Thirst and water regulation are largely controlled by vasopressin (also known as anti-diuretic hormone, ADH; or arginine vasopressin, AVP). This hormone is synthesized in the hypothalamus and then migrates in neurosecretory granules along axonal pathways to the posterior pituitary. Pituitary disease alone without hypothalamic involvement therefore does not lead to AVP-deficiency (also referred to as 'cranial diabetes insipidus'), as the hormone can still 'leak' from the damaged end of the intact axon.

At normal concentrations, the kidney is the predominant site of action of vasopressin. Vasopressin stimulation of the V_2 receptors (**Box 34.48**) allows the collecting ducts to become permeable to water via the migration of aquaporin-2 water channels, thus permitting reabsorption of hypotonic luminal fluid. Vasopressin therefore reduces diuresis and results in overall retention of water. At high concentrations, vasopressin also causes vasoconstriction via the V_1 receptors in vascular tissue.

Changes in plasma osmolality are sensed by osmoreceptors in the anterior hypothalamus. Vasopressin secretion is suppressed at levels below 280 mOsm/kg, thus allowing maximal water diuresis. Above this level, plasma vasopressin increases in direct proportion to plasma osmolality. At the upper limit of normal (295 mOsm/kg), maximum antidiuresis is achieved and thirst is experienced at about 298 mOsm/kg (**Fig. 34.35**).

Other factors affecting vasopressin release are shown in **Box 34.49**.

Disorders of vasopressin secretion or activity include:

- AVP-deficiency (previously 'cranial diabetes inspidus') as a result of hypothalamic disease
- AVP-resistance (previously 'nephrogenic DI')—where the renal tubules are insensitive to vasopressin, and an example of a receptor abnormality
- inappropriate excess of the hormone (syndrome of inappropriate diuresis, SIAD), also called syndrome of inappropriate antidiuretic hormone (SIADH), a common cause of hyponatraemia in hospital patients.

While AVP-deficiency and AVP-resistance (previously diabetes insipidus) is uncommon, patients need to be distinguished from the occasional patient with 'primary polydipsia' and from those whose renal tubular function has been impaired by electrolyte abnormalities, such as hypokalaemia or hypercalcaemia. Similarly other causes of hyponatraemia need to be excluded prior to diagnosing and investigating SIAD.

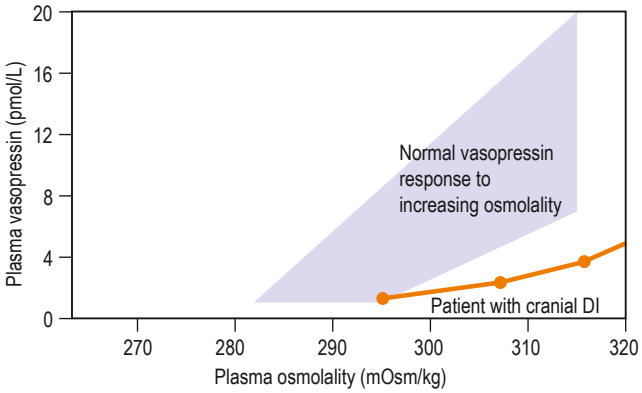

Fig. 34.35 **Plasma vasopressin response to increasing osmolality in normal subjects and in a patient with diabetes insipidus (DI).**

Box 34.49 Factors affecting vasopressin (AVP) release

Increased by
- Increased osmolality
- Hypovolaemia
- Hypotension
- Nausea
- Hypothyroidism
- Angiotensin II
- Adrenaline (epinephrine)
- Cortisol
- Nicotine
- Antidepressants

Decreased by
- Decreased osmolality
- Hypervolaemia
- Hypertension
- Ethanol
- α-Adrenergic stimulation

Diabetes insipidus

History and examination

Deficiency of vasopressin (AVP) or insensitivity to its action leads to excess excretion of dilute urine with a compensatory increase in thirst (polydipsia). Daily urine output may reach as much as 10–15 L, leading to dehydration that may be very severe if the thirst mechanism or consciousness is impaired or the patient is denied fluid (see also Chapter 27).

Diabetes insipidus (DI) may be masked by simultaneous cortisol deficiency; cortisol replacement allows a water diuresis and DI then becomes apparent.

Aetiology

Disorders of the hypothalamo-pituitary axis cause the condition of ***vasopressin deficiency (AVP-deficiency***), while renal disorders and electrolyte disturbance lead to vasopressin resistance (AVP-resistance). Causes of ***vasopressin deficiency (AVP-deficiency)*** are listed in **Box 34.50**. The most common is HP surgery, following which transient DI is common, frequently remitting after a few days or weeks. Typically, inflammatory lesions of the pituitary stalk are associated with DI (**Fig. 34.36**).

Familial isolated vasopressin deficiency causes DI from early childhood and is dominantly inherited, caused by a mutation in the *AVP-NPII* gene. ***DIDMOAD (Wolfram's) syndrome*** is a rare autosomal recessive disorder comprising DI, diabetes mellitus, optic atrophy, and deafness and is caused by mutations in the *WFS1* gene on chromosome 4. MRI may show an absent or poorly developed posterior pituitary.

Biochemistry

- High or high-normal plasma osmolality with low urine osmolality (in primary polydipsia, plasma osmolality tends to be low).

Box 34.50 Causes of diabetes insipidus

AVP-deficiency
- Familial (e.g., DIDMOAD)
- Idiopathic (often autoimmune)
- Tumours:
  - Craniopharyngioma
  - Hypothalamic tumour, e.g., glioma, germinoma
  - Metastases, especially breast
  - Lymphoma/leukaemia
  - Pituitary with suprasellar extension (rare)
- Infections:
  - Tuberculosis
  - Meningitis
  - Cerebral abscess
- Infiltrations:
  - Sarcoidosis
  - Langerhans' cell histiocytosis
- Inflammatory:
  - Hypophysitis
- Post-surgical:
  - Transfrontal
  - Trans-sphenoidal
- Vascular:
  - Haemorrhage/thrombosis
  - Sheehan's syndrome
  - Aneurysm
- Trauma (e.g., head injury)

AVP-resistance
- Familial (e.g., vasopressin receptor gene, aquaporin-2 gene defect)
- Idiopathic
- Renal disease (e.g., renal tubular acidosis)
- Hypokalaemia
- Hypercalcaemia
- Drugs (e.g., lithium, demeclocycline, glibenclamide)
- Sickle cell disease
- Prolonged polyuria due to any cause, including AVP-deficiency and primary polydipsia—can cause mild temporary AVP-resistance

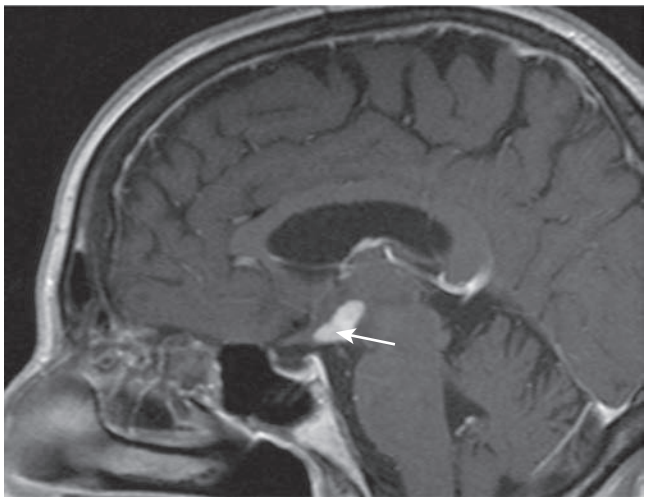

Fig. 34.36 **MRI showing a thickened pituitary stalk in hypophysitis.**

- Resultant high or high-normal plasma sodium (hypernatraemia).
- High 24-hour urine volumes (<2 L excludes the need for further investigation).
- Failure of urinary concentration with fluid deprivation.
- Restoration of urinary concentration with vasopressin or an analogue.

The latter two points are studied with a formal water deprivation test (**Box 34.51**). In normal subjects, plasma osmolality remains normal while urine osmolality rises above 600 mOsm/kg. In DI, plasma osmolality rises while the urine remains dilute, only concentrating after exogenous vasopressin is given (in AVP-deficiency), or not concentrating after vasopressin if AVP-resistance is present. An alternative is measurement of plasma vasopressin during hypertonic saline infusion, but these measurements are not widely available.

Management

The synthetic vasopressin (AVP) analogue, desmopressin, is the treatment of choice in AVP-deficiency. It has a longer duration of

Box 34.51 Water deprivation test

Indications
- Diagnosis or exclusion of diabetes insipidus (DI).

Procedure
- Fasting and no fluids from 07:30 h (or overnight if only mild DI is expected and polyuria is only modest).
- Monitor serum and urine osmolality, urine volume, and weight hourly for up to 8 h.
- Abandon fluid deprivation if weight loss >3% occurs.
- If serum osmolality is >300 mOsm/kg and/or urine osmolality <600 mOsm/kg, give desmopressin 2 μg i.m. at end of test. Allow free fluid but measure urine osmolality for 2–4 h.

Interpretation
- ***Normal response***—serum osmolality remains within normal range (275–295 mOsm/kg). Urine osmolality rises to >600 mOsm/kg.
- ***Diabetes insipidus (DI)***—serum osmolality rises above normal without adequate concentration of urine osmolality (i.e., serum osmolality >300 mOsm/kg; urine osmolality <600 mOsm/kg).
- ***AVP-resistance***—if desmopressin does not concentrate urine.
- ***AVP-deficiency***—if urine osmolality rises by >50% after desmopressin.

action than vasopressin and has no vasoconstrictive effects. It can be given intranasally as a spray 10–40 μg once or twice daily, orally as 100–200 μg three times daily, or intramuscularly 2–4 μg daily. Response is variable and must be monitored carefully with enquiry about fluid input/output and plasma osmolality measurements. The main problem is avoiding water overload and consequent hyponatraemia. Where there is an underlying cause (e.g., a hypothalamic tumour), this should be investigated and treated.

Alternative agents in mild DI, probably working by sensitizing the renal tubules to endogenous vasopressin, include thiazide diuretics, carbamazepine (200–400 mg daily), or chlorpropamide (200–350 mg daily) but these are rarely used.

AVP-resistance

In this condition, renal tubules are resistant to normal or high levels of plasma vasopressin (AVP). AVP-resistance may be inherited as a rare sex-linked recessive disorder, with an abnormality in the vasopressin-2 receptor, or as an autosomal post-receptor defect in an AVP-sensitive water channel, aquaporin-2. More commonly, it can be acquired as a result of renal disease, sickle cell disease, drug ingestion (e.g., lithium), hypercalcaemia, or hypokalaemia. Wherever possible, the cause should be reversed (see **Box 34.50**). Polyuria is helped by thiazide diuretics.

Other causes of polyuria and polydipsia

Diabetes mellitus, hypokalaemia, and hypercalcaemia should be excluded. In the case of diabetes mellitus, the cause is an osmotic diuresis secondary to glycosuria, which leads to dehydration and an increased perception of thirst owing to hypertonicity of the extracellular fluid.

Primary polydipsia

This is a relatively common cause of thirst and polyuria. It is a psychiatric disturbance characterized by the excessive intake of water. Plasma sodium and osmolality fall as a result and the urine produced is appropriately dilute. Vasopressin levels become virtually undetectable. Prolonged primary polydipsia may lead to the phenomenon of 'renal medullary washout', with a fall in the concentrating ability of the kidney.

Characteristically, the diagnosis is made by a water deprivation test. A low plasma osmolality is usual at the start of the test, and since vasopressin secretion and action can be stimulated, the patient's urine becomes concentrated (although 'maximum' concentrating ability may be impaired); the initially low urine osmolality gradually increases with the duration of the water deprivation.

Syndrome of inappropriate antidiuresis (SIAD)

History and examination

Inappropriate secretion of AVP (also called vasopressin) leads to retention of water and hyponatraemia. The presentation of the syndrome of inappropriate antidiuresis (SIAD, also known as the syndrome of inappropriate antidiuretic hormone, SIADH) is usually vague, with confusion, nausea, irritability, and, later, fits and coma. There is no oedema. Mild symptoms usually occur with plasma sodium levels below 125 mmol/L and serious manifestations are likely below 115 mmol/L. The elderly may show symptoms with milder abnormalities.

The syndrome must be distinguished from dilutional hyponatraemia due to excess infusion of glucose/water solutions or diuretic administration. The clinical approach to the patient with hyponatraemia is discussed further in Chapter 27.

Investigations

The usual features are:
- dilutional hyponatraemia due to excessive water retention
- euvolaemia (in contrast to hypovolaemia of sodium and water depletion states)
- low plasma osmolality with 'inappropriate' urine osmolality >100 mOsm/kg (and typically higher than plasma osmolality)
- continued urinary sodium excretion >30 mmol/L (lower levels suggest sodium depletion or 'hypovolaemic hyponatraemia' and should respond to 0.9% saline infusion)
- absence of hypokalaemia (or hypotension)
- normal renal and adrenal and thyroid function.

The causes are listed in **Box 34.52**.

Hyponatraemia is very common during illness in frail elderly patients and it may sometimes be clinically difficult to distinguish SIAD from salt and water depletion, particularly when mixed clinical features are present. Under these circumstances, a trial infusion of 1–2 L 0.9% saline is given. SIAD will not respond (but will excrete the sodium and water load effectively); sodium depletion will respond. ACTH deficiency can give a very similar biochemical picture to SIAD; therefore it is necessary to ensure that the HPA axis is intact, particularly in neurosurgical patients, in whom ACTH deficiency may be relatively common.

Management

The underlying cause should be corrected where possible. Symptomatic relief can be obtained by the following measures:
- ***Fluid intake*** should be restricted to 500–1000 mL daily. If tolerated and complied with, this will correct the biochemical abnormalities in almost every case.
- ***Frequent measurement*** of plasma osmolality, serum sodium, and body weight is needed.
- ***Demeclocycline*** (600–1200 mg daily) is given if water restriction is poorly tolerated or ineffective; this inhibits the action of vasopressin on the kidney, causing a reversible form of AVP-resistance. However, it often causes photosensitive rashes.
- ***Hypertonic saline*** may be indicated when the syndrome is very severe (i.e., acute and symptomatic), but this is potentially dangerous and should only be used with extreme caution.

Box 34.52 Common causes of the syndrome of inappropriate antidiuresis (SIAD)

Tumours
- Small-cell carcinoma of lung
- Prostate
- Thymus
- Pancreas
- Lymphomas

Pulmonary lesions
- Pneumonia
- Tuberculosis
- Lung abscess

Central nervous system causes
- Meningitis
- Tumours
- Head injury
- Subdural haematoma
- Cerebral abscess
- Systemic lupus erythematosus
- Vasculitis

Metabolic causes
- Alcohol withdrawal
- Porphyria

Drugs
- Chlorpropamide
- Carbamazepine
- Cyclophosphamide
- Vincristine
- Phenothiazines

- ***Vasopressin V_2 antagonists***, e.g., tolvaptan 15 mg daily, are being used with good results.

DISORDERS OF CALCIUM METABOLISM

Serum calcium levels are mainly controlled by parathyroid hormone (PTH) and vitamin D. Hypercalcaemia is much more common than hypocalcaemia and is frequently detected incidentally with multichannel biochemical analysers. Mild asymptomatic hypercalcaemia occurs in about 1 in 1000 of the population, with an incidence of 25–30 per 100 000 population. It occurs mainly in elderly females and is usually due to primary hyperparathyroidism.

Parathyroid hormone

There are normally four parathyroid glands, which are situated posterior to the thyroid; occasionally, additional glands exist or they may be found elsewhere in the neck or mediastinum. PTH, an 84-amino-acid hormone derived from a 115-residue pre-prohormone, is secreted from the chief cells of the parathyroid glands. PTH levels rise as serum ionized calcium falls. The latter is detected by specific G-protein-coupled, calcium-sensing receptors on the plasma membrane of the parathyroid cells. PTH has several major actions, all serving to increase plasma calcium by:
- increasing osteoclastic resorption of bone (occurring rapidly)
- increasing intestinal absorption of calcium (a slow response)
- increasing synthesis of 1,25-dihydroxyvitamin D_3
- increasing renal tubular reabsorption of calcium
- increasing excretion of phosphate.

PTH effects are mediated at specific membrane receptors on the target cells, resulting in an increase of adenyl cyclase messenger activity.

Vitamin D metabolism is discussed in Chapter 33 ('Vitamin D metabolism' section).

PTH measurements use two-site immunometric assays that measure only the intact PTH molecule; interpretation requires a simultaneous calcium measurement in order to differentiate most causes of hyper- and hypocalcaemia.

Box 34.53 Causes of hypercalcaemia

Excessive parathyroid hormone (PTH) secretion
- Primary hyperparathyroidism (most common by far), adenoma (common), hyperplasia, or carcinoma (rare)
- Tertiary hyperparathyroidism
- Ectopic PTH secretion (very rare indeed)

Malignant disease—low PTH levels (second most common cause)
- Myeloma
- Secondary deposits in bone
- Production of osteoclastic factors by tumours
- PTH-related protein secretion

Excess action of vitamin D
- Iatrogenic or self-administered excess
- Granulomatous diseases, e.g., sarcoidosis, tuberculosis
- Lymphoma

Excessive calcium intake
- 'Milk-alkali' syndrome

Other endocrine disease (mild hypercalcaemia only)
- Thyrotoxicosis
- Addison's disease

Drugs
- Thiazide diuretics
- Vitamin D analogues
- Lithium administration (chronic)
- Vitamin A

Miscellaneous
- Long-term immobility
- Familial hypocalciuric hypercalcaemia

Hypercalcaemia

Pathophysiology and aetiology

The major causes of hypercalcaemia are listed in **Box 34.53**; primary hyperparathyroidism and malignancies are by far the most common (>90% of cases). Hyperparathyroidism itself may be primary, secondary or tertiary. Primary hyperparathyroidism is caused by single (>80%) parathyroid adenomas or by diffuse hyperplasia of all the glands (15%–20%); multiple parathyroid adenomas are rare. Involvement of multiple parathyroid glands may be part of a familial syndrome (e.g., MEN type 1 or 2a). Parathyroid carcinoma is rare (<1%), though it usually produces severe and intractable hypercalcaemia. Hyperparathyroidism–jaw tumour syndrome is a rare familial cause of hyperparathyroidism that may be associated with parathyroid carcinoma and maxillary or mandibular tumours.

Primary hyperparathyroidism

Primary hyperparathyroidism is of unknown cause, though it appears that adenomas are monoclonal. Hyperplasia may also be monoclonal. Chromosomal rearrangements in the 5′ regulatory region of the parathyroid hormone gene have been identified, and inactivation of some tumour suppressor genes at a variety of sites may also be involved.

Secondary hyperparathyroidism

Secondary hyperparathyroidism (see Chapter 26, 'CKD mineral and bone disorder [CKD-MBD]' section) is physiological compensatory hypertrophy of all parathyroids because of hypocalcaemia, such as occurs in chronic kidney disease or vitamin D deficiency. PTH levels are raised but calcium levels are low or normal, and PTH falls to

normal after correction of the cause of hypocalcaemia where this is possible.

Tertiary hyperparathyroidism

Tertiary hyperparathyroidism is the development of apparently autonomous parathyroid hyperplasia after longstanding secondary hyperparathyroidism, most often in renal failure. Plasma calcium and phosphate are both raised, the latter often grossly so. Use of calcimimetic medications, or surgical parathyroidectomy, is generally necessary at this stage.

Clinical features

Mild hypercalcaemia

Mild hypercalcaemia (e.g., adjusted calcium <3 mmol/L) is frequently asymptomatic, but more severe hypercalcaemia can produce a number of symptoms:

- ***General.*** There may be tiredness, malaise, dehydration, and depression.
- ***Renal.*** Renal colic occurs from stones, and primary hyperparathyroidism is present in about 5% of patients who present with renal calculi. Polyuria or nocturia, haematuria, and hypertension are seen. The polyuria results from the effect of hypercalcaemia on renal tubules, reducing their concentrating ability—a form of mild AVP-resistance.
- ***Bones.*** There may be bone pain. Hyperparathyroidism mainly affects cortical bone, and bone cysts and locally destructive 'brown tumours' occur but only in advanced disease. Only 5%–10% of all cases have definite bony lesions even when sought. Bone disease may be more apparent when there is coexisting vitamin D deficiency.
- ***Abdomen.*** There may be abdominal pain.
- ***Chondrocalcinosis*** and ectopic calcification. These are occasional features.
- ***Corneal calcification.*** This is a marker of longstanding hypercalcaemia but causes no symptoms.

There may also be symptoms from the underlying cause. Malignant disease is usually advanced by the time hypercalcaemia occurs, typically with bony metastases. The common primary tumours are bronchus, breast, myeloma, oesophagus, thyroid, prostate, lymphoma, and renal cell carcinoma. True 'ectopic PTH secretion' by tumours is very rare, and most cases are associated with raised levels of PTH-related protein. This is a 144-amino-acid polypeptide that is necessary in fetal development but does not have a clearly defined role in the adult, the initial sequence of which shows an approximate homology with the biologically active part of PTH. Bone-resorbing cytokines and prostaglandins may be involved locally where there are metastatic skeletal lesions, leading to local mobilization of calcium by osteolysis with subsequent hypercalcaemia.

Severe hypercalcaemia

Severe hypercalcaemia (>3 mmol/L) is usually associated with malignant disease, hyperparathyroidism, chronic kidney disease, or vitamin D therapy.

Investigations and differential diagnosis

Biochemistry

A combination of serum calcium, phosphate, PTH, and vitamin D concentrations is required to define the clinical phenotype.

- ***Serum PTH.*** The hallmark of primary hyperparathyroidism is hypercalcaemia and hypophosphataemia with detectable or elevated intact PTH levels during hypercalcaemia. When this combination is present in an asymptomatic patient, then further investigation is usually unnecessary. However, undetectable PTH level in the context of hypercalcaemia always requires further investigation to exclude malignancy or other pathology (see **Box 34.53**).
- ***Renal function.*** This is usually normal but should be measured as a baseline. Advancing CKD leads to the development first of secondary and then tertiary hyperparathyroidism, as the PTH glands initially function physiologically in the face of hypocalcaemia associated with CKD, before then demonstrating hypertrophy and autonomous secretion in the face of a rising serum calcium.
- ***24-h urinary calcium*** or single calcium creatinine ratio. This should be measured in a young patient with modest elevation in calcium and PTH to exclude familial hypocalciuric hypercalcaemia (see Chapter 26, 'Hypercalciuria' section).
- ***Elevated serum alkaline phosphatase.*** This is found in severe parathyroid bone disease, but otherwise, it suggests an alternative cause for hypercalcaemia.

Where PTH is undetectable or equivocal, a number of other tests may lead to the diagnosis:

- Protein electrophoresis and serum light chain immunofixation: to exclude myeloma.
- Serum TSH: to exclude hyperthyroidism.
- 9 a.m. cortisol and/or ACTH test: to exclude Addison's disease.
- Serum ACE: may be helpful in the diagnosis of sarcoidosis.

Imaging

The success of parathyroid imaging is highly operator-dependent and choice therefore depends on local skills and experience. Imaging is frequently far less accurate than parathyroid exploration by an expert surgeon, where the success rate is at least 90%. Methods include:

- Radioisotope scanning using ^{99m}Tc-sestamibi, which is approximately 90% sensitive in detecting adenomas; it is enhanced with single-photon emission computed tomography (SPECT). Choline-PET scanning is a newer technique which may prove superior to more traditional approaches.
- Ultrasound, which is simple and safe, although insensitive for small tumours.
- High-resolution CT scan or MRI (more sensitive). A CT scan of the thorax, abdomen, and pelvis will often show malignancy or granulomatous disease in patients with hypercalcaemia and a suppressed PTH level.

Dual-energy X-ray absorptiometry (DXA) bone density scanning is useful to detect bone effects in asymptomatic people with hyperparathyroidism in whom conservative management is planned.

Abdominal X-rays may show renal calculi or nephrocalcinosis. High-definition hand X-rays can show subperiosteal erosions in the middle or terminal phalanges. Neither is required as part of diagnosis unless symptoms of renal calculi are present or there is evidence of renal failure.

Management of hypercalcaemia

Details of emergency treatment for severe hypercalcaemia are given in **Box 34.54**. This should be followed by oral therapy unless the underlying disease can be treated.

Management of primary hyperparathyroidism

Medical management

A high fluid intake should be maintained. Calcimimetic agents (that target the calcium-sensing receptors in the parathyroid gland, e.g.,

Box 34.54 Management of acute severe hypercalcaemia

Acute hypercalcaemia often presents with dehydration, nausea and vomiting, nocturia and polyuria, drowsiness, and altered consciousness. The serum Ca^{2+} is >3 mmol/L and sometimes as high as 5 mmol/L. While investigation of the cause is underway, immediate treatment is mandatory if the patient is seriously ill or if the Ca^{2+} is >3.5 mmol/L.

- ***Rehydrate*** using at least 4–6 L of 0.9% saline on day 1, and 3–4 L for several days thereafter. Central venous pressure (CVP) may need to be monitored to control the hydration rate.
- ***Intravenous bisphosphonates*** are the treatment of choice for the hypercalcaemia of malignancy or of undiagnosed cause. Pamidronate is preferred (60–90 mg as an intravenous infusion in 0.9% saline or glucose over 2–4 h or, if less urgent, over 2–4 days). Levels fall after 24–72 h, lasting for approximately 2 weeks. Zoledronic acid is an alternative.
- ***Prednisolone*** (30–60 mg daily) is effective in some instances (e.g., in myeloma, sarcoidosis and vitamin D excess) but in most cases is ineffective.
- ***Calcitonin*** (200 units i.v. 6-hourly) has a short-lived action and is little used.
- ***Oral phosphate*** (sodium cellulose phosphate 5 g three times daily) produces diarrhoea.

cinacalcet) are of proven value in parathyroid carcinoma and in dialysis patients (see Chapter 26, 'CKD mineral and bone disorder [CKD-MBD]' section) and are increasingly used in primary hyperparathyroidism as an alternative to surgical intervention.

Surgery

Surgery is indicated in primary hyperparathyroidism for:

- symptoms of hypercalcaemia such as thirst, frequent or excessive urination, or constipation or
- end-organ disease (renal stones, fragility fractures, or osteoporosis) or
- an albumin-adjusted serum calcium level of 2.85 mmol/L or above.

The situation where plasma calcium is mildly raised (2.65–2.85 mmol/L) is more controversial. Most authorities feel that young patients should be operated on, as should those who have reduced cortical bone density or significant hypercalciuria, as this is associated with stone formation.

In older patients without these problems, or in those unfit for or unwilling to have surgery, conservative management is indicated. Regular measurement of serum calcium and of renal function is necessary. Bone density of cortical bone should be monitored if conservative management is used. Hyperparathyroidism can cause non-specific symptoms of weakness, fatigue, and depression, and it can be difficult to determine whether these symptoms are related to hypercalcaemia or coincidental.

Surgical technique and complications

Parathyroid surgery should be performed only by experienced surgeons, as the minute glands may be very difficult to define, and it is difficult to distinguish between an adenoma and normal parathyroid. In expert centres, over 90% of operations are successful, involving removal of the adenoma or removal of all four hyperplastic parathyroids. Minimal access surgery is used, and some centres measure PTH levels intraoperatively to ensure that the adenoma has been removed.

Other than postoperative hypocalcaemia (see below), the other rare complications are those of thyroid surgery: bleeding and recurrent laryngeal nerve palsies (<1%). Vocal cord function should be checked preoperatively.

If initial exploration is unsuccessful, a full work-up, including venous catheterization and detailed scanning, is essential, remembering that parathyroid tissue can be ectopic.

Postoperative care

The major danger after operation is hypocalcaemia, which is more common in patients who have significant bone disease and/or vitamin D deficiency—the 'hungry bone' syndrome. Some authorities pre-treat such patients with alfacalcidol 2 μg daily from 2 days preoperatively for 10–14 days, and routine vitamin D replacement (preferably without calcium) is always indicated if deficiency is diagnosed. Chvostek's and Trousseau's signs (see below) are monitored, as well as biochemistry. Plasma calcium measurements are performed at least daily until stable, with or without replacement; a mild transient hypoparathyroidism often continues for 1–2 weeks. Depending on its severity, oral or intravenous calcium should be given temporarily, as only a few patients (<1%) will develop long-standing surgical hypoparathyroidism.

Familial hypocalciuric hypercalcaemia

This uncommon autosomal dominant, and usually asymptomatic, condition demonstrates increased renal reabsorption of calcium despite hypercalcaemia. PTH levels are normal or slightly raised and urinary calcium is low. Familial hypocalciuric hypercalcaemia is caused by loss-of-function mutations in the gene on the long arm of chromosome 3 encoding for the calcium ion–sensing G-protein-coupled receptor in the kidney and parathyroid gland. Family members are often affected and this is detected by genetic analysis. The course is generally benign. This diagnosis can be differentiated from hyperparathyroidism in an isolated case by the calcium:creatinine ratio in blood and urine.

