.

Box 32.36 Non-articular problems in spondyloarthritis

- Uveitis, in all types
- Cutaneous lesions in reactive arthritis (keratoderma blennorrhagica), histologically identical to pustular psoriasis
- Nail dystrophy, in psoriasis and reactive arthritis
- Aortitis, occasionally in ankylosing spondylitis and reactive arthritis

flexion deformities of the hips and further deterioration of posture. Young teenage males occasionally present with a lower-limb monoarthritis, which later develops into AS.

- ***Acute anterior uveitis*** occurs in approximately 30% of patients with AxSpA and related diseases, and is occasionally the presenting complaint. Severe eye pain, photophobia, and blurred vision are an emergency (see Chapter 31).
- ***Other extra-articular features*** include:
  - cardiovascular disease—aortic incompetence occurs in up to 1% of patients with established AS and cardiac conduction abnormalities in around 5%
  - respiratory disease—rarely, chest wall rigidity is associated with interstitial lung disease resulting in pulmonary fibrosis with an upper lobe predilection
  - renal impairment—reported in 10%–35% of patients with AS and most commonly linked to chronic NSAID use
  - axial osteoporosis—occurs in approximately 25%, with vertebral fracture in 10%.

Overall clinical assessment of disease activity is based on a 1–10 score for levels of fatigue, spinal pain, arthralgia, swelling, localized tenderness, inflammation of tendons/enthesis, and duration and severity of morning stiffness. It is measured using instruments such as the Bath Ankylosing Spondylitis Disease Activity Index and increasingly the Ankylosing Spondylitis Disease Activity Score that includes laboratory measures as well as patient perspective (see Further reading).

Investigations

- ***Blood.*** ESR and CRP are usually raised.
- ***HLA-B27 testing.*** This test is not definitive due to the high frequency of HLA-B27 in the population, but may strengthen or confirm suspected diagnoses in the absence of sacroiliitis on imaging.
- ***X-rays.*** The medial and lateral cortical margins of both sacroiliac joints lose definition owing to erosions and eventually become sclerotic (**Fig. 32.28**). Radiological appearances in the spine of blurring of the upper or lower vertebral rims at the thoracolumbar junction are caused by an enthesitis at the insertion of the intervertebral ligaments and may eventually affect the whole spine causing bony spurs (syndesmophytes), bony ankylosis and permanent stiffening. The sacroiliac joints eventually fuse, as may the costovertebral joints, reducing chest expansion. Calcification of the intervertebral ligaments and fusion of the spinal facet joints and syndesmophytes leads to a 'bamboo' spine (**Fig. 32.29**).
- ***MRI.*** MRI with gadolinium demonstrates sacroiliitis before it is seen on X-rays, as well as persistent enthesitis.

Management

- Effective management of AS requires early diagnosis so that a regimen of preventative exercises is started before syndesmophytes have formed. Morning exercises aim to maintain spinal mobility, posture, and chest expansion; regular NSAIDs to improve symptoms and signs of SpA are often required to achieve this goal.

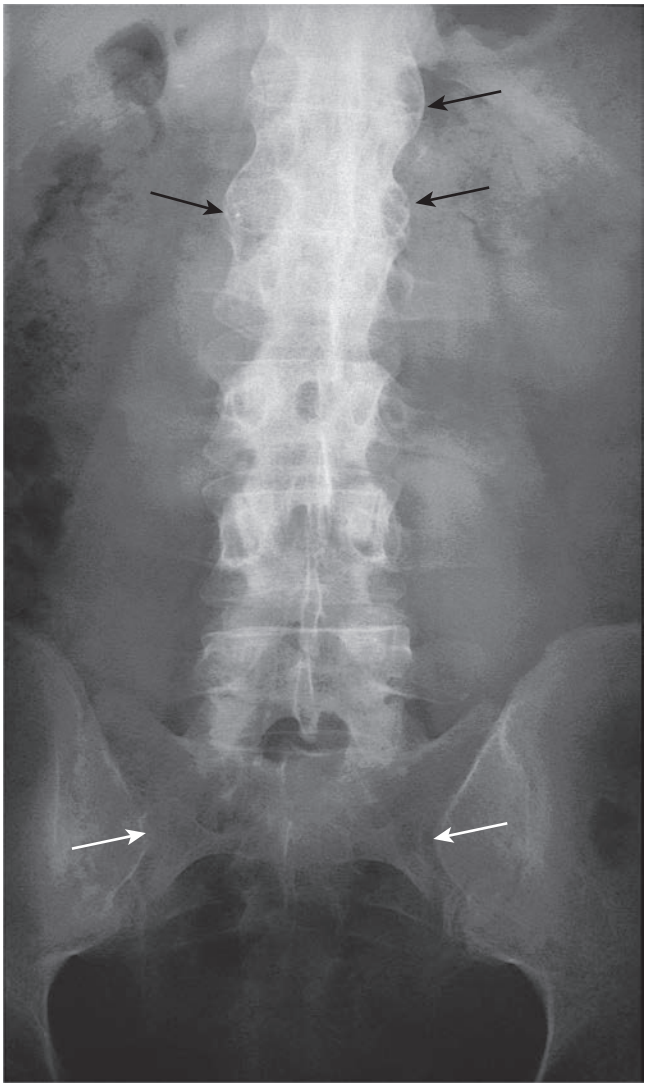


Fig. 32.28 X-ray of ankylosing spondylitis. The sacroiliac joints are eroded and show marginal sclerosis *(white arrows)*. There is bridging syndesmophyte formation at the thoracolumbar junction *(black arrows)*.

- Failure to control pain and to encourage regular spinal and chest exercises leads to an irreversible dorsal kyphosis and wasted paraspinal muscles, which, along with stiffening of the cervical spine, makes forward vision difficult.
- When the inflammation is active and the morning pain and stiffness are too severe to permit effective exercise, an evening dose of a long-acting or slow-release NSAID or an NSAID suppository improves sleep, pain control, and exercise compliance.
- Sulfasalazine, methotrexate, and leflunomide may help peripheral arthritis but not spinal disease.
- When NSAIDs have failed, the TNF-α-blocking drugs adalimumab, etanercept, golimumab, certolizumab, and infliximab (see **Box 32.32**) all reduce symptoms of spinal and peripheral joint inflammation substantially and improve function, as well as quality of life. There are some reports of reduction of bony progression. Relapse occurs on stopping therapy but may be delayed by several months making intermittent treatment feasible.
- Other bDMARDs including the IL-17 blockers ixekizumab and secukinumab or JAK inhibitors (tofacitinib and upadacitinib) are

Fig. 32.29 X-ray of bamboo spine in ankylosing spondylitis. In advanced disease, there is calcification of the interspinous ligaments and fusion of the facet joints, as well as syndesmophytes at all levels. The sacroiliac joints fuse.

alternative options in patients with persistently high disease activity despite conventional treatments.

Prognosis

With exercise and pain relief, the prognosis is excellent. The advent of bDMARD and tsDMARD therapies has reduced the morbidity of severe disease, lowering the risk of permanent spinal stiffness and progressive peripheral joint disease.

Psoriatic arthritis

The prevalence of psoriasis is 2%–3% worldwide; in this population, around 10% have arthritis, which precedes skin disease in around 15% of cases. A family history of psoriasis may be a clue to the diagnosis. The aetiology and pathogenesis are described in Chapter 45.

Clinical features

Patterns of psoriatic arthritis include:

- ***Mono- or oligoarthritis***.
- ***Polyarthritis:*** often begins with an asymmetrical pattern and progresses to be virtually indistinguishable from RA.
- ***Spondylitis:*** unilateral or bilateral sacroiliitis and early cervical spine involvement; only 50% are HLA-B27-positive.
- ***Distal interphalangeal arthritis:*** the most typical pattern of joint involvement in psoriasis, often with adjacent nail dystrophy (see Chapter 45) reflecting enthesitis extending into the nail root. Dactylitis, in which an entire finger or toe is swollen, with joint and tendon sheath involvement, is characteristic of this condition.
- ***Arthritis mutilans:*** affects about 5% of patients who have psoriatic arthritis and causes marked periarticular osteolysis and bone shortening ('telescopic' fingers) (Fig. 32.30).

Fig. 32.30 Hand showing psoriatic arthritis mutilans. All the fingers are shortened and the joints unstable, owing to underlying osteolysis.

Fig. 32.31 X-ray of psoriatic arthritis. There is osteolysis of the metatarsal heads and central erosion of the proximal phalanges to produce the 'pencil in cup' appearance *(circle)*. All the lesser toes are subluxed.

Radiologically, psoriatic arthritis is erosive but the erosions are central in the joint, not juxta-articular, and produce a 'pencil in cup' appearance (Fig. 32.31). The skin and nail disease can be mild and may develop after the arthritis.

Management and prognosis

NSAIDs are recommended to reduce pain with consideration of the benefit-to-risk ratio in patients with potential cardiovascular comorbidities. Local synovitis responds to intra-articular corticosteroid injections. A csDMARD (preferably methotrexate) is recommended in patients with persistent peripheral joint synovitis, although none are proven to slow the development of joint damage. Hydroxychloroquine is best avoided because it may exacerbate psoriatic skin reactions. Similarly, oral corticosteroids may destabilize skin disease; they are best avoided but corticosteroids are valuable when injected into a single inflamed joint.

Various bDMARDs and tsDMARDs are now available and highly effective for severe skin and joint disease in patients where csDMARDs, principally methotrexate, have failed. The bDMARDs include anti-TNF-α agents (see 'TNF-α blockers' section); IL-17 inhibitors, secukinumab and ixekizumab; the IL-12/23 inhibitor, ustekinumab; and IL-23 inhibitors, guselkumab and risankizumab. The tsDMARDs include an oral PDE4 inhibitor (apremilast) and JAK inhibitors (tofacitinib and upadacitinib). The choice of drug depends on disease manifestations, with a preference for TNF-α blockers or IL-17 inhibitors in predominantly axial disease.

Reactive arthritis

Reactive arthritis is a sterile synovitis, which occurs following an infection. Spondyloarthritis develops in 1%–2% of patients after an acute attack of dysentery, or after a sexually acquired infection—non-specific urethritis (NSU) in the male, non-specific cervicitis in the female. In males, positivity for HLA-B27 increases the risk of developing reactive arthritis after such an infection by thirty- to fiftyfold but not all patients are HLA-B27-positive. Females are less commonly affected.

Aetiology

A variety of organisms can be the trigger, including strains of *Salmonella* or *Shigella* spp. in bacillary dysentery. *Yersinia enterocolitica* causes diarrhoea and a reactive arthritis. In NSU, the organisms are *Chlamydia trachomatis* or *Ureaplasma urealyticum*.

People with reactive arthritis are not more susceptible to infection but appear to respond differently. Bacterial antigens or bacterial DNA have been found in the inflamed synovium of affected joints, so persistent antigenic material may drive the inflammatory process. HLA-B27 increases susceptibility to reactive arthritis by:

- T-cell receptor repertoire selection
- molecular mimicry causing autoimmunity against HLA-B27 and/or other self-antigens
- mode of presentation of bacteria-derived peptides to T lymphocytes.

There are other organisms that also trigger reactive arthritis but have a different genetic basis; see post-streptococcal arthritis (see Chapter 42), gonococcal arthritis (see 'Gonococcal arthritis' section), and brucellosis (see 'Brucellosis' section). In these conditions, the line between reactive arthritis and septic arthritis is more indistinct and they can cause both.

Clinical features

Typically an acute, asymmetrical, lower-limb arthritis, occurring days to weeks after the infection. The arthritis may be the presenting complaint if the infection is mild or asymptomatic. Enthesitis is common, causing plantar fasciitis or Achilles tendon enthesitis (see 'Plantar fasciitis' and 'Achilles tendonosis' sections), and dactylitis may also occur (**Fig. 32.32**); 70% of patients recover fully within 6 months but many have a relapse.

In susceptible individuals with reactive arthritis, sacroiliitis and spondylitis may also develop. Sterile conjunctivitis occurs in 30%. Acute anterior uveitis complicates more severe or relapsing disease but is not synchronous with the arthritis.

The skin lesions resemble psoriasis:

- ***Circinate balanitis*** in the uncircumcised male causes painless superficial ulceration of the glans penis. In the circumcised male, the lesion is raised, red, and scaly. Both heal without scarring.
- ***Keratoderma blennorrhagica*** involves the skin of the feet and hands, which develops painless, red, and often confluent raised plaques and pustules that are histologically similar to pustular psoriasis.
- ***Nail dystrophy*** occurs.

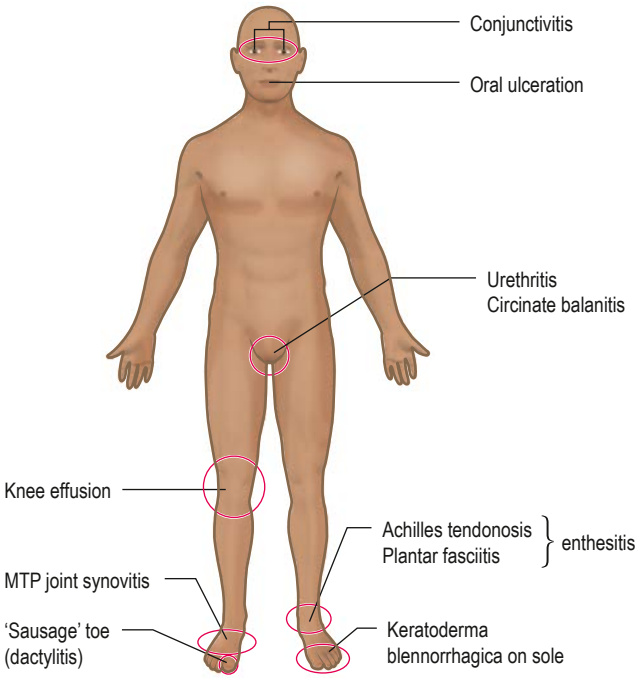

Fig. 32.32 Clinical features of reactive arthritis. *MTP,* Metatarsophalangeal.

Management

Treating persisting infection with antibiotics alters the course of the arthritis, once it has developed. Cultures should be taken and any infection treated. Sexual partners must be screened.

Pain responds well to NSAIDs and locally injected or oral corticosteroids. The majority of individuals with reactive arthritis have a single attack that settles, but a few develop a disabling, relapsing, and remitting arthritis. Relapsing cases are sometimes treated with sulfasalazine or methotrexate (see **Box 32.32**).

Enteropathic arthritis associated with inflammatory bowel disease

Enteropathic synovitis occurs in up to 10%–15% of patients who have ulcerative colitis or Crohn's disease (see Chapter 22). The link between the bowel disease and the inflammatory arthritis is not clear. The arthritis is asymmetrical and predominantly affects lower-limb joints. An HLA-B27-associated sacroiliitis or spondylitis also occurs. The joint symptoms may predate the development of bowel disease and lead to its diagnosis.

Remission of ulcerative colitis or total colectomy usually leads to remission of the joint disease, but arthritis can persist even in well-controlled Crohn's disease.

Management

Inflammatory bowel disease should be treated (see Chapter 22). In all cases of enteropathic arthritis, the symptoms are helped by NSAIDs, although they may make diarrhoea worse. A monoarthritis is best treated by intra-articular corticosteroids. Sulfasalazine is more frequently prescribed than mesalazine, as it may help both bowel and joint disease. The bDMARDs that are used to treat arthritis and inflammatory bowel disease are the TNF-α-blocking drugs infliximab, adalimumab, golimumab, and certolizumab, and ustekinumab, the IL-12/23 inhibitor. The JAK inhibitors baricitinib, filgotinib, tofacitinib, and upadacitinib may also be used.

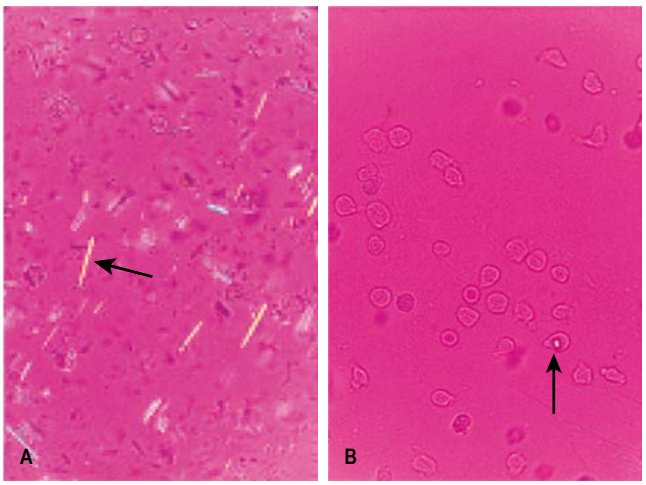

Fig. 32.33 Crystal arthritis. **(A)** Needle-shaped urate crystals *(arrowed)*. **(B)** A small, intracellular pyrophosphate crystal *(arrowed)*. Both are viewed under polarized light with a red filter.

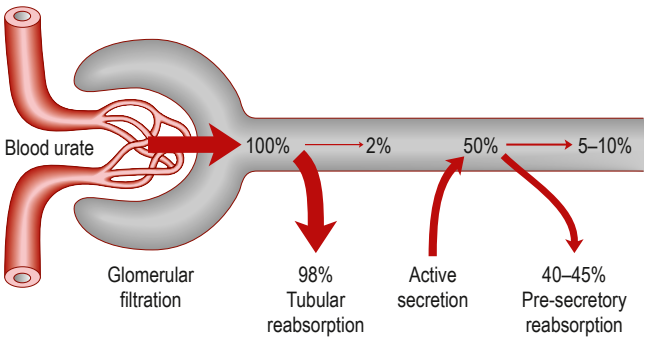

Fig. 32.34 Urate renal transport. The net result is that about 5%–10% of the glomerular load is excreted in the urine under normal circumstances.

CRYSTAL ARTHRITIS

The two main types of crystal-induced arthritis are caused by sodium urate and calcium pyrophosphate crystals, which are distinguished by their different shapes and refringence properties under polarized light with a red filter (Fig. 32.33). Rarely, crystals of calcium apatite (see 'Crystal-associated OA' section) or cholesterol cause acute synovitis.

Gout and hyperuricaemia

Gout is an inflammatory arthritis associated with hyperuricaemia and intra-articular sodium urate crystals.

Epidemiology

The prevalence of gout has increased in recent decades to 2.5% in the UK and 3.9% in the USA. Asian populations are also increasingly at risk as their diet becomes more Western. This rising prevalence is due to changing diets with purine-rich foods, high saturated fats, and fructose-containing drinks; alcohol misuse; increasing comorbidities that promote hyperuricaemia; and suboptimal management. Gout is more common in males than females (5:1); it rarely occurs before young adulthood (when it suggests a specific genetic defect), and seldom in premenopausal females. Some 85%–90% of cases are idiopathic. Hyperuricaemia is common in certain ethnic groups (e.g., Maoris).

The last two steps of purine metabolism in humans are the conversion of hypoxanthine to xanthine, and of xanthine to uric acid, catalyzed by the enzyme xanthine oxidase. Serum uric acid (SUA) levels are higher in males than in females. Pathological hyperuricaemia is defined as an SUA level of 408 μmol/L above which monosodium urate crystal formation occurs in vitro at physiological pH and temperature, although it may occur in peripheral joints with lower tissue pH and temperature, for example, 360 μmol/L at 35°C and 300 μmol/L at 30°C. Hyperuricaemia is mostly asymptomatic, although OA joints are more prone to attacks of gout. The range of SUA for individuals with gout is higher than in healthy controls. SUA levels increase with age, obesity, a 'Western' diet (see earlier) and combined hyperlipidaemia, diabetes mellitus, ischaemic heart disease, and hypertension (metabolic syndrome; see Chapter 37). Gout is often familial.

Pathogenesis of hyperuricaemia and gout

Uric acid is the final product of endogenous and dietary purine metabolism in humans, and SUA depends on the balance between purine synthesis, ingestion of dietary purines, and the elimination of urate by the kidney (66%) and intestine (33%).

Some 90% of people with gout have impaired excretion of uric acid (10% have increased production due to high cell turnover and <1% due to an inborn error of metabolism). Renal excretion is coordinated by a group of secretory and reabsorptive renal tubular urate transport molecules, some of which are targets of urate-lowering drugs. These molecules can be grouped into reabsorptive urate anion exchangers (URAT1/SLC22A12, OAT4/SLC22A11, and OAT10/SLC22A3), the resorptive GLUT9/SLC2A9 urate transporter, secretory anion-exchange transporters (OAT1, OAT2, and OAT3) and sodium-phosphate transporter proteins (NPT1/SLC17A1 and NPT4/SLC17A3), and the ATP-driven secretory pump MRP4/SLC17A3 (Fig. 32.34). The secretory transporter ABCG2 is significant in the gut, with reduced functioning contributing to extrarenal under-excretion. GWAS have identified prominent loci encoding urate transporters: primarily SLC2A9 and ABCG2; with a second tier dominated by genes encoding SLC22A11, SLC22A12, SLC17A1, and SLC17A3. Causes of hyperuricaemia are shown in Box 32.37.

Gout as an autoinflammatory disease

The involvement of the innate immune system and inflammasomes indicates that gout is an autoinflammatory disease, similar to the hereditary periodic fevers (see 'Miscellaneous arthropathies' section). This response is initiated when monosodium urate crystals interact with resident macrophages to form and activate NLRP3 inflammasome. Caspase 1 is recruited by the activated inflammasome (see Chapter 6) leading to activation of IL-1β and cellular activation, which triggers an IL-8-mediated influx of neutrophils. Ingestion by polymorphonuclear leucocytes of monosodium urate crystals causes the release of pro-inflammatory cytokines, particularly IL-1β and complement. Colchicine inhibits the microtubule formation that is necessary for this process to occur.

Clinical features

Hyperuricaemia may be asymptomatic or may cause:

- ***Acute gout***, followed by an asymptomatic intercritical phase; a second acute attack is likely within 2 years.
- ***Chronic interval gout***, with acute attacks superimposed on low-grade inflammation and potential joint damage.

Box 32.37 Causes of hyperuricaemia

Impaired excretion of uric acid
- Chronic renal disease (clinical gout unusual)
- Drug therapy, e.g., thiazide diuretics, low-dose aspirin
- Hypertension
- Lead toxicity
- Primary hyperparathyroidism or hypothyroidism
- Increased lactic acid production from alcohol, exercise, starvation
- Glucose-6-phosphatase deficiency (interferes with renal excretion)

Increased production of uric acid

Increased purine synthesis de novo due to:
- Hypoxanthine–guanine–phosphoribosyl transferase (HGPRT) reduction (an X-linked inborn error causing the Lesch–Nyhan syndrome)
- Phosphoribosyl-pyrophosphate synthase overactivity
- Glucose-6-phosphatase deficiency with glycogen storage disease type 1

Increased turnover of purines due to:
- Myeloproliferative disorders, e.g., polycythaemia vera
- Lymphoproliferative disorders, e.g., leukaemia
- Others, e.g., carcinoma, severe psoriasis

- ***Chronic polyarticular tophaceous gout***, which is rare and characterized by chronic joint pain, activity limitation, structural joint damage, and frequent flares.
- ***Urate renal stone*** formation (see Chapter 26).

Acute gout presents typically in a middle-aged male with a sudden onset of agonizing pain, swelling, and redness of the first MTP joint (**Fig. 32.16**). The attack may be precipitated by excess food, alcohol, dehydration, or diuretic therapy. Untreated attacks last about 7 days. Recovery is typically associated with desquamation of the overlying skin. In 25% of attacks, a joint other than the great toe is affected. Triggers for flares include acute medical or surgical illness, dehydration, or dietary factors such as alcohol intake or purine-rich foods.

In severe attacks, overlying crystal cellulitis makes gout difficult to distinguish clinically from infective cellulitis. A family or personal history of gout and the finding of a raised SUA suggest the diagnosis but, if in doubt, blood and joint fluid cultures should be taken to exclude sepsis.

Chronic tophaceous gout is described below.

Investigations

The clinical picture is often diagnostic, as is the rapid response to NSAIDs or colchicine.

- ***Joint fluid microscopy*** is the most specific and diagnostic test but is technically difficult.
- ***Serum uric acid*** is usually raised (>600 μmol/L). If it is not, it should be rechecked several weeks after the attack, as levels fall immediately after an acute episode. Acute gout rarely occurs with SUA in the lower half of the normal range below the saturation point of 360 μmol/L.
- ***Serum urea, creatinine***, and estimated glomerular filtration rate (eGFR) are monitored for signs of renal impairment.

Management

The use of NSAIDs or coxibs in high doses rapidly reduces the pain and swelling. The first dose should be taken at the first indication of an attack:

- ***Naproxen:*** 750 mg immediately, then 500 mg every 8–12 h
- ***Diclofenac:*** 75–100 mg immediately, then 50 mg every 6–8 h.

After 24–48 hours, reduced doses are given for a further week.

Caution: NSAIDs may cause renal impairment. In individuals with renal impairment or a history of peptic ulceration, alternative treatments include:

- ***Colchicine:*** loading doses will cause diarrhoea or colicky abdominal pain, so 500 μg 2–3 times per day is usually sufficient to terminate attacks without side-effects.
- ***Corticosteroids:*** oral prednisolone or intramuscular or intra-articular depot methylprednisolone is used.

Dietary advice

The first attacks may be separated by up to 2 years and are managed symptomatically. Recognition and prompt treatment, including lifestyle modifications, are paramount. Advice to reduce alcohol intake, especially beer, which is high in purines and fructose, and consumption of non-diet carbonated soft drinks, also high in fructose, is essential; other dietary change include reduction of total calorie and cholesterol intake, and avoidance of purine-rich foods, such as offal, red meat, shellfish and spinach. These modifications can reduce serum urate by 15% and delay the need for drugs that reduce serum urate levels. Dietary advice is readily available on the Internet.

Treatment with agents that reduce serum uric acid levels

The aim of treatment is to reduce and maintain the uric acid level below 360 μmol/L in all patients, and in those with severe gout, such as tophi or frequent attacks, a lower level below 300 μmol/L is required to achieve clinical remission.

Allopurinol

Allopurinol should only be used when the attacks are frequent and severe (despite dietary changes), or associated with renal impairment or tophi, or when the patient finds NSAIDs or colchicine difficult to tolerate. Allopurinol is a xanthine oxidase inhibitor, which reduces SUA levels rapidly; it is relatively non-toxic but should be used at low doses (50–100 mg) in renal impairment. It can be started during an acute attack and always under cover of NSAIDs or colchicine for the first 2–4 weeks before and 4 weeks after starting allopurinol, as it may induce acute gout. Theories to explain allopurinol-induced exacerbation of gout are controversial and lack evidence, generally implicating urate concentration flux and remodelling/destabilization of intra-articular microscopic tophi. The dose can be increased gradually from 100 mg every few weeks until the uric acid level is below the 360 μmol/L level. Skin rashes and gastrointestinal intolerance are the most common side-effects. A hypersensitivity reaction is the most serious but rare adverse event, as is bone marrow suppression. Xanthine oxidase inhibitors (including both allopurinol and febuxostat) may provoke life-threatening agranulocytosis and pancytopaenia if inadvertently prescribed to patients taking the anti-metabolite immunosuppressant drugs azathioprine or 6-mercaptopurine at conventional doses.

Febuxostat

Febuxostat (80–120 mg) is a non-purine analogue inhibitor of xanthine oxidase that is well tolerated and is an effective alternative to allopurinol. It is safer in renal impairment, as it undergoes hepatic metabolism rather than renal excretion, and is helpful in patients who cannot tolerate allopurinol. All-cause mortality and cardiovascular mortality, however, are higher with febuxostat than with allopurinol.

Pegloticase

Pegloticase, a pegylated recombinant uricase given intravenously, lowers urate levels dramatically and is recommended in US

guidance for patients with severe, refractory gout in whom target serum urate concentrations are not achieved or who cannot tolerate oral urate-lowering therapy (ULT). The drug was withdrawn from use in the European Union in 2016 due to reports of infusion reactions or anaphylaxis with concomitant use of oral ULT.

Uricosuric agents

These also lower the SUA but their use is restricted throughout Europe by the very rare occurrence of serious hepatotoxicity. ***Benzbromarone*** acts on the URAT1 transporter and is well tolerated. ***Sulfinpyrazone*** and ***probenecid*** are best avoided in renal impairment. Availability of these drugs varies between countries—in the UK, benzbromarone and probenecid can be obtained for treating named patients.

Losartan

Losartan is an angiotensin I receptor antagonist and is uricosuric in hypertensive patients with gout. It may reduce the risk of gout in patients with the metabolic syndrome.

Targeted therapies

The IL-1 receptor inhibitor anakinra, canakinumab (an anti-human IL-1β monoclonal antibody), and rilonacept (a dimeric fusion protein consisting of portions of IL-1R and the IL-1R accessory protein linked to the Fc portion of IgG1) have shown efficacy. The high cost of these agents, however, means they may only be considered in patients resistant to standard therapy.

Chronic tophaceous gout

Individuals with persistently high levels of uric acid can present with chronic tophaceous gout, as sodium urate forms smooth white deposits (tophi) in skin and around joints, on the ear, fingers (Fig. 32.35) or the Achilles tendon. Large deposits are unsightly and ulcerate. There is chronic joint pain and sometimes superimposed acute gouty attacks.

Periarticular deposits lead to a halo of radio-opacity and clearly defined ('punched out') bone cysts on X-ray.

Tophaceous gout is often associated with renal impairment and/or the long-term use of diuretics. There may be acute or chronic urate nephropathy or renal stone formation. Whenever possible, diuretics should be stopped or changed to less urate-retaining ones, such as bumetanide. Treatment is with allopurinol and/or uricosuric agents (see above).

Calcium pyrophosphate dihydrate deposition arthropathy

Deposition of calcium pyrophosphate dehydrate (CPP) crystals in hyaline and fibrocartilage is the most common cause of CC.

Fig. 32.35 Gout with tophi. *(Courtesy of Dr Varkey Alexander, Al-Sabah Hospital, Kuwait.)*

Previous terms, including pseudogout, have been unified into calcium pyrophosphate dihydrate deposition (CPPD) arthropathy. CPPD-associated arthritis is the third most common inflammatory arthritis, which increases with age, OA, joint trauma/injury, and metabolic disease (hyperparathyroidism, haemochromatosis, hypomagnesaemia), and has a familial predisposition. Shedding of crystals into a joint precipitates acute synovitis that resembles gout, except that it is more common in elderly females and usually affects the knee, ankle, or wrist (Fig. 32.16).

Diagnosis

Diagnosis is made by detecting rhomboidal, weakly positively birefringent crystals in joint fluid (see Fig. 32.33), or is deduced from the presence of CC on X-ray. Joint fluid looks purulent so should be sent for culture to exclude septic arthritis, as the attacks may also be associated with fever and a raised white blood cell count.

Management

There is no specific treatment to eliminate calcium pyrophosphate crystals. Therefore, management is focused on symptom control and treatments overlap with those for gout and OA. An evidence base is lacking in this condition, however, and there have been no randomized controlled clinical trials of acute management. Aspiration of the joint reduces the pain dramatically but it is usually necessary to use an NSAID or colchicine, as for gout. If infection can be excluded, an intra-articular injection of a corticosteroid helps. CPP crystals activate the NLRP3 inflammasome-IL-1 pathway (see Chapter 6) and although benefits have been shown with anakinra in small studies, it was not superior to prednisolone.

Basic calcium phosphate deposition disease

Basic calcium phosphate (BCP) crystals, including hydroxyapatite, tricalcium phosphate, and octacalcium phosphate, can be deposited in any tissues, particularly at intra-articular and periarticular locations. Crystal formation is thought to be partly regulated by the effects of extracellular inorganic phosphate on chondrocytes and is linked with the development of OA. BCP crystals cause joint damage through induction of fibroblast proliferation, inflammatory cytokines (IL-1β and TNF-α), nitric oxide, and metalloproteinases.

BCP crystal deposits in periarticular soft tissue may be asymptomatic or can cause acute calcific periarthritis (particularly in the supraspinatus tendon), tendonitis, bursitis, and enthesitis. Less frequently, they can cause arthritis. In acute attacks, periarticular tissues or joints can be swollen, tender, and hot. This presentation may mimic cellulitis, gout, CPPD disease, and septic arthritis. Periarticular or articular BCP crystal deposits are also found in an extremely destructive chronic arthropathy of the elderly that occurs most often in shoulders (Milwaukee shoulder) or other large joints, such as the hips and knees, and in erosive OA of the fingers.

Diagnosis

The diagnosis is made clinically and septic arthritis should be excluded. A neutrophilia with elevation of ESR and CRP may occur during an acute attack. Intra- and/or periarticular calcifications, with or without erosive, destructive, or hypertrophic changes, may be seen on X-ray. Alizarin red S staining is not specific for BCP crystals in synovial fluid and other calcium-containing particulates are also stained by this method.

Management

Management of acute attacks is similar to that of CPPD disease with NSAIDs, oral colchicine, aspiration of effusions, and/or

intra-/periarticular injection of steroids to try to shorten the duration of symptoms. In patients with underlying progressive articular changes, the response to medical therapy is usually less rewarding. Total joint replacement may be required for patients with severe destructive arthropathy in large joints.

INFECTION OF JOINTS

For general principles in diagnosis and management of the acutely septic joint and discussion of common pathogens, see Chapter 11.

Specific types of bacterial arthritis

Gonococcal arthritis

Disseminated gonococcal infection occurs in 0.5%–3% of patients infected with *Neisseria gonorrhoeae*. It is a common cause of acute arthritis in previously fit young adults, with increasing rates in males in general and men who have sex with men.

Patients present with a fever and characteristic pustules on the distal limbs, often in association with polyarthralgia and tenosynovitis. Blood cultures are reportedly positive in up to 70% of cases, particularly those with skin lesions, tenosynovitis, and polyarthralgia. Nucleic acid amplification tests may be positive even when cultures are negative. Patients should be screened for other STIs. Later, large-joint mono- or pauciarticular arthritis may follow. Culture is usually positive from the genital tract, although the joint fluid may be sterile. It is not clear whether this joint inflammation is simply a septic arthritis (which responds rapidly to antibiotics), or whether there is also a reactive element to a variety of virulence and growth factors specific to *N. gonorrhoeae*.

Management consists of initial i.v. ceftriaxone (or cefotaxime or ceftizoxime) repeatedly until clinical improvement occurs, plus a single oral dose of azithromycin or alternatively a week of doxycycline. In the absence of purulent arthritis after 2–3 days of improvement a 7-day course of therapy may be completed with intramuscular ceftriaxone. Purulent arthritis, however, often requires 7–14 days of i.v. therapy and joint drainage.

Tuberculous arthritis

Around 1% of people with tuberculosis develop joint and/or bone involvement. It occurs as the primary disease in children. In adults, it is usually due to haematogenous spread from pulmonary or renal lesions. The onset is insidious and diagnosis often delayed.

The organism invades the synovium or intervertebral disc. There are caseating granulomas and rapid destruction of cartilage and adjacent bone. Some patients develop a reactive polyarthritis (Poncet's disease).

Osteoarticular TB most commonly affects the spine (50%), hip (12%–15%), knee (10%), and ribs (10%). Patients become febrile with night sweats, anorexia, and weight loss. The usual risk factors for tuberculosis apply—debility, excess alcohol use, or immunosuppression. People with untreated or poorly controlled HIV infection or AIDS are at particular risk.

Investigations should include culture of fluid, and culture and biopsy of the synovium. *Mycobacterium tuberculosis* is the usual organism but atypical mycobacteria are occasionally implicated. A chest X-ray should be performed. Initially, joint or spinal X-rays may be normal but joint-space reduction and bone destruction develop rapidly if treatment is delayed. MRI shows the abnormality earlier in the spine and CT-guided biopsy from the affected disc is often necessary to obtain cultures.

Management is as for pulmonary tuberculosis with 6 months therapy in people with active TB without CNS involvement and 12 months in the presence of CNS involvement. The joint should be rested and the spine immobilized in the acute phase.

Meningococcal arthritis

Joint inflammation may complicate meningococcal septicaemia, presenting as a migratory polyarthritis. Organisms are rarely cultured from the joint and most cases are due to immune-complex deposition. Treatment is urgent with immediate penicillin therapy.

Infective endocarditis

This condition may present with arthralgia, PMR-like symptoms, or an infective arthritis (see Chapter 17).

Lyme arthritis

About 25% of people with Lyme disease develop arthralgia, less commonly an acute pauciarticular arthritis (see Chapter 42); this usually resolves but 10% of untreated cases go on to develop a chronic arthritis. There are no positive markers of an ongoing infection in these patients).

Diagnosis is by the detection of IgM antibodies against the spirochaete *Borrelia burgdorferi*.

Treatment with antibiotics (amoxicillin or doxycycline) is highly effective in early disease.

Brucellosis

Brucellosis (see Chapter 42) has a worldwide distribution. The most common cause of chronic brucellosis and of arthritis is *Brucella melitensis*. There is usually a migratory large-joint mono- or oligoarticular arthritis, which is septic or reactive. Arthritis is more common in chronic infections of more than 6 months.

Leprosy

Acute or chronic symmetrical polyarthritis resembling RA, swollen hands and feet due to lepra reactions, tenosynovitis, and thickened nerves with or without cutaneous manifestations are seen in leprosy (see Chapter 42).

Arthritis in viral disease

A transient polyarthritis or arthralgia can occur before, during, or after many viral illnesses. These include infectious mononucleosis, chickenpox, mumps, adenovirus, rubella, erythrovirus B19, hepatitis B and C, arboviral infections, and HIV. In most of these, it is due to a direct toxic effect or immune-complex deposition.

Rubella

In rubella (see Chapter 42), the virus can occasionally be isolated from the joint. This arthritis is rare in countries where rubella vaccination is routine. It occurs in up to 50% of young adult females a few days after rubella infection (6% of males). It is a symmetrical polyarthritis involving the MCP or PIP joints most commonly, but many joints can be affected. It closely resembles RA. IgM rubella antibodies are present. It resolves within a few weeks in most cases. A mild arthritis occurs rarely 2–4 weeks after rubella vaccination.

Erythrovirus B19

Erythrovirus B19 (see Chapter 42) causes an acute, self-limiting arthritis and is associated with erythema infectiosum ('slapped cheek disease').

Hepatitis

In hepatitis B infection (see Chapter 23), a sudden, symmetrical polyarticular arthritis of the small joints of the hands occurs in approximately one-third of patients, often in the prodromal phase, and mostly resolves before the onset of jaundice. Hepatitis C infection causes type II mixed cryoglobulinaemia (see Chapter 26).

Arbovirus

Arbovirus infections (see Chapter 42), which are endemic in many parts of the world, give rise to an arthralgia and/or arthritis. For example, the Ross River virus causes an epidemic polyarthritis in Australia and the South Pacific; it involves the small joints of the hands and clears in 2–4 weeks. Other viral infections causing epidemic arthritis include chikungunya and o'nyong-nyong.

Musculoskeletal aspects of infection with HIV and AIDS

Musculoskeletal manifestations are common in these patients and are often caused by triggers such as opportunistic infections and drug therapy rather than HIV itself. Infective arthritis seen in these immunosuppressed patients often has minimal symptoms and signs. Certain of the antiviral agents cause an acute arthritis, possibly because of crystallization in the joint.

Arthralgia is common in AIDS. There is a ***seronegative, predominantly lower-limb arthritis***, similar to psoriasis or reactive arthritis. ***Spondylitis*** also occurs but is not associated with HLA-B27. ***Avascular necrosis***, possibly associated with corticosteroids or alcohol, is seen.

Non-articular diseases, such as Sjögren- and lupus-like syndromes, systemic vasculitis of the necrotizing and hypersensitivity types, and myositis also occur.

Fungal infections

Fungal infections of joints occur rarely. Bone abscesses may be seen. Destructive joint lesions can also occur with blastomycosis. A benign polyarthritis accompanied by erythema nodosum occasionally occurs in coccidioidomycosis and histoplasmosis. Culture of purulent synovial fluid and skin tests for fungi may help the diagnosis.

AUTOIMMUNE RHEUMATIC DISEASES

Autoimmune diseases are conditions in which the immune system attacks tissues of the body. The antigens can be present in multiple organs so the clinical manifestations are systemic and diverse. In some diseases, such as Graves' disease, Hashimoto's thyroiditis, and type 1 diabetes mellitus, only a single organ is affected. Each individual autoimmune rheumatic disease (ARD) has a characteristic pattern of symptoms and signs, which are used to make the diagnosis. In some ARDs, there are also characteristic autoantibodies (i.e., antibodies that recognize antigens that are normal constituents of the body, such as DNA and phospholipids). Positive blood tests for autoantibodies are useful but not essential in the diagnosis of ARDs (Box 32.38).

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is an inflammatory, multisystem autoimmune disorder with arthralgia and rashes as the most common clinical features, and cerebral and renal disease as the most serious problems.

Epidemiology

SLE occurs worldwide and is about nine times as common in females as in males, with a peak age of onset between 20 and 40 years. The prevalence varies between ethnic groups, being highest (at 1:250) in females of African or Caribbean background. In other populations, the prevalence varies between 1:1000 and 1:10000.

Aetiology

The cause is unknown but there are several predisposing factors:

- ***Heredity.*** There is a higher concordance rate in monozygotic twins (up to 25%) compared with dizygotic twins (3%).

Box 32.38 Antinuclear autoantibodies and disease associations

Antibody	Disease	Prevalence
ds-DNA	SLE	70%
Anti-histone	Drug-induced lupus	–
Anti-centromeric	Limited scleroderma	70%
Anti-Ro (SS-A)	SLE	40%–60%
	Primary Sjögren's	60%–90%
Anti-La (SS-B)	SLE	15%
	Primary Sjögren's	35%–85%
Anti-Sm	SLE	10%–25% (Caucasian)
		30%–50% (black African)
Anti-UI-RNP	SLE	30%
	Overlap syndrome	
Anti-Jo-1 (antisynthetase)	Polymyositis	30%
	Dermatomyositis	
Anti-topoisomerase-1 (Scl-70)	Diffuse cutaneous SSc	30%

ds-DNA, Double-stranded DNA; *RNP,* ribonucleoprotein; *Ro, La,* first two letters of name of patients; *SLE,* systemic lupus erythematosus; *Sm,* Smith, patient's name; *SS-A, SS-B,* Sjögren's syndrome A and B; *SSc,* systemic scleroderma.

First-degree relatives have a 3% chance of developing the disease but approximately 20% have autoantibodies.

- ***Genetics.*** Over 50 whole-genome analyses have led to the identification of a large number of genes linked to the development of SLE. These include some HLA genes, as well as genes involved in T- and B-lymphocyte function and genes related to autophagy and interferon function. Homozygous deficiencies of the complement genes C1q, C2, or C4 are very rare but convey a high risk of developing SLE.
- ***Sex hormone status.*** Premenopausal females are most frequently affected.
- ***Drugs.*** Drugs such as hydralazine, isoniazid, procainamide, and penicillamine can induce a form of SLE that is usually mild, in that the kidneys and CNS are not affected.
- ***Ultraviolet light.*** This can trigger flares of SLE, especially in the skin.
- ***Exposure to Epstein–Barr virus.*** This has been suggested as a trigger for SLE.

Pathogenesis

When cells die by apoptosis, the cellular remnants appear on the cell surface as small blebs that carry self-antigens. These antigens include nuclear constituents (e.g., DNA and histones), which are normally hidden from the immune system. In people with SLE, removal of these blebs by phagocytes is inefficient, so that they are transferred to lymphoid tissues, where they can be taken up by antigen-presenting cells. The self-antigens from these blebs can then be presented to T cells, which in turn stimulate B cells to produce autoantibodies directed against these antigens (see Chapter 6). It has been shown that, in some patients, the autoantibodies are present in stored blood samples that were taken years before the patient developed clinical features of SLE. The combination of availability of self-antigens and failure of the immune system to inactivate B cells and T cells that recognize these self-antigens (i.e., a breakdown of *tolerance*; see Chapter 6) leads to the following immunological consequences:

- Development of autoantibodies that either form circulating complexes or deposit by binding directly to tissues.
- Activation of complement and influx of neutrophils, causing inflammation in those tissues.
- Abnormal cytokine production: increased blood levels of IL-10 and interferon-alpha are particularly closely linked to high activity of inflammation in SLE, and anifrolumab—a monoclonal antibody that targets the interferon receptor—has been shown to be effective in the treatment of some patients with SLE.

More recently, other cells have been implicated in the pathogenesis of SLE. These include dendritic cells, which are activated by immune complexes containing nucleic acids to produce interferon, and invariant natural killer T cells (iNKT cells), which are reduced in number and function in patients with SLE.

Pathology

SLE of the skin and kidneys is characterized by deposition of complement and IgG antibodies, and by influx of neutrophils and lymphocytes. Biopsies of other tissues are carried out less frequently but can show vasculitis affecting capillaries, arterioles, and venules. The synovium of joints can be oedematous and may contain immune complexes. Haematoxylin bodies (rounded, blue, homogeneous haematoxylin-stained deposits) are seen in inflammatory infiltrates and are thought to result from the interaction of antinuclear antibodies and cell nuclei.

The pathology of lesions in other organs is described in the appropriate chapters.

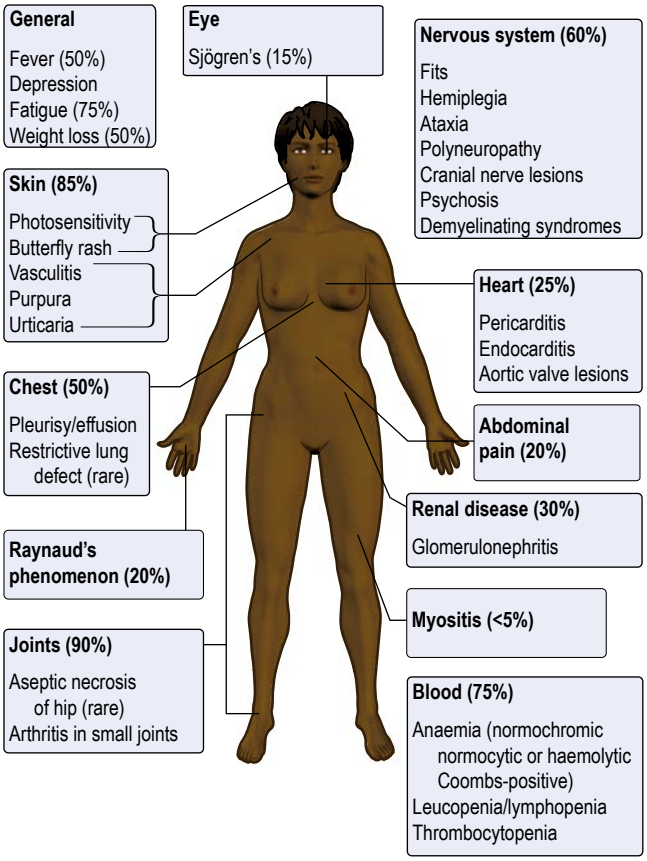

Fig. 32.36 Clinical features of systemic lupus erythematosus.

Clinical features

The manifestations of SLE vary greatly between patients. Most patients suffer fatigue, arthralgia, and/or skin problems. Involvement of major organs is less common but more serious (Fig. 32.36).

General features

Fever is common in exacerbations. Patients complain of marked malaise and tiredness, and these symptoms do not correlate with disease activity or severity of organ-based complications.

Joints and muscles

Joint involvement is the most common clinical feature (>90%). Patients often present with symptoms resembling RA with symmetrical small joint arthralgia. Joints are painful but characteristically appear clinically normal, although sometimes there is slight soft tissue swelling surrounding the joint. Deformity because of joint capsule and tendon contraction is rare, as are bony erosions. Rarely, major joint deformity resembling RA (known as ***Jaccoud's arthropathy***) is seen. These deformities are reducible, unlike those seen in severe RA. Avascular necrosis affecting the hip or knee is a rare complication of the disease or of treatment with corticosteroids.

Myalgia is present in up to 50% of patients but a true myositis is seen in only less than 5%. If myositis is prominent, the patient may well have an overlap ARD with both polymyositis and SLE.

Skin

The skin (see Chapter 45) is affected in 85% of cases. Erythema, in a 'butterfly' distribution on the cheeks of the face and across the bridge of the nose (see Fig. 45.42), is characteristic. Vasculitic lesions on the fingertips and around the nail folds, purpura, and urticaria

occur. In 40%–50% of cases, there is photosensitivity (especially in patients positive for anti-Ro antibodies). Prolonged exposure to sunlight can lead to exacerbations of the disease. Livedo reticularis, palmar and plantar rashes, pigmentation, and alopecia are seen. Scarring alopecia can lead to irreversible bald patches. Raynaud's phenomenon (see Chapter 17) is common and may precede the development of other clinical problems by years.

Discoid lupus is a benign variant of lupus in which only the skin is involved. The rash is characteristic and appears on the face as well-defined erythematous plaques that progress to scarring and pigmentation (see Chapter 45). Subacute cutaneous lupus erythematosus, a rare variant, is also described in Chapter 45.

Lungs

Up to 50% of patients will have lung involvement at some time during the course of the disease (see Chapter 20). Recurrent pleurisy and pleural effusions (exudates) are the most common manifestations and are often bilateral. Pneumonitis and atelectasis are seen; in some patients a restrictive lung defect develops, with loss of lung volumes and raised hemidiaphragms. This 'shrinking lung syndrome' is poorly understood but may have a neuromuscular basis. Rarely, pulmonary fibrosis occurs, more commonly in overlap syndromes (see "Overlap' syndromes and undifferentiated autoimmune rheumatic disease' section). Intrapulmonary haemorrhage associated with vasculitis is a rare but potentially life-threatening complication.

Heart and cardiovascular system

The heart is involved in 25% of cases. Pericarditis, with small pericardial effusions detected by echocardiography, is common, although rarely large effusions may occur resulting in cardiac tamponade. A mild myocarditis also occurs, giving rise to arrhythmias. Aortic valve lesions and a cardiomyopathy can rarely be present. A non-infective endocarditis involving the mitral valve (Libman–Sacks syndrome) is very rare. Raynaud's, vasculitis, and arterial and venous thromboses can occur, especially in association with the antiphospholipid syndrome (see below). There is an increased frequency of ischaemic heart disease and stroke in people with SLE, which is partly due to altered levels of common risk factors such as hypertension and lipid levels, but the presence of chronic inflammation over many years may also be contributory. It is not known whether intensive treatment of cardiovascular risk factors or use of statins in SLE will alter the risk of developing coronary disease or stroke.

Kidneys

A classification of types of nephritis is given in Chapter 36. Postmortem studies suggest that histological changes are very frequent, but clinical renal involvement occurs in only approximately 30% of cases. All patients should have regular screening of urine for blood and protein. An asymptomatic patient with proteinuria may be in the early stages of lupus nephritis, and treatment may prevent progression to renal impairment. Proteinuria should be quantified and haematuria should prompt examination for urinary casts or dysmorphic red cells that suggest glomerulonephritis. Renal biopsy is used to define the type and severity of nephritis. Renal vein thrombosis can occur in nephrotic syndrome or in association with antiphospholipid antibodies.

Nervous system

Involvement of the nervous system occurs in up to 60% of cases and symptoms often fluctuate. There may be a mild depression, but occasionally, more severe psychiatric disturbances occur. Epilepsy, migraines, cerebellar ataxia, aseptic meningitis, cranial nerve lesions, cerebrovascular disease, or a polyneuropathy may be seen. The pathogenic mechanism for cerebral lupus is complex. Lesions may be due to vasculitis or immune complex deposition, thrombosis, or non-inflammatory microvasculopathy. In people with cerebral lupus, infection should be excluded, or treated in parallel with administration of corticosteroids and immunosuppression.

Eyes

Retinal vasculitis can cause infarcts, which appear as hard exudates, and haemorrhages. There may be episcleritis, conjunctivitis, or optic neuritis, but blindness is uncommon. Secondary Sjögren's syndrome is seen in about 15% of cases.

Gastrointestinal system

Mouth ulcers are common and may be a presenting feature. These may be painless or become secondarily infected and painful. Mesenteric vasculitis can produce inflammatory lesions involving the small bowel (infarction or perforation). Liver involvement and pancreatitis are uncommon.

Investigations

Blood

- ***A full blood count*** may show a leucopenia, lymphopenia, and/or thrombocytopenia. Anaemia of chronic disease or autoimmune haemolytic anaemia also occurs. The ESR is raised in proportion to the disease activity. In contrast, the CRP is usually normal but may be high when the patient has lupus pleuritis or peritonitis, arthritis, or a coexisting infection.
- ***Urea and creatinine*** only rise when renal disease is advanced. Low serum albumin, high urine albumin/creatinine ratio, or an active urinary sediment are earlier indicators of lupus nephritis.
- ***Autoantibodies*** of many different types may be present in SLE but the most significant are ANA, anti-dsDNA, anti-Ro, anti-Sm, and anti-La (see **Box 32.38**). Antiphospholipid antibodies are present in 25%–40% of cases but not all of these patients develop antiphospholipid syndrome (see later).
- ***Serum complement*** C3 and C4 levels are often reduced during active disease. The combination of high ESR, high anti-dsDNA, and low C3 may herald a flare of disease. All these markers tend to return towards normal as the flare improves, but in some patients, anti-dsDNA levels will remain high even during clinical remission.

Histology

Characteristic histological and immunofluorescent abnormalities (deposition of IgG and complement) are seen in biopsies from the kidney and skin.

Diagnostic imaging

CT scans of the brain sometimes show infarcts or haemorrhage with evidence of cerebral atrophy. MRI can detect lesions in white matter that are not seen on CT. However, it can be very difficult to distinguish true vasculitis from small thrombi.

Management

General measures

The disease and its management should be discussed with the patient, particularly the effect upon the patient's lifestyle: for example, appearance and debility due to fatigue. Patients are advised to avoid excessive exposure to sunlight and it is also necessary to reduce cardiovascular risk factors.

Symptomatic treatment

Arthralgia, arthritis, fever, and serositis all respond well to standard doses of NSAIDs (see 'Non-steroidal anti-inflammatory drugs' section). Topical corticosteroids are effective and widely used in cutaneous lupus. Antimalarial drugs (chloroquine or hydroxychloroquine) help mild skin disease, fatigue, and arthralgias that cannot be controlled with NSAIDs, but patients require regular eye checks because of potential retinal toxicity. It is now thought that retinal changes occur in up to 7.5% of patients on long-term treatment with hydroxychloroquine, with increased risk in those taking more than 5 mg/kg per day.

Corticosteroids and immunosuppressive drugs

Single intramuscular injections of long-acting corticosteroids or short courses of oral corticosteroids are useful in treating severe flares of arthritis, pleuritis, or pericarditis. In some cases, these symptoms can only be kept under control using long-term oral corticosteroids.