Hypocalcaemia

Pathophysiology

Hypocalcaemia may be due to deficiencies of calcium homeostatic mechanisms, or secondary to high phosphate levels or other causes of hypocalcaemia (Box 34.55). All forms of hypoparathyroidism, except transient surgical effects, are uncommon.

Aetiology

- ***Chronic kidney disease*** is the most common cause of hypocalcaemia.
- ***Severe vitamin D deficiency*** may cause mild, and occasionally severe, hypocalcaemia.
- ***Hypocalcaemia after thyroid or parathyroid surgery*** is common but usually transient; fewer than 1% of thyroidectomies leave permanent damage (see above).
- ***Idiopathic hypoparathyroidism*** is one of the rarer autoimmune disorders and is often accompanied by vitiligo, cutaneous candidiasis, and other autoimmune disease.
- ***DiGeorge's syndrome*** is a familial condition in which hypoparathyroidism is associated with intellectual impairment, cataracts, and calcified basal ganglia, and occasionally with specific autoimmune disease.
- ***Pseudohypoparathyroidism*** is a syndrome of end-organ resistance to PTH owing to a mutation in the $G_S\alpha$-protein (GNAS1), which is coupled to the PTH receptor. It is associated with short stature, short metacarpals, subcutaneous calcification, and sometimes intellectual impairment. Variable degrees of resistance involving other G-protein-linked hormone receptors may also be seen (TSH, LH, FSH).
- ***Pseudo-pseudohypoparathyroidism*** describes the phenotypic defects but without any abnormalities of calcium metabolism.

Box 34.55 Causes of hypocalcaemia

Increased phosphate levels
- Chronic kidney disease (common)
- Phosphate therapy

Hypoparathyroidism
- Surgical—after neck exploration (thyroidectomy, parathyroidectomy—common)
- Congenital deficiency (DiGeorge's syndrome)
- Idiopathic hypoparathyroidism (rare)
- Severe hypomagnesaemia

Vitamin D deficiency
- Osteomalacia/rickets
- Vitamin D resistance

Resistance to PTH
- Pseudohypoparathyroidism

Drugs
- Calcitonin
- Bisphosphonates
- Other
  - Acute pancreatitis (quite common)
  - Citrated blood in massive transfusion (not uncommon)
  - Low plasma albumin, e.g., malnutrition, chronic liver disease
  - Malabsorption, e.g., coeliac disease

Individuals with this condition may share the same gene defect as those with pseudohypoparathyroidism and be members of the same families.

Clinical features

Hypoparathyroidism presents as neuromuscular irritability and neuropsychiatric manifestations. Paraesthesiae, circumoral numbness, cramps, anxiety, and tetany (Box 34.56) are followed by convulsions, laryngeal stridor, dystonia, and psychosis. Two signs of hypocalcaemia are Chvostek's sign (gentle tapping over the facial nerve causes twitching of the ipsilateral facial muscles) and Trousseau's sign (inflation of the sphygmomanometer cuff above systolic pressure for 3 min induces tetanic spasm of the fingers and wrist). Severe hypocalcaemia may cause papilloedema and, frequently, a prolonged QT interval on the ECG.

Investigations

The clinical history and picture is usually diagnostic and is confirmed by a low serum calcium (after correction for any albumin abnormality). Additional tests include:
- ***Serum and urine creatinine.*** These test for renal disease.
- ***PTH levels*** in the serum. These are absent or inappropriately low in hypoparathyroidism, high in other causes of hypocalcaemia.
- ***Parathyroid antibodies.*** These are present in idiopathic hypoparathyroidism.
- ***25-hydroxyvitamin D serum level.*** This is low in vitamin D deficiency.
- ***Magnesium level.*** Severe hypomagnesaemia results in functional hypoparathyroidism, which is reversed by magnesium replacement.
- ***X-rays of metacarpals.*** Short fourth metacarpals occur in pseudohypoparathyroidism.

Management

In vitamin D deficiency, colecalciferol is the most appropriate treatment. In other cases, alpha-hydroxylated derivatives of vitamin D are preferred for their shorter half-life, and especially in renal disease, as the others require renal hydroxylation. Usual daily maintenance doses are 0.25–2 μg for alfacalcidol (1α-OH-D_3). During treatment, plasma calcium must be monitored frequently to detect hypercalcaemia. Oral calcium supplements may be used in the early stages of treatment, and severe hypocalcaemia presenting as an emergency may occasionally require replacement with intravenous calcium gluconate. In hypoparathyroidism, PTH therapy is being used in clinical trials.

Box 34.56 Causes of tetany

In the presence of alkalosis
- Hyperventilation
- Excess antacid therapy
- Persistent vomiting
- Hypochloraemic alkalosis, e.g., primary hyperaldosteronism

In the presence of hypocalcaemia
See Box 34.54

HYPOGLYCAEMIA IN THE NON-DIABETIC PATIENT

Hypoglycaemia develops when hepatic glucose output falls below the rate of glucose uptake by peripheral tissues. Hepatic glucose output may be reduced by:
- inhibition of hepatic glycogenolysis and gluconeogenesis by insulin
- depletion of hepatic glycogen reserves by malnutrition, fasting, exercise, or advanced liver disease
- impaired gluconeogenesis (e.g., following alcohol ingestion).

In the first of these categories, insulin levels are raised, the liver contains adequate glycogen stores, and the hypoglycaemia can be reversed by injection of glucagon. In the other two situations, insulin levels are low and glucagon is ineffective. Peripheral glucose uptake is accelerated by high insulin levels and by exercise, but these conditions are normally balanced by increased hepatic glucose output.

The most common symptoms and signs of hypoglycaemia are neurological. The brain consumes about 50% of the total glucose produced by the liver. This high energy requirement is needed to generate ATP, used to maintain the potential difference across axonal membranes.

Insulinomas

Insulinomas are pancreatic islet cell tumours that secrete insulin. Most are sporadic but some patients have multiple tumours arising from neural crest tissue (MEN). Some 95% of these tumours are benign. The classic presentation is with fasting hypoglycaemia, but early symptoms may also develop in the late morning or afternoon. Recurrent hypoglycaemia is often present for months or years before the diagnosis is made, and the symptoms may be atypical or even bizarre; the presenting features in one series are given in Box 34.57. Common misdiagnoses include psychiatric disorders,

Box 34.57 Presenting features of insulinoma

- Diplopia
- Sweating, palpitations, weakness
- Confusion or abnormal behaviour
- Loss of consciousness
- Grand mal seizures

particularly pseudodementia in elderly people, epilepsy, and cerebrovascular disease.

Whipple's triad remains the basis of clinical diagnosis. This is satisfied when:

- symptoms are associated with fasting or exercise
- hypoglycaemia is confirmed during these episodes
- glucose relieves the symptoms.

A fourth criterion—demonstration of inappropriately high insulin levels during hypoglycaemia—may usefully be added.

The diagnosis is confirmed by the demonstration of hypoglycaemia in association with inappropriate and excessive insulin secretion. Hypoglycaemia is demonstrated by:

- Measurement of overnight fasting (16 h) glucose and insulin levels on three occasions. About 90% of patients with insulinomas will have low glucose and non-suppressed (normal or elevated) insulin levels.
- A prolonged 72-hour supervised fast if overnight testing is inconclusive and symptoms persist.

Autonomous insulin secretion is demonstrated by lack of normal feedback suppression during hypoglycaemia. This may be shown by measuring insulin, C-peptide, or proinsulin during a spontaneous episode of hypoglycaemia.

Management

The most effective therapy is surgical excision of the tumour but insulinomas are often very small and difficult to localize. Many techniques can be used to attempt to localize insulinomas. Sensitivity and specificity vary between centres and between operators. These include highly selective angiography, contrast-enhanced high-resolution CT scanning, scanning with radiolabelled somatostatin (some insulinomas express somatostatin receptors), and endoscopic and intraoperative ultrasound scanning. Venous sampling for the detection of 'hot spots' of high insulin concentration in the various intra-abdominal veins is still used occasionally.

Medical treatment with diazoxide is useful when the insulinoma is malignant, when a tumour cannot be located, and when elderly patients have mild symptoms. Symptoms may also remit on treatment with a somatostatin analogue (octreotide or lanreotide).

Hypoglycaemia with other tumours

Hypoglycaemia may develop in the course of advanced neoplasia and cachexia and has been described in association with mesenchymal tumours such as sarcomas including tumours involving gastrointestinal tract, classically termed ***non-islet cell tumour hypoglycaemia*****.** Hypoglycaemia is due to excessive secretion of IGF-2 and pro-IGF-2 leading to activation of insulin receptor. True ectopic insulin secretion is extremely rare.

Postprandial hypoglycaemia

If frequent venous blood glucose samples are taken following a prolonged glucose tolerance test, about 1 in 4 subjects will have at least one value below 3 mmol/L. The arteriovenous glucose difference is quite marked during this phase, so very few are truly hypoglycaemic in terms of arterial (or capillary) blood glucose content. Failure to appreciate this simple fact led some authorities to believe that postprandial (or reactive) hypoglycaemia was a potential 'organic' explanation for a variety of complaints that might otherwise have been considered psychosomatic. Later work showed a poor correlation between symptoms and biochemical hypoglycaemia. Even so, a number of otherwise normal people occasionally become pale, weak, and sweaty at times when meals are due and report benefit from advice to take regular snacks between meals.

True postprandial hypoglycaemia may develop in the presence of alcohol, which 'primes' the cells to produce an exaggerated insulin response to carbohydrate. The person who substitutes alcoholic beverages for lunch is particularly at risk. Postprandial hypoglycaemia sometimes occurs after gastric surgery, owing to rapid gastric emptying and mismatching of nutrient absorption and insulin secretion. This is referred to as 'dumping' but it is now rarely encountered.

Hepatic and renal causes of hypoglycaemia

The liver can maintain a normal glucose output despite extensive damage, and hepatic hypoglycaemia is uncommon. It is, however, a particular problem with acute hepatic failure.

The kidney has a subsidiary role in glucose production (via gluconeogenesis in the renal cortex), and hypoglycaemia is sometimes a problem in terminal renal failure.

Endocrine causes of hypoglycaemia

Deficiencies of hormones antagonistic to insulin are rare but well-recognized causes of hypoglycaemia. These include hypopituitarism, isolated ACTH deficiency, and Addison's disease.

Drug-induced hypoglycaemia

Many drugs have been reported to produce isolated cases of hypoglycaemia, including sulfonylureas, quinine (during treatment for falciparum malaria), and propranolol.

Alcohol-induced hypoglycaemia

Alcohol inhibits gluconeogenesis. Alcohol-induced hypoglycaemia occurs in poorly nourished chronic alcohol users, binge drinkers, and children who have taken relatively small amounts of alcohol, since they have a diminished hepatic glycogen reserve. They present with coma and hypothermia (hypothermia is a feature of hypoglycaemia, due to the suppression of central thermoregulation, particularly the shivering response; children manifest hypothermia more frequently due to their high ratio of surface area to body mass).

Factitious hypoglycaemia

This is a relatively common variant of self-induced disease and is more common than an insulinoma. Hypoglycaemia may be produced by surreptitious self-administration of insulin or sulphonylureas. Many patients in this category have been extensively investigated for an insulinoma. Measurement of C-peptide levels during hypoglycaemia should identify patients who are injecting insulin; sulphonylurea abuse can be detected by chromatography of plasma or urine.

OTHER ENDOCRINE DISORDERS

Diseases of many glands

Polyglandular autoimmune syndromes

Primary endocrine gland failure is commonly caused by autoantibodies (see **Box 34.4**) and there may be multiple gland deficiencies. Most common are the associations of primary hypothyroidism and type 1 diabetes, and either of these with Addison's disease or pernicious anaemia. IgG4 disease may affect multiple endocrine glands (see Chapter 6).

Autoimmune polyendocrinopathy type 1

Autoimmune polyendocrinopathy type 1 (APS-1) is an autosomal recessive disorder and is caused by *AIRE* gene mutations. This condition is also associated with non-endocrine manifestations. The *AIRE* gene is present in the epithelium of the thymus and is involved in the presentation of self-antigens to thymocytes. Mutations will allow persistence of thymic lymphocytes, which react against self-antigens and cause development of autoimmune disorders. Mucocutaneous candidiasis often develops before the onset of endocrine deficiencies, such as hypothyroidism, Addison's disease, type 1 diabetes, hypoparathyroidism, primary hypogonadism, nail dystrophy, vitiligo, and dental enamel hypoplasia.

Autoimmune polyendocrinopathy type 2

Autoimmune polyendocrinopathy type 2 (APS-2) is not associated with candidiasis and is also known as Schmidt's syndrome, typically when hypothyroidism, Addison's disease, type 1 diabetes, myasthenia gravis, and primary hypogonadism are present in combination; coeliac disease is also an association.

Multiple endocrine neoplasias

Multiple endocrine neoplasia (MEN) is the name given to the simultaneous or metachronous occurrence of tumours involving a number of endocrine glands (**Box 34.58**). The condition is inherited in an autosomal dominant manner and arises from the expression of recessive oncogenic mutations, most of which have been isolated. Affected persons may pass on the mutation to their offspring in the germ cell, but for the disease to become evident, a somatic mutation must also occur, such as deletion or loss of a normal homologous chromosome.

MEN 1

The defect in MEN 1 is in a novel gene *(menin)* on the long arm of chromosome 11, which encodes for a 610-amino-acid protein. *Menin* represses a transcription factor *(JunD)*, and lack of *JunD* suppression leads to decreased apoptosis and oncogenesis. People with the *MEN1* gene carry one mutant gene and a wild-type gene (i.e., are heterozygous). When the wild-type gene undergoes a random somatic mutation during life, this leads to loss of heterozygosity and explains the late onset of tumours at any stage (the 'two hit' hypothesis). MEN 1 is classically associated with pancreatic, parathyroid, and pituitary tumours, although other glands may be affected (see **Box 34.58**; **Fig. 34.37**).

MEN 2a and 2b

MEN 2a and 2b are caused by mutations of the *RET* proto-oncogene on chromosome 10 (see medullary thyroid cancer, 'Medullary carcinoma' section). This gene encodes for a transmembrane glycoprotein receptor. For MEN 2a, the mutation is in the extracellular domain; for 2b, it is in the intracellular domain. MEN 2 is classically associated with parathyroid tumours, phaeochromocytoma, and MTC (see **Box 34.58**). Unlike MEN 2a, MEN 2b is associated with a marfanoid phenotype and intestinal and visceral ganglioneuromas, as well as neuromas around the lips and tongue.

Box 34.58 Multiple endocrine neoplasia (MEN) syndromes

Organ	Frequency	Tumours/manifestations
Type 1		
Parathyroid	95%	Adenomas/hyperplasia
Pituitary	70%	Adenomas—prolactinoma, ACTH- or GH-secreting (acromegaly)
Pancreas	50%	Islet cell tumours (secreting insulin, glucagon, somatostatin, VIP, pancreatic polypeptide, GH-releasing factor) Zollinger–Ellison syndrome (gastrinoma) Non-functional tumour
Adrenal	40%	Non-functional adenoma
Thyroid	20%	Adenomas—multiple or single
Type 2a		
Adrenal	Most	Phaeochromocytoma (70% bilateral) Cushing's syndrome
Thyroid	Most	Medullary carcinoma (calcitonin-producing)
Parathyroid	60%	Hyperplasia
Type 2b		
Type 2a with marfanoid phenotype and intestinal and visceral ganglioneuromas but not hyperparathyroidism. Neuromas also present around lips and tongue		

ACTH, Adrenocorticotrophic hormone; *GH*, growth hormone; *VIP*, vasoactive intestinal peptide.

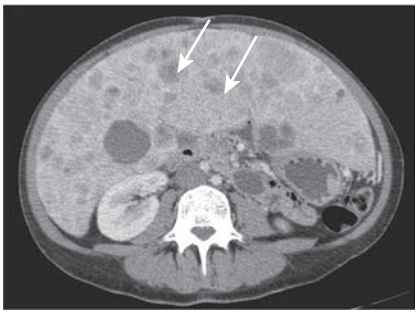

Fig. 34.37 Multiple liver metastases *(arrowed)* from a pancreatic endocrine tumour in multiple endocrine neoplasia type 1.

Management

Management of established tumours in MEN is largely the same as treatment for similar tumours occurring sporadically. In MEN 1, four-gland parathyroidectomy is usually recommended when surgery is needed since all glands are typically involved. However, the essence of management in MEN is annual screening to detect tumours at an early, treatable stage.

Screening

A careful family history is essential. If the precise gene mutation has been identified in a particular family, then family members at risk

can be offered genetic screening for the presence of the mutation, ideally in childhood. In affected individuals, biochemical screening and periodic imaging are then required.

Screening for MEN 1

Hyperparathyroidism is usually the first manifestation, and serum calcium is the simplest screening test in families with no identified mutation. In an established case (or gene-positive family member), other screening bloods include prolactin, GH/IGF-1, and 'gut hormones'. Periodic imaging of pancreas, adrenals, and pituitary is usually performed. People with MEN 1 can develop metastases to the liver from non-functional pancreatic tumours that are clinically silent; this emphasizes the need for regular screening imaging.

Screening for MEN 2

Serum calcium levels will easily detect hyperparathyroidism.

- ***Medullary carcinoma of thyroid (MCT).*** With the known presence of the gene defect, total thyroidectomy is recommended in early childhood or as soon as the gene defect is identified. Calcitonin is a useful tumour marker.
- ***Phaeochromocytoma.*** Metanephrine or catecholamine estimations are required.

McCune–Albright syndrome

This condition is associated with autonomous hypersecretion of a number of endocrine glands at a young age. Gonadotrophin-independent puberty occurs, with Leydig cell hyperplasia in males and ovarian oestrogen production in girls. Pituitary hypersecretion may lead to hyperprolactinaemia, acromegaly, or gigantism. Cushing's syndrome due to nodular hyperplasia of the adrenal cortex is observed, as well as autonomous functioning thyroid nodules. Non-endocrine manifestations include café-au-lait patches and increased bone deformity and fractures due to polyostotic fibrous dysplasia. The pathological basis is a point mutation of the *GNAS1* gene that inhibits GTPase activity, leading to persistent activation of cAMP-mediated endocrine secretion.

Ectopic hormone secretion

This term refers to hormone synthesis, and normally secretion, from a neoplastic non-endocrine cell, most usually seen in tumours that have some degree of embryological resemblance to specialist endocrine cells. The clinical effects are those of the hormone produced, with or without manifestations of systemic malignancy. The most common situations seen are the following:

- ***Hypercalcaemia of malignant disease***, often from squamous cell tumours of lung and breast, often with bone metastases. Where metastases are not present, most cases are mediated by secretion of PTH-related protein (PTHrP), which has considerable sequence homology to PTH; a variety of other factors may sometimes be involved but very rarely PTH itself. Treatment is discussed in Chapter 11 ('Acute hypercalcaemia' section).
- ***SIAD*** (see 'Syndrome of inappropriate antidiuresis [SIAD]' section). Again, this is most commonly caused by a primary lung tumour.
- ***Ectopic ACTH syndrome*** (see 'The adrenal cortex' section). Small-cell carcinoma of the lung, carcinoid tumours, and MTCs are the most common causes, though many other tumours rarely cause it.
- ***Production of insulin-like activity.*** This may result in hypoglycaemia.
- ***Carcinoid syndrome.*** This is the collection of symptoms (diarrhoea, abdominal pain and loss of appetite; flushing of the skin, particularly the face; tachycardia; breathlessness and wheezing) when a neuroendocrine tumour, usually one that has spread to the liver, releases hormones such as serotonin into the bloodstream. Measurement of 24-hour urinary 5HIAAs is required for diagnosis.

CORE SKILLS AND KNOWLEDGE

Diabetes is the most prevalent and clinically important endocrine disorder, affecting around 10% of the adult population. Many people with diabetes go on to develop life-limiting complications, including cardiovascular, renal, eye and neurological disease. Most consultant diabetologists are trained in both diabetes and endocrinology as well as general internal medicine, although many diabetes specialists focus solely on diabetes. Some subspecialize, focusing on areas of practice including inpatient care, diabetes in pregnancy, technology (insulin pumps and continuous glucose monitoring [CGM]), and pancreas or islet cell transplantation.

Most people with diabetes are seen in outpatient clinics either in primary or secondary care, although approximately 15% of all inpatients have diabetes. Many people are admitted for other reasons, but diabetes may complicate their hospital stays.

Key skills within diabetes include:

- Listening to people with diabetes (as with any person with a long-term condition), involving them actively in the management of their illness, and understanding the role of the multidisciplinary team in preventing and managing long-term diabetes-related complications
- Learning about the acute management of diabetic emergencies (hypoglycaemia, diabetic ketoacidosis (DKA), and hyperosmolar hyperglycaemic state [HHS]); see Chapter 11
- Developing confidence in prescribing insulin therapy and the wide range of oral and injectable antidiabetes agents.

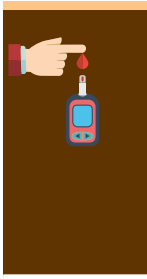
Diabetes is best understood in outpatient settings by listening to people with diabetes. Because diabetes is a chronic condition, there is an opportunity to build up long-term patient relationships. Diabetic emergencies are common reasons for admission to hospital, and people presenting with these may be found in the hospital emergency department or acute admissions unit.

CLINICAL SKILLS

Diabetes mellitus is a chronic condition, and people with diabetes may present to healthcare services for routine monitoring of their condition or for a host of reasons related or unrelated to their diabetes. Treatment for diabetic emergencies, which may be the presentation when diabetes is first diagnosed, is covered in the chapter on acute medicine (see Chapter 11). A typical approach to people with diabetes in non-emergency settings is shown in **Box 35.1**.

Routine checks in people with diabetes

All people with diabetes should be screened regularly to assess their glycaemic levels and for the emergence of any complications. **Box 35.2** shows the checks (covering history, examination, and



selected investigations) that should form part of this screening process, which should be undertaken at least every year.

Examination

The physical examination carried out in people with diabetes should be determined by the clinical context and any presenting complications. Fig. 35.1 presents a range of physical signs seen in people with diabetes: some are a direct result of complications of hyperglycaemia, and some are conditions associated with diabetes (e.g., vitiligo, an autoimmune disease sometimes found in people with type 1 diabetes).

Box 35.3 lists features to look for when examining the feet of a person with diabetes.

Language matters

There has been a recognition that the way language is used by healthcare professionals has a profound effect on how people with diabetes (and their carers) experience the condition and feel about living with diabetes. This convention has been adopted in the chapter and is an important change in focus, reflecting the primary role of putting people with diabetes at the centre of the management of their condition.

BACKGROUND

Diabetes mellitus is a complex metabolic disorder characterized by chronic hyperglycaemia caused by relative insulin deficiency, resistance, or both. In 2021, the International Diabetes Federation estimated that 537 million adults aged 20 to 79 years (10.5% of the global population) had diabetes, and this number is projected to reach 643 million by 2030 and 783 million by 2045 (Fig. 35.2).

Diabetes is associated with a number of short- and long-term complications that reduce quality of life and life expectancy and are associated with major health costs, estimated globally to be US$ 966 billion in 2021. Complications include acute metabolic disturbance; macrovascular disease (leading to an increased prevalence of coronary artery disease, peripheral vascular disease, and stroke); and microvascular damage causing retinopathy, nephropathy, and neuropathy.

Box 35.1 Taking a history in diabetes mellitus (see also Box 1.7)

Presenting complaint
- Why has the person with diabetes attended?
- Could their presenting complaints be related to a complication of diabetes?

Diagnosis of diabetes
- When were they diagnosed?
- Did they present as an emergency or with symptomatic hyperglycaemia, or was diabetes picked up without symptoms through routine screening?
- What type of diabetes do they have?
  - Might it be secondary to another disease process?
  - Is there any reason to suspect monogenic diabetes?

Management of the disease
- What do they understand about the role of self-management in diabetes?
- Do they monitor their capillary or interstitial glucose?
  - Do they keep a diary of the results?
  - What are the usual readings?
  - Is there evidence of hypoglycaemia or hyperglycaemia?
- Have they ever required hospital (or intensive care) admission for diabetic emergencies?
- Have they ever experienced hypoglycaemic episodes?
  - Do they have impaired awareness if they are becoming hypoglycaemic?
  - Have they needed external help to manage an episode of hypoglycaemia?
- Do they drive or engage in any other activities that may raise safety concerns in the context of hypoglycaemia?

Medications
- Do they see a primary care or hospital team to manage their diabetes?
  - Are they in contact with a specialist nurse or dietitian?
- What medication do they use to manage their blood glucose?
- If they inject insulin, do they rotate injection sites?
  - What size needles do they use?
- Are they able to adjust doses of insulin or other medications according to blood glucose levels and carbohydrate intake?
- What other medications are they taking?

Complications
- Have they had any cardiovascular events?
  - What is their cardiovascular risk, and is this being appropriately managed?
- Are they undergoing regular retinal screening?
  - Have they required any retinal intervention?
- Do they supply regular urine samples to screen for diabetic nephropathy?
  - Are they taking angiotensin-converting enzyme inhibitors or angiotensin receptor blockers or other renoprotective medication?
- Have they had any problems with neuropathy or vascular disease affecting their feet?
  - Have they experienced a foot ulcer?
  - Have they needed an amputation?
  - Have they experienced any adverse psychological sequelae of diabetes, for example diabetes distress, depression, anxiety, or disordered eating?

Social history
- Do they smoke? If so, have they tried to quit?
- Are they aware of key health behavioural interventions around healthy eating, weight reduction, and exercise?

Box 35.2 Screening checks in people with diabetes (performed at least annually)

General health
- Level of knowledge about diabetes
- Weight and body mass index
- Diet and eating habits
- Exercise

Glycaemic management
- Glycated haemoglobin
- Glucose monitoring
- Medication
- Review of insulin injection sites

Development of complications
- Retinal screening, ideally by retinal photography
- Visual acuity
- Urine albumin:creatinine ratio
- Serum urea and electrolytes; estimated glomerular filtration rate
- Examination of feet for vascular disease and neuropathy
- Full blood count
- Thyroid function
- Liver function

Cardiovascular risk
- Smoking status
- Blood pressure
- Lipid profile
- Overall cardiovascular risk using validated risk model (e.g., QRISK)

General observation
Does patient look well/ unwell?
Weight loss (T1DM)
Weight gain (T2DM)
Dehydrated?
Breathing (air hunger, Kussmaul breathing)

Face
Cranial nerve palsy, particularly CN III
Eye movements
Ptosis

Skin
Vitiligo (autoimmune)
Pigmentation (e.g., axillary acanthosis nigricans in insulin resistance)
Granuloma annulare
Bullosis

Vitiligo

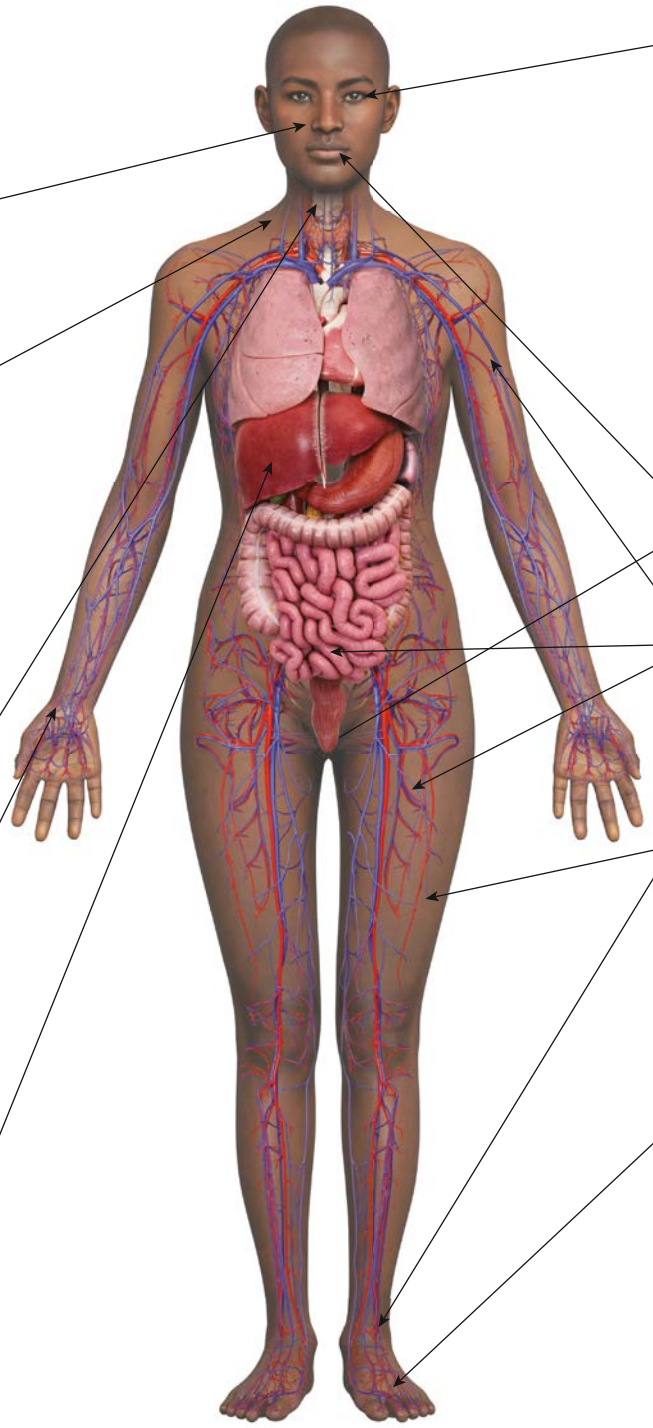
Neck
Carotid pulses/bruits
Check thyroid gland for goitre (autoimmune)

Hands
Carpal tunnel
Dupuytren's contracture
Muscle wasting
Limited joint movement

Dupuytren's contracture

(From Palastanga N. Anatomy and Human Movement, 6th edn, with permission.)

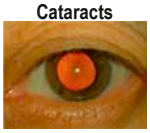
Abdomen
Hepatomegaly (fatty liver)



Eyes
Fundoscopy
- Cataracts, against red reflex
- Retinopathy (see Chapter 31)
- Visual acuity

Eyelids – xanthelasma

Cataracts



Retinopathy

Mouth and genitalia
Candidiasis

Insulin injection sites
Bruising
Lipohypertrophy
Lipoatrophy (rare)

Legs
Muscle wasting
Hair loss
Sensory neuropathy (glove and stocking)
Reflexes (lost in sensorimotor neuropathy)
Necrobiosis lipoidica

Feet
- Feel for peripheral pulses
- Skin – colour, ulcers, gangrene
- Look between toes for infection
- Sensory loss
  - Neuropathic foot ulcer
  - Charcot neuroarthropathy

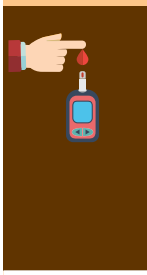
Neuropathic ulcer

Charcot joints

(From Miller MD. Presentation, Imaging and Treatment of Common Musculoskeletal Conditions, Saunders 2011, with permission.)

Aims of physical examination in people with diabetes:
* Assessing for diabetic emergencies — diabetic ketoacidosis, hypoglycaemia.
* Establishing the presence of complications — neuropathy, eyes and retinopathy, kidney disease, skin changes including ulceration, cardiovascular disease including peripheral vascular disease, foot complications, soft tissue infection
* Assessment of cardiovascular risk factors — blood pressure, stigmata of hyperlipidaemia, weight, and Body Mass Index
* Revealing signs of autoimmune disease — vitiligo, thyroid disease
* Assessment of injection sites

Fig. 35.1 Physical examination of people with diabetes. This is determined by the clinical context and any presenting complications. *CN,* Cranial nerve; *T1DM,* type 1 diabetes mellitus; *T2DM,* type 2 diabetes mellitus.



Box 35.3 Examination of the feet

Features of vascular disease

- Pale discoloration
- Loss of hair
- Cool temperature
- Absent pulses (begin in the foot and proceed up the legs)
- Reduced capillary refill time
- Evidence of gangrene or infection

Features of neuropathy

- Clawing of toes, loss of plantar arch
- Neuropathic ulcers
- Joint deformity (Charcot's joint)
- Glove and stocking sensory loss (check with monofilament)
- Loss of vibration sense, proprioception, and pain
- Loss of ankle jerk

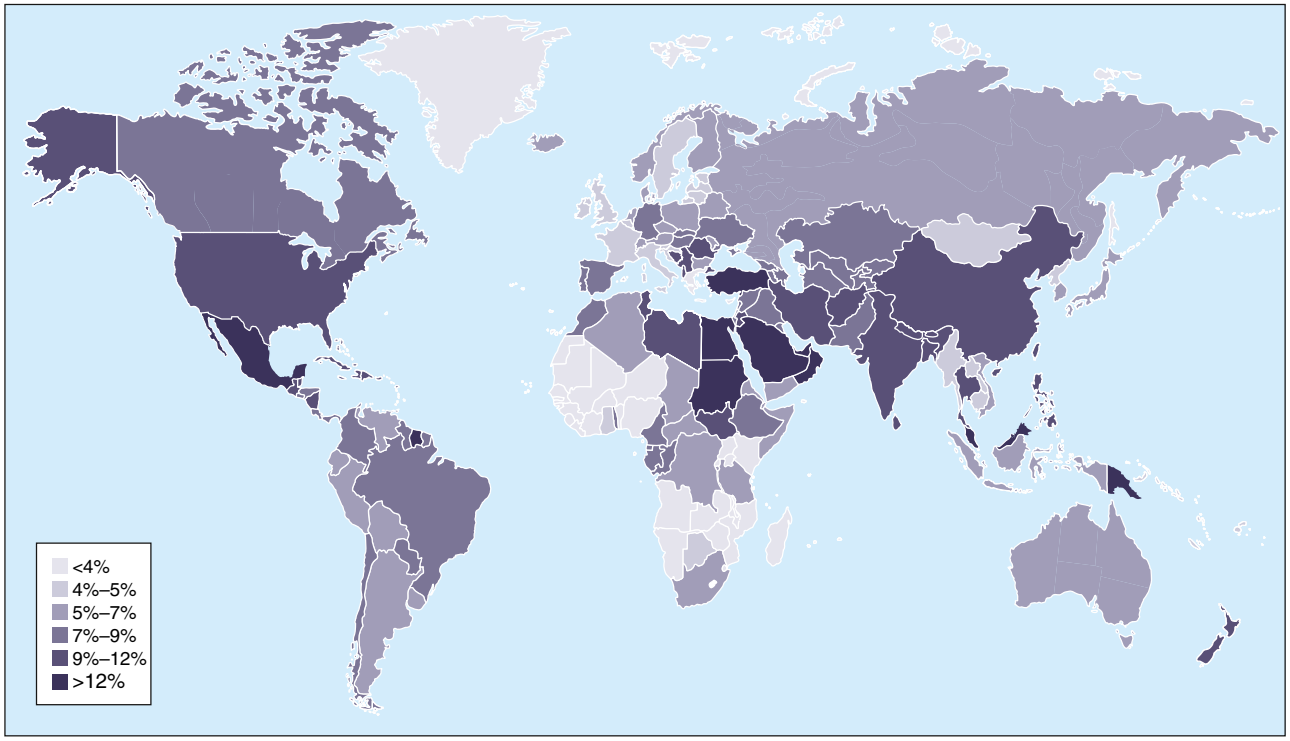


Fig. 35.2 Estimated age-adjusted prevalence of diabetes in adults aged 20 to 79 years in 2021. *(From IDF Diabetes Atlas, 10th edition.)* Map lines delineate study areas and do not necessarily depict accepted national boundaries.

Diabetes was responsible for approximately 6.7 million deaths or 12.2% of all deaths in 2021, outnumbering the combined number of global deaths from HIV, tuberculosis, and malaria. Globally, diabetes is among the top 10 causes of death. Approximately one-third of all diabetes-related deaths occur in people of working age (younger than 60 years of age). Although the number of years lost to diabetes is decreasing with time, a diagnosis of diabetes in a man or woman at the age of 18 years reduces life expectancy by 6.5 and 6.0 years, respectively. By contrast, diabetes diagnosed at the age of 60 years reduces life expectancy by 2.4 years in a man and 6.5 years in a woman; a diagnosis after 80 years has a limited effect on life expectancy. For many years, heart disease was the commonest cause of death accouting for approximately two-thirds of all deaths in people with diabetes. The large decline in vascular disease in the first two decades of the 21st century now means that cancers are the leading cause of death in people with diabetes.

PHYSIOLOGY OF INSULIN SECRETION AND ACTION

Insulin is the key hormone involved in the regulation of cellular energy supply and macronutrient balance derived from food. It is a 51–amino acid peptide hormone consisting of two polypeptide chains, the A and B chains, and is synthesized in the β cells of the pancreatic islets of Langerhans (Fig. 35.3). The synthesis, intracellular processing, and secretion of insulin by the β cells is typical of the way that the body produces and manipulates many peptide hormones. Fig. 35.4 illustrates the cellular events triggering the release of insulin-containing granules. After secretion, insulin enters the portal circulation and is carried to the liver, its prime target organ. About 50%–70% of secreted insulin is extracted and degraded in the liver; the remainder is broken down by the kidneys. C-peptide is only partially extracted by the liver (and hence provides a useful index of the rate of insulin secretion) but is mainly degraded by the kidneys.

Insulin is secreted at a slow background rate throughout the day, resulting in a low plasma insulin concentration between meals and overnight. In response to eating, there is a rapid rise in circulating insulin concentration, which falls back to baseline within 2 hours (Fig. 35.5).

The insulin receptor

Insulin exerts its actions through binding to a receptor, which straddles the cell membrane of many cells (Fig. 35.6). The receptor comprises a dimer with two α-subunits, which include the binding sites

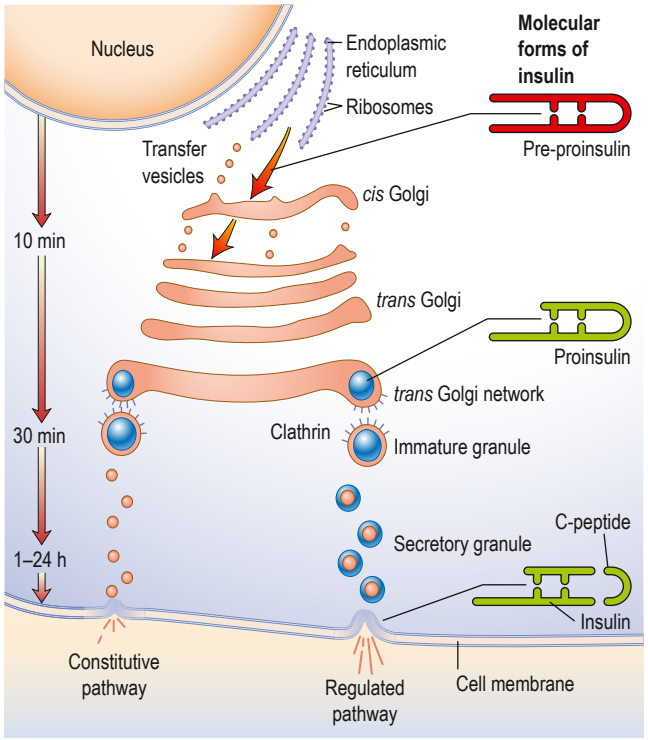

Fig. 35.3 Part of a β cell. The ribosomes manufacture pre-proinsulin from insulin messenger RNA (mRNA). The hydrophobic 'pre' portion of pre-proinsulin allows it to transfer to the Golgi apparatus and is subsequently enzymatically cleaved off. Proinsulin is parceled into secretory granules in the Golgi apparatus. These mature and pass towards the cell membrane, where they are stored before release. The proinsulin molecule folds back on itself and is stabilized by disulphide bonds. The biochemically inert peptide fragment known as connecting (C-)peptide splits off from proinsulin in the secretory process, leaving insulin as a complex of two linked peptide chains. Equimolar quantities of insulin and C-peptide are released into the circulation via the 'regulated pathway'. A small amount of insulin is secreted by the β cell directly via the 'constitutive pathway', which bypasses the secretory granules.

for insulin, and two β-subunits, which traverse the cell membrane. When insulin binds to the α-subunits, it induces a conformational change in the β-subunits, resulting in activation of tyrosine kinase and initiation of a cascade response involving a host of other intracellular substrates. The insulin–receptor complex is then internalized by the cell, insulin is degraded, and the receptor is recycled to the cell surface.

Glucose metabolism

Blood glucose levels are tightly regulated in health and rarely stray outside the range of 3.5 to 8.0 mmol/L (63–144 mg/dL) despite the widely varying effects of food, fasting, and exercise. Tight regulation of glucose is necessary because some tissues, particularly the brain, are highly dependent on glucose as an energy source, but a high glucose concentration irreversibly damages cellular proteins.

The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (as glycogen) in the post-absorptive state and releases it into the circulation between meals to match the rate of glucose utilization by peripheral tissues. The liver also combines three carbon molecules derived from breakdown of fat (glycerol), muscle glycogen (lactate), and protein (e.g., alanine) into the six-carbon glucose molecule by the process of gluconeogenesis.

Glucose production

More than 90% of the approximately 200 g of glucose used daily is derived from liver glycogen and hepatic gluconeogenesis, with the remainder coming from renal gluconeogenesis.

Glucose utilization

The major consumer of glucose is the brain, whose function depends on an uninterrupted supply of this substrate. Its requirement is 1 mg/kg body weight per minute, or approximately 100 g daily in a 70-kg person. Glucose uptake by the brain is obligatory and is not dependent on insulin, and the glucose used is oxidized to carbon dioxide and water. Tissues such as muscle and fat have insulin-responsive glucose transporters and absorb glucose in response to postprandial peaks in glucose and insulin. At other times, energy requirements are largely met by fatty acid oxidation. Glucose taken up by muscle is stored as glycogen or metabolized to lactate or carbon dioxide and water. Fat uses glucose as a substrate for triglyceride synthesis; lipolysis releases fatty acids from triglyceride together with glycerol, a substrate for hepatic gluconeogenesis.

Glucose transport

Cell membranes are not inherently permeable to glucose. A family of specialized glucose transporter (GLUT) proteins carry glucose through the membrane into cells. The function of GLUT-1 to -3 is insulin independent, but insulin stimulates glucose uptake into muscle and adipose tissue through GLUT-4. GLUT-4 is normally present in the cytoplasm, but after insulin binds to its receptor, GLUT-4 moves to the cell surface, where it creates a pore for glucose entry (Fig. 35.6).

Hormonal regulation

Insulin is a major regulator of intermediary metabolism, but its actions in the fasting and postprandial states differ (Fig. 35.7). In the fasting state, insulin's main action is to regulate glucose release by the liver; in the postprandial state, it additionally promotes glucose uptake by fat and muscle.

A number of 'counter-regulatory hormones' that antagonize the action of insulin are also important in maintaining normoglycaemia. As glucose concentration falls below the normal range, glucagon is secreted from the pancreatic α-cells. At the same time, several other hormones, including noradrenaline (norepinephrine), cortisol, and growth hormone, are released. These counter-regulatory hormones increase hepatic glucose production and reduce its utilization in fat and muscle for any given insulin concentration.

CLASSIFICATION OF DIABETES

Diabetes may be primary (idiopathic) or secondary (Box 35.4). Gestational diabetes refers to glucose intolerance appearing for the first time in pregnancy and is described in more detail later in the chapter (see 'Diabetes in pregnancy' section). Primary diabetes is classified into:

- ***Type 1 diabetes***, which usually has an immune pathogenesis and is characterized by severe insulin deficiency
- ***Type 2 diabetes***, which results from a combination of insulin resistance and less severe insulin deficiency

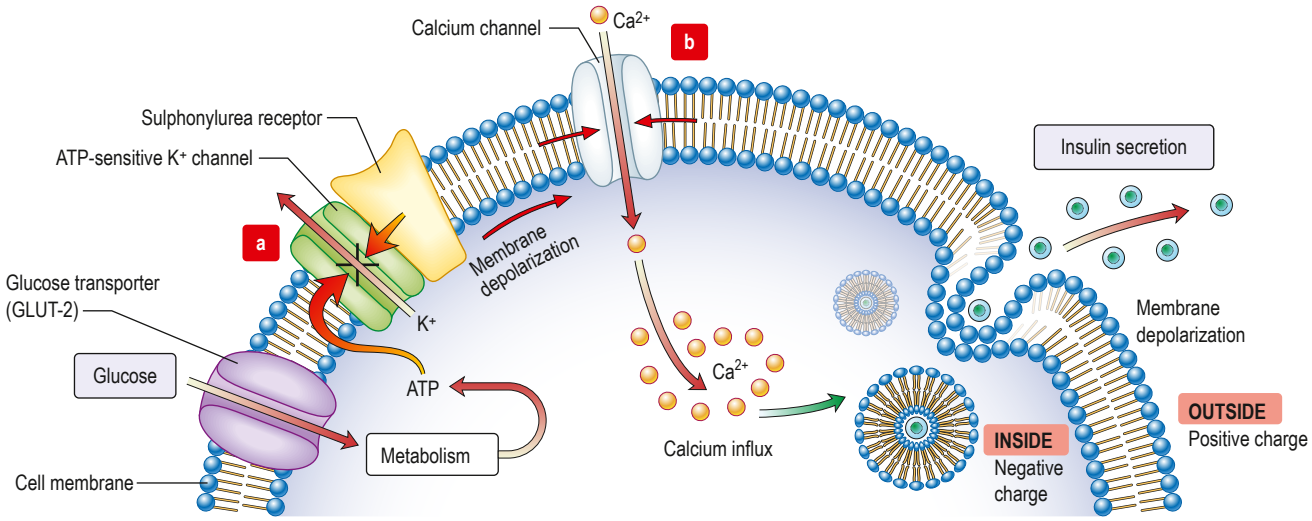

Fig. 35.4 The local regulation of insulin secretion from β cells. Glucose *(left)* enters the β cell via the glucose transporter 2 (GLUT-2) transporter protein, which is closely associated with the glycolytic enzyme glucokinase. Metabolism of glucose within the β cell generates adenosine triphosphate (ATP). ATP closes potassium channels in the cell membrane **(a)**. If a sulphonylurea binds to its receptor, this also closes potassium channels. Closure of potassium channels predisposes to cell membrane depolarization, allowing calcium ions to enter the cell via calcium channels in the cell membrane **(b)**. The rise in intracellular calcium triggers activation of calcium-dependent phospholipid protein kinase, which, via intermediary phosphorylation steps, leads to fusion of the insulin-containing granules with the cell membrane and exocytosis of the insulin-rich granule contents. Similar mechanisms produce hormone-granule secretion in many other endocrine cells.

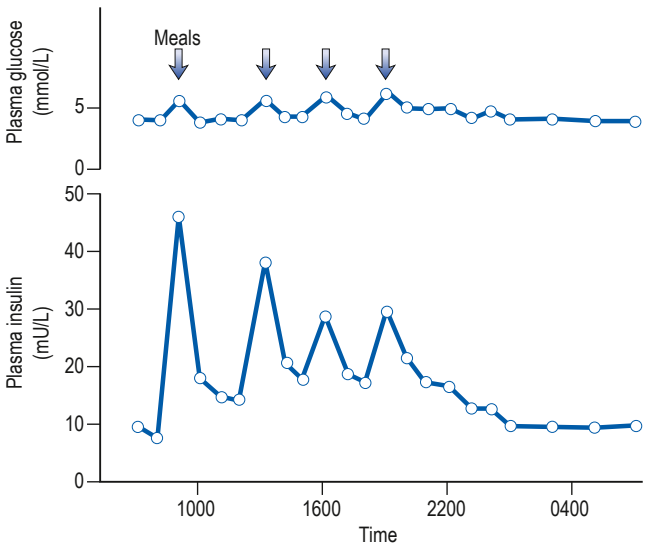

Fig. 35.5 Glucose and insulin profiles in people without diabetes.

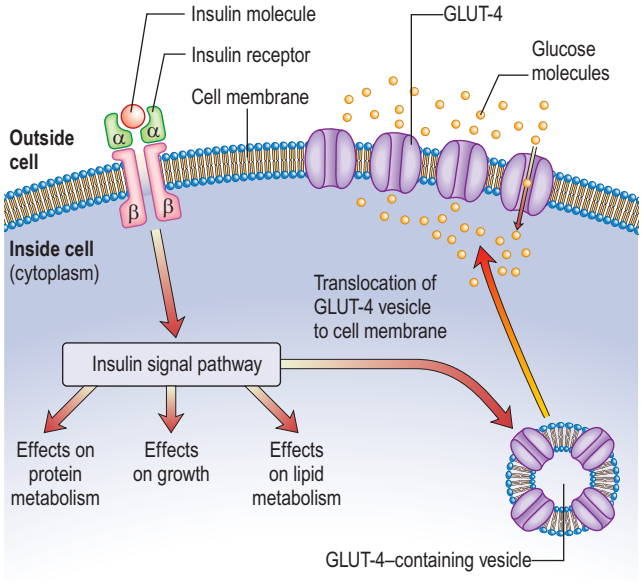

Fig. 35.6 Insulin signalling in peripheral cells (e.g., muscle and adipose tissue). The insulin receptor consists of α- and β-subunits linked by disulphide bridges *(top left)*. The β-subunits straddle the cell membrane. The transporter protein glucose transporter 4 (GLUT-4) *(bottom right)* is stored in intracellular vesicles. The binding of insulin to its receptor initiates many intracellular actions, including translocation of these vesicles to the cell membrane, carrying GLUT-4 with them; this allows glucose transport into the cell.

- ***Hybrid forms of diabetes***, which have features of both type 1 diabetes and type 2 diabetes
- ***Secondary diabetes*** can be subdivided into:
  - Diabetes secondary to single gene (monogenic) defects
  - Diabetes secondary to exocrine pancreatic disease
  - Diabetes secondary to endocrine disease
  - Diabetes secondary to drugs and chemicals
  - Diabetes secondary to infection
- **Uncommon forms** of immune-mediated diabetes
- **Other genetic syndromes** sometimes associated with diabetes
- **Unclassified diabetes.**

Box 35.5 lists the key features of the different types of diabetes. Type 1 diabetes and type 2 diabetes represent two distinct diseases from the epidemiological point of view, but from a clinical perspective, the two conditions appear as a spectrum, distinct at the two ends but overlapping in the middle.

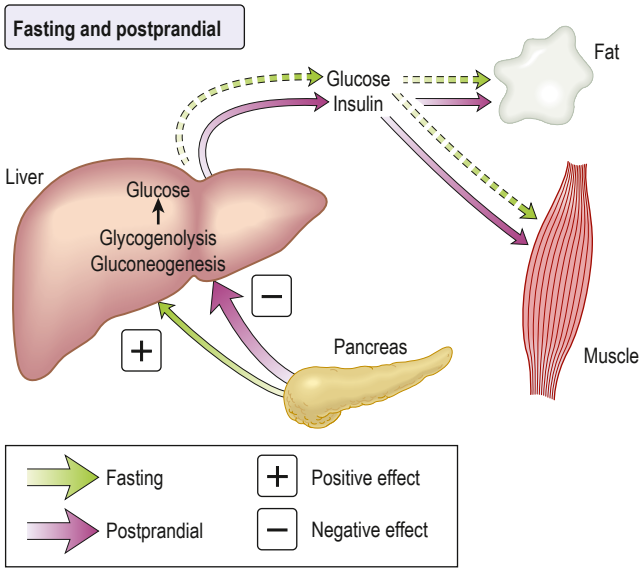

Fig. 35.7 Fasting and postprandial effects of insulin. In the fasting state, insulin concentrations are low, and it acts mainly as a hepatic hormone, modulating glucose production (via glycogenolysis and gluconeogenesis) from the liver. Hepatic glucose production rises as insulin levels fall. In the postprandial state, insulin concentrations are high, and it then suppresses glucose production from the liver and promotes the entry of glucose into peripheral tissues, particularly skeletal muscle and fat (increased glucose utilization).

Approximately 1% to 3% of cases of diabetes diagnosed before the age of 30 years are caused by mutations in a single gene (monogenic mutation). Although uncommon, it is important to recognize because the treatments and implications are different from those for type 1 diabetes or type 2 diabetes.

All forms of diabetes result from inadequate insulin secretion relative to the body's needs, and progressive insulin secretory failure is characteristic of both common forms of diabetes. Thus, a few people with immune-mediated type 1 diabetes may not require insulin at the point of diagnosis, whereas many with type 2 diabetes will eventually require it.

Type 1 diabetes

Epidemiology

Type 1 diabetes is a disease of insulin deficiency and accounts for 5% to 10% of all cases of diabetes. It typically presents in childhood and young adulthood, reaching a peak incidence around the time of puberty, but it can present at any age. In 2021, globally, more than 1.2 million children and adolescents had type 1 diabetes with approximately 184 100 new cases every year. The incidence of type 1 diabetes varies dramatically throughout the world, with the highest rates being in populations of Northern European origin and in a number of countries in the Middle East and North Africa.

Type 1 diabetes is subdivided into type 1A (immune-mediated) and type 1B (non–immune-mediated). The vast majority of those affected, especially in Western countries, have type 1A disease. A 'slowly evolving' immune-mediated variant with slower progression to insulin deficiency occurring in adults, often with features of the metabolic syndromes in later life, is termed *latent autoimmune diabetes in adults*.

Aetiology

Type 1 diabetes belongs to a family of immune-mediated organ-specific diseases, which include autoimmune thyroid disease, coeliac disease, Addison's disease, and pernicious anaemia. The precise molecular mechanisms that lead to type 1 diabetes are incompletely understood but involve the triggering of a selective autoimmune destruction of the insulin producing cells of a genetically predisposed individual. Initially, autoantibodies directed against pancreatic islet constituents appear in the circulation and often predate clinical onset by many years (stage 1). The islet antigens include insulin itself, the enzyme glutamic acid decarboxylase, protein tyrosine phosphatase (IA-2, also known as ICA512), the cation transporter ZnT8, and tetraspanin 7 (Fig. 35.8).

This is followed by a phase of asymptomatic loss of β-cell secretory capacity (stage 2); histologically, this is characterized by a chronic inflammatory mononuclear cell infiltrate of T lymphocytes and macrophages in the islets, known as insulitis (Fig. 35.9). Eventually, when the remaining β cells are no longer able to produce enough insulin to meet the body's needs, diabetes symptoms start to develop (stage 3).

Some recovery of endogenous insulin secretion may occur over the first few months after diagnosis and treatment initiation (the 'honeymoon period'). During this time, the insulin dose may need to be reduced. Some people with type 1 diabetes continue to produce small amounts of insulin for many decades after diagnosis. It is unclear why this occurs, but it seems that strict glucose management from diagnosis can prolong β-cell function.

The ability to detect autoantibodies in children before the development of type 1 diabetes is paving the way for trials to prevent the disease by immune modulation, but these interventions are still in early development.

Genetic susceptibility and inheritance

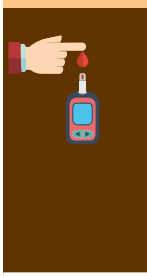
Approximately 10% to 20% of children with newly diagnosed type 1 diabetes have an affected first-degree relative. An increased susceptibility to type 1 diabetes is inherited, but the disease is not genetically predetermined. The identical twin of a person with type 1 diabetes has a 30% to 50% chance of developing the disease, which implies that non-genetic factors must also be involved. The risk of developing diabetes by age 20 years is greater with a father with diabetes (5%–8%) than with a mother with diabetes (2%–5%). If one child in a family has type 1 diabetes, each sibling has a 4% to 6% risk of developing diabetes. This risk rises to about 20% in siblings with the same human leucocyte antigen (HLA) genotype as the proband.

Human leucocyte antigen system

Genetic susceptibility is polygenic but the greatest contribution comes from polymorphisms in the HLA region. HLA genes are highly polymorphic and modulate the body's immune defence system. More than 90% of people with type 1 diabetes carry HLA-DR3-DQ2, HLA-DR4-DQ8, or both compared with about 35% to 40% of the background population. By contrast, certain HLA alleles confer protective effects (e.g., DQB1*0602).

Other genes or gene regions

Genome-wide association studies have greatly broadened our understanding of the genetic background of type 1 diabetes and have identified more than 250 non-HLA genes or gene regions that influence risk to a minor extent. These include the gene encoding insulin and other genes involved in immune responses. This has allowed the creation of genetic risk scores comprising between 9 and 67 single nucleotide polymorphisms that can usefully discriminate between type 1 diabetes and type 2 diabetes or those without diabetes in European populations.