Renal or cerebral disease and severe haemolytic anaemia or thrombocytopenia must be treated with high-dose oral corticosteroids, and the first two of these require immunosuppressive drugs in addition. Cyclophosphamide was most commonly used to achieve remission in these severe forms of lupus but has largely been replaced by mycophenolate mofetil, which has fewer side-effects. Azathioprine is also used to maintain remission. Calcineurin inhibitors (ciclosporin, tacrolimus, or voclosporin) and methotrexate are also used, but in fewer cases than azathioprine or mycophenolate. Newer agents, which specifically target cells or cytokines in the immune system, are coming into use, especially in refractory cases. These include rituximab (anti-CD20) and belimumab (anti-BLyS), which are both monoclonal antibodies acting against B lymphocytes, and the anti-interferon receptor agent anifrolumab. There have been case reports of successful use of chimeric antigen receptor T cells (CAR-T cells) targeted against B cells in refractory SLE. Currently biologics remain second-line options where standard immunosuppressives have failed and CAR-T cells have only been used in a small number of cases of severe refractory disease.

Prognosis

An episodic course is characteristic, with exacerbations and complete remissions that may last for long periods. However, SLE can also be a chronic persistent condition. The mortality rate in SLE has fallen dramatically over the last 50 years; the 10-year survival rate is about 90%, but this is lower if major organ-based complications are present. Deaths early in the course of disease are mainly due to renal or cerebral disease or infection. Later, coronary artery disease and stroke become more prevalent. Chronic progressive destruction of joints, as seen in RA and OA, occurs rarely, but a few patients develop deformities such as ulnar deviation. People with SLE have an increased long-term risk of developing some cancers, especially lymphoma.

Pregnancy and SLE

Fertility is usually normal, except in severe disease, and there is no major contraindication to pregnancy. Recurrent miscarriages can occur, especially in women with antiphospholipid antibodies. Exacerbations can arise during pregnancy and are frequent postpartum. The patient's medications should be reviewed. Mycophenolate is teratogenic and should be stopped at least 6 weeks in advance of conception, whereas azathioprine, hydroxychloroquine, and low-dose oral corticosteroids are safe. Hypertension must be controlled.

People with anti-Ro or anti-La antibodies have a 2% risk of giving birth to babies with neonatal lupus syndrome (rash, hepatitis, and fetal heart block).

Antiphospholipid syndrome

Patients who have thrombosis (arterial or venous) and/or recurrent miscarriages (see Chapter 47), and who also have persistently positive blood tests for antiphospholipid antibodies (aPL), have the antiphospholipid syndrome (APS). Antiphospholipid antibodies can be detected by several different tests:

- The ***anticardiolipin test***, which detects antibodies (IgG or IgM) that bind the negatively charged phospholipid, cardiolipin.
- The ***lupus anticoagulant test***, which detects changes in the ability of blood to clot in a test tube. Despite the name, it is not a test for lupus. It is a test for APS. The ***anticoagulant*** effect caused by aPL in the test tube causes an opposite ***procoagulant*** effect inside the body because the balance of factors stimulating thrombosis is different there.
- The ***anti-β_2-glycoprotein I test***, which detects antibodies that bind β_2-glycoprotein I, a molecule that interacts closely with phospholipids.

A persistently positive test (i.e., positive on at least two occasions ≥12 weeks apart) in one or more of these assays is needed to diagnose APS. However, some people who test positive for aPL will never develop APS; that is, not all aPLs are harmful. APS can present in patients who already have another ARD, especially SLE. APS can also occur on its own (primary APS).

New diagnostic tests for APS are being developed and include anti-prothrombin assays, tests for IgA aPL, and tests for antibodies to the N-terminal domain of β_2-glycoprotein I. Although not currently used in clinical practice, these tests may soon be helpful for assessing the overall thrombosis risk of a patient with APS, or for diagnosing patients with non-criteria APS who have typical clinical features but test negative for anticardiolipin, lupus anticoagulant and anti–β_2-glycoprotein I.

Pathogenesis

Negatively charged phospholipids and β-glycoprotein I are present on the outer surface of apoptotic blebs, and so aPLs are believed to arise by a similar mechanism to the lupus autoantibodies described above. Pathogenic aPLs bind to the N-terminal domain of β_2-glycoprotein I. Changes in the oxidation state of β_2-glycoprotein I in patients with APS enhance the availability of this domain to bind aPLs, and this interaction is facilitated when the protein is bound to phospholipid on the surface of cells such as endothelial cells, platelets, monocytes, and trophoblasts. This change alters the functioning of those cells, leading to thrombosis and/or miscarriage.

Clinical features

Ischaemic strokes occur in about 20% of patients and DVT in about 40%. Unlike most causes of thrombophilia, APS can cause either arterial or venous thrombosis (though rarely both in the same patient). Some 27% of women who have had two or more spontaneous miscarriages have APS.

Large studies, however, show that people with APS can also have many other features, including:

- thrombocytopenia
- chorea, migraine, and epilepsy
- valvular heart disease
- cutaneous manifestations (e.g., livedo reticularis)
- positive Coombs test

- renal impairment due to ischaemia in the small renal vessels.

Catastrophic APS is a rare variant (about 1% of cases) in which multiple infarcts in different organs of the body cause failure of multiple organs simultaneously. There is a high mortality from catastrophic APS.

Management

Guidelines for managing patients with APS and people with aPL who have never had thrombosis have been published by the European Alliance of Associations for Rheumatology. In people with APS who have had one thrombosis or more, the recommended treatment to prevent further thrombosis is long-term anticoagulation with warfarin, although the guidelines say that indefinite anticoagulation may not be necessary if a particular event clearly provoked the thrombosis. The target INR is lower in people with a history of venous compared to arterial thrombosis. Pregnant women with APS, in whom warfarin is contraindicated, are given oral aspirin and subcutaneous low-molecular-weight heparin from early in gestation. This therapy reduces the chance of a miscarriage but pre-eclampsia and poor fetal growth remain common. Aspirin or clopidogrel are sometimes given prophylactically in aPL-positive people who have never had a thrombosis, especially if they are triple positive in all three of the aPL-tests—which is a known predictor of high thrombotic risk. Warfarin is given much more rarely in these circumstances, but may be indicated in patients at particularly high risk; for example, those who have other risk factors for thrombosis as well as aPL. Direct oral anticoagulants (DOACs, including factor Xa and direct thrombin inhibitors) are not routinely prescribed in APS in light of clinical trials which did not favour their use in comparison with warfarin.

Systemic sclerosis (scleroderma)

Systemic sclerosis (SSc, or scleroderma; see Chapter 45) is a multisystem disease and is distinct from localized scleroderma syndromes, such as morphea, that do not involve internal organ disease and are rarely associated with vasospasm (Raynaud's phenomenon). SSc has the highest case-specific mortality of any of the autoimmune rheumatic diseases. It occurs worldwide but there may be racial or ethnic differences in clinical features. For example, renal involvement is less frequent in Japanese people.

The incidence of SSc is 10/million population per year with a 3:1 female to male ratio. The peak incidence is between 30 and 50 years of age. It is rare in children.

Environmental risk factors for scleroderma-like disorders include exposure to vinyl chloride, silica dust, adulterated rapeseed oil, and trichloroethylene. Drugs such as bleomycin also produce a similar picture. Although unusual, familial cases are reported and twin cohorts suggest higher concordance in monozygotic pairs, consistent with genetic determinants of aetiology.

Pathology and pathogenesis

Vascular features

Widespread vascular damage involving small arteries, arterioles, and capillaries is an early lesion. There is initial endothelial cell damage with release of cytokines, including endothelin-1, which causes vasoconstriction. There is continued intimal damage with increasing vascular permeability, leading to cellular activation and activation of adhesion molecules (E-selectin, VCAM, intercellular adhesion molecule 1 [ICAM-1]), with migration of cells into the extracellular matrix. Migrating lymphocytes are IL-2-producing cells, expressing surface antigens such as CD3, CD4, and CD5. All these factors cause release of other mediators (e.g., IL-1, 4, 6, and 8, TGF-β and platelet-derived growth factor) with activation of fibroblasts. Plasma levels of the chemokine CXCL4 are elevated in SSc and correlate with skin and lung fibrosis.

The damage to small blood vessels also produces widespread obliterative arterial lesions and subsequent chronic ischaemia.

Fibrotic features

Fibroblasts synthesize increased quantities of collagen types I and III, as well as fibronectin and glycosaminoglycans, producing fibrosis in the lower dermis of the skin as well as the internal organs. It is possible that antibodies to platelet-derived growth factor receptor, which have been found in blood of people with SSc, stimulate fibroblasts to cause fibrosis.

Clinical features

See Fig. 32.37.

Raynaud's phenomenon

Raynaud's phenomenon is seen in almost all cases and can precede the onset of the full-blown disease by many years.

Limited cutaneous scleroderma (LcSSc): 70% of cases

This condition usually starts with Raynaud's phenomenon many years (up to 15) before any skin changes. The skin involvement is limited to the hands, face, feet, and forearms. The skin is tight over the fingers and often produces flexion deformities of the fingers. Involvement of the skin of the face produces a characteristic 'beak'-like nose and a small mouth (microstomia). Painful digital ulcers and telangiectasia with dilated nail-fold capillary loops are seen. Digital ischaemia may lead to gangrene. Gastrointestinal tract involvement is common. Pulmonary hypertension develops

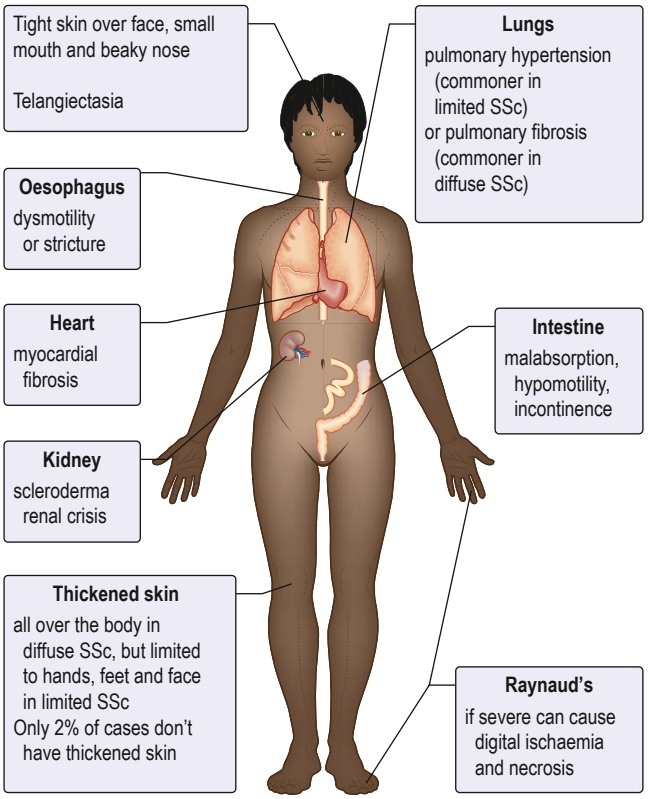

Fig. 32.37 Clinical features of systemic sclerosis (SSc).

in 21% of people with LcSSc and pulmonary interstitial disease also occurs.

Diffuse cutaneous scleroderma (DcSSc): 30% of cases

Initially oedematous in onset, skin sclerosis rapidly follows. Raynaud's phenomenon usually starts just before or concomitant with the oedema.

Diffuse swelling and stiffness of the fingers is rapidly followed by more extensive skin thickening, which can involve most of the body in the severest cases. Later, the skin becomes atrophic. Early involvement of other organs occurs with general symptoms of lethargy, anorexia, and weight loss.

- ***Gastrointestinal involvement*** includes heartburn, reflux, or dysphagia due to oesophageal involvement (see Chapter 22), which is almost invariable. Anal incontinence occurs in many patients. Malabsorption from bacterial overgrowth due to dilatation and atony of the small bowel is not infrequent; more rarely, dilatation and atony of the colon occurs. Pseudo-obstruction is a known complication.
- ***Renal involvement*** is acute or chronic (see Chapter 26). Acute hypertensive renal crisis used to be the most common cause of death in systemic sclerosis. Angiotensin-converting enzyme (ACE) inhibitors and better care, along with dialysis and renal transplantation, have changed this.
- ***Lung disease***, both fibrosis (in 41% of cases) and pulmonary hypertension (17% of cases), contributes significantly to mortality in SSc. Pulmonary hypertension can be isolated or secondary to fibrosis, and high plasma levels of endothelin-1 are seen.
- ***Myocardial fibrosis*** leads to arrhythmias and conduction defects. Pericarditis is found occasionally.

Sometimes, these systemic features occur without skin involvement (SSc *sine* scleroderma).

Investigations

- ***Full blood count.*** A normochromic, normocytic anaemia occurs and a microangiopathic haemolytic anaemia with thrombocytopaenia is seen in some people with hypertension and renal disease.
- ***Serum creatinine and electrolytes.*** Urea and creatinine rise in acute kidney injury.
- ***Autoantibodies*** (see **Box 32.38**):
  - ***In LcSSc:*** speckled, nucleolar, or anti-centromere antibodies (ACAs) occur in 70% of cases. Anti-Th/To antibodies target small nuclear ribonucleoproteins and are found in up to 7% of cases of LcSSC.
  - ***In DcSSc:*** there are anti-topoisomerase-1 antibodies (called anti–Scl-70) in 30% of cases, and anti-RNA polymerase (I, II, and III) antibodies in 20%–25%. Anti–Scl-70 is highly specific for DcSSC. Anti-RNA polymerase positivity is associated with an increased risk of renal involvement. Anti-U3RNP antibodies bind a small nuclear ribonucleoprotein called fibrillarin and are present in up to 6% of patients with SSc—more commonly in DcSSc than LcSSc.
  - ***RF*** is positive in 30%.
  - ***ANA*** is positive in 95%.
  - ***Urine*** microscopy and, if there is proteinuria, the urine albumin/creatinine ratio should be measured.
- Imaging:
  - ***Chest X-ray:*** to exclude other pathology, for changes in cardiac size and established lung disease.
  - ***Hands:*** deposits of calcium around the fingers (in severe cases, erosion and absorption of the tufts of the distal phalanges, termed 'acro-osteolysis').
  - ***Barium swallow:*** generally confirms impaired oesophageal motility. Scintigraphy, manometry, impedance, and upper gastrointestinal endoscopy are also valuable.
  - ***Echocardiogram and lung function tests*** should be carried out annually to monitor for development of pulmonary fibrosis or pulmonary hypertension.
  - ***High-resolution CT:*** to demonstrate fibrotic lung involvement.
- ***Other investigations*** of gastrointestinal tract, lung, renal, and cardiac as appropriate.

Management

Treatment should be organ-based in order to try to control the disease. Currently, there is no cure. In contrast to many other ARDs, corticosteroids and immunosuppressants are rarely used in SSc, with the exception of SSc-related pulmonary fibrosis.

- ***Education***, counselling, and family support are essential.
- ***Regular exercises*** and skin lubricants may limit contractures and methotrexate is given in early diffuse SSc to improve skin fibrosis.
- ***Raynaud's phenomenon*** may be improved by hand warmers and oral vasodilators (calcium-channel blockers, ACE inhibitors, angiotensin receptor blockers). In severe cases, especially where there are digital ulcers, oral phosphodiesterase inhibitors such as sildenafil are used as second-line therapy and parenteral vasodilators (prostacyclin analogues and calcitonin gene-related peptide) as third-line. Lumbar sympathectomy can help foot symptoms. Radical micro-arteriolysis (digital sympathectomy) can be used where individual fingers or toes are severely ischaemic, and thoracic sympathectomy under video-assisted thoracic surgery is now performed.
- ***Oesophageal symptoms*** can almost always be improved by proton pump inhibitors but prokinetic drugs are rarely helpful.
- ***Symptomatic malabsorption*** requires nutritional supplements and rotational antibiotics to treat small intestinal bacterial overgrowth.
- ***Renal involvement*** requires intensive control of hypertension. The first drug of choice is an ACE inhibitor. Vigilance for hypertensive scleroderma renal crisis (SRC) is critical, especially in early-stage DcSSc with rapidly progressive skin and tendon friction rubs. High-dose corticosteroids (above 10 mg prednisolone daily) may increase the risk of SRC.
- ***Pulmonary hypertension*** is treated with oral vasodilators, oxygen, and warfarin. Advanced cases should receive prostacyclin therapy (inhaled, subcutaneous, or intravenous) or the oral endothelin-receptor antagonist, bosentan. Right heart failure is treated conventionally and transplantation (heart–lung or single lung) is used in eligible cases.
- ***Pulmonary fibrosis*** is currently treated with immunosuppression, most often with cyclophosphamide or azathioprine combined with low-dose oral prednisolone.

Prognosis

In limited cutaneous scleroderma, the disease is often milder, with much less severe internal organ involvement and a 70% 10-year survival. Pulmonary hypertension is a significant later cause of death. Lung fibrosis and severe gut involvement also determine mortality. In diffuse disease, where organ involvement is often severe at an earlier stage, many patients die of pulmonary, cardiac, or renal involvement. Overall, pulmonary involvement (vascular or interstitial) accounts for around 50% of scleroderma-related deaths.

Localized forms of scleroderma occur either in patches (morphea; see Chapter 45) or linear forms. These are more commonly seen in children and adolescents, and do not convert into systemic forms, although ANA may occur in localized scleroderma and, very occasionally, localized and systemic forms coexist.

Polymyositis and dermatomyositis

Polymyositis (PM) is a rare disorder of unknown cause, in which the clinical picture is dominated by inflammation of striated muscle, causing proximal muscle weakness. When the skin is involved, it is called 'dermatomyositis' (DM). The incidence is about 2–10/million population *per annum* and it occurs in all races and at all ages. The aetiology is unknown, although viruses (e.g., *Coxsackie*, rubella, influenza) have been implicated and persons with HLA-B8/DR3 appear to be genetically predisposed.

Clinical features

Adult polymyositis

Females are affected three times more commonly than males.

The onset can be insidious, over months, or acute. General malaise, weight loss, and fever can develop during the acute phase, but the cardinal symptom is proximal muscle weakness. The shoulder and pelvic girdle muscles become wasted but are not usually tender. Face and distal limb muscles are not usually affected. Movements such as squatting and climbing stairs become difficult. As the disease progresses, involvement of pharyngeal, laryngeal, and respiratory muscles can lead to dysphonia and respiratory failure. These severe complications are rare if the disease is treated early.

Adult dermatomyositis

This condition is also more common in females. Apart from muscle weakness, these patients often suffer from myalgia, polyarthritis, and Raynaud's phenomenon, but DM is primarily distinguished from PM by the characteristic rash. This typically affects the eyelids, where heliotrope (purple) discoloration is accompanied by periorbital oedema, and the fingers, where purple–red, raised vasculitic patches are seen. These patches occur over the knuckles (Gottron's papules; **Fig. 32.38**) in 70% of patients, and this appearance is highly specific for DM. Ulcerative vasculitis and calcinosis of the subcutaneous tissue are seen in 25% of cases. In the long term, muscle fibrosis and contractures of joints occur.

Antisynthetase syndrome

Some 20%–30% of people with PM or DM have antibodies to tRNA synthetase enzymes, of which anti-Jo1 is the most common. These people are more likely to develop pulmonary interstitial fibrosis, Raynaud's phenomenon, arthritis, and hardening and fissuring of skin over the pulp surface of the fingers (mechanic's hands). This variant of PM/DM is sometimes called antisynthetase syndrome and often has a poor outcome. Respiratory muscles are affected in PM/DM and this compounds the effects of interstitial fibrosis. Dysphagia is seen in about 50% of patients owing to oesophageal muscle involvement.

Association with other ARDs

There is an association with other ARDs (e.g., SLE, RA, and SSc) and their associated clinical features, such as deforming arthritis, malar rash, and skin sclerosis.

Association with malignancies

The relative risk of cancer is 2.4 for male and 3.4 for female patients, and a wide variety of cancers have been reported. The onset and clinical picture do not differ in malignancy-associated disease from those of typical DM/PM. The associated cancer may not become apparent for 2–3 years, and recurrent, refractory, or ANA-negative DM should prompt a search for occult malignancy.

Malignancy (e.g., lung, ovary, breast, stomach) can also predate the onset of myositis, particularly in males with DM.

Fig. 32.38 Purplish Gottron's papules over the knuckles (dermatomyositis). *(Courtesy of David Paige, London.)*

Childhood dermatomyositis

This variant most commonly affects children between the ages of 4 and 10 years. The typical rash of DM is usually accompanied by muscle weakness. Muscle atrophy, subcutaneous calcification, and contractures may be widespread and severe. Ulcerative skin vasculitis is common and recurrent abdominal pain due to vasculitis is also a feature. Adults who have suffered from childhood DM may have chronic damage (e.g., contractures) or show effects of long-term corticosteroid or immunosuppressive therapy.

Investigations

- ***Serum creatine kinase (CK)***, aminotransferases, lactate dehydrogenase (LDH), and aldolase are usually raised and are useful guides to muscle damage, but may not reflect activity.
- ***ESR*** and ***CRP*** may be raised.
- ***Serum autoantibody studies*** include antinuclear antibody testing, which is usually positive in people with DM. RF is present in up to 50%, and many ***myositis-specific antibodies*** (MSAs) have been recognized and correlate with certain subsets. Antisynthetase antibodies have been described above.
- ***Electromyography (EMG)*** shows a typical triad of changes with myositis: spontaneous fibrillation potentials at rest, polyphasic or short-duration potentials on voluntary contraction, and salvos of repetitive potentials on mechanical stimulation of the nerve.
- ***MRI*** can be used to detect abnormally inflamed muscle.
- ***Needle muscle biopsy*** shows fibre necrosis and regeneration in association with an inflammatory cell infiltrate with lymphocytes around the blood vessels and between muscle fibres. Open biopsy allows more thorough assessment.
- ***Screening for malignancy*** is usually limited to relatively non-invasive investigations such as chest X-ray, mammography, pelvic/abdominal ultrasound and CT scanning, urine microscopy, and a search for circulating tumour markers.
- ***PET*** scanning can be considered as enhanced screening for malignancy in selected patients deemed to be at high risk (e.g., older age, resistance to immunosuppressive therapy, negative myositis-specific autoantibody panel).

Management

Bed rest may be helpful but must be combined with an exercise programme. Prednisolone is the mainstay of treatment: 0.5–1.0 mg/kg body weight as initial therapy, continued until at least 1 month after myositis has become clinically and enzymatically inactive. Tapering of steroids must be slow. Early intervention with steroid-sparing agents, such as methotrexate, azathioprine, ciclosporin, cyclophosphamide, and mycophenolate mofetil, is common, especially where there is clinical relapse or a rise in CK as the dose of steroids is reduced. Intravenous immunoglobulin therapy (IVIG) is helpful in some recalcitrant cases. Treatment of childhood DM tends to be more intensive, with earlier use of immunosuppressive agents. Use of biological agents such as rituximab has been described. Rituximab is more likely to be effective in autoantibody-positive cases.

Inclusion body myositis

Inclusion body myositis is an idiopathic inflammatory myopathy usually occurring in males over 50 years. Weakness of the pharyngeal muscles causes difficulty in swallowing in over 50%. It is a slowly progressive weakness of mainly distal muscles. In contrast to polymyositis, the CK is only slightly elevated; the EMG shows both myopathic and neuropathic changes. On MRI, the changes are often more distal but can be similar to those of polymyositis. A muscle biopsy shows inflammation and basophilic rimmed vacuoles with diagnostic filamentous inclusions and vacuoles on electron microscopy. A trial of corticosteroids is worthwhile but generally the response is poor.

Sjögren's syndrome

The syndrome of dry eyes (keratoconjunctivitis sicca) in the absence of RA or any of the autoimmune diseases is known as 'primary Sjögren's syndrome'. There is an association with HLA-B8/DR3. Dryness of the mouth, skin, or vagina may also be a problem. Salivary and parotid gland enlargement is seen. In the majority of cases, dryness and fatigue are the only symptoms, and Sjögren's syndrome is irritating and inconvenient rather than dangerous. However, in a minority there may be systemic symptoms such as:

- arthralgia and occasional non-progressive polyarthritis, like that seen in SLE (but much less common)
- Raynaud's phenomenon
- dysphagia and abnormal oesophageal motility, as seen in systemic sclerosis (but less common)
- other organ-specific autoimmune disease, including thyroid disease, myasthenia gravis, primary biliary cirrhosis, autoimmune hepatitis, tubulo-interstitial nephritis and pancreatitis
- renal tubular defects (uncommon) causing AVP-resistance (also referred to as 'nephrogenic diabetes insipidus') and renal tubular acidosis
- pulmonary diffusion defects and fibrosis
- polyneuropathy, fits, and depression
- vasculitis
- increased incidence of non-Hodgkin's B-cell lymphoma.

Pathology and investigations

Biopsies of the salivary gland or of the lip show a focal infiltration of lymphocytes and plasma cells.

- ***Schirmer tear test.*** A standard strip of filter paper is placed on the inside of the lower eyelid; wetting of less than 10 mm in 5 minutes indicates defective tear production.
- ***Rose Bengal staining.*** Staining of the eyes shows punctate or filamentary keratitis.
- ***Laboratory abnormalities.*** These include raised immunoglobulin levels, circulating immune complexes and autoantibodies. RF is usually positive. Antinuclear antibodies are found in 80% of cases and anti-mitochondrial antibodies are found in 10%. Anti-Ro (SSA) antibodies are found in 60%–90%, compared with 10% of cases of RA and secondary Sjögren's syndrome.

Management

Symptomatic treatment is with artificial tears and saliva replacement solutions. Hydroxychloroquine may help fatigue and arthralgia. Corticosteroids are rarely needed but are used to treat persistent salivary gland swelling or neuropathy. Pilocarpine can be used to stimulate secretion of saliva and tears. A trial of rituximab in Sjögren's syndrome did not demonstrate efficacy and this drug is not used.

'Overlap' syndromes and undifferentiated autoimmune rheumatic disease

An ***overlap syndrome*** is one where the patient shows the characteristic clinical features of more than one ARD. Treatment of each ARD is usually the same as when they occur separately.

Undifferentiated ARD is a term used for the condition of patients who have evidence of autoimmunity (e.g., positive autoantibody test) and some clinical features of such diseases (commonly, Raynaud's phenomenon and/or arthralgia) but not enough to make a clear diagnosis of any individual ARD. These patients sometimes develop a clearer ARD over time, but some always remain undifferentiated and tend to have relatively mild disease without major organ problems.

SYSTEMIC INFLAMMATORY VASCULITIS

Vasculitis is a histological term describing inflammation of the vessel wall. Vasculitis can be seen in many diseases (**Boxes 32.39 and 32.40**). The group of diseases described in this section (systemic inflammatory vasculitides) is characterized by widespread vasculitis leading to systemic symptoms and signs, generally requiring treatment with corticosteroids and/or immunosuppressive drugs. Two main features are helpful in classifying these vasculitides: the ***size of the blood vessels involved*** and the ***presence or absence of anti-neutrophil cytoplasmic antibodies (ANCAs)*** in the blood. Revisions in the commonly used terms for various vasculitides have been proposed to reflect increased pathophysiological understanding of these conditions (**Fig. 32.39** and see **Box 32.39**).

- ***Large-vessel vasculitis*** refers to the aorta and its major tributaries.
- ***Medium-vessel vasculitis*** refers to medium- and small-sized arteries and arterioles.

Box 32.39 Types of systemic vasculitis

Large vessel
- Giant cell arteritis/polymyalgia rheumatica
- Takayasu's arteritis

Medium vessel
- Classical polyarteritis nodosa (PAN)
- Kawasaki's disease

Small vessel
- Microscopic polyangiitis
- Granulomatosis with polyangiitis
- Eosinophilic granulomatosis with polyangiitis (30%–50% ANCA-positive)

ANCA-associated

- Immunoglobulin A (Henoch–Schönlein) vasculitis
- Cutaneous leucocytoclastic vasculitis
- Essential cryoglobulinaemia

ANCA-negative

Box 32.40 Other conditions associated with vasculitis[a]

Infective
- E.g., subacute infective endocarditis

Non-infective
- Vasculitis with rheumatoid arthritis
- Systemic lupus erythematosus
- Scleroderma
- Polymyositis/dermatomyositis
- Drug-induced Behçet's disease
- Goodpasture's syndrome
- Hypocomplementaemia
- Serum sickness
- Paraneoplastic syndromes
- Inflammatory bowel disease

[a]See also **Box 32.39**.

- ***Small-vessel vasculitis*** refers to small arteries, arterioles, venules, and capillaries.

Large-vessel vasculitis

PMR and giant cell (temporal) arteritis are systemic illnesses of the elderly. Both are associated with the finding of a giant cell arteritis (GCA) on temporal artery biopsy.

Polymyalgia rheumatica

Polymyalgia rheumatica (PMR) causes a sudden onset of severe pain and stiffness of the shoulders and neck, and of the hips and lumbar spine, which is a limb-girdle pattern. These symptoms are worse in the morning, lasting from 30 minutes to several hours. The clinical history is usually diagnostic and the patient is always over 50 years old. Up to 25% of patients may have some inflammation of peripheral joints.

Approximately one-third of patients develop systemic features of tiredness, fever, weight loss, depression, and occasionally nocturnal sweats, especially if PMR is not diagnosed and treated early. A differential diagnosis is shown in **Box 32.41**.

Investigation of PMR

- ***A raised ESR and/or CRP*** is a hallmark of this condition. It is rare to see PMR without an acute-phase response. If it is absent, the diagnosis should be questioned and the tests repeated a few weeks later before treatment is started.
- ***Serum alkaline phosphatase and γ-glutamyl-transpeptidase*** may be raised as markers of the acute inflammation.
- ***Anaemia of inflammation*** (mild normochromic, normocytic) is often present.
- ***Temporal artery biopsy*** shows GCA in 10%–30% of cases, but is rarely performed unless GCA is also suspected.

Giant cell arteritis

Giant cell arteritis (GCA) is inflammatory granulomatous arteritis of large cerebral arteries, which occurs in association with PMR. The patient may have current PMR or a history of recent PMR, or may be on treatment for PMR. It is extremely rare under 50 years of age. Presenting symptoms of GCA include severe headaches, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, and tenderness and swelling of one or more temporal or occipital arteries. The most feared manifestation is sudden, painless, temporary, or permanent loss of vision in one eye due to involvement of the ophthalmic artery (see Chapter 28). Systemic manifestations of severe malaise, tiredness, and fever occur.

Investigations in GCA

- Normochromic, normocytic anaemia.
- ESR is usually raised (in the region of 50–120 mm/h) and the CRP is very high.
- Liver biochemistry may be abnormal, as in PMR. The albumin may be low.
- A temporal artery biopsy from the affected side is the definitive diagnostic test. This should be taken before, or within 7 days of starting, high doses of corticosteroids. The lesions are patchy and the whole length of the biopsy (>1 cm long) must be examined; even so, negative biopsies occur.
- Ultrasound scanning of the temporal arteries is increasingly used—if diagnostic features are seen, biopsy can be avoided.

The ***histological features*** of GCA are:
- Cellular infiltrates of $CD4^+$ T lymphocytes, macrophages, and giant cells in the vessel wall. Note that giant cells are not visible in all cases.
- Granulomatous inflammation of the intima and media.
- Breaking up of the internal elastic lamina.
- Giant cells, lymphocytes, and plasma cells in the internal elastic lamina.

Management of PMR or GCA

Corticosteroids produce a dramatic reduction of symptoms of PMR within 24–48 hours of starting treatment, provided the dose is adequate. If this improvement does not occur, the diagnosis should be questioned and an alternative cause sought, such as RA, vasculitis, infection, or malignancy. Corticosteroid treatment should reduce the risk of patients who have PMR developing GCA. NSAIDs are less effective and should not be used.

In GCA, corticosteroids are obligatory because they significantly reduce the risk of irreversible visual loss and other focal ischaemic lesions, but much higher doses are needed than in PMR. If GCA is suspected, it may not be possible to arrange an ultrasound scan or temporal artery biopsy rapidly. In these circumstances, treatment should not be delayed, especially if there have already been episodes of visual loss or stroke.

Starting daily doses of prednisolone are:
- ***PMR:*** 15 mg prednisolone as a single dose in the morning
- ***GCA:*** 60–100 mg prednisolone, usually in divided doses.

The dose should then be reduced gradually in weekly or monthly steps. While the dose is above 20 mg, the step reductions are 5 mg, reducing the evening doses first. Between 20 mg and 10 mg, the reduction can be in 2.5-mg steps, but below 10 mg, the rate should be slower and the steps of 1 mg each. Most patients will eventually be able to stop corticosteroids after 12–18 months but up to 25% may need low doses long term. Steroid-sparing immunosuppressive

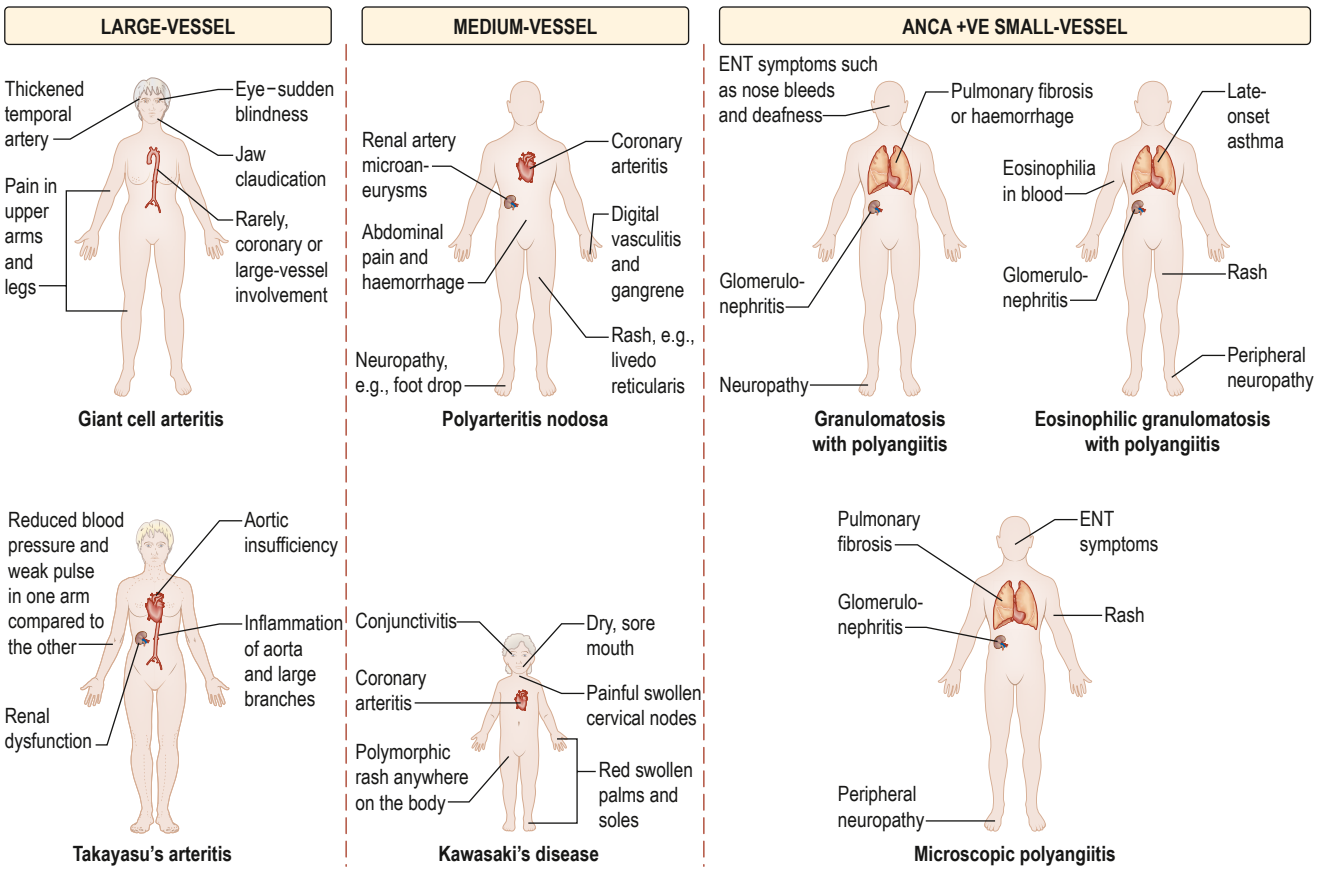

Fig. 32.39 Clinical features of systemic inflammatory vasculitides. These illnesses all frequently present with joint pain, as well as systemic symptoms such as fatigue, malaise, and weight loss. The most common organ-specific manifestations are shown. Giant cell arteritis is usually seen in people over 50, whereas Takayasu's disease is seen in people under 50. Kawasaki's disease is usually seen in children under 5. *ANCA,* Anti-neutrophil cytoplasmic antibodies; *ENT,* ear, nose and throat.

? Box 32.41 Symptom patterns in some muscle disorders

- Polymyositis—proximal muscle ache and weakness
- Polymyalgia rheumatica—proximal morning stiffness and pain
- Myopathy—weakness, but no pain or stiffness

agents are used in refractory cases where it is hard to reduce the corticosteroid dose without causing a flare of disease or a rise in ESR or CRP. A clinical trial showed that a combination of the anti-interleukin receptor 6 receptor agent tocilizumab with corticosteroid gave higher rates of remission than corticosteroid alone and this biologic is now used in refractory cases of GCA.

Calcium and vitamin D supplements, and sometimes bisphosphonates, are necessary to prevent osteoporosis while high-dose steroids are being used (see Chapter 33).

Takayasu's arteritis

Takayasu's arteritis is a granulomatous inflammation of the aorta and its major branches (see Chapter 17).

Medium-sized vessel vasculitis

Polyarteritis nodosa

Classical polyarteritis nodosa (PAN) is a rare condition that usually occurs in middle-aged males. It is accompanied by severe systemic manifestations, and its occasional association with hepatitis B antigenaemia suggests a vasculitis secondary to the deposition of immune complexes. Pathologically, there is fibrinoid necrosis of vessel walls with microaneurysm formation, thrombosis, and infarction.

Clinical features

These include fever, malaise, weight loss, and myalgia. These initial symptoms are followed by dramatic acute features that are due to organ infarction.

- ***Neurological.*** Mononeuritis multiplex is due to arteritis of the vasa nervorum.
- ***Abdominal.*** Pain is due to arterial involvement of the abdominal viscera, mimicking acute cholecystitis, pancreatitis, or appendicitis. Gastrointestinal haemorrhage occurs because of mucosal ulceration.
- ***Renal.*** Presentation is with haematuria and proteinuria. Hypertension and acute/chronic kidney disease occur.
- ***Cardiac.*** Coronary arteritis causes myocardial infarction and heart failure. Pericarditis also occurs.
- ***Skin.*** Subcutaneous haemorrhage and gangrene occur. A persistent livedo reticularis is seen in chronic cases. Cutaneous and subcutaneous palpable nodules occur but are uncommon.
- ***Lung.*** Involvement is rare.

Investigations and management

- ***Blood count.*** Anaemia, leucocytosis, and a raised ESR occur.
- ***Biopsy.*** Material from an affected organ shows features listed above.

- ***Angiography.*** Microaneurysms in hepatic, intestinal, or renal vessels can be demonstrated if necessary.
- ***Other investigations.*** These are performed as appropriate (e.g., electrocardiogram and abdominal ultrasound), depending on the clinical problem. ANCA is positive but rarely in classic PAN.

Treatment is with corticosteroids, usually in combination with immunosuppressive drugs such as azathioprine.

Kawasaki's disease

Kawasaki's disease is an acute systemic vasculitis involving medium-sized vessels, affecting mainly children under 5 years of age. It is very frequent in Japan and an infective trigger is suspected. Fewer than 10% of cases occur in adults.

Clinical features and management

The characteristic clinical features are fever lasting longer than 4 days, bilateral conjunctival congestion, dry red lips and oral cavity, cervical lymphadenopathy, rash and redness of the palms and soles.

Cardiovascular changes in the acute stage include pancarditis and coronary arteritis, leading to aneurysms or dilatation visible on echocardiography, MRI, or angiography.

Treatment is with a single dose of high-dose intravenous immunoglobulin (2 g/kg), which prevents the coronary artery disease, followed after the acute phase by aspirin 200–300 mg daily. There is no evidence that steroid treatment improves the outcome.

Small-vessel vasculitis

The two revised categories of small-vessel vasculitis (SVV) are:

- ANCA-associated vasculitis (AAV), characterized by a ***paucity of vessel wall immunoglobulin*** and presence (in many but not all patients) of ANCA, including:
  - granulomatosis with polyangiitis (GPA; see Chapter 20)
  - eosinophilic granulomatosis with polyangiitis (EGPA; see Chapter 20)
  - microscopic polyangiitis (MPA; see Chapter 20).
- Immune complex (ANCA-negative) SVV, with a ***prominence of vessel wall immunoglobulin*** including:
  - anti-glomerular basement membrane (anti-GBM) disease (see Chapter 20)
  - IgA vasculitis (IgAV, Henoch–Schönlein) (see Chapter 26)
  - cryoglobulinaemic vasculitis (CV) (see Chapter 26)
  - hypocomplementaemic urticarial vasculitis (HUV, anti-C1q vasculitis)
  - cutaneous leucocytoclastic vasculitis (see Chapter 45).

Cutaneous leucocytoclastic vasculitis is the characteristic acute purpuric lesion that histologically involves the dermal postcapillary venules. This lesion affects only the skin (a form of 'single-organ vasculitis') and should be differentiated from similar lesions produced in systemic vasculitis. The purpura may be accompanied by arthralgia, although the appearance of additional organ disease (e.g., glomerulonephritis) suggests evolution towards a systemic vasculitis. Hepatitis C infection is common and may be an aetiological agent. The condition can also be caused by drugs such as sulphonamides and penicillin.

Primary CNS vasculitis is a very rare condition (incidence 2–4 cases per million person-years) characterized by clinical features confined to the CNS and characteristic appearances on angiography or cerebral biopsy. The most common clinical features are headache, altered cognition, focal weakness, and stroke. Blood tests, including inflammatory markers and autoantibodies, are usually normal but a normal cerebral MRI essentially excludes the diagnosis.

Management of small-cell vasculitis

The treatment depends on the organs involved. Vasculitis confined to the skin may not require systemic treatment, whereas involvement of major organs (e.g., lungs or kidneys in GPA) requires high-dose corticosteroids, immunosuppression, and, sometimes, plasma exchange. Clinical trials have shown that depletion of B cells with rituximab is as effective as cyclophosphamide in treating AAV and can help reduce the dose of corticosteroids required to maintain remission. In EGPA, the anti-interleukin 5 agent mepolizumab has been found to be effective in a clinical trial.

Behçet's disease

Behçet's disease is an inflammatory disorder of unknown cause. There is a striking geographical distribution, it being most common in Turkey, Iran, and Japan. The prevalence per 100 000 is 10–15 in Japan and 80–300 in Turkey. There is a link to the HLA-B51 allele, with a relative risk of 5–10; this association is not seen in patients in the USA and Europe.

Clinical features

The cardinal clinical feature is recurrent oral ulceration. The ***international criteria for diagnosis*** require oral ulceration and any two of the following:

- genital ulcers
- defined eye lesions, including an anterior or posterior uveitis or retinal vascular lesions
- defined skin lesions—erythema nodosum, pseudofolliculitis, and papulopustular lesions
- positive skin pathergy test (see below)
- oral ulcers—aphthous or herpetiform.

Other manifestations include a self-limiting peripheral mono- or oligoarthritis affecting knees, ankles, wrists, and elbows; gastrointestinal symptoms of diarrhoea, abdominal pain, and anorexia; pulmonary and renal lesions; thrombophlebitis (especially in the legs); vasculitis; and a brainstem syndrome, organic confusional states and a meningoencephalitis. All the common manifestations are self-limiting except for the ocular attacks. Repeated attacks of uveitis can cause blindness.

The ***pathergy reaction*** is highly specific to Behçet's disease. Skin injury—by a needle prick, for example—leads to papule or pustule formation within 24–48 hours. Blood tests usually show raised ESR and CRP but not autoantibodies.

Management

Corticosteroids, immunosuppressive agents, and ciclosporin are used for chronic uveitis and the rare neurological complications. Colchicine helps erythema nodosum and joint pain. Thalidomide may be useful in some cases, although side-effects of drowsiness and peripheral neuropathy are common. It should not be used in pregnant women because of phocomelia (limb abnormalities) and females of childbearing potential must use effective contraception for at least 4 weeks before, during, and for at least 4 weeks after stopping treatment (the combined oral contraceptive pill is not recommended due to increased risk of thromboembolism). Anti-TNF agents can be used to control severe uveitis and serious manifestations such as neurological and gastrointestinal Behçet's disease.

ARTHRITIS IN CHILDREN

Joint and limb pains are common in children but arthritis is, fortunately, rare. Discussion here is limited to juvenile idiopathic arthritis, as a disease which may persist into adulthood (and so falling under the care of adult rheumatologists).

Juvenile idiopathic arthritis

A full description of juvenile idiopathic arthritis (JIA) is beyond the scope of this textbook. A brief account is provided below.

JIA is classified according to the extent and type of joint involvement. A particularly severe form, ***systemic onset JIA (Still's disease)*** presents with high fever (>39°C), rash, lymphadenopathy, hepatosplenomegaly, and/or serositis. Joint involvement is often not the most prominent symptom.

In contrast, patients with ***oligoarticular*** (<5 joints involved) and ***polyarticular*** (≥5 joints) JIA experience mainly of joint pain and swelling.

The oligoarticular form is more common. In childhood, these patients can develop uveitis and require regular screening by slit lamp examination. Outlook is usually good but approximately 25% develop an extended form where more joints can be involved over time leading to destructive arthritis persisting into adulthood.

Polyarticular JIA is divided into RF-positive and RF-negative subtypes, of which the RF-positive form is more aggressive.

Enthesitis-related arthritis tends to affect teenage and younger boys, mainly involves lower limb joints and entheses and is associated with HLA-B27 positivity.

Children with JIA are generally managed by specialist paediatric rheumatologists but come under the care of adult rheumatologists later in life. Treatment recommendations are based on clinical phenotypes involving cs/b/tsDMARDs for which management and monitoring are as for adult-onset inflammatory arthritis. The goal of therapy is to rapidly reduce disease activity to inactive disease or clinical remission, minimize drug side-effects, and achieve quality of life comparable to peers. Joint replacement surgery in patients who have had JIA may be required earlier in life than in other groups.

RHEUMATOLOGICAL PROBLEMS SEEN IN OTHER DISEASES

Gastrointestinal and liver disease

- Enteropathic synovitis (see 'Enteropathic arthritis associated with inflammatory bowel disease' section).
- Autoimmune hepatitis (see Chapter 23) may be accompanied by an arthralgia similar to that seen in SLE. Joint pain occurs in a bilateral, symmetrical distribution, predominantly affecting the small joints of the hands. Joints usually look normal but sometimes there is a slight soft tissue swelling. These patients often have positive tests for antinuclear antibodies.
- Primary biliary cholangitis patients occasionally have a symmetrical arthropathy.
- Hereditary haemochromatosis is associated with arthritis in 50% of cases, which is often the first sign of the disease and CC is common.
- Whipple's disease (see Chapter 22) is accompanied by fever and arthralgia.

Respiratory disease

Sarcoidosis

- Sarcoidosis (see Chapter 20) is a multisystem granulomatous disease associated with erythema nodosum in 20% of cases at or soon after the onset of the disease. A chest X-ray shows hilar lymphadenopathy in 80% of cases. The serum ACE may be raised.
- Several patterns of arthritis occur later in the disease. These include a transient rheumatoid-like polyarthritis and an acute monoarthritis that can be mistaken for gout. Bone cysts can also develop.
- ***Treatment*** is with NSAIDs; if these fail to control the symptoms, corticosteroids are usually very effective.

Malignant disease

It is not uncommon for malignant diseases to present with musculoskeletal symptoms. Gout occurs in conditions such as chronic myeloid leukaemia. Neoplastic disease of bone is described in Chapter 33.

Hypertrophic pulmonary osteoarthropathy

Hypertrophic pulmonary osteoarthropathy (HPO) is a paraneoplastic, non-metastatic complication, frequently associated with carcinoma of the bronchus. It may be the presenting feature of the disease. It rarely occurs with other conditions that also cause clubbing, presenting most often in middle-aged men with pain and swelling of the wrists and ankles. Other joints are occasionally involved. Primary HPO is a hereditary condition involving a mutation in the *HPGD* gene that degrades prostaglandin E_2 (PGE_2), thus allowing over-production of PGE_2, which may cause clubbing.

The diagnosis is made on the presence of clubbing of the fingers (usually gross in primary HPO) and periosteal new bone formation along the shafts of the distal ends of the radius, ulna, tibia, and fibula on X-ray. A chest X-ray usually shows the malignancy.

Management should be directed at the underlying carcinoma; if this can be removed, the arthropathy disappears. NSAIDs relieve the symptoms.

Paraneoplastic polyarthritis

This condition is seen with carcinoma of the breast in women and of the lung in men, and also with renal cell carcinoma. The neoplasm may be occult at onset and the diagnosis is then difficult to make.

Skin disease

Psoriatic arthritis

This disease is discussed earlier (see 'Psoriatic arthritis' section).

Erythema nodosum

Erythema nodosum (see Chapter 45) is accompanied by arthritis in over 50% of cases. The knees and ankles are particularly affected,

being swollen, red, and tender. The arthritis subsides, along with the skin lesions, within a few months. Treatment is with NSAIDs or occasionally steroids.

Neurological disease

Neuropathic (Charcot's) joints

These are damaged by trauma as a result of the loss of the protective pain sensation. The site of the neuropathic joint depends on the localization of the pain loss:

- In tabes dorsalis (spinal cord degeneration resulting from neurosyphilis), the knees and ankles are most often affected.
- In diabetes mellitus, the joints of the tarsus are involved.
- In syringomyelia, the shoulder is involved.

Neuropathic joints are not painful, although there may be painful episodes associated with crystal deposition. Presentation is usually with swelling and instability. Eventually, severe deformities develop.

The characteristic finding is a swollen joint with abnormal but painless movement, in association with neurological findings that depend on the underlying disease (e.g., dissociated sensory loss in syringomyelia or polyneuropathy in diabetes). X-ray changes are characteristic, with gross joint disorganization and bony distortion.

Treatment is symptomatic. Surgery may be required in advanced cases.

Blood disease (see also Chapter 38)

Arthritis due to haemarthrosis is a common presenting feature of people with ***haemophilia***. Attacks begin in early childhood in most cases and are recurrent. The knee is the most commonly affected joint but the elbows and ankles are sometimes involved. The arthritis can lead to bone destruction and disorganization of joints. Apart from replacement of factor VIII, affected joints require initial immobilization followed by physiotherapy to restore movement and measures to prevent and correct deformities.

Sickle cell crises are often accompanied by joint pain that particularly affects the hands and feet in a bilateral, symmetrical distribution. Affected joints usually look normal but are occasionally swollen. This condition may also be complicated by avascular necrosis and by osteomyelitis.

Arthritis can also occur in ***acute leukaemia*** (see Chapter 39); it may be the presenting feature in childhood. The knee is particularly affected and is very painful, warm, and swollen. Treatment is directed at the underlying leukaemia. Arthritis may also occur in chronic leukaemia, with leukaemic deposits in and around the joints.

Individuals with ***transfusion-dependent thalassaemia*** are living longer and are presenting with back pain due to premature disc degeneration, secondary spondylosis, and crush fractures caused by osteoporosis. There is marked discal calcification.

Endocrine and metabolic disorders

Hypothyroid patients may complain of pain and stiffness of proximal muscles, resembling PMR. They may also have carpal tunnel syndrome. Less often, there is an arthritis accompanied by joint effusions, particularly in the knees, wrist, and small joints of the hands and feet. These problems respond rapidly to thyroxine.

Hyperparathyroidism may be complicated by CC and acute CPPD.

In ***acromegaly***, arthralgia occurs in about 50% of patients, particularly in the small joints of the hands and knees. There may be a carpal tunnel syndrome.

In ***Cushing's disease***, back pain is common.

Joint disorders related to ***diabetes mellitus*** are described in Chapter 35.

Familial hypercholesterolaemia is associated with oligo- or polyarthritis, usually with tendon xanthomata. Arthritis also occurs in combined hyperlipidaemia.

MISCELLANEOUS ARTHROPATHIES

Familial Mediterranean fever

Periodic fever syndromes are a group of autoinflammatory disorders that present with recurrent attacks of fever in childhood and adult life.

Familial Mediterranean fever (FMF) is the most common inherited autoinflammatory disease. It is an autosomal recessive condition recognized worldwide but most prevalent in populations originating from the eastern Mediterranean. Mutations in the *MEFV* gene on chromosome 16 that encodes for pyrin, a suppressor of the activation of caspase 1, lead to increased biosynthesis of IL-1β and inflammation in FMF.

Symptoms of FMF are recurrent episodes of fever, arthritis, and serositis. Peritonitic abdominal pain occurs in 80% of attacks. Pleuritic chest pain occurs in 15% of cases and is unilateral. Arthritis is rare and usually monoarticular, lasting up to 1 week. The CRP is markedly raised during the attacks. The condition may be mistaken for palindromic rheumatism (see 'Other presentations' section), but such attacks are not usually accompanied by fever.

The diagnosis can be made by PCR, if available, but is based on the clinical picture and exclusion of other conditions.

Treatment involves lifelong colchicine 1000–1500 μg daily, which can usually prevent the attacks. In resistant patients, IL-1 inhibitors (anakinra and canakinumab) are licensed. In general, the disorder is benign, but in 25% of cases, renal amyloidosis develops (see Chapter 26).

Other periodic fevers are being increasingly recognized. These include tumour necrosis factor receptor-associated periodic syndrome (TRAPS), mevalonate kinase deficiency (MKD), cryopyrin-associated periodic syndrome (CAPS), and periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA).

SAPHO (synovitis, acne, palmoplantar pustulosis, hyperostosis, osteitis)

This rare autoinflammatory disorder, linked to various HLA associations, dysregulation of IL-1, and *Cutibacterium acnes* infection, is considered on a spectrum with SpA, autoinflammatory disorders, and pustular dermatoses. It produces chronic multifocal osteitis with anterior chest wall pain and peripheral synovitis. There is inflammatory cytokine release and global neutrophil activation. NSAIDs, methotrexate, or TNF inhibitors (see 'Rheumatoid arthritis, Drug therapy' section) may help.

Osteochondromatosis

In this condition, foci of cartilage form within the synovial membrane. These foci become calcified and then ossified (osteochondromas). They may give rise to loose bodies within the joint. The condition occurs in a single joint of a young adult and X-rays are usually diagnostic.

Management involves removal of loose bodies and synovectomy.

Pigmented villonodular synovitis

This is characterized by exuberant synovial proliferation that occurs either in joints or in tendon sheaths. The main manifestation in joints is recurrent haemarthrosis. It may produce progressive local bone destruction. A malignant form is seen occasionally.

Management is synovectomy or radiotherapy for more widespread cases or those that have failed surgery.

Relapsing polychondritis

Relapsing polychondritis is a rare inflammatory condition of cartilage. It occurs equally in males and females, usually the elderly. Tenderness, inflammation, and eventual destruction of cartilage occur, mainly in the ear, nose, larynx, or trachea. A seronegative polyarthritis occurs, as well as episcleritis and evidence of a vasculitis (e.g., glomerulonephritis). The diagnosis is clinical with laboratory evidence of acute inflammation.

Treatment involves corticosteroids and immunosuppressive agents.