Box 35.4 Aetiological classification of diabetes mellitus, based on the classification by the 2019 World Health Organization

Type of diabetes	Brief description
Type 1 diabetes	β-cell destruction (mostly immune mediated) and absolute insulin deficiency; onset peaks in childhood and early adulthood
Type 2 diabetes	Most common type; various degrees of β-cell dysfunction and insulin resistance; commonly associated with overweight and obesity
Hybrid forms of diabetes	
Slowly evolving, immune-mediated diabetes of adults	Similar to slowly evolving type 1 diabetes in adults but more often has features of the metabolic syndrome, a single glutamic acid decarboxylase autoantibody, and retains greater β-cell function
Ketosis-prone type 2 diabetes	Presents with ketosis and insulin deficiency but later does not require insulin; common episodes of ketosis; not immune mediated
Secondary forms of diabetes	
Monogenic defects of β-cell function Maturity-onset diabetes of the young Glucokinase mutations Hepatic nuclear factor mutations Neonatal diabetes Mitochondrial diabetes	Caused by specific gene mutations; has several clinical manifestations requiring different treatment; some occurring in the neonatal period and others by early adulthood
Monogenic defects in insulin action Leprechaunism Type A insulin resistance Rabson–Mendenhall syndrome Lipoatrophic diabetes	Caused by specific gene mutations; has features of severe insulin resistance without obesity; diabetes develops when β cells do not compensate for insulin resistance
Diseases of the exocrine pancreas Chronic pancreatitis Haemochromatosis Pancreatic surgery or trauma Cystic fibrosis Neoplasia Fibrocalculous pancreatopathy	Various conditions that affect the pancreas can result in hyperglycaemia (e.g., trauma, tumour, inflammation)
Endocrine disorders Acromegaly Cushing's syndrome Phaeochromocytoma Glucagonoma Hyperthyroidism Somatostatinoma Aldosteronoma	Occur in diseases with excess secretion of hormones that are insulin antagonists
Drug or chemical induced Glucocorticoids Thiazide diuretics Antipsychotics β-Adrenergic receptor blockers	Some medicines and chemicals impair insulin secretion or action; some can destroy β cells
Infection-related diabetes Congenital rubella Cytomegalovirus Mumps COVID-19	Some viruses have been associated with direct β-cell destruction
Uncommon specific forms of immune-mediated diabetes Stiff man syndrome Anti-insulin receptor antibodies	Associated with rare immune-mediated diseases
Other genetic syndromes sometimes associated with diabetes Down's syndrome Klinefelter's syndrome Turner's syndrome Prader–Willi syndrome Wolfram's syndrome Friedreich's ataxia Huntington's chorea Laurence–Moon–Biedl syndrome Myotonic dystrophy Porphyria	Many genetic disorders and chromosomal abnormalities increase the risk of diabetes
Unclassified diabetes	Used to describe diabetes that does not clearly fit into other categories; this category should be used temporarily when there is not a clear diagnostic category, especially close to the time of diagnosis
Hyperglycaemia first detected during pregnancy	
Diabetes in pregnancy	Type 1 diabetes or type 2 diabetes first diagnosed during pregnancy
Gestational diabetes	Hyperglycaemia below diagnostic thresholds for diabetes in pregnancy

Box 35.5 Spectrum of diabetes: a comparison of the different types of diabetes mellitus

Features	Type 1	Type 2	Monogenic	Secondary
Age	Younger (usually younger than 30 years)	Older (usually older than 30 years)	Neonates to early adulthood	Usually middle or older age
Weight loss	Usually present	Usually no	No	Depends on underlying cause
Obesity	Population frequency	Common	Population frequency	Depends on underlying cause
Time course of symptoms duration	Weeks	Months to years	Months	Weeks or months
Severity of symptoms	Can be marked	Variable but not usually severe	Not usually severe	Depends on underlying cause
Seasonal onset	Yes	No	No	No
Heredity	10%–20% have an affected first-degree relative	Heritability estimated to be 25% to 80% No HLA links	Present in almost all with onset in childhood or early adulthood	Unusual unless diabetes secondary to genetic conditions such as haemochromatosis
Pathogenesis	Autoimmune disease	No immune disturbance	No immune disturbance	No immune disturbance
Ketone formation	Yes	Unusual but may occur in ketosis-prone type 2 diabetes	No or minimal	May be present
Biochemical	C-peptide disappears	C-peptide persists	C-peptide persists	C-peptide persists

HLA, Human leucocyte antigen.

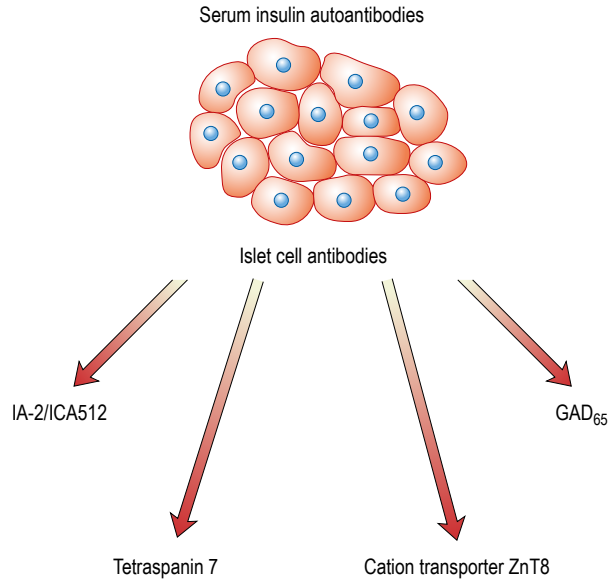


Fig. 35.8 Islet autoantibodies. Islet cell antibodies (ICAs) are detected by a fluorescent antibody technique that detects binding of autoantibodies to islet cells. Much of this staining reaction is caused by antibodies specific for glutamic acid decarboxylase (GAD) and protein tyrosine phosphatase (IA-2, also known as ICA512). Other islet autoantibodies involved are the cation transporter ZnT8 and the recently identified tetraspanin 7. Insulin autoantibodies also appear in the circulation but do not contribute to the ICA reaction.

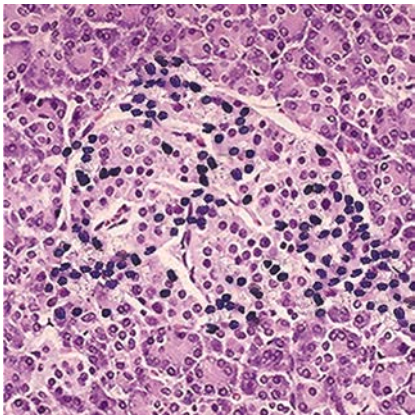

Fig. 35.9 Pancreatic islet showing infiltration by chronic inflammatory cells (insulitis).

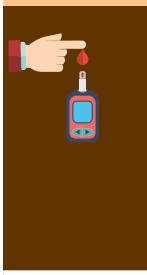
Environmental factors

Despite the genetic susceptibility to type 1 diabetes, 80% to 90% of people with newly diagnosed type 1 diabetes do not have a close family history of diabetes, and only 10% of individuals with HLA-susceptible genes develop type 1 diabetes. This implies that genetic factors do not account entirely for the development of type 1 diabetes, but environmental triggers are also important in initiating the autoimmune process, modulating the progression of islet autoimmunity to clinical type 1 diabetes and precipitating the disease in those with advanced pre-clinical disease.

Many putative environmental factors have been identified, but none of these is either necessary or sufficient to cause type 1 diabetes. They include:

- ***Maternal factors***, such as gestational infection and older age
- ***Perinatal factors***, such as birth order, mode of delivery, and birth weight
- ***Viral infections***, including enteroviruses such as coxsackie B4
- ***Exposures to dietary constituents***, such as early introduction of cow's milk and relative deficiency of vitamin D
- ***Environmental toxins***, such as alloxan or Vacor
- ***Childhood obesity***
- ***Psychological stress.***



How these environment factors interact with the immune system is uncertain, and there are several theories to explain this:

- The environmental factor damages the β cells, leading to presentation of self-antigens to the T-helper cells, which trigger the autoimmune response against the remaining healthy β cells.
- The self-antigens may be modified and become antigenic.
- An immune response against the environment factor may cross-react with self-antigens, so-called 'molecular mimicry'.
- The 'hygiene hypothesis' proposes that a cleaner environment with less early stimulation of the immune system in childhood may lead to a relatively immature immune system prone to autoimmunity.
- Early life antibiotic use is associated with the subsequent development of type 1 diabetes, perhaps because depletion of the gut microbiome compromises its role in inducing immune tolerance.

Type 2 diabetes

Epidemiology

Type 2 diabetes is the most common form of diabetes, accounting for around 95% of all cases; it is also one of the most common non-communicable diseases. The prevalence of type 2 diabetes is rising rapidly because of a combination of population growth, an ageing population and longer survival with type 2 diabetes, earlier age at onset, and better diagnosis. Type 2 diabetes is a disease of nutrient excess and the incidence has increased with the obesity epidemic (see Chapter 37), poor-quality diet, and reduced physical activity.

The prevalence of type 2 diabetes varies markedly across the world with the highest rates being in the Middle East and Pacific Islands and the lowest in Africa and Europe. Although often viewed as a disease of affluence, around three-quarters of those with type 2 diabetes live in low- and middle-income countries, and the most rapid rise in incidence is occurring in countries with rapidly growing economies, such as India and China. Two-thirds of people with diabetes live in urban areas.

Aetiology

Genetic susceptibility and inheritance

Type 2 diabetes clusters in families, and the risk of developing type 2 diabetes is dependent on genetic factors, with heritability estimates of between 25% and 80% in different countries. Identical twins of people with type 2 diabetes have about a 70% chance of developing diabetes; whereas the risk to non-identical twins or siblings is approximately 20% to 30%, the lifetime risk of developing type 2 diabetes is 40% for those with one parent with type 2 diabetes and about 70% if both parents are affected.

Type 2 diabetes is a polygenic disorder, and genome-wide studies of association between common DNA variants and disease have allowed identification of more than 1000 susceptibility loci. The vast majority of type 2 diabetes–associated risk variants (e.g., *TCF7L2*, *CDKAL*, *SLC30A*) appear to influence β-cell function. Most of the identified genetic markers exert very modest risk and together explain less than 20% of the heritability of type 2 diabetes.

Ageing

Pancreatic β-cell function declines with age, so the incidence of type 2 diabetes increases with age; most people are diagnosed after the age of 40 years, and one-third of those living with type 2 diabetes are older than 65 years. However, type 2 diabetes is becoming increasingly common in children and young adults.

Fetal origins of diabetes

There is a J-shaped relationship between low weight at birth and at 12 months of age and glucose intolerance later in life, particularly in those who gain excessive weight in adulthood. The concept is that poor nutrition early in life impairs β-cell development and function, predisposing to diabetes later on. Low birth weight also predisposes to a number of other chronic diseases in adulthood, including heart disease, hypertension, and osteoporosis.

Obesity

Obesity increases the risk of type 2 diabetes up to 80- to 100-fold and accounts for 80% to 85% of the overall risk of developing type 2 diabetes. In Western Europe and North America, 80% to 90% of adults with type 2 diabetes are overweight, and nearly a half have obesity. A central distribution of fat increases the risk of type 2 diabetes, so for any given level of obesity, the more visceral fat an individual has, the higher the risk of type 2 diabetes.

Diet

Although diet can affect the risk of diabetes through changes in body weight, certain dietary patterns are associated with higher or lower risks of type 2 diabetes. Components that increase the risk include dietary fat, particularly saturated fat; red meat; ultra-processed foods; fried foods, including French fries; white rice; and sugar-sweetened beverages. Wholegrains, increased fruit and vegetable intakes, nuts and seeds, pulses, fermented dairy products, oily fish, and a Mediterranean dietary pattern are associated with lower rates of type 2 diabetes.

Physical inactivity

Physical inactivity and sedentary behaviour are also associated with an increased risk of diabetes.

Other factors

Other risk factors include urbanization, poverty, abnormal sleep patterns, environmental toxins, and mental illness.

Pathogenesis

The relative role of defects in insulin secretion and action in the pathogenesis of type 2 diabetes has been much debated and likely differs between different people. However, both defects are necessary to develop diabetes.

Abnormalities of insulin action

Insulin action is diminished in type 2 diabetes through the development of insulin resistance, which is defined as the inability of insulin to produce its usual biological effects at physiological concentrations. It is characterized by an impaired ability of insulin to:

- Inhibit hepatic glucose output
- Stimulate glucose uptake into skeletal muscle
- Suppress lipolysis in adipose tissue.

The underlying mechanisms of insulin resistance are not fully understood but result from nutrient excess. Intracellular triglyceride accumulates in the liver and skeletal muscle and impedes the phosphorylation of the post-receptor insulin receptor substrate. Although this defect reduces insulin action with regards to glucose and lipid metabolism, insulin is still able to activate the mitogen-activated protein kinase pathway, which regulates a number of intracellular pathways involved in inflammation, cellular proliferation, and atherosclerosis.

Abnormalities of insulin secretion

Insulin resistance alone does not explain the development of diabetes because only one-fifth of those with the degree of insulin resistance characteristic of diabetes develop the condition. As insulin resistance develops, the body's response is to increase insulin secretion, so early type 2 diabetes is often associated with insulin hypersecretion. This observation led some to question the role of β-cell function in the aetiology of diabetes. Nevertheless, insulin secretory abnormalities manifest early in the course of type 2 diabetes and progress with time; an early sign is loss of the first phase of the normal biphasic insulin secretion. Even though circulating insulin concentrations are higher than in people without diabetes, they are still inadequate to restore glucose homeostasis. By the time of diagnosis, at least 50% of β-cell mass and function has been lost. Relative insulin lack is associated with increased glucose production from the liver (owing to inadequate suppression of gluconeogenesis) and reduced insulin-mediated glucose uptake by peripheral tissues. Hyperglycaemia and lipid excess are toxic to β cells, at least *in vitro*, a phenomenon known as glucotoxicity, which is thought to cause further β-cell loss and further deterioration of glucose homeostasis. With time, insulin secretion declines, an observation referred to as the 'Starling curve' of the pancreas. This time course varies widely between individuals.

Type 2 diabetes is thus a condition in which insulin deficiency relative to increased demand leads to insulin hypersecretion by a depleted β-cell mass and progression towards absolute insulin deficiency, requiring insulin therapy.

Other hormonal abnormalities

Glucagon secretion is increased in type 2 diabetes, likely because of diminished intra-islet insulin, and leads to increased hepatic glucose output.

The insulin response to oral glucose is greater than the response to intravenous (i.v.) glucose, a phenomenon known as the incretin effect. The effect is mostly mediated by two hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), which are released by the gastrointestinal tract after eating. Their major action is to increase glucose-induced β-cell insulin secretion while suppressing glucagon secretion, but they also slow gastric emptying and induce satiety. Both hormones have short half-lives in the circulation, being degraded within minutes predominantly by the enzyme dipeptidyl peptidase-4 (DPP-4). The incretin effect is impaired in type 2 diabetes.

Glucose reabsorption in the kidney

The sodium–glucose transporter 2 (SGLT2) is a sodium-dependent glucose transport protein located in the proximal renal tubules, whose function is to reabsorb glucose from the renal filtrate and restore it to the circulation. Its activity thus determines the renal threshold for glucose, which normally averages approximately 10 to 11 mmol/L (180–200 mg/dL). This prevents urinary glucose loss but is maladaptive in type 2 diabetes because this process is upregulated and serves to maintain hyperglycaemia.

Monogenic diabetes

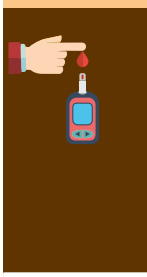
Approximately 1% to 3% of people with diabetes diagnosed before the age of 30 years have monogenic diabetes, previously called 'maturity-onset diabetes of the young' (**Box 35.6**). Monogenic diabetes is caused by a single gene mutation, which is dominantly inherited and predominantly affects β-cell function. Extra-pancreatic features may also be present. Many people with monogenic diabetes are misdiagnosed with either type 1 diabetes or type 2 diabetes, so monogenic diabetes should be considered in people presenting with early-onset diabetes in association with an affected parent and early-onset diabetes in approximately 50% of relatives. It is likely that as awareness improves, the diagnosis rate will increase.

? Box 35.6 Monogenic causes of diabetes[a]

Type	Features
Glucokinase	• 44% of all cases of MODY • Glucokinase gene is involved in the glucose-sensing mechanism within the pancreatic β cell; mutations lead to a change in the set-point in glucose with mild fasting hyperglycaemia • Non-progressive • Present from birth • No treatment needed except during pregnancy
HNF1A	• 24% of all cases of MODY • Transcription factor variants reduce insulin secretion • Progressive deterioration of glycaemia with age presenting during adolescence or early adulthood • Sensitive to sulfonylurea treatment • Associated with development of microvascular complications • Extrapancreatic features include low renal glucose threshold (glycosuria), raised HDL cholesterol, raised cardiovascular risk (in excess of type 2 diabetes), and liver adenomas
HNF4A	• 10% of all cases of MODY • Transcription factor variants reduce insulin secretion • Progressive deterioration of glycaemia with age presenting during adolescence or early adulthood • Sensitive to sulfonylurea treatment • Associated with development of microvascular complications • Extrapancreatic features include increased birth weight or macrosomia, neonatal hypoglycaemia, low HDL cholesterol, low lipoprotein A1 and A2, and raised LDL cholesterol
HNF1B	• 6% of all cases of MODY • Transcription factor regulates gene expression in several tissues, including the pancreas, kidney, liver, genital tract, and gut • Progressive deterioration of glycaemia with age presenting during adolescence or early adulthood • Initially sensitive to sulfonylurea treatment, but most require insulin • Associated with development of microvascular complications • Extrapancreatic features include renal cysts, renal development disorders, gout, liver enzyme derangement, short stature, and neurodevelopmental disorders
Maternally inherited diabetes and deafness	• 8% of monogenic diabetes • Maternally inherited • Variant in mitochondrial DNA affects the mitochondrial respiratory chain and results in cellular energy deficiency, leading to β-cell dysfunction and insulin deficiency • Mean age of diabetes onset is 37 years (range, 11–68 years) • Insulin treatment is usually required • Extrapancreatic features include deafness, short stature, cardiomyopathy, focal segmental glomerulosclerosis, and myopathy

[a]Other genes accounting for the remaining 8% of case include *ABCC8, WFS1, INSR, PPARG, INS, LMNA, PDX1, KCNJ11, NEUROD1, GATA6, SLC19A2*, and *TRMT10A*.

HDL, High-density lipoprotein; *LDL*, low-density lipoprotein; *MODY*, maturity-onset diabetes of the young.



Type 1 diabetes very rarely presents in children before 6 months of age, so infants who develop diabetes at this age are likely to have a monogenic defect. Transient neonatal diabetes mellitus occurs soon after birth and resolves at a median of 12 weeks; around 50% of people ultimately relapse later in life. Most have an abnormality of imprinting of the *ZAC* and *HYMAI* genes on chromosome 6q. The most common cause of permanent neonatal diabetes mellitus is mutations in the *KCNJ11* gene encoding the Kir6.2 subunit of the β-cell potassium–adenosine triphosphate (ATP) channel.

CLINICAL APPROACH TO THE PERSON WITH DIABETES

Presentation

The presentation of diabetes may be acute, subacute, or asymptomatic, or an individual may present with a complication of diabetes.

Acute presentation

Young adults often present with a 2- to 6-week history of the classic triad of symptoms plus tiredness.

- ***Polyuria*** caused by the osmotic diuresis that results when blood glucose levels exceed the renal threshold
- ***Thirst and polydipsia*** caused by the resulting loss of fluid and electrolytes
- ***Weight loss*** caused by fluid depletion and accelerated breakdown of fat and muscle secondary to insulin deficiency.

These can be remembered by the four Ts (toilet, thirst, thin, tired). Ketonuria is often present in young people and may progress to ketoacidosis if these early symptoms are not recognized and treated.

Subacute presentation

The clinical onset may be prolonged over several months or years, particularly in older people. Thirst, polyuria, and weight loss are usually present, but the individual may complain of other symptoms such as lack of energy, visual blurring (owing to glucose-induced changes in refraction), or pruritus vulvae or balanitis caused by *Candida* infection.

Complications as the presenting feature

These include:

- Staphylococcal skin infections
- Retinopathy noted during a visit to the optician
- A polyneuropathy causing tingling and numbness in the feet
- Erectile dysfunction
- Arterial disease, resulting in myocardial infarction or peripheral gangrene.

Asymptomatic diabetes

It is estimated that approximately half of adults with diabetes are unaware of their condition. This proportion varies across the world, from about one-third in high-income countries to three-quarters in some low-income countries. Consequently, up to one-third of diagnoses are made as an incidental finding, and several countries have introduced screening programmes to identify those with asymptomatic undiagnosed diabetes.

Physical examination at diagnosis

Evidence of weight loss and dehydration may be present, and the breath may smell of ketones. Older people may present with established complications. Occasionally, there will be physical signs of an illness causing secondary diabetes (see **Boxes 23.4 and 23.5**). People with severe insulin resistance may have acanthosis nigricans, which is characterized by blackish pigmentation at the nape of the neck and in the axillae (see **Fig. 22.37**). Hypertension is present in 50% of people with type 2 diabetes and in a higher proportion of people of African and Caribbean ethnicity.

Diagnosis and investigations

Once considered, diabetes is easy to diagnose. This may be by a laboratory measurement of fasting plasma glucose, random glucose, or 2-hour plasma glucose after a 75-g oral glucose tolerance test (OGTT). The use of glycated haemoglobin (HbA_{1c}; also called A_{1c} in the USA) was introduced as an alternative method in 2011. HbA_{1c} is an integrated measure of an individual's prevailing blood glucose concentration over the previous 6 to 8 weeks and is also used to guide treatment decisions.

Diabetes can be diagnosed if the fasting plasma glucose is higher than or equal to 7.0 mmol/L (126 mg/dL) or the random or 2-hour OGTT plasma glucose is more than or equal to 11.1 mmol/L (200 mg/dL) or the HbA_{1c} is higher than or equal to 48 mmol/mol (6.5%).

When overt symptoms are present, only one biochemical test is needed, but in the absence of clear symptoms, two abnormal glucose or HbA_{1c} tests are required (**Boxes 35.7 and 35.8**). Fasting, 2-hour glucose, and HbA_{1c} identify slightly different populations of people with diabetes; that is, someone may be diagnosed by one criterion but not another. However, with time, people will eventually cross the diagnostic threshold for the other tests.

The diagnostic criteria recognize two further categories of abnormal glucose concentrations: impaired fasting glycaemia (IFG) and impaired glucose tolerance (IGT). Collectively, these have been described as 'pre-diabetes', but this is not strictly accurate because the majority will never develop diabetes. Neither IFG nor IGT are clinical entities in their own right, but they identify people who are at high risk of diabetes and cardiovascular disease. Individuals with IGT have a similar risk of cardiovascular disease as those with frank diabetes but do not develop microvascular complications. IFG only overlaps with IGT to a limited extent, and the associated risks of cardiovascular disease and future diabetes are not directly comparable.

Box 35.7 World Health Organization diagnostic criteria for diabetes[a]

- Fasting plasma glucose ≥7.0 mmol/L (126 mg/dL)
- 2-hour plasma glucose ≥11.1 mmol/L (200 mg/dl) during OGTT
- HbA_{1c} ≥6.5% (48 mmol/mol)
- Random plasma glucose ≥11.1 mmol/L (200 mg/dL) in a person with classic symptoms of hyperglycaemia

[a]Any one of these tests can be used to diagnose diabetes. Fasting is defined as no caloric intake for at least 8 hours. Glycated haemoglobin (HbA_{1c}) should be performed by a standardized laboratory method. One abnormal laboratory value is diagnostic in symptomatic individuals; two values are needed in asymptomatic people. The oral glucose tolerance test (OGTT; **Box 35.8**) is only required when there is diagnostic uncertainty and for diagnosis of cystic fibrosis diabetes and gestational diabetes.

Box 35.8 The 75-g oral glucose tolerance test: World Health Organization criteria[a]

Timing of test	Normal	Impaired glucose tolerance	Diabetes mellitus
Fasting	<6.0 mmol/L <106 mg/dL	<7.0 mmol/L <126 mg/dL	≥7.0 mmol/L ≥126 mmol/L
2 hours after glucose	<7.8 mmol/L <140 mg/dL	7.8–11.0 mmol/L 140–200 mg/dL	≥11.1 mmol/L ≥200 mg/dL

[a]An oral glucose tolerance test should be performed using a standardized protocol. The test should not be performed in people who are under physical stress (e.g., postsurgery, trauma, infection, within 6 weeks of a myocardial infarction or major surgery). Drugs that may interfere with the test (glucocorticoids, beta-blockers, thiazide, and loop diuretics) should be withdrawn for 3 days before the test if possible. Smoking and physical exercise should not be undertaken in the morning before and during the test. The person undergoing the test eat an unrestricted carbohydrate diet (>150 g per day) for at least 3 days before the test. The test should be performed in the morning after an overnight fast of at least 8 hours (water is allowed). The person should rest for at least 30 minutes before the test. After a fasting blood sample is collected, 75 g of glucose in 300 mL of water should be consumed over 5 minutes. The patient should rest and not smoke, eat, or drink (except sips of water). The second sample is collected 2 hours later. Results are for venous plasma; whole-blood values are lower.

IGT can only be diagnosed with an OGTT (**Box 35.8**) and is complicated by poor reproducibility of the key 2-hour value in this test. IFG is defined as a fasting plasma glucose between 6.1 and 6.9 mmol/L (110–126 mg/dL) and has the practical advantage that it avoids the need for an OGTT. The American Diabetes Association (ADA) definition of IFG differs slightly from the World Health Organization criteria in that the ADA threshold is 100 mg/dL (5.6 mmol/L).

Glycosuria cannot be used to diagnose diabetes but requires further investigation. It is commoner in older people, who have an altered renal threshold for glucose. It may also occur in familial renal glycosuria, which is a monogenic disorder affecting function of the SGLT2 and found in about 1 in 400 of the population.

Determining the type of diabetes

Whereas type 1 diabetes is frequently mistaken for type 2 diabetes in adulthood, other types of diabetes (e.g., monogenic diabetes) can be misdiagnosed as type 1 or type 2 diabetes. A misdiagnosis can cause inappropriate treatment choices and distress for the patient. No single clinical feature differentiates type 1 diabetes from type 2 diabetes, but the most discriminative feature is younger age at diagnosis (younger than 35 years), with lower body mass index (BMI) (<25 kg/m^2), unintentional weight loss, ketoacidosis, and glucose greater than 20 mmol/L (>360 mg/dL) at presentation all pointing to type 1 diabetes. In those with clinical features of type 1 diabetes, the measurement of islet autoantibodies at diagnosis is recommended. The presence of one or more of these antibodies is highly predictive of rapid progression and severe insulin deficiency, and these individuals should be considered to have type 1 diabetes.

However, the absence of autoantibodies does not exclude type 1 diabetes because approximately 5% to 10% of White European people with new-onset type 1 diabetes have negative islet antibodies, and further consideration of the diagnosis is necessary. Furthermore, antibodies may disappear with time. Here clinical judgement is needed to decide whether to initiate insulin therapy.

Insulin secretion continues to diminish with duration of diabetes to the point that C-peptide is less than 200 pmol/L after 3 years in those with type 1 diabetes, and this test may help differentiate type 1 diabetes from type 2 diabetes if uncertainty remains.

Genetic testing may be appropriate if there are features of monogenic diabetes.

Other investigations

Other routine investigations include urine testing for microalbuminuria (urine albumin:creatinine ratio [uACR]), a full blood count, urea and electrolytes, liver biochemistry, and random lipids. The latter test is useful to exclude associated hyperlipidaemia (see Chapter 19), and if elevated, it should be repeated as a fasting measurement after diabetes has been brought under control. Investigations of secondary causes of diabetes or associated autoimmune disease may be appropriate (**Box 35.4**).

Prevention of type 2 diabetes

A dramatic reduction in the incidence of diabetes in adults was documented during the Second World War when food was scarce. More recently, clinical trials in individuals with IGT have shown that it is possible to prevent or at least delay the development of type 2 diabetes by lifestyle or pharmacological interventions (or both). A range of diet, exercise, and medical and surgical interventions are described in detail in Chapter 37, which have been demonstrated to reduce the incidence of frank diabetes in high-risk individuals.

Given limited healthcare resources, interventions are targeted at those at highest risk and who will benefit most. Several risk assessment algorithms are available to identify those at highest risk of diabetes. Measurement of blood glucose identifies people with IFG or IGT.

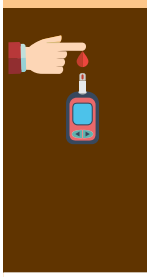
MANAGEMENT OF DIABETES

Aims of diabetes care

For most people, diabetes is a life-long condition. Except for a few hours a year spent in contact with healthcare professionals, the majority of people with diabetes look after their condition themselves for most of the time. It is therefore vital that people develop the skills to manage their condition effectively. The aims of diabetes care and management are fivefold:

- Prevention of life-threatening diabetes emergencies such as DKA and hypoglycaemia, with effective management when they do occur
- Treatment of hyperglycaemic symptoms
- Minimization of long-term complications through screening and effective management of hyperglycaemia and other cardiovascular risk factors
- Avoidance of iatrogenic side-effects, such as hypoglycaemia
- Minimizing the psychosocial burden of living with diabetes, while promoting psychological well-being.



Fortunately, individuals with diabetes usually do not experience life-threatening diabetes emergencies frequently (the incidence of DKA is ≈28 episodes per 1000 person-years, and the rate of severe hypoglycaemia is ≈1–4 events per person-year), and hyperglycaemic symptoms are easily treated. Therefore, most of the discussions regarding diabetes management revolve around maintaining optimal glycaemia to prevent long-term complications while balancing the short-term adverse events associated with treatment. Hyperglycaemia drives microvascular complications, and it is unsurprising that the impact of improved glucose levels on small-vessel complications, such as retinopathy and nephropathy, has been compellingly demonstrated.

The Diabetes Control and Complications Trial (DCCT) compared standard and intensive insulin therapy in a large cohort of young people with type 1 diabetes, some who had no evidence of retinopathy or microalbuminuria (primary prevention group) at the beginning of the trial and others who already had evidence of these complications (secondary prevention group). Despite intensive therapy, mean blood glucose levels were still 40% above the normal physiological range, but even at this level of glycaemia, the risk of primary progression to retinopathy was reduced by 60%, nephropathy by 30%, and neuropathy by 20% over 7 years with intensive insulin therapy. These benefits persisted beyond the end of the trial despite equivalent glucose levels in the post-trial period.