CORE SKILLS AND KNOWLEDGE

Bone disease is common in the general population, although frequently undiagnosed and often asymptomatic. Some 50% of females and 25% of males will suffer an osteoporotic fracture in their lifetime. Bone diseases are even more prevalent in those with coexisting medical conditions and the elderly. Bone disease specialists work in a variety of disciplines including general practice, rheumatology, endocrinology, and medicine for the elderly, dividing their time between outpatient bone health clinics and inpatient fracture liaison services. Specialist nurses, radiographers, orthopaedic surgeons, and allied health professionals all have important roles in helping to care for patients with bone disease.

Key learning objectives in bone disease include:

- Understanding osteoporosis—its causes, diagnosis, and treatment
- Knowing when to investigate for other bone disorders, including bone infections and malignancy
- Understanding 'bone profile' blood tests, dual-energy X-ray absorptiometry (DXA) scanning, and fracture risk assessment tools.

Learning opportunities in bone health include attending specialist bone health clinics, and attending fracture liaison service ward rounds where the underlying causes of fragility fractures are addressed.

CLINICAL SKILLS

History

Clinical features

- Bone disease such as osteoporosis is often asymptomatic.
- ***Severe, acute-onset pain*** suggests a fracture (Box 33.1), which can occur with minimal trauma if the bone is fragile due to osteoporosis or malignancy.
- ***Progressive localized bone pain*** may suggest primary or secondary malignancy, or localized Paget's disease.

Risk factors for osteoporosis

- Increased age.
- Early menopause without use of hormone replacement therapy.
- Hypogonadism in males.
- Corticosteroid use.
- Intestinal malabsorption.
- Obesity.
- Immobility.
- Other medical conditions (Box 33.4).

Examination

Bone disease often presents with no physical signs, at least until secondary consequences ensue. This is particularly true of osteoporosis. The commonest anatomical sites for various diseases of bone to occur are shown in the diagram; physical signs will vary from severe acute deformity and pain (if fracture occurs), through varying levels of tenderness, swelling, and deformity in slowly progressive disease, to no observable changes in clinically silent disease.

Biochemical tests

A number of biochemical tests can be used to investigate the presence of bone disease. These are best described by their use in different clinical settings: in a patient with a fracture, or in patients with bony pain, or no symptoms at all (when these abnormalities may be picked up incidentally during routine or screening blood tests) (Boxes 33.2 and 33.3).

Box 33.1 Evaluation of a patient with a fracture

Why has fracture occurred?
- Traumatic—high impact trauma
- Fragility—force equivalent to fall from less than standing height—implies osteoporosis or other bone disorder
- Pathological—consider when multiple fractures, systemic symptoms, unusual sites.

Investigations of fragility fracture
- Calcium/phosphate/magnesium
- 1,25 dihydroxyvitamin D/parathyroid hormone/alkaline phosphatase
- Myeloma screening—serum electrophoresis, serum, and urine-free light chains, immunoglobulins
- Thyroid function tests, coeliac testing
- Dual-energy X-ray absorptiometry (DXA) scanning.

Treatment of fragility fracture
- Fracture risk assessment
- Most patients with fragility fracture have osteoporosis and warrant treatment
- Calcium/vitamin D if required
- Bisphosphonate
  - Denosumab is alternative
  - Consider recombinant parathyroid hormone (PTH) if very high risk.

Box 33.2 Evaluation of a patient with a fragility fracture

Ca	ALP	PTH	Probable diagnosis	Confirmatory test
N	N/H	N	**Osteoporosis**	DXA scanning
H	H	L	**Malignancy**	Nuclear medicine bone scan, investigation for likely site of primary (e.g., CT chest/abdomen/pelvis, mammogram)
N/H	H	H	**Primary hyperparathyroidism**	MIBI nuclear medicine parathyroid scan (see Chapter 34)
L	H	H	**Secondary hyperparathyroidism**	Check renal function for evidence of chronic kidney disease mineral and bone disorder (CKD-MBD, Chapter 26)

ANATOMY AND PHYSIOLOGY OF BONE

Bone is a specialized connective tissue serving three major functions:

- ***mechanical***—supplying structure and muscle attachment for movement
- ***metabolic***—providing the body's primary store of calcium and phosphate
- ***protective***—enclosing the marrow and other vital organs.

This chapter covers the connective tissue functions of bone; bone marrow function is discussed in Chapter 38.

Bone structure

Bone comprises cells and a matrix of organic protein and inorganic mineral. Long bones (femur, tibia, humerus) and flat bones (skull, scapula) have different embryological templates, with varying proportions of cortical and trabecular bone.

- ***Cortical (compact or lamellar) bone*** forms the shaft of long bones and the outer shell of flat bones. Formed of concentric rings of bone, it is particularly adapted to withstand bending strain.
- ***Trabecular (cancellous) bone*** is found at the ends of long bones and inside flat bones. Comprising a network of interconnecting rods and plates of bone, it offers resistance to compressive loads. It is also the main site of bone turnover for mineral homeostasis.
- ***Woven bone*** lacks an organized structure. It appears in the first few years of life, at sites of fracture repair and in high-turnover bone disorders such as Paget's disease.

Matrix components

- ***Type I collagen*** is the main protein, forming parallel lamellae of differing density (which impairs spreading of cracks). In cortical

bone, concentric lamellae form around a central blood supply (Haversian system), which communicates via transverse (Volkmann's) canals.

- ***Non-collagen proteins*** include osteopontin, osteocalcin and fibronectin.
- ***Bone mineral*** largely consists of calcium and phosphate in the form of hydroxyapatite.

Bone cells

Osteoblasts

Derived from local mesenchymal stem cells, these cells synthesize matrix (osteoid) and regulate its mineralization. After bone formation, the majority of osteoblasts are removed by apoptosis, others remaining at the bone/marrow interface as lining cells or within the bone as osteocytes. Osteoblasts regulate bone resorption through the balance in expression of the stimulatory receptor activator of nuclear factor kappa B ligand (RANKL) and its antagonist, osteoprotegerin (OPG). Osteoblasts are rich in alkaline phosphatase and express receptors for parathyroid hormone (PTH), oestrogen, glucocorticoids, vitamin D, inflammatory cytokines, and the transforming growth factor-beta (TGF-β) family, all of which may therefore influence bone remodelling.

Osteocytes

These small cells, derived from osteoblasts, are embedded in bone and interconnected with each other and with bone-lining cells through cytoplasmic processes. They respond to mechanical strain by undergoing apoptosis or through altered cell signalling, which in turn activates bone formation with or without prior resorption. As osteocytes also express RANKL and OPG, the relative importance of osteocytes and osteoblasts in bone resorption function continues to be explored.

Osteoclasts

These cells have the unique capacity to resorb bone and are derived from haemopoietic precursors of the macrophage lineage. In response to RANKL, macrophage colony-stimulating factor (M-CSF), and local adhesion factors (integrins), osteoclasts attach to bone, creating a ruffled border that forms a number of extracellular lysosomal compartments. Hydrogen ions are actively secreted into these spaces and the acid environment removes the mineral phase before specialized cysteine proteases (e.g., cathepsin K) resorb the collagen matrix.

Bone growth and remodelling

Longitudinal growth occurs at the epiphyseal growth plate, a cartilage structure between the epiphysis and metaphysis (**Fig. 33.1**). Cartilage production is tightly regulated, with subsequent mineralization and growth finally arrested at 18 to 21 years, when the epiphysis and metaphysis fuse.

In adults, bone is regularly remodelled to ensure repair of microdamage and turnover of calcium and phosphate for homeostasis. This remodelling cycle is carried out by the basic multicellular unit (BMU; **Fig. 33.2**). Signals initiating resorption include osteocyte apoptosis and altered signalling (sclerostin, prostaglandins, RANKL, and other molecules), resulting in localized retraction of bone-lining cells and binding of multinucleate osteoclasts to the bone surface, followed by bone resorption. Bone formation involves reciprocal effects of *wnt* versus *dickkopf (Dkk)* and sclerostin on the LRP5/6-β-catenin pathway. The switch from resorption to formation may rely on osteocyte signalling or on release of signals from the bone matrix, such as TGF-β. Bone remodelling is said to be coupled when formation follows resorption, but may be unbalanced when the amount of bone removed is not replaced with an equal amount.

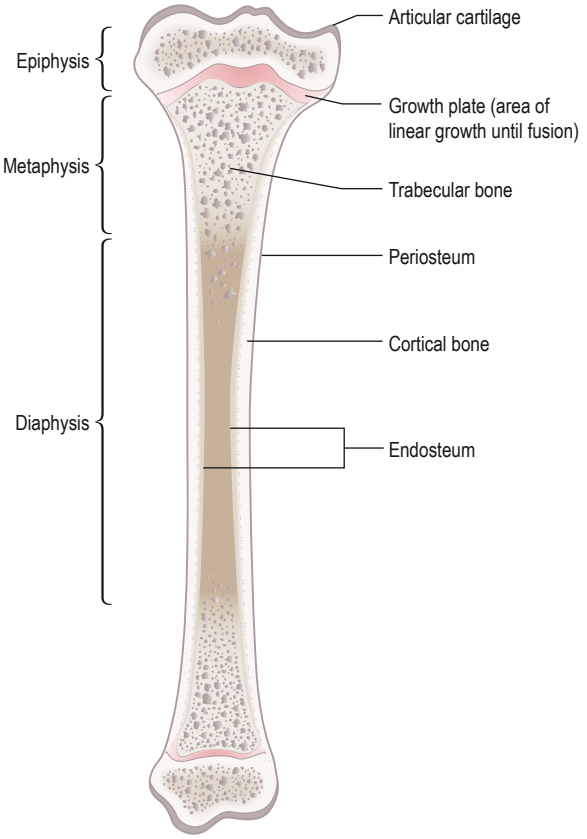

Fig. 33.1 **A longitudinal section of a growing long bone.**

Examples of bone remodelling include

- Myeloma cells have dual lytic effects, with enhanced expression of RANKL and *Dkk.*
- In rheumatoid arthritis, RANKL and *Dkk* are increased.
- In spondyloarthritis (characterized by new bone formation alongside erosion), *Dkk* is inhibited, with the increased *wnt* activity also increasing OPG relative to RANKL.
- Corticosteroids may increase osteocyte SOST expression, and stimulate expression of *Dkk.*

Calcium homeostasis and its regulation

Calcium homeostasis is regulated by the effects of PTH and 1,25-dihydroxyvitamin D_3 on gut, kidney, and bone. Calcium-sensing receptors are present in the parathyroid glands, kidney, and brain.

Calcium absorption and distribution

Daily calcium consumption (**Fig. 33.3**), primarily from dairy foods, is 20 to 25 mmol (800–1000 mg). The combined effect of calcium and vitamin D deficiency contributes to the bone fragility seen in some older people. Intestinal absorption of calcium is reduced by vitamin D deficiency and in malabsorption states (see Chapter 25).

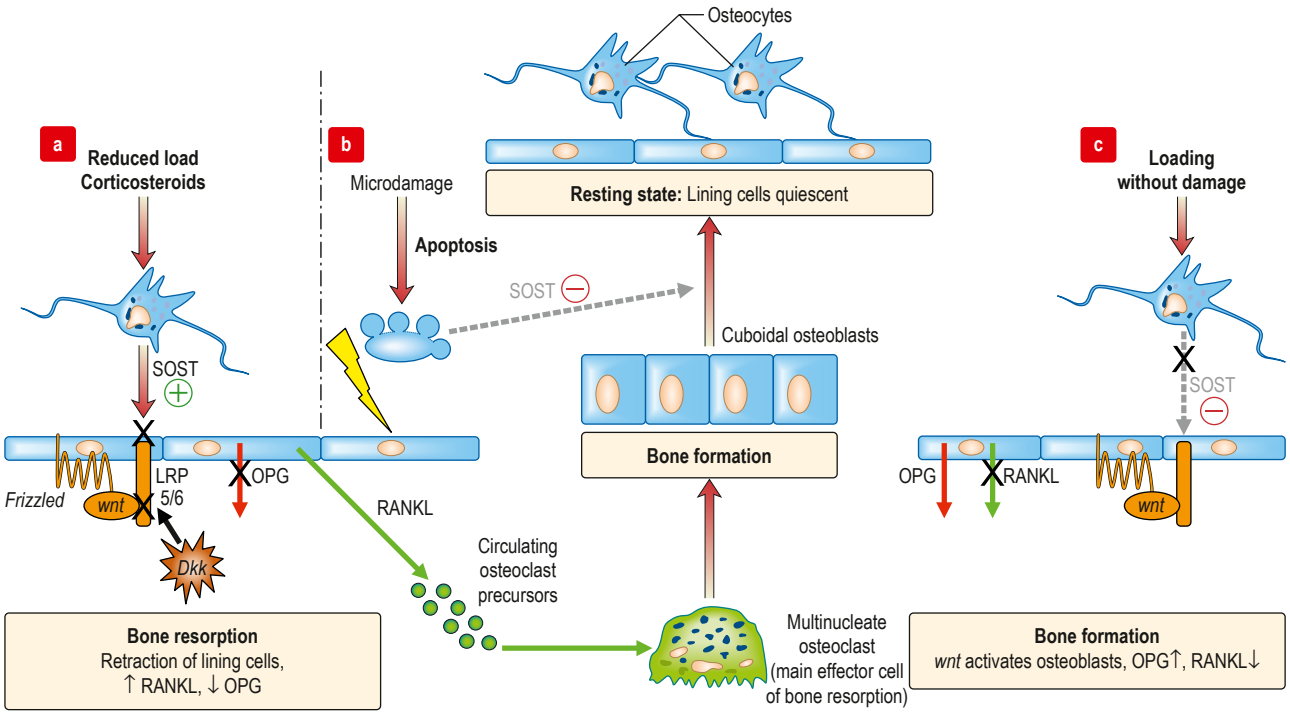

Fig. 33.2 Bone is remodelled in response to alterations in two reciprocal systems. (a) ***Quiescent bone*** may experience *reduced load*, in response the osteocyte increases expression of ***sclerostin (SOST+)***, inhibiting the response to *wnt* via the ***LRP5/frizzled co-receptor complex*** (orange). **(b)** ***Microdamage*** causes osteocyte apoptosis with direct osteoclast-generating effects via receptor activator of nuclear factor kappa B ligand (RANKL), and loss of the inhibitory effect of SOST on later bone formation (dashed line, SOST–). The osteoblastic lining cells retract from an area of bone, forming a bone remodelling unit, while increased expression of RANKL and reduced osteoprotegerin (OPG) activates the formation of bone-resorbing multinucleate osteoclasts from circulating precursors; the resorbed area is then replaced by new osteoid, formed by cuboidal osteoblasts. As new osteocytes are formed, SOST levels rise and the osteoblasts cease formation, the majority undergoing apoptosis. **(c)** If bone experiences *loading without damage*, ***sclerostin expression*** is reduced (SOST–), increasing signal response to *wnt*, activation of osteoblast bone formation, and increased OPG expression.

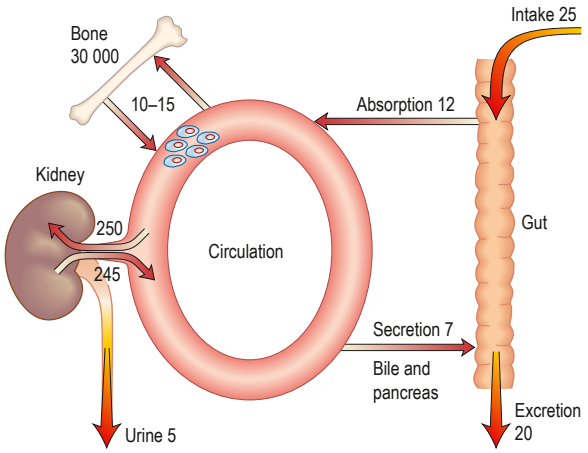

Fig. 33.3 Calcium exchange in the normal human. The amounts are shown in mmol per day.

Vitamin D metabolism

The primary source of vitamin D (Fig. 33.4) in humans is photoactivation in the skin of 7-dehydrocholesterol to cholecalciferol, which is then converted first in the liver to 25-hydroxyvitamin D (25(OH)D_3) and subsequently in the kidney (by the enzyme 1α-hydroxylase) to 1,25-dihydroxyvitamin D_3. (This step can occur in lymphomatous and sarcoid tissue, resulting in hypercalcaemia.) Regulation of the latter step is by PTH, phosphate, and feedback inhibition by 1,25-dihydroxyvitamin D_3.

Parathyroid hormone

Parathyroid hormone (PTH), an 84-amino-acid hormone, is secreted from the chief cells of the parathyroid gland, which have calcium-sensing and vitamin D receptors. PTH increases renal phosphate excretion and increases plasma calcium by

- increasing osteoclastic activity in bone (a rapid response)
- increasing intestinal absorption of calcium (a slower response)
- increasing 1α-hydroxylation of vitamin D (the rate-limiting step)
- increasing renal tubular reabsorption of calcium.

Hypomagnesaemia can suppress the normal PTH response to hypocalcaemia.

Calcitonin

Calcitonin is produced by thyroid C cells. Although calcitonin inhibits osteoclastic bone resorption and increases the renal excretion of calcium and phosphate, neither excess calcitonin (seen in medullary carcinoma of the thyroid) nor its deficiency following thyroidectomy has significant skeletal effects in humans.

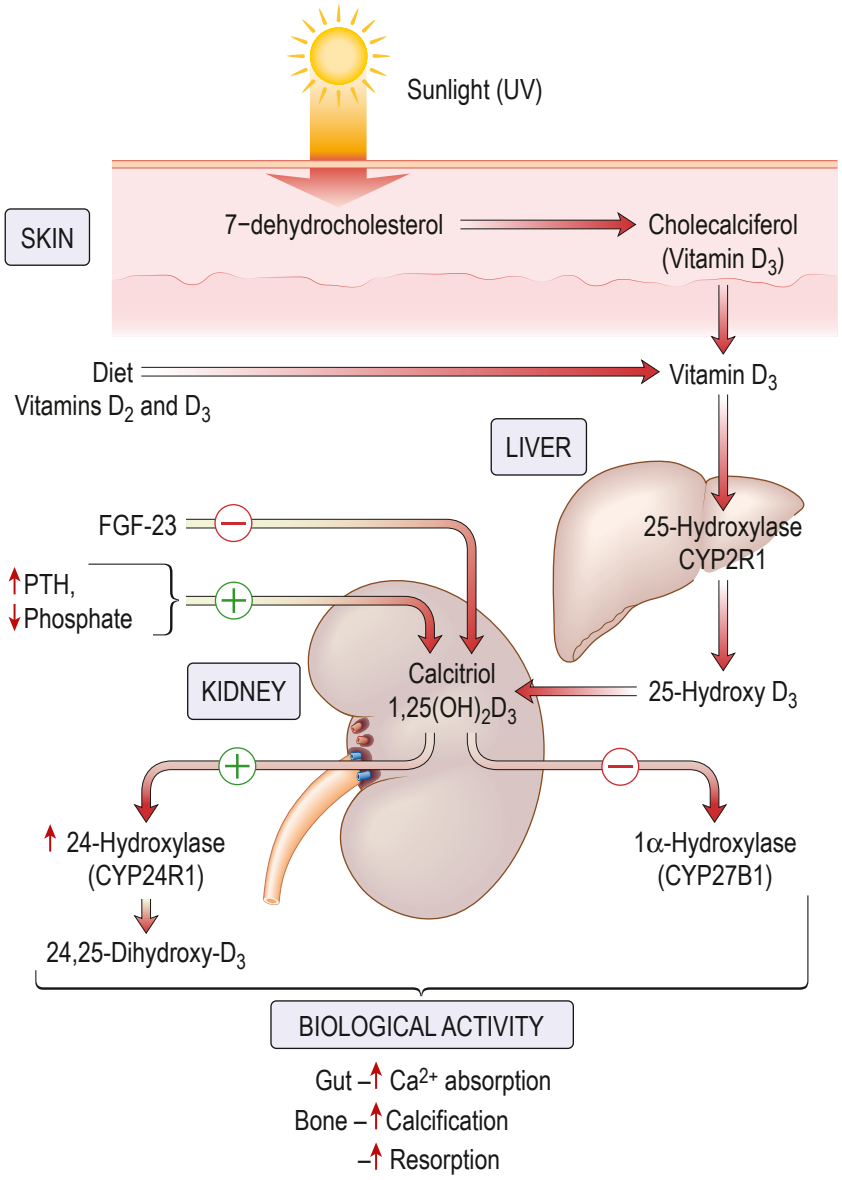

Fig. 33.4 The metabolism and actions of vitamin D. The biologically active agent is 1,25-dihydroxycholecalciferol (calcitriol). It inhibits 1α-hydroxylase and stimulates 24-hydroxylase to produce 24,25-dihydroxy-D_3, which is not biologically active. *CYP,* Cytochrome P enzyme; *FGF23,* fibroblast growth factor 23 secreted mainly by osteocytes (see Chapter 27).

INVESTIGATION OF BONE AND CALCIUM DISORDERS

See **Box 33.1**.

Total plasma calcium

Normal range is 2.2 to 2.6 mmol/L. About 40% of circulating calcium is ionized and physiologically active; the remainder is complexed or protein bound. As ionized calcium is difficult to measure, normal practice is to measure total calcium, correcting the value to allow for protein binding according to the following formula: add or subtract 0.02 mmol/L for each g/L of a simultaneous albumin level below or above 40 g/L. For critical measurements, samples should be taken in the fasting state and without a tourniquet (the latter may increase local plasma calcium concentration).

Plasma phosphate

Normal range is 0.8 to 1.4 mmol/L. Phosphate is essential to most biological systems. High levels are found in chronic kidney disease (CKD) and hypoparathyroidism, while low levels are associated with primary hyperparathyroidism, hypophosphataemic rickets and osteomalacia, and other disorders associated with reduced renal tubular phosphate reabsorption.

Plasma PTH

Normal range is 10 to 65 ng/L (1.3–7.6 pmol/L). The PTH assay measures the intact hormone. In hypercalcaemia not due to hyperparathyroidism, serum PTH levels are suppressed. Lithium toxicity may be associated with raised PTH levels; in familial hypocalciuric hypercalcaemia (FHH), serum PTH may be normal or marginally elevated.

Serum 25-hydroxyvitamin D

Vitamin D status is best assessed using serum 25-hydroxyvitamin D_3, as 1,25-dihydroxyvitamin D_3 has a short half-life and does not accurately reflect true vitamin D status. ***Vitamin D deficiency*** is defined as <25 nmol/L (10 ng/mL) and ***vitamin D insufficiency*** as less than 75 nmol/L (30 ng/mL). Rickets and osteomalacia occur with prolonged vitamin D deficiency.

The extra-skeletal significance of vitamin D insufficiency is uncertain but it has been linked to a wide range of conditions, including ischaemic heart disease, multiple sclerosis, and a variety of cancers. Recent evidence suggests that racial differences are present in the assessment of vitamin D status. Black Americans have consistently lower levels of 25-hydroxyvitamin D_3 than white Americans but also lower levels of ***vitamin D-binding protein***, resulting in equivalent bioavailable 25-hydroxyvitamin D_3.

24-hour urinary calcium

Normal range 2.5 to 7.5 mmol/24 h (100–300 mg/24 h). This is increased where renal tubular reabsorption of calcium is decreased, and in hypercalcaemia. One exception is FHH, where the genetic defect leads to inappropriately reduced calcium excretion. Measurement of 24-hour urinary calcium excretion should be performed in the assessment of hypercalcaemic patients.

Biochemical markers of bone formation and resorption

The clinical use of these biochemical markers is limited by large biovariability and measurement variance. Serial measurements at the same time of day in individual patients are useful in assessing response to treatment of metabolic bone diseases.

- ***Bone-specific alkaline phosphatase.*** Circulating alkaline phosphatase is derived from bone, liver, neutrophils, and placenta. The bone-specific isoenzyme can be measured as a marker of formation, although there is some overlap with the liver isoenzyme. Elevated serum levels occur during bone growth: for example, in adolescents, fracture repair and high-bone-turnover states.
- ***Type 1 collagen pro-peptides.*** These are by-products of collagen synthesis. Serum levels of both the carboxyterminal (P1CP) and aminoterminal (P1NP) pro-peptides reflect bone formation.
- ***Serum osteocalcin.*** This is another bone formation marker.
- ***Serum or urine levels of N-terminal (NTX) and C-terminal (CTX) cross-linked telopeptides.*** These reflect bone resorption. They may change rapidly in response to anti-resorptive drugs or in disease states, and have been used to assess fracture risk.

Diagnostic imaging

- ***Plain radiographs.*** These identify fractures, tumours, and infections. Other specific features may be seen (see following sections).
- ***Radionucleotide imaging.*** The uptake of a ^{99m}technetium-labelled bisphosphonate in bone reflects bone turnover and blood flow. Increased uptake is therefore seen in fractures, tumour and metastatic deposits, infection, and Paget's disease of bone.
- ***Magnetic resonance imaging (MRI).*** This is the most sensitive and specific test for the diagnosis of osteomyelitis. It is also useful in the detection of stress fractures, which may not be demonstrated on plain radiographs. A technique to suppress the high signal associated with bone marrow (such as STIR sequences; see Chapter 8) allows highly sensitive recognition of 'bone marrow oedema', a non-specific feature of a number of bone disorders, including osteonecrosis.
- ***Bone biopsy*** (Fig. 33.5). A core of bone is removed, including both cortices of the iliac crest, using a trephine. The non-decalcified specimen is examined for static and dynamic (bone turnover) indices. An oral tetracycline is given to the patient prior to the biopsy, for 2 days on two occasions 10 days apart, allowing assessment of the rate of bone turnover and mineralization. Biopsy is rarely performed but is useful in the assessment of renal bone disease and osteomalacia.
- ***Bone densitometry measurements*** (see 'Bone density' section).

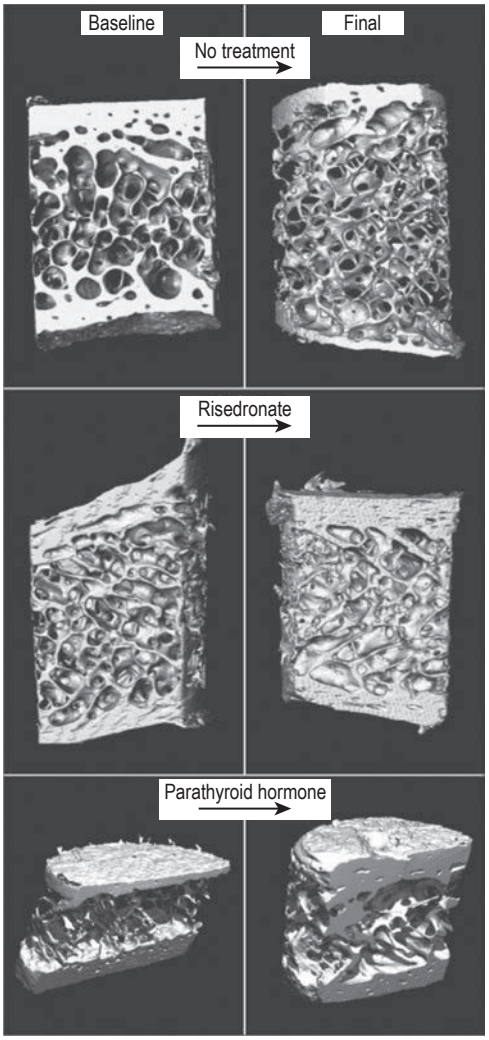

Fig. 33.5 Computerized images of bone biopsies in osteoporosis. These images demonstrate changes in bone architecture over time. ***Upper pair:*** Without treatment, the bone cortex becomes thinner and numerous trabecular rods and plates are lost. ***Centre pair:*** In response to bisphosphonate treatment, resorption is reduced, with preservation of bone mineral and structure. ***Lower pair:*** In response to anabolic therapy, bone is increased at both trabecular and cortical sites. *(From Jiang Y, Zhao JJ, Mitlak BH et al. Recombinant human parathyroid hormone [1–34] improves both cortical and cancellous bone structure.* J Bone Miner Res *2003; 18:1932–1941, with permission of the American Society for Bone and Mineral Research.)*

OSTEOPOROSIS

Osteoporosis is defined as 'a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and an increase in fracture risk'.

Using bone densitometry at the hip or spine measured by dual-energy X-ray absorptiometry (DXA), the World Health Organization (WHO) also defines osteoporosis as a bone density of 2.5 standard deviations (SDs) below the young healthy adult mean value (T-score ≤–2.5) or lower. Values between –1 and –2.5 SDs below the young adult mean are termed 'osteopenia'. The rationale for this definition is the inverse relationship between bone mineral density (BMD) and fracture risk in postmenopausal females and older males. However, this definition should not be applied to younger populations.

Fractures due to osteoporosis are a major cause of morbidity and mortality in elderly populations, with osteoporotic fractures of the spine causing acute pain or deformity and postural back pain. One in two females and one in five males aged 50 years will have an osteoporotic fracture during their remaining lifetime. As the risk of fracture increases with age, changing population demographics will increase the burden of disease.

Pathogenesis

Osteoporosis results from increased bone breakdown by osteoclasts and decreased bone formation by osteoblasts, leading to loss of bone mass.

Bone mass decreases with age (Fig. 33.6) but will depend on the 'peak' mass attained in adult life and on the rate of loss in later life. Genetic factors are the single most significant influence on peak bone mass. Multiple genes are involved, including collagen type 1A1, vitamin D receptor, and oestrogen-receptor genes. Nutritional factors, sex hormone status, and physical activity also affect peak mass. Not all causes of osteoporosis affect bone remodelling and architecture in the same way.

Oestrogen deficiency results in increased numbers of remodelling units, premature arrest of osteoblastic synthetic activity, and perforation of trabeculae, with a loss of resistance to fracture that is not fully reflected in the bone density measurement.

Glucocorticoids induce a high-turnover state initially, with increased fracture risk evident within 3 months of starting therapy. More prolonged use leads to a reduced-turnover state but with a net loss due to reduced synthesis (through inhibition of the *wnt*-LRP5/6 axis).

Ageing results in increased turnover at the bone/vascular interface within cortical bone, resulting in structural weakness (trabecularization of cortical bone).

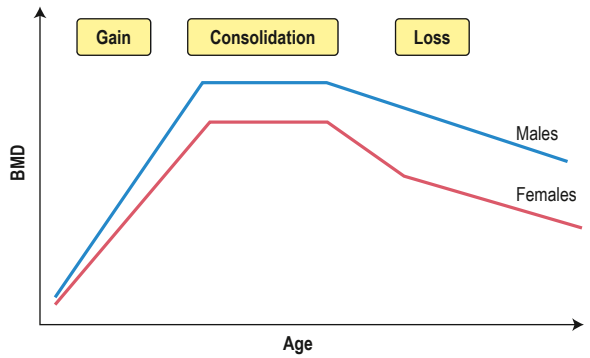

Fig. 33.6 Lifetime changes in bone mineral density (BMD). Peak bone mass is achieved between 20 and 30 years of age, and consolidated up to around the age of 40 years. Then, age-related bone loss occurs in both males and females, with an accelerated loss in females starting around the time of menopause, which lasts between 5 and 10 years.

Risk factors

Risk factors for fracture may exert their effect through reducing BMD, or they may increase risk over that attributable to BMD (BMD independent; Box 33.4). Oestrogen deficiency is a major factor in the pathogenesis of accelerated bone loss due to a normal or premature menopause, or amenorrhoea in patients with anorexia nervosa and in athletes. In the elderly, vitamin D insufficiency and consequent hyperparathyroidism reduce BMD. However, previous fracture, increasing age, glucocorticoid therapy, smoking, and falls increase the risk of fracture at any given BMD. For instance, 10% of females who are 65 years old and have a T-score of –2 at the hip would be expected to sustain a fracture over the next 10 years; if similar females had a Colles' fracture, smoked, and had prolonged exposure to steroids, their risk would be closer to 26% in the same period.

Box 33.4 Risk factors for fragility fractures

Bone mineral density-dependent
- Female sex
- White/Asian ethnicity
- Gastrointestinal disease
- Hypogonadism
- Immobilization
- Chronic liver disease
- Chronic kidney disease
- Low dietary calcium intake
- Vitamin D insufficiency
- Chronic obstructive pulmonary disease
- Cushing's syndrome
- Hyperthyroidism
- Hyperparathyroidism
- Diabetes mellitus
- Mastocytosis
- Multiple myeloma
- Osteogenesis imperfecta

Drugs
- Heparin
- Calcineurin inhibitors, e.g., ciclosporin
- Anticonvulsants
- Thiazolidinediones
- Aromatase inhibitors
- Anti-androgens
- Gonadotrophin-releasing hormone (GnRH) analogues
- Proton pump inhibitors
- ?Selective serotonin reuptake inhibitors

Bone mineral density-independent
- Increasing age
- Previous fragility fracture
- Family history of hip fracture
- Low body mass index
- Smoking
- Excess alcohol use
- Glucocorticoid therapy
- High bone turnover
- Increased risk of falling
- Rheumatoid arthritis

BMD-dependent risk factors respond to bone-directed treatment. BMD-independent risk factors benefit from additional targeted intervention (e.g., reduction of falls risk—see Chapter 49).

Clinical features

Fracture is the only cause of symptoms in osteoporosis. ***Vertebral fracture*** is suggested by the sudden onset of severe back pain. However, two in every three vertebral fractures are asymptomatic. Pain from mechanical derangement, increasing kyphosis, height loss, and abdominal protuberance may follow vertebral fracture. ***Colles' fractures*** typically follow a fall on an outstretched arm. ***Fractures of the proximal femur*** usually occur in older individuals falling on their side or back.

Other causes of low-trauma fractures must not be overlooked, including metastatic disease and myeloma.

Investigations

Plain X-rays (Fig. 33.7) may show fractures including previously asymptomatic vertebral fractures. Such clinically silent fractures may also be detected during DXA scanning with an additional analysis (called ***vertebral fracture assessment***, Box 33.5) carried out with a much lower radiation dose than conventional imaging. Increased bone radiolucency suggests low BMD but requires confirmation with DXA.

Bone density

DXA measures areal bone density (mineral per surface area rather than a true volumetric density), usually of the lumbar spine and proximal femur. It is precise and accurate, uses low doses of radiation and is the 'gold standard' in diagnosis of osteoporosis (Fig. 33.8). Because of osteophytes, spinal deformity, and vertebral fractures, spinal values may be artefactually elevated and should be interpreted with caution in the elderly.

Associated disease and risk factors

Investigations to exclude other diseases or identify contributory factors associated with osteoporosis should be performed and they are particularly necessary in males, in whom secondary causes are more common (see Box 33.4).

Selection of individuals for treatment: risk assessment

The goal of osteoporosis treatment is to reduce fracture risk (Box 33.6). Thus, assessment of absolute fracture risk should be made in every case. A previous fracture is the strongest risk factor for further fractures. DXA is useful in guiding treatment decisions (Box 33.7; Fig. 33.8). Patients with a previous fragility fracture or a BMD T-score less than or equal to –2.5 should be considered for treatment. It is vital to recognize, however, that the majority of fragility fractures occur in females with a T-score better than –2.5 (Fig. 33.9). In these patients, an assessment for future fracture risk should be made; this can be performed using clinical judgement by an experienced physician or using formal risk calculators, for example FRAX (Box 33.8). The threshold for recommending treatment in this setting will be determined by the cost-effectiveness of treatment in a particular healthcare setting and by clinical judgement. For example,

Box 33.5 Vertebral fracture assessment (VFA)

- Radiographic image of lateral spine generated using DXA
- Lower radiation than formal X-ray
- Can be done at same time as DXA
- Used to identify previously unsuspected vertebral fractures
- If vertebral fragility fracture identified, treatment for osteoporosis indicated irrespective of T-score

DXA, Dual-energy X-ray absorptiometry.

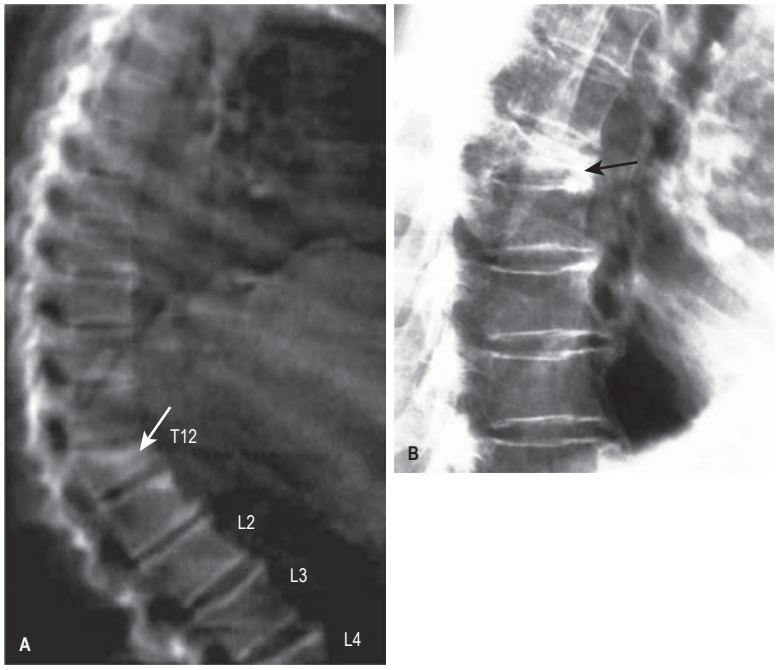

Fig. 33.7 Vertebral fracture as seen on DXA vertebral fracture assessment (VFA) and plain radiograph. (A) The VFA image shows a vertebra with reduced height at T12 *(arrow)*. **(B)** The radiograph shows a typical wedge compression fracture.

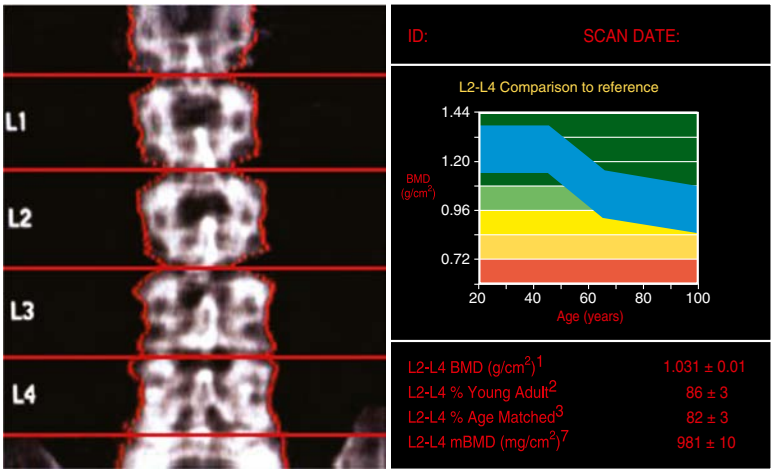

Fig. 33.8 Dual-energy X-ray absorptiometry (DXA) of the lumbar spine. **(A)** Anteroposterior image of the lumbar spine. **(B)** The patient's value is expressed in relation to the reference range.

i Box 33.6 Management of osteoporosis: summary

Treatment is guided by risk of fracture, not BMD alone.
Fracture risk assessment should be performed, either using clinical judgement or a formal risk assessment calculator (e.g., http://www.shef.ac.uk/FRAX and many others; see **Box 33.8**).

Do not under-estimate the risk from steroids or previous fracture.

Oral bisphosphonates (alendronate, risedronate) are first-line treatment in many cases. Other options include:

- ***denosumab:***
  - difficulty taking bisphosphonate
  - poor adherence to treatment
  - falling BMD on bisphosphonate
  - new fracture on a bisphosphonate
  - after 5–10 years on bisphosphonate
- ***teriparatide*** if there are multiple vertebral fractures or very low BMD
- ***romosozumab*** in very low BMD
- ***i.v. zoledronate*** if difficulty tolerating oral bisphosphonate

***BMD monitoring* is recommended in:**

- all treated patients to monitor therapy
- all untreated cases if a BMD reduction would lead to treatment.

BMD, Bone mineral density.

i Box 33.7 DXA scanning

Indications for DXA scanning

- Females aged ≥65
- Males aged ≥70
- Fragility fracture
- Females <65 with risk factors (see **Box 33.4**)
- Males <70 with risk factors (see **Box 33.4**)
- Monitoring of BMD in those on treatment

Features of DXA scanning

- Low-dose radiation X-ray
- Measures a real BMD
- Gives BMD in g/cm^2, which is difficult to interpret so translated to T- or Z-score
- T-score generated by comparing result with female, white, aged 20–29 years taken from the NHANES III study database
- Z-score generated by comparing result with person of same age and ethnicity and used to report BMD in premenopausal females and males aged <50

Interpretation of DXA

BMD measured at lumbar spine, total hip, femoral next (± radius)

In postmenopausal females and males aged ≥50:

- T-score ≤–2.5 = osteoporosis
- T-score ≤–1.0 to <–2.5 = osteopenia/low BMD
- T-score >–1.0 = normal BMD
- Z-scores ≤–2.0 is 'low BMD for age'

Interpretation of Z-scores is complex and beyond the scope of this text

BMD, Bone mineral density; *DXA*, dual-energy X-ray absorptiometry.

in the USA, the Bone Health and Osteoporosis Foundation recommends treatment if the 10-year probability of hip fracture is more than or equal to 3% or if major osteoporotic fracture is more than or equal to 20%. In the UK, the National Osteoporosis Guideline Group (NOGG) models a FRAX-based age-dependent intervention threshold that ranges from 7.5% to 30% for 10-year probability of major osteoporotic fracture.

Prevention and management

- ***Symptomatic management.*** New vertebral fractures may require bed rest for 1 to 2 weeks with strong analgesia and gradual physiotherapy to restore confident mobilization (see also Chapter 32). Pain following vertebral fracture takes an average of 3 months to resolve. Non-spinal fractures should be treated by conventional orthopaedic means. In fractured neck of femur, early surgical intervention, and early mobilization post surgery, are associated with improved outcomes.
- ***Calcium and vitamin D.*** Daily intakes of 800 to 1200 mg of calcium and 400 to 800 IU of vitamin D are recommended throughout life for optimum bone health. Dietary intake of calcium, and vitamin D from sunshine and diet, are preferable. For those not meeting calcium intake targets, or those with low serum 25-hydroxyvitamin D_3 levels, supplements are recommended (**Box 33.9**).
- ***Lifestyle measures.*** Weight-bearing exercise for 30 minutes three times a week may increase BMD, while gentle exercise in the elderly may reduce the risk of falls and improve the protective

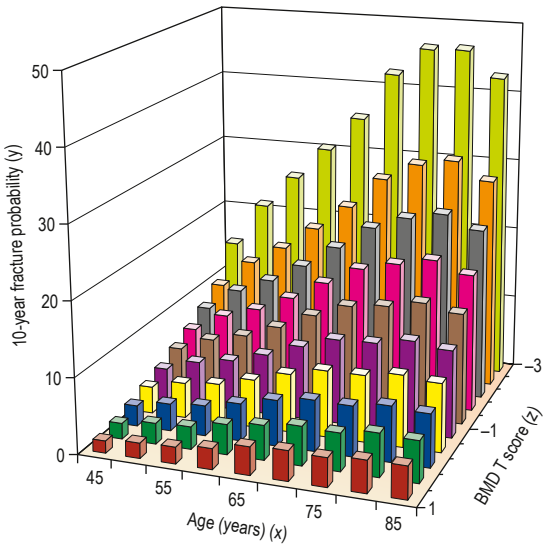

Fig. 33.9 Graph illustrating the combined effects of age (x-axis) and reduced bone mass (expressed as T-scores on the z-axis) on the 10-year probability of fracture (y-axis) in a population of females. Reduced bone mass osteopenia, T-scores between –1 and –2.5. Osteoporotic bone (T-scores <–2.5) is shown in pale green. Note that the risk of fracture may be greater in older females with osteopenia than in young females with osteoporosis. *(Data from Kanis JA. Diagnosis of osteoporosis and assessment of fracture risk.* Lancet *359:1929–1936.)*

Box 33.8 Fracture risk assessment

Fracture risk assessment:
- Should be performed in all patients
- Can be performed clinically or using risk assessment calculators.

FRAX is one of a number of fracture risk assessment tools available:
- Treatment is generally indicated if a 10-year major fracture risk ≥20% or hip fracture risk ≥3%
- These tools enable quantification of fracture risk and guide treatment decisions
- They provide estimates of fracture risk based on a set number of variables
- In certain situations they will not accurately estimate fracture risk so must be used in combination with clinical judgement

Box 33.9 Management of vitamin D deficiency

Treatment phase
- Vitamin D 50 000 IU weekly PO × 6–8 weeks

Maintenance phase
- Vitamin D 800–1000 IU daily PO × lifelong

responses to falling (see Chapter 49). Smoking and excess alcohol use should be avoided.
- ***Reduction of falls.*** Physiotherapy and assessment of home safety are helpful. Hip protectors do reduce fractures in the elderly in residential care when worn correctly, but compliance is poor.

Pharmacological intervention

Most interventions (see **Box 33.6**) act by inhibiting bone resorption (anti-resorptives), the exception being PTH peptides and romosozumab, which stimulate bone formation.

Box 33.10 Evidence for fracture risk reduction of current treatment options at specific sites in postmenopausal females

Intervention	Vertebral fracture	Non-vertebral fracture	Hip fracture
Alendronate	+	+	+
Risedronate	+	+	+
Ibandronate	+	+[a]	ND
Zoledronate	+	+	+
Bazedoxifene	+	ND	ND
Raloxifene	+	ND	ND
Denosumab	+	+	+
Teriparatide	+	+	ND
Abaloparatide	+	+	ND
Romosozumab	+	+	+

[a]Demonstrated only in high-risk subgroup.
ND, Not demonstrated.

The evidence base for the ***anti-fracture efficacy*** of interventions varies. Treatments with proven efficacy at all major fracture sites (particularly spine and hip) are preferable (**Box 33.10**). The bisphosphonates are generally regarded as the first-line option in the majority of postmenopausal females with osteoporosis.

Bisphosphonates

As synthetic analogues of bone pyrophosphate, bisphosphonates adhere to hydroxyapatite and inhibit osteoclasts. Alendronate and risedronate are given as once-weekly doses, zoledronate as a once-yearly infusion, and ibandronate usually as a once-monthly oral therapy (a 3-monthly intravenous injection is rarely used).

Oral bisphosphonates should be taken fasting, with a large drink of water, while standing or sitting upright. The patient should then remain upright and avoid food and drink for at least 30 minutes.

Bisphosphonates are generally well tolerated but may be associated with upper gastrointestinal side-effects such as oesophagitis, particularly if the dosing instructions are not closely followed. Bisphosphonates should be used with careful monitoring in patients who have CKD (stage 4 or 5). Osteonecrosis of the jaw is a rare complication of high-dose intravenous bisphosphonates in patients who have malignant disease. It is associated with poor dental hygiene. As prolonged suppression of bone turnover is linked with atypical femoral fractures, it is currently advised to reassess bisphosphonate treatment after 5 years for oral agents and 3 years for zoledronate. For those estimated to remain at high risk of fracture, a further 5 years of oral treatment or 3 years of intravenous treatment is appropriate.

Denosumab

Denosumab is a fully human monoclonal antibody to RANKL administered as a single subcutaneous injection every 6 months. It is an anti-resorptive agent that increases BMD and reduces fractures at the spine, hip, and other non-vertebral sites. Fracture risk reduction is equivalent to that of bisphosphonates. Unlike bisphosphonates, the benefit of denosumab is rapidly lost on cessation. This results in a precipitous drop in BMD and often multiple vertebral fractures. Therefore, it should generally not be stopped and should continue as a lifelong treatment. Strategies to substitute other agents such as bisphosphonates to allow denosumab cessation appear partially effective at best. Adverse effects are infrequent: most commonly

dysuria, rarely cellulitis. Osteonecrosis of the jaw and atypical femoral fractures have also been reported.

Selective oestrogen-receptor modulators

Selective oestrogen-receptor modulators (SERMs) include raloxifene and bazedoxifene. They are rarely used to treat osteoporosis. They have no stimulatory effect on the endometrium but activate oestrogen receptors in bone. Both prevent BMD loss at the spine and hip in postmenopausal females but have been found to reduce only vertebral fracture rates. Leg cramps and flushing may occur, and the risk of thromboembolic complications is also increased to a degree similar to that seen with hormone replacement therapy (HRT; see Chapter 47 and Box 47.16). The use of SERMs is associated with a small increase in the risk of stroke.

Recombinant human parathyroid hormone

Recombinant human PTH peptide 1–34 (teriparatide) and recombinant human PTH 1–84 are anabolic agents that stimulate bone formation. Teriparatide reduces vertebral and non-vertebral fractures in postmenopausal females with established osteoporosis, although specific data on hip fracture are not available. It is given by daily subcutaneous injection for 24 months. Recombinant human PTH 1–84 is also administered by once-daily subcutaneous injection but has been shown to reduce only vertebral fractures. An anti-resorptive drug should be given on completion of PTH peptide therapy to maintain the increase in BMD. Non-osteoporotic bone diseases, such as osteomalacia, should be excluded prior to treatment. PTH peptide therapy is difficult for patients to take and associated with more adverse events than other agents and therefore is mainly indicated in severe cases of vertebral osteoporosis or in those who fail to respond to other therapies. Teriparatide may cause mild transient hypercalcaemia but routine monitoring is not required. Nausea and headache may occur. Recombinant human PTH 1–84 is associated with a higher incidence of hypercalcaemia and hypercalciuria, and routine monitoring is advised. Neither agent should be used in people with skeletal metastases or osteosarcoma.

Romosozumab

Romosozumab is a monoclonal antibody that binds sclerostin. It is an anabolic agent that has been demonstrated to reduce vertebral, hip, and non-vertebral fracture. Treatment is by monthly subcutaneous injection for 1 year and should be followed by an anti-resorptive agent. There is a concern over increased adverse cardiovascular events from one study, and therefore romosozumab is best avoided in patients at increased risk of cardiovascular events. Romosozumab has a similar role in treatment to PTH agents, and is best reserved for those with severe osteoporosis or who fail to respond to other agents.

Hormone replacement therapy

Because of its adverse effects profile and the availability of effective bone-specific agents, HRT is generally not indicated solely for osteoporosis, but may benefit bone health early postmenopausal females who commence HRT for perimenopausal symptoms.

Calcitriol (1,25-dihydroxyvitamin D_3) and calcitonin

These may reduce vertebral fracture rate, although the data are inconsistent.

Combination therapies

Combination therapies, either with two anti-resorptive agents, or an anti-resorptive and an anabolic agent, often produce larger increases in BMD than monotherapy but have not been shown to result in greater fracture reduction. Therefore, they are generally not advised. An exception to this may be in non-responding denosumab-treated patients, who may benefit from the addition of recombinant PTH.

Surgery

This is very rarely indicated in osteoporotic vertebral fractures. Percutaneous vertebroplasty and balloon kyphoplasty are discussed in Chapter 32. Hip fractures are dealt with by hip replacements or stabilization with pins.

Treatment of specific conditions

Glucocorticoid-induced osteoporosis

Individuals requiring continuous oral glucocorticoid therapy for 3 months or more (at any dose) should be assessed for coexisting risk factors (age, previous fracture, hormone status). Postmenopausal females, males aged over 50 years and any individuals who have sustained a fragility fracture should receive treatment without waiting for DXA scanning. DXA results and fracture risk assessment guide treatment for other patients (see Boxes 33.5, 33.7, and 33.8). Bisphosphonates, denosumab, and teriparatide are approved in this setting. Bisphosphonates are generally preferred due to the cost and adverse event profile of teriparatide, and the often temporary nature of treatment making denosumab less preferable.

Osteoporosis in males

Alendronate, risedronate, zoledronate, denosumab, and teriparatide are approved for use in males. In males with osteoporosis who have clinical and biochemical evidence of hypogonadism, testosterone replacement is also used.

OSTEONECROSIS

This is also known as aseptic, avascular, or ischaemic necrosis of bone. Over 80% of cases are attributed to glucocorticoid treatment or alcohol excess. Less frequent causes include sickle cell disease, systemic lupus erythematosus (SLE), deep-sea diving (Caisson's disease), endocrine disorders (e.g., Cushing's, diabetes mellitus), trauma, human immunodeficiency virus (HIV) infection, and irradiation.

Osteonecrosis usually presents with joint pain, the shoulder or hip being most commonly affected, but can be asymptomatic, particularly on the opposite side in the same person. It may only be recognized when it results in collapse of the articular bone.

MRI best confirms the diagnosis by showing bone marrow oedema. If advanced, it can be seen on plain X-rays.

Management is mainly symptomatic. Surgical options include drilling through the bone cortex (decompression), vascularized bone grafts, or rotation of the affected bone away from the load-bearing area; however, joint replacement is often required. Bisphosphonates may reduce pain and progression but the evidence is mixed.

PAGET'S DISEASE OF BONE

Paget's disease of bone is a focal disorder of bone remodelling. Increased osteoclastic bone resorption is followed by a compensatory increase in new bone formation, increased local bone blood flow, and fibrous tissue in adjacent bone marrow. Ultimately, formation exceeds resorption but the new woven bone is weaker than normal bone, which leads to deformity and increased fracture risk. Paget's disease does not spread but can become symptomatic at previously silent sites.

Epidemiological studies are difficult because most affected individuals are asymptomatic. Paget's disease is most often seen in Europe and particularly in northern England. It affects males and females (2:3) over the age of 40 years. The incidence approximately doubles per decade thereafter, with up to 10% of individuals radiologically affected by the age of 90. For unknown reasons, the incidence and severity of Paget's disease have decreased in recent years.

Aetiology and pathogenesis

Genetic factors are implicated in Paget's disease. A positive family history is noted in about 15%. Mutations in *SQSTM1*, which encodes the osteoclast mediator protein p62, have been reported in up to 10% of cases. Intracellular inclusions in the osteoclasts in pagetic lesions are believed to be paramyxovirus nucleocapsid (e.g., canine distemper virus, measles, or respiratory syncytial virus). However, similar inclusions are seen in other bone disorders, and theories of a viral aetiology in Paget's remain contentious. Altered expression of *c-fos* (an oncogene) is one suggested mechanism linking viral infection with the pathogenic changes in osteoclasts, which are more numerous and contain an increased number of nuclei (up to 100).

Clinical features

Clinical features are summarized in Fig. 33.10A. Between 60% and 80% of people with radiologically identified Paget's disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, or a plain X-ray performed for other indications. The disease may involve one bone (monostotic, in 15%) or many (polyostotic). The most common sites, in order of frequency, are pelvis, femur, lumbar spine, skull, and tibia (see Fig. 33.10C). Small bones of the feet and hands are rarely involved.

Symptoms and complications include:

- bone pain
- joint pain when an involved bone is close to a joint, leading to cartilage damage and osteoarthritis
- deformities, in particular bowed tibia and skull changes
- neurological complications—nerve compression (deafness from VIIIth cranial nerve involvement; cranial nerves II, V, and VII may also be involved); spinal stenosis; hydrocephalus due to blockage of the aqueduct of Sylvius
- high-output cardiac failure and myocardial hypertrophy due to increased bone blood flow (rarely seen with modern management)
- hypercalcaemia—rarely seen outside the setting of fracture
- pathological fractures
- osteosarcoma—occurs in fewer than 1% of cases of Paget's and may be heralded by an increase in bone pain or swelling in a previous pagetic bone area.