The UK Prospective Diabetes Study (UKPDS) compared standard and intensive treatment in a large trial in people with recently diagnosed type 2 diabetes. Intensive treatment was associated with a 25% overall reduction in microvascular disease end-points, a 33% reduction in albuminuria, and a 30% reduction in the need for laser treatment for retinopathy in the more intensively treated people. Similar to the DCCT, these benefits persisted for many years after conclusion of the trial (the 'legacy effect'). This study also showed blood pressure management to be equally necessary in the prevention of retinopathy, but there is no legacy effect, and optimal blood pressure needs to be maintained.

Although there is an association between glucose and large-vessel disease, which extends well into the glucose range of the general population, with no clear cut-off for risk, the benefits of reducing hyperglycaemia are less certain for macrovascular disease. This may be because diabetes affects not only carbohydrate metabolism but also metabolism of lipid and protein. People with diabetes often have other cardiovascular risk factors, such as dyslipidaemia, hypertension, and obesity, and these risk factors may play a more important role than hyperglycaemia. Both the DCCT and UKPDS studies showed a reduction in cardiovascular events in the post-trial follow-up period in the intensive treatment groups, suggesting that early management of hyperglycaemia may improve the long-term risk of cardiovascular disease.

Risks of tight glycaemic management

In both the DCCT and UKPDS, the achieved glucose levels were above those of people without diabetes, so further trials were undertaken in people with type 2 diabetes to assess whether further lowering of glucose to normoglycaemia would yield greater benefits. These trials confirmed the benefits for microvascular disease but did not improve cardiovascular outcomes, and in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, more people died in the intensively treated group than the standard arm. Exactly why this occurred is uncertain, but it seems likely that any benefit of improved glucose levels was outweighed by iatrogenic side-effects, such as hypoglycaemia and weight gain.

Box 35.9 Factors to consider with individualizing glycaemic targets for people with diabetes

Stringent glycaemic targets
- No hypoglycaemia
- Less complexity or polypharmacy
- Lifestyle or metformin only
- Short disease duration
- Long life expectancy
- No cardiovascular disease

Less stringent targets
- History of severe hypoglycaemia
- High burden of therapy
- Longer disease duration
- Limited life expectancy
- Extensive co-morbidity
- Cardiovascular disease

Most guidelines advocate HbA_{1c} targets between 48 and 58 mmol/mol (6.5%–7.5%), but because the benefits and risks of improved glucose levels differ between people with diabetes, the actual glycaemic targets should be determined for each individual, taking into account the factors shown in **Box 35.9**. Realistic goals should be agreed with each person, considering what is likely to be achievable. This applies particularly to older people and those with a short life expectancy.

Role of self-management education

Because the onus of diabetes management lies with the individual with diabetes, it is essential that the individual is equipped with the skills for this task. People with diabetes need to understand the risks of diabetes and the potential benefits of improving their glucose levels and other measures such as maintaining a lean weight, stopping smoking, and taking care of their feet. If healthcare professionals do not provide accurate information, misinformation from others will take its place. To address this need, diabetes self-management education has become an important cornerstone of diabetes care, delivered by all members of the diabetes multidisciplinary team (**Fig. 35.10**). The education needs to be tailored to the individual by embracing a patient-centred approach.

Structured educational programmes with a clear philosophy, such as Dose Adjustment for Normal Eating (DAFNE), using trained facilitators using a written curriculum are seen as the gold standard. These programmes improve diabetes knowledge and quality of life, glycaemic levels and reduce mortality. Education should not be viewed as a once-off inoculation, and regular ongoing support and updates are needed.

Lifestyle measures

Diet

Diet plays a key role in the management and clinical care of all people with diabetes. However, there has been a lot of controversy about what constitutes an ideal or optimal diet for a person with or at risk of diabetes. Previous guidance focused on the ideal macronutrient composition of the diet, but the latest guidance highlights the role of certain foods and dietary patterns. In common with the general population, people should be encouraged to eat more vegetables, fruits, wholegrains, fish, nuts, and pulses while reducing the consumption of red and processed meat, refined carbohydrates, and sugar-sweetened beverages. Because no single diet is effective in managing diabetes, it is important to adopt an individualized approach, taking into consideration the person's personal and

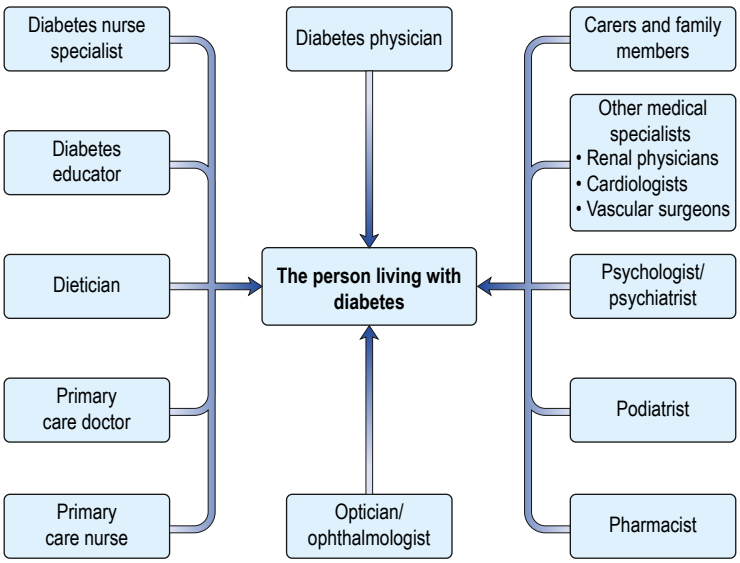


Fig. 35.10 **Members of the diabetes team.**

Box 35.10 Abbreviated summary of the evidence-based nutrition guidelines for the management of diabetes, hyperlipidaemia, and hypertension

- Nutrition advice should be offered to all people with diabetes, hyperlipidaemia, and hypertension and those at risk of developing type 2 diabetes as part of an integrated package of education and clinical care.
- Dietary advice should be individualized and culturally sensitive.
- People with type 1 diabetes should be supported to identify and quantify their dietary carbohydrate intake to support the adjustment of insulin dose to carbohydrate intake.
- People with type 2 diabetes, hyperlipidaemia, or hypertension or at risk of developing type 2 diabetes who are overweight should be supported to lose at least 5% of their weight by reducing calorie intake and increasing energy expenditure.
- Foods with a low glycaemic index are encouraged.
- A Mediterranean-style diet or equivalent healthy eating pattern should be encouraged. Key features of these diets include:
  - Decreasing salt intake to <6 g/day
  - Eating two portions of oily fish each week
  - Eating more wholegrains, fruits and vegetables, fish, nuts, and legumes (pulses)
  - Consuming less red and processed meat, refined carbohydrates, and sugar-sweetened beverages
  - Replacing saturated fats with unsaturated fats and limiting intake of trans-fatty acids
  - Limiting alcohol intake to ≤14 units/week

Based on the Diabetes UK evidence-based nutrition guidelines for the management of diabetes.

cultural preferences. **Box 35.10** summarizes the latest Diabetes UK dietary recommendations for people with diabetes.

One exception to the food-based recommendations concerns carbohydrate intake, which is important for people using intensive insulin regimens, particularly those with type 1 diabetes. In people without diabetes, the amount of insulin produced after eating depends on the carbohydrate consumed. To optimize glycaemia, people need to match their insulin dose to the carbohydrate in the meal, so it is important to teach people how to 'carbohydrate count'. Several books and apps are available to help with this process.

The peak blood glucose after a meal varies with the type of carbohydrate. For example, the glucose profile after eating pasta is much flatter than that seen after eating the same amount of carbohydrate as a sugary drink because pasta has a lower 'glycaemic index'. Foods with a low glycaemic index are encouraged to prevent rapid swings in plasma glucose.

Weight loss

For many years, it was thought that type 2 diabetes was an incurable progressive condition; however, there is now significant evidence to challenge this view. People who can be supported to lose 10 to 15 kg of body weight through lifestyle or pharmacological or surgical treatment can enter remission. Chapter 37 describes various weight-reduction interventions (including lifestyle modification, pharmacological treatments such as GLP-1 receptor agonists, and bariatric surgery), some of which have been shown to induce full remission of diabetes.

Physical activity

No treatment for diabetes is complete without exercise because physical activity has profound benefits, including improved fitness, reduced insulin requirement and improved glycaemic levels, lower cardiovascular risk, and greater life expectancy. The maxim that *some exercise is better than no exercise and more exercise is better than some exercise* applies. People with diabetes should be advised to take at least 150 minutes of aerobic exercise and resistance training per week, spread over a minimum of 3 days.

People with type 1 diabetes should be advised that physical activity can reduce the insulin requirement and lead to unstable glucose levels during and immediately after exercise and a later risk of severe hypoglycaemia.

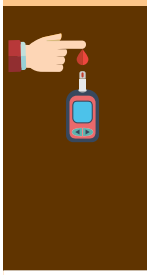
Tobacco smoking

Smoking can adversely affect glucose management and increase the risk of a number of medical conditions, so healthcare professionals should support people who smoke to quit.

MEDICATION FOR DIABETES

Insulin

Before discovery of insulin in 1921, the life expectancy of people with type 1 diabetes was only several months. Many people died from DKA, but it was possible to survive for several years on diets



of around 500 to 700 calories/day; these individuals had a wretched existence until either the person broke their diet or died from starvation. The discovery of insulin is rightly considered one of the greatest medical advances of the 20th century because the lives of millions of people with diabetes have been transformed by its discovery. Insulin is always indicated in people with type 1 diabetes and is often needed in those with type 2 diabetes as the condition progresses.

The philosophy of insulin therapy is to mimic the normal physiological secretion of insulin as closely as possible (Fig. 35.5). This involves the use of both long-acting insulin to replicate the basal secretion of insulin and short-acting insulin to cover mealtimes.

Insulin was historically derived from beef or pig pancreas, but this has been replaced by highly purified biosynthetic insulin, which is produced by adding a DNA sequence coding for insulin or proinsulin into cultured yeast or bacterial cells.

Short-acting insulins

Soluble human insulin is absorbed slowly, reaching a peak 60 to 90 minutes after subcutaneous injection. Its action tends to persist after meals, predisposing to hypoglycaemia. Absorption is delayed because soluble insulin forms stable hexamers (six insulin molecules around a zinc core), which need to dissociate to monomers or dimers before it can enter the circulation.

This delay is inconvenient for people with diabetes because the insulin should be injected 20 to 30 minutes before a meal, which often is not feasible. ***Short-acting insulin analogues*** (***insulin lispro***, ***insulin aspart***, and ***insulin glulisine***) have been engineered that dissociate more rapidly after injection without altering the biological effect (Fig. 35.11). These ***insulin analogues*** enter and disappear from the circulation more rapidly than soluble insulin. Newer formulations of insulin aspart and insulin lispro have been developed that dissociate and enter the circulation even more rapidly.

The use of short-acting insulin analogues in people with type 1 diabetes reduces total and nocturnal hypoglycaemic episodes and improves glycaemic levels as judged by postprandial glucose concentrations and HbA_{1c}. The benefits in people with type 2 diabetes are more modest, but short-acting insulin analogues seem to improve HbA_{1c} and postprandial glucose compared with soluble human insulin.

Intermediate- and longer-acting insulins

The action of synthetic human insulin can be prolonged by the addition of zinc or protamine. The most widely used form is NPH (neutral protamine Hagedorn), or 'isophane insulin', but its use is hampered by variability from one injection to another, the need to re-suspend the insulin before injection, and a peak action that generally occurs in the middle of the night.

Long-acting analogues have been developed to delay absorption and prolong the duration of action (Fig. 35.11). Insulin glargine is soluble in the vial as a slightly acidic (pH, 4) solution but precipitates at subcutaneous pH, thus prolonging its duration of action. A concentrated formulation of insulin glargine is now available with a longer and flatter duration of action than the standard preparation. ***Insulin detemir*** and ***insulin degludec*** have a fatty acid 'tail' that binds to serum albumin; the slow dissociation from the bound state prolongs the duration of action. In the case of insulin degludec, it forms long multihexamer chains at the site of injection, which only dissociate very slowly. Long-acting insulin analogues reduce hypoglycaemia for people with both type 1 diabetes and type 2 diabetes, particularly at night. A once-weekly basal insulin, insulin icodec, is currently in clinical development.

Because insulin analogues are more expensive than NPH insulin, in the case of type 2 diabetes, the National Institute for Health and Care Excellence (NICE) recommends that insulin analogues are reserved for people who do not respond well to NPH insulin. The European Association of the Study of Diabetes and ADA consensus report on the management of type 2 diabetes notes the benefits of insulin analogues but highlights that the way in which insulin is used has a greater impact on the effectiveness and adverse effects of insulin than differences between insulin formulations.

Strengths of insulin

Most insulin is formulated as 100 units/mL, but more concentrated forms are available, for example, insulin glargine is available as U300 (300 units/mL) as described earlier. Insulin degludec is available in two concentrations: 100 and 200 units/mL. The pen devices for these insulins indicate how many units of insulin are given, but there is a significant danger of overdose if the insulin is withdrawn from the pen and administered using an insulin syringe. A number of warnings have been issued to prevent this practice.

Some people with diabetes experience severe insulin resistance and require massive insulin doses. U500-strength insulin is available for these individuals, allowing them to inject the same dose of insulin in one-fifth of the usual volume. Rare syndromes of insulin resistance exist, but most cases are unexplained (Box 35.4). Insulin resistance associated with antibodies directed against the insulin receptor has been reported in people with acanthosis nigricans.

Insulin regimens

Many different combinations of insulin are used to treat people with diabetes, but several regimens are more commonly used. The possible treatment options should be discussed with the individual to find the one that is most suitable to their needs and lifestyle.

Basal-bolus regimen

The basal-bolus regimen involves the administration of both short- and long-acting insulin. Long-acting insulin is injected one or two times per day to provide the background (basal) insulin to keep the glucose concentration consistent during periods of fasting (Fig. 35.12). Short-acting insulin is given shortly before eating as a bolus to control glucose concentration after a meal. This regimen most closely mimics normal insulin physiology and is more flexible than other regimens because each injection can be adjusted individually.

This regimen is the treatment of choice for people with type 1 diabetes but is increasingly used in younger people with type 2 diabetes. The flexibility is of great value to people who have busy jobs and work shifts and travel regularly. The main disadvantage of a basal-bolus regimen is the number of injections.

Twice-daily mixed insulin regimen

A mixture of short- and long-acting insulin is injected before breakfast and the evening meal (Fig. 35.12). There are a number of insulin preparations with premixed insulin. This regimen is used more commonly for people with type 2 diabetes but may be used by people with type 1 diabetes when it is not possible to inject four times a day. The main disadvantage of this regimen is the lack of a lunchtime bolus and higher basal levels between meals, which increase the risk of hypoglycaemia.

Basal-only and basal-plus insulin regimens

Because people with type 2 diabetes are able to produce insulin, it may be possible to use a less intensive insulin regimen. Basal long-acting insulin at night, together with other non-insulin treatments during the

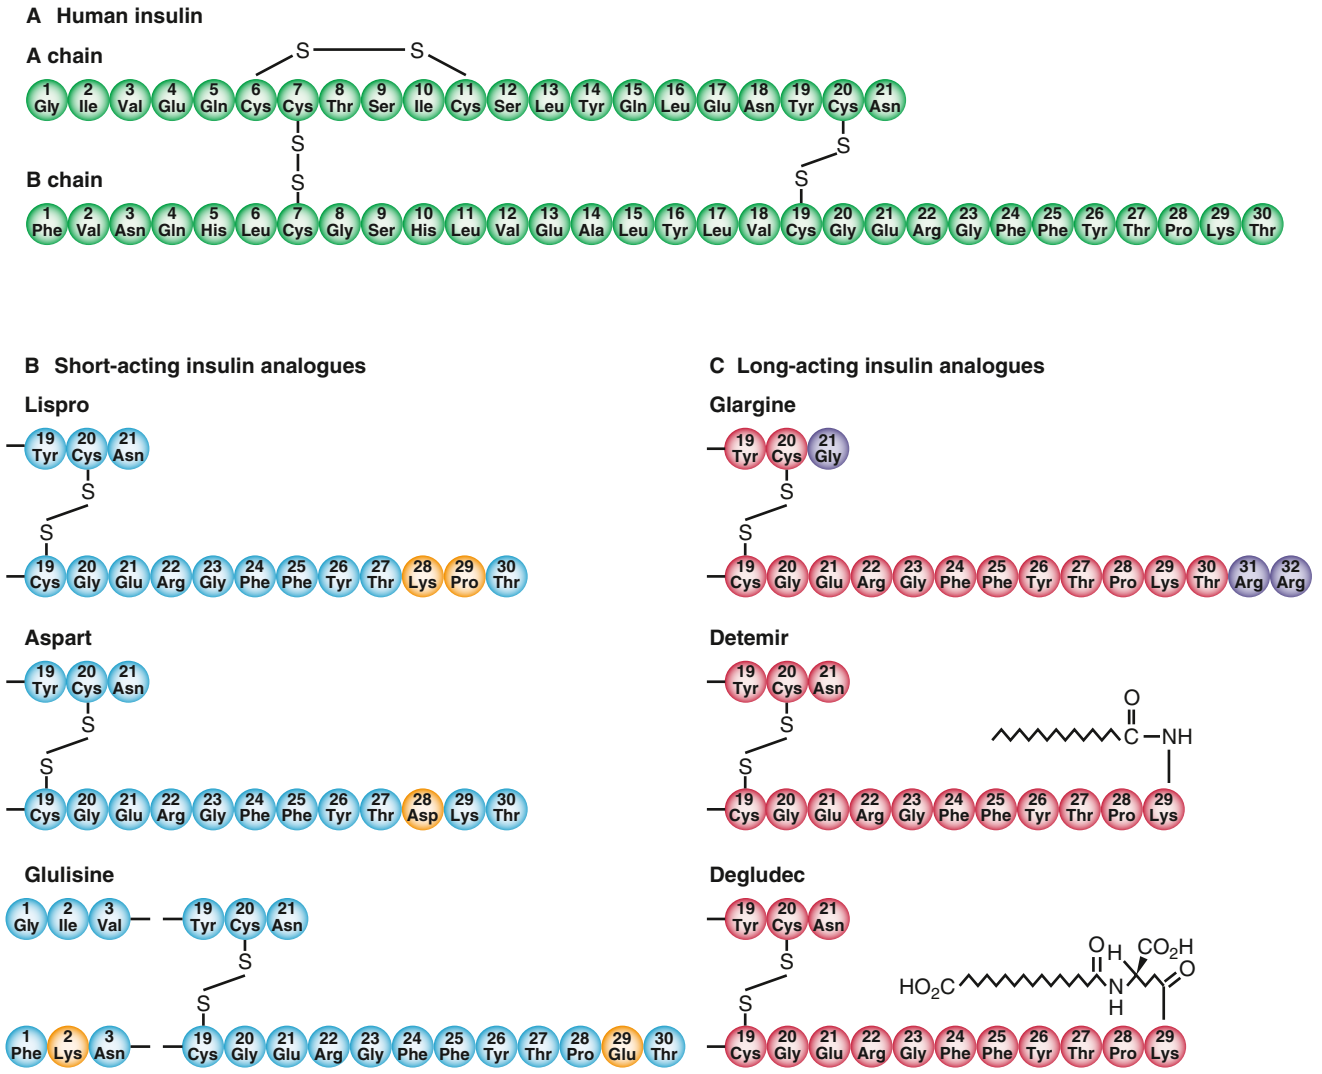


Fig. 35.11 Amino acid structure of insulin. **(A)** Human insulin. **(B)** Modification of human insulin produces rapid-acting insulin analogues. Lispro is created by reversing the order of the amino acids proline and lysine in positions 28 and 29 of the B chain. Aspart is a similar analogue created by replacing proline at position 28 of the B chain with an aspartic acid residue. Glulisine is a similar analogue created by replacing asparagine at position B3 with lysine and the lysine in position B29 is replaced by glutamic acid. **(C)** Modification of human insulin produces long-acting insulin analogues. Insulin glargine is created by replacing asparagine in position 21 of the A chain with a glycine residue and adding two arginines to the end of the B chain. Detemir discards threonine in position 30 of the B chain and adds a fatty acyl chain to lysine in position B29. Degludec is created by removing the threonine at position 30 of the B chain and the attachment via a glutamic acid linker of a 16-carbon fatty diacid to the lysine at position 29 of the B chain.

day, is initially as effective as multidose insulin regimens and is less likely to promote weight gain. Over time, addition of mealtime insulin may become necessary to prevent postprandial hyperglycaemia.

Insulin administration

Insulin is administered subcutaneously by intermittent injection or by insulin pumps (continuous subcutaneous insulin infusion [CSII]).

Insulin injection

The usual injection sites are the front and upper outer side of the thigh, abdominal wall, buttocks, and upper outer arms. Injection technology has improved dramatically since insulin was first discovered. Although insulin may be drawn up from a vial into special plastic insulin syringes, many people now use insulin pens, which may be disposable with prefilled insulin or reusable by changing the insulin cartridge when empty. The pens are portable, use a fine 4- to 5-mm needle, and have a simplified procedure for dialing the insulin dose. Compared with needles and syringes, pens are more convenient, more accurate, and easier to use, and they produce a less painful injection. Even though most injections are virtually painless, people are understandably apprehensive and must learn how to give insulin safely and effectively. Modern pens record when the last dose was given and how much insulin was administered and can connect with glucose monitoring systems.

Insulin pumps

Introduced nearly 40 years ago, insulin pumps are small battery-operated programmable devices that continuously infuse insulin

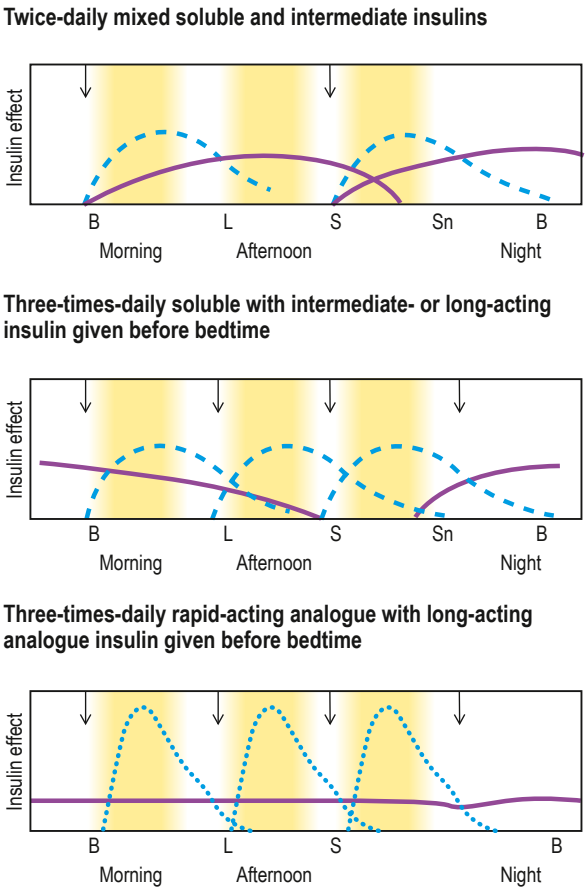

Fig. 35.12 Insulin regimens. Profiles of soluble insulins are shown as *dashed lines*, intermediate- and long-acting insulin as *solid lines (purple)*, and rapid-acting insulin as *dotted lines (blue)*. The *arrows* indicate when the injections are given. *B,* Breakfast; *L,* lunch; *S,* supper; *Sn,* snack (bedtime).

into the subcutaneous tissue. Conventional pumps deliver insulin through a catheter inserted into the subcutaneous tissue, but tubeless pumps (also called patch pumps) that do not use plastic tubing and adhere directly to the skin are increasingly available.

The technology has progressively improved and allows the user to give varying amounts of basal insulin throughout the day with mealtime boluses, guided by the pump software. Newer models are smaller and more portable and have greater technological capabilities, including bolus calculators, advanced bolus delivery options, and the ability to integrate with continuous glucose monitors.

- *Sensor-augmented pumps* alter insulin delivery in response to changes or predicted changes in glucose without input from the user.
- *Hybrid closed-loop systems* are currently the most advanced form of insulin delivery; they use a control algorithm to automatically adjust basal insulin delivery every few minutes based on sensor glucose levels but still require the user to calculate and deliver meal-related boluses.

Fully automated closed-loop insulin delivery systems have been developed by members of the diabetes community, but these devices are not approved, commercialized, or regulated.

Pump therapy in people with type 1 diabetes improves glycaemic levels, reduces hypoglycaemia, and leads to better quality of life compared with multiple daily injections. These benefits have led to an increasing number of pump users, although the uptake of CSII varies across the world; up to 40% of people with type 1 diabetes use pumps in the USA compared with 11.7% in the UK.

The disadvantages of pump therapy include the nuisance of being attached to a gadget, skin reactions, the risk of ketoacidosis if the flow of insulin is interrupted (because there is no protective reservoir of injected basal insulin), and the cost.

Injection site complications

Fatty lumps, known as lipohypertrophy, may occur after the overuse of a single injection site with any type of insulin. As well as being unsightly, lipohypertrophy interferes with insulin absorption, thereby compromising insulin action, and is a cause of glycaemic variability, leading to both hyper- and hypoglycaemia.

Local allergic responses sometimes occur early in therapy but usually resolve spontaneously. Formerly, insulin could produce local atrophy of fat tissue (lipoatrophy), but this is rare because modern insulin is highly purified. Insulin allergy is rare, but reactions may occur to the excipients.

Generalized allergic responses and injection site abscesses are exceptionally rare.

Alternative routes of insulin administration

The first inhaled insulin was withdrawn from the market in 2007 on the grounds of limited clinical demand and safety concerns, but the US Food and Drug Administration approved a new formulation (Afrezza) in July 2014. Oral insulin preparations are in development, but they must overcome the challenges of peptide digestion by the gastrointestinal tract and barriers to absorption.

Challenges of insulin therapy

Although insulin and the means of administering insulin continue to improve, achieving optimal glycaemic levels is extremely challenging for people living with diabetes for a number of reasons:

- The amount of insulin needed to reduce glucose levels in the postprandial state causes hypoglycaemia in the fasted state. If too little insulin is administered, glucose concentrations rise outside the normal range, but if too much insulin is administered, glucose concentrations fall into the hypoglycaemic range.
- Insulin requirements are highly variable from one person to another and vary within the same individual within a day and between days.
- In people without diabetes, insulin is secreted directly into the portal circulation and reaches the liver in high concentration, where 50% is cleared on first passage. By contrast, insulin injected subcutaneously passes into the systemic circulation. People treated with insulin therefore have lower portal insulin levels and higher systemic levels relative to normal physiology.
- Subcutaneous insulin takes longer to enter and achieve peak plasma levels and is slower to leave the circulation.
- The absorption of subcutaneous insulin into the circulation from one injection to the next is variable.
- Basal insulin levels adapt to the metabolic needs of people without diabetes, but injected insulin peaks and declines, with resulting swings in glucose levels in those with diabetes.
- Bolus insulin doses should ideally be adjusted to the carbohydrate content of the meal.
- Carbohydrate counting is difficult because many foods do not list the carbohydrate content.
- It is not always possible to determine how much will be eaten because the appetite may change.

- The rate of absorption of glucose is affected by the glycaemic index and the amount of protein and fat in the meal, as well as the timing of the meal.
- Alcohol and caffeine consumption affect insulin requirements.
- Calculating the appropriate dose of insulin requires advanced mathematical skills.
- Several environmental factors, including temperature and altitude, affect insulin requirements
- The type, duration and timing of exercise, as well as sleep and stress, affect glucose levels.
- There are no holidays from diabetes; an individual using a basal bolus regimen needs to inject approximately 1500 times a year.
- The price of giving too much insulin is hypoglycaemia, which is unpleasant and often embarrassing.
- The pens or devices can fail.

It is critically important that people are trained to use their insulin effectively and safely, and this forms a central component of diabetes self-management education for people with diabetes. As their insulin requirement changes, people should be encouraged to adjust their insulin doses with a view to maintaining blood glucose values between 4 and 7 mmol/L (70–126 mg/dL) before meals and between 4 and 10 mmol/L (70–180 mg/dL) after meals, assuming that this can be achieved without troublesome hypoglycaemia (**Box 35.11**).

Professional advice should be available to support people with diabetes who experience problems; alongside this is a responsibility for healthcare professionals to prescribe insulin safely (**Box 35.12**). Insulin prescribing errors, with potentially fatal consequences, are some of the most common causes of iatrogenic harm. There are many different types of insulin, often with similar sounding names, that are used in different ways and contribute to the confusion surrounding prescription.