Investigations

- ***Increased serum alkaline phosphatase*** with normal serum calcium and phosphate reflects increased bone turnover.

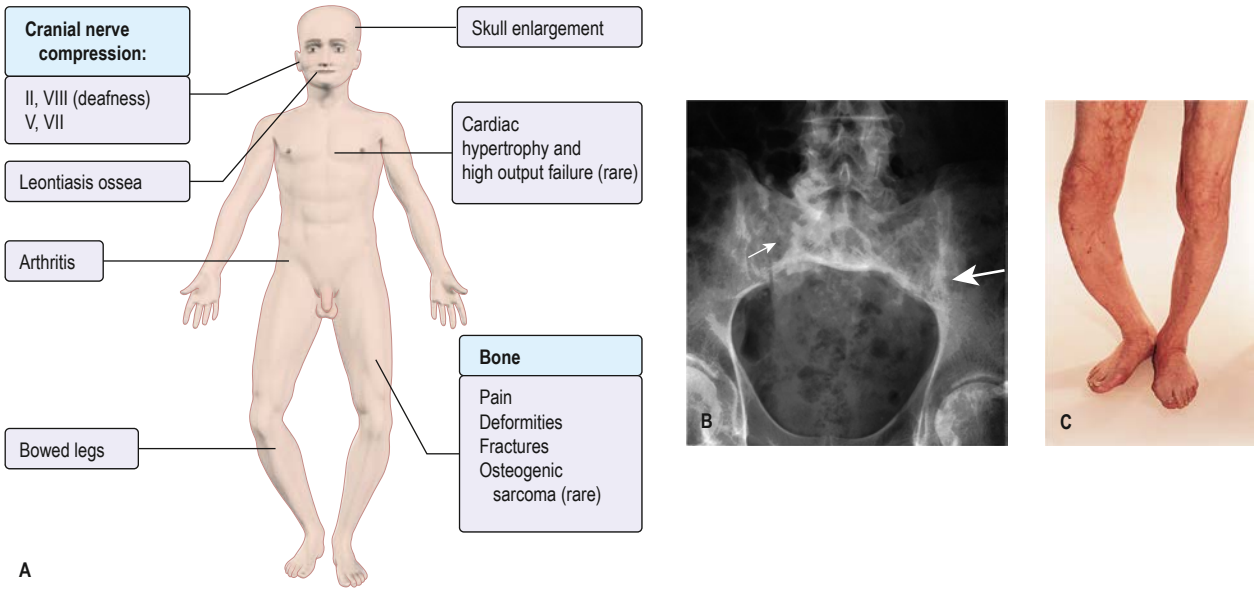

Fig. 33.10 Paget's disease. **(A)** Clinical features. **(B)** X-ray appearance of the pelvis, showing osteolytic *(thin arrow)* and osteosclerotic *(thick arrow)* lesions. **(C)** Legs showing bowing of the tibia caused by increased bone growth. Note the erythema ab igne on the medial aspect of the thigh.

Levels may be normal with limited or monostotic Paget's disease. Levels are reduced with treatment and increased during relapse.

- ***Vitamin D*** should be measured, as deficiency is frequent in the age group affected by Paget's disease and should be corrected (see **Box 33.9**) to avoid hypocalcaemia following bisphosphonate treatment.
- ***X-ray*** features (see **Fig. 33.10B**) vary from predominantly lytic lesions (osteoporosis circumscripta in the skull is characteristic), through a mixed phase, to a mainly sclerotic phase of bone expansion, cortical thickening and coarsening of the trabecular pattern.
- ***Isotope bone scans*** are useful to determine the extent of skeletal involvement but are unable to distinguish between Paget's disease and sclerotic metastatic carcinoma (especially breast and prostate).

Management

Bisphosphonates are the mainstay of treatment. New bone formed after treatment is lamellar, not woven (reflecting normalization of bone turnover rather than a direct effect on osteoblasts). Repeat treatment courses are guided by recurrence of symptoms and by rising alkaline phosphatase. In addition to treatment of symptomatic patients, treatment of asymptomatic lesions is appropriate if there is a significant risk of potential complications, such as fracture in weight-bearing long bones or the spine, nerve entrapment, or deafness with skull involvement, and before orthopaedic procedures in involved bone (to reduce vascularity).

Intravenous bisphosphonates

Zoledronate is the most commonly used agent for Paget's disease, administered as a single infusion over 15 minutes. ***Pamidronate*** is an alternative but takes longer to infuse and is less potent; some patients develop drug resistance for unknown reasons. Both drugs can be associated with a first-dose reaction characterized by 'flu-like' symptoms, including transient pyrexia over 24 to 48 hours, which can be ameliorated with paracetamol.

Oral bisphosphonates

Oral bisphosphonates are used at doses higher than those for osteoporosis (e.g., 30 mg risedronate daily for 2 months, or 40 mg alendronate daily for 6 months) and are less effective than intravenous zoledronic acid.

Surgery

Joint replacement or osteotomy is sometimes necessary to correct deformity or pain due to associated degenerative joint disease. Neurosurgery may be needed where there is spinal disease. Osteosarcoma usually requires amputation, though wide excision and limb salvage can be successful at distal sites.

RICKETS AND OSTEOMALACIA

Osteomalacia is defective mineralization of newly formed bone matrix or osteoid. Rickets is defective mineralization at the epiphyseal growth plate and is found in association with osteomalacia in children.

Aetiology

Many factors can result in defective mineralization of the osteoid. For normal mineralization, adequate levels of vitamin D, calcium, and phosphate, adequate activity of alkaline phosphatase, a normal pH at the osteoid surface, and normal osteoid composition are all necessary (**Box 33.11**).

The most common cause of osteomalacia is hypophosphataemia due to hyperparathyroidism secondary to vitamin D deficiency. The most common cause of vitamin D deficiency worldwide is dietary deficiency. Bread, milk, and cereals in high-income countries are now fortified with vitamin D. This has led to a much-reduced incidence of osteomalacia and rickets.

Vitamin D is produced in the skin through the action of sunlight on 7-dehydrocholesterol (see **Fig. 33.4**). Lack of sun exposure can lead to vitamin D deficiency, especially in individuals living in temperate regions who keep large parts of the skin covered throughout the year.

Vitamin D is a fat-soluble vitamin, so gastrointestinal disease can result in malabsorption. Gastrectomy, various forms of bariatric surgery, cystic fibrosis, coeliac disease, Crohn's disease, and primary biliary cirrhosis are well-recognized causes.

Due to the intimate involvement of the kidney in phosphate balance, a number of causes of osteomalacia are mediated by the kidney (see Chapter 26). Primary renal phosphate wasting occurs in tumour-induced osteomalacia, multiple myeloma, and Fanconi's syndrome. Proximal (type 2) renal tubular acidosis can cause osteomalacia due to both renal phosphate wasting and abnormal osteoid pH secondary to metabolic acidosis.

Clinical features

Osteomalacia may be asymptomatic and identified incidentally on routine investigations following a fragility fracture. When symptomatic, it characteristically causes muscle weakness and widespread bone pain. Muscle weakness is due to a multifactorial proximal myopathy, with low vitamin D, hypophosphataemia, and high PTH levels all contributing. It results in a characteristic waddling gait with difficulty climbing stairs and getting out of a chair. Generalized bone pain and tenderness are thought to be caused by hydration of the

? Box 33.11 Causes of rickets/osteomalacia

Deficient intake or absorption of vitamin D
- Inadequate sun exposure or deficient synthesis in skin
- Low dietary intake
- Malabsorption: coeliac disease, Crohn's disease, gastrectomy, bariatric surgery, primary biliary cirrhosis

Defective 1α-hydroxylation
- Chronic kidney disease
- Vitamin D-dependent rickets type I—due to deficiency of 1α-hydroxylase

Primary renal phosphate wasting
- Renal tubular acidosis (also by causing metabolic acidosis)
- Hereditary hypophosphataemic rickets (vitamin D-resistant rickets)
- Dent's disease
- Fanconi's syndrome
- Multiple myeloma
- Tumour-induced osteomalacia

Inhibitors of mineralization
- Fluoride, aluminium, bisphosphonates
- Metabolic acidosis

Defective vitamin D receptors
- Hereditary vitamin D-resistant rickets (previously known as vitamin D-dependent rickets type II)

demineralized matrix, resulting in periosteal distension. The pain is typically a dull ache that is worse on weight-bearing and walking. It can be reproduced by pressure on the sternum or tibia. Insufficiency fractures can occur when the quality of the bone is insufficient to handle the stress of weight-bearing.

At birth, neonatal rickets may present as craniotabes (a thin, deformed skull). In the first few years of life, there may be widened epiphyses at the wrists and beading at the costochondral junctions, producing the 'rickety rosary', or a groove in the rib cage (Harrison's sulcus). In older children, lower limb deformities are seen. A myopathy may also occur. Hypocalcaemic tetany may occur in severe cases.

Investigations

- ***Serum alkaline phosphatase*** is elevated in 90% of cases.
- ***Low serum calcium***, ***low phosphate***, and ***elevated PTH*** are each present in approximately half of the cases.
- ***Serum*** 25-hydroxyvitamin D_3 is low, usually less than 25 nmol/L (10 ng/mL).
- ***Serum FGF-23*** is elevated in many people with tumour-induced osteomalacia and in hypophosphataemic rickets.
- ***Plain radiographs*** demonstrate decreased bone mineralization. The characteristic finding in osteomalacia is Looser's pseudofractures. These are narrow radiolucent lines with sclerotic borders running perpendicular to the cortex. They can be found at any site but are most commonly seen in the femur and pelvis.
- ***Tetracycline-labelled bone biopsy*** is the gold standard diagnostic test. This is not practical in most clinical settings and is used mainly in research studies.

Management

Vitamin D replacement is the cornerstone of treatment. Treatment involves two stages: an initial loading stage to replenish body stores of vitamin D, and a subsequent maintenance phase to avoid repeat deficiency (see **Box 33.9**). All patients should also receive supplementary calcium of 1000 to 1200 mg/day. In nutritional deficiency, recommended initial replacement is with vitamin D 50 000 units per week orally. The initial replacement dose should be continued for 6 to 8 weeks. Adequacy of vitamin D replacement should be confirmed by repeat measuring of vitamin D levels. This should be followed by maintenance supplementation with 800 to 1000 units of vitamin D per day.

Doses for children are lower and are age-dependent. People with gastrointestinal disease and vitamin D deficiency due to malabsorption need higher doses of 10 000 to 50 000 units per day of vitamin D.

Tumour-induced osteomalacia is best treated by removal of the causative neoplasm, which is usually occult and frequently benign. This leads to rapid resolution of symptoms.

BONE INFECTIONS

Acute and chronic osteomyelitis

Osteomyelitis is more common in children and arises due to haematogenous spread to the vascular metaphysis. In high-income countries, it occurs in around 8 per 100 000 children per year, but it is more common in low-income countries, with males affected twice as often as females. In adults, it generally occurs in the setting of other medical conditions, such as type 2 diabetes mellitus and chronic skin ulceration where it infiltrates the bone through direct spreading.

Staphylococcus is the organism responsible for 90% of cases of acute osteomyelitis. Other organisms include *Haemophilus influenzae* and *Salmonella*; infection with the latter may occur as a complication of sickle cell disease. The classic presentation is with fever and localized bone pain with overlying tenderness and erythema.

Diagnosis

- Imaging:
  - Plain X-ray is not sensitive in early infection but demonstrates chronic damage.
  - MRI is highly sensitive in early disease.
  - Nuclear medicine bone scans are also helpful.
- ***Blood cultures*** may be positive.
- ***Bone biopsy and culture*** identifies the organism and sensitivities.

Management

Treatment of osteomyelitis is with intravenous antibiotics. Switching to oral antibiotics can be considered after 2 weeks with continuation for a further 4 weeks. Choice of antibiotic is determined by the causative agent and local guidelines. Surgical drainage and removal of dead bone (sequestrum) may be necessary but recurrence is common.

Delayed treatment leads to chronic osteomyelitis. In chronic osteomyelitis, sinus formation is common. Subacute osteomyelitis is associated with a chronic abscess within the bone (Brodie's abscess).

Tuberculous osteomyelitis

This is usually due to haematogenous spread from a reactivated primary focus in the lungs or gastrointestinal tract. The disease starts in intra-articular bone. The spine is commonly involved ***(Pott's disease)***, with damage to the bodies of two neighbouring vertebrae leading to vertebral collapse and acute angulation of the spine (gibbus). Later, an abscess forms ('cold abscess'). Pus can track along tissue planes and discharge at a point far from the affected vertebrae. Symptoms consist of local pain and later swelling if pus has collected. Systemic symptoms of malaise, fever, and night sweats occur.

Management is as for pulmonary tuberculosis but extended to 9 months (see Chapter 20), together with initial immobilization.

NEOPLASTIC DISEASE OF BONE

Bone pain may be due to multiple myeloma, lymphoma, a primary tumour of bone, or secondary deposits. The pain is typically unremitting and worse at night, and there are other clinical clues such as weight loss or ill-health.

Malignant tumours of bone are shown in **Box 33.12**. The most common tumours are metastases from the bronchus, breast and prostate. Metastases from kidney and thyroid are less common. Primary bone tumours are rare and most commonly seen in children and young adults.

Symptoms are usually related to the anatomical position of the tumour, with local bone pain. Systemic symptoms (e.g., malaise and

Box 33.12 Malignant neoplasms of bone

- Metastases (osteolytic):
  - Lung
  - Breast
  - Prostate (often osteosclerotic as well)
  - Thyroid
  - Kidney
- Multiple myeloma
- Primary bone tumours (rare; seen in the young), e.g.:
  - Osteosarcomas
  - Fibrosarcomas
  - Chondromas
  - Ewing's tumour

pyrexia) and aches and pains occur and may be related to hypercalcaemia. The diagnosis of metastases may be evident from the history and examination, particularly in the setting of a known primary tumour. Symptoms from bony metastases may also be the first presenting feature of a malignancy, however.

Investigations

- ***Skeletal isotope scans*** show bony metastases as 'hot' areas.
- ***X-rays*** may show metastases as osteolytic areas with bony destruction. Osteosclerotic metastases are characteristic of prostatic carcinoma.
- ***MRI*** is used particularly for vertebral lesions.
- ***CT and computed tomography-positron emission tomography (CT-PET)*** are useful.
- ***Serum alkaline phosphatase*** may be raised.
- ***Hypercalcaemia*** occurs in 10% to 20% of patients who have metastatic malignancies, or can be due to ectopic parathormone or PTH-related protein secretion.
- ***Prostate-specific antigen*** (PSA) and serum acid phosphatase are raised in the presence of prostatic metastases.

Management

Treatment is usually with analgesics and anti-inflammatory drugs. Local radiotherapy to bone metastases relieves pain and reduces the risk of pathological fracture. Some tumours respond to chemotherapy; others are hormone-dependent and respond to hormonal therapy. Bisphosphonates (see 'Bisphosphonates' section) can help symptomatically. Occasionally, pathological fractures require internal fixation.

SCHEUERMANN'S DISEASE

This disease predominantly occurs in adolescent males. The main feature is a progressive dorsal kyphosis of the thoracic spine. Pain may or may not be present. The cause is unknown. A genetic predisposition, exacerbated by excessive exercise prior to epiphyseal fusion, is one suggested explanation. Older patients with kyphosis may be referred with suspected osteoporotic fractures but found to have long-standing kyphosis due to Scheuermann's. Management is focused on postural exercises and avoidance of precipitants. Surgery may be undertaken to correct kyphosis in severe cases.

CORE SKILLS AND KNOWLEDGE

Many endocrine conditions are common and seen outside the hospital setting. They often affect young people and can usually be cured or completely controlled with appropriate therapy. For example, the UK prevalence of hypothyroidism is 2%, and it is usually managed in primary care. Excluding obesity (Chapter 33) and diabetes mellitus (Chapter 35), the commonest endocrine disorders are thyroid disorders; menstrual disorders; disorders affecting reproduction; hyperparathyroidism; and increasingly incidental findings in endocrine organs found on scans being done for other reasons—termed 'incidentalomas'.

Most endocrinologists specialize in both diabetes and endocrinology, seeing patients in outpatient clinics and often looking after general medical inpatients. Joint clinics that include specialist endocrine surgeons, endocrine oncologists, obstetricians, gynaecologists, and paediatricians combine the expertise patients require in one clinical environment. Specialist nurses oversee dynamic testing of endocrine function and coordinate education and management of patients with endocrine conditions.

Key skills required in endocrinology include:

- Mastering key principles of hormone action (such as negative feedback) in order to distinguish primary from secondary gland failure
- Understanding the concept of dynamic endocrine tests and interpreting their results
- Becoming familiar with the hormones most commonly used in endocrine replacement including levothyroxine, hydrocortisone, testosterone, and oestrogen/progestogen.

The best way to learn about endocrinology is to attend specialist and general outpatient clinics, where patients presenting with endocrine syndromes are evaluated and complex dynamic tests are planned and interpreted. Attend specialist multidisciplinary team meetings (MDTs) to learn about the radiology, histology, and different management approaches to endocrine disease.

CLINICAL SKILLS

History and examination

Specific features of the history relevant to endocrine disease are described in **Box 34.1**. On examination, weight, height, body mass index (BMI), blood pressure, and general habitus should be documented, together with the presence or absence of specific signs of deficiency or excess of individual hormone axes indicated in the diagram opposite. Emergency presentations are listed in **Box 34.2**. In addition:

- In people with suspected pituitary disease, visual fields and adjacent cranial nerves should be assessed.
- In thyroid disease, the presence of goitre or orbitopathy should be documented.
- In hypogonadism both sexes require assessment of other secondary sexual characteristics, and testicular volumes in males should be documented as well as presence or absence of gynaecomastia.

Dynamic endocrine tests

Because of intra-individual and diurnal variations in the levels of many clinically relevant hormones, a single blood test often does not provide the information necessary to make a diagnosis. Dynamic endocrine tests assess the response of an endocrine axis to a specific challenge and are performed according to detailed protocols, which must be followed precisely. There are two types of dynamic tests: stimulation and suppression tests (**Box 34.3**).

Box 34.1 Taking a history in endocrine assessment

General symptoms of a variety of endocrine disorders

- Tiredness, weakness, lack of energy, or drive

Other common 'hormonal' symptoms

- Changes in body size and shape
- Changes in appetite or thirst
- Problems with libido and sexual function
- Changes in menstrual cycle
- Changes in the skin (dryness, greasiness, acne, bruising, thinning or thickening)
- Abnormal hair distribution (loss or excess)
- Subfertility or pregnancy loss

Role of hormones in physical development

- Growth and development in childhood
- Age of menarche
- Age of puberty
- Problems of sexual development

Risk factors common to a range of endocrine disorders

- Previous surgery or radiation involving endocrine glands
- Current or previous medication with endocrine side-effects
- A previous or family history of autoimmune disease
- A previous or family history of atypical tumours
- A family history of obesity, early-onset cardiovascular disease, or any symptoms similar to those the patient is experiencing

Box 34.2 The 'top 10' endocrine emergencies

Diagnosis	Presentation	Location in chapter/book
Severe hyponatraemia	Non-specific neurological symptoms and signs including confusion, drowsiness, coma, and seizures if severe	Box 27.13
Severe hypercalcaemia	Thirst, dehydration, polyuria	Box 34.54
Hypoadrenal crisis	Collapse, postural hypotension, hypoglycaemia, history of chronic steroid use	Box 34.18
Rapid dehydration in diabetes insipidus	Severe dehydration with ongoing polyuria; thirst; drowsiness, coma, or seizures; history of diabetes insipidus or chronic lithium use	'Diabetes insipidus/History and examination' section
Pituitary apoplexy	Sudden severe headache (may be mistaken for subarachnoid haemorrhage) in a patient with known or undiagnosed pituitary tumour	'Pituitary apoplexy' section
Thyrotoxicosis	Fever, tachycardia, anxiety, tremor, dysrhythmia, e.g., fast atrial fibrillation	'Thyroid crisis or 'thyroid storm" section
Severe hypothyroidism	Bradycardia, hypotension, drowsiness, or coma	'Myxoedema coma' section
Hypoglycaemia	Sweating, confusion, drowsiness, or coma. Regular user of insulin or sulphonylurea	Chapter 11, 'Hypoglycaemia' section
Diabetic ketoacidosis	Vomiting, fever, dehydration, acidosis with Kussmaul respiration, hyperglycaemia. History of type 1 diabetes	Chapter 11, 'Diabetic ketoacidosis' section
Hyperglycaemic hyperosmolar state	Drowsiness or coma. Severe dehydration and hyperglycaemia. Signs of intercurrent illness. History of type 2 diabetes	Chapter 11, 'Hyperosmolar hyperglycaemic state' section

Box 34.3 Dynamic endocrine tests

	Stimulation test	Suppression test
Assess for	**Hormone deficiency**	**Hormone excess**
Abnormal result	Inadequate rise in hormone level after stimulation, suggesting damage to target gland limiting maximum secretory output	Inadequate suppression of hormone level, indicating failure of negative feedback control and likely autonomous hormone secretion
Example	Short ACTH (synacthen) test for adrenal insufficiency	Dexamethasone suppression test for Cushing's disease

BACKGROUND

The endocrine system consists of glands that exert their actions at distant parts of the body via the production of biologically active hormones secreted into the bloodstream. Unlike the neurological system, which produces an immediate response, the endocrine system typically has a slower and longer-lasting effect on the body. The main endocrine glands are the pituitary, thyroid, adrenals, gonads, parathyroids, and pancreas, and the common endocrine problems seen in clinical practice are shown in Fig. 34.1. The pituitary gland, a pea-sized structure situated at the base of the brain, plays a key role in the control and feedback mechanisms of the endocrine system and has been termed the 'conductor of the endocrine orchestra'.

Hormonal activity

Synthesis, storage, and release of hormones

Hormones have several chemical structures: polypeptide, glycoprotein, steroid, or amine. Hormone release is the end-product of a cascade of intracellular events. In the case of polypeptide hormones neural or endocrine stimulation of the cell causes increased transcription from DNA to a specific messenger RNA (mRNA), which is, in turn, translated to the peptide product. This is often a precursor molecule that may itself be biologically inactive. This 'prohormone' is further processed before being packaged into granules in the Golgi apparatus. These granules are transported to the plasma membrane before release, which is itself regulated by a complex combination of intracellular regulators. Hormone release may be in a brief spurt caused by the sudden stimulation of granules, often induced by an intracellular Ca^{2+}-dependent process, or 'constitutive' (immediate and continuous secretion).

Plasma transport

Most classical hormones are secreted into the systemic circulation. In contrast, hypothalamic releasing hormones are released into the pituitary portal system so that higher concentrations of the releasing hormones reach the pituitary than occur in the systemic circulation.

Many hormones are bound to proteins within the circulation. In most cases only the free (unbound) hormone is available and thus biologically active. This binding serves to buffer against rapid changes in plasma levels of the hormone, and some binding protein interactions are also involved in the active regulation of hormone action. Many tests of endocrine function measure total rather than free hormone, which can give rise to difficulties in interpretation when binding proteins are altered in disease states or by drugs.

Binding proteins comprise both specific, high-affinity proteins of limited capacity, such as thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), sex-hormone-binding globulin (SHBG), and insulin-like growth factor (IGF)–binding proteins (e.g., IGF-BP3), and other less specific, low-affinity ones, such as prealbumin and albumin.

Hormone action and receptors

Hormones act by binding to specific receptors in the target cell. Most hormone receptors are proteins with complex tertiary structures. The structure of the hormone-binding domain of the receptor complements the tertiary structure of the hormone, while changes in other parts of the receptor in response to hormone binding are responsible for the effects of the activated receptor within the cell. The structure of common hormones and their receptors is described under individual hormone axes.

Hormone receptors are broadly divided into:

- ***cell surface or membrane receptors:*** transmembrane receptors that contain hydrophobic sections spanning the lipid-rich plasma membrane and trigger internal cellular messengers

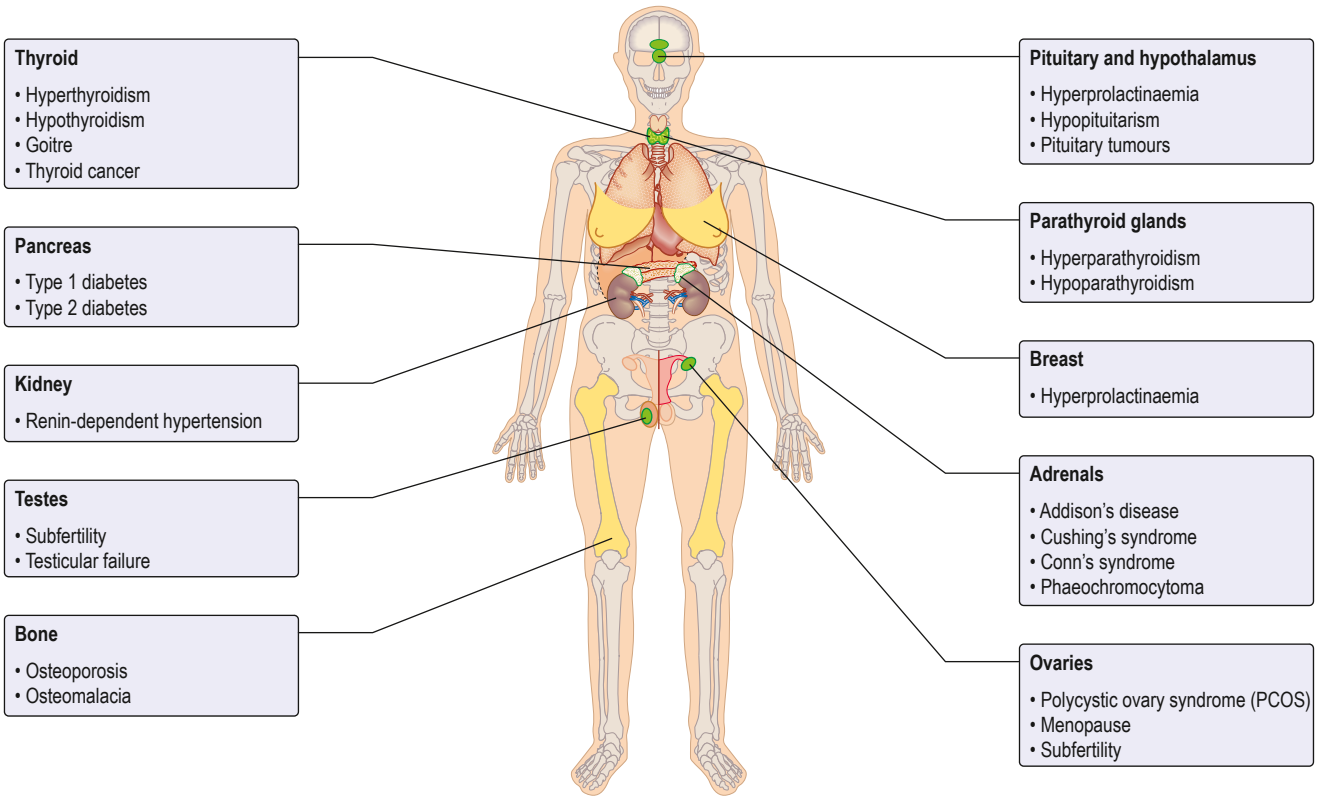

Fig. 34.1 The major endocrine organs and common endocrine problems.

- ***nuclear receptors:*** they bind hormones and translocate them to the nucleus, where they bind hormone response elements of nuclear DNA via characteristic amino acid sequences (e.g., so-called 'zinc fingers').

Abnormal receptors are an occasional cause of endocrine disease.

Mechanisms of hormone–receptor action

Common structural mechanisms of hormone–receptor action include:

- ***G-protein coupled receptors (7-transmembrane or serpentine receptors).*** These bind hormones on their extracellular domain and activate the membrane G-protein complex with their intracellular domain. The activated complex may then:
  - Stimulate cyclic AMP (cAMP) generation by adenylate cyclase—activating further intracellular kinases and leading to phosphorylation
  - Activate phospholipase C (PLC), leading to generation of inositol 1,4,5-triphosphate (IP_3) and release of intracellular calcium—in turn, leading to calmodulin-dependent kinase activity and phosphorylation
  - Lead to diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation
  - Most peptide hormones act via G-protein coupled receptors.
- ***Dimeric transmembrane receptors.*** These receptors, from several receptor superfamilies, bind hormone in their extracellular components (sometimes causing dimerization of the receptor monomer) and directly phosphorylate intracellular messengers via intracellular components, leading to a variety of intracellular activation cascades. Growth hormone (GH), prolactin, and IGF-1 act via this type of receptor.
- ***Lipid-soluble molecules.*** These pass through the cell membrane and bind with their ***nuclear receptors*** in the cell cytoplasm before translocation of the activated hormone–receptor complex to the nucleus; here, it binds to nuclear DNA, often in combination with a multi-component complex of promoters, inhibitors, and transcription factors. This interaction leads to increased transcription of the relevant gene product. Steroid and thyroid hormones act via this type of receptor.

Effects of hormone binding on target tissues

The activation of intracellular kinases, phosphorylation, release of intracellular calcium and other 'second messenger' pathways, and the direct stimulation of DNA transcription may result in the following:

- stimulation/release of pre-formed secondary hormones from storage granules
- stimulation/synthesis of secondary hormones and other cellular components
- opening/closing of ion or water channels in the cell membrane (e.g., calcium channels or aquaporin water channels)
- activation/deactivation of other DNA binding proteins, leading to stimulation or inhibition of DNA transcription.

In each case, binding of the hormone to its receptor is the first step in a cascade of intracellular events, which eventually lead to the overall effects of that hormone on cellular function.

The sensitivity and/or number of receptors for a hormone are often decreased after prolonged exposure to a high hormone concentration, the receptors thus becoming less sensitive ('downregulation', e.g., angiotensin II receptors, β-adrenoceptors). The reverse is true when stimulation is absent or minimal, the receptors showing increased numbers or sensitivity ('upregulation').

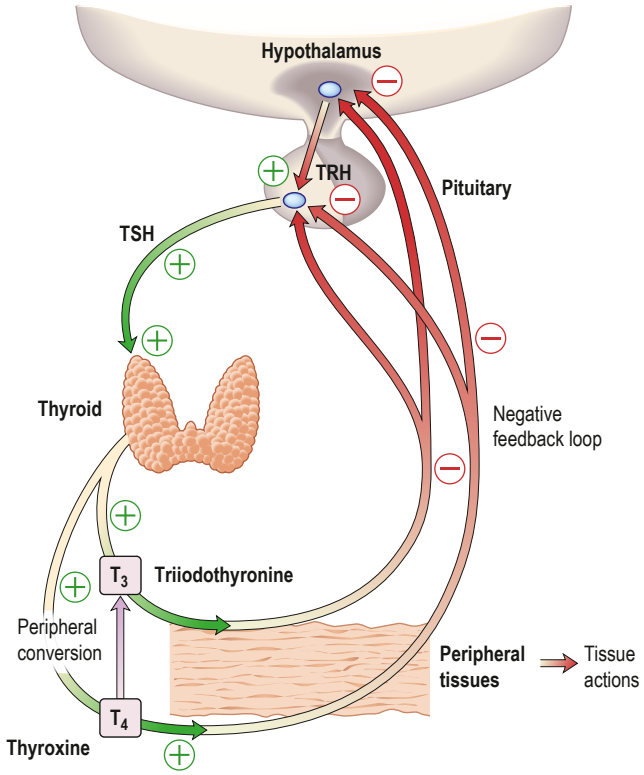

Fig. 34.2 The hypothalamic–pituitary–thyroid axis. Pituitary thyroid-stimulating hormone (TSH) is secreted in response to hypothalamic thyrotrophin-releasing hormone (TRH) and stimulates secretion of T_4 and T_3 from the thyroid. T_4 and T_3 have actions in peripheral tissues and exert negative feedback on the pituitary and hypothalamus.

Control and feedback

Most hormone systems are under tight regulatory control (typically by the hypothalamic–pituitary [HP] axis) by a system known as negative feedback. An example of the negative feedback system in the hypothalamic–pituitary–thyroid axis is demonstrated in Fig. 34.2 and described here:

- Thyrotrophin-releasing hormone (TRH) is secreted in the hypothalamus and travels via the portal system to the pituitary, where it stimulates the thyrotrophs to produce thyroid-stimulating hormone (TSH).
- TSH is secreted into the systemic circulation, where it stimulates increased iodine uptake by the thyroid, and synthesis and release of thyroxine (T_4) and triiodothyronine (T_3).
- Serum levels of T_3 and T_4 are increased by TSH; in addition, the conversion of T_4 to T_3 (the more active hormone) in peripheral tissues is stimulated by TSH.
- T_3 and T_4 enter cells, where they bind to nuclear receptors and promote increased metabolic and cellular activity.
- Levels of T_3, from the blood and from local conversion of T_4, are sensed by receptors in the pituitary and the hypothalamus. If they rise above normal, TRH and TSH production is suppressed, leading to reduced T_3 and T_4 secretion.
- Peripheral T_3 and T_4 levels fall to normal.
- If T_3 and T_4 levels are low—for example, after thyroidectomy, increased amounts of TRH and TSH are secreted, stimulating the

remaining thyroid to produce more T_3 and T_4; blood levels of T_3 and T_4 may be restored to normal, at the expense of increased TSH drive, reflected by a high TSH level: 'compensated euthyroidism'.

- Conversely, in thyrotoxicosis, when factors other than TSH itself are maintaining high T_3 and T_4 levels, the same mechanisms lead to suppression of TSH secretion.

Primary and secondary gland failure

It is useful in clinical endocrinology to distinguish between 'primary' disease of the end-organ gland (e.g., due to autoimmune destruction, atrophic change, infiltration or surgical removal of the gland) and 'secondary' disorders of the same axis, caused by disease of the pituitary gland. An understanding of the negative feedback system is key to interpreting endocrine blood results and diagnosing the site of the disease process in clinical practice. In general terms:

- ***'Primary' gland failure*** due to a disease process in the endocrine end-organ (thyroid, adrenal or gonad) will lead to deficiency of the hormone produced by that gland and a loss of negative feedback and subsequent elevation in the corresponding anterior pituitary hormone.
- In ***'secondary gland failure'***, there are low or 'inappropriately normal' levels of the pituitary trophic hormone in the face of a low end-organ hormone level. For example, if a patient has low circulating free T_3 (fT_3) and T_4 levels in the context of a low TSH, pituitary disease should be suspected.

Hormone excess

Abnormal hormone excess due to a disease process in the primary endocrine gland, or excess amount of exogenous hormone, will lead to increased negative feedback and suppression of the corresponding pituitary hormones. For example, in autoimmune hyperthyroidism, free T_3 and T_4 levels are elevated in the context of a suppressed TSH. Equally, the presence of a non-suppressed plasma pituitary hormone in the context of excess primary hormone implies that the pituitary, rather than the primary gland itself, is the cause. For example, in pituitary-driven Cushing's disease, cortisol levels are elevated but adrenocorticotrophin (ACTH) is not suppressed.

Hormone resistance

In certain situations, receptor abnormalities can give rise to abnormal negative feedback due to hormone resistance, which can lead to an unusual pattern of blood results. For example, thyroid hormone resistance, due to mutations in the thyroid hormone receptor, is characterized by an elevation in thyroid hormones with a non-suppressed TSH. With this pattern of thyroid results, the clinician should also consider the rare diagnosis of a TSH-secreting pituitary tumour, as well as the possibility of assay issues.

Measurement of hormones

Hormones are routinely measured by biochemical assays in the laboratory. It is possible to measure pituitary trophic hormones and the hormones produced by the end-organ glands, but hypothalamic hormones are not measured in practice because of their low concentration and local action within the HP axis. Circulating levels of most hormones are very low (10^{-9}–10^{-12} mol/L) and cannot be measured by simple chemical techniques. Hormones are therefore usually measured by immunoassays, which rely on highly specific polyclonal or monoclonal antibodies, which bind to the hormone being measured. This hormone–antibody interaction is measured by use of labelled hormone after separation of bound and free fractions (Fig. 34.3).

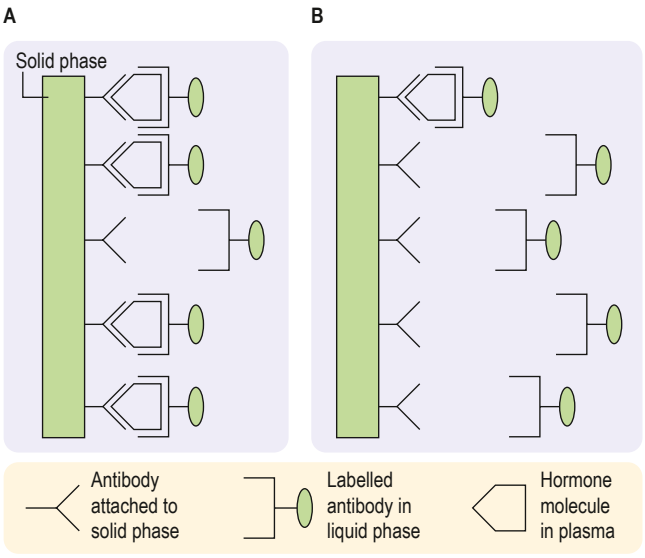

Fig. 34.3 Principles of measurement of hormone levels in plasma by immunoassay. (Precise details vary with different assays and manufacturers.) Immunoassays use two antibodies specific to the hormone being measured: one typically attached to a solid phase and one labelled antibody in the liquid phase. **(A)** High hormone levels in plasma: a large amount of hormone binds to antibody in solid phase; a large amount of labelled antibody is linked to solid phase via molecules of the hormone. **(B)** Low hormone levels in plasma: less hormone, and therefore less labelled antibody, is linked to the solid phase. Label (radioactive, chemiluminescent, enzymatic or fluorescent) can be measured in either solid or liquid phase after separation of phases; levels of label will be proportional to the amount of hormone in the sample.

Immunoassays are sensitive but have limitations. In particular, the immunological activity of a hormone, as used in developing the antibody, may not necessarily correspond to biological activity and there may be false-positive and negative results. The patient's blood may also contain heterophile antibodies, which interact with the animal antibodies used in the assay and produce falsely low or high values. When there is a discrepancy between endocrine blood results and the clinical presentation, the clinician must question the validity of an endocrine result and liaise with chemical pathology. It may be necessary for the sample to be measured in a different laboratory using an alternative antibody, or to measure hormones in ways other than immunoassay. Examples of alternative techniques include equilibrium dialysis, high-pressure liquid chromatography (HPLC), and mass spectroscopy.

Hormone-binding proteins

Many hormones are transported in the bloodstream by a specific binding protein (see 'Hormonal activity' section). It is more helpful to measure the free hormone rather than total bound hormone level, as this is the part that is biologically active. Some modern assays attempt to measure the free hormone level directly (e.g., free T_4) and are a more accurate reflection of biological activity, although many assays still measure total hormone level.

Cortisol, which is bound to CBG, and testosterone, which is bound to SHBG, are still usually measured in their total form and can be affected by alterations in binding protein levels. In women who are pregnant or on the combined oral contraceptive pill, high oestrogen levels may lead to an elevation in CBG, which can overestimate cortisol and give the false impression of hypercortisolaemia. In people with diabetes mellitus or other insulin-resistant states

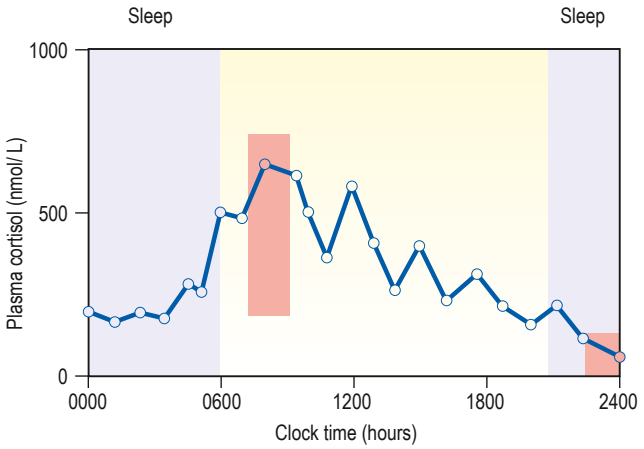

Fig. 34.4 Plasma cortisol levels during a 24-hour period. Note both the pulsatility and the shifting baseline. Normal ranges for 09:00 hours (180–700 nmol/L) and 24:00 hours (<100 nmol/L; must be taken when asleep) are shown in the *red* boxes. *Grey shading* shows sleep.

that may lower SHBG levels, low total testosterone levels may give the false impression of androgen deficiency. Conversely, hyperthyroidism or oestrogen excess can cause an elevation in SHBG, leading to apparently high total testosterone levels.

Patterns of hormonal secretion

Hormone secretion can be continuous or intermittent, for example:

- ***Continuous secretion*** is shown by the thyroid hormones, with a half-life of 7–10 days for T_4 and 6–10 h for T_3, and with little variation in levels over the day, month, and year.
- ***Pulsatile secretion*** is the normal pattern for the gonadotrophins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH), with major pulses released every 1–2 h, depending on the phase of the menstrual cycle. GH is also secreted in a pulsatile fashion, with undetectable levels in between pulses. A single measurement is therefore not helpful to diagnose GH deficiency or excess.

Biological rhythms

Circadian means changes over the 24 hours of the day–night cycle and is best shown for the pituitary–adrenal axis. Fig. 34.4 shows plasma cortisol measured over 24 hours; levels are highest in the early morning and lowest overnight. Additionally, cortisol release is pulsatile, following the pulsatility of pituitary ACTH. Thus 'normal' cortisol levels vary during the day and great variations can be seen in samples taken only 30 minutes apart.

The menstrual cycle is an example of a longer and more complex (28-day) biological rhythm (see 'Hypothalamo–pituitary–gonadal axis' section).

Other regulatory factors

- ***Stress.*** Physiological 'stress' and acute illness produce rapid increases in ACTH and cortisol, GH, prolactin, adrenaline (epinephrine), and noradrenaline (norepinephrine). These can occur within seconds or minutes.
- ***Sleep.*** Secretion of GH and prolactin is increased during sleep, especially the rapid eye movement (REM) phase.
- ***Feeding and fasting.*** Many hormones regulate the body's control of energy intake and expenditure and are therefore influenced by feeding and fasting. Secretion of insulin increases, while testosterone and GH decrease after ingestion of food, and secretion of a number of hormones is altered during prolonged food deprivation.

Box 34.4 Types of autoimmune disease affecting endocrine organs

Organ and frequency, if known[a]	Antibody	Antigen, if known	Clinical syndrome
Stimulating			
Thyroid (1 in 100)	Thyroid-stimulating immunoglobulin (TSI, TSAb)	Thyroid-stimulating hormone (TSH) receptor	Graves' disease, neonatal thyrotoxicosis
Destructive			
Thyroid (1 in 100)	Thyroid microsomal	Thyroid peroxidase enzyme (TPO)	Primary hypothyroidism (myxoedema)
	Thyroglobulin	Thyroglobulin	
	Immunoglobulin (Ig) G4		Riedel's thyroiditis
Adrenal (1 in 20 000)	Adrenal cortex	21-Hydroxylase enzyme	Primary hypoadrenalism (Addison's disease)
Pancreas (1 in 500)	Islet cell	Glutamic acid decarboxylase (GAD; see Fig. 35.8)	Type 1 diabetes
Stomach	Gastric parietal cell	Gastric parietal cell	Pernicious anaemia
	Intrinsic factor	Intrinsic factor	
Skin	Melanocyte		Vitiligo
Ovary (1 in 500)	Ovary		Primary ovarian failure
Testis	Testis		Primary testicular failure
Parathyroid	Parathyroid chief cell		Primary hypoparathyroidism
Pituitary	Pituitary-specific cells		Autoimmune hypophysitis
			Selective hypopituitarism (e.g., growth hormone [GH] deficiency, diabetes insipidus)

[a]Frequencies are approximate and refer to the population in Northern Europe.
Note: Other related diseases include myasthenia gravis and autoimmune liver diseases.

Aetiology and pathology

Aetiological mechanisms common to many endocrine disorders are described as follows.

Autoimmune disease

Organ-specific autoimmune diseases can affect every major endocrine organ (Box 34.4). They are characterized by the presence of specific antibodies in the serum, often present years before clinical symptoms are evident, usually more common in women, and have a strong genetic component, often with an identical-twin concordance rate of 50% and with human leucocyte antigen (HLA) associations (see individual diseases).

Endocrine tumours

Most endocrine tumours are benign, although a cytological or histological diagnosis may be needed if there is suspicion of malignancy. Clinical presentation depends on whether the tumour is functional or non-functional, the latter presenting only as a mass clinically or on imaging. Palpable thyroid nodules are common, and mass effects are a frequent presentation of pituitary adenomas, but the increased use of high-resolution ultrasound and detailed cross-sectional imaging has revealed a very high prevalence of asymptomatic, incidentally discovered thyroid, adrenal and pituitary lesions, commonly termed 'incidentalomas'.

Functional tumours cause their effects via excess secretion of the relevant hormone. While often considered to be 'autonomous'—that is, independent of the physiological control mechanisms—many functional tumours do show evidence of feedback occurring at a higher 'set-point' than normal (e.g., adrenocorticotrophic hormone [ACTH] secretion from a corticotroph adenoma). This is relevant in the dynamic assessment of endocrine diseases, such as in the differential diagnosis of Cushing's syndrome.

Endocrine adenomas typically present in a single gland, although rarer multiple endocrine neoplasia (MEN) syndromes exist that are due to very specific mutations of a single gene, such as the mutations of the *RET* proto-oncogene in MEN 2 or the *MEN1* gene mutation in MEN 1 (see 'Diseases of many glands' section). The diagnosis of some endocrine tumours, particularly at a young age, or the identification of a family history should prompt genetic screening.

Enzyme defects

The biosynthesis of most hormones involves many stages. Deficient or abnormal enzymes can lead to absent or reduced production of the secreted hormone. In general, severe deficiencies present early in life with obvious signs; partial deficiencies usually present later with mild signs or are only evident under stress. An example of an enzyme deficiency is congenital adrenal hyperplasia (CAH), whose molecular basis has also been identified as mutations or deletions of the gene encoding the relevant enzymes (see 'Hypothalamo–pituitary–adrenal axis' section).

Receptor abnormalities

There are rare conditions in which hormone secretion and control are normal but the receptors are defective; thus, if androgen receptors are defective, normal levels of androgen will not produce masculinization (e.g., androgen insensitivity syndrome). There are also a number of rare syndromes of diabetes and insulin resistance from receptor abnormalities (see **Box 23.4**); other examples include AVP-resistance (also referred to as 'nephrogenic diabetes insipidus'), pseudohypoparathyroidism, and thyroid hormone resistance.

Endocrine investigations

Endocrine function is assessed by measurement of hormone levels in blood (or, more precisely, in plasma or serum) and sometimes in other body fluids on samples obtained basally and in response to stimulation and suppression tests.

Basal blood levels

Assays for all clinically relevant pituitary and end-organ hormones are available.

The time, day, and conditions of measurement make great differences to hormone levels, and the method and timing of samples therefore depend upon the characteristics of the endocrine system involved. There are also gender, pubertal, and age differences.

Basal levels are especially useful for systems with long half-lives (e.g., T_4 and T_3, IGF-1, androstenedione, SHBG). These vary little over the short term and random samples are therefore satisfactory.

Basal samples for many hormones need to be interpreted with respect to normal ranges for the time of day/month, diet, or posture concerned. Hormones with a marked circadian rhythm (e.g., testosterone and cortisol) must be measured at an appropriate time of day. Testosterone should be measured before 11 a.m. in the fasting state; cortisol should be checked between 8 a.m. and 10 a.m. to exclude hypoadrenalism, but at midnight to demonstrate normal low levels (to exclude Cushing's). LH/FSH, oestrogen, and progesterone vary with time of menstrual cycle, and renin/aldosterone may vary with sodium intake, posture, and age. For these hormones, all relevant details must be recorded or the results may prove uninterpretable.

Stress-related hormones

Measurement of stress-related hormones may be problematic either because the patient is stressed by hospital attendance or venepuncture, leading to falsely high levels (e.g., catecholamines, prolactin; sampling via an indwelling needle may be required, some time after initial venepuncture), or because low levels in a non-stressed individual are unable to confirm an adequate reserve required for normal physiological stress (cortisol and GH).

Urine collections

Collections over 24 hours have the advantage of providing an 'integrated mean' of a day's secretion but, in practice, are often incomplete or wrongly timed. They also vary with sex and body size or age. Written instructions should be provided for the patient to ensure accurate collection. Examples of hormones measured in this way are catecholamines and urinary free cortisol levels.

Saliva

Saliva is sometimes used for steroid estimations, especially in children or for samples taken at home. Midnight salivary cortisol levels are increasingly used for the diagnosis of Cushing's syndrome due to the practical difficulties in obtaining a midnight blood sample.

Stimulation and suppression tests

These tests are used when basal levels give equivocal information. In general, stimulation tests are used to confirm suspected deficiency of hormone secretion, and suppression tests to confirm suspected excess (see **Box 34.3**). These tests are valuable in many instances. For example, where the secretory capacity of a gland is damaged, maximal stimulation by the trophic hormone will give a diminished output. Thus, in the short ACTH stimulation test for adrenal reserve (**Box 34.5**; **Fig. 34.5A**), the healthy subject shows a normal response, while the subject with primary hypoadrenalism (Addison's disease) demonstrates an impaired cortisol response to tetracosactide (an ACTH analogue).

A patient with a hormone-producing tumour usually fails to show normal negative feedback. A patient with Cushing's disease (excess pituitary ACTH) will thus fail to suppress ACTH and cortisol production when given a dose of synthetic steroid, in contrast to normal subjects. **Fig. 34.5B** shows the response of a normal subject given dexamethasone 1 mg at midnight; cortisol is suppressed the following morning. The subject with Cushing's disease shows inadequate suppression.

The detailed protocol for each test must be followed exactly, since differences in technique will produce variations in results.

Box 34.5 Short ACTH (tetracosactide) stimulation test

Indications
- Diagnosis of Addison's disease
- Screening test for ACTH deficiency

Procedure
- I.V. cannula for sampling
- Any time of day, but best at 09:00 h; non-fasting
- Tetracosactide 250 μg, i.v. or i.m. at time 0
- Measure serum cortisol at time 0 and time +30 min

Normal response
- 30 min cortisol >600 nmol/L[a]
  - (400–600 nmol/L borderline and may indicate deficiency)

[a]Precise cortisol normal ranges are variable between laboratories and assays; appropriate local reference ranges must be used.

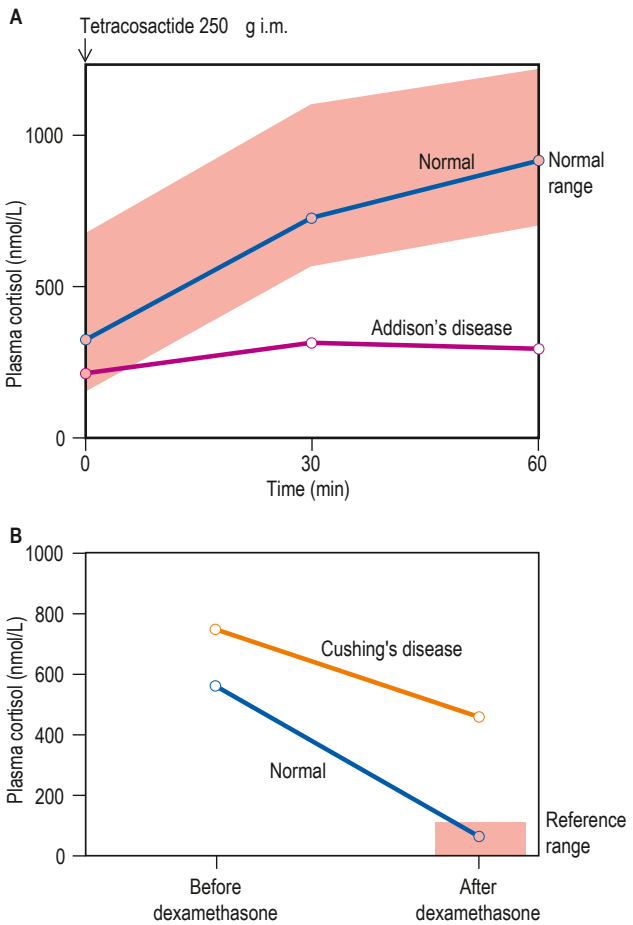

Fig. 34.5 Short ACTH stimulation and dexamethasone suppression tests. **(A)** The short ACTH stimulation test shows a normal response in a healthy subject and a decreased response in a patient with Addison's disease. **(B)** Dexamethasone suppression tests in a normal subject and in a patient with Cushing's disease, showing inadequate suppression.

Radiological investigations

Magnetic resonance imaging (MRI), computed tomography (CT) and ultrasound give detailed images of endocrine glands but should be interpreted in clinical and biochemical context. Incidental endocrine tumours are common ('incidentalomas') and may have no clinical significance. Conversely, functional endocrine tumours may be too small to visualize on routine imaging. There is an increasing role for functional imaging, for example, positron emission tomography (PET), to detect endocrine tumours. Selective venous sampling is a useful interventional technique to localize hormone excess and is discussed in the relevant section.

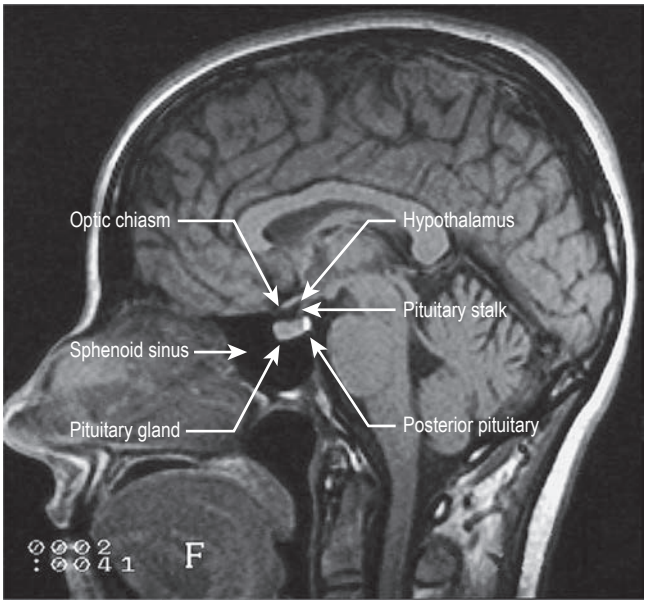

Fig. 34.6 Magnetic resonance imaging (MRI) of a sagittal section of the brain, showing the pituitary fossa and adjacent structures. *(By kind permission of Dr Martin Jeffree.)*

THE PITUITARY GLAND AND HYPOTHALAMUS

Anatomy

Most peripheral hormone systems are controlled by the hypothalamus and pituitary. The hypothalamus is sited at the base of the brain around the third ventricle and above the pituitary stalk, which leads down to the pituitary itself, carrying the hypophyseal–pituitary portal blood supply.

The anatomical relations of the hypothalamus and pituitary (Fig. 34.6) include the optic chiasm above the pituitary fossa; any expanding lesion from the pituitary or hypothalamus can thus produce visual field defects by pressure on the chiasm. Such upward expansion of the gland through the diaphragma sellae is termed 'suprasellar extension'. Lateral extension of pituitary lesions may involve the vascular and nervous structures in the cavernous sinus and may rarely reach the temporal lobe of the brain. The pituitary is itself encased in a bony box; therefore any lateral, anterior, or posterior expansion must cause bony erosion.

Embryologically, the anterior pituitary is formed from an upgrowth of Rathke's pouch (ectoderm); this meets an outpouching of the third ventricular floor, which becomes the posterior pituitary. This combination of primitive gut and neural tissue provides an essential link between the rapidly responsive central nervous system and the longer-acting endocrine system. Several transcription factors—LHX3, HESX1, PROP1, POU1F1—are responsible for the differentiation and development of the pituitary cells. Mutation of these produces pituitary disease.

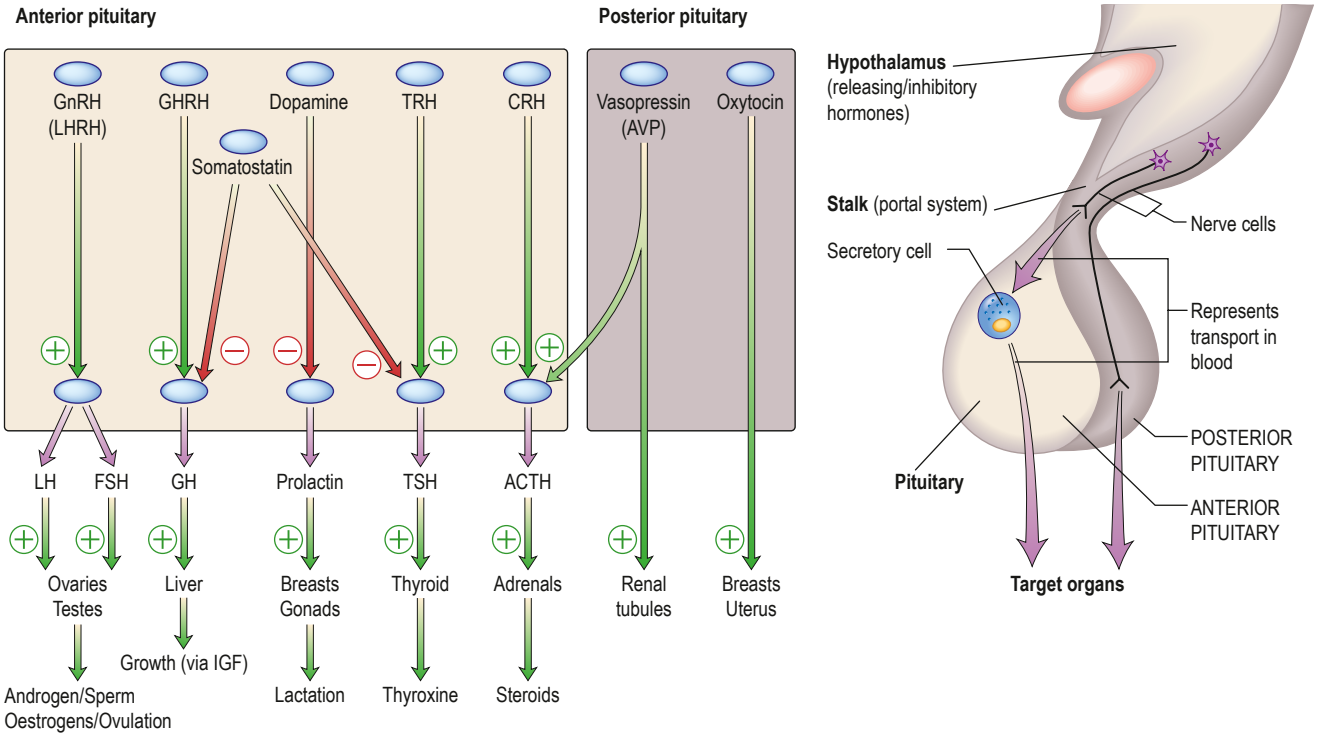

Fig. 34.7 Hypothalamic releasing hormones and the pituitary trophic hormones. *AVP,* Arginine vasopressin; *CRH,* corticotrophin-releasing hormone; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GHRH,* growth hormone-releasing hormone; *GnRH,* gonadotrophin-releasing hormone; *IGF,* insulin-like growth factor; *LH,* luteinizing hormone; *TRH,* thyrotrophin-releasing hormone.

Physiology

Hypothalamus

This contains many vital centres for such functions as appetite, thirst, thermal regulation, and sleeping/waking. It acts as an integrator of many neural and endocrine inputs to control the release of pituitary hormone-releasing factors. It plays a role in circadian rhythm, menstrual cyclicity, and responses to stress, exercise, and mood.

Hypothalamic neurones secrete pituitary hormone releasing and inhibiting factors and hormones into the portal system; these run down the stalk to the pituitary. As well as the classical hormones (Fig. 34.7), the hypothalamus also contains large amounts of other neuropeptides and neurotransmitters such as neuropeptide Y, vasoactive intestinal peptide (VIP), and nitric oxide, which can also alter pituitary hormone secretion.

Synthetic hypothalamic hormones and their antagonists are available for the testing of many aspects of endocrine function and for treatment.

Anterior pituitary

The majority of anterior pituitary hormones are under predominantly positive control by the hypothalamic releasing hormones; the exception is prolactin, which is under tonic inhibition by dopamine. Pathological conditions interrupt the flow of hormones between the hypothalamus and pituitary gland and therefore cause deficiency of most hormones but oversecretion of prolactin. There are five major anterior pituitary axes: the gonadotrophin axis, the growth axis, prolactin, the thyroid axis, and the adrenal axis.

Posterior pituitary

The posterior pituitary is neuroanatomically connected to specific hypothalamic nuclei and acts merely as a storage organ. Arginine vasopressin (AVP, also called vasopressin) and oxytocin, both nonapeptides, are synthesized in the supraoptic and paraventricular nuclei in the anterior hypothalamus. They are then transported along the axon and stored in the posterior pituitary (see Fig. 34.7). This means that damage to the stalk or pituitary alone does not prevent synthesis and release of AVP and oxytocin. AVP is discussed in 'The thirst axis' section; oxytocin produces milk ejection and uterine myometrial contraction.

Presentation of pituitary and hypothalamic disease

Diseases of the pituitary can cause under- or overactivity of each hypothalamic–pituitary–end-organ axis. The clinical features of the syndromes associated with such altered pituitary function, such as Cushing's syndrome, can be the presenting symptom of pituitary disease or of end-organ disease and are discussed later. First, however, we look at the clinical features of pituitary disease that are common to all hormonal axes.

Pituitary space-occupying lesions and tumours

Pituitary tumours (Box 34.6) are the most common cause of pituitary disease, and the great majority are benign pituitary adenomas, usually monoclonal in origin. Problems are caused by:

- local effects of a tumour
- excess hormone secretion
- inadequate production of hormone by the remaining normal pituitary, i.e., hypopituitarism.

Approach for a possible or proven mass

Is there a tumour?

If there is, how big is it and what ***local anatomical effects*** is it exerting? Pituitary and hypothalamic space-occupying lesions, hormonally active or not, can cause symptoms by pressure on, or infiltration of:

- the visual pathways, with field defects and visual loss (most common)
- the cavernous sinus, with III, IV, and VI cranial nerve lesions
- bony structures and the meninges surrounding the fossa, causing headache
- hypothalamic centres: altered appetite, obesity, thirst, somnolence/wakefulness, or precocious puberty
- the ventricles, causing interruption of cerebrospinal fluid (CSF) flow and hydrocephalus
- the sphenoid sinus, causing CSF rhinorrhoea.

Box 34.6 Characteristics of common pituitary and related tumours

Tumour or condition	Usual size	Most common clinical presentation
Prolactinoma	Most <10 mm (microprolactinoma)	Galactorrhoea, amenorrhoea, hypogonadism, erectile dysfunction
	Some >10 mm (macroprolactinoma)	As above plus headaches, visual field defects, and hypopituitarism
Acromegaly	Few mm to several cm	Change in appearance, visual field defects, and hypopituitarism
Cushing's disease	Most small: few mm (some cases are hyperplasia)	Central obesity, cushingoid appearance (local symptoms rare)
Nelson's syndrome	Often large: >10 mm	Post-adrenalectomy, pigmentation, sometimes local symptoms
Non-functioning tumours	Usually large: >10 mm	Visual field defects; hypopituitarism (microadenomas may be incidental finding)
Craniopharyngioma	Often very large and cystic (skull X-ray abnormal in >50%; calcification common)	Headaches, visual field defects, growth failure (50% occur below age 20; about 15% arise from within sella)

Investigations

- ***MRI of the pituitary.*** MRI is superior to CT (Fig. 34.8) and readily shows any significant pituitary mass. Small lesions within the pituitary fossa, 'microadenomas', are very common on MRI (10% of normal individuals in some studies). Such small lesions are sometimes detected during MRI of the head for other reasons—so-called 'pituitary incidentalomas'.
- ***Visual fields.*** These should be plotted formally by automated computer perimetry or Goldmann perimetry, but clinical assessment by confrontation using a small red pin as the target is also sensitive and valuable. Common defects are upper temporal quadrantanopia and bitemporal hemianopia (see Fig. 28.6).

Is there a hormonal excess?

There are three major conditions that are usually caused by excess secretion from pituitary adenomas and which will show positive immunostaining for the relevant hormone:

- prolactin excess ***(prolactinoma or hyperprolactinaemia):*** histologically, prolactinomas are 'chromophobe' adenomas (a description of their appearance on classical histological staining)
- GH excess ***(acromegaly or gigantism):*** somatotroph adenomas, usually 'acidophil', and sometimes due to specific G-protein mutations (see 'Presentation of pituitary and hypothalamic disease' section)
- excess ACTH secretion ***(Cushing's disease and Nelson's syndrome):*** corticotroph adenomas, usually 'basophil'.

Many tumours are able to synthesize several pituitary hormones, and occasionally more than one hormone is secreted in clinically significant excess (e.g., both GH and prolactin).

The clinical features of acromegaly, Cushing's disease, or hyperprolactinaemia are usually (but not always) obvious (see 'Presentation of pituitary and hypothalamic disease' section). Tumours producing LH, FSH, or TSH are well described but very rare.

Some common pituitary tumours cause no clinically apparent hormone excess and are referred to as 'non-functioning' tumours.

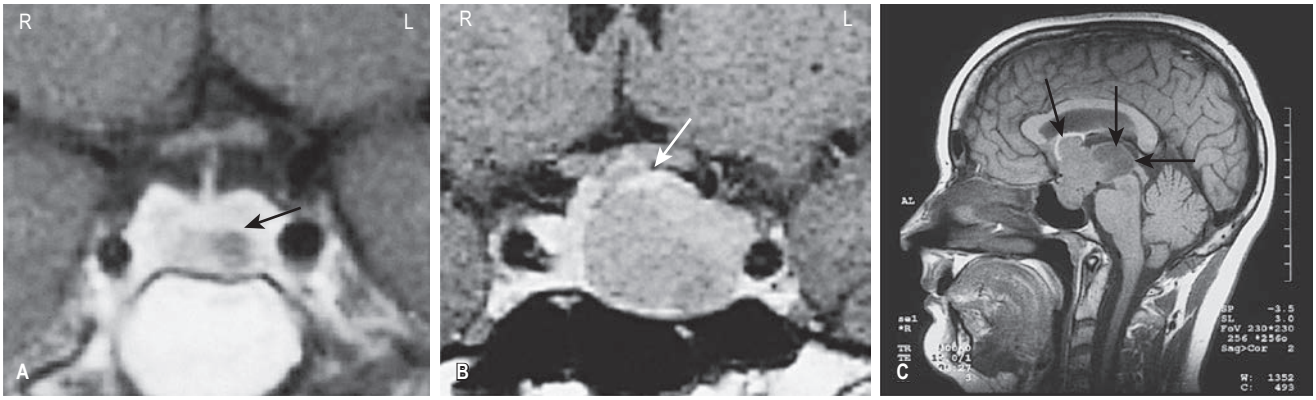

Fig. 34.8 Investigation of the pituitary gland. **(A)** Left-sided lucent intrasellar microadenoma *(arrowed)* (coronal MRI). The pituitary stalk is deviated slightly to the right. **(B)** Macroadenoma with moderate suprasellar extension and lateral extension compressing the left cavernous sinus (coronal MRI). The top of the adenoma is compressing the optic chiasm *(arrowed)*. **(C)** Pituitary macroadenoma with massive suprasellar extension *(arrowed)* (sagittal MRI).

Box 34.7 Tests of hypothalamic–pituitary (HP) function

All hormone levels are measured in plasma unless otherwise stated.
Tests **shown in bold** are those normally measured on a single basal 09:00 h sample in the initial assessment of pituitary function.

Axis	Basal investigations		Common dynamic tests	Other tests
	Pituitary hormone	End-organ product/function		
Anterior pituitary				
HP–ovarian	**LH** **FSH**	**Oestradiol** Progesterone (day 21 of cycle)		Ovarian ultrasound LHRH test[a]
HP–testicular	**LH** **FSH**	**Testosterone**		Sperm count LHRH test[a]
Growth hormone	GH	**IGF-1** IGF-BP3	Insulin tolerance test Glucagon test Macimorelin test	Other tests available but lack sufficient evidence base
Prolactin	**Prolactin**		–	–
HP–thyroid	**TSH**	**Free T_4, T_3**		TRH test[a]
HP–adrenal	ACTH	**Cortisol**	Insulin tolerance test Short ACTH (tetracosactide) stimulation test	Glucagon test CRH test[a] Metyrapone test
Posterior pituitary				
Thirst and osmoregulation		Plasma/urine osmolality	Water deprivation test	Hypertonic saline infusion

[a]Releasing hormone tests were a traditional part of pituitary function testing but have been largely replaced by the advent of more reliable assays for basal hormones. They test only the 'readily releasable pool' of pituitary hormones, and normal responses may be seen in hypopituitarism. Bold text indicates commonly performed investigations.
ACTH, Adrenocorticotropic hormone; *CRH,* corticotrophin-releasing hormone; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GHRH,* growth hormone-releasing hormone; *IGF,* insulin-like growth factor; *LH,* luteinizing hormone; *LHRH,* luteinizing hormone-releasing hormone; *TRH,* thyroid-releasing hormone; *TSH,* thyroid-stimulating hormone.

Laboratory studies such as immunocytochemistry or *in situ* hybridization show that these tumours may often produce small amounts of LH and FSH or the α-subunit of LH, FSH, and TSH, and occasionally ACTH.

Is there a deficiency of any hormone?

Clinical examination may give clues; thus, short stature in a child with a hypothalamic or pituitary mass is likely to be due to GH deficiency. An adult complaining of lethargy with pale skin is likely to be deficient in TSH and/or ACTH. Milder deficiencies may not be obvious and require specific testing (**Box 34.7**).

Management

Management depends on the type and size of tumour (**Box 34.8**). Decisions about pituitary tumour management are made in an MDT setting, which typically comprises an endocrinologist, pituitary surgeon, and radiologist. In general, therapy has three aims: removal/control of the tumour, reduction of excess hormone secretion, and replacement of hormone deficiencies.

Removal/control of tumour

This is only required if the tumour is large enough to cause, or is likely to cause, anatomical effects, or if it is secreting excess hormones. Small tumours producing no significant symptoms, pressure, or endocrine effects may be observed with appropriate clinical, visual field, imaging, and endocrine assessments.

- ***Surgery*** via the trans-sphenoidal route is usually the treatment of choice. Very large tumours are occasionally removed via the open transcranial (usually transfrontal) route.
- ***Radiotherapy***—by conventional linear accelerator or newer stereotactic techniques—is usually employed when surgery is impracticable or incomplete, as it controls but rarely abolishes tumour mass. The conventional regimen involves a dose of 45 Gy, given as 20–25 fractions via three fields. Stereotactic techniques use either a linear accelerator or multiple cobalt sources ('gamma-knife'; see Chapter 41).

Box 34.8 Comparisons of primary treatments for pituitary tumours

Treatment method	Advantages	Disadvantages
Surgical		
Trans-sphenoidal adenomectomy or hypophysectomy	Relatively minor procedure Potentially curative for microadenomas and smaller macroadenomas	Some extrasellar extensions may not be accessible Risk of CSF leakage and meningitis
Transcranial (usually transfrontal) route	Good access to suprasellar region	Major procedure; danger of frontal lobe damage High chance of subsequent hypopituitarism
Radiotherapy		
External (40–50 Gy)	Non-invasive Reduces recurrence rate after surgery	Slow action, often over many years Not always effective Possible late risk of tumour induction
Stereotactic	Precise administration of high dose to lesion	Long-term follow-up data limited
Medical		
Dopamine agonist therapy (e.g., bromocriptine, cabergoline)	Non-invasive; reversible	Usually not curative; significant side-effects in minority Concerns about fibrotic reactions
Somatostatin analogue therapy (octreotide, lanreotide)	Non-invasive; reversible	Usually not curative; causes gallstones; expensive
Growth hormone receptor antagonist (pegvisomant)	Highly selective	Usually not curative; very expensive

Box 34.9 Replacement therapy for hypopituitarism

Axis	Usual replacement therapies
Adrenal	Hydrocortisone 15–25 mg daily (starting dose 10 mg on rising/5 mg lunch-time/5 mg evening) (Normally no need for mineralocorticoid replacement)
Thyroid	Levothyroxine 100–150 μg daily
Gonadal	
Male	Testosterone intramuscularly, orally, transdermally, or implant
Female	Cyclical oestrogen/progestogen orally or as patch
Fertility	HCG plus FSH (purified or recombinant) or pulsatile GnRH to produce testicular development, spermatogenesis or ovulation
Growth	Recombinant human GH used routinely to achieve normal growth in children
	Also advocated for replacement therapy in adults, where GH has effects on muscle mass and wellbeing
Thirst	Desmopressin 10–20 μg one to three times daily by nasal spray or orally 100–200 μg three times daily Carbamazepine, thiazides, and chlorpropamide are very occasionally used in mild diabetes insipidus
Breast (prolactin inhibition)	Dopamine agonist (e.g., cabergoline 500 μg weekly)

FSH, Follicle-stimulating hormone; *GH*, growth hormone; *HCG*, human chorionic gonadotrophin.

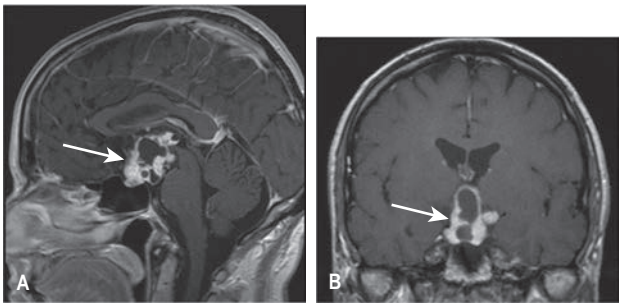

Fig. 34.9 Craniopharyngioma *(arrowed)*: a partially cystic pituitary and suprasellar mass. **(A)** Sagittal MRI. **(B)** Coronal MRI.

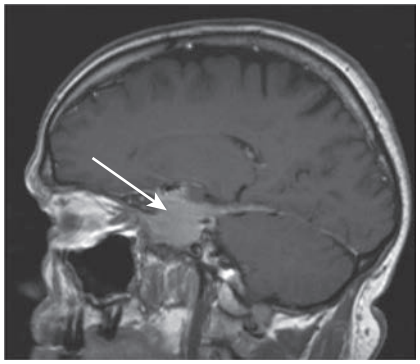

Fig. 34.10 Meningioma *(arrowed)* involving the pituitary fossa. Note the typical 'dural tail'.

- ***Medical therapy*** with somatostatin analogues and/or dopamine agonists sometimes causes shrinkage of specific tumour types and, if successful, can be used as primary therapy, particularly in the case of prolactinomas.

Reduction of excess hormone secretion

Reduction is usually obtained by surgical removal but sometimes by medical treatment. Useful control can be achieved with dopamine agonists for prolactinomas or somatostatin analogues for acromegaly, but ACTH secretion usually cannot be controlled by medical means. GH antagonists are also available for acromegaly (see 'Presentation of pituitary and hypothalamic disease' section).

Replacement of hormone deficiencies

See **Box 34.9**. Replacement of hormone deficiencies, i.e., hypopituitarism, is discussed further in the 'Presentation of pituitary and hypothalamic disease' section.

Differential diagnosis of pituitary or hypothalamic masses

Although pituitary adenomas are the most common mass lesion of the pituitary (90%), a variety of other conditions may also present as a pituitary or hypothalamic mass and form part of the differential diagnosis.

Other tumours

- ***Craniopharyngioma*** (1%–2%), a usually cystic hypothalamic tumour that is often calcified and arises from Rathke's pouch. It is the most common pituitary tumour in children but may present at any age (**Fig. 34.9**).
- ***Uncommon tumours*** include meningiomas (**Fig. 34.10**), gliomas, chondromas, germinomas, and pinealomas. Primary pituitary carcinomas are very rare, but occasionally prolactin- and ACTH-secreting tumours present in an aggressive manner, which may require chemotherapy in addition to conventional treatment. Metastases occasionally present as apparent pituitary tumours, typically accompanied by headache and DI.

Hypophysitis and other inflammatory masses

A variety of inflammatory masses occur in the pituitary or hypothalamus. These include rare pituitary-specific conditions (e.g., autoimmune [lymphocytic] hypophysitis, giant cell hypophysitis, postpartum hypophysitis), or pituitary manifestations of more generalized disease processes (sarcoidosis, Langerhans' cell histiocytosis, granulomatosis with polyangiitis). These lesions may be associated with DI and/or an unusual pattern of hypopituitarism.

Other lesions

Carotid artery aneurysms may masquerade as pituitary tumours and must be diagnosed before surgery. Cystic lesions may also present as a pituitary mass, including arachnoid and Rathke cleft cysts.

Hypopituitarism

Pathophysiology

Deficiency of hypothalamic releasing hormones or of pituitary trophic hormones can be selective or multiple. Thus isolated deficiencies of GH, LH/FSH, ACTH, TSH, and vasopressin (AVP) are all seen, some cases of which are genetic and congenital, and others sporadic and autoimmune or idiopathic in nature.

Multiple deficiencies usually result from tumour growth or other destructive lesions. There is generally a progressive loss of anterior pituitary function. GH and gonadotrophins are usually first affected. Hyperprolactinaemia, rather than prolactin deficiency, occurs relatively early because of loss of tonic inhibitory control by dopamine. TSH and ACTH are usually last to be affected.

Box 34.10 Causes of hypopituitarism

Congenital
- Isolated deficiency of pituitary hormones (e.g., Kallmann's syndrome)
- *POU1F1 (Pit-1)*, *Prop1*, *HESX1* mutations

Infective
- Basal meningitis (e.g., tuberculosis)
- Encephalitis
- Syphilis

Vascular
- Pituitary apoplexy
- Sheehan's syndrome (postpartum necrosis)
- Carotid artery aneurysm

Immunological
- Autoimmune (lymphocytic) hypophysitis
- Pituitary antibodies

Neoplastic
- Pituitary or hypothalamic tumour
- Craniopharyngioma
- Meningioma
- Gliomas
- Pinealoma
- Secondary deposits, especially breast
- Lymphoma

Traumatic
- Skull fracture through base
- Surgery, especially transfrontal
- Perinatal trauma

Infiltrations
- Sarcoidosis
- Langerhans' cell histiocytosis
- Hereditary haemochromatosis
- Hypophysitis:
  - Postpartum
  - Giant cell

Others
- Radiation damage
- Fibrosis
- Chemotherapy
- Immunotherapy (ipilimumab, pembrolizumab, nivolumab)
- Empty sella syndrome

'Functional'
- Anorexia nervosa
- Starvation
- Emotional deprivation

Panhypopituitarism refers to deficiency of all anterior pituitary hormones; it is most commonly caused by pituitary tumours, surgery, or radiotherapy. Vasopressin (AVP) will only be significantly affected if the hypothalamus is involved by a hypothalamic tumour or major suprasellar extension of a pituitary lesion, or if there is an infiltrative/inflammatory process. Posterior pituitary deficiency with DI is rare in an uncomplicated pituitary adenoma.

Genetics

Specific genes are responsible for the development of the anterior pituitary, involving interaction between signalling molecules and transcription factors. For example, mutations in *PROP1* and *POU1F1* (previously *PIT-1*) prevent the differentiation of anterior pituitary cells (precursors to somatotroph, lactotroph, thyrotroph and gonadotroph cells), leading to deficiencies of GH, prolactin, TSH, and gonadotrophin-releasing hormone (GnRH). In addition, novel mutations within GH and growth hormone-releasing hormone (GHRH) receptor genes have been identified, which explain the pathogenesis of isolated GH deficiency in some children. Despite these advances, most cases of hypopituitarism do not have specific identifiable genetic causes.

Aetiology

Disorders that cause hypopituitarism are listed in **Box 34.10**. Pituitary and hypothalamic tumours, and surgical or radiotherapy treatment, are the most common.

Clinical features

Symptoms and signs depend upon the extent of hypothalamic and/or pituitary deficiencies, and mild deficiencies may not lead to any complaint. In general, symptoms of deficiency of a pituitary-stimulating hormone are the same as those of primary deficiency of the peripheral endocrine gland (e.g., TSH deficiency and primary hypothyroidism cause similar symptoms due to lack of thyroid hormone secretion).

- ***Secondary hypothyroidism, hypoadrenalism, hypogonadism***, and ***GH deficiency*** lead to tiredness and general malaise and reduced quality of life.
- ***Hypothyroidism*** causes weight gain, slowness of thought and action, dry skin, cold intolerance, constipation, and potentially bradycardia and hypothermia.
- ***Hypoadrenalism*** causes mild hypotension, hyponatraemia, and, ultimately, cardiovascular collapse during severe intercurrent stressful illness.
- ***Hypogonadism*** leads to loss of libido, loss of secondary sexual hair, amenorrhoea and erectile dysfunction, and, eventually, osteoporosis.
- ***Hyperprolactinaemia*** may cause galactorrhoea and hypogonadism, including amenorrhoea.
- ***GH deficiency*** causes growth failure in children and impaired wellbeing in some adults.
- ***Weight gain*** (due to hypothyroidism; see above), or ***weight loss*** in severe combined deficiency.
- Longstanding ***panhypopituitarism*** gives the classic picture of pallor with hairlessness ('alabaster skin').

Particular syndromes related to hypopituitarism are described below.

Kallmann's syndrome

This is isolated gonadotrophin (GnRH) deficiency (see 'Hypothalamo–pituitary–gonadal axis' section) caused by mutations in the *KAL1* gene, which is located on the short (p) arm of the X chromosome. Kallmann's classically causes anosmia because the *KAL1* gene provides instructions to make anosmin, which has a role both in development of the olfactory system and in migration of GnRH-secreting neurones.

Septo-optic dysplasia

This rare congenital syndrome (rarely associated with mutations in the *HESX1* gene) presents in childhood with two out of the clinical triad of midline forebrain abnormalities, optic nerve hypoplasia, and hypopituitarism.

Sheehan's syndrome

This is due to pituitary infarction following postpartum haemorrhage and is rare in high-income countries but not uncommon in countries where there are not established obstetric services.

Pituitary apoplexy

A pituitary tumour occasionally enlarges rapidly owing to infarction or haemorrhage. This may produce severe headache, double vision, and sudden severe visual loss, sometimes followed by acute life-threatening hypopituitarism. Often, pituitary apoplexy can be managed conservatively with replacement of hormones and close monitoring of vision, although if there is a rapid deterioration in visual acuity and fields, surgical decompression of the optic chiasm may be necessary (**Fig. 34.11**).

'Empty sella' syndrome

An 'empty sella' is sometimes reported on pituitary imaging. This is sometimes due to a defect in the diaphragma and extension of the subarachnoid space (cisternal herniation) or may follow spontaneous infarction or regression of a pituitary tumour. All or most of the sella turcica is devoid of apparent pituitary tissue but,

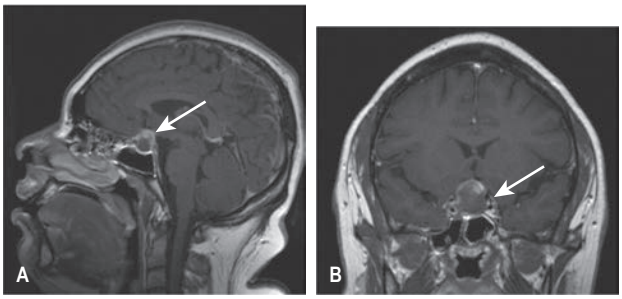

Fig. 34.11 Pituitary apoplexy. A bright area of haemorrhage at the top of a pituitary adenoma *(arrowed)* is shown. **(A)** Sagittal MRI. **(B)** Coronal MRI.

despite this, pituitary function is usually normal, with the pituitary being eccentrically placed and flattened against the floor or roof of the fossa.

Investigations

Each axis of the HP system requires separate investigation. However, the presence of normal gonadal function in women as evidenced by the menstrual cycle obviates the need for investigation.

Investigations range from measurement of simple basal levels (e.g., TSH and free T_4 for the thyroid axis) to stimulatory tests for the pituitary and tests of feedback for the hypothalamus (see **Box 34.7**). Assessment of the hypothalamic–pituitary–adrenal (HPA) axis is complex: depending on the assay basal 9 a.m. cortisol levels above 400 nmol/L usually indicate adequate reserve, while levels below 100 nmol/L predict an inadequate stress response. In many cases, basal levels are equivocal and a dynamic test is essential. The insulin tolerance test (**Box 34.11**) is widely regarded as the 'gold standard' but the short ACTH stimulation test (see **Box 34.5**), though an indirect measure, is used by many as a routine test of HPA status as long as it is performed 6 weeks after any pituitary insult. Occasionally, the difference between ACTH deficiency and normal HPA axis can be subtle, and interpretation requires experience.

Management

- Glucocorticoid and thyroid hormones are essential for life. Both are given as oral replacement drugs, hydrocortisone and levothyroxine, respectively, as in primary thyroid and adrenal failure, with the aim of restoring the patient to clinical and biochemical normality (see **Box 34.9**); for levothyroxine replacement, levels are monitored by routine hormone assays, whereas for hydrocortisone replacement monitoring is limited to symptoms. ***Note:*** Thyroid replacement therapy should not commence until normal adrenal axis function has been demonstrated or glucocorticoid replacement therapy initiated, as an adrenal 'crisis' may otherwise be precipitated.
- Sex hormone replacement is with testosterone in males and a combination of oestrogen and progestogen in females, both for symptomatic control and for prevention of long-term problems related to deficiency (e.g., osteoporosis).
- When fertility is desired, gonadal function is stimulated directly by human chorionic gonadotrophin (HCG, mainly acting as LH) or by purified or biosynthetic gonadotrophins, or indirectly by pulsatile GnRH (also known as luteinizing hormone-releasing hormone, LHRH) if gonadotrophs are undamaged; their use should be restricted to specialist units. HCG and biosynthetic gonadotrophins combination therapy is a recognized novel way of inducing male puberty.
- GH replacement therapy is given for growth in a child, under the care of a paediatric endocrinologist. If the adolescent remains deficient at the achievement of adult height, GH replacement therapy can be offered until patients reach their mid-20s to maximize muscle and bone mass. In adult GH deficiency, GH replacement therapy also produces improvements in body composition, work capacity, and psychological wellbeing, together with reversal of lipid abnormalities associated with high cardiovascular risk, and often results in significant symptomatic benefit. The National Institute for Health and Care Excellence (NICE) recommends GH replacement for children and adolescents with GH deficiency, and in adults with severe GH deficiency and significant quality-of-life impairment. It is expensive, and in the UK it costs £2500–6000 per annum.
- Glucocorticoid deficiency may mask impaired urine concentrating ability, with DI only becoming apparent after glucocorticoid replacement therapy because glucocorticoids are required for excretion of free water.

i Box 34.11 Insulin tolerance test

Indications

- Diagnosis or exclusion of ACTH and GH deficiency

Procedure

- Test explained to patient and consent obtained
- Should only be performed in experienced, specialist units
- Exclude cardiovascular disease (ECG), epilepsy, or unexplained blackouts; exclude severe untreated hypopituitarism (basal cortisol must be >100 nmol/L; normal free T_4)
- I.V. hydrocortisone and glucose available for emergency
- Overnight fast, begin at 08:00–09:00 h
- Soluble insulin, 0.15 U/kg, i.v. at time 0
- Glucose, cortisol and GH levels at 0, 30, 45, 60, 90, 120 min

Normal response

- Cortisol rises above 550 nmol/L[a]
- GH rises above 7 μg/L (severe deficiency ≤ 3 μg/L (<9 mU/L))
- Glucose must be <2.2 mmol/L to achieve adequate stress response

[a]Precise cortisol normal ranges are variable between laboratories and assays; appropriate local reference ranges must be used.

HYPOTHALAMO–PITUITARY–ADRENAL AXIS

Anatomy and physiology

The human adrenals (**Box 34.12**) together weigh 8–10 g and comprise an outer cortex and inner medulla. The cortex has three zones: the zona glomerulosa, which secretes aldosterone under the control of

Box 34.12 Hormones and receptors of the hypothalamic–pituitary–adrenal axis

Hormone	Source	Site of action	Hormone structure	Receptor	Post-receptor activity
Corticotrophin-releasing hormone (CRH)	Hypothalamus	Pituitary	Peptide—41 AA	Membrane—7TM CRF1	G-proteins cAMP

Cortisol	Adrenal	All tissues	Steroid ring	Nuclear GRα	Transcription GRE

7TM, 7 transmembrane (G-protein coupled receptor); *AA*, amino acids; *GRE*, glucocorticoid response element.

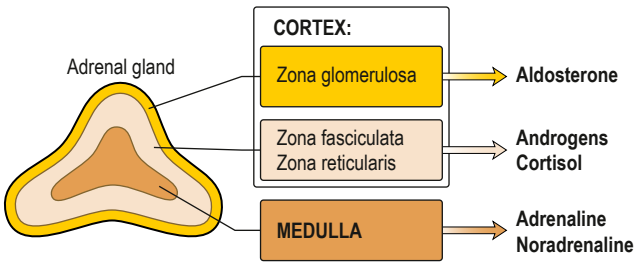

Fig. 34.12 **The adrenal gland and its hormones.**

Box 34.13 The major actions of glucocorticoids

Increased or stimulated:
- Gluconeogenesis
- Glycogen deposition
- Protein catabolism
- Fat deposition
- Sodium retention
- Potassium loss
- Free water clearance
- Uric acid production
- Circulating neutrophils

Decreased or inhibited:
- Protein synthesis
- Host response to infection
- Lymphocyte transformation
- Delayed hypersensitivity
- Circulating lymphocytes
- Circulating eosinophils

the renin–angiotensin system, and the zona fasciculata and zona reticularis, which produce glucocorticoids, cortisol, and sex steroids and androgens under feedback control of the HPA axis. The inner medulla synthesizes, stores, and secretes catecholamines (see later and Fig. 34.12).

The adrenal cortex

The steroids produced by the adrenal cortex are grouped into three classes, based on their predominant physiological effects: glucocorticoids, mineralocorticoids, and androgens.

Glucocorticoids

These are named after their effects on carbohydrate metabolism. Major actions are listed in Box 34.13. They act on intracellular corticosteroid receptors and combine with coactivating proteins to bind the 'glucocorticoid response element' (GRE) in specific regions of DNA to cause gene transcription. Glucocorticoid action is modified locally by the action of 11β-hydroxysteroid dehydrogenase (11βHSD). 11βHSD type 1 converts inactive cortisone into active cortisol, hence amplifying the hormone signal, while 11βHSD type 2 does the opposite.

The relative potency of common steroids is shown in Box 34.14.

Mineralocorticoids

The predominant effect of mineralocorticoids is on the extracellular balance of sodium and potassium in the distal tubule of the kidney. Aldosterone, produced solely in the zona glomerulosa, is the predominant mineralocorticoid in humans (about 50%); corticosterone makes a small contribution to overall mineralocorticoid activity. Mineralocorticoids act on type 1 corticosteroid receptors, while glucocorticoids act on type 2 receptors, both having a very similar structure. The mineralocorticoid activity of cortisol is weak but cortisol is present in considerable excess. The mineralocorticoid receptor in the kidney is protected from this excess by the intrarenal conversion ('shuttle') of cortisol to cortisone by 11βHSD type 2.

Box 34.14 The relative potency of equal amounts of common natural and synthetic steroids

Steroid	Glucocorticoid effect	Mineralocorticoid effect
Cortisol (hydrocortisone)[a]	1	1
Prednisolone	4	0.7
Dexamethasone	40	2
Aldosterone	0.1	400
Fludrocortisone	10	400

[a]Cortisol is arbitrarily defined as 1.

Androgens

Although secreted in considerable quantities, most androgens have relatively weak intrinsic androgenic activity until metabolized peripherally to testosterone or dihydrotestosterone. Dihydrotestosterone is metabolized from testosterone by 5α-reductase and is a potent androgen receptor agonist. The androgen receptor has been well characterized and mutations within this gene may cause androgen insensitivity syndromes.

Biochemistry

All steroids have the same basic skeleton (Fig. 34.13B) and the chemical differences between them are slight. The major biosynthetic pathways are shown in Fig. 34.13A.

Physiology

Glucocorticoid production by the adrenal is under HP control (Fig. 34.14).

Corticotrophin-releasing hormone (CRH) is secreted in the hypothalamus in response to circadian rhythm, stress, and other stimuli. CRH travels down the portal system to stimulate ***adrenocorticotrophin (ACTH)*** release from the anterior pituitary. Hypothalamic vasopressin (AVP) also stimulates ACTH secretion and acts synergistically. ACTH is derived from the prohormone

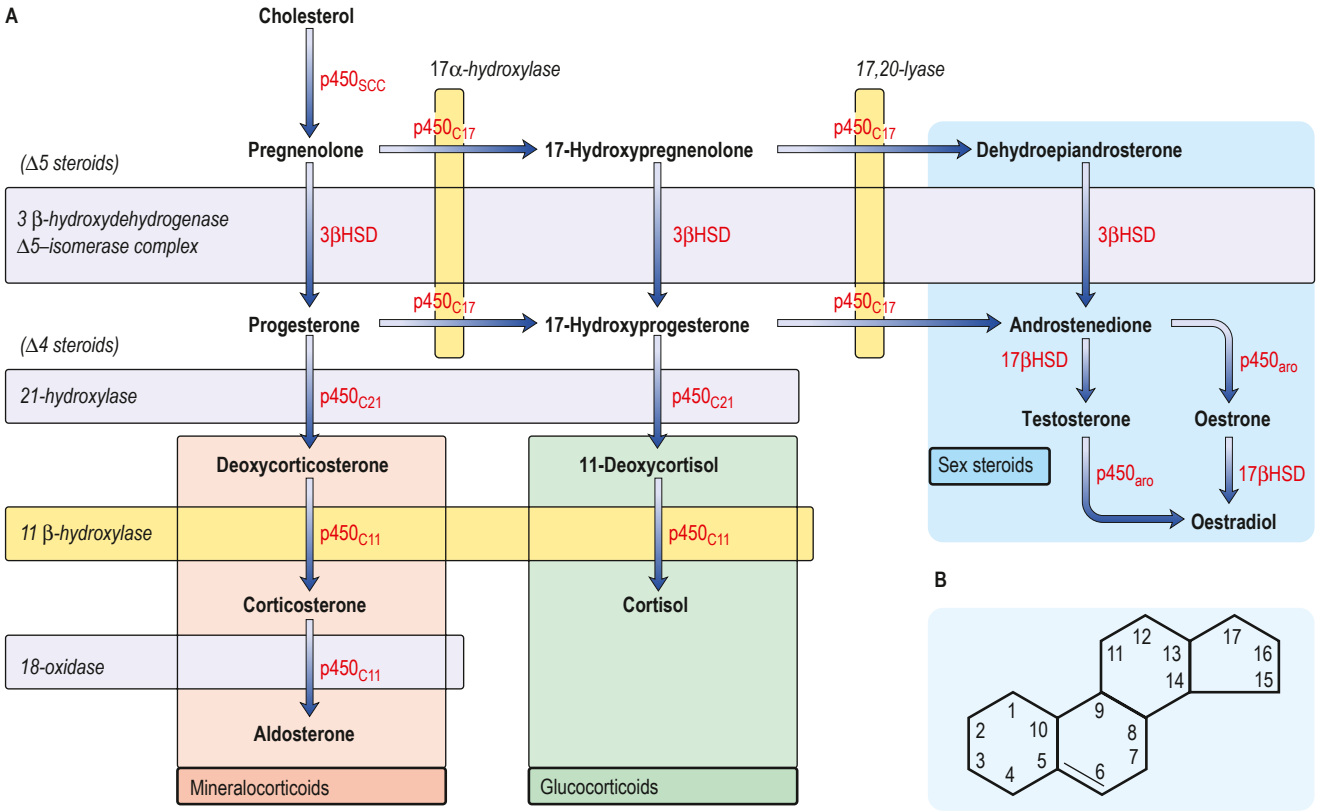

Fig. 34.13 Steroid pathways and molecule. **(A)** The major steroid biosynthetic pathways. Steroid hormones are synthesized in the adrenal glands and gonads from the initial substrate via a series of interconnected enzymatic steps. The reactions catalyzed are shown by shaded boxes with italic labels. The molecular identity of the enzymes is shown in *red*; some catalyze more than one reaction. The p450 enzymes are in mitochondria, 3β-hydroxysteroid dehydrogenase (3βHSD) in cytoplasm; 17βHSD and $p450_{aro}$ (aromatase) are found mainly in gonads. **(B)** The steroid molecule.

pro-opiomelanocortin (POMC), which undergoes processing within the pituitary to produce ACTH and a number of other peptides, including beta-lipotrophin and beta-endorphin. Many of these peptides, including ACTH, contain melanocyte-stimulating hormone (MSH)–like sequences, which cause pigmentation when levels of ACTH are markedly raised as in Addison's disease.

Circulating ACTH stimulates cortisol production in the adrenal. The secreted cortisol (or any other synthetic corticosteroid administered to the patient) causes negative feedback on the hypothalamus and pituitary to inhibit further CRH/ACTH release. The set-point of this system varies through the day according to the circadian rhythm and is usually overridden by severe stress. Unlike cortisol, mineralocorticoids and sex steroids do not cause negative feedback on the CRH/ACTH axis.

Following adrenalectomy or other adrenal damage (e.g., Addison's disease), cortisol secretion is absent or reduced; ACTH levels will therefore rise.

Mineralocorticoid secretion is mainly controlled by the renin–angiotensin system (see 'The adrenal cortex' section).

Investigation of glucocorticoid abnormalities

Basal levels

Cortisol has a circadian rhythm and increases in response to stress. When taking a blood sample, remember:

- Sampling time should be recorded.
- Basal cortisol levels should be taken between 8 a.m. and 10 a.m., near the peak of the circadian variation, if investigating for deficiency, and at midnight, near the peak of variation, if investigating for excess.
- Stress should be minimized.
- Appropriate reference ranges (for time and assay method) should be used.

The measurement of ACTH levels is only really required once an abnormality in cortisol levels has been identified. A plasma sample is required and has to be transported on ice to the lab immediately.

Suppression tests are used if excess cortisol is suspected, and stimulation tests are used if cortisol deficiency is suspected.

Dexamethasone suppression tests

Administration of a synthetic glucocorticoid (dexamethasone) to a normal subject produces suppression of CRH and ACTH levels and thus of endogenous cortisol secretion (dexamethasone is not measured by most cortisol assays). Three forms of the test, used in the diagnosis and differential diagnosis of Cushing's syndrome, are available (**Box 34.15**).

ACTH stimulation tests

Synthetic ACTH (tetracosactide, which consists of the first 24 amino acids of human ACTH) is given to stimulate adrenal cortisol production (see **Box 34.5** and **Fig. 34.5**).

Cushing's syndrome

Cushing's syndrome describes the clinical state of increased free circulating glucocorticoid. It is most often iatrogenic following the

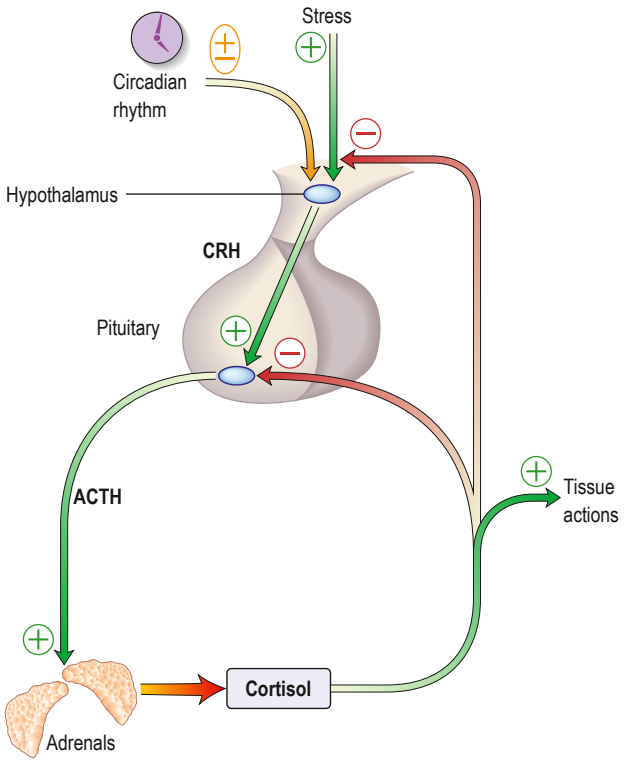

Fig. 34.14 Control of the hypothalamic–pituitary–adrenal axis. Pituitary adrenocorticotrophic hormone (ACTH) is secreted in response to hypothalamic corticotrophin-releasing hormone (CRH), triggered by circadian rhythm, stress, and other factors, and stimulates secretion of cortisol from the adrenal. Cortisol has multiple actions in peripheral tissues and exerts negative feedback on the pituitary and hypothalamus.

therapeutic administration of synthetic steroids. The next most common cause is excess endogenous secretion of ACTH from a pituitary adenoma, when it is called Cushing's disease (see below).

Pathophysiology and aetiology

Spontaneous Cushing's syndrome is rare, with an incidence of fewer than 5/million per year.

Causes of Cushing's syndrome are usually subdivided into two groups (Box 34.16):

- Increased circulating ACTH from the pituitary (65% of cases), known as Cushing's disease, or from an 'ectopic', non-pituitary, ACTH-producing tumour elsewhere in the body (10%) with consequent glucocorticoid excess ('ACTH-dependent' Cushing's).
- A primary excess of endogenous cortisol secretion (25%) by an adrenal tumour or, more rarely, by bilateral primary pigmented nodular hyperplasia (PPNH) with suppression of ACTH ('non-ACTH-dependent' Cushing's). Rare cases are due to aberrant expression of receptors for other hormones (e.g., glucose-dependent insulinotropic peptide [GIP], LH, or catecholamines) in adrenal cortical cells. Germline changes in protein kinase A (PKA) can also result in adrenal hyperplasia and adenomas.

History and examination

The clinical features of Cushing's syndrome are illustrated in Fig. 34.15.

- ***Pigmentation*** occurs only with ACTH-dependent causes (most frequently in ectopic ACTH syndrome).

Box 34.15 Dexamethasone suppression test in the diagnosis of Cushing's syndrome

Test and protocol	Measurement[a]	Normal test result or positive suppression	Use and explanation
Dexamethasone (for Cushing's): overnight			
Take 1 mg on going to bed at 23:00 h	Plasma cortisol at 09:00 h next morning	Plasma cortisol <100 nmol/L	Outpatient screening test Some 'false-positives'
'Low-dose'			
0.5 mg 6-hourly Eight doses from 09:00 h on day 0	Plasma cortisol at 09:00 h on days 0 and +2	Plasma cortisol <50 nmol/L on second sample	For diagnosis of Cushing's syndrome
'High-dose' used in differential diagnosis			
2 mg 6-hourly Eight doses from 09:00 h on day 0	Plasma cortisol at 09:00 h on days 0 and +2	Plasma cortisol on day +2 <50% of that on day 0 suggests pituitary-dependent disease	Differential diagnosis of Cushing's syndrome Pituitary-dependent disease suppresses in about 90% of cases

[a]Plasma cortisol values are very dependent upon the assay used; local reference ranges must be consulted.

Box 34.16 Causes of Cushing's syndrome

ACTH-dependent disease
- Pituitary-dependent (Cushing's disease)
- Ectopic ACTH-producing tumours

Non-ACTH-dependent disease
- Adrenal adenomas
- Adrenal carcinomas
- Exogenous steroids

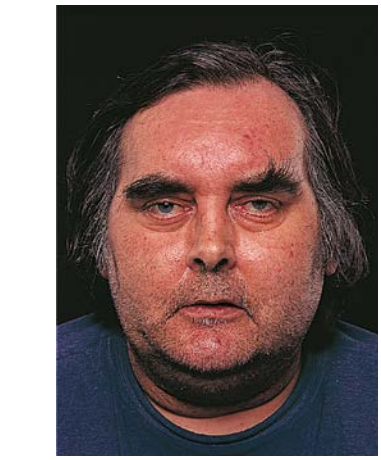
- ***A cushingoid appearance*** can also be caused by excess alcohol consumption (pseudo-Cushing's syndrome); the pathophysiology is poorly understood.
- ***Impaired glucose tolerance*** or frank diabetes is common, especially with ectopic ACTH.
- ***Hypokalaemia*** due to the mineralocorticoid activity of cortisol is common with ectopic ACTH secretion.
- ***Hypertension*** is common in all causes of Cushing's syndrome.

Investigations

There are two phases to investigation.

Confirmation

Most patients with obesity and hypertension or women with obesity and hirsutism do not have Cushing's syndrome, but some cases of genuine Cushing's can also have relatively subtle clinical signs. Confirmation rests on demonstrating inappropriate cortisol secretion that is not suppressed by exogenous glucocorticoids; difficulties occur with obesity and depression, where cortisol dynamics are often abnormal. Random cortisol measurements are of no value.



Symptoms

General
Change of appearance
Weight gain (central)
Hair growth/acne
Thin skin/easy bruising

Mental changes
Depression
Psychosis
Insomnia

Muscular weakness
Back pain

Amenorrhoea/oligomenorrhoea

Poor libido

Growth arrest in children

Polyuria/polydipsia

Old photographs may be useful

Signs

General
Plethora
Moon face
Hypertension
'Buffalo hump'
Central obesity
Depression/psychosis
Glycosuria
Oedema

Skin
Thin skin
Hirsutism
Acne
Bruising
Poor wound healing
Skin infections
Striae (purple or red)
Pigmentation

Musculoskeletal
Osteoporosis
Pathological fractures (esp. vertebrae and ribs)
Kyphosis
Rib fractures

Proximal myopathy
Proximal muscle wasting

Fig. 34.15 Cushing's syndrome: symptoms and signs. ***Bold italic*** type indicates signs of most value in discriminating Cushing's syndrome from simple obesity and hirsutism.

Occasional patients are seen with 'cyclical Cushing's', in which the abnormalities come and go.

Investigations to confirm the diagnosis include:

- ***48-h low-dose dexamethasone test*** (see Box 34.15). Normal individuals suppress plasma cortisol to less than 50 nmol/L. People with Cushing's syndrome fail to show complete suppression of plasma cortisol levels (although levels may fall substantially in a few cases). This test is highly sensitive (>97%). The overnight dexamethasone test is simpler but has a higher false-positive rate, so often used as an initial screening test, before progressing to the longer test.
- ***24-hour urinary free cortisol measurements.*** This is another screening test. It is simple but less reliable; repeatedly normal values render the diagnosis unlikely, but some people with Cushing's syndrome have normal values on some collections (approximately 10%).
- ***Circadian rhythm.*** After 48 h in hospital, cortisol samples are taken at 09:00 and 24:00 h (without warning the patient and ideally when they are asleep). Normal subjects show a pronounced circadian variation (see Fig. 34.4); those with Cushing's syndrome have high midnight cortisol levels (>100 nmol/L), though the 09:00 h value may be normal. Increasingly, loss of circadian rhythm recorded using ***midnight or late-night salivary cortisol*** collected at home can be used for the diagnosis and surveillance of Cushing's, removing the need for a hospital stay.
- ***Other tests.*** There are frequent exceptions to the classic responses to diagnostic tests in Cushing's syndrome. If any clinical suspicion of Cushing's remains after preliminary tests, then specialist investigations are still indicated. These ***may include the insulin stress test, desmopressin stimulation test*** (see Box 34.53), and ***corticotrophin-releasing hormone (CRH)*** tests.

Differential diagnosis of the cause

This can be extremely difficult on symptoms and signs alone since all causes can result in clinically identical Cushing's syndrome. The classical ectopic ACTH syndrome is distinguished by a short history, pigmentation, weight loss, hypokalaemia, diabetes, and plasma ACTH levels above 200 ng/L, but many ectopic tumours are benign and mimic pituitary disease closely, both clinically and biochemically. Severe hirsutism/virilization suggests an adrenal tumour.

Biochemical and radiological procedures for diagnosis include:

- If ***plasma ACTH levels*** are low or undetectable (<10 ng/L) on two or more occasions, this is a reliable indicator of non-ACTH-dependent disease and adrenal imaging should be planned, using ***adrenal CT or MRI scan.*** Adrenal adenomas and carcinomas causing Cushing's syndrome are relatively large and always detectable by CT. Carcinomas are distinguished by their large size and irregular outline, as well as signs of infiltration or metastases. Bilateral adrenal hyperplasia may be seen in ACTH-dependent causes or in ACTH-independent nodular hyperplasia.
- If ***plasma ACTH levels*** are normal or high on two or more occasions, this is a reliable indicator of ACTH-dependent disease and pituitary imaging should be planned in the first instance and biochemical tests to distinguish between pituitary and ectopic sources of ACTH.
- ***Pituitary MRI.*** A pituitary adenoma may be seen but the adenoma is often small and not visible in a significant proportion of cases.
- ***High-dose dexamethasone suppression test*** (see Box 34.15). Failure of significant plasma cortisol suppression suggests an ectopic source of ACTH (or an adrenal tumour).
- ***Desmopressin stimulation test.*** An exaggerated ACTH and cortisol response to exogenous desmopressin suggests

pituitary-dependent Cushing's disease, as ectopic sources rarely respond. This has replaced the CRH test.

- ***Chest, abdominal, and pelvic imaging.*** A carcinoma of the bronchus or a bronchial carcinoid is sought. Carcinoid lesions may be very small, and whole-body CT or PET imaging may be indicated.

Further investigations may involve:

- ***Selective catheterization*** of the inferior petrosal sinus to measure ACTH for pituitary lesions, or blood samples taken throughout the body to look for ectopic sources.
- ***Radiolabelled octreotide*** (^{111}In octreotide) and/or **Gallium-68 DOTATATE PET-CT** are occasionally helpful in locating ectopic ACTH sites.

Management

Cushing's syndrome

Successful treatment with a normal biochemical profile should lead to reversal of clinical features. However, untreated Cushing's syndrome has a very poor prognosis, with death from venous thromboembolism, hypertension, myocardial infarction, infection, and heart failure. Whatever the underlying cause, cortisol hypersecretion should be controlled prior to surgery or radiotherapy. Considerable morbidity and mortality are otherwise associated with operating on unprepared patients, especially when abdominal surgery is required.