Box 35.11 Guide to adjusting insulin dosage according to blood glucose test results[a]

Time	Blood glucose persistently too high	Blood glucose persistently too low
Before breakfast	Increase evening long-acting or premixed insulin	Reduce evening long-acting or premixed insulin
Before lunch	Increase morning short-acting or premixed insulin	Reduce morning short-acting or premixed insulin or eat a mid-morning snack
Before evening meal	Increase morning long-acting or premixed insulin or lunch short-acting insulin	Reduce morning long-acting or premixed insulin or lunch short-acting insulin or increase mid-afternoon snack
Before bed	Increase evening short-acting or premixed insulin	Reduce evening short-acting or premixed insulin

[a]Adjustment should be approximately 10% of the current dose.

- The right time

Hypoglycaemia

The clinical features and acute management of hypoglycaemia are covered in Chapter 11. After the acute event has been treated, it is important to ascertain why the hypoglycaemia occurred to try to prevent future episodes.

Hypoglycaemia (low blood glucose) is the most common side-effect of insulin therapy and is the major limitation to what can be achieved with insulin treatment. A recent consensus report defined a glucose concentration below 3.0 mmol/L (54 mg/dL) as 'clinically significant hypoglycaemia' but recognized that any value below 4.0 mmol/L (70 mg/dL) represented an 'alert value' that required treatment. 'Severe hypoglycaemia' is defined as hypoglycaemia leading to severe cognitive impairment and requiring external help for recovery.

Most people treated with insulin experience several episodes of symptomatic hypoglycaemia per week and one to two severe episodes per year. Despite the advances in insulin therapy, the incidence of hypoglycaemia has not changed over the past 25 years. Interestingly, with the advent of CGM, it is apparent that asymptomatic hypoglycaemia occurs much more frequently than previously thought. Hypoglycaemia is more common in people with type 1 diabetes, when there is an absolute insulin deficiency, and with longer duration of diabetes. It occurs more frequently in young children and those trying to achieve normal or near-normal glucose levels.

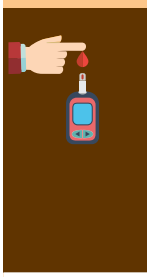
Hypoglycaemia greatly impairs quality of life and induces fear and anxiety in the person with diabetes and their family and carers. In an older study, the fear of severe hypoglycaemia was worse than the fear of developing blindness or end-stage renal disease. Nocturnal hypoglycaemia can be particularly disruptive. In addition to the psychological effects, hypoglycaemia is associated with a number of long-term medical consequences, including cardiovascular events and falls.

Hypoglycaemia is caused when more insulin is injected than is needed. Irregular eating habits, unusual exertion, and alcohol excess may all precipitate hypoglycaemic episodes, but insulin errors and variation in insulin absorption are also important. The times of greatest risk are before meals, during the night, and during and after exercise.

The mechanisms that protect against hypoglycaemia in people without diabetes are compromised because of abnormal islet cell function or defective counter-regulatory hormone secretion. The delivery of insulin after injection cannot be halted, and glucagon secretion is impaired because its main regulator is a fall of intra-islet insulin. Even the third line defence of counter-regulatory hormones and other sympathetic nervous system responses to hypoglycaemia may become diminished in people with longstanding diabetes or recurrent hypoglycaemia.

Weight gain

Because insulin is an anabolic hormone and the absence of insulin leads to profound weight loss, it is unsurprising that many people gain weight while treated with insulin. Restoration of normal weight is a therapeutic effect, but some individuals experience excessive weight gain, especially if the insulin dose is increased inappropriately. Excessive weight gain may be the consequence of frequent hypoglycaemia if an individual takes excess carbohydrate to treat or prevent hypoglycaemia (so-called 'defensive eating'). Weight gain can be offset, to some extent, by dietary measures and exercise.



Non-insulin antidiabetes treatments

Unlike type 1 diabetes, there are alternative pharmacological treatments for people with type 2 diabetes and other types of diabetes when dietary and other lifestyle changes do not adequately bring the glucose into the target range (**Box 35.13**). These treatments are adjuncts rather than alternatives to dietary and lifestyle management. Metformin, SGLT2 inhibitors (or 'flozins'), and GLP-1 receptor agonists have strong evidence supporting health benefits (e.g., mortality benefit and reduction of cardiovascular disease) that extend well beyond their glucose-lowering effects. Most clinical guidelines therefore recommend these agents as first-line antidiabetes medications for people with type 2 diabetes.

First-line treatments

Biguanides: metformin

Metformin is currently the only available biguanide. It was introduced into clinical practice in the 1950s alongside two other biguanides, phenformin and buformin, but these latter two agents were withdrawn because of a high risk of lactic acidosis.

Mode of action

The precise mechanism of action of metformin remains unclear but involves a range of insulin-dependent and insulin-independent actions that improve insulin sensitivity and reduce blood glucose. Metformin enhances post-receptor signaling of insulin and alters cellular energy metabolism by activating the enzyme adenosine monophosphate kinase. Metformin reduces the rate of gluconeogenesis and hence hepatic glucose output. It does not affect insulin secretion, does not induce hypoglycaemia, and does not predispose to weight gain.

Box 35.13 Examples of oral and injectable antidiabetes drugs other than insulin[a]

Drug class	Examples
First-line treatments	
Biguanides	Metformin
SGLT2 inhibitors	Dapagliflozin Empagliflozin Canagliflozin
GLP-1 receptor agonists	Exenatide Liraglutide Lixisenatide Dulaglutide Semaglutide
Second-line treatments	
DPP-4 inhibitors	Sitagliptin Linagliptin Vildagliptin Alogliptin Saxagliptin
Sulphonylureas	Gliclazide Glimepiride Glibenclamide Glipizide Tolbutamide
Thiazolidinediones	Pioglitazone
Meglitinides	Repaglinide Nateglinide
Alpha-glucosidase inhibitors	Acarbose Miglitol Voglibose

[a]This list is not exhaustive, and other drugs are in development in many of these classes.
DPP-4, Dipeptidyl peptidase-4; *GLP-1,* glucagon-like peptide-1; *SGLT2,* sodium–glucose transporter 2.

Clinical use

Metformin is the best-validated treatment for type 2 diabetes and appears as a first-line pharmacological agent in type 2 diabetes guidelines. Metformin may be given in combination with all other oral diabetes treatments as well as GLP-1 receptor agonists or insulin. It lowers fasting plasma glucose by 2 to 4 mmol/L (36–72 mg/dL), corresponding to a fall in HbA_{1c} of 11 to 22 mmol/mol (1%–2%). In UKPDS, metformin treatment led to an unexpected reduction in cardiovascular events. Metformin has been used alongside insulin in people with type 1 diabetes but only with limited efficacy.

Adverse effects

Unwanted effects include gastrointestinal side-effects (10%–20%), such as anorexia, nausea, abdominal discomfort, and diarrhoea. The effects can be mitigated by starting at low dose and gradually increasing it until the desired therapeutic effect is achieved. A slow-release preparation of metformin appears to be better tolerated.

Metformin is contraindicated in renal impairment, cardiac failure, and hepatic failure because of the risk of lactic acidosis. Metformin should not be started in someone whose estimated glomerular filtration rate (eGFR) is less than 45 mL/min per 1.73 m^2 and should be stopped if the eGFR falls below 30 mL/min per 1.73 m^2.

Metformin must be stopped before intravascular administration of iodinated contrast agent because of the risk of renal failure and subsequent lactic acidosis. Treatment can be restarted 48 hours after the test if there has been no deterioration in renal function. Similarly, metformin should be stopped temporarily around surgery or during other intercurrent illnesses that may affect lactate clearance. Metformin should be avoided in people with a history of alcohol misuse.

Metformin reduces gastrointestinal vitamin B_{12} absorption but only rarely causes anaemia.

Sodium-glucose transporter 2 inhibitors ('flozins')

SGLT2 inhibitors have been available since 2011 (**Box 35.13**). Because of strong evidence of their cardioprotective and renoprotective effects, they are recommended as second-line agents or first-line agents in people with diabetes with established or at high risk of atherosclerotic cardiovascular disease or heart failure.

Mode of action

SGLT2 inhibitors lower the renal threshold for glucose, consequently increasing urinary glucose excretion. This has the effect of removing both glucose and calories from the circulation, thus lowering blood glucose by 7 to 13 mmol/mol (0.6%–1.2%) and facilitating weight loss (≈2–4 kg over 6–12 months). They alter glomerular haemodynamics, which may underlie the observed benefits on renal function.

Exactly how SGLT2 inhibitors reduce the risk of myocardial infarction, stroke, cardiovascular death, and heart failure is uncertain; however, several hypotheses have been suggested, including:

- Increased natriuresis leading to fluid loss and small reductions in systolic blood pressure
- Increased production of ketones acting as a 'superfuel' for the heart
- Vasodilation through blockade of the renin–angiotensin system
- Direct effects on the heart, including improved myocardial energetics.

Clinical use

SGLT2 inhibitors can be used as monotherapy, but because their blood glucose–lowering effects glucose are relatively modest, they are used more typically in combination with all other antidiabetes drugs. They are licensed to slow renal progression in people with diabetic nephropathy and are recommended for other cardiac and renal indications in people without diabetes. The glucose-lowering effect is dependent on good renal function, but the renoprotective benefits are seen in people with lower eGFR.

Adverse effects

The most common adverse effects are genital candidiasis and dehydration. Rarer side-effects include DKA, Fournier's gangrene, and lower limb amputation. DKA may occur in people with diagnosed type 2 diabetes. In general, these people have insulin deficiency, and some may have unrecognized type 1 diabetes. A diagnostic trap is that glucose concentrations may be normal or minimally raised in this situation.

GLP-1 receptor agonists

GLP-1 receptor agonists are a heterogeneous class of drugs that act by enhancing the incretin effect. The class is divided into two main groups; the first are drugs that are derived from the protein exendin, which is found in the saliva of Arizonian desert lizards. Exendin has 53% sequence homology with human GLP-1 and is resistant to cleavage by DPP-4, the enzyme that rapidly degrades native GLP-1. The second group are analogues of human GLP-1.

The pharmacokinetics have been modified to prolong the duration of action. The first GLP-1 receptor agonists were given twice daily, but now most are given once-weekly. Most GLP-1 receptor agonists must be given by injection, but there is an oral formulation of semaglutide that has similar effects on blood glucose, body weight, cardio-renal protection, and adverse event profile as injectable semaglutide. To prevent breakdown in the stomach and facilitate absorption across the gastric epithelium, semaglutide has been combined with the absorption enhancer sodium hydroxybenzoylamino-caprylate. Oral semaglutide is taken daily on an empty stomach, and food should be avoided for at least 30 minutes to allow adequate drug absorption.

There is strong clinical trial evidence that GLP-1 receptor agonists reduce the risk of myocardial infarction, stroke, cardiovascular death, and heart failure. The GLP-1 receptor agonists may also have reno- and neuroprotective effects, and may have a major role in the treatment of people with obesity (see Chapter 37 for details of GLP-1 agonists in weight loss programmes).

Mode of action

GLP-1 receptor agonists enhance the incretin effect by activating the GLP-1 receptor. Unlike DPP-4 inhibitors that restore physiological GLP-1 levels (see later), GLP-1 receptor agonists achieve supraphysiological levels and are therefore more potent than DPP-4 inhibitors. In addition to their effects on the pancreas to increase insulin secretion and decrease glucagon, they also act on the hypothalamus to reduce appetite and food intake, leading to weight loss. The size of effect has led to the licensing of liraglutide and semaglutide as anti-obesity treatments (see Chapter 37).

GLP-1 receptors are widely expressed in the cardiovascular system, and GLP-1 receptor agonists appear to protect the heart against ischaemic damage, both through direct effects on the heart as well as indirect effects, such as lowered blood pressure and free fatty acids.

Clinical use

Despite the need for injection, clinical guidelines presently endorse use of GLP-1 receptor agonists in combination with other antidiabetes agents, as second-line therapies. They should not be combined with DPP-4 inhibitors because DPP-4 inhibitors do not confer any additional benefit. Clinical trials have shown reductions of HbA_{1c} in the ranges 9 to 19 mmol/mol (0.8%–1.8%) and reduction of weight from –0.6 to 4.3 kg. As increasing evidence builds of the effectiveness of GLP-1 receptor agonists in reducing weight and cardiovascular risk, they are recommended as first-line agents in those with established or high risk of cardiovascular disease.

Adverse effects

The most common side-effects of GLP-1 receptor agonists are gastrointestinal and include nausea and vomiting, bloating, and diarrhoea. These tend to diminish with time and occur less frequently with longer-lasting GLP-1 receptor agonists. There is a low risk of hypoglycaemia, but this may occur if GLP-1 receptor agonists are combined with insulin or sulphonylureas. GLP-1 receptor agonists should not be used in people with a history of pancreatitis because of a risk of acute pancreatitis. Recent studies have not confirmed earlier concerns about links with pancreatic and thyroid cancer.

Dual GIP-GLP-1-receptor agonists

The dual GIP–GLP-1 receptor agonist tirzepatide has been developed for once-weekly subcutaneous injection and exerts greater reductions in HbA_{1c} and body weight in individuals with type 2 diabetes than GLP-1 receptor agonists. Further dual or triple agonists are in clinical development.

Second-line treatments

The following classes of antidiabetes agents may be used in people unable to tolerate first-line agents or when additional glucose management is required.

DPP-4 or 'gliptins'

DPP-4 inhibitors have been used since 2006 and improve glycaemia by enhancing the incretin effect.

Mode of action

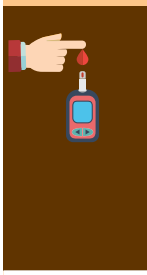
These drugs inhibit the enzyme DPP-4, which prevents the rapid inactivation of GLP-1, which in turn increases insulin secretion and reduces glucagon secretion.

Clinical use

DPP-4 inhibitors are most effective in the early stages of type 2 diabetes, when insulin secretion is relatively preserved, and are currently recommended for second-line use in combination with metformin. Although they only have relatively modest effects on glucose lowering, they are included in most type 2 diabetes treatment algorithms because they are well tolerated. DPP-4 inhibitors do not promote weight gain, have a low risk of hypoglycaemia, and can be used safely in people with renal impairment.

Adverse effects

Nausea may occur, and there have been occasional reports of acute pancreatitis. DPP-4 inhibitors do not alter the incidence of myocardial infarction, but saxagliptin may increase the risk of heart failure.



Sulphonylureas

Sulphonylureas were originally derived from sulfonamide antibiotics after it was recognized that the latter caused hypoglycaemia during a typhoid epidemic in Marseilles, France, in 1942 (**Box 35.13**).

Mode of action

Sulphonylureas act on the β cell to induce insulin secretion. They are ineffective in people without a functional β-cell mass and therefore have no effect in people with type 1 diabetes. Sulphonylureas bind to the sulphonylurea receptor 1 on the β-cell membrane, which closes ATP-sensitive potassium channels and blocks potassium efflux. The resulting depolarization promotes calcium influx and stimulates insulin release (**Fig. 35.4**).

Clinical use

As monotherapy, sulphonylureas typically reduce fasting plasma glucose by 2 to 4 mmol/L (36–72 mg/dL), corresponding to a fall in HbA_{1c} of 11 to 22 mmol/mol (1–2%). Although this is more effective than many other oral agents in the short term (1–3 years), the sulphonylurea effect wears off as the β-cell mass declines. Sulphonylureas can also be used in combination with other oral antidiabetes agents or basal insulin, although it is usually stopped when the individual requires short-acting insulin at mealtimes.

Adverse effects

Weight gain, typically 1 to 4 kg, and hypoglycaemia are the most common side-effects. Hypoglycaemia affects about one-fifth of those taking the drug, but severe hypoglycaemia is uncommon. The risk of hypoglycaemia is increased with longer-acting sulphonylureas, excessive alcohol intake, and older age and during intercurrent infection. Severe sulphonylurea-induced hypoglycaemia should be managed in hospital for up to 48 hours with glucose support until the drug has cleared from the circulation. Sulphonylureas should be used with care in people with liver or renal disease.

Thiazolidinediones or 'glitazones'

Three thiazolidinediones have been launched, but troglitazone was withdrawn because of liver toxicity, and rosiglitazone has been withdrawn or restricted because of concerns about cardiovascular safety. In many countries, pioglitazone is the only available thiazolidinedione.

Mode of action

Thiazolidinediones reduce insulin resistance by interaction with peroxisome proliferator-activated receptor-gamma, a nuclear receptor that regulates large numbers of genes, including those involved in lipid metabolism and insulin action. Thiazolidinediones increase fatty acid uptake by adipocytes and increase lipogenesis. This lowers circulating non-esterified free fatty acids, which in turn promotes glucose utilization in muscle and liver via the glucose–fatty acid (Randle) cycle. Thiazolidinediones reduce hepatic glucose production, an effect that is synergistic with that of metformin, and enhance peripheral glucose uptake. Like metformin, the glitazones potentiate the effect of endogenous or injected insulin.

Clinical use

Thiazolidinediones can be used as monotherapy if first-line agents are not tolerated or in combination with other antidiabetes drugs, including insulin. Thiazolidinediones do not cause hypoglycaemia as monotherapy, and pioglitazone may specifically benefit people with metabolic dysfunction-associated steatotic liver disease, a frequent co-morbidity of type 2 diabetes. Because the effect on plasma glucose is indirect, thiazolidinediones may take up to 3 months to reach their maximal effect.

Adverse effects

The most common adverse effect is weight gain of 5 to 6 kg, but pioglitazone may also cause fluid retention precipitating heart failure. Mild anaemia and osteoporosis resulting in peripheral bone fractures have been reported.

Other antidiabetes agents

Meglitinides or postprandial insulin releasers

Meglitinides are short-acting agents that promote insulin secretion in response to meals. Like sulphonylureas, meglitinides act by closing the K^+-ATP channel in the β cells (**Fig. 35.4**). They are rapidly metabolized and have a short duration of action of less than 3 hours. They may be used to treat people with postprandial hyperglycaemia and normal fasting glucose levels. They may be useful in older frail people in whom there is an imperative to avoid hypoglycaemia. However, meglitinides are less effective than other drugs, and their role in diabetes management is not well established.

Alpha-glucosidase inhibitors

Alpha-glucosidase inhibitors, such as acarbose, are drugs that reduce carbohydrate absorption after a meal by preventing the action of α-glucosidase, the last enzyme involved in carbohydrate digestion, from breaking down disaccharides to monosaccharides. This slows the absorption of glucose after a meal and lowers postprandial glucose.

Although α-glucosidase inhibitors can be used as monotherapy or in combination with all other antidiabetes drugs, they are not widely used because of their limited efficacy and gastrointestinal side-effects.

Quick-release bromocriptine

Abnormal circadian rhythm is associated with the development of insulin resistance, obesity, and diabetes. When administered at daybreak, quick-release bromocriptine appears to reset hypothalamic dopamine circadian rhythms. It lowers HbA_{1c} by 5 to 8 mmol/mol (0.5%–0.7%) either as monotherapy or in combination with other antidiabetes medications. The drug is well tolerated.

Colesevelam

Colesevelam is a bile acid–binding resin that lowers cholesterol and can reduce blood glucose concentrations by an unknown gastrointestinal mechanism.

Amylin analogues

Pramlintide is an analogue of amylin and is approved in the USA for use in people with either type 1 diabetes or insulin-treated type 2 diabetes. Amylin is co-secreted with insulin and delays gastric emptying, suppresses postprandial glucagon secretion, and increases satiety. It is not widely used.

Which drug and when?

With the introduction of increasing numbers of drugs to treat type 2 diabetes, the choice of which drug and when becomes more and more relevant. Because type 2 diabetes is characterized by progressive β-cell failure and glucose levels deteriorate over time, this requires a progressive and pre-emptive escalation of diabetes therapy. There is strong evidence of delays in treatment escalation,

Box 35.14 Considerations when choosing treatment for a person with type 2 diabetes

Characteristics of the person with diabetes
- Current lifestyle
- Co-morbidities
  - Atherosclerotic vascular disease
  - Heart failure
  - Chronic kidney disease
- Clinical characteristics
  - Age
  - Weight
  - Current HbA_{1c}
- Psychosocial issues such as motivation and depression
- Cultural and socioeconomic context

Specific factor
- Individualized HbA_{1c} target
- Impact on weight and hypoglycaemia
- Medication side-effects
- Treatment complexity
- Choose regimen to optimize medication taking
- Access, cost and medication availability

Shared decision-making
- Involves an educated and informed person with diabetes (and their family or caregiver)
- Seeks patient preferences
- Ensures effective consultation
- Empowers the person with diabetes
- Ensures access to diabetes self-management education

HbA_{1c}, Glycated haemoglobin.

which exposes the individual with diabetes to prolonged periods of hyperglycaemia and the inherent risks of complications.

Decisions about treatment should be individualized and shared with the person with diabetes. The importance of diabetes self-management education is highlighted to enable the person with diabetes to make an informed choice. Clinicians are advised to consider specific patient characteristics and factors that will inform the discussion (**Box 35.14**).

Metformin is recommended as the first-line treatment for most people with type 2 diabetes whose glucose levels remain above target despite optimal lifestyle management. However, for those with or at high risk of atherosclerotic cardiovascular disease, SGLT2 inhibitors or GLP-1 receptor agonists with proven cardiovascular disease benefit are preferred. SGLT2 inhibitors are also preferred for individuals with heart failure or chronic kidney disease (CKD).

If there is a pressing need to minimize weight gain or promote loss, again GLP-1 receptor agonists or SGLT2 inhibitors are recommended. Where there is a need to avoid hypoglycaemia, GLP-1 receptor agonists, SGLT2 inhibitors, a DPP-4 inhibitor, and thiazolidinediones may be used. Sulphonylureas or thiazolidinediones are preferred when cost is a major issue.

When dual or triple therapy is needed, other recommended drugs can be added. For example, if a GLP-1 receptor agonist is used first in someone with established atherosclerotic cardiovascular disease, an SGLT2 inhibitor would be an appropriate second-line choice or vice versa. Beyond triple therapy, insulin is required because further additional treatments have only a minimal effect, if any.

Several fixed-dose oral combinations and fixed-ratio injectable combinations of insulin and GLP-1 receptor agonists are available and reduce the pill or injection burden for the person with diabetes as treatment is escalated.

PANCREATIC ISLET AND WHOLE-PANCREAS TRANSPLANTATION

Islet transplantation

Since 2000, there has been remarkable progress in the technical aspects of islet cell processing and the outcomes of islet cell transplantation. The process involves harvesting pancreatic islets from cadavers (two or three pancreata are usually needed), which are then injected into the portal vein and seed themselves into the liver. It is one of the safest and least invasive transplant procedures. Islet cell transplantation is indicated for people with type 1 diabetes who have problematic hypoglycaemia, defined as two or more episodes of severe hypoglycaemic episodes per year, impaired awareness of hypoglycaemia, or persistent hyperglycaemia despite optimal diabetes management. The goal of treatment is to prevent severe hypoglycaemia, but about 30% of people receiving islet cell transplants maintain insulin independence after 5 years.

Whole-pancreas transplantation

Worldwide, more than 63 000 whole-pancreas transplantations have been performed. They are most often undertaken in people with type 1 diabetes and end-stage kidney disease at the same time as kidney transplantation ('simultaneous pancreas–kidney' transplants). Pancreas transplant may be performed less frequently after a kidney transplant or alone. Pancreatic transplantation can establish normoglycaemia and greatly improve quality of life. There is some evidence of protection against or reversal of some diabetes complications, but this comes at the cost of long-term immunosuppression.

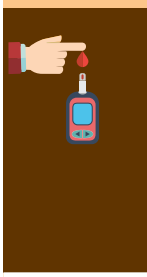
MONITORING GLUCOSE LEVELS IN PEOPLE WITH DIABETES

Measures of glucose levels are needed to help people with diabetes and their healthcare professionals make rational choices about therapy. CGM of interstitial glucose is now the measure of choice for people with type 1 diabetes and many people with insulin treated type 2 diabetes. Measurements of glucose levels can be divided into short-term measures that provide an almost instantaneous record of the current glucose concentration and long-term measures that provide an assessment of average glucose concentration over the preceding weeks or months.

Short-term measures of glucose levels

Self-monitoring of capillary blood glucose

Handheld meters allow people with diabetes to measure their capillary blood glucose concentration regularly throughout the day wherever they are. Blood is taken from the side of a fingertip (not from the top, which is densely innervated) using a special lancet. Single blood glucose concentrations are of limited value because of their wide variability, but repeated glucose measurements offer invaluable feedback that permits appropriate adjustment of treatment to be made. Some meters include bolus calculators that advise the individual on the appropriate dose of mealtime insulin based on the current glucose and estimated carbohydrate of the meal. The parameters of the automated bolus calculator (the ratio of insulin dose to carbohydrate intake and the amount by which one unit of insulin will reduce glucose levels) need to be programmed into the meter, usually during a consultation.



Self-monitoring of capillary blood glucose is recommended for everyone treated with insulin, but some people with diet- or tablet-treated type 2 diabetes may also find testing a useful guide to therapy. Like any investigation, measuring capillary blood glucose should inform future management, so if individuals are unable or unwilling to adjust their treatment, then 'testing for testing's sake' should be discouraged. Blood glucose monitoring does not, in itself, improve glucose levels but is essential to those wishing to achieve it.

Continuous glucose monitoring

CGM systems measure interstitial glucose every few minutes, allowing the user to see trends in glucose levels throughout the day, in particular at times when testing is not usually done, for example, at night. By tracking the glucose, the user can act earlier if the glucose starts to rise or fall. These devices have three parts, a sensor that sits just underneath the skin, a transmitter attached to the sensor, and a display device that shows the glucose level. The sensors need to be changed frequently, but some devices can be worn for up to 14 days.

The technology is developing extremely rapidly; some systems have alarms that alert the user to either high or low glucose levels. CGM devices can be integrated with pumps, allowing the insulin infusion to be suspended if the glucose levels are low or predicted to become low. *Hybrid closed-loop systems* (see 'Insulin pumps' section, earlier in the chapter) use a control algorithm to automatically adjust basal insulin delivery every few minutes based on sensor glucose levels. Results can be shared with healthcare professionals or others via the cloud to allow remote monitoring.

Clinical studies have shown that the use of CGM improves HbA_{1c} while reducing glucose variability and thereby lowering the risk of hypoglycaemia in type 1 diabetes.

The main disadvantage of CGM is the lag of 15 to 20 minutes between changes in blood glucose and interstitial glucose. Caution is needed if the glucose levels are changing rapidly, and if an individual experiences hypoglycaemic symptoms, they should test their capillary glucose even if the CGM reading is normal. Although many people with type 1 diabetes find CGM incredibly helpful, the wealth of data and alarms can overburden others.

CGM is recommended for people with type 1 diabetes. It is also recommended for people with type 2 diabetes on multiple daily injections if they have recurrent or severe hypoglycaemia, impaired aware of hypoglycaemia, or a condition or disability that means that they cannot self-monitor or if they would otherwise need to test eight times a day.

Long-term measures of glycaemia

Glycated haemoglobin

HbA_{1c} is a measure of an individual's average blood glucose concentration over the previous 6 to 8 weeks. The glycation occurs as a two-step reaction, resulting in the formation of a covalent bond between the glucose molecule and the terminal valine of the β chain of the haemoglobin molecule. The rate at which this reaction occurs is related to the prevailing glucose concentration. HbA_{1c} is expressed as the mmol concentration of HbA_{1c} per mole of normal haemoglobin (standardized range, 20–42 mmol/mol); formerly, it was expressed as the percentage of total haemoglobin that is glycated (normal range, 4%–6%).

Because HbA_{1c} provides an integrated measure of blood glucose concentration over the life of the haemoglobin molecule (≈6 weeks), the result may be misleading if the lifespan of the red blood cell is altered (**Box 35.15**).

Box 35.15 Limitations of HbA_{1c}

Analytical variability

- Different methods for measuring HbA_{1c} may give different results:
  - Largely addressed by standardization of the reference method
- Molecular variants of haemoglobin:
  - Fetal haemoglobin

Biological variability

- Interindividual variability:
  - An individual with a mean glucose of 10 mmol/L (180 mg/dL) may have an HbA_{1c} value that ranges from 6.0% to 9.0% (42–75 mmol/mol), probably reflecting differences in rates of protein glycation
  - Ageing
  - Ethnicity
  - Variation in erythrocyte lifespan:
- Shortened lifespan can give spuriously low results:
  - Haemolytic anaemia
  - Acute or chronic blood loss
  - Pregnancy
- Longer lifespan can give spuriously high results:
  - Iron deficiency
- Renal failure
- HIV infection

Clinical variability

- Predictive link between HbA_{1c} and clinical outcomes is not clear-cut

HbA_{1c}, Glycated haemoglobin.

Fructosamine

Glycation albumin measured as fructosamine relates to glycaemic levels over the preceding 2 to 3 weeks. It may be useful in people with anaemia or haemoglobinopathy or during pregnancy but is only rarely used.