The usual drug is ***metyrapone***, an 11β-hydroxylase blocker, which is given in doses of 750 mg to 4 g daily in 3–4 divided doses. ***Osilodrostat*** has a similar mechanism of action to metyrapone and appears more effective. ***Ketoconazole*** (200 mg three times daily) is also used and is synergistic with metyrapone. Plasma cortisol should be monitored, aiming to reduce the mean level during the day to 150–300 nmol/L, equivalent to normal production rates.

Aminoglutethimide, ***trilostane*** (which reversibly inhibits 3-hydroxysteroid dehydrogenase/5-5,4 isomers), and ***etomidate*** infusion (in severe cases) are occasionally used.

Choice of further treatment depends on the cause.

Cushing's disease (pituitary-dependent hypercortisolism)

- ***Trans-sphenoidal removal of the tumour*** is the treatment of choice. Selective adenomectomy nearly always leaves the patient ACTH-deficient immediately postoperatively, and this is a good prognostic sign. Overall, pituitary surgery results in remission in 75%–80% of cases, but results vary considerably and an experienced surgeon is essential.
- ***External pituitary irradiation*** alone is slow-acting, only effective in 50%–60% even after prolonged follow-up, and mainly used after failed pituitary surgery. Children respond much better to radiotherapy, with 80% being cured. Stereotactic radiotherapy can be useful in selected cases.
- ***Medical therapy*** to reduce ACTH (e.g., bromocriptine, cabergoline and cyproheptadine) is rarely effective. The somatostatin analogue pasireotide may provide medical control of Cushing's in some patients but is associated with hyperglycaemia as a common side-effect. Aggressive corticotroph adenomas may respond to temozolomide chemotherapy.
- ***Bilateral adrenalectomy*** is an effective last resort if other measures fail to control the disease (see 'Nelson's syndrome' later). This can be performed laparoscopically.

Cushing's syndrome due to other causes

Adrenal adenomas should be resected laparoscopically. Contralateral adrenal suppression may last for a year or more.

Adrenal carcinomas are highly aggressive and the prognosis is poor. In general, if there are no widespread metastases, tumour bulk should be reduced surgically. The adrenolytic drug mitotane may inhibit growth of the tumour and prolong survival, though it can cause nausea and ataxia. Sometimes radiotherapy is directed to the tumour bed after surgery.

Tumours secreting ACTH ectopically should be removed if possible. Otherwise chemotherapy/radiotherapy may be used, depending on the tumour type and location. Control of Cushing's syndrome with metyrapone or ketoconazole is beneficial for symptoms, and bilateral adrenalectomy may be appropriate to give complete control of Cushing's syndrome if prognosis from the tumour itself is reasonable.

If the source of ACTH is not clear, cortisol hypersecretion should be controlled with medical therapy until a diagnosis can be made.

Nelson's syndrome

Nelson's syndrome occurs in about 20% of cases after bilateral adrenalectomy for Cushing's disease and is characterized by increased pigmentation (because of high levels of ACTH), associated with an enlarging pituitary tumour. The syndrome is rare now that adrenalectomy is an uncommon primary treatment, and its incidence may be reduced by pituitary radiotherapy soon after adrenalectomy. The Nelson's adenoma may be treated by pituitary surgery and/or radiotherapy (unless given previously).

Addison's disease

Pathophysiology and aetiology

In this condition, there is destruction of the entire adrenal cortex. Glucocorticoid, mineralocorticoid, and sex steroid production are therefore all reduced. This differs from adrenal insufficiency caused by HP disease, in which mineralocorticoid secretion remains largely intact, being predominantly stimulated by angiotensin II. Adrenal sex steroid production is also largely independent of pituitary action. In Addison's disease, reduced cortisol levels lead, through feedback, to increased CRH and ACTH production, the latter being directly responsible for the hyperpigmentation.

Addison's disease is rare, with an incidence of 3–4/million per year and prevalence of 40–60/million. Primary adrenal insufficiency shows a marked female preponderance and is usually caused by autoimmune disease (>90% in the UK), but in countries with a high prevalence of HIV/AIDS, tuberculosis is a common cause. Autoimmune adrenalitis results from the destruction of the adrenal cortex by organ-specific autoantibodies, with 21-hydroxylase as the common antigen. There are associations with other autoimmune conditions in polyglandular autoimmune syndromes types I and II (e.g., type 1 diabetes mellitus, pernicious anaemia, thyroiditis, hypoparathyroidism, premature ovarian insufficiency; see 'Diseases of many glands' section).

All other causes are rare (**Box 34.17**). In patients with degenerative neurological symptoms, a diagnosis of adrenoleukodystrophy should be excluded. In childhood the most common cause of primary adrenal insufficiency is CAH.

History and examination

See Fig. 34.16. The symptomatology of Addison's disease is often non-specific. These symptoms may be the prelude to an addisonian crisis with severe hypotension and dehydration precipitated by intercurrent illness, accident, or operation.

Pigmentation (dull, slaty, grey–brown) is the predominant sign in over 90% of cases.

Postural systolic hypotension, due to hypovolaemia and sodium loss, is present in 80%–90% of cases, even if supine blood pressure is normal. Mineralocorticoid deficiency is the cause of the hypotension.

Investigations

Once Addison's disease is suspected, investigation is urgent. If the patient is seriously ill or hypotensive, hydrocortisone 100 mg should be given intravenously or intramuscularly, together with intravenous 0.9% saline. Ideally, this should be done immediately after a blood sample is taken for later measurement of plasma cortisol. Full investigation should be delayed until emergency treatment (see below) has improved the patient's condition. Otherwise, tests are as follows:

- ***Single cortisol measurements*** are of little value, although a random cortisol below 100 nmol/L during the day is highly suggestive, and a random cortisol higher than 550 nmol/L makes the diagnosis unlikely.
- ***The short ACTH stimulation test*** should be performed (see Box 34.5 and Fig. 34.5). Note that an absent or impaired cortisol response confirms the presence of hypoadrenalism but does not differentiate Addison's disease from ACTH deficiency or iatrogenic suppression by steroid medication. The long ACTH test is no longer used because of the availability of accurate ACTH assays.
- ***A 09:00-hours plasma ACTH level*** is measured, a high level (>80 ng/L) with low cortisol confirming primary adrenal insufficiency.
- ***Adrenal antibodies*** are present in approximately 90% of cases of autoimmune adrenalitis.
- ***Abdominal imaging*** (plain radiographs, CT, or MRI) may show evidence of tuberculosis and/or calcified adrenals (Fig. 34.17).
- ***Plasma renin activity*** is high due to low serum aldosterone.
- ***Hyponatraemia, hyperkalaemia, and acute kidney injury*** may be present, but electrolytes can be normal.
- ***Blood glucose*** may be low.
- ***Hypercalcaemia and anaemia*** (after rehydration) are sometimes seen.

? Box 34.17 Causes of primary hypoadrenalism

- Autoimmune disease
- Tuberculosis (<10% in UK)
- Surgical removal
- Haemorrhage/infarction:
  - Meningococcal septicaemia
  - Venography
- Infiltration:
  - Malignant destruction
  - Amyloid
- Schilder's disease (adrenal leukodystrophy)

Management

Acute hypoadrenalism needs urgent treatment (Box 34.18).

Long-term treatment is with replacement glucocorticoid and mineralocorticoid; tuberculosis must be treated if present or suspected. Replacement dosage details are shown in Box 34.19. Dual-release, oral, once-daily hydrocortisone preparations are becoming increasingly available. Once-daily prednisolone may also be effective at doses of 3–4 mg. Dehydroepiandrosterone (DHEA) replacement has also been advocated by some for quality of life; some studies suggest that this may cause symptomatic improvements, although others show no clear benefit and acne and hirsutism occur.

Adequacy of glucocorticoid dose is judged by:

- clinical wellbeing and restoration of normal, but not excessive, weight; ideally aiming for a low dose, for example, total dose of hydrocortisone between 15 and 25 mg split in two or three divided doses throughout the day

Symptoms

Weight loss
Malaise
Weakness
Fever

Anorexia
Nausea/vomiting
Diarrhoea
Abdominal pain
Constipation
Depression
Confusion
Myalgia
Joint or back pain

Impotence/amenorrhoea

Syncope from postural hypotension

Signs

General
Loss of weight
General wasting
Pigmentation, especially of new scars and palmar creases
Buccal pigmentation
Postural hypotension
Loss of body hair (vitiligo)
Dehydration

Fig. 34.16 Primary hypoadrenalism (Addison's disease): symptoms and signs. *Bold italic* type indicates signs of greater discriminant value.

Fig. 34.17 CT scan showing bilateral adrenal calcification.

Box 34.18 Management of acute hypoadrenalism

Clinical context

Hypotension, hyponatraemia, hyperkalaemia, hypoglycaemia, dehydration, and pigmentation often with precipitating infection, infarction, trauma, or operation. The major deficiencies are of salt, steroid, and glucose.

Requirements

Assuming normal cardiovascular function, the following are required:

- 1 L of 0.9% saline should be given over 30–60 min with 100 mg of i.v. bolus hydrocortisone
- Subsequent requirements are several litres of saline within 24 h (assessing with central venous pressure line if necessary) plus hydrocortisone, 100 mg i.m., 6-hourly, until the patient is clinically stable
- Glucose should be infused if there is hypoglycaemia
- Oral replacement medication is then started, unless the patient is unable to take oral medication: initially, hydrocortisone 20 mg, 8-hourly, reducing to 20–30 mg in divided doses over a few days (see **Box 34.19**)
- Fludrocortisone is unnecessary acutely, as the high cortisol doses provide sufficient mineralocorticoid activity—it should be introduced before discharge

Box 34.19 Average replacement steroid dosages for adults with primary hypoadrenalism

Drug	Dose
Glucocorticoid	
Hydrocortisone	20–30 mg daily (e.g., 10 mg on waking, 5 mg at 12:00 h, 5 mg at 18:00 h)
rarely	
Prednisolone	5 mg daily on waking
very rarely	
Dexamethasone	0.75 mg daily (0.5 mg on waking, 0.25 mg at 18:00 h)
Mineralocorticoid	
Fludrocortisone	50–300 μg daily

- measuring cortisol levels during the day while on replacement hydrocortisone (cortisol levels cannot be used for synthetic steroids) is not recommended as an assessment of dose adequacy. Adequacy of fludrocortisone replacement is assessed by:
- restoration of serum electrolytes to normal
- no evidence of hypertension or postural hypotension (it should not fall >10 mmHg systolic after 2 minutes' standing)
- suppression of plasma renin activity to high normal.

Patient advice

All patients requiring replacement steroids should:

- know how to increase steroid replacement by doubling the dose for intercurrent illness
- carry a 'steroid card'
- wear a MedicAlert bracelet (or similar), which gives details of their condition so that emergency replacement therapy can be given if found unconscious
- keep an (up-to-date) ampoule of hydrocortisone at home in case oral therapy is impossible, for administration by self, family, ambulance, or doctor.

Secondary hypoadrenalism

Pituitary disease

Most people with HP disease have panhypopituitarism (see 'Presentation of pituitary and hypothalamic disease' section) and need T_4 replacement, as well as cortisol; in this case, hydrocortisone must be started before T_4.

Adrenal suppression due to long-term corticosteroid therapy

Long-term corticosteroid medication for non-endocrine disease is the most common cause of secondary hypoadrenalism. The HP axis and the adrenal may both be suppressed and the patient may have vague symptoms of feeling unwell. ACTH levels are low in secondary hypoadrenalism. Weaning off steroids is often a long and difficult process.

Congenital adrenal hyperplasia

Pathophysiology

Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder resulting in deficiency of an enzyme in the cortisol synthetic pathways. There are six major types; most common is 21-hydroxylase deficiency (CYP21A2), which occurs in about 1 in 15 000 births and is due to defects on chromosome 6 near the HLA region, affecting one of the cytochrome p450 enzymes (p450C21).

As a result, cortisol secretion is reduced and feedback leads to increased ACTH secretion, causing adrenal hyperplasia. Diversion of the steroid precursors into the androgenic steroid pathways occurs (see **Fig. 34.13A**). Thus, 17-hydroxyprogesterone, androstenedione, and testosterone levels are increased, leading to virilization. Aldosterone synthesis may be impaired with resultant salt wasting.

The other forms affect 11β-hydroxylase, 17α-hydroxylase, 3β-hydroxysteroid dehydrogenase, and a cholesterol side-chain cleavage enzyme (p450scc) (see **Fig. 34.13A**).

History and examination

Classical CAH presents at birth with:

- Ambiguous genitalia in females (clitoral hypertrophy, urogenital abnormalities and labioscrotal fusion are common) *or*
- Adrenal failure (collapse, hypotension, hypoglycaemia), sometimes with a salt-losing state (hypotension, hyponatraemia). The syndrome may be unrecognized in the male until a salt-losing crisis occurs, usually within 10 days of birth.

Non-classical disease presents later as precocious puberty with hirsutism; rare, milder cases present in adult life, usually accompanied by primary amenorrhoea. Hirsutism developing before puberty is suggestive of CAH.

Investigations

In many high-income countries neonatal screening for CAH takes place by assessing 17OHP in dried blood spots soon after birth. This approach would prevent undiagnosed children presenting with adrenal failure and identify those that may present later with precocious puberty.

Expert advice is essential in the confirmation and differential diagnosis of 21-hydroxylase deficiency; with ambiguous genitalia, advice must be sought urgently before any assignment of sex is made.

Unless 17OHP levels are very elevated (>30 nmol/L) a synacthen test should be performed with measurement of 17OHP and cortisol at 0 and 60 minutes. If 17OHP levels at baseline or after synacthen are above 30 nmol/L 21-hydroxylase deficiency is confirmed.

Assessment of mineralocorticoid activity is also required.

Management

Glucocorticoid activity must be replaced, as must mineralocorticoid activity if deficient. In ***adults***, clinical features and biochemistry (plasma renin, androstenedione and 17-hydroxyprogesterone) are used to modify treatment. The use of modified-release hydrocortisone may have a role in the management of CAH.

Prenatal diagnosis

Prenatal genetic counselling is essential (see Chapter 2). There is a 1:4 chance of an affected child if one child in the family is already affected. In a parent with CAH, genetic testing of the partner provides important information about the risk of having an affected child. Dexamethasone can be offered to the mother as it may prevent virilization of an affected female fetus by suppressing ACTH levels. There are, however, concerns about the potential adverse consequences of this practice.

Problems of therapeutic steroid therapy

Apart from their use as therapeutic replacement for endocrine deficiency states, synthetic glucocorticoids are widely used for many non-endocrine conditions. Short-term use (e.g., for acute asthma) carries only small risks of significant side-effects. In general, therapy for 3 weeks or less, or a dose of prednisolone of less than 5 mg per day, will not result in significant long-term suppression of the normal adrenal axis.

Long-term therapy with synthetic or natural steroids will, in most respects, mimic endogenous Cushing's syndrome. Exceptions are the relative absence of hirsutism, acne, hypertension, and severe sodium retention, as the common synthetic steroids have low androgenic and mineralocorticoid activity.

Excessive doses of steroids may also be absorbed from skin when strong dermatological preparations are used, and along with inhaled steroids may rarely cause Cushing's syndrome; they may, however, quite commonly cause adrenal suppression.

The major hazards are detailed in **Box 34.20**. In the long term, many are of such severity that the clinical need for high-dose steroids should be continually and critically assessed. Steroid-sparing agents should always be considered, and screening and prophylactic therapy for osteoporosis introduced (see Chapter 33, 'Osteoporosis' section). New targeted biological therapies for inflammatory conditions may reduce the incidence of steroid-induced adrenal suppression.

Supervision of steroid therapy

All patients receiving steroids should carry a 'steroid card'. They should be made aware of the following points:

- Long-term steroid therapy must never be stopped suddenly.
- Doses should be reduced gradually, with most being given in the morning at the time of withdrawal; this minimizes adrenal suppression. 'Alternate-day therapy' may produce less suppression.
- Depending on current dose, doses need to be increased at times of serious intercurrent illness, accident, and stress. Double doses should be taken during these periods.
- Other physicians, anaesthetists, and dentists must be told about steroid therapy.

Patients should also be informed of potential side-effects, and all this information should be documented in the clinical record. If prophylactic use of bisphosphonate therapy is required to prevent the development of osteoporosis (following NICE guidance), patients should be informed of the rationale.

Box 34.20 Major adverse effects of corticosteroid therapy

Physiological
- Adrenal suppression (secondary)

Pathological

Cardiovascular
- Increased blood pressure

Gastrointestinal
- Pancreatitis

Renal
- Polyuria
- Nocturia

Central nervous
- Depression
- Euphoria
- Psychosis
- Insomnia

Endocrine
- Weight gain
- Glycosuria/hyperglycaemia/diabetes
- Impaired growth
- Amenorrhoea

Bone and muscle
- Osteoporosis
- Proximal myopathy and wasting
- Avascular necrosis of the hip
- Pathological fractures

Skin
- Thinning
- Easy bruising

Eyes
- Cataracts

Increased susceptibility to infection

(Signs and fever are frequently masked)
- Septicaemia
- Fungal infections
- Reactivation of tuberculosis
- Skin infections (e.g., fungi)

Steroids and surgery

Any patient receiving steroids, or who has recently received a 4-week course of steroids (within the last 6 months) and may still have adrenal suppression, requires steroid cover around the time of surgery (**Box 34.21**).

Incidental adrenal tumours ('incidentalomas')

With the advent of abdominal CT, MRI, and high-resolution ultrasound scanning, unsuspected adrenal masses have been discovered in 3%–10% of scans (increasing with age). The two issues with an incidental adrenal mass are:

- whether the lesion is functional or non-functional
- whether it is benign or malignant.

Most incidentalomas are asymptomatic and benign, but direct questioning may reveal symptoms of endocrine hypersecretion such as cushingoid features, catecholamine excess, virilization in women, or evidence of endocrine hypertension (see **Box 31.2**). Even in the absence of symptoms, biochemical tests to exclude secretory activity should be performed, as adrenal adenomas often secrete cortisol at a low level—'autonomous cortisol secretion', which may confer increased cardiovascular risk. If no endocrine activity is found, then most guidelines recommend removal only of large adrenal tumours (>4–5 cm) because of the risk of malignancy. Smaller, hormonally inactive lesions are usually left alone. Adrenal biopsy

Box 34.21 Steroid cover for operative procedures[a]

Procedure	Premedication	Intra- and postoperative	Resumption of normal maintenance
Simple procedures (e.g., gastroscopy, simple dental extractions)	Hydrocortisone 100 mg i.m.	–	Immediately if no complications and eating normally
Minor surgery (e.g., laparoscopic surgery, veins, hernias)	Hydrocortisone 100 mg i.m.	Hydrocortisone 20 mg orally 6-hourly or 50 mg i.m. 6-hourly for 24 h if not eating	After 24 h if no complications
Major surgery (e.g., hip replacement, vascular surgery)	Hydrocortisone 100 mg i.m.	Hydrocortisone 50–100 mg i.m. 6-hourly for 72 h	After 72 h if normal progress and no complications Perhaps double normal dose for 2–3 days
GI tract surgery or major thoracic surgery (not eating or ventilated)	Hydrocortisone 100 mg i.m.	Hydrocortisone 100 mg i.m. 6-hourly for 72 h or longer if still unwell	When patient eating normally again Until then, higher doses (to 50 mg 6-hourly) may be needed

[a]A useful summary of surgical steroid guidelines can be found at: http://www.addisons.org.uk/.

is usually contraindicated in evaluation of adrenal tumours, as the procedure can precipitate potentially fatal phaeochromocytoma crisis from sudden catecholamine surge or can breach the capsule of an adrenal malignancy, facilitating metastasis due to the procedure.

Phaeochromocytoma must be excluded before surgery due to the risk of perioperative hypertensive or hypotensive crises (see 'The adrenal medulla' section).

Primary hyperaldosteronism

Increased mineralocorticoid secretion from the adrenal cortex, termed primary hyperaldosteronism, is one of the endocrine causes of 5%–10% of all hypertension, which is termed 'secondary' (see Chapter 18). Other endocrine causes of hypertension should also be considered if there is clinical suspicion (**Box 34.22**). It is impracticable to screen all hypertensive patients for secondary endocrine causes. The highest chances of detecting such causes are in patients:

- under 35 years, especially those without a family history of hypertension
- with accelerated (malignant) hypertension
- with hypokalaemia
- resistant to conventional antihypertensive therapy (e.g., more than three drugs) *or*
- with unusual symptoms (e.g., sweating attacks or weakness).

Pathophysiology

Primary hyperaldosteronism is characterized by excess aldosterone production leading to sodium retention, potassium loss, and the combination of hypokalaemia and hypertension. This must be distinguished from secondary hyperaldosteronism (see Chapter 27), which arises when there is excess renin (and hence angiotensin II) stimulation of the zona glomerulosa. Common causes of secondary hyperaldosteronism include:

- renal artery stenosis or renin-secreting renal tumours, when the patient will also be hypertensive
- heart failure and cirrhosis, when the patient is typically normotensive. Excess aldosterone production contributes to the sodium retention and excess extracellular fluid accumulation seen in these conditions.

Box 34.22 Endocrine causes of hypertension

Excessive renin, and thus angiotensin II, production
- Renal artery stenosis
- Other local renal disease
- Renin-secreting tumours

Excessive production of catecholamines
- Phaeochromocytoma

Excessive growth hormone (GH) production
- Acromegaly

Excessive aldosterone production
- Adrenal adenoma (Conn's syndrome)
- Idiopathic adrenal hyperplasia
- Dexamethasone-suppressible hyperaldosteronism

Excessive production of other mineralocorticoids
- Cushing's syndrome (massive excess of cortisol, a weak mineralocorticoid)
- Congenital adrenal hyperplasia (in rare cases)
- Tumours producing other mineralocorticoids, e.g., corticosterone

Exogenous 'mineralocorticoids' or enzyme inhibitors
- Liquorice ingestion (inhibits 11β-hydroxylase)
- Misuse of mineralocorticoid preparations

Aetiology

Adrenal adenomas (Conn's syndrome; see **Box 34.22**) originally accounted for 60% of cases of primary hyperaldosteronism but represented a rare cause of hypertension. The use of the aldosterone:renin ratio (ARR) in the routine investigation of hypertension now suggests that hyperaldosteronism due to bilateral adrenal hyperplasia (idiopathic hyperaldosteronism) is much more common than the classical Conn's adenoma. There is an increasing recognition that primary hyperaldosteronism may have a genetic basis in certain individuals and families.

History and examination

The usual presentation is simply hypertension; hypokalaemia (<3.5 mmol/L) is frequently not present. The few symptoms are nonspecific; rarely, muscle weakness, nocturia, and tetany are seen. Hypertension may be severe and associated with renal, cardiac, and retinal damage.

Adenomas, often very small, are more common in young females, while bilateral hyperplasia rarely occurs before the age of 40 years and is more common in males.

Investigations

Beta-blockers and other drugs may interfere with renin activity, and spironolactone, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin II receptor antagonists will all affect results; all should be discontinued, if possible. The characteristic features of investigation are as follows:

- ***High plasma aldosterone:renin ratio (ARR).*** This is now the most frequently used screening test for the condition, but raised ARR alone does not confirm the diagnosis (if the renin is low

enough, ARR will always be high). Note that normal ranges are highly assay-dependent.

- ***Elevated plasma aldosterone levels*** which are not suppressed with 0.9% saline infusion (2 L over 4 h) or fludrocortisone administration. Between 30% and 50% of people with a raised ARR on screening will suppress normally, excluding the diagnosis.
- ***Suppressed plasma renin activity*** or immunoreactivity is seen.
- ***Hypokalaemia*** is often present but a normal potassium does not exclude the diagnosis.
- ***Urinary potassium loss*** greater than 30 mmol daily during hypokalaemia is inappropriate.

Once a diagnosis of hyperaldosteronism is established, differentiation of adenoma from hyperplasia involves adrenal CT or MRI, but small adenomas may be missed and non-functioning incidentalomas also occur. Further information is obtained from diurnal/postural changes in plasma aldosterone levels (which tend to rise with adenomas between 09:00 hours supine and 13:00 hours erect samples; in contrast, they fall with hyperplasia), measurement of 18-OH cortisol levels (raised in adenoma), and venous catheterization for aldosterone levels. All of these tests have pitfalls and exceptions.

Management

An adenoma can be removed surgically, usually laparoscopically; blood pressure falls in 70% of patients. Those with hyperplasia should be treated with the aldosterone antagonist, spironolactone (100–400 mg daily); frequent side-effects include nausea, rashes, and gynaecomastia. The pure aldosterone receptor antagonist, eplerenone, is a useful alternative if side-effects preclude the use of spironolactone (see Chapter 27, 'Potassium-sparing diuretics' section). Amiloride and calcium-channel blockers are moderately effective in controlling hypertension but do not correct the hyperaldosteronism.

Glucocorticoid (or dexamethasone)-suppressible hyperaldosteronism

This rare condition is caused by a chimeric gene on chromosome 8. A fusion gene resulting from an unusual crossover at meiosis between the genes encoding aldosterone synthase and adrenal 11β-hydroxylase produces aldosterone, which is under ACTH control. Treatment with glucocorticoid resolves the problem.

Syndrome of apparent mineralocorticoid excess

This causes the clinical syndrome of primary hyperaldosteronism but with low renin and aldosterone levels. Reduced activity of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) prevents the normal conversion in the kidney of cortisol (which is active at the mineralocorticoid receptor) to cortisone (which is not) and therefore 'exposes' the mineralocorticoid receptor in the kidney to the usual molar excess of cortisol over aldosterone in the blood. While the inherited syndrome is rare, the same clinical syndrome can occur with excessive ingestion of liquorice, which inhibits the 11βHSD2 enzyme.

The adrenal medulla

The adrenal medulla is the innermost part of the adrenal gland, consisting of cells that secrete the major catecholamines, noradrenaline (norepinephrine), and adrenaline (epinephrine), which produce the sympathetic nervous response. The catecholamines are interconverted in the adrenal medulla, and an increase in levels of their metabolites in the urine is a marker of abnormal hypersecretion (Fig. 34.18).

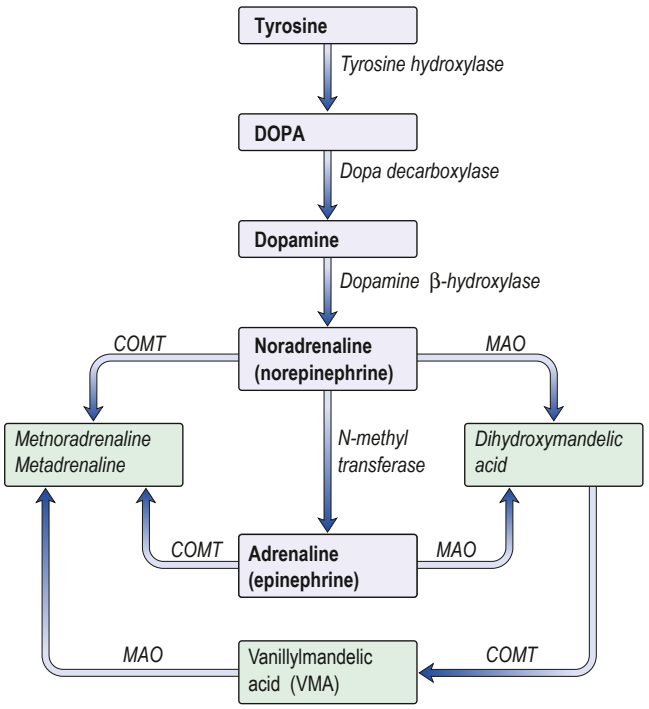

Fig. 34.18 The synthesis and metabolism of catecholamines.
COMT, Catechol-O-methyl transferase; *MAO,* monoamine oxidase.

Phaeochromocytoma and paraganglioma

These are very rare tumours of the sympathetic nervous system (less than 1 in 1000 cases of hypertension) that secrete catecholamines, noradrenaline (norepinephrine), adrenaline (epinephrine), and their metabolites (see Fig. 34.18):

- 90% arise in the adrenal medulla ***(phaeochromocytomas)***
- 10% occur elsewhere in the sympathetic chain ***(paragangliomas).***

Some are associated with MEN 2 (see below), succinate dehydrogenase (*SDHB* and *SDHD*) mutations, von Hippel–Lindau's (VHL) syndrome (see 'Diseases of many glands' section), and less commonly neurofibromatosis type 1. Most tumours release both noradrenaline (norepinephrine) and adrenaline (epinephrine), but large tumours and extra-adrenal tumours produce almost entirely noradrenaline.

Paragangliomas typically occur in the head and neck but are also found in the thorax, pelvis, and bladder. They are more closely associated with other genetic associations than phaeochromocytoma. The association of paraganglioma, bilateral adrenal phaeochromocytomas, positive family history, or young age at presentation is seen in MENs (see 'The adrenal medulla' section). Mutations in the *SDHB* and *SDHD* genes have been shown to be strongly associated with the development of paraganglioma.

Pathology

Oval groups of cells occur in clusters and stain for chromogranin A; 25% are multiple and 10% malignant, the latter being more frequent in extra-adrenal tumours. Malignancy cannot be determined on simple histological examination alone.

History and examination

The clinical features are those of catecholamine excess and are frequently, but not necessarily, intermittent (Box 34.23). All people with

Box 34.23 Symptoms and signs of phaeochromocytoma

Symptoms
- Anxiety or panic attacks
- Palpitations
- Tremor
- Sweating
- Headache
- Flushing
- Nausea and/or vomiting
- Weight loss
- Constipation or diarrhoea

- Glycosuria
- Fever
- (Signs of hypertensive damage)

suspected phaeochromocytomas must be investigated because phaeochromocytomas may cause acute cardiovascular compromise during routine medical procedures and can also present with sudden death if the diagnosis is missed.

Investigations

Specific tests are:

- ***Measurement of urinary catecholamines and metabolites*** is a useful screening test (metanephrines are most sensitive and specific; see Fig. 34.18); normal levels on three 24-hour collections of metanephrines virtually exclude the diagnosis. Many drugs, e.g., tricyclics, and dietary vanilla interfere with these tests.
- ***Resting plasma metanephrines*** are raised.
- ***Plasma chromogranin A*** (a storage vesicle protein) is raised.
- ***Clonidine suppression test*** may be appropriate but should only be performed in specialist centres.
- ***CT/MRI scans***, initially of the abdomen, are helpful to localize the tumours, which are often large (Fig. 34.19).
- ***Scanning with [^{131}I]meta-iodobenzylguanidine (MIBG)*** produces specific uptake in sites of sympathetic activity with about 90% success. It is particularly useful with extra-adrenal tumours. ^{18}F-deoxyglucose PET is also used by some centres (Fig. 34.20).
- ***68-Gallium PET scans*** may be useful in non-MIG avid phaeochromocytomas
- ***Genetic testing*** for *MEN2*, *VHL*, *SDHB*, and *SDHD* mutations should be performed in all people with confirmed phaeochromocytoma or paraganglioma.

Management

Tumours should be removed if possible; 5-year survival is about 95% for non-malignant tumours. Medical preoperative and perioperative treatment is vital and includes complete alpha- and beta-blockade with phenoxybenzamine (20–80 mg daily in divided doses), then propranolol (120–240 mg daily), plus intravenous hydration to re-expand the contracted plasma volume. Alpha-blockade must precede the beta-blockade, as worsened hypertension may otherwise result. Labetalol is not recommended. Surgery in the unprepared patient is fraught with dangers of both hypertension and hypotension; expert anaesthesia and an experienced surgeon are vital, and sodium nitroprusside, phentolamine (a rapid-acting α-blocker), and magnesium should be available in case sudden severe hypertension develops.

When operation is not possible, combined alpha- and beta-blockade can be used long term. Radionucleotide treatment with MIBG has been employed but has had limited success in malignant phaeochromocytoma.

Patients should be kept under clinical and biochemical review after tumour resection, as over 10% of tumours recur or a further tumour develops. Catecholamine excretion measurements should be performed at least annually.

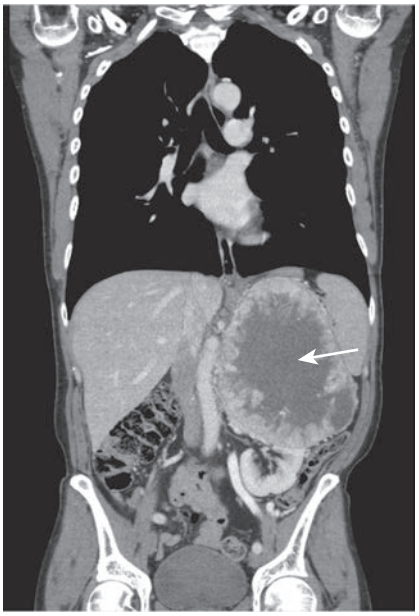

Fig. 34.19 MRI scan showing a massive left-sided phaeochromocytoma.

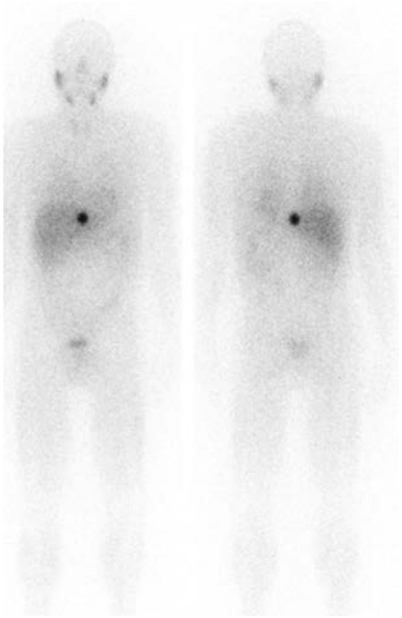

Fig. 34.20 MIBG scan showing a solitary area of increased uptake in the liver consistent with metastasis from a phaeochromocytoma. *MIBG,* Meta-iodobenzylguanidine.

THE THYROID AXIS

The metabolism of virtually all nucleated cells of many tissues is controlled by the thyroid hormones. Overactivity or underactivity of the gland is the most common of all endocrine problems.

Anatomy and physiology

Anatomy

The thyroid gland consists of two lateral lobes connected by an isthmus. It is closely attached to the thyroid cartilage and to the upper end of the trachea and thus moves on swallowing. It is often palpable in healthy women.

Embryologically, it originates from the base of the tongue and descends to the middle of the neck. Remnants of thyroid tissue can sometimes be found at the base of the tongue (lingual thyroid) and along the line of descent. The gland has a rich blood supply from superior and inferior thyroid arteries.

The thyroid gland consists of follicles lined by cuboidal epithelioid cells. Inside is colloid (the iodinated glycoprotein thyroglobulin), which is synthesized by the follicular cells. Each follicle is surrounded by basement membrane, and between them are parafollicular cells containing calcitonin-secreting C cells.

Physiology

Synthesis

The thyroid synthesizes two hormones:

- triiodothyronine (T_3), which acts at the cellular level
- L-thyroxine (T_4), which is the prohormone.

Inorganic iodide is trapped by the gland via an enzyme-dependent system, oxidized, and incorporated into the glycoprotein thyroglobulin to form mono- and diiodotyrosine and then T_4 and T_3 (Fig. 34.21).

More T_4 than T_3 is produced, but T_4 is converted in some peripheral tissues (liver, kidney and muscle) to the more active T_3 by 5′-monodeiodination; an alternative 3′-monodeiodination yields the inactive reverse T_3 (rT_3). The latter step occurs particularly in severe non-thyroidal illness (see later).

In plasma, more than 99% of all T_4 and T_3 is bound to hormone-binding proteins (thyroxine-binding globulin, TBG; thyroid-binding prealbumin, TBPA; and albumin). Only free hormone is available for action in the target tissues, where T_3 binds to specific nuclear receptors within target cells. Many drugs and other factors affect TBG; all may result in confusing total T_4 levels in blood, and most laboratories therefore now measure free T_4 levels.

Control of the hypothalamic–pituitary–thyroid axis

Thyrotrophin-releasing hormone (TRH), a peptide produced in the hypothalamus, stimulates the pituitary to secrete thyroid-stimulating

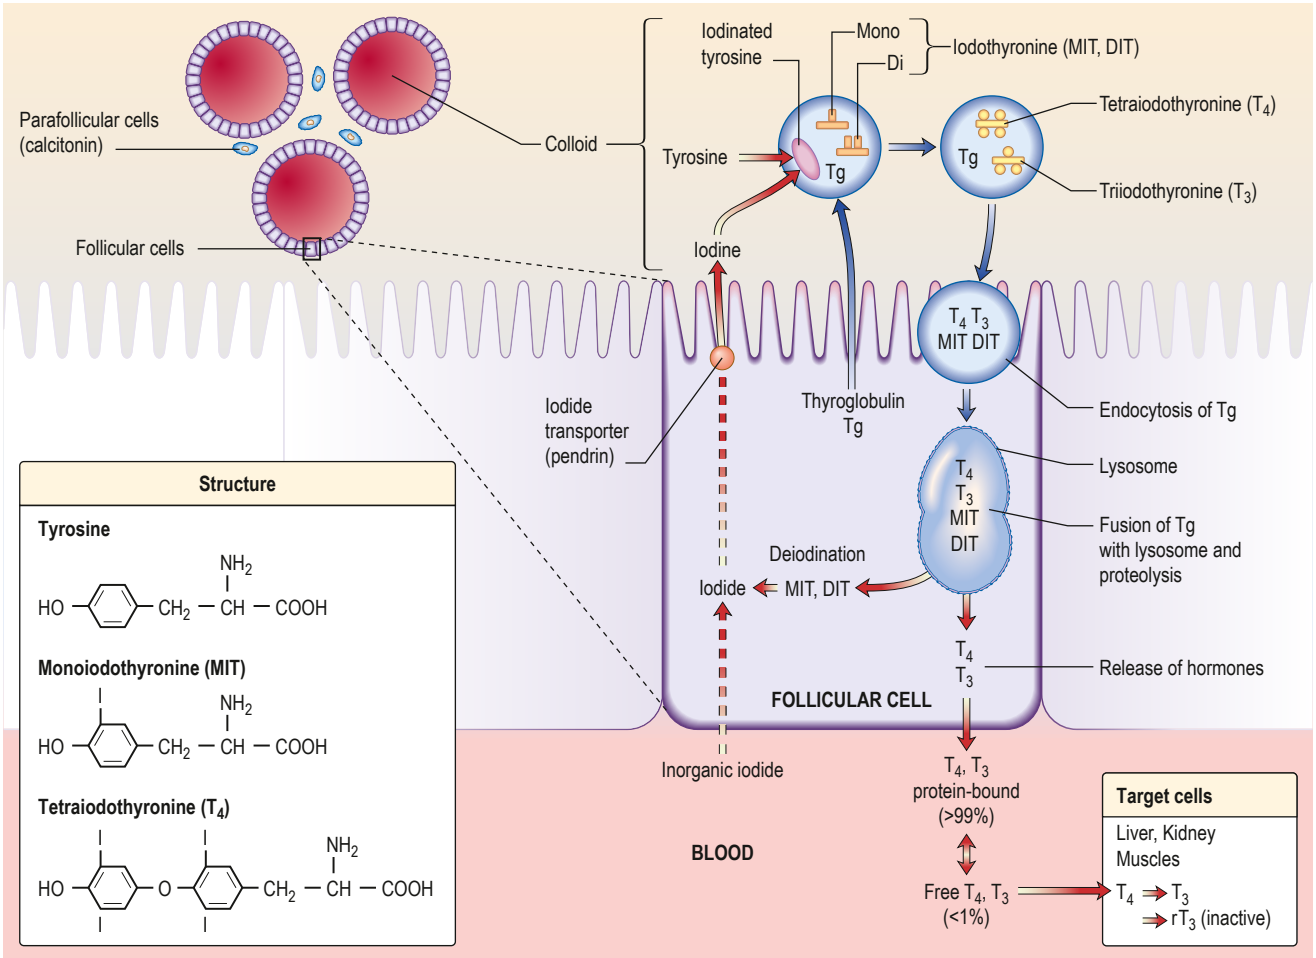

Fig. 34.21 Synthesis and metabolism of the thyroid hormones. *Tg,* Thyroglobulin.

Box 34.24 Hormones and receptors of the hypothalamic–pituitary–thyroid axis

hormone (TSH) (see **Fig. 34.2**). TSH, in turn, stimulates growth and activity of the thyroid follicular cells via the G-protein-coupled TSH membrane receptor (**Box 34.24**). The T_3 and T_4 subsequently secreted into the circulation by follicular cells exert negative feedback on the hypothalamus, as described in the 'Dynamic endocrine tests' section.

Circulating T_4 is peripherally deiodinated to T_3, which binds to the thyroid hormone nuclear receptor (TR) on target organ cells to cause modified gene transcription. There are two TR receptors (TR-α and TR-β) and the tissue-specific effects of T_3 are dependent on the local expression of these TR receptors. TR-α knockout mice show poor growth, bradycardia, and hypothermia, while TR-β knockout mice show thyroid hyperplasia and high T_4 levels in the presence of inappropriately normal circulating TSH, suggesting a role for the latter receptors in thyroid hormone resistance (see 'Thyroid hormone resistance' section).

Physiological effects of thyroid hormones

The physiological effects of thyroid hormones are summarized in **Box 34.25**.

Box 34.25 Physiological effects of thyroid hormone

Target	Effect
Cardiovascular system	Increases heart rate and cardiac output
Bone	Increases bone turnover and resorption
Respiratory system	Maintains normal hypoxic and hypercapnic drive in respiratory centre
Gastrointestinal system	Increases gut motility
Blood	Increases red blood cell 2,3-BPG[a], facilitating oxygen release to tissues
Neuromuscular function	Increases speed of muscle contraction/relaxation and muscle protein turnover
Carbohydrate metabolism	Increases hepatic gluconeogenesis/ glycolysis and intestinal glucose absorption
Lipid metabolism	Increases lipolysis and cholesterol synthesis and degradation
Sympathetic nervous system	Increases catecholamine sensitivity and β-adrenergic receptor numbers in heart, skeletal muscle, adipose cells, and lymphocytes Decreases cardiac α-adrenergic receptors

[a]2,3-BPG, 2,3-bisphosphoglyceric acid.

Dietary iodine requirement

Globally, dietary iodine deficiency is a major cause of thyroid disease, as iodine is an essential requirement for thyroid hormone synthesis. The recommended daily intake of iodine should be at least 140 μg, and dietary supplementation of salt and bread has reduced the number of areas where 'endemic goitre' still occurs (see later).

Investigations: thyroid function tests

Immunoassays for free T_4, free T_3, and TSH are widely available. There are only minor circadian rhythms and measurements may be made at any time. Particular uses of the tests are summarized in **Box 34.26**, with typical findings in common disorders.

TSH measurement

In most circumstances, TSH levels can discriminate between hyperthyroidism, hypothyroidism, and euthyroidism (normal thyroid gland function). Exceptions are hypopituitarism, and the 'sick euthyroid' syndrome, where low levels (which normally imply hyperthyroidism) occur in the presence of low or normal T_4 and T_3 levels. As a single test of thyroid function, TSH measurement is the most sensitive in most circumstances, but accurate diagnosis requires at least two tests: for example, TSH plus free T_4 or free T_3 where hyperthyroidism is suspected; TSH plus serum free T_4 where hypothyroidism is likely.

TRH test

This has been rendered almost obsolete by modern sensitive TSH assays, except for investigation of HP dysfunction. TRH (protirelin) is occasionally used to differentiate between thyroid hormone resistance and a pituitary TSH-secreting tumour (TSHoma) in the context of raised fT_4 and TSH levels. Typically, after TRH administration, there is a rise in TSH in thyroid hormone resistance, while in TSHoma there is a flat response due to continued autonomous TSH secretion, which does not respond to TRH.

Problems in interpretation of thyroid function tests

There are three major areas of difficulty: serious acute or chronic illness, pregnancy and use of oral contraceptives, and certain drugs.

Serious acute or chronic illness

Thyroid function is affected in several ways:

- reduced concentration and affinity of binding proteins
- decreased peripheral conversion of T_4 to T_3 with more rT_3
- reduced HP TSH production.

Systemically ill patients can therefore have an apparently low total and free T_4 and T_3 with a normal or low basal TSH (the 'sick euthyroid' syndrome). Levels are usually only mildly below normal and are thought to be mediated by interleukins IL-1 and IL-6; the tests should be repeated after resolution of the underlying illness.

Box 34.26 Characteristics of blood thyroid function tests in common thyroid disorders[a]

	TSH (0.3–3.5 mU/L)	Free T_4 (10–25 pmol/L)	Free T_3 (3.5–7.5 pmol/L)
Thyrotoxicosis	**Suppressed (<0.05 mU/L)**	**Increased**	**Increased**
Primary hypothyroidism	Increased (>10 mU/L)	Low/low-normal	Normal or low
TSH deficiency	Low-normal or subnormal	**Low/low-normal**	Normal or low
T_3 toxicosis	Suppressed (<0.05 mU/L)	Normal	**Increased**
Compensated euthyroidism	**Slightly increased (5–10 mU/L)**	**Normal**	Normal

TSH, Thyroid-stimulating hormone.
[a]The clinically most informative tests in each situation are shown in **bold**.

Pregnancy and oral contraceptives

These lead to greatly increased TBG levels and thus to high or high-normal total T_4. Free T_4 is usually normal. Normal ranges for free T_4 and TSH alter with the normal physiological changes during pregnancy and TSH is often slightly suppressed in the first trimester, but this rarely causes clinical problems. See Chapter 48 for management of thyroid disease in pregnancy.

Drugs

Amiodarone decreases T_4 to T_3 conversion and free T_4 levels may therefore be above normal in a euthyroid patient; conversely, amiodarone may induce both hyper- and hypothyroidism—the TSH level is usually reliable.

Many drugs affect thyroid function tests by interfering with protein binding but this now rarely causes a problem with free T_4 assays.

Anti-thyroid antibodies

Serum antibodies to the thyroid are common.

- ***Destructive antibodies*** are directed against the microsomes or against thyroglobulin; the antigen for thyroid microsomal antibodies is the thyroid peroxidase (TPO) enzyme. TPO antibodies are found in up to 20% of the normal population, especially older women, but only 10%–20% of these develop overt hypothyroidism.
- ***TSH receptor IgG antibodies (TRAb)*** typically stimulate, but occasionally block, the receptor. They are specific for Graves' disease.

Hypothyroidism

Pathophysiology

Underactivity of the thyroid is usually primary, caused by disease of the thyroid, but may be secondary to HP disease (reduced TSH drive) (**Box 34.27**). Primary hypothyroidism is one of the most common endocrine conditions, with an overall UK prevalence of over 2% in women but under 0.1% in men; lifetime prevalence for an individual is higher—perhaps as high as 9% for women and 1% for men, with mean age at diagnosis around 60 years. The worldwide prevalence of subclinical hypothyroidism varies from 1% to 10%.

Box 34.27 Causes of hypothyroidism

Primary disease of thyroid

Congenital

Hypopituitarism
- Isolated TSH deficiency

Peripheral resistance to thyroid hormone

Aetiology of primary hypothyroidism

See **Box 34.27**.

Autoimmune

Atrophic (autoimmune) hypothyroidism

This is the most common cause of hypothyroidism and is associated with anti-thyroid autoantibodies, leading to lymphoid infiltration of the gland and eventual atrophy and fibrosis. It is six times more common in females and the incidence increases with age. The condition is associated with other autoimmune diseases, such as pernicious anaemia, vitiligo, and other endocrine deficiencies. Occasionally, intermittent hypothyroidism occurs with subsequent recovery; antibodies that block the TSH receptor may sometimes be involved in the aetiology.

Hashimoto's thyroiditis

This form of autoimmune thyroiditis, again more common in women and most common in late middle age, produces atrophic changes with regeneration, leading to goitre formation. The gland is usually firm and rubbery but may range from soft to hard. TPO antibodies are present, often in very high titres (>1000 IU/L). Patients may be hypothyroid or euthyroid, though they may go through an initial toxic phase, 'Hashi-toxicity'. Levothyroxine therapy may shrink the goitre, even when the patient is not hypothyroid.

Postpartum thyroiditis

This is usually a transient phenomenon observed following pregnancy. It may cause hyperthyroidism, hypothyroidism, or the two sequentially. It is believed to result from the modifications to the immune system necessary in pregnancy, and histologically is a lymphocytic thyroiditis. The process is normally self-limiting, but when conventional antibodies are found there is a high chance of this proceeding to permanent hypothyroidism. Postpartum thyroiditis may be misdiagnosed as postnatal depression, emphasizing the need for thyroid function tests in this situation. See Chapter 48.

Defects of hormone synthesis

Iodine deficiency

Dietary iodine deficiency still exists as 'endemic goitre' in some areas where goitre, occasionally massive, is common. The patients may be euthyroid or hypothyroid, depending on the severity of iodine deficiency. The mechanism is thought to be borderline hypothyroidism, leading to TSH stimulation and thyroid enlargement in the face of continuing iodine deficiency. Iodine deficiency is still a problem in the

Netherlands, Western Pacific, India, South-east Asia, Russia, and parts of Africa. Efforts to prevent deficiency by providing iodine in salt continue worldwide but often with incomplete success, and iodine deficiency continues to cause a high prevalence of congenital hypothyroidism (cretinism) in some parts of India.

Dyshormonogenesis

This rare condition is due to genetic defects in the synthesis of thyroid hormones; patients develop hypothyroidism with goitre. One particular familial form is associated with sensorineural deafness due to a deletion mutation in chromosome 7, causing a defect of the transporter pendrin (Pendred's syndrome) (see Fig. 34.21).

History and examination

Hypothyroidism produces many symptoms (Fig. 34.22). The alternative term 'myxoedema' refers to the accumulation of mucopolysaccharide in subcutaneous tissues. The classic picture of the slow, dry-haired, thick-skinned, deep-voiced patient with weight gain, cold intolerance, bradycardia, and constipation makes the diagnosis easy. Milder symptoms are, however, more common and hard to distinguish from other causes of non-specific tiredness. Many cases are detected on biochemical screening.

Special difficulties in diagnosis may arise in certain circumstances:

- ***Children with hypothyroidism*** may not show classic features but often have a slow growth velocity, poor school performance, and sometimes arrest of pubertal development.
- ***Young women with hypothyroidism*** may not show obvious signs. Hypothyroidism should be excluded in all people with oligomenorrhoea/amenorrhoea, menorrhagia, infertility, or hyperprolactinaemia.
- ***The elderly*** show many clinical features that are difficult to differentiate from normal ageing. Hypothyroidism should be excluded in elderly patients with cognitive impairment.

Investigation of primary hypothyroidism

Serum TSH is the investigation of choice; a high TSH level confirms primary hypothyroidism. A low free T_4 level confirms the hypothyroid state (and is also essential to exclude TSH deficiency if clinical hypothyroidism is strongly suspected and TSH is normal or low).

Thyroid and other organ-specific antibodies may be present. Other abnormalities include the following:

- ***anaemia***, which is usually normochromic and normocytic but, where co-morbidity exists, may be macrocytic (sometimes this is due to associated pernicious anaemia) or microcytic (in women, due to menorrhagia or undiagnosed coeliac disease)
- ***increased serum aspartate transferase levels***, from muscle and/or liver
- ***increased serum creatine kinase levels***, with associated myopathy
- ***hypercholesterolaemia*** and ***hypertriglyceridaemia***
- ***hyponatraemia*** due to an increase in AVP and impaired free water clearance.

Management

Replacement therapy

Replacement therapy with levothyroxine (thyroxine, i.e., T_4) is given for life. The starting dose will depend upon the severity of the deficiency and on the age and fitness of the patient, especially their cardiac performance: 100 μg daily for the young and fit, 50 μg (increasing to 100 μg after 2–4 weeks) for the small, old, or frail. People with ischaemic heart disease require even lower initial doses, especially if the hypothyroidism is severe and longstanding. Most physicians would then begin with 25 μg daily and perform serial electrocardiograms (ECGs), increasing the dose at 3- to 4-week intervals if angina does not occur or worsen, and the ECG does not deteriorate. Occasional patients develop 'thyrotoxic' (hyperthyroid) symptoms despite normal fT_4 levels if the dose is increased too rapidly. It is unclear whether replacement with liothyronine (T_3) as monotherapy or with levothyroxine is beneficial to patients.

Symptoms

General
Tiredness/malaise
Weight gain
Cold intolerance
Change in appearance
Goitre

Depression
Psychosis
Coma
Poor memory

Hair – dry, brittle, unmanageable
Skin – dry, coarse

Arthralgia
Myalgia
Muscle weakness/stiffness
Poor libido
Puffy eyes
Deafness
Constipation
Anorexia

Signs

Mental slowness
Psychosis/dementia
Ataxia
Poverty of movement
Deafness

'Peaches and cream' complexion
Dry thin hair
Loss of eyebrows

Hypertension
Hypothermia
Heart failure
Bradycardia
Pericardial effusion

Cold peripheries
Carpal tunnel syndrome
Oedema

Periorbital oedema
Deep voice
(Goitre)

Dry skin
Mild obesity

Myotonia
Muscular hypertrophy
Proximal myopathy
Slow-relaxing reflexes

Anaemia

Fig. 34.22 Hypothyroidism: symptoms and signs. ***Bold italic*** type indicates symptoms or signs of greater discriminant value. A history from a relative is often revealing. Symptoms of other autoimmune disease may be present.

Monitoring

The aim is to restore T_4 and TSH to well within the normal range. Adequacy of replacement is assessed clinically and by thyroid function tests after at least 6 weeks on a steady dose. If serum TSH remains high, the dose of T_4 should be increased in increments of 25–50 μg, and the tests repeated at 6–8-week intervals until TSH becomes normal, ideally in the lower third of the normal range. Complete suppression of TSH should be avoided because of the risk of atrial fibrillation and osteoporosis. The usual maintenance dose is 100–150 μg given as a single daily dose. An annual thyroid function test is recommended—this is usually performed in the primary care setting, often assisted and prompted by district 'thyroid registers'.

Clinical improvement on T_4 may not begin for 2 weeks or more, and full resolution of symptoms may take 6 months. The necessity for lifelong therapy must be emphasized and the possibility of other autoimmune endocrine disease developing, especially Addison's disease or pernicious anaemia, should be considered. During pregnancy, an increase in T_4 dosage of about 25–50 μg is often needed to maintain relatively stricter TSH range of 0.3–2.5 mU/L, and the necessity for optimal replacement during pregnancy is emphasized by the finding of reductions in cognitive function in children of mothers with elevated TSH during pregnancy.

In cases where there is difficulty normalizing the TSH, compliance issues, concurrent medication that can interfere with thyroxine absorption (such as iron, calcium compounds and proton pump inhibitors), and undiagnosed coeliac disease should be considered.

A few people with primary hypothyroidism complain of incomplete symptomatic response to T_4 replacement. Combination T_4 and T_3 replacement has been advocated in this context, but randomized clinical trials show no consistent benefit in quality-of-life symptoms.

Borderline hypothyroidism or 'compensated euthyroidism'

Patients are frequently seen with low-normal serum T_4 levels and slightly raised TSH levels. Treatment with levothyroxine is normally recommended where the TSH is consistently above 10 mU/L, or when possible symptoms, high-titre thyroid antibodies, or lipid abnormalities are present. Where the TSH is only marginally raised, the tests should be repeated 3–6 months later, as a significant proportion will be normal on repeat testing. Conversion to overt hypothyroidism is more common in men or when TPO antibodies are present. In practice, vague symptoms in people with marginally elevated TSH (below 10 mU/L) rarely respond to treatment, but a 'therapeutic trial' of replacement may be needed to confirm that symptoms are unrelated to the thyroid. It is also considered best to normalize TSH during (and ideally before) pregnancy to avoid potential fetal adverse effects.

Myxoedema coma

Severe hypothyroidism, especially in the elderly, may present with confusion or even coma. Myxoedema coma is very rare; hypothermia is often present and the patient may have severe cardiac failure, pericardial effusions, hypoventilation, hypoglycaemia, and hyponatraemia. The mortality was previously at least 50% and patients require full intensive care. Optimal treatment is controversial and data are lacking; most physicians would advise T_3 orally or intravenously in doses of 2.5–5 μg every 8 hours, then increasing as above. Large intravenous doses should not be used. Additional measures, though unproven, should include:

- oxygen (by ventilation if necessary)
- monitoring of cardiac output and pressures
- gradual rewarming
- hydrocortisone 100 mg i.v. 8-hourly
- glucose infusion to prevent hypoglycaemia.

'Myxoedema madness'

Depression is common in hypothyroidism. Rarely, with severe hypothyroidism in the elderly, the patient may become frankly demented or psychotic, sometimes with striking delusions. This may occur shortly after starting T_4 replacement.

Screening for hypothyroidism

The incidence of ***congenital*** hypothyroidism is approximately 1 in 3500 births. Untreated, severe hypothyroidism produces permanent neurological and intellectual damage ('cretinism'). Routine screening of the newborn using a blood spot, as in the Guthrie test, to detect a high TSH level as an indicator of primary hypothyroidism is efficient and cost-effective; cretinism is prevented if T_4 is started within the first few months of life.

Screening of ***elderly*** patients for thyroid dysfunction has a low pick-up rate, is controversial, and is not currently recommended unless as part of a confusion screen. However, patients who have undergone thyroid surgery or received radio-iodine should have regular thyroid function tests, as should those receiving lithium or amiodarone therapy.

Hyperthyroidism

Hyperthyroidism (thyroid overactivity, thyrotoxicosis) is common, affecting perhaps 2%–5% of all females at some time and having a sex ratio of 5:1; it most often occurs between the ages of 20 and 40 years. Nearly all cases (>99%) are caused by intrinsic thyroid disease; a pituitary cause is extremely rare (**Box 34.28**). Most common patterns of hyperthyroidism and their distinctive features are outlined in **Box 34.29**.

Graves' disease

This is the most common cause of hyperthyroidism and is due to an autoimmune process. Serum IgG antibodies bind to TSH receptors in the thyroid, stimulating thyroid hormone production; that is, they behave like TSH. These TSH receptor antibodies (TSHR-Ab) are specific for Graves' disease. Persistent high levels predict a relapse when drug treatment is stopped. There is an association with HLA-B8, DR3, and DR2; the concordance rate among monozygotic twins is 50% and that in dizygotic twins is 5%. There is an association with cytotoxic T lymphocyte-associated antigen 4

? Box 34.28 Causes of hyperthyroidism

Common
- Graves' disease (autoimmune)
- Toxic multinodular goitre
- Solitary toxic nodule/adenoma

Uncommon
- Acute thyroiditis
  - Viral (e.g., de Quervain's)
  - Autoimmune
  - Post-irradiation
  - Postpartum
- Gestational thyrotoxicosis (HCG-stimulated)
- Neonatal thyrotoxicosis (maternal thyroid antibodies)
- Exogenous iodine
- Drugs—amiodarone, immunotherapy (ipilimumab, pembrolizumab, nivolumab)
- Thyrotoxicosis factitia (secret T_4 consumption)

Rare
- TSH-secreting pituitary tumours
- Metastatic differentiated thyroid carcinoma
- HCG-producing tumours
- Hyperfunctioning ovarian teratoma (struma ovarii)

(CTLA-4), HLA-DRBP*08, and DRB3*0202 on chromosome 6. The mechanism of immune damage is illustrated in Fig. 3.16.

Yersinia enterocolitica, *Escherichia coli,* and other Gram-negative organisms contain TSH-binding sites. This raises the possibility that the initiating event in the pathogenesis may be an infection with possible 'molecular mimicry' in a genetically susceptible individual, but the precise initiating mechanisms remain unproven in most cases.

Thyroid eye disease is a feature of Graves' disease. It may accompany the hyperthyroidism in many cases but patients may also be euthyroid or hypothyroid. Other components of Graves' disease, such as Graves' dermopathy, are very uncommon. Rarely, lymphadenopathy and splenomegaly may occur. Graves' disease is also associated with other autoimmune disorders such as pernicious anaemia, vitiligo, and myasthenia gravis.

The natural history is one of fluctuation, with many patients showing a pattern of alternating relapse and remission; perhaps only 40% of subjects have a single episode. Many patients eventually become hypothyroid.

Other causes of hyperthyroidism/thyrotoxicosis

Solitary toxic adenoma/nodule

This is the cause of about 5% of cases of hyperthyroidism. While the hyperthyroidism will be controlled by anti-thyroid drugs, it does not usually remit after a course of anti-thyroid drugs.

Toxic multinodular goitre

This commonly occurs in older women. Again, anti-thyroid drugs are rarely successful in inducing a remission, although they can control the hyperthyroidism.

de Quervain's thyroiditis

This is transient hyperthyroidism from an acute inflammatory process, probably viral in origin. Apart from the toxicosis, there is usually fever, malaise, and pain in the neck with tachycardia and local thyroid tenderness. Thyroid function tests show initial hyperthyroidism, the erythrocyte sedimentation rate (ESR) and plasma viscosity are raised, and thyroid uptake scans show suppression of uptake in the acute phase. Hypothyroidism, usually transient, may then follow after a few weeks. Treatment of the acute phase is with aspirin, using short-term prednisolone in severely symptomatic cases.

Postpartum thyroiditis

This is described in Chapter 48.

Amiodarone-induced thyrotoxicosis

Amiodarone, a class III antiarrhythmic drug (see Chapter 17), causes two types of hyperthyroidism.

- ***Type I amiodarone-induced thyrotoxicosis (AIT)*** is associated with pre-existing Graves' disease or multinodular goitre. In this situation, hyperthyroidism is probably triggered by the high iodine content of amiodarone.
- ***Type II AIT*** is not associated with previous thyroid disease and is thought to be due to a direct effect of the drug on thyroid follicular cells, leading to a destructive thyroiditis with release of T_4 and T_3. Type II AIT may be associated with a hypothyroid phase several months after presentation. Because amiodarone inhibits the deiodination of T_4 to T_3, biochemical presentation of both types of AIT may be associated with higher T_4:T_3 ratios than usual.

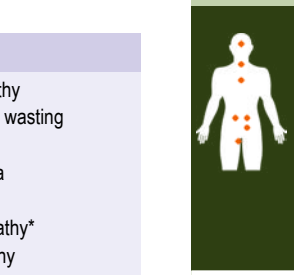
Immunotherapy-induced thyrotoxicosis

Cancer immunotherapy drugs that block negative regulators on T cell, called immune checkpoint inhibitors (ipilimumab, pembrolizumab, nivolumab), have been found to be effective in a wide range of cancers. These drugs cause immune-related adverse events (irAEs) in various organs, including in endocrine glands, resulting in thyroiditis (15%), hypophysitis (9%), adrenalitis (1%), and type 1 diabetes mellitus (<1%). Thyroiditis is the most common of endocrine irAEs and occurs between 3 and 12 weeks after initiation of the drug. Treatment is with beta-blockers, analgesia and, rarely, with anti-thyroid medication if thyrotoxicosis persists, especially with symptoms.

History and examination

The symptoms and signs of hyperthyroidism affect many systems (Fig. 34.23). Symptomatology and signs vary with age and with the underlying aetiology.

- ***The eye signs—lid lag and 'stare'***—may occur with hyperthyroidism of any cause but other features of thyroid eye disease (see below) occur only in Graves' disease.
- ***Graves' dermopathy*** is rare and can occur on any extensor surface. ***Pretibial myxoedema*** is the most commonly described and is an infiltration of the skin on the shin. ***Thyroid acropachy*** is very rare and consists of clubbing, swollen fingers, and periosteal new bone formation.
- ***In the elderly***, a frequent presentation is with atrial fibrillation, other tachycardias, and/or heart failure, often with few other



Symptoms
General
Weight loss
Irritability/behaviour change
Restlessness
Malaise
Itching
Sweating
Tall stature (in children)
Breathlessness
Palpitations
Heat intolerance
Stiffness
Muscle weakness
Tremor
Choreoathetosis
Thirst
Vomiting
Diarrhoea
Eye complaints*
Oligomenorrhoea
Loss of libido
Gynaecomastia
Onycholysis
Goitre
*Only in Graves' disease

Signs	
Tremor	Proximal myopathy
Hyperkinesis	Proximal muscle wasting
Psychosis	Onycholysis
	Palmar erythema
Tachycardia or atrial fibrillation	Graves' dermopathy*
Full pulse	Thyroid acropachy
Warm vasodilated peripheries	Pretibial myxoedema
Systolic hypertension	
Cardiac failure	
Exophthalmos*	
Lid lag and 'stare'	
Conjunctival oedema	
Ophthalmoplegia*	
Periorbital oedema	
Goitre, bruit	
Weight loss	
*Only in Graves' disease	

Fig. 34.23 Hyperthyroidism: symptoms and signs. ***Bold italic*** type indicates symptoms or signs of greater discriminant value.

signs. Thyroid function tests are mandatory in any patient with atrial fibrillation.

- ***Children*** frequently present with excessive height or excessive growth rate, or with behavioural problems such as hyperactivity. They may also show weight gain rather than loss.
- ***So-called 'apathetic thyrotoxicosis'*** in some elderly patients presents with a clinical picture more like that of hypothyroidism. There may be very few signs and a high degree of clinical suspicion is essential.

Differential diagnosis

Clinical differentiation from anxiety states may be difficult; useful positive clinical markers are weight loss, eye signs, a diffuse goitre, proximal myopathy with wasting, and evidence of a hyperdynamic circulation.

Investigations

- ***Serum TSH*** is suppressed in hyperthyroidism (<0.05 mU/L), except for the very rare instances of TSH hypersecretion.
- ***A raised free T_4 or T_3*** confirms the diagnosis; T_4 is almost always raised but T_3 is more sensitive, as there are occasional cases of isolated 'T_3 toxicosis'.
- ***TSH receptor stimulating antibodies (TSHR-Ab)*** are now measured routinely and the third-generation tests are 97%–99% specific for Graves' disease.
- ***Thyroid peroxidase (TPO)*** and thyroglobulin antibodies are present in 80% of cases of Graves' disease but are also found in normal individuals.
- ***Scintiscan ^{99}Tm*** is used in patients who are antibody negative to look for toxic nodular disease.

Management

Three possibilities are available: anti-thyroid drugs, radio-iodine, and surgery. Practices and beliefs differ widely within and between countries.

Anti-thyroid drugs

Carbimazole is most often used in the UK, and propylthiouracil (PTU) is also an option. ***Thiamazole*** (methimazole), the active metabolite of carbimazole, is used in the USA. These drugs inhibit the formation of thyroid hormones and also have other minor actions; carbimazole/thiamazole is also an immunosuppressive agent. Initial doses and side-effects are detailed in **Box 34.30**.

Although thyroid hormone synthesis is reduced very quickly, the long half-life of T_4 (7 days) means that clinical benefit is not apparent for 10–20 days.

As many of the manifestations of hyperthyroidism are mediated via the sympathetic system, ***beta-blockers*** are used to provide rapid partial symptomatic control; they also decrease peripheral conversion of T_4 to T_3. Preferred drugs are those without intrinsic sympathomimetic activity, e.g., propranolol (see **Box 34.30**). They should not be used alone for hyperthyroidism except when the condition is self-limiting, as in subacute thyroiditis.

Subsequent management is either by gradual dose titration or by a 'block and replace' regimen. Neither regimen has been shown to be unequivocally superior. TSH often remains suppressed for

Box 34.30 Drugs used in the treatment of hyperthyroidism

Drug	Usual starting dose	Side-effects	Remarks
Anti-thyroid drugs			
Carbimazole	20–40 mg daily, 8-hourly or in single dose	Rash, nausea, vomiting, arthralgia, agranulocytosis (0.1%), jaundice	Active metabolite is thiamazole (methimazole) Mild immunosuppressive activity
Propylthiouracil (PTU)	100–200 mg 8-hourly	Rash, nausea, vomiting, agranulocytosis, hepatotoxicity	Additionally blocks conversion of T_4 to T_3
Beta-blocker for symptomatic control			
May need higher doses than normal			
Propranolol	40–80 mg every 6–8 h		Avoid in asthma Use agents without intrinsic sympathomimetic activity as receptors are highly sensitive

many months after clinical improvement and normalization of T_4 and T_3.

Dosage regimen

Gradual dose titration

1. Start carbimazole 20–40 mg daily alongside propranolol for symptomatic control.
2. Review after 4–6 weeks and reduce the dose of carbimazole, depending on clinical state and fT_4/fT_3 levels. TSH levels may remain suppressed for several months and are unhelpful at this stage.
3. When the patient is clinically and biochemically euthyroid, stop beta-blockers.
4. Review thyroid function regularly during the planned course of treatment (typically 18 months—but some use courses between 6 and 24 months).
5. Reduce carbimazole if fT_4 falls below or TSH rises above normal, and when approaching the end of the planned course.
6. Increase carbimazole if fT_4 or fT_3 is above normal (and consider if TSH remains suppressed after several months with a normal fT_4).
7. Stop treatment at the end of the course if the patient is euthyroid on 5 mg daily carbimazole. PTU is used in a similar fashion (see **Box 34.30**).

'Block and replace' regimen

With this policy, full doses of anti-thyroid drugs, usually carbimazole 40 mg daily, are given to suppress the thyroid completely while replacing thyroid activity with 100 μg of levothyroxine daily once euthyroidism has been achieved. This is continued usually for 18 months, the claimed advantages being the avoidance of over- or undertreatment and the better use of the immunosuppressive action of carbimazole. This regimen is contraindicated in pregnancy, as T_4 crosses the placenta less well than carbimazole.

Relapse

About 50% of patients will relapse after a course of carbimazole or PTU, mostly within the following 2 years but occasionally much later. Long-term anti-thyroid therapy is then used, or surgery or radiotherapy is considered (see below). Most patients (90%) with hyperthyroidism have a diffuse goitre, but those with large single or multinodular goitres are unlikely to remit after a course of anti-thyroid drugs and will usually require definitive treatment. Severe biochemical hyperthyroidism is also less likely to remain in remission.

Toxicity

The major side-effect of drug therapy is agranulocytosis, which occurs in approximately 1 in 1000 patients, usually within 3 months of treatment. All patients must be warned to seek immediate medical attention and to have a check of their white blood cell count if they develop unexplained fever or sore throat; written information is essential. Rashes are more frequent and usually require a change of drug. If toxicity occurs on carbimazole, PTU may be used, and vice versa; side-effects are only occasionally repeated on the other drug.

Radioactive iodine

Radioactive iodine (RAI) is given to patients of all ages, although it is contraindicated in pregnancy and while breast-feeding. RAI is the most common treatment modality in the USA, whereas anti-thyroid drugs tend to be favoured in Europe.

^{131}Iodine is given in an empirical dose (usually 400–550 MBq) because of variable uptake and radiosensitivity of the gland. It accumulates in the thyroid and destroys the gland by local radiation, although it takes several months to be fully effective.

Patients must be rendered euthyroid before treatment. They should stop anti-thyroid drugs at least 4 days before radio-iodine, and not recommence until 3 days after radio-iodine. Patients on PTU should stop anti-thyroid medication before RAI earlier than those on carbimazole because it has a radioprotective action. Many patients do not need to restart anti-thyroid medication after treatment.

Early discomfort in the neck and immediate worsening of hyperthyroidism are sometimes seen. If worsening occurs, the patient should receive propranolol (see **Box 34.30**); if necessary, carbimazole can be restarted. Euthyroidism normally returns in 2–3 months. People with dysthyroid eye disease are more likely to show worsening of eye problems after radio-iodine than after anti-thyroid drugs; this represents a partial contraindication to RAI, although worsening can usually be prevented by steroid administration.

Long-term surveillance

Hypothyroidism affects the majority of subjects over the following 20 years. Some 75% of patients are rendered euthyroid in the short term, but a small proportion remain hyperthyroid and may require a second dose of radio-iodine. Long-term surveillance of thyroid function is necessary, with frequent tests in the first year after therapy and at least annually thereafter.

There is no increased risk of malignancy after RAI.

Surgery

Thyroidectomy should be performed only in patients who have previously been rendered euthyroid. Conventional practice is to stop

the anti-thyroid drug 10–14 days before operation and to give potassium iodide (60 mg three times daily), which reduces the vascularity of the gland and reduces thyroid hormone synthesis by inhibiting organification of iodine (Wolff–Chaikoff effect).

The operation should be performed only by experienced surgeons to reduce the chance of complications:

- Early postoperative bleeding causing tracheal compression and asphyxia is a rare emergency that mandates immediate removal of all clips/sutures to allow escape of the blood/haematoma.
- Laryngeal nerve palsy occurs in 1%. Vocal cord movement should be checked preoperatively. Mild hoarseness is more common and thyroidectomy is best avoided in professional singers.
- Transient hypocalcaemia occurs in up to 10% but with permanent hypoparathyroidism in fewer than 1%.
- Ongoing thyroid function depends on the operation performed. With a single toxic nodule, excision of the lesion is curative. With Graves' disease or multinodular goitre, the traditional 'subtotal' thyroidectomy, aiming for euthyroidism on no treatment, results in recurrent hyperthyroidism in 1%–3% within 1 year, then 1% per year and hypothyroidism in about 10% of patients within 1 year, and then increasing with time. 'Near-total' thyroidectomy is therefore now preferred, with inevitable hypothyroidism but a much-reduced risk of recurrence.

  Indications for either surgery or radio-iodine are given in **Box 34.31**.

Special situations in hyperthyroidism

Thyroid crisis or 'thyroid storm'

This rare condition, with a mortality of 10%, is a rapid deterioration of hyperthyroidism with hyperpyrexia, severe tachycardia, extreme restlessness, cardiac failure, and liver dysfunction. It is usually precipitated by stress, infection, or surgery in an unprepared patient, or by radio-iodine therapy. With careful management, it should no longer occur and most cases referred to as a 'crisis' are simply severe but uncomplicated thyrotoxicosis.

Treatment is urgent. Propranolol in full doses is started immediately together with potassium iodide, anti-thyroid drugs, corticosteroids (which suppress many of the manifestations of hyperthyroidism) and full supportive measures. Control of cardiac failure and tachycardia is also necessary.

Occasionally, hyperthyroidism can lead to a thyrotoxic cardiomyopathy, which causes ischaemic changes on a 12-lead ECG; these reverse after euthyroidism is achieved (**Fig. 34.24**).

Hyperthyroidism in pregnancy and neonatal life

This is covered in Chapter 48.

Thyroid hormone resistance

Thyroid hormone resistance is an inherited condition, caused by an abnormality of the thyroid hormone receptor. Mutations to the receptor (TR β) result in the need for higher levels of thyroid hormones to achieve the same intracellular effect. As a result, the normal feedback control mechanisms (see **Fig. 34.2**) result in high blood levels of T_4 with a normal TSH in order to maintain a euthyroid state. This has two consequences:

- Thyroid function tests appear abnormal, even when the patient is euthyroid and requires no treatment. Specialist review is needed to differentiate this condition from hyperthyroidism due to inappropriate TSH secretion.
- Different tissues contain different thyroid hormone receptors and, in some families, receptors in certain tissues may have normal activity. In this case, the level of thyroid hormones to maintain euthyroidism at pituitary and hypothalamic levels (which controls secretion of TSH) may be higher than that required in other tissues such as heart and bone, so these tissues may exhibit 'thyrotoxic' effects in spite of a normal serum TSH. This 'partial thyroid hormone resistance' can be very difficult to manage effectively.

Thyroid hormone resistance is diagnosed on the basis of a raised T_4/T_3 in the context of a non-elevated TSH. The differential diagnosis of this pattern of blood results includes TSHoma and laboratory assay interference. There is evidence that there may be increased cardiovascular mortality in patients with thyroid hormone resistance, similar to those with hyperthyroidism.

Long-term consequences of hyperthyroidism

Long-term follow-up studies of hyperthyroidism show a slight increase in overall mortality, which affects all age groups, is not fully explained, and tends to occur in the first year after diagnosis. Thereafter, the only long-term risk of adequately treated hyperthyroidism appears to be an increased risk of osteoporosis. People with persistently suppressed TSH levels have an increased likelihood of developing atrial fibrillation, which may predispose to thromboembolic disease.

Box 34.31 Choice of surgery or radio-iodine therapy for hyperthyroidism

Indications for surgery or radio-iodine

- Patient choice
- Persistent drug side-effects
- Poor compliance with drug therapy
- Recurrent hyperthyroidism after drugs

Indications for surgery

- A large goitre, which is unlikely to remit after anti-thyroid medication

Graves' orbitopathy (ophthalmopathy)

Pathophysiology

Graves' orbitopathy is due to a specific immune response that causes retro-orbital inflammation (**Fig. 34.25**). Swelling and oedema of the extraocular muscles lead to limitation of movement and to proptosis, which is usually bilateral but can sometimes be unilateral. Ultimately, increased pressure on the optic nerve may cause optic atrophy. Histology of the extraocular muscles shows focal oedema and glycosaminoglycan deposition followed by fibrosis. The precise autoantigen that leads to the immune response remains to be

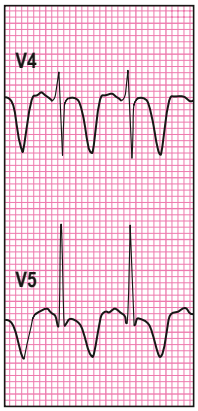


Fig. 34.24 Thyrotoxic cardiomyopathies. ECG showing marked lateral T-wave inversion.

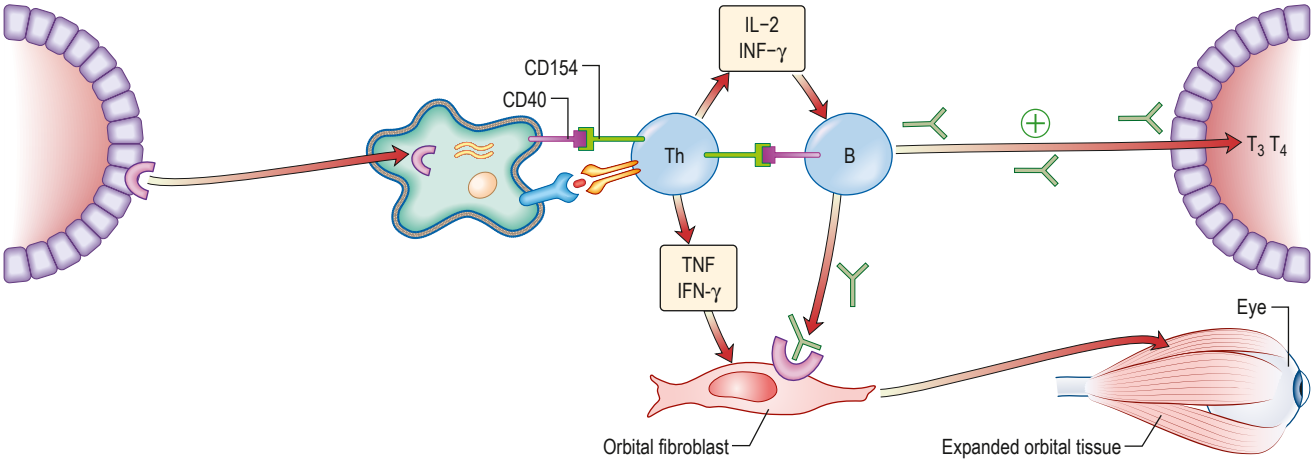

Fig. 34.25 Model of the initiation of thyrotrophin-receptor autoimmunity in Graves' ophthalmopathy and its consequences. Thyrotrophin receptor is internalized and degraded by antigen-presenting cells that present thyrotrophin-receptor peptides, in association with major histocompatibility complex (MHC) class II antigens, to helper T (Th) cells. These cells become activated, interact with autoreactive B cells through CD154–CD40 bridges, and secrete interleukin 2 (IL-2) and interferon-gamma (IFN-γ). These cytokines induce the differentiation of B cells into plasma cells that secrete anti-thyrotrophin-receptor antibodies. Anti-thyrotrophin-receptor antibodies *(green)* recognize the thyrotrophin receptor on orbital fibroblasts and, in conjunction with the secreted type 1 helper T cytokines, IFN-γ, and tumour necrosis factor (TNF), initiate the tissue changes characteristic of Graves' ophthalmopathy. These antibodies stimulate the thyrotrophin receptor on thyroid follicular epithelial cells, leading to hyperplasia and increased production of the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4). *(Adapted from Bahn RS. Graves' ophthalmology.* N Engl J Med *2010; 362:726–738.)*

identified, but it appears to be an antigen in retro-orbital tissue with similar immunoreactivity to the TSH receptor.

Eye disease is a manifestation of Graves' disease and can occur in patients who may be hyperthyroid, euthyroid, or hypothyroid. Thyroid dysfunction and orbitopathy usually occur within 2 years of each other, although sometimes a gap of many years is seen. TSH receptor antibodies are almost invariably found in the serum; their role in the pathogenesis is becoming clearer (see Fig. 34.25). Orbitopathy is more common and more severe in smokers.

Clinical features

The clinical appearances are characteristic (see Fig. 34.23) but thyroid eye disease demonstrates a wide range of severity. A high proportion of people with Graves' disease notice some soreness, painful watering, or prominence of the eyes, and the 'stare' of lid retraction is relatively common. More severe proptosis occurs in a minority of cases, and limitation and discomfort of eye movement and visual impairment due to optic nerve compression are relatively uncommon. Proptosis and lid retraction may limit the ability to close the eyes completely so that corneal damage may occur. There is periorbital oedema, and conjunctival oedema and inflammation.

Eye manifestations do not parallel the degree of biochemical thyrotoxicosis or the need for anti-thyroid therapy, but exacerbation of eye disease is more common after radio-iodine treatment (15% versus 3% on anti-thyroid drugs). Sight is threatened in only 5%–10% of cases, but the discomfort and cosmetic problems cause great patient anxiety.

Investigations

If the appearance is characteristic, consideration is needed as to whether the patient requires review by an ophthalmologist. Investigation includes:

- TSH, fT_3, and fT_4 measurement.
- MRI or CT of the orbits to exclude retro-orbital space-occupying lesions. In Graves' orbitopathy, there may be enlarged muscles and oedema, with a taut optic nerve due to raised intra-orbital pressure.
- Assessment of vision, particularly optic nerve function.

Management

If the patient is thyrotoxic, this should be treated, but treatment will not directly result in an improvement of the ophthalmopathy; hypothyroidism must be avoided, as it may exacerbate the eye problem. Smoking should be stopped. Treatment of the eyes may be either local or systemic and always requires close liaison between specialist endocrinologist and ophthalmologist:

- ***Methylcellulose or hypromellose eyedrops*** or ointment are given to aid lubrication and improve comfort.
- ***Sleeping upright*** affords some patients relief.
- ***Taping the eyelids*** ensures closure at night.
- ***Systemic steroids*** (prednisolone 30–120 mg daily) usually reduce inflammation if more severe symptoms are present. Pulse intravenous methylprednisolone may be used initially and is more rapidly effective in severe cases.
- ***Surgical decompression of the orbit(s)*** may be required, particularly if pressure of orbital contents on the optic nerve threatens vision (often called a 'hot' decompression) and at a later, stable stage for cosmetic reasons ('cold' decompression).
- ***Lid surgery*** will protect the cornea if lids cannot be closed and can be useful later for cosmetic reasons.
- ***Corrective eye muscle surgery*** may improve diplopia due to muscle changes; it should be deferred until the situation has been stable for 6 months and should follow any orbital decompression.
- ***Irradiation of the orbits*** (20 Gy in divided doses) is used in some centres. This reduces inflammation and ocular motility but has little effect on proptosis; its precise role is debated.

- ***Immunomodulatory agents*** may produce a response in some patients when conventional treatments fail, although clinical trial evidence is inconsistent.
- ***Selenium*** may have a beneficial effect on mild orbitopathy in some patients.

Goitre (thyroid enlargement)

Goitre is more common in women than in men and may be either physiological or pathological.

Clinical features

Goitres are present on examination in up to 9% of the population. Most commonly, a goitre is noticed as a cosmetic defect by the patient or by friends or relatives. The majority are painless, but pain or discomfort can occur in acute varieties. Large goitres can produce dysphagia and difficulty in breathing, implying oesophageal or tracheal compression.

A small goitre may be more easily visible (on swallowing) than palpable. Clinical examination should record the size, shape, consistency, and mobility of the gland, as well as whether its lower margin can be demarcated (thus implying the absence of retrosternal extension). A bruit may be present. Associated lymph nodes should be sought and the tracheal position determined if possible. Examination should never omit an assessment of the patient's clinical thyroid status.

Specific enquiry should be made about any medication, especially iodine-containing preparations, and possible exposure to radiation.

Particular points of note are as follows:

- Puberty and pregnancy may produce a diffuse increase in size of the thyroid.
- Pain in a goitre may be caused by thyroiditis, bleeding into a cyst, or (rarely) a thyroid tumour.
- Excessive doses of carbimazole or PTU will induce goitre.
- Iodine deficiency and dyshormonogenesis (see earlier) can also cause goitre.

Diagnosis

There are four major aspects to any goitre: its pathological nature, whether it is causing any compressive symptoms, the patient's thyroid status, and whether it is of cosmetic concern. The nature can often be judged clinically. Goitres (**Box 34.32**) are usually separable into diffuse and nodular types, the causes of which differ.

Box 34.32 Goitre: causes and types

Diffuse
- Simple:
  - Physiological (puberty, pregnancy)
- Autoimmune:
  - Graves' disease
  - Hashimoto's disease
- Thyroiditis:
  - Acute (de Quervain's thyroiditis)
- Iodine deficiency (endemic goitre)
- Dyshormonogenesis
- Goitrogens (e.g., sulphonylureas)

Nodular
- Multinodular goitre
- Solitary nodular
- Fibrotic (Riedel's thyroiditis)
- Cysts

Tumours
- Adenomas
- Carcinoma
- Lymphomas

Miscellaneous
- Sarcoidosis
- Tuberculosis

Diffuse goitre

Simple goitre

In this instance, no clear cause is found for enlargement of the thyroid, which is usually smooth and soft. It may be associated with thyroid growth-stimulating antibodies.

Autoimmune thyroid disease

Hashimoto's thyroiditis and Grave's disease thyrotoxicosis are both associated with firm diffuse goitre of variable size. A bruit is often present in thyrotoxicosis.

Thyroiditis

Acute tenderness in a diffuse swelling, sometimes with severe pain, is suggestive of an acute viral thyroiditis (de Quervain's). It may produce transient clinical hyperthyroidism with an increase in serum T_4.

Nodular goitres

Multinodular goitre

Most common is the multinodular goitre, especially in older patients. The patient is usually euthyroid but may have clinical hyperthyroidism or subclinical hyperthyroidism (suppressed or low TSH levels but normal free T_4 and T_3). Multinodular goitre is the most common cause of tracheal and/or oesophageal compression and can lead to laryngeal nerve palsy. It may also extend retrosternally (**Fig. 34.26**).

The classical 'multinodular goitre' is usually readily apparent clinically, but it should be noted that modern, high-resolution ultrasound frequently reports multiple small nodules in glands, which are clinically diffusely enlarged and associated with autoimmune thyroid disease. These nodules are also found in up to 40% of the normal population.

Solitary nodular goitre

Such a goitre presents a difficult problem of diagnosis. Malignancy should be of concern in any solitary nodule; however, the majority of such nodules are cystic or benign and, indeed, may simply be the largest nodule of a multinodular goitre. The diagnostic challenge is to differentiate the small minority of malignant nodules, which require surgery, from the majority of benign nodules, which do not. Sometimes, a history of rapid enlargement, associated lymph nodes, or pain may suggest an aggressive malignancy, but most thyroid cancers are painless and slow-growing, so investigations are paramount. Risk factors for malignancy include previous irradiation, longstanding iodine deficiency, and occasional familial cases.

Solitary toxic nodules are quite uncommon and may be associated with T_3 toxicosis.

Fibrotic goitre (Riedel's thyroiditis)

Fibrotic goitre is a rare condition, usually producing a 'woody' gland. It is associated with other midline fibrosis and is often difficult to distinguish from carcinoma, being irregular and hard. Clinical clues include systemic symptoms of inflammation and elevation in inflammatory markers; it has been shown to be an IgG4-related disease (see Chapter 6).

Malignancy

In addition to thyroid carcinomas (see later), the thyroid is rarely the site of a metastatic deposit or the site of origin of a lymphoma.

Investigations

Clinical findings will dictate the appropriate initial tests:

- ***Thyroid function tests*** should include measurement of TSH plus free T_4 or T_3 (see **Box 34.7**).

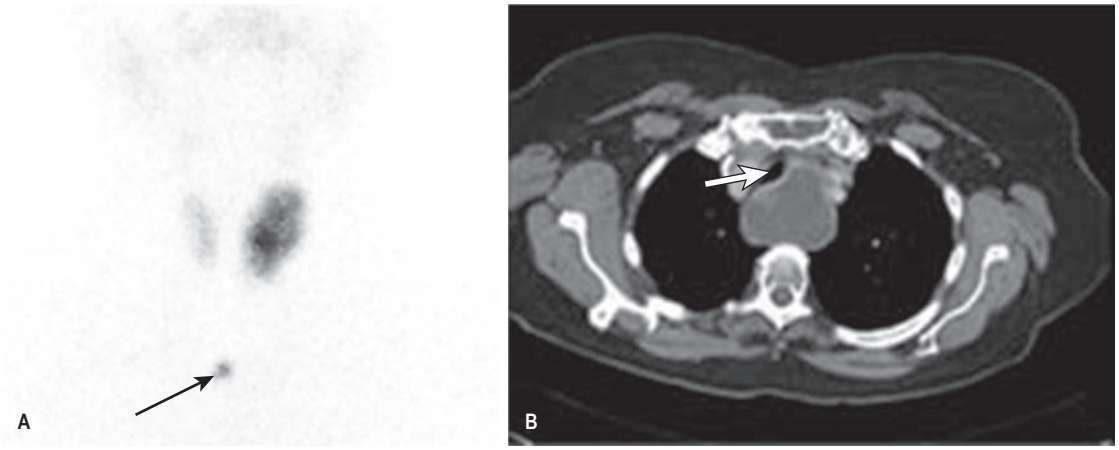

Fig. 34.26 Imaging of goitre. **(A)** Tc scan showing a multinodular goitre, with predominant involvement of the left lobe of the thyroid (anterior view with *arrowed* anatomical marker at the sternal notch). **(B)** Retrosternal goitre showing deviation and compression of the trachea *(arrowed)* on CT.

- ***Thyroid antibodies*** are assessed to exclude an autoimmune aetiology.
- ***Ultrasound*** with high resolution is a sensitive method for delineating nodules and can demonstrate whether they are cystic or solid. In addition, a multinodular goitre may be demonstrated when only a single nodule is palpable. Unfortunately, even cystic lesions can be malignant and thyroid tumours may arise within a multinodular goitre; therefore fine-needle aspiration (see below) is often required and is performed under ultrasound control at the same time as the scan.
- ***Chest and thoracic inlet X-rays or CT scan*** may detect tracheal compression and large retrosternal extensions in people with a very large goitre or clinical symptoms.
- ***Fine-needle aspiration (FNA)*** should be performed in the outpatient clinic or during ultrasound if the appearance is suggestive of potential malignancy, based on defined ultrasound criteria, as in people with a solitary nodule or a dominant nodule in a multinodular goitre, there is a 5% chance of malignancy. Cytology in expert hands can usually differentiate the suspicious or definitely malignant nodule. FNA reduces the necessity for surgery but there is a 5% false-negative rate, which must be borne in mind (and the patient appropriately counselled). Continued observation is required when an isolated thyroid nodule is assumed to be benign without excision.
- ***Thyroid scan*** (^{99m}Tc) can be useful to distinguish between functioning (hot) or non-functioning (cold) nodules. A hot nodule is only rarely malignant; however, a cold nodule is malignant in 10% of cases, and FNA has largely replaced isotope scans in the diagnosis of thyroid nodules.

Management

Euthyroid goitre

Many goitres are small, cause no symptoms, and can be observed (including self-monitoring by the patient in the long term). In particular, during puberty and pregnancy, a goitre associated with euthyroidism rarely requires intervention and the patient can be reassured that spontaneous resolution is likely. Indications for surgical intervention are:

- ***The possibility of malignancy.*** A positive or suspicious FNA makes surgery mandatory, and surgery may be necessary if doubt persists, even in the presence of a negative FNA (especially if the patient is concerned by the false-negative rate).
- ***Pressure symptoms on the trachea or, more rarely, the oesophagus.*** The possibility of retrosternal extension should be excluded.
- ***Cosmetic reasons.*** A large goitre often causes considerable anxiety to the patient, even though it is functionally and anatomically benign.

RAI has also been advocated for the treatment of euthyroid goitre, particularly when surgery is an unattractive option.

Toxic nodule

This is initially treated with anti-thyroid drugs but surgery or radioiodine is often required.

Thyroid cancer

Types of thyroid carcinoma, with their characteristics and treatment, are listed in **Box 34.33**. While not common, these tumours are responsible for 400 deaths annually in the UK and there is an annual incidence of 30 000 cases in the USA. Over 75% occur in women. They present in 90% of cases as thyroid nodules (see above), but occasionally with cervical lymphadenopathy (about 5%), or with lung, cerebral, hepatic, or bone metastases.

Carcinomas derived from thyroid epithelium may be papillary or follicular (differentiated) or anaplastic (undifferentiated). Medullary carcinomas (about 5% of all thyroid cancers) arise from the calcitonin-producing C cells. The pathogenesis of thyroid epithelial carcinomas is not understood, except for occasional familial papillary carcinoma, and those cases related to previous head and neck irradiation or ingestion of RAI (e.g., post-Chernobyl). These tumours are minimally active hormonally and are extremely rarely associated with hyperthyroidism; over 90%, however, secrete thyroglobulin, which can therefore act as a tumour marker after thyroid ablation.

Papillary and follicular carcinomas

The primary treatment is surgical: normally total or near-total thyroidectomy for local disease. Regional or more extensive neck dissection is needed where there is local nodal spread or involvement of local structures.

Most tumours will take up iodine, and UK and other guidelines currently recommend RAI ablation of residual thyroid tissue postoperatively for most people with differentiated thyroid cancer. After ablation of normal thyroid in this way, RAI may be used to localize

residual disease (scanning using low doses) or to treat it (using high doses: 5.5–7.5 GBq). When disease does recur, local invasion and lymph node involvement is most common, and lungs and bone are the most common sites of distant metastases.

To minimize risk of recurrence patients are treated with suppressive doses of levothyroxine (sufficient to suppress TSH levels below the normal range). Patient progress is monitored, both clinically and biochemically, using serum thyroglobulin levels as a tumour marker. The measurement of thyroglobulin is most sensitive when TSH is high but this requires the withdrawal of levothyroxine therapy. Recombinant TSH (thyrotropin alpha, rhTSH) 900 μg (2 doses over 48 h) is used to stimulate thyroglobulin without stopping levothyroxine therapy. Detectable thyroglobulin suggests recurrence, in which case whole-body ^{131}I scanning is required. Unfortunately, the presence of anti-thyroglobulin antibodies can make the assay unreliable.

The ***prognosis*** is extremely good when differentiated thyroid cancer is excised while confined to the thyroid gland, and the specific therapies available lead to a relatively good prognosis even in the presence of metastases at diagnosis. Accepted markers of high risk include greater age (>40 years), larger primary tumour size (>4 cm), and macroscopic invasion of capsule and surrounding tissues. Recently, oral sorafenib has shown a good short-term response in locally advanced and metastatic differentiated thyroid cancers that were refractory to RAI.

Medullary carcinoma

Medullary thyroid carcinoma (MTC) is a neuroendocrine tumour of the calcitonin-producing C cells of the thyroid. This condition is often associated with MEN 2 (see 'Diseases of many glands' section). Approximately 25% of patients diagnosed with MTC have a mutation of the *RET* proto-oncogene, although the other manifestations of MEN 2 may be absent, hence the importance of genetic counselling and family screening. People with MEN 2 mutations are advised to have a prophylactic thyroidectomy as early as 5 years of age to prevent the development of MTC.

Total thyroidectomy and wide lymph node clearance are usually indicated in MTC. Local invasion or metastasis is frequent, and the tumour responds poorly to treatment, although progression is often slow. Biological therapy with vandetanib and cabozantinib has shown benefit in advanced medullary thyroid carcinoma.

Box 34.33 Types of thyroid malignancy

Cell type	Frequency	Behaviour	Spread	Prognosis
Papillary	70%	Occurs in young people	Local, sometimes lung/bone secondaries	Good, especially in young
Follicular	20%	More common in females	Metastases to lung/bone	Good if resectable
Medullary cell	5%	Often familial	Local and metastases	Poor, but indolent course
Anaplastic	<5%	Aggressive	Locally invasive	Very poor
Lymphoma	2%	Variable		Sometimes responsive to radiotherapy

Anaplastic carcinomas and lymphoma

These typically do not respond to RAI, and external radiotherapy produces only a brief respite, although molecular-based treatments are proving promising.

HYPOTHALAMO–PITUITARY–GONADAL AXIS

The hypothalamo–pituitary–gonadal axis controls progress through puberty and the capacity for reproduction. Terminology in reproductive medicine is shown in **Box 34.34**.

Anatomy and physiology

Embryology

Up to 8 weeks of gestation, the sexes share a common development, with a primitive genital tract including the Wolffian and

Box 34.34 Definitions in reproductive medicine

Term	Definition
Erectile dysfunction	Inability of the male to achieve or sustain an erection adequate for satisfactory intercourse
Azoospermia	Absence of sperm in the ejaculate
Oligospermia	Reduced numbers of sperm in the ejaculate
Libido	Sexual interest or desire; often difficult to assess and greatly affected by stress, tiredness and psychological factors
Menarche	Age at first period
Primary amenorrhoea	Failure to begin spontaneous menstruation by age 16
Secondary amenorrhoea	Absence of menstruation for 3 months in a woman who has previously had cycles
Oligomenorrhoea	Irregular long cycles; often used for any length of cycle above 35 days
Dyspareunia	Pain or discomfort in the female during intercourse
Menstruation	Onset of spontaneous (usually regular) uterine bleeding in the female
Virilization	Occurrence of male secondary sexual characteristics in the female

Müllerian ducts. Additionally, there are a primitive perineum and primitive gonads.

- In the presence of a Y chromosome, the potential testis develops while the ovary regresses.
- In the absence of a Y chromosome, the potential ovary develops and related ducts form a uterus and the upper vagina.

Production of Müllerian inhibitory factor from the early 'testis' produces atrophy of the Müllerian duct, while, under the influence of testosterone and dihydrotestosterone, the Wolffian duct differentiates into an epididymis, vas deferens, seminal vesicles, and prostate. Androgens induce transformation of the perineum to include a penis, penile urethra, and scrotum containing the testes, which descend in response to androgenic stimulation. At birth, testicular volume is 0.5–1 mL. The number of oocytes in the ovaries of a female fetus has reached a maximum by the end of the second trimester of *in utero* development. At birth, the ovaries contain about 3 million oocytes, of which only 400 000 will remain by the time puberty occurs. With the onset of menarche, these oocytes will activate and grow, leading to ovulation and then menstruation.

Physiology

An outline of the hypothalamic–pituitary–gonadal axis is shown in Fig. 34.27.

Pulses of GnRH are released from the hypothalamus and stimulate LH and FSH release from the pituitary. LH and FSH are composed of two glycoprotein chains (α and β subunits). The α subunits are identical and are shared with TSH, while the β subunit confers specific biological activity (Box 34.35)

The male

1. LH stimulates testosterone production from Leydig cells of the testis.
2. Testosterone acts via nuclear androgen receptors, which interact with co-regulatory proteins to produce the appropriate tissue responses: progress through puberty, anabolism, and the maintenance of libido. It also acts locally within the testis to aid spermatogenesis. Testosterone circulates largely bound to sex-hormone-binding globulin (SHBG). Testosterone feeds back on the hypothalamus/pituitary to inhibit GnRH secretion.
3. FSH stimulates the Sertoli cells in the seminiferous tubules to produce mature sperm and the inhibins A and B.
4. Inhibin feeds back to the pituitary to decrease FSH secretion. Activin, a related peptide, counteracts inhibin.

The female

Female physiology is more complex (see Figs. 34.27 and 34.28).

1. During puberty, in response to pulses of hypothalamic GnRH, the pituitary secretes LH and FSH, which stimulate androgen and oestrogen production from the ovaries resulting in progress through puberty followed by menarche and the establishment of the menstrual cycle.
2. The menstrual cycle depends upon the activity of hypothalamic GnRH. Pulses of GnRH, at about 2-hour intervals, stimulate release of pituitary LH and FSH. The KNDy neurons in the hypothalamus control GnRH secretion. Kisspeptin and neurokinin B are stimulatory and dynorphin A is inhibitory.
3. Menstrual cycles are often irregular during adolescence, particularly the interval from the first cycle to the second cycle as immaturity of the hypothalamic–pituitary–ovarian axis during the early years after menarche often results in anovulation and cycles may be somewhat long (90% of cycles: 21–45 days). By the third year after menarche, 60%–80% of menstrual cycles are 21–34 days long, as is typical of adults.

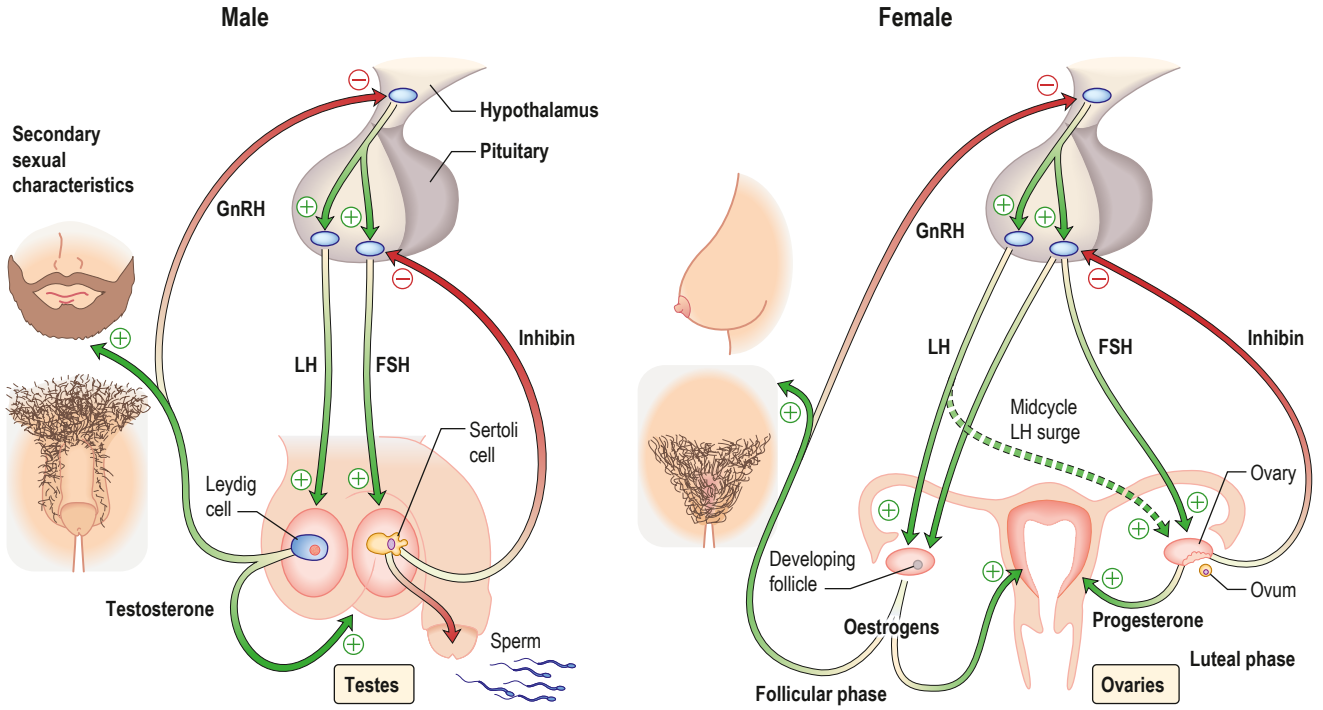

Fig. 34.27 Male and female hypothalamic–pituitary–gonadal axes. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are secreted in pulses in response to hypothalamic gonadotrophin-releasing hormone (GnRH) and have different effects on the gonads (see text). Testosterone and oestrogens have multiple peripheral effects and exert negative feedback on LH secretion. Inhibin exerts negative feedback on FSH secretion.

4. LH stimulates ovarian androgen production by the ovarian theca cells.
5. FSH stimulates follicular development and activity of aromatase (an enzyme required to convert ovarian androgens to oestrogens) in the ovarian granulosa cells. FSH also stimulates release of inhibin from ovarian stromal cells, which inhibits FSH release. Activin counteracts inhibin (see Fig. 34.27).
6. Although many follicles are 'recruited' for development in early folliculogenesis, by day 8–10, a 'leading' (or 'dominant') follicle is selected for development into a mature Graafian follicle.
7. Oestrogens have a double feedback action on the pituitary (see Fig. 34.27). Initially, they inhibit gonadotrophin secretion (negative feedback) but, later, high-level exposure results in increased GnRH secretion and increased LH sensitivity to GnRH (positive feedback), which leads to the mid-cycle LH surge, inducing ovulation from the leading follicle (see Fig. 34.28).
8. The follicle then differentiates into a corpus luteum, which secretes both progesterone and oestradiol during the second half of the cycle (luteal phase).
9. Oestrogen (initially) and then progesterone cause uterine endometrial proliferation in preparation for possible implantation; if implantation does not occur, the corpus luteum regresses and progesterone secretion and inhibin levels fall so that the endometrium is shed (menstruation), allowing increased GnRH and FSH secretion.
10. If implantation and pregnancy follow, HCG production from the trophoblast maintains corpus luteum function until 10–12 weeks of gestation, by which time the placenta will be making sufficient oestrogen and progesterone to support itself.

Clinical features of disorders of sex and reproduction

A detailed history and examination of all systems are required (Box 34.36). A man having regular satisfactory intercourse or a woman with regular ovulatory periods is most unlikely to have significant endocrine disease, assuming the history is accurate.

Investigation of gonadal function

In adults much can be deduced from basal measurements of the gonadotrophins, oestrogens/testosterone, and prolactin:

- High gonadotrophins with low testosterone or oestradiol indicate primary gonadal disease.
- Low levels of testosterone/oestradiol with low or normal LH/FSH imply HP disease.
- Demonstration of ovulation (by measurement of luteal phase serum progesterone and/or by serial ovarian ultrasound in the follicular phase) or a healthy sperm count (20–200 million/mL, >60% grade I motility and <20% abnormal forms) provides absolute confirmation of normal female or male reproductive endocrinology, but these tests are not always essential.
- Pregnancy provides complete demonstration of normal male and female function.
- Hyperprolactinaemia can be confirmed or excluded by direct measurement. Levels may increase with stress; if this is suspected, a cannula should be inserted and samples taken through it 30 minutes later. More detailed tests are indicated in Box 34.37.

Box 34.36 Sexual and menstrual disorders

History
- Menstruation—timing of bleeding and cycle
- Relationship of symptoms to cycle
- Breasts (tenderness/galactorrhoea)
- Hirsutism and acne
- Libido and potency
- Problems with intercourse
- Past fertility and future plans

Physical signs
- Evidence of systemic disease
- Secondary sexual characteristics
- Extent/distribution of hair
- Genital size (testes, ovaries, uterus)
- Clitoromegaly
- Breast development, gynaecomastia
- Galactorrhoea

Box 34.37 Tests of gonadal function

Test	Uses/comments
Male	
Basal testosterone	Normal levels exclude hypogonadism
Sperm count	Normal count excludes deficiency Motility and abnormal sperm forms should be noted
Female	
Basal oestradiol	Normal levels exclude hypogonadism
Luteal phase progesterone (days 18–24 of cycle)	If >30 nmol/L, suggests ovulation
Ultrasound of ovaries	To confirm ovulation
Both sexes	
Basal LH/FSH	Demonstrates state of feedback system for hormone production (LH) and germ cell production (FSH)
HCG test (testosterone or oestradiol measured)	Response shows potential of ovary or testis; failure demonstrates primary gonadal problem
Clomifene test (LH and FSH measured)	Tests hypothalamic negative feedback system; clomifene is an oestrogen antagonist and causes LH/FSH to rise
LHRH test (rarely used)	Shows adequacy (or otherwise) of LH and FSH stores in pituitary

FSH, Follicle-stimulating hormone; *HCG,* human chorionic gonadotrophin; *LH,* luteinizing hormone; *LHRH,* luteinizing hormone-releasing hormone.

Box 34.38 Effects of androgens and consequences of androgen deficiency in the male

Physiological effect	Consequences of deficiency
General	
Maintenance of libido	Loss of libido
Deepening of voice	High-pitched voice (if prepubertal)
Frontotemporal balding	No temporal recession
Facial, axillary, and limb hair	Decreased hair
Maintenance of erectile and ejaculatory function	Loss of erections/ejaculation
Pubic hair	
Maintenance of male pattern	Thinning and loss of pubic hair
Testes and scrotum	
Maintenance of testicular size/consistency (needs gonadotrophins as well)	Small, soft testes
Rugosity of scrotum	Poorly developed penis/scrotum
Stimulation of spermatogenesis	Subfertility
Musculoskeletal	
Epiphyseal fusion	Eunuchoidism (if prepubertal)
Maintenance of muscle bulk and power	Decreased muscle bulk
Maintenance of bone mass	Osteoporosis

Box 34.39 Causes of male hypogonadism

- Reduced gonadotrophins (hypothalamic–pituitary disease):
  - Hypopituitarism
  - Selective gonadotrophic deficiency, Kallmann's syndrome, normosmic idiopathic hypogonadotropic hypogonadism
  - Severe systemic illness
  - Severe underweight
- Hyperprolactinaemia
- Primary gonadal disease (congenital):
  - Anorchia/Leydig cell agenesis
  - Cryptorchidism (testicular maldescent)
  - Chromosome abnormality (e.g., Klinefelter's syndrome)
  - Enzyme defects: 5α-reductase deficiency
- Primary gonadal disease (acquired):
  - Testicular torsion
  - Orchidectomy
  - Local testicular disease
  - Chemotherapy/radiation toxicity
  - Orchitis (e.g., mumps)
  - Chronic kidney disease
  - Cirrhosis/alcohol
  - Sickle cell disease
- Androgen receptor deficiency/abnormality

Disorders in the male

Hypogonadism

History and examination

How a male presents depends on age. Hypogonadism in an adolescent would present with delayed puberty and/or growth, whereas an adult may present with poor libido, erectile dysfunction, and loss of secondary sexual hair (Box 34.38). Hypogonadism may also be an incidental finding, such as one that emerges during investigation for subfertility. Semen volume is usually maintained as sperm makes up for only a very small proportion of seminal fluid volume; most is prostatic fluid. The testes may be small and soft, and there may be gynaecomastia. Except with subfertility, the symptoms are usually those of androgen deficiency.