DIABETES-RELATED METABOLIC EMERGENCIES

The two main diabetes-related hyperglycaemic emergencies are DKA and HHS. Together with severe hypoglycaemia, these are covered in detail in Chapter 11 on acute medicine, alongside the emergency management of hypoglycaemia (see Chapter 11). DKA and HHS are both life-threatening emergencies that require prompt treatment to reduce morbidity and mortality. Although often considered as clinically distinct phenomena, DKA and HHS exist on a spectrum. Both are characterized by hyperglycaemia with insulin deficiency, with only the degree of hyperglycaemia, level of associated dehydration, and severity of the associated metabolic acidosis distinguishing them.

COMPLICATIONS OF DIABETES

When effective treatment allowed people to survive the acute metabolic consequences of diabetes, it became apparent that long-term diabetes was associated with the development of a number of complications. These can be broadly divided into two groups: the microvascular complications that affect the capillaries and arterioles throughout the body but particularly involve the eyes (retinopathy), kidneys (nephropathy), and nerves (neuropathy), and macrovascular complications, which increase the risk of myocardial infarction, stroke, and peripheral vascular disease. With improved treatment of people with diabetes, the incidence of diabetes complications has fallen for each individual, but overall the prevalence has gone up as the number of people with diabetes has increased.

Microvascular complications

Microvascular complications are specific to diabetes and affect more than 80% of individuals with diabetes. They are unusual in the first 10 years after the diagnosis of type 1 diabetes but are found in 20% to 50% of people with newly diagnosed type 2 diabetes as a result of the preceding undiagnosed hyperglycaemia. With the advent of screening for type 2 diabetes, the numbers with complications at presentation are falling.

Pathology of microvascular complications

Thickening of the capillary and arteriole basement membrane is the cardinal feature of microvascular complications. Although basement membrane thickening is seen in most people with diabetes, organ damage occurs much less frequently; however, with time, the small vessels become progressively narrower and eventually become blocked, leading to ischaemia and tissue dysfunction. The tissues damaged by hyperglycaemia are those that have high blood flow and cannot downregulate glucose uptake in the presence of hyperglycaemia.

The mechanisms leading to damage are ill-defined but likely to be multifactorial. There is no doubt that the duration and degree of hyperglycaemia play a major role in the development of complications. However, other factors also seem to play a role because some people are relatively protected against microvascular complications despite longstanding diabetes. Twin studies suggest that genetic polymorphisms may affect the risk of complications. There are also racial differences in the overall rates of nephropathy; in the USA, the prevalence is highest in Pima Native American people followed by Hispanics and Mexican Americans, then Black Americans with the lowest rates in people of White Northern European ancestry.

The following are consequences of hyperglycaemia and likely contribute to the development of microvascular complications. The common feature of each stems from a single hyperglycaemia-induced process of overproduction of superoxide by the mitochondrial electron chain.

Formation of advanced glycation end-products

When a wide variety of proteins are exposed to increased glucose concentrations, glucose binds irreversibly to the protein to form advanced glycation end-products (AGEs). These accumulate in proportion to hyperglycaemia and time; one example of this is HbA_{1c}, which is used to diagnose diabetes and monitor treatment. AGEs cause tissue injury and inflammation via stimulation of pro-inflammatory factors, such as complement and cytokines.

Increased flux of glucose through the sorbitol–polyol pathway

When hyperglycaemia occurs, excess glucose is metabolized to sorbitol via the polyol pathway. This leads to accumulation of sorbitol and fructose, which cause changes in vascular permeability, cell proliferation, and capillary structure via stimulation of protein kinase C and transforming growth factor-beta (TGF-β).

Abnormal microvascular blood flow

Hyperglycaemia swamps the normal autoregulatory mechanisms that limit tissue blood flow and the high flow rates damage the tissue, particularly when hypertension is present. Endothelial damage occurs and vasoconstrictors, such as endothelins and thrombogenesis, are released that can lead to microvascular occlusion. Nutrients and oxygen supply are impeded.

Blockage of the renin–angiotensin system slows the progression of microvascular complications to a greater extent than other blood pressure–lowering agents, suggesting the renin–angiotensin system may have a role in the development of microvascular complications.

Growth factors and cytokines

Through increased expression of protein kinase C β (PKCβ), a number of mitogenic cytokines and growth factors, including TGF-β, tumour necrosis factor, and vascular endothelial growth factor (VEGF), are upregulated.

Growth hormone–insulin-like growth factor axis

The reduction in portal insulin concentrations impairs the ability of growth hormone to generate insulin-like growth factor 1 in the liver, which in turn leads to growth hormone hypersecretion by the pituitary gland. Growth hormone excess has been implicated in the development of microvascular complications, and indeed, pituitary ablation was used to treat patients with retinopathy before laser therapy became available.

Diabetic retinopathy

Diabetic retinopathy (damage to the retina) is the most commonly diagnosed diabetes-related complication (**Fig. 35.13**, see Chapter 31). Its prevalence increases with the duration of diabetes and affects around one-third of all people with diabetes (**Fig. 35.14**). Approximately 20% of people with type 1 diabetes will have retinal changes after 10 years, rising to 90% after 20 years (**Box 35.16**); 20% to 30% of people with type 2 diabetes have retinopathy at diagnosis, 10% of people with diabetes develop sight-threatening retinopathy,

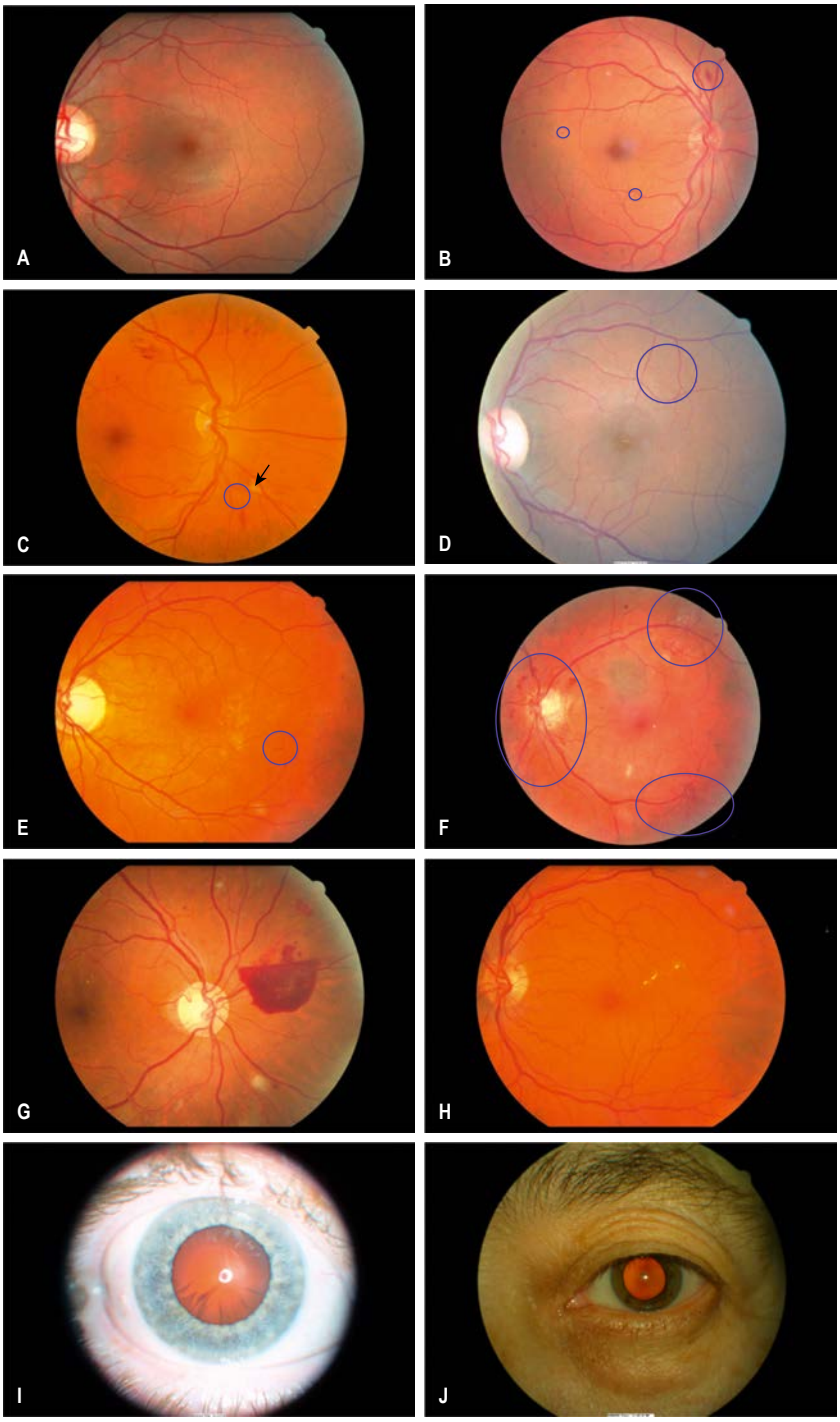

Fig. 35.13 Features of diabetic eye disease. **(A)** The normal macula *(centre)* and optic disc *(to left)*. **(B)** Microaneurysms *(small circles)* and blot haemorrhage *(larger circle)* indicating early non-proliferative retinopathy. **(C)** Hard exudates *(circled)* and single cotton wool spot *(arrow)* in addition to multiple blot haemorrhages in non-proliferative retinopathy. **(D)** Intraretinal microvascular abnormalities (IRMAs) indicating pre-proliferative retinopathy *(circled)*. **(E)** Venous loop *(circled)* also indicates pre-proliferative change. **(F)** Fronds of new vessels on the disc and elsewhere (proliferative; *circled*). **(G)** Pre-retinal haemorrhage in proliferative disease. **(H)** Hard exudates within a disc-width of the macula (maculopathy). **(I)** Cortical cataracts and **(J)** central cataracts can be seen against the red reflex with the ophthalmoscope.

and worldwide diabetic retinopathy is the most common cause of blindness in people of working age. However, the incidence and prevalence vary considerably between countries. In countries with good diabetes healthcare and systematic population screening, retinopathy develops less frequently and is more likely to be detected before sight-threatening changes have occurred. Approximately 1% to 7% of people with diabetes will require laser photocoagulation to prevent or limit progression to proliferative retinopathy.

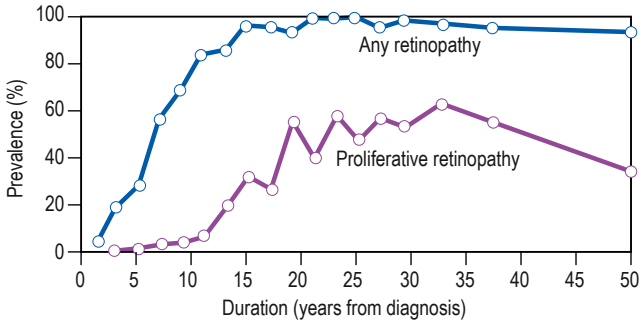

Fig. 35.14 Prevalence of retinopathy. Prevalence is shown in relation to duration of the disease in people with type 1 diabetes mellitus diagnosed before the age of 33 years. Almost all eventually develop background change, and 60% progress to proliferative retinopathy. The incidence of retinopathy and progression to proliferative retinopathy has declined substantially with improved glycaemic management. (*Data from* Archives of Ophthalmology. *1984;102:520.*)

Early changes without vision loss

The earliest changes in the retina are known as non-proliferative or background retinopathy (**Box 35.16**). Damage to the wall of small vessels causes microaneurysms (small red dots) within the retina. When vessel walls are breached, superficial (blot) haemorrhages occur in the ganglion cell and outer plexiform layers. Damaged blood vessels leak fluid into the retina. The fluid is cleared into the retinal veins, leaving behind protein and lipid deposits, which are seen as hard exudates. These are eventually cleared by macrophages. Micro-infarcts within the retina caused by occluded vessels cause cotton wool spots. The spot is swelling of the retinal nerve fibers because normal axoplasmic transport is disrupted, leading to the accumulation of axoplasmic debris. This debris is removed by macrophages. As this occurs, there may be white dots at the site of the previous cotton wool spot (cytoid bodies).

Sequential retinal photographs have demonstrated that all these lesions can heal, and it is not uncommon for changes to be seen on one occasion but not the next.

Transition to sight-threatening retinopathy

The next stage of retinopathy is known as pre-proliferative retinopathy (**Box 35.16**). Damage to the walls of veins causes their calibre to vary (venous beading) and elongation to occur, causing venous loops.

Sight-threatening retinopathy

With further progression, proliferative retinopathy develops (**Box 35.16**). Blockage of blood vessels leads to areas of capillary non-perfusion. Ischaemia in these areas causes the release of vascular growth factors such as VEGF. These factors cause new blood vessels to grow in the retina (neovascularization).

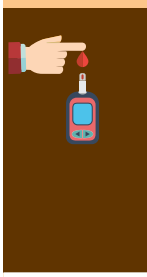
Some of these new blood vessels are inside the retina and are helpful. These new intraretinal vessels and other vessels whose walls are damaged and dilated give the appearance of intraretinal microvascular abnormalities (IRMAs). IRMAs are a feature of pre-proliferative retinopathy.

Other new vessels emerge through the retina and lie on its surface, usually at the margin of an area of capillary closure. The normal shearing stresses that occur within the eye can cause these poorly supported new vessels to bleed. Small haemorrhages give rise to pre-retinal haemorrhages (boat-shaped haemorrhages). With further bleeding, vitreous haemorrhage may occur with sudden loss of vision. Later, collagen tissue grows along the margins of the new vessels and gives rise to fibrotic bands. These bands may contract and pull on the retina, causing further haemorrhage and ***retinal detachment***. Sometimes vessels may be induced to grow on the pupil margin ***(rubeosis)*** and in the angle of the anterior chamber of the eye, giving rise to a rapid increase in intraocular pressure ***(rubeotic glaucoma)***.

Box 35.16 Grading and management of pathological changes in diabetic retinopathy

Retinopathy grade	Retinal abnormality (cause)	Action needed
Peripheral retina		
Nonproliferative (R1)	Dot haemorrhages (capillary microaneurysms) usually appear first Blot haemorrhages (leakage of blood into deeper retinal layers) Hard exudates (exudation of plasma rich in lipids and protein)[a] Cotton wool spots or cytoid bodies[b]	Annual screening only
Pre-proliferative (R2)	Venous beading or loops Intraretinal microvascular abnormalities Multiple deep, round haemorrhages	Non-urgent referral to an ophthalmologist
Proliferative (R3)	New blood vessel formation or neovascularization Pre-retinal or subhyaloid haemorrhage Vitreous haemorrhage	Urgent referral to an ophthalmologist
Advanced retinopathy	Retinal fibrosis Traction retinal detachment	Urgent referral to an ophthalmologist, but much vision has already been lost
Central retina		
Maculopathy (M1)	Hard exudates within 1 disc width of the macula Lines or circles of hard exudates within 2 disc widths of the macula Microaneurysms or retinal haemorrhages within 1 disc width of the macula if associated with an unexplained visual acuity of 6 of 12 or worse	Prompt referral to an ophthalmologist

[a]Hard exudates have a bright yellowish-white colour and are often irregular in outline with a sharply defined margin.
[b]Cotton-wool spots are greyish-white and have indistinct margins and a dull matt surface, unlike the glossy appearance of hard exudates.



Fluorescein angiography (a fluorescent dye is injected into an arm vein and photographed in transit through the retinal vessels) may be needed to define the extent of the potentially sight-threatening diabetic retinopathy.

Maculopathy

The progression of early diabetic retinopathy may result in the development of retinal oedema or exudates within the macular area, which is responsible for fine vision (**Box 35.16**). Fluid from leaking vessels is cleared poorly in this area because its anatomy differs from that of the rest of the retina. Above a certain rate of formation, clearance fails, and macular oedema occurs. This distorts and thickens the retina at the macula. If sustained, this distortion causes loss of central vision. Capillary occlusion in the macular area also causes loss of central vision.

Macular oedema is not visible with the ophthalmoscope or with retinal photography, and ocular coherence tomography is used to image the content of the layers of the macula and measure retinal thickness.

Management of retinopathy

Prevention is the best way of managing retinopathy; the DCCT and UKPDS showed conclusively that the risk of the development and progression of diabetic retinopathy can be reduced by optimal management of both glucose and blood pressure. However, a short-term deterioration of retinopathy may occur after rapid improvement in glycaemic levels, during pregnancy, and by nephropathy. The lipid-lowering drug fenofibrate has been shown to slow the progression of retinopathy, including macular oedema. Smoking cessation is recommended.

Intravitreal injection

Repeated injections of anti-VEGF drugs, such as bevacizumab, aflibercept, and ranibizumab, can control proliferative diabetic retinopathy and sight-threatening maculopathy. Studies have shown benefit over laser phototherapy for this type of maculopathy, but side-effects include infection, glaucoma, cataract, and retinal detachment. The corticosteroid triamcinolone reduces macular oedema in the short term and may be useful while other treatments exert a more permanent effect.

Laser photocoagulation

Laser photocoagulation therapy is used to treat the new vessels of proliferative retinopathy. New vessels on the disc carry the worst prognosis and warrant urgent laser therapy. The laser should be directed at the new vessels and at the associated areas of capillary non-perfusion (ischaemia). If the proliferative retinopathy has progressed to development of new vessels on the optic disc, then a technique known as panretinal photocoagulation is carried out. Rubeosis is also treated with panretinal photocoagulation. This involves multiple laser burns to the peripheral retina, especially in the areas of capillary non-perfusion. The principle is that by destroying the peripheral retina, the ischaemic stimulus for new vessel formation is diminished. Patients with maculopathy may also be treated with localized laser photocoagulation.

Although laser treatment prevents blindness, the main adverse effects result from the destruction of retinal tissue. The visual field becomes permanently smaller, and there is reduced dark adaptation. In essence, peripheral vision is sacrificed to maintain central vision.

Vitreoretinal surgery

Vitreoretinal surgery is used if bleeding is recurrent and preventing laser therapy. It is also used to try to salvage some vision if an intravitreal haemorrhage fails to clear and to treat fibrotic traction retinal detachment in advanced retinopathy.

Other ways in which diabetes can affect the eye

Cataract

Cataracts are caused by the denaturation of the protein and other components of the lens of the eye, which renders it opaque (see Chapter 31). Cataracts develop earlier in people with diabetes than in the general population. Sustained marked hyperglycaemia with a degree of ketosis can cause an acute cataract (snowflake cataract) to develop rapidly.

Extraction and intraocular lens implantation are indicated if the cataract is causing visual disability or an inability to view the retina adequately. Cataract extraction is straightforward if there is no retinopathy present. Pre-existing retinopathy may worsen after cataract extraction.

Refractory defects

The lens can also be affected by fluctuations in blood glucose concentration, which cause refractive variability, as a result of osmotic changes within the lens (the absorption of water into the lens causes temporary hypermetropia). This presents as fluctuating difficulty in reading, but people should be reassured that this resolves with better metabolic control of the diabetes.

External ocular palsies

These most commonly affect the sixth and the third nerves and are described in the section on neuropathies (see Chapter 28). These nerve palsies usually recover spontaneously within a period of 3 to 6 months.

Glaucoma

The prevalence of open-angle glaucoma is increased in people with diabetes.

Blindness

If sight loss occurs, individuals should be advised to register as blind and may require additional aids to help them to manage their diabetes. Less severe visual impairment is a bar to driving.

Eye screening

In the UK, the National Screening Committee has established universal digital photography–based screening across the country based on a national set of standards. As a result of the early detection of retinopathy, diabetes is no longer the most common cause of blindness in those younger than 65 years of age in the UK. All people with diabetes older than the age of 12 years are offered annual measurement of their acuity and retinal photographs. There are ongoing discussions about whether the screening interval might be extended in those with no retinopathy while more frequent screening is required in some groups (e.g., pregnant women). **Box 35.17** shows standardized criteria for screening schemes; these are regularly inspected.

Diabetic nephropathy

Classical diabetic nephropathy is characterized by gradually increasing urinary albumin excretion and blood pressure as the GFR falls insidiously towards end-stage renal disease. It is slowly progressive, and diabetic nephropathy usually manifests 15 to 25 years after the diagnosis of diabetes but affects 25% to 35% of people diagnosed before the age of 30 years. It is the leading cause of

Box 35.17 Criteria for a successful local screening scheme for sight-threatening diabetic retinopathy

- Clearly defined geographical area for the screening programme
- Adequate number of people with diabetes for viability (>12 000)
- Identified screening programme manager
- Identified clinical screening lead
- Identified hospital eye service for diagnosis and laser treatment
- Computer software capable of supporting call and recall of patients and image grading
- Centralized appointment administration
- Single collated list of all people with diabetes in the area older than the age of 12 years
- Equipment to obtain adequate disc- and macula-centred images of each eye
- Single image grading centre
- Process to manage people with poor-quality images
- Clear route of referral for treatment and for feedback from the treatment centre to the screening unit
- Accreditation of screening staff
- Annual reporting of service performance

premature death in young people with diabetes. A small number of people with type 1 diabetes and about 30% of those with type 2 diabetes who develop CKD have a non-classical natural history with progressive fall in GFR with no or minimal albuminuria.

The incidence of end-stage kidney disease has fallen in recent decades among people with type 1 diabetes, probably because of better management of blood glucose and blood pressure, but has increased in people with type 2 diabetes. Most people commencing renal replacement therapy have type 2 diabetes. The proportion of individuals commencing kidney replacement therapy because of diabetes varies across the world, ranging from 13% to 66%. Diabetic nephropathy increases the risk of cardiovascular risk, and most people with nephropathy die from cardiovascular disease before progressing to end-stage renal disease.

Pathophysiology

The earliest functional abnormality in the diabetic kidney is renal hypertrophy associated with a raised GFR ('glomerular hyperfiltration'). This appears soon after diagnosis and is related to hyperglycaemia. As the kidney becomes damaged by diabetes, the afferent arteriole (leading to the glomerulus) becomes vasodilated to a greater extent than the efferent glomerular arteriole. This increases the intraglomerular filtration pressure, further damaging the glomerular capillaries. Raised intraglomerular pressure also leads to increased local shearing forces, which likely contribute to mesangial cell hypertrophy and increased secretion of extracellular mesangial matrix material. This process eventually leads to glomerular sclerosis. The initial structural lesion in the glomerulus is thickening of the basement membrane. Associated changes result in disruption of the protein cross-linkages that normally make the membrane an effective filter. In consequence, there is a progressive leak of large molecules (particularly protein) into the urine.

Light-microscopic changes of both diffuse and nodular glomerulosclerosis become manifest; the latter is known as the Kimmelstiel–Wilson lesion. At the later stage of glomerulosclerosis, the glomerulus is replaced by hyaline material.

Albuminuria

Gradually increasing urinary albumin excretion is the hallmark of classical diabetic nephropathy. The earliest evidence of this is 'microalbuminuria', so called because the amounts of urinary albumin are so small as to be undetectable by standard dipsticks and only demonstrable by measurement of uACR. Microalbuminuria may, after some years, progress to persistent proteinuria (Fig. 35.15).

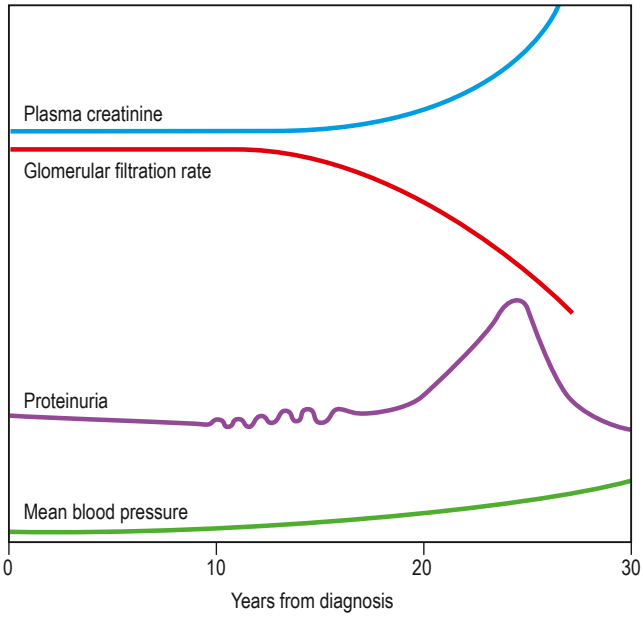


Fig. 35.15 Schematic representation of the natural history of nephropathy. The typical onset is 15 years after diagnosis. Intermittent proteinuria leads to persistent proteinuria. In time, the plasma creatinine rises as the glomerular filtration rate falls.

At the stage of persistent proteinuria, the plasma creatinine is normal, but when this stage is reached, end-stage kidney disease ensues within 5 to 10 years, although the rate of progression varies widely between individuals. Hypertension is a common development and may itself damage the kidney still further. Rising plasma creatinine is a late feature.

The proteinuria may become so heavy as to induce a transient nephrotic syndrome, with peripheral oedema and hypoalbuminaemia.

Hypertension may also contribute to the progression of CKD in people with diabetes, and they are also more prone to urinary tract infections. Autonomic neuropathy may result in bladder dysfunction and urinary retention.

Screening for diabetic nephropathy

The urine of all people with diabetes should be checked regularly (at least annually) for the presence of microalbuminuria. The uACR, tested on a midstream first morning urine sample, should be less than 2.5 mg/mmol in healthy men and less than 3.5 mg/mmol in healthy women. If microalbuminuria is detected, the test should be repeated because false-positive readings are common.

Investigation of microalbuminuria and proteinuria

When proteinuria is present, other possible causes should be considered, but after these are excluded, a presumptive diagnosis of diabetic nephropathy can be made. Clinical suspicion of a non-diabetic cause of kidney disease may be provoked by an atypical history, the absence of diabetic retinopathy (usually, but not invariably, present alongside diabetic nephropathy) and the presence of microscopic haematuria. Renal biopsy should be considered in

such cases but is rarely necessary or helpful. Renal function should be measured regularly.

Management of nephropathy

The management of diabetic nephropathy is similar to that of other causes of CKD, with a number of provisos. Although diabetic nephropathy is progressive, the time course can be markedly slowed by aggressive early therapy. Mainstays of treatment include:

- **Use of angiotensin-converting (ACE) inhibitors or angiotensin receptor blockers**, which reduce proteinuria through a reduction of intraglomerular pressure. They also contribute to blood pressure control but should be prescribed in people with diabetic nephropathy and persistent microalbuminuria even if the blood pressure is normal.
- **Use of SGLT2 inhibitors**, which slow the progression of diabetic nephropathy, even in those with low eGFR in whom the glucose-lowering effect is diminished. The explanation for these benefits is unclear but may involve effects on intraglomerular pressure, hypoxia, blood pressure, obesity, and other metabolic effects. There have been no studies of SGLT2 in diabetic nephropathy in people with type 1 diabetes, but the benefit is likely to be as in type 2 diabetes.
- **Use of non-steroidal mineralocorticoid receptor antagonists** such as finerenone, which are also effective in reducing albumin excretion and have been shown to reduce end-stage kidney disease, renal death, and cardiovascular events.
- **Tight blood pressure control**, with a target of less than 130/80 mmHg.
- **Meticulous glycaemic management.**

The development of nephropathy also has implications for glycaemic management. Metformin should be stopped when the eGFR drops below 30 mL/min. Because insulin clearance is reduced in advanced renal disease, the insulin dosage is usually reduced.

Management of end-stage renal disease

Managing end-stage renal disease is made more difficult by the fact that patients often have other complications of diabetes, such as blindness, autonomic neuropathy, or peripheral vascular disease. The failure rate of renal transplants is higher than in people without diabetes.

Diabetic neuropathy

Diabetes can damage peripheral nervous tissue in several ways. The vascular hypothesis postulates occlusion of the vasa nervorum as the prime cause. This seems likely in isolated mononeuropathies, but the diffuse symmetrical nature of the common forms of neuropathy implies a metabolic cause. Because hyperglycaemia leads to increased formation of sorbitol and fructose in Schwann cells, accumulation of these sugars may disrupt function and structure.

The earliest functional change in nerves of people with diabetes is delayed nerve conduction velocity; the earliest histologic change is segmental demyelination caused by damage to Schwann cells. In the early stages, axons are preserved, implying prospects of recovery; at a later stage, irreversible axonal degeneration develops. Unlike retinopathy or nephropathy in which there are good tools to assess early complications, the field of neuropathy is hampered by the lack of such investigative methods. However, recently, corneal confocal microscopy has been developed as a rapid, non-invasive, objective, and reproducible ophthalmic imaging technique that evaluates corneal nerve morphology and can be used as a surrogate marker for peripheral neuropathies.

Diabetic neuropathy can manifest in a number of different ways (Fig. 35.16).