Causes of male hypogonadism are shown in Box 34.39.

Investigations

Hypogonadism may be immediately apparent but basal levels of testosterone, LH, and FSH should be measured. These will allow the distinction to be made between primary gonadal (testicular) failure and HP disease.

If primary gonadal failure is identified, chromosomal analysis (e.g., to exclude Klinefelter's syndrome) is required. In secondary gonadal failure, gonadotrophin deficiency, pituitary MRI scan, prolactin levels, and other pituitary function tests are needed.

A frequent cause of referral is males with poor libido or erectile dysfunction with equivocal lowering of serum testosterone (7–10 nmol/L) without elevation of gonadotrophins. If the testosterone was taken in the morning, such test results can be interpreted as mild gonadotrophin deficiency or lower end of the normal but may also be seen in people with obesity and diabetes mellitus, who commonly have low circulating SHBG levels associated with insulin

Box 34.40 Androgen replacement therapy

Route	Preparation	Dose	Remarks
Dermal	Testosterone gel Testosterone patch	50–100 mg 300 μg/24 h	Rubs on shoulders Self-adhesive
Intramuscular	Testosterone enanthate Testosterone undecanoate Testosterone propionate	250 mg every 3 weeks 1 g every 3 months 50–100 mg every 2–3 weeks	Frequent injections Painful Large-volume injection Very frequent injections Short half-life
Oral	Testosterone undecanoate	120–160 mg daily, in divided doses	Variable dose, irregular absorption
Implant	Testosterone implant	600 mg every 4–5 months	Requires implant procedure Scarring, infection

resistance and therefore low total testosterone levels but normal free testosterone levels. Regular use of opiate analgesia may lead to gonadotrophin deficiency and should be considered. 'Anabolic' steroid (i.e., androgen) abuse causes similar biochemical findings and is likely if the patient appears well virilized. A therapeutic trial of testosterone replacement is often justified and forms part of the investigation in some patients; full pituitary evaluation may be required in such cases to exclude other pituitary disease.

Management

The cause of hypogonadism can rarely be reversed and testosterone replacement therapy should be commenced to control current symptoms and prevent osteoporosis in the long term. Replacement is usually given by transdermal gel or by intramuscular injection (**Box 34.40**). In gonadotrophin deficiency, LH and FSH (purified or synthetic) or pulsatile GnRH may be used when fertility is required.

Special instances of hypogonadism

Cryptorchidism

Cryptorchidism (or undescended testes) is usually treated by surgical exploration and orchidopexy in early childhood. After that age, the germinal epithelium is increasingly at risk, and lack of descent by puberty is associated with subfertility. A short trial of HCG occasionally induces descent; an HCG test with a testosterone response 72 hours later excludes anorchia. Intra-abdominal testes have an increased risk of developing malignancy; if presentation is after puberty, orchidectomy is advised. Patients may present in adulthood with a history of cryptorchidism with primary testicular failure (due to the testicular damage before or during surgery) or gonadotrophin deficiency (presumably the initial cause of maldescent).

Klinefelter's syndrome

Klinefelter's syndrome is a common chromosomal abnormality, affecting 1 in 1000 males. Patients are phenotypically male, but with an extra chromosome (47XXY and variants, e.g., 46XY/47XXY mosaicism). There is both a loss of Leydig cells and seminiferous tubular dysgenesis. If not identified on amniocentesis, only 10% are diagnosed prepuberty; early indications of the condition include cryptorchidism, behavioural problems, and learning disabilities as well as tall stature. In adolescence, there may be gynaecomastia and micro-orchidism (mostly from the age of 14 years), as well as a poor muscular bulk with excessive long legs (due to lack of epiphyseal closure); small shoulders and broad hips should raise suspicion. Most patients have a normal puberty. In adulthood, infertility is one of the most common presentations. There is also a predisposition to diabetes mellitus, breast cancer, emphysema, and bronchiectasis; these are all unrelated to the testosterone deficiency.

Clinical examination shows a wide spectrum of features with small, pea-sized but firm testes, usually gynaecomastia and other signs of ***androgen deficiency***. Confirmation is by chromosomal analysis.

Treatment is androgen replacement therapy if deficient in testosterone. The majority of men with Klinefelter's syndrome have relative testosterone deficiency (low-normal levels). The evidence that testosterone replacement in these men has positive benefits is lacking but should be discussed and trialled. No treatment is possible for the abnormal seminiferous tubules and infertility, although advances in fertility techniques and microdissection testicular sperm extraction ***(microTESE)*** offer some hope to men wanting to father their own child.

Kallmann's syndrome

This is isolated GnRH deficiency. It is associated with decreased or absent sense of smell (anosmia) and sometimes with other bony (cleft palate), renal, and cerebral abnormalities (e.g., colour blindness). It is often familial and is usually X-linked, resulting from a mutation in the *KAL1* gene, which encodes anosmin-1 (producing loss of smell); one sex-linked form is due to an abnormality of a cell adhesion molecule. Management is that of secondary hypogonadism. Fertility is possible with gonadotrophin therapy.

Normosmic idiopathic hypogonadotropic hypogonadism

This refers to isolated GnRH deficiency in the absence of anosmia. Known mutations account for less than 15% of normosmic idiopathic hypogonadotropic hypogonadism (nIHH). Mutations include the *KISS1* gene, which codes for kisspeptin, the protein that acts on the GPR54 receptor, and the *FGFR1* gene.

Oligospermia and azoospermia

These may be secondary to gonadotrophin deficiency and can be corrected by gonadotrophin therapy. More often, they result from primary testicular diseases, in which case they are rarely treatable, although advances in fertility techniques and microdissection testicular sperm extraction (microTESE) offer some hope to men with primary hypogonadism wanting to father their own child.

Azoospermia with normal testicular size and low FSH levels suggests a vas deferens block, which is sometimes reversible by surgical intervention.

Gynaecomastia

Gynaecomastia is development of breast tissue in the male. Causes are shown in **Box 34.41**. It is due to an imbalance between free oestrogen and free androgen effects on breast tissue.

Box 34.41 Causes of gynaecomastia

- Physiological:
  - Neonatal
  - Pubertal
  - Old age
- Hyperthyroidism
- Hyperprolactinaemia
- Renal disease
- Liver disease
- Hypogonadism (see Box 34.39)
- Oestrogen-producing tumours (testis, adrenal)
- HCG-producing tumours (testis, lung)
- Starvation/re-feeding
- Carcinoma of breast
- Drugs:
  - Oestrogenic: oestrogens, cannabis, digoxin, diamorphine
  - Antiandrogens: spironolactone, cimetidine, cyproterone
  - Others: gonadotrophins, cytotoxics

Pubertal gynaecomastia

This occurs in perhaps 50% of normal boys, often asymmetrically. It usually resolves spontaneously within 6–18 months, but after this duration, it may require surgical removal, as fibrous tissue will have been laid down. The cause is thought to be relative oestrogen excess, and the oestrogen antagonist tamoxifen is occasionally helpful.

Gynaecomastia in the older male

This requires a full assessment to exclude potentially serious underlying disease, such as bronchial carcinoma and testicular tumours (e.g., Leydig cell tumour). However, aromatase activity increases with age and may be the cause of gynaecomastia in this group. Aromatase is an enzyme of the cytochrome P450 family and converts androgens to produce oestrogens. Drug effects are common (especially digoxin and spironolactone), and once these and significant liver diseases are excluded, most cases have no definable cause. Painful gynaecomastia may be treated with a 3–6-month trial of tamoxifen, and surgery is occasionally necessary if the symptoms or cosmetic appearance are unacceptable.

The ageing male

In the male, there is no sudden menopause or 'change of life'. However, there is a progressive loss of sexual function with reduction in morning erections and frequency of intercourse.

The age of onset varies widely. Typically, overall testicular volume diminishes and SHBG and gonadotrophin levels gradually rise, but other men present with low or borderline testosterone without elevation of LH/FSH. Low testosterone certainly increases the risk of osteoporosis and, in some studies, is associated with increased cardiovascular risk. It remains unclear to what extent general symptoms of lack of energy, drive, muscle strength, and general well-being may relate to these hormonal changes, but a recent trial of testosterone replacement showed no benefit in general symptoms, although there was an improvement in sexual function. Loss of libido and erectile dysfunction are, however, common symptoms, even when hormones are normal, and long-term outcome studies of testosterone replacement are still awaited. Therefore, the decision to offer testosterone replacement to an ageing male is currently based on full clinical and biochemical assessment and full discussion of potential risks (including prostate disease) as well as benefits. If testosterone is unequivocally low (<7 pmol/L) and there are symptoms specific to androgen deficiency (low libido, erectile dysfunction and loss of early morning erections), most authorities would recommend replacement. However, few would treat if testosterone is higher than 12 pmol/L with normal LH/FSH. Clinically, a large proportion of cases are in the borderline range (7–12 pmol/L), which can lead to difficulties in reaching a firm diagnosis. There is an increasing move towards measuring fasting testosterone levels, as food intake may decrease testosterone, leading to an incorrect diagnosis of androgen deficiency.

Box 34.42 Effects of oestrogens and consequences of oestrogen deficiency

Physiological effect	Consequences of deficiency
Breast	
Development of connective and duct tissue	Small, atrophic breast
Nipple enlargement and areolar pigmentation	
Pubic hair	
Maintenance of female pattern	Thinning and loss of pubic hair
Vulva and vagina	
Vulval growth	Atrophic vulva
Vaginal glandular and epithelial proliferation	Atrophic vagina
Vaginal lubrication	Dry vagina and dyspareunia
Uterus and tubes	
Myometrial and tubal hypertrophy	Small, atrophic uterus and tubes
Endometrial proliferation	Amenorrhoea
Skeletal	
Epiphyseal fusion	Eunuchoidism (if prepubertal)
Maintenance of bone mass	Osteoporosis

Disorders in the female

Hypogonadism

Impaired ovarian function, whether primary or secondary, will lead to both oestrogen deficiency and abnormalities of the menstrual cycle. The latter is very sensitive to disruption, with cycles becoming anovulatory and irregular before disappearing altogether. Symptoms will depend on the age at which failure develops. Thus, before puberty, primary amenorrhoea will occur, possibly with delayed puberty; after puberty, there may be secondary amenorrhoea and symptoms of oestrogen deficiency.

Oestrogen deficiency

The physiological effects of oestrogens and symptoms/signs of deficiency are shown in Box 34.42.

Amenorrhoea

Absence of periods or markedly irregular infrequent periods (oligomenorrhoea) is the most common presentation of female gonadal disease. The clinical assessment of such patients is shown in Box 34.43, and common causes are listed in Box 34.44. Causes can be divided into whether amenorrhoea is primary or secondary, whether associated with oestrogen deficiency or not, whether oestrogen deficiency is due to gonadotrophin deficiency or ovarian insufficiency, whether it is associated with another condition, and whether amenorrhoea is due to structural problems.

Polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) is an example of amenorrhoea that could either be primary or secondary and is not associated with

Box 34.43 Clinical assessment of amenorrhoea

History
- Ensure not pregnant
- Date of onset
- Age of menarche, if any

- Normality of vagina, cervix and uterus

oestrogen deficiency. It is the most common cause of oligomenorrhoea and amenorrhoea (see below).

Hypothalamic and weight-related amenorrhoea

Amenorrhoea with low oestrogen and gonadotrophins in the absence of organic pituitary disease is described as hypothalamic amenorrhoea. This may be related to 'stress'; low body weight; excessive exercise or previous weight loss; stopping the contraceptive pill; or severe illness. However, some patients appear to have defective cycling mechanisms without apparent explanation.

A minimum body weight is necessary for regular menstruation. While anorexia nervosa represents an extreme form of weight loss (see Chapter 30, 'Anorexia nervosa' section), amenorrhoea is common and may also be seen at weights within the 'normal' range. It is possible that alterations in leptin levels are responsible for the hypothalamic dysfunction seen in this situation. Restoration of body weight to above the 50th centile for height is usually effective in restoring menstruation, but in the many cases where this cannot be achieved oestrogen replacement is necessary.

Premature ovarian insufficiency

Premature ovarian insufficiency is the preferred term to describe premature menopause or ovarian failure of onset before the age of 40. The cause may be autoimmune or may rarely be identifiable genetic causes such as the fragile X pre-mutation or Turner's syndrome; most commonly, however, it is of unknown aetiology, although often familial.

Repeat measurements of LH/FSH levels are necessary before a diagnosis of premature ovarian insufficiency is given because of the psychological impact of this diagnosis and the possibility that a single elevation of LH/FSH might simply be the mid-cycle ovulatory surge. Iatrogenic causes, such as bilateral oophorectomy or cancer therapy with radiotherapy and some chemotherapy agents, can also cause premature ovarian insufficiency. In some scenarios, ovarian function can fluctuate; therefore, in younger women, consideration needs to be given as to whether contraception is required and whether the combined oral contraceptive pill is the best option for hormone replacement therapy (HRT).

Turner's syndrome (caused by presence of a single X chromosome) is a cause of premature ovarian insufficiency, frequently with delayed puberty and primary amenorrhoea, although some girls do undergo menarche and establish a menstrual cycle but remain at risk of premature ovarian insufficiency. The phenotype is female with female external genitalia. There is gonadal dysgenesis with streak ovaries. Features include short stature, webbing of the neck (up to 40%), a wide carrying angle of the elbows, high-arched palate, and low-set ears. These patients also have an increased incidence of autoimmune disease (2%), bicuspid aortic valves, aortic coarctation and dissection, coronary artery disease, hypertension, type 2 diabetes, horseshoe kidneys, lymphoedema, reduced bone density, hearing problems, and inflammatory bowel disease.

Investigation of oligo-amenorrhoea

Basal levels of FSH, LH, oestrogen, and prolactin allow initial distinction between primary gonadal and HP causes (see **Box 34.44**). Elevation of LH and FSH to menopausal levels usually confirms the diagnosis. Subsequent investigations are also shown in **Box 34.44**.

Anti-Müllerian hormone (AMH) released from granulosa cells of preantral and small antral follicles in the ovary, a marker of *'ovarian reserve'*, is being increasingly used in the context of secondary amenorrhoea, especially in infertility centres: it is elevated in PCOS, low in premature ovarian insufficiency and after menopause, and either normal or low in hypogonadotropic hypogonadism. It is shown to be helpful in deciding the type of infertility treatment strategy to be adopted, specifically in premature ovarian insufficiency or hypogonadotropic hypogonadism cases where low AMH level indicates poor follicular reserve, when oocyte donation is recommended. Conversely, adequate AMH level means there is hope for oocyte retrieval following gonadotrophin stimulation protocols to facilitate *in vitro* fertilization (IVF).

Management

Treatment is that of the cause wherever possible (e.g., hypothyroidism, low weight, stress, excessive exercise). Hyperprolactinaemia should be corrected (see below). PCOS is discussed in detail below.

When oestrogen deficiency is not reversed, HRT should almost always be given, as the risk of osteoporosis and other conditions related to oestrogen deficiency almost always outweighs the risks of HRT at this younger age. HRT may still also be actively recommended when normal menopause occurs relatively early (e.g., before the age of 50).

In younger and older women with premature ovarian insufficiency ovarian function may recover or fluctuate, and therefore consideration should be given to using the combined oral contraceptive pill if fertility is not desired.

When fertility is desired, in gonadotrophin deficiency, gonadotrophins can be given to achieve ovulation. Ovarian insufficiency is rarely treatable, and often the option for pregnancy is donor eggs. There is a rare condition called 'resistant' ovary, where high-dose gonadotrophin therapy can occasionally lead to folliculogenesis.

Hirsutism

Normal hair versus hirsutism

The extent of normal hair growth varies between individuals, families, and races, being more extensive in the Mediterranean and some Asian subcontinent populations. These normal variations in body hair, and the more extensive hair growth seen in patients complaining of hirsutism, represent a continuum from no visible hair to extensive cover with thick, dark hair. It is therefore impossible to draw an absolute dividing line between 'normal' and 'abnormal' degrees of facial and body hair in the female. Soft vellus hair is normally present all over the body; this type of hair on the face and elsewhere is 'normal' and is not sex hormone dependent. Hair in the beard, moustache, breast, chest, axilla, abdominal midline, and pubic and thigh areas is sex hormone dependent. Any excess in the latter regions is

thus a marker of increased ovarian or adrenal androgen production: most commonly, PCOS, but occasionally other rarer causes.

Aetiology

- ***Polycystic ovarian syndrome (PCOS).*** This is the most common cause of hirsutism; see below.
- ***Idiopathic hirsutism.*** People with hirsutism, no elevation of serum androgen levels, and no other clinical features are sometimes labelled as having 'idiopathic hirsutism'. However, studies suggest that most people with 'idiopathic hirsutism' have some radiological or biochemical evidence of PCOS on more detailed investigation, and several studies have demonstrated

evidence of mild PCOS in up to 20% of the normal female population. Familial or idiopathic hirsutism does occur but usually involves a distribution of hair growth that is not typically androgenic.

- ***Ovarian hyperthecosis.*** This is a non-malignant ovarian disorder characterized by luteinized thecal cells in the ovarian stroma, which secrete testosterone. The clinical features are similar to those of PCOS but tend to present in perimenopausal women, and serum testosterone levels are higher than typically seen in PCOS.
- ***Iatrogenic hirsutism.*** This occurs after treatment with androgens, or more weakly androgenic drugs such as progestogens or danazol.
- ***Non–androgen-dependent hair growth (hypertrichosis).*** This occurs with drugs such as phenytoin, diazoxide, minoxidil, and ciclosporin.
- ***Other causes.*** Rarer and more serious endocrine causes of hirsutism and virilization include CAH (see 'Congenital adrenal hyperplasia' section), Cushing's syndrome (see 'The adrenal cortex' section), and androgen-secreting (virilizing) tumours of the ovary and adrenal.

Polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) is the most common cause of hirsutism in clinical practice, affecting about 1 in 5 women worldwide. It is characterized by multiple small cysts within the ovary (Fig. 34.29) (which represent arrested follicular development) and by excess androgen production from the ovaries (and to a lesser extent from the adrenals).

Measured levels of androgens in blood vary widely from patient to patient and may remain within the normal range, but SHBG levels are often low (due to insulin resistance and high insulin levels), leading to high free androgen levels. In PCOS, there is thought to be an increased frequency of the GnRH pulse generator, causing an increase in LH pulses and androgen secretion. The response of the hair follicle to circulating androgens also seems to vary between individuals with otherwise identical clinical and biochemical features, and the reason for this variation in end-organ response remains poorly understood.

Fig. 34.29 Polycystic ovary syndrome. Ultrasound of the ovary, revealing multiple cysts with central ovarian stroma showing increased echo texture.

PCOS is frequently associated with:

- ***hyperinsulinaemia and insulin resistance***, the prevalence of type 2 diabetes being 10 times higher than in normal women
- ***hypertension, hyperlipidaemia, and increased cardiovascular risk*** ('metabolic syndrome'), which is 2–3 times higher in PCOS. Studies suggest that PCOS *per se* confers an absolute increase in cardiovascular end-points.

Obesity (see Chapter 37) with PCOS is an additional risk factor for insulin resistance. The precise mechanisms that link the aetiology of polycystic ovaries, hyperandrogenism, anovulation, and insulin resistance are still to be elucidated, and whether the basic defect is in the ovary, adrenal, or pituitary, or is a more generalized metabolic defect, remains unknown. Frequently, there is a family history of either PCOS or type 2 diabetes, suggesting a genetic component.

In routine clinical practice, the majority of people with objective signs of androgen-dependent hirsutism will have PCOS, and investigation is mainly required to exclude rarer and more serious causes of virilization.

History and examination

Most patients with PCOS present with amenorrhoea/oligomenorrhoea, hirsutism, and acne, shortly after menarche. Frequently, patients are also obese with evidence of insulin resistance. Clinical, biochemical, and radiological features of PCOS merge imperceptibly into those of the normal populations.

- ***Hirsutism.*** This should be recorded objectively, ideally using a scoring system, both to document the problem and to monitor treatment. The method and frequency of physical removal (e.g., shaving, plucking) should also be recorded. The development of hirsutism commonly provokes severe distress in young women and may lead to avoidance of normal social activities. Most patients who complain of hirsutism will have an objective excess of hair on examination, but occasionally very little will be found (and appropriate counselling is then indicated).
- ***Age and speed of onset.*** Hirsutism related to PCOS usually begins around the time of the menarche and increases slowly and steadily in the teens and twenties. Rapid progression and prepubertal or late onset suggest a more serious cause.
- ***Accompanying virilization.*** Hirsutism due to PCOS may be severe and affect all androgen-dependent areas on the face and body. However, more severe virilization (clitoromegaly, recent-onset frontal balding, male phenotype) implies substantial androgen excess and usually indicates a rarer cause rather than PCOS. Thinning of head hair in a male pattern—androgenic alopecia—occurs in a proportion of women with uncomplicated PCOS, typically with a familial tendency for premature androgen-related hair loss in both sexes.
- ***Menstruation.*** Most people with PCOS will have some disturbance of menstruation, typically oligo-/amenorrhoea, although more frequent erratic bleeding can also occur. However, PCOS can present as hirsutism with regular periods or as irregular periods, with no evidence of hirsutism or acne.
- ***Weight.*** Many people with PCOS are also overweight or obese. The obesity worsens the underlying androgen excess and insulin resistance and inhibits the response to treatment; it is an indication for appropriate advice on diet and exercise. In severe cases, the insulin resistance may have a visible manifestation as acanthosis nigricans on the neck and in the axillae. In addition to worsening the symptoms of PCOS, central obesity in PCOS significantly increases the likelihood of developing diabetes and cardiovascular disease.

Investigations and differential diagnosis

- ***Serum total testosterone.*** This is often elevated in PCOS and is invariably substantially raised in virilizing tumours (usually >5 nmol/L). People with hirsutism and normal testosterone levels frequently have low levels of SHBG, leading to high free androgen levels. The ***free androgen index*** ([testosterone/SHBG] *100) is often used and is high; free testosterone is difficult to measure directly.
- ***Other androgens.*** Androstenedione and DHEA sulphate are frequently elevated in PCOS, and even higher in CAH and virilizing tumours.
- ***17α-Hydroxyprogesterone.*** This is elevated in classical CAH but may be apparent in late-onset CAH only after stimulation tests.
- ***Gonadotrophin levels.*** LH hypersecretion is a frequent feature of PCOS, but the pulsatile nature of secretion of this hormone means that a 'classic' increased LH/FSH ratio is not always observed on a random sample.
- ***Oestrogen levels.*** Oestradiol is usually normal in PCOS, but oestrone levels (which are rarely measured) are elevated because of peripheral conversion. Levels are variable in other causes.
- ***Ovarian ultrasound.*** This is a useful investigation (see Fig. 34.28). Typical features are those of a thickened capsule, multiple 3–5 mm cysts, and a hyperechogenic stroma. Prolonged hyperandrogenization from any cause may lead to polycystic changes in the ovary. Ultrasound may also reveal virilizing ovarian tumours, although these are often small.
- ***Serum prolactin.*** Mild hyperprolactinaemia is common in PCOS but rarely exceeds 1500 mU/L.

If an androgen-secreting tumour is suspected clinically or after investigation, then more complex investigations include dexamethasone suppression tests, CT or MRI of adrenals, and selective venous sampling.

Diagnosis

Most patients presenting with a combination of hirsutism and menstrual disturbance will be shown to have PCOS, but the rarer alternative diagnoses should be excluded; the latter include late-onset CAH (early onset, raised serum 17α-hydroxyprogesterone), Cushing's syndrome (look for other clinical features), and virilizing tumours of the ovary or adrenals (severe virilization, markedly elevated serum testosterone).

The consensus ***(Rotterdam) criteria 2003*** retain international support for diagnosis of PCOS, requiring at least two of the following:

- clinical and/or biochemical evidence of hyperandrogenism
- oligo-ovulation and/or anovulation
- polycystic ovaries on ultrasound.

Management

Local therapy for hirsutism

Regular plucking, bleaching, depilatory cream, waxing, or shaving is used. Such removal neither worsens nor improves the underlying severity of hirsutism. More 'permanent' solutions include electrolysis and a variety of 'laser' hair removal systems; all appear effective but have not been evaluated in long-term studies, but they are expensive, and still often require repeated long-term treatment. ***Eflornithine cream*** (an antiprotozoal) inhibits hair growth by inhibiting ornithine decarboxylase but is effective in only a minority of cases and should be discontinued if there is no improvement after 4 months.

Systemic therapy for hirsutism

This always requires a year or more of treatment for maximal benefit, and long-term therapy is frequently required as the problem tends to recur when treatment is stopped. The patient must therefore always be an active participant in the decision to use systemic therapy and must understand the rare risks as well as the benefits. Weight loss (at least 5%) should also be encouraged, as many patients have improvement in symptoms.

- ***Oestrogens*** (e.g., oral contraceptives) suppress ovarian androgen production and reduce free androgens by increasing SHBG levels. Combined hormone pills will produce a slow improvement in hirsutism in a majority of cases and should normally be used first unless there is a contraindication, such as a history of thrombosis. After menopause, HRT preparations that contain medroxyprogesterone (rather than more androgenic progestogens) may be helpful.
- ***Cyproterone acetate*** (50–100 mg daily) is an antiandrogen but is also a progestogen, teratogen, and a weak glucocorticoid. Given continuously, it produces amenorrhoea and so is normally given for days 1–14 of each cycle. In women of childbearing age, contraception is essential.
- ***Spironolactone*** (200 mg daily) also has antiandrogen activity and can cause useful improvements in hirsutism. In women of childbearing age, contraception is essential.
- ***Finasteride*** (5 mg daily), a 5α-reductase inhibitor that prevents the formation of dihydrotestosterone in the skin, has also been shown to be effective but long-term experience is limited. In women of childbearing age, contraception is essential.
- ***Flutamide***, another antiandrogen, is less commonly used owing to the high incidence of hepatic side-effects. In women of childbearing age, contraception is essential.

Treatment of menstrual disturbance

- ***Cyclical oestrogen/progestogen*** administration will regulate the menstrual cycle and remove the symptom of oligo- or amenorrhoea. This is most frequently an additional benefit of the treatment of hirsutism but may also be used when menstrual disturbance is the only symptom.
- ***Metformin*** (500 mg three times daily) is commonly used in this condition because of the recognized association between PCOS and insulin resistance. It may improve menstrual cyclicity and ovulation; some patients also report improvement in hirsutism and ease of weight loss, but gastrointestinal upset may limit use.

Treatment for fertility in PCOS

- ***Clomifene or letrozole*** is given daily on days 2–6 of the cycle and is effective in 75% of women in achieving ovulation. It can occasionally cause ***ovarian hyperstimulation syndrome***, an iatrogenic complication of ovulation induction therapy, consisting of ovarian enlargement, oedema, hypovolaemia, acute kidney injury, and possibly shock; specialist supervision is essential. It is recommended that clomifene and letrozole should not normally be used for more than six cycles (owing to a possible increased risk of ovarian cancer in patients treated for longer than recommended).
- ***Low-dose FSH*** is used for non-responders to clomifene.
- ***Metformin*** alone may improve ovulation and achieve conception.

Wedge resection of the ovary was a traditional therapy but is now rarely required, although laparoscopic ovarian electrodiathermy may be helpful.

It is recognized that patients with PCOS often require psychological input to their condition.

Disorders of sex development

Disorders of sex development (DSDs) are a rare group of conditions that can be divided into 46XY and 46XX DSD and encompass:

- conditions of abnormalities in androgen synthesis, action, and excess
- disorders of gonadal development
- persistent Müllerian duct syndrome
- sex chromosomal DSDs (**Box 34.45**).

Such cases always require extensive, multidisciplinary clinical management. There is a fuller discussion on the interaction between sex and gender in Chapter 47.

Acromegaly and gigantism

Disorders of childhood growth and pubertal development are managed by paediatric endocrinologists. Since GH stimulates skeletal and soft tissue growth, excess produces gigantism in children (if acquired before epiphyseal fusion) and acromegaly in adults. Both are due to a GH-secreting pituitary tumour (somatotroph adenoma) in almost all cases. Hyperplasia due to ectopic GHRH excess is very rare. The overall incidence is approximately 3–4/million per year and the prevalence is 50–80/million worldwide. Acromegaly usually occurs sporadically, although gene mutations can rarely give rise to familial acromegaly: typically, the *AIP* gene in familial isolated pituitary adenoma. In familial acromegaly, there is an increased onset before puberty compared with sporadic cases, leading to a higher prevalence of gigantism.

Physiology

Growth hormone (GH) is the pituitary factor responsible for stimulation of body growth in humans. Its secretion is stimulated by GHRH, released into the portal system from the hypothalamus; it is also under inhibitory control exerted by somatostatin (**Fig. 34.30**). A separate GH-stimulating system involves a distinct receptor (GH secretagogue receptor), which interacts with ghrelin. It is not known how these two systems interact but, because ghrelin is synthesized in the stomach, a nutritional role is suggested for GH.

- ***GH*** acts by binding to a specific (single transmembrane) receptor located mainly in the liver (**Box 34.46**). This induces an intracellular phosphorylation cascade involving the Janus kinase/signal transducing activators of transcription (JAK/STAT) pathway. STAT proteins are translocated from the cytoplasm into the cell nucleus and cause GH-specific effects by binding to nuclear DNA.
- ***Insulin-like growth factor-1 (IGF-1)***, a somatomedin, stimulates growth. Its hepatic secretion is stimulated by a tissue-specific effect of GH on the liver. There are multiple IGF-binding proteins (IGF-BP) in plasma; IGF-BP3 can be measured clinically to improve assessment of GH status, particularly in children.

The metabolic actions of the system are:

- increasing collagen and protein synthesis
- promoting retention of calcium, phosphorus, and nitrogen, necessary substrates for anabolism
- opposing the action of insulin (a 'counter-regulatory' hormone effect).

GH release is intermittent and mainly nocturnal, especially during REM sleep. The frequency and size of GH pulses increase

Box 34.45 Disorders of sexual differentiation

Condition	Chromosomes	Gonads	Phenotype	Remarks
Turner's syndrome	45X (50%) 46,X,i (Xq) (5%–10%) 45,X, mosaicism (remainder)	Streak	Female	Often morphological features (e.g., short stature, web neck, coarctation of aorta)
Gonadal dysgenesis	46XY	Streak or minimal testes[a]	Immature female	
Congenital adrenal hyperplasia	46XX	Ovary	Female with variable virilization	Obvious androgen excess
Virilizing tumour	46XX	Ovary	Female with variable virilization	Obvious androgen excess
True hermaphroditism	46XX/XY or mosaic	Testis and ovary	Male or ambiguous	
Klinefelter's syndrome	47XXY	Small testes	Male, often with gynaecomastia	Many are hypogonadal
Testicular feminization	46XY	Testes[a]	Ambiguous or infantile female	Androgen receptor defective
Testicular synthetic defects	46XY	Testes[a]	Cryptorchid, ambiguous	
5α-Reductase deficiency	46XY	Testes	Cryptorchid, ambiguous	Impaired conversion of testosterone to dihydrotestosterone
Anorchia	46XY	Absent	Immature female	

[a]Gonadectomy advised because of high risk of malignancy.
i, Isochromosome.

during the growth spurt of adolescence and decline thereafter. Acute stress and exercise both stimulate GH release, while, in the normal subject, hyperglycaemia suppresses it.

IGF-1 may, in addition, play a major role in maintaining neoplastic growth. A relationship has been shown between circulating IGF-1 concentrations and breast cancer in premenopausal women and prostate cancer in men.

History and examination

Symptoms and signs of acromegaly are shown in Fig. 34.31. One-third of patients present with changes in appearance, and one-quarter with visual field defects or headaches; in the remainder, the diagnosis is made by an alert observer in another clinic: for example, in general practice, or in diabetes, hypertension, dental, or dermatology departments. Sleep apnoea is common and requires investigation and treatment if there are suggestive symptoms (see Chapter 20, 'Obstructive sleep apnoea' section). Sweating, headaches, and soft tissue swelling are particularly useful symptoms of persistent GH secretion. Headache is very common in acromegaly and may be severe, even with small tumours; it is often improved after surgical cure or with somatostatin analogues.

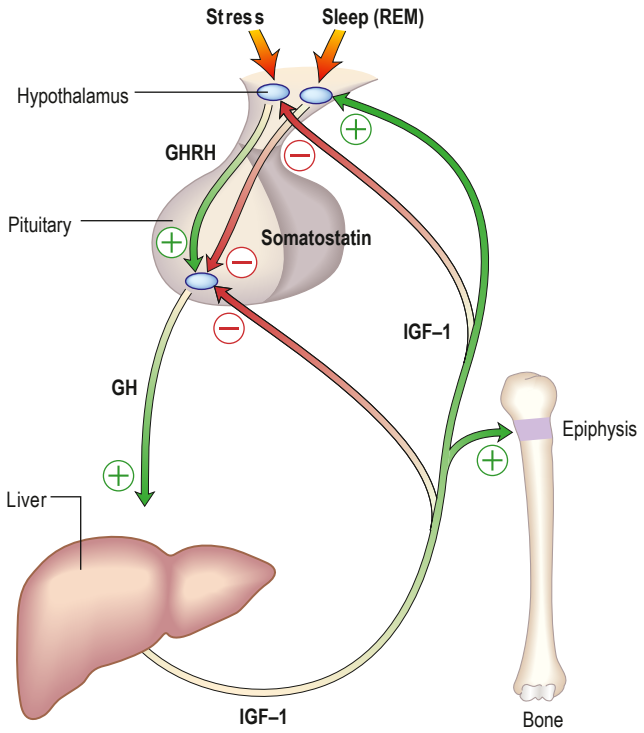

Fig. 34.30 The control of growth hormone (GH) and insulin-like growth factor-1 (IGF-1). Pituitary GH is secreted under dual control of growth hormone-releasing hormone (GHRH) and somatostatin and stimulates release of IGF-1 in the liver and elsewhere. IGF-1 has peripheral actions, including bone growth, and exerts negative feedback to the hypothalamus and pituitary. *REM,* Rapid eye movement.

Investigations

- ***GH levels*** may exclude acromegaly if they are undetectable, but a detectable value is non-diagnostic taken alone. Normal adult levels are below 0.5 μg/L for most of the day, except during stress or a 'GH pulse'.
- ***A glucose tolerance test*** is diagnostic if there is no suppression of GH. Acromegalics fail to suppress GH below 0.3 μg/L and some show a paradoxical rise; about 25% of acromegalics have a positive diabetic glucose tolerance test.
- ***IGF-1 levels*** are almost always raised in acromegaly; a single plasma level of IGF-1 reflects mean 24-hour GH levels and is useful in diagnosis. A normal IGF-1, together with random GH of less than 1 μg/L, may be taken to exclude acromegaly if the diagnosis is clinically unlikely.
- ***Visual field examination*** commonly reveals defects, such as bitemporal hemianopia.
- ***MRI scan*** of the pituitary is carried out if the above tests are abnormal. This will almost always reveal the pituitary adenoma. In cases where no clear lesion is present, or in postoperative cases where residual disease is being sought, there is increasing interest in the use of functional imaging such as methionine PET.
- ***Pituitary function*** commonly demonstrates partial or complete anterior hypopituitarism.
- ***Prolactin*** levels show mild to moderate hyperprolactinaemia in 30% of patients (Fig. 34.32). In some, the adenoma secretes both GH and prolactin.

Management

Untreated acromegaly results in markedly reduced survival. Most deaths occur from heart failure, coronary artery disease, and hypertension-related causes. In addition, there is an increase in deaths due to neoplasia, particularly large bowel tumours; guidance advocates regular colonoscopy to detect and remove colonic polyps in order to reduce the risk of colonic cancer, although the evidence is inconclusive. Treatment is therefore indicated in all except the elderly or those with minimal abnormalities. The aim of therapy is to achieve a mean GH level below 2.5 μg/L; this is not always

Box 34.46 Hormones and receptors of the hypothalamic–pituitary–GH axis

Symptoms

Head and neck
Change in facial appearance
Headaches
Visual deterioration
Deep voice
Goitre

General
Tiredness
Weight gain
Breathlessness
Excessive sweating
Muscular weakness
Joint pain

Hormonal
Amenorrhoea or oligomenorrhoea in women
Galactorrhoea
Impotence or poor libido

Increased glove or hat size

Signs

Facial
Prominent supraorbital ridge
Prognathism
Interdental separation
Large tongue
Visual field defects

General
Hirsutism
Thick greasy skin

Hands
Spade-like hands and feet
Tight rings on fingers
Carpal tunnel syndrome

Other
Galactorrhoea
Hypertension
Heart failure
Oedema
Arthopathy
Proximal myopathy
Glycosuria (plus possible signs of hypopituitarism)

Fig. 34.31 Acromegaly: symptoms and signs. *Bold italic* type indicates signs of greater discriminant value.

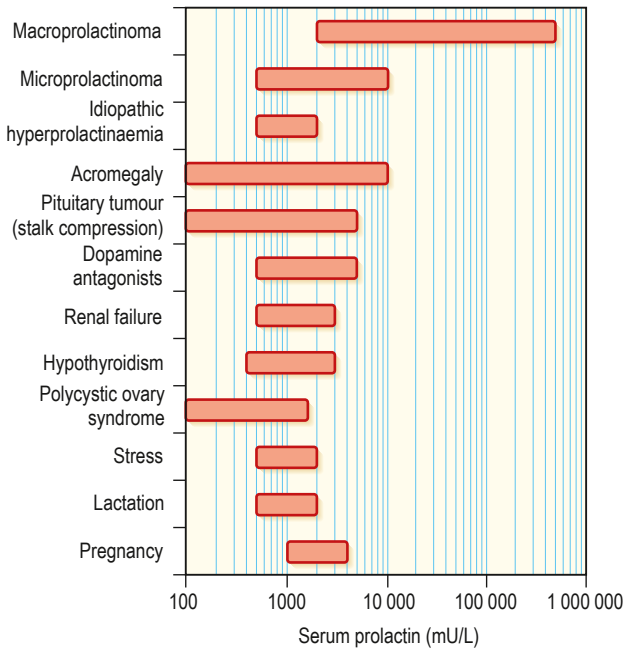

Fig. 34.32 Range of serum prolactin seen in common causes of hyperprolactinaemia.

'normal' but has been shown to reduce mortality to normal levels and is therefore considered a 'safe' GH level. A normal IGF-1 is also a goal of therapy. Occasionally, there can be discordance between GH and IGF-1 levels, which can create management dilemmas.

When present, hypopituitarism should be corrected and concurrent diabetes and/or hypertension should be treated conventionally; both usually improve with treatment of the acromegaly.

The general advantages and disadvantages of surgery, radiotherapy, and medical treatment are discussed in the 'Management' section of the 'Pituitary space-occupying lesions and tumours' section. Progress can be assessed by monitoring GH and IGF-1 levels.

Surgery

Trans-sphenoidal surgery is the appropriate first-line therapy. It will result in clinical remission in a majority of cases (60%–90%) with pituitary microadenoma but in only 50% of those with macroadenoma. Very high preoperative GH and IGF-1 levels are also poor prognostic markers of surgical cure. Surgical success rates are variable and highly dependent upon experience, and a specialist pituitary surgeon is essential. Transfrontal surgery is rarely required except for massive macroadenomas. There is a recurrence rate of approximately 10%.

Pituitary radiotherapy

External radiotherapy is normally used after pituitary surgery fails to normalize GH levels rather than as primary therapy. It is often combined with medium-term treatment using a somatostatin analogue, dopamine agonist, or GH antagonist because of the slow biochemical response to radiotherapy, which may take 10 years or more; it is also often associated with hypopituitarism, which makes it unattractive in patients of reproductive age. Stereotactic (gamma-knife) radiotherapy is used in some centres, as it delivers a more concentrated field of radiation.

Medical therapy

There are three receptor targets for the treatment of acromegaly: pituitary somatostatin receptors and dopamine (D_2) receptors, and GH receptors in the periphery.

Somatostatin receptor agonists

Octreotide and ***lanreotide*** are synthetic analogues of somatostatin, which act selectively on somatostatin receptor subtypes

(SSTR2 and SSTR5) and are highly expressed in GH-secreting tumours. These drugs were used as a short-term treatment while other modalities became effective, but now are sometimes used as primary therapy. They reduce GH and IGF levels in most patients but often do not achieve treatment targets. Both drugs are typically administered as monthly depot injections and are generally well tolerated; they are, however, associated with an increased incidence of gallstones and are expensive. Pasireotide (acting on SSTR1, 2, 3, and 5) is a newer agent but its role in acromegaly is still being evaluated.

Dopamine agonists

Dopamine agonists act on D_2 receptors and can be given to shrink tumours prior to definitive therapy or to control symptoms and persisting GH secretion; they are probably most effective in mixed GH-producing (somatotroph) and prolactin-producing (mammotroph) tumours. Typical doses are bromocriptine 10–60 mg daily or cabergoline 0.5 mg daily (higher than for prolactinomas). Given alone, they reduce GH to 'safe' levels in only a minority of cases but are useful for mild residual disease or in combination with somatostatin analogues. Drugs with combined somatostatin and dopamine receptor activity are under development.

Growth hormone antagonists

Pegvisomant (a genetically modified analogue of GH) is a GH receptor antagonist that exerts its effect by binding to and preventing dimerization of the GH receptor. It does not lower GH levels or reduce tumour size but has been shown to normalize IGF-1 levels in 90% of patients. It is given by daily injection and its main role at the present time is treatment of patients in whom GH and IGF levels cannot be reduced to safe levels with somatostatin analogues alone, or by surgery or radiotherapy.

Hyperprolactinaemia

The HP control of prolactin secretion is illustrated in Fig. 34.33. Prolactin is a large peptide secreted in the pituitary and acts via a transmembrane receptor stimulating JAK2 and other pathways (Box 34.47).

Prolactin is under tonic dopamine inhibition; factors known to increase prolactin secretion (e.g., TRH) are probably of less relevance unless the patient has primary hypothyroidism. Prolactin stimulates milk secretion (but not breast tissue development) but also inhibits gonadal activity. It decreases GnRH pulsatility at the hypothalamic level and, to a lesser extent, blocks the action of LH on the ovary or testis, producing hypogonadism even when the pituitary–gonadal axis itself is intact.

The role of prolactin outside pregnancy and lactation is not well defined, although there is some epidemiological evidence of a link between high prolactin levels and breast cancer, which has led to an interest in the development of prolactin receptor antagonists.

The range of serum prolactin seen in common causes of hyperprolactinaemia is illustrated in Fig. 34.32. Mildly increased prolactin levels (400–600 mU/L) may be physiological and asymptomatic but higher levels require a diagnosis. Levels above 5000 mU/L always imply a prolactin-secreting pituitary tumour.

Aetiology

Hyperprolactinaemia has many causes:

- ***Physiological.*** These include pregnancy, lactation, stress, sleep, exercise, and coitus.
- ***Pathological.*** These include prolactinoma, co-secretion of prolactin in tumours causing acromegaly, stalk compression due to pituitary adenomas and other pituitary masses, polycystic ovarian syndrome, primary hypothyroidism, and idiopathic hyperprolactinaemia. Rarer causes include renal failure, liver failure, postictal state, and chest wall injury (e.g., following herpes zoster).
- ***Drug-induced.*** Drug causes include ***oestrogens*** (e.g., contraceptive pill), ***dopamine antagonists*** (e.g., antipsychotics such as phenothiazines), ***antidepressants*** (e.g., tricyclics, selective serotonin reuptake inhibitors [SSRIs]), ***antiemetics*** (e.g., metoclopramide, domperidone), and ***others*** (e.g., verapamil, cimetidine, methyldopa).

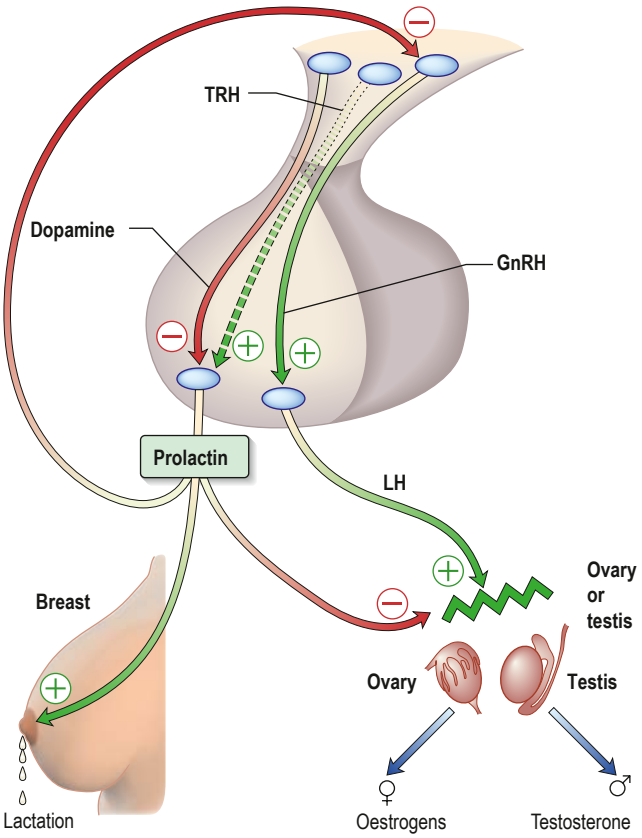

Fig. 34.33 The control and actions of prolactin. Prolactin is mainly controlled by tonic inhibition by hypothalamic dopamine. Prolactin stimulates lactation but also inhibits both hypothalamic gonadotrophin-releasing hormone (GnRH) secretion and the gonadal actions of luteinizing hormone (LH). *TRH,* Thyrotrophin-releasing hormone.

History and examination

Patients may present with features of hyperprolactinaemia or structural symptoms from a pituitary tumour with headaches and visual loss. This latter presentation is more common in males.

Common symptoms include:

- Galactorrhoea, spontaneous or expressible (60% of cases). Note that many people with galactorrhoea do not have hyperprolactinaemia. This is termed 'normoprolactinaemic galactorrhoea' and the causes are poorly understood.
- Oligomenorrhoea or amenorrhoea.
- Decreased libido in both sexes.
- Male impotence.
- Subfertility.
- Symptoms or signs of oestrogen or androgen deficiency—in the long term osteoporosis may result, especially in women.

Box 34.47 Hormones and receptors of the prolactin axis

Hormone	Source	Site of action	Hormone structure	Receptor	Post-receptor activity
Dopamine	Hypothalamus	Pituitary	Amine	Membrane—7TM D2 receptor	G-proteins Inhibit cAMP
Prolactin	Pituitary	Breast Other tissues	Peptide—199 AA	Transmembrane PRLR Class 1 cytokine	JAK2 and other pathways

7TM, 7 transmembrane (G-protein coupled receptor); *AA,* amino acids; *cAMP,* adenylate cyclase → cyclic adenosine monophosphate; *JAK,* Janus kinase.

- Delayed or arrested puberty in the peripubertal patient.
- Mild gynaecomastia—often seen in men due to the associated hypogonadism rather than being a direct effect of prolactin.

Additionally, headaches and/or visual field defects occur if there is a pituitary macroadenoma (more common in men).

Investigations

Hyperprolactinaemia should be confirmed by repeat measurement. It should be excluded in all patients presenting with a pituitary mass.

If there are no clinical features of hyperprolactinaemia, the possibility of ***macroprolactinaemia*** should be considered. This is a higher-molecular-weight complex of prolactin bound to IgG, which is physiologically inactive but occurs in a small proportion of normal people and can therefore lead to unnecessary treatment. Macroprolactinaemia can be diagnosed in the laboratory by precipitation of immunoglobulin G (IgG) with polyethylene glycol, after which prolactin levels will be normal on testing; most laboratories will do this routinely.

Further tests are appropriate after physiological and drug causes have been excluded:

- ***Visual fields*** should be checked.
- ***Primary hypothyroidism*** must be excluded since this is a cause of hyperprolactinaemia.
- ***Anterior pituitary function*** should be assessed if there is any clinical evidence of hypopituitarism or radiological evidence of a pituitary tumour.
- ***MRI of the pituitary*** is necessary if there are any clinical features suggestive of a pituitary tumour, and it is desirable in all cases when prolactin is significantly elevated (>1000 mU/L).

In the presence of a pituitary mass on MRI, the level of prolactin helps determine whether the mass is a prolactinoma or a non-functioning pituitary tumour causing stalk-disconnection hyperprolactinaemia: levels of above 5000 mU/L in the presence of a macroadenoma, or above 2000 mU/L in the presence of a microadenoma (or with no radiological abnormality) strongly suggest a prolactinoma. Macroprolactinoma refers to tumours above 10 mm in diameter, microprolactinoma to smaller ones. Tumours that are approximately 10 mm are termed mesoadenomas.

Occasionally, very large prolactinomas can be associated with such high serum prolactin levels that some assays give an artefactual falsely low result (known as the 'hook effect'). If suspected, this can be excluded by serial dilutions of the serum sample.

Management

Treatment is recommended in all patients with a macroprolactinoma to reduce the size of the tumour. It is also recommended in those with troublesome galactorrhoea. In those with sex steroid deficiency, lowering prolactin levels should reverse hypogonadism and avoid the long-term effects of deficiency, although for those intolerant of prolactin-lowering medication, sex steroid replacement is an alternative approach. Therefore some patients (for example, postmenopausal women with microprolactinomas) may not require any treatment.

Medical treatment

Hyperprolactinaemia is controlled with a dopamine agonist.

- ***Cabergoline*** (500 μg once or twice a week, judged on clinical response and prolactin levels) is the best-tolerated and longest-acting drug and is the drug of choice.
- ***Bromocriptine*** is the longest-established therapy and is therefore preferred if pregnancy is planned; initial doses should be small (e.g., 1 mg), taken with food and gradually increased to 2.5 mg two or three times daily. Side-effects, which prevent effective therapy in a minority of cases, include nausea and vomiting, dizziness and syncope, constipation, and cold peripheries.
- ***Quinagolide*** (75–150 μg once daily) is an alternative.

Complications (similar to those seen when cabergoline is used in higher doses in Parkinson's disease) include pulmonary, retroperitoneal, and pericardial fibrotic reactions and cardiac valve lesions. Patients need monitoring, although studies suggest that adverse effects appear to be very rare in those on lower, 'endocrine' doses. In addition, patients can also develop neuropsychiatric side-effects, including compulsive behaviours such as gambling (termed 'impulse control disorders').

In most cases, a dopamine agonist will be the first and only therapy and can be used in the long term, although a trial of discontinuation can be considered in microprolactinomas after 2–3 years, as a significant percentage may not recur. Prolactinomas usually shrink in size on a dopamine agonist, and in macroadenomas any pituitary mass effects commonly resolve (Fig. 34.34). Macroprolactinomas may not recur after several years of dopamine agonist therapy in a minority of cases, but in the majority, hyperprolactinaemia will return if treatment is stopped.

In patients planning pregnancy, it is useful to know the size of the pituitary lesion before starting dopamine agonist therapy. Rarely, tumours enlarge during pregnancy to produce headaches and visual field defects. Dopamine agonists, which are traditionally stopped after conception, particularly when used in the treatment of microprolactinomas, can be restarted if there are any signs of tumour growth during pregnancy.

Trans-sphenoidal surgery

Surgery may rarely be needed in patients who are intolerant of or unresponsive to dopamine agonists. Surgery may restore normoprolactinaemia in people with microadenoma but is rarely completely successful in those with macroadenomas and risks damage to normal pituitary function. Therefore, most patients and physicians elect to continue medical therapy rather than proceed to surgery. Prolactin should therefore always be measured before surgery on any mass in the pituitary region. Some surgeons believe that long-term bromocriptine increases the hardness of the adenoma and makes resection more difficult, but others dissent from this view.

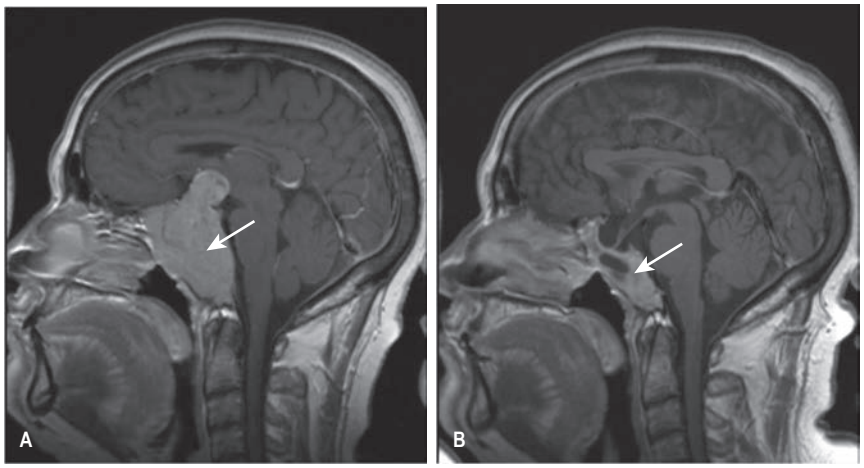

Fig. 34.34 Macroprolactinoma *(arrowed)*. **(A)** Before treatment. **(B)** After 2 years' treatment with the dopamine agonist cabergoline, showing marked adenoma shrinkage.

Box 34.48 Hormones and receptors of the posterior pituitary axes

Hormone	Source	Site of action	Hormone structure	Receptor	Post-receptor activity
Vasopressin (arginine vasopressin, AVP)	Hypothalamus → pituitary	Kidney	Peptide—9 AA	Membrane—7TM AVPR2	G-proteins cAMP Aquaporin-2
	Hypothalamus → pituitary	Vascular	Peptide—9 AA	Membrane—7TM AVPR1A	G-proteins PLC/IP_3
	Hypothalamus → portal veins	Pituitary (ACTH secretion)	Peptide—9 AA	Membrane—7TM AVPR1B	G-proteins PLC/IP_3
Oxytocin	Hypothalamus → pituitary	Uterus and breast	Peptide—9 AA	Membrane—7TM OXTR	G-proteins

7TM, 7 transmembrane (G-protein coupled receptor); *AA,* amino acids; *ARE,* androgen response element; *AVPR,* arginine vasopressin receptor; *cAMP,* adenylate cyclase → cyclic adenosine monophosphate; *OXTR,* oxytocin receptor.

Radiotherapy

Also rarely needed, radiotherapy usually controls adenoma growth and is slowly effective in lowering prolactin but causes progressive hypopituitarism. It may be advocated after medical tumour shrinkage or after surgery in larger tumours, especially when patients have completed their family or if the drug treatment is poorly tolerated, but most simply advocate continuation of dopamine agonist therapy in responsive cases.

THE THIRST AXIS