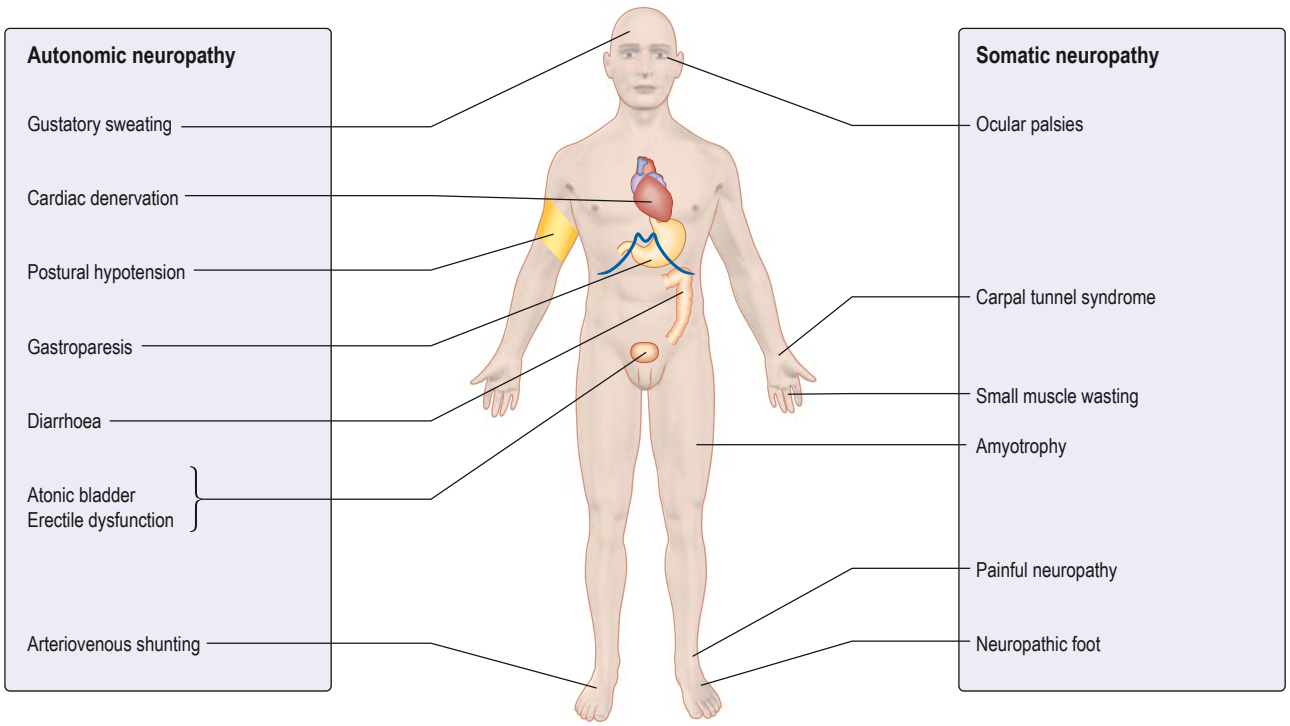

Fig. 35.16 **The effects of neuropathy in people with diabetes.**

Symmetrical distal polyneuropathy

Peripheral neuropathy is often unrecognized by the person with diabetes in its early stages. Early clinical signs are mainly sensory and include loss of vibration sense, pain sensation (deep before superficial), and temperature sensation in the feet. At later stages, people may complain of a feeling of 'walking on cotton wool' and can lose their balance when washing their faces or walking in the dark owing to impaired proprioception. Early involvement of the hands is less common and should prompt a search for non-diabetic causes. Complications include unrecognized trauma because of the loss of pain sensation.

Involvement of motor nerves to the small muscles of the feet gives rise to interosseous wasting. Unbalanced traction by the long flexor muscles leads to a characteristic shape of the foot, with a high arch and clawing of the toes, which in turn causes abnormal distribution of pressure on walking, resulting in callus formation under the first metatarsal head or on the tips of the toes. The hands show small-muscle wasting, as well as sensory changes, but these signs and symptoms must be differentiated from those of carpal tunnel syndrome, which occurs with increased frequency in diabetes and may be amenable to treatment (see Chapter 28).

Acute painful neuropathy

A diffuse, painful neuropathy is less common. The individual describes burning or crawling pains in the feet, shins, and anterior thighs. These symptoms are typically worse at night, and pressure from bedclothes may be intolerable. The condition may present at diagnosis or after sudden improvement in glycaemic levels (e.g., when insulin is started). It usually remits spontaneously after 3 to 12 months if near-normal glucose levels are maintained. A more chronic form, developing later in the course of the disease, is sometimes resistant to almost all forms of therapy. Neurological assessment is difficult because of the hyperaesthesia experienced by the individual, but muscle wasting is not a feature and objective signs can be minimal.

It is important to explore non-diabetic causes (see Chapter 28). However, if no other cause is found, explanation and reassurance about the likelihood of remission within months may be all that is needed. Duloxetine, venlafaxine, pregabalin, oxcarbazepine, tricyclic antidepressants, atypical opioids, and botulinum toxin all reduce the perception of neuropathic pain but usually not as much as patients hope for. The limited benefit of any one agent alone reflects the complex aetiology of neuropathic pain. Transepidermal nerve stimulation benefits some people. Topical capsaicin-containing creams or local anaesthetics help occasionally. A few report that acupuncture has been of value. There are several emerging treatments in clinical development.

Mononeuritis and mononeuritis multiplex (multiple mononeuropathy)

Any nerve in the body can be involved in diabetic mononeuritis; the onset is typically abrupt and sometimes painful. Radiculopathy (i.e., involvement of a spinal root) may also occur.

Isolated palsies of nerves to the external eye muscles, especially the third and sixth nerves, are more common in people with diabetes. A characteristic feature of diabetic third nerve lesions is that they are painless, and the pupillary reflexes are retained owing to sparing of pupillomotor fibres. Full spontaneous recovery is the rule for most episodes of mononeuritis over 3 to 6 months. Lesions are more likely to occur at common sites for external pressure palsies or nerve entrapment (e.g., the median nerve in the carpal tunnel).

Diabetic amyotrophy

This condition is usually seen in older men with diabetes. Presentation is with painful wasting, usually asymmetrical, of the quadriceps muscles. The wasting may be very marked, and knee reflexes are diminished or absent. The affected area is often extremely tender. Extensor plantar responses sometimes develop, and cerebrospinal fluid protein content is elevated. Diabetic amyotrophy is usually associated with periods of more severe hyperglycaemia and may be present at diagnosis. It often resolves over time with improved glycaemic levels.

Autonomic neuropathy

Asymptomatic autonomic disturbances can be demonstrated on testing in many people with diabetes (**Box 35.18**), but symptomatic autonomic neuropathy is rare. It affects both the sympathetic and parasympathetic nervous systems and can cause disabling postural hypotension.

Cardiovascular system

Vagal neuropathy results in tachycardia at rest and loss of sinus arrhythmia. At a later stage, the heart may become denervated (resembling a transplanted heart). Cardiovascular reflexes, such as the Valsalva manoeuvre, are impaired. Postural hypotension occurs owing to loss of sympathetic tone to peripheral arterioles. A warm foot with a bounding pulse is often seen in a polyneuropathy as a result of peripheral vasodilation.

Gastrointestinal tract

Vagal damage can lead to gastroparesis, often asymptomatic but sometimes leading to intractable vomiting. Implantable devices that stimulate gastric emptying and injections of botulinum toxin into the pylorus (to paralyse the sphincter partly) have each shown benefit in cases of this previously intractable problem.

Other symptoms resulting from altered gastrointestinal motility include dysphagia, dyspepsia, abdominal pain, constipation, diarrhoea, and faecal incontinence. Autonomic diarrhoea characteristically occurs at night, accompanied by urgency and incontinence.

Small intestinal dysmotility predisposes to bacterial overgrowth, which can cause bile salt deconjugation, fat malabsorption, and diarrhoea. Bacterial overgrowth may also lead to features such as anaemia and macrocytosis; treatment is with antibiotics such as tetracycline.

Bladder involvement

Loss of tone, incomplete emptying, and stasis (predisposing to infection) can occur and may ultimately result in an atonic, painless,

Box 35.18 Bedside testing of autonomic function

Test	Normal	Abnormal
Supine to erect BP		
Systolic BP fall (mmHg)	10	≥30
Heart rate responses to:		
Deep breathing (6 breaths over 1 min) maximum to minimum. HR	≥15	≤10
Valsalva manoeuvre (15 s): ratio of longest to shortest R–R interval	≥1.21	≤1.20
Lying-to-standing ratio of R–R interval of 30th to 15th beats	≥1.04	≤1.00

BP, Blood pressure; *HR*, heart rate; *R–R*, time between R wave and next R wave on electrocardiography.

Fig. 35.17 How diabetes can affect the foot. **(A)** High arch and clawing of the toes. **(B)** Typical neuropathic plantar ulceration. **(C)** Vascular pattern of ulceration.

distended bladder. Treatment is with intermittent self-catheterization, permanent catheterization if that fails, and prophylactic antibiotic therapy for those prone to recurrent infections.

Sexual dysfunction

Sexual dysfunction is common in both men and women with diabetes. The overall prevalence in men is 35% to 50% but increases with age. Approximately 60% of men with diabetes aged 60 years or older are affected. The first manifestation is incomplete erection, which may, in time, progress to total failure; retrograde ejaculation also occurs in men with autonomic neuropathy.

The mechanisms involved in erectile dysfunction in diabetes are multifactorial and include inadequate vascular supply owing to atheroma in pudendal arteries, autonomic neuropathy, primary or secondary gonadal failure, hypothyroidism, anxiety, depression, alcohol excess, and drugs (e.g., thiazides and beta-blockers).

When a man presents with erectile dysfunction, a detailed history and examination is needed to search for these causes. Blood is taken for luteinizing hormone, follicle-stimulating hormone, testosterone, prolactin, and thyroid function.

Treatment should ideally include sympathetic counselling of both partners. Phosphodiesterase type 5 inhibitors (sildenafil, tadalafil, vardenafil, avanafil), which enhance the effects of nitric oxide on smooth muscle and increase penile blood flow, are the first-line treatment in those who do not take nitrates for angina. Although less effective in people with diabetes, approximately 60% of men benefit from this therapy.

Alternative treatments include:

- Apomorphine 2 mg or 3 mg sublingually 20 minutes before sexual activity
- Alprostadil (prostaglandin E1 preparation), given as a small pellet inserted with a device into the urethra (125 μg initially to a maximum of 1 mg). If the partner is pregnant, barrier contraception must be used to prevent fetal exposure to the prostaglandin
- Intracavernosal injection of alprostadil (2.5 μg initially to a maximum of 60 μg). Side-effects include priapism, which needs urgent treatment if erection lasts longer than 3 hours
- Vacuum devices
- Penile prostheses.

Women with diabetes may complain of vaginal dryness and impaired sexual arousal.

Diabetes-related foot problems

Up to 50% of older people with type 2 diabetes have risk factors for foot problems, and 10% to 15% of people with diabetes develop foot ulcers at some stage in their lives. Diabetes-related foot problems (Fig. 35.17) are responsible for nearly 50% of all diabetes-related hospital admissions. Diabetes is the most common cause of non-traumatic lower limb amputation, but many amputations could be delayed or prevented by more effective self-management education and medical supervision.

Ischaemia, resulting from peripheral vascular disease, neuropathy, and infection, produces tissue necrosis and ulceration. Peripheral vascular disease tends to affect more distal vessels and occurs at a younger age in people with diabetes. Ischaemia compromises the ability to heal after minor trauma or infection.

Pain is a protective mechanism, and the diminished sensation that results from peripheral neuropathy means that the individual is less able to perceive trauma and may continue to walk on a wounded foot, thereby worsening the injury. Autonomic neuropathy reduces sweating and alters blood flow, resulting in dry skin that is prone to crack and fissure.

Although ischaemia and neuropathy may coexist, certain features allow an ischaemic to be distinguished from a predominantly neuropathic aetiology (Box 35.19).

Charcot neuroarthropathy

Charcot arthropathy is a complication of severe neuropathy. It occurs in a well-perfused foot and can be divided into three phases:

- Acute onset
- Bony destruction
- Radiological consolidation and stabilization.

Individuals present with an acutely swollen, hot foot, and about one-third have pain. At this stage, it may be difficult to differentiate between Charcot arthropathy and cellulitis; if in doubt, both conditions should be treated. Acute gout and deep vein thrombosis may also masquerade as Charcot arthropathy. If treatment is delayed, the foot can become deformed as bone is destroyed, often very rapidly over a few weeks. After 6 to 12 months, the destructive process stabilizes. Rehabilitation is always necessary after a long period in a cast, and reconstructive surgery may be needed.

The aim of treatment is to prevent or minimize bony destruction and deformity. Any resulting deformity can alter the pressure distribution across the foot and predisposes the foot to future ulceration. Immobilization in a non–weight-bearing cast is the treatment of choice and should be continued until the swelling and temperature in the foot has resolved.

Management of diabetes-related foot problems

The key to managing diabetes-related foot problems is prevention. Learning about the principles of foot care is essential (Box 35.20). Healthcare professionals should screen for foot problems at least once a year; this process should include questions about past or

Box 35.19 Distinguishing features between ischaemia and neuropathy

Feature	Ischaemia	Neuropathy
Symptoms	Claudication	Usually painless
	Rest pain	Sometimes painful neuropathy
Inspection	Dependent rubor	High arch
	Trophic changes	Clawing of toes
		No trophic changes
Palpation	Cold	Warm
	Pulseless	Bounding pulses
Ulceration	Painful	Painless
	Heels and toes	Plantar

Box 35.20 Principles of foot care for people with diabetes

- Inspect the feet daily.
- Moisturize dry skin.
- Seek early advice for any damage.
- Take care if walking barefoot.
- Check shoes inside and out for sharp bodies or areas before wearing them.
- Ensure shoes fit well with plenty of room for the toes.
- Keep feet away from sources of heat (hot sand, hot-water bottles, radiators, fires).
- Check the bath temperature before stepping in.
- Do not treat corns or callosities without professional help.
- Attend a podiatrist regularly:
  - Older people with diabetes may require help to cut their toenails.

present ulceration, an examination of the foot to detect structural abnormalities or callus formation, and an assessment of neuropathy and peripheral vascular disease. Although a clinical examination may reveal a distal loss of sensation, the use of monofilament, applied perpendicular to the foot and that buckles at a force of 10 g, has allowed reproducible assessments. The ability to feel this level of pressure provides protective sensation against foot ulceration. Both the VibraTip 128-Hz (a device which tests vibration perception) and the Ipswich Touch Test (a quick test involving lightly touching the first, third, and fifth toes of both feet) are reliable and sensitive tests for identifying those at risk of foot ulceration. Doppler ultrasound is a useful addition to a clinical examination of the lower limb pulses. If neuropathy or impaired blood supply is detected, the individual should be warned that their foot is at increased risk of ulceration.

Foot ulceration

The key to healing an ulcer is to ensure that the foot is non–weight bearing. Resting the affected leg may need to be supplemented with special shoes and insoles to move pressure away from critical sites or by removable or non-removable leg casts. After healing, special shoes and insoles are likely to be needed in the long term to protect the feet and prevent abnormal pressure repeating damage to a healed area. In neuropathic feet particularly, sharp surgical debridement by a podiatrist is necessary to prevent callus distorting the local wound architecture and causing damage through abnormal pressure on normal skin nearby.

Ischaemia

Clinical signs of ischaemia may be confirmed by femoral angiography, which is used to localize areas of occlusion that may be amenable to bypass surgery or angioplasty.

Infection

Foot infections can take hold rapidly and should be treated as medical emergencies. Some people have termed this a 'foot attack' akin to heart attacks to emphasize the seriousness of this condition. Clinical signs may include purulent discharge, erythema, local warmth, and swelling.

Early broad-spectrum antibiotics are essential, with therapy adjusted in the light of culture results. The organism grown from the skin surface may not be the organism causing deeper infection. Collections of pus are drained and excision of infected bone may be needed if osteomyelitis develops and does not respond to appropriate antibiotic therapy. Regular X-rays of the foot are needed to check on progress.

Wound environment

Dressings are used to absorb or remove exudate, maintain moisture, and protect the wound from contaminating agents; they should be easily removable. Various newer approaches to aid healing of diabetes-related foot ulcers include new dressings containing growth factors and other biologically active agents, hyperbaric oxygen, negative-pressure wound therapy, and bioengineered skin substitutes.

Multidisciplinary diabetes foot team

A multidisciplinary diabetes foot team, involving diabetologists working with podiatrists, orthopaedic and vascular surgeons, specialist nurses, orthotists, and other healthcare professionals, improves the outcome for people with diabetes-related foot ulcers. Rapid access to services is needed and people with diabetes should know how to contact the foot team if they develop problems.

Macrovascular complications

Atherosclerotic vascular disease

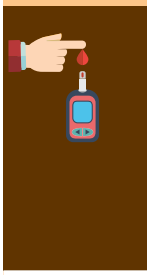
Diabetes is a risk factor for the development of atherosclerosis. Myocardial infarction, stroke, peripheral vascular disease, and cardiovascular death are increased two- or threefold compared with the background population. This risk is increased up to 10-fold in premenopausal women, who lose their normal protection against cardiovascular disease.

Pathogenesis

Atherosclerotic vascular disease in people with diabetes tends to occur at an earlier age, progress more rapidly, and is more distal and diffuse than in people without diabetes. Although hyperglycaemia contributes to the development of macrovascular disease, unlike microvascular disease, other more important haemodynamic and metabolic mechanisms are involved. The relationship between glycaemic levels and cardiovascular disease is less strong than microvascular disease but continues across the normal glucose range. Other more important factors include hypertension, dyslipidaemia (characterized by low high-density lipoprotein cholesterol and high triglyceride concentrations), obesity, hyperinsulinaemia, and proteinuria.

Management of atherosclerotic cardiovascular risk

Addressing cardiovascular risk involves the aggressive and systematic management of each of the predisposing factors (**Box 35.21**). As discussed earlier, early tight glycaemic management reduces the long-term risk of cardiovascular disease. In people with type 2 diabetes with established or at risk of cardiovascular disease, the use



Box 35.21 Target goals for cardiovascular risk factor management of people with diabetes

Parameter	Ideal	Reasonable but not ideal
HbA_{1c}	<7% (53 mmol/mol)	<8% (64 mmol/mol)
Blood pressure (mmHg)	<130/80	<140/85
Total cholesterol (mmol/L)	<4.0	<5.0
Low-density lipoprotein (mmol/L)	<2.0	<3.0
High-density lipoprotein (mmol/L)	>1.1 men >1.3 women	>0.8
Triglycerides (mmol/L)	<1.7	<2.0

Standards from the American Diabetes Association (2023).
HbA_{1c}, Glycated haemoglobin.

of SGLT2 inhibitors and GLP-1 receptor agonists is recommended because of their protective effect. Antihypertensive treatment produces a marked reduction in adverse cardiovascular outcomes as well as microvascular events. To achieve the target for blood pressure, most people with diabetes need combination drug therapy, usually beginning with an ACE inhibitor or angiotensin receptor blocker. Treating people with diabetes and at least one other major cardiovascular risk factor with an ACE inhibitor produces a 25% to 35% lowering of the risk of heart attack, stroke, overt nephropathy, or cardiovascular death. Angiotensin II receptor antagonists are sometimes preferred initially and are also used for those who are intolerant to ACE inhibitors.

Statins are recommended for those with diabetes over the age of 40 years or after a 10-year history of diabetes if microvascular complications are present as cardiovascular events are reduced by 20% for every 1-mmol/L reduction in low-density lipoprotein cholesterol. Other lipid-lowering agents, such as ezetimibe or PCSK9 inhibitors, are indicated if statins are not tolerated or do not bring the cholesterol to target.

As in the general population, smoking cessation is important, and help should be offered to those wishing to quit.

Low-dose aspirin reduces macrovascular risk but is associated with a morbidity and mortality from bleeding. The benefits of aspirin outweigh the bleeding risk when used for secondary prevention, but in Europe, it is not recommended for primary prevention.

The management of established cardiovascular disease by angioplasty or surgery is discussed in Chapter 17.

Heart failure

Heart failure is more common than atherosclerotic cardiovascular disease in people with diabetes, and both heart failure with preserved ejection fraction and heart failure with reduced ejection fraction occur more frequently. Around two-thirds of people with type 2 diabetes have evidence of left ventricular dysfunction 5 years after the diagnosis of diabetes. The prognosis after the development of heart failure is poor, with only 10% alive after 5 years.

Despite this, heart failure has received less attention than atherosclerotic cardiovascular disease and is frequently under-diagnosed. The prevalence of undiagnosed heart failure is higher in those with increasing age, obesity, hypertension, dyspnoea, or fatigue and in women.

The diagnosis and management of heart failure is similar to the general population, but it is important to consider the effects of diabetes medications on the heart failure. Pioglitazone and saxagliptin, a DPP-4 inhibitor, increased the risk of heart failure in clinical trials, but epidemiological studies show an association between the use of insulin and sulphonylureas with heart failure. GLP-1 receptor agonists have no effect on heart failure, but SGLT2 inhibitors substantially reduce the risk and have been used to treat heart failure in people without diabetes.

Other complications of diabetes

Metabolic dysfunction-associated steatotic liver disease and other gastrointestinal manifestations of diabetes

Metabolic dysfunction-associated steatotic liver disease (MASLD), formerly called non-alcoholic fatty liver disease, is characterized by intrahepatic fat accumulation with varying degrees of hepatic inflammation and fibrosis. A small proportion of people progress to cirrhosis. MASLD is present in up to one-fifth of the general population, but the prevalence is increased in people with type 2 diabetes. More than one-third of people with MASLD have diabetes, and MASLD is an independent predictor of the development of diabetes and cardiovascular disease. It is associated with central obesity and insulin resistance (see Chapter 37). Management is through weight loss and exercise. Pioglitazone may also reduce intrahepatic fat.

Malabsorption secondary to gastrointestinal dysmotility is described earlier, but people with diabetes may also develop malabsorption through chronic exocrine pancreatic insufficiency. This is unusual because only 10% of pancreatic function is sufficient for normal digestion. Treatment is with pancreatic enzymes. People with type 1 diabetes have a higher prevalence of coeliac disease.

Infections

Although people with well-managed diabetes are not more prone to infection, hyperglycaemia leads to more frequent infection through multiple disturbances in innate immunity; by contrast, humoral immunity appears relatively unaffected. Microvascular disease may further impede the immune system and likely contributes to the severity of certain infections, including malignant otitis externa, emphysematous pyelonephritis, and necrotizing fasciitis. Some microorganisms, such as *Klebsiella* serotypes and *Burkholderia pseudomallei*, are more virulent in hyperglycaemic environments.

Urinary tract infections and asymptomatic bacteriuria are more common in people with diabetes, with autonomic neuropathy a common and important underlying factor. Mycotic genital infections are more common, particularly in women. Skin and soft tissue infections are more common. The risk of tuberculosis is increased in people with diabetes. Certain viral infections, such as hepatitis C, and treatment for HIV/AIDS increase the risk of diabetes.

Cancer

In several high-income countries, cancer has become the leading cause of death among people with diabetes as deaths from cardiovascular diseases decline. Certain types of cancer, including hepatocellular carcinoma, endometrial cancer, and pancreatic cancer, are more common in those with type 2 diabetes. These associations appear to be mediated, at least in part, by obesity, which confers similar levels of risk in the absence of hyperglycaemia, although there is also an element of reverse causation with carcinoma of the pancreas, which can precipitate or cause diabetes.

Skin and joints

Diabetic cheiroarthropathy refers to joint contractures in the hands as a result of longstanding diabetes. This may be diagnosed by asking the individual to join the hands as if in prayer; the metacarpophalangeal and interphalangeal joints cannot be opposed. Thickened, waxy skin can be noted on the backs of the fingers. These features may be caused by glycation of collagen and are not progressive. Frozen shoulder, Dupuytren's contracture, trigger finger, and carpal tunnel syndrome all occur more commonly in those with diabetes.

Fracture risk is increased in those with type 1 diabetes and type 2 diabetes. Although bone mineral density is decreased in type 1 diabetes, it is increased in type 2 diabetes, so other mechanisms are at play. Thiazolidinediones decrease bone formation and bone mineral density and increase fracture risk in type 2 diabetes. After a fracture, healing may be delayed in people with diabetes. The risk of gout is also increased in people with type 2 diabetes.

Psychosocial implications of diabetes

The interaction between mind and body is central to the management and outcome of all chronic diseases but is particularly fascinating in the case of diabetes. People with diabetes have an increased risk of developing a number of psychological conditions, and a range of psychiatric disorders are associated with an increased risk of diabetes (**Box 35.22**). People with chronic stress, low stress resilience, sleeping problems, depression, or severe mental illness are at increased risk of developing type 2 diabetes. Diabetes affects the quality of many aspects of life, including emotional wellbeing, financial situation, leisure and work activities, and relationships with friends and families.

Psychological problems associated with diagnosis

Most people show remarkable psychological resilience to a diagnosis of diabetes despite the implications for self-management and long-term health. In some people, the diagnosis may lead to symptoms of anxiety and depression, but others develop an 'adjustment disorder'. Transient psychological symptoms begin within 3 months of the diagnosis of diabetes but usually resolve within 6 months. These symptoms are seen as part of the normal 'grieving process' that often accompanies the development of any chronic illness.

Diabetes-related distress

Living with diabetes is demanding; it is estimated that people with type 1 diabetes need to devote up to 2 hours a day to self-management, but around half of people with diabetes report that taking medication interferes with their ability to live a normal life. Diabetes self-management is often frustrating when blood glucose levels remain stubbornly out of target despite the individual's best efforts. More than 50% of people develop psychological symptoms, which are collectively known as diabetes distress, in response to living with the constant burden of diabetes. These include:

- Experiencing worries about the future and the possibility of serious complications
- Feeling guilty or anxious when their diabetes management goes awry
- Feeling scared or depressed when thinking about living with diabetes
- Feeling discouraged with their diabetes regimen.

Fear of hypoglycaemia

Episodes of hypoglycaemia are frequently unpredictable and are associated with unpleasant, embarrassing symptoms associated with activation of the nervous system. It is perhaps unsurprising that many people worry about future occurrences of hypoglycaemia, and some people develop significant fear of hypoglycaemia. This fear may also be experienced by other family members. Significant fear of hypoglycaemia is more common in people who have experienced loss of consciousness during a previous episode.

Depression

The prevalence of depression is increased twofold in people with diabetes. Significant depressive symptoms affect approximately one in four adults with diabetes, and a formal diagnosis of depressive disorders is made in 10% to 15% of people with diabetes. Depression is more common in women, those who are divorced, and those who have experienced childhood adversity and social deprivation. In addition, a number of diabetes-specific risk factors are associated with depression, including the development of complications and after initiation of insulin in type 2 diabetes.

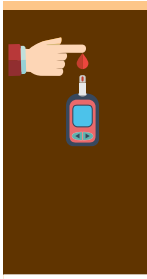
Box 35.22 Bidirectional relationship between diabetes and psychiatric and psychological conditions

Psychiatric and psychological conditions that occur more frequently in people with diabetes

- Adjustment disorders
- Diabetes-related distress
- Fear of hypoglycaemia
- Stigma and discrimination
- Anxiety
- Depression
- Phobia
- Eating disorders

Psychiatric and psychological conditions that increase the risk of diabetes

- Chronic stress
- Low resilience
- Sleeping problems
- Anxiety
- Depression
- Bipolar disorder
- Schizophrenia
- Other psychotic conditions treated with antipsychotics



Disordered eating

Eating disorders and disordered eating in diabetes encompass a broad spectrum of conditions ranging from well-defined eating disorders such as anorexia or bulimia nervosa to harmful diabetes self-care behaviours driven by fear of weight gain, with direct and indirect insulin restriction being the most common one.

Consequences of psychological and psychiatric disorders of diabetes

As well as affecting quality of life, the psychological sequelae of diabetes often impair the individual's ability to manage their diabetes. They are less likely to follow a healthy diet and exercise and less likely to take medication as prescribed, and it is therefore no wonder that psychological problems are associated with higher HbA_{1c}, more frequent admissions with hypoglycaemia and DKA, a higher incidence of complications, and shortened life expectancy.

Management of psychological issues

The key step to managing the psychological sequelae of diabetes is identifying the problem. It is important to ask the person with diabetes how they feel about their diabetes and whether they are experiencing difficulties with it. The diabetes specialist team will undertake much of the psychological management, but this should include liaison with the mental health teams to ensure appropriate referral of those with more complex problems. Some diabetes teams now include a psychologist.

A range of psychological interventions, including cognitive behavioural therapy and problem solving, has been used successfully to improve the psychological wellbeing of people with diabetes.

For people with depression, antidepressants are effective as long as they are used in adequate doses.

Social aspects of diabetes

Diabetes may affect the safety of driving for people who have hypoglycaemia, visual impairment (from either retinopathy or cataract), or disability from leg amputation or neuropathy. Because hypoglycaemia is the most common cause of accidents in people with insulin-treated diabetes, people with diabetes must take precautions to avoid hypoglycaemia while driving. In most countries, a driver with diabetes will need to inform the relevant authorities and insurance companies of their diagnosis.

Diabetes should not prevent access to most occupations, but certain occupations, including the armed forces, emergency services, commercial pilots, prison and security services, and jobs in potentially dangerous areas (e.g., at heights, underwater, and offshore) are barred or require special precautions. Shift work can make insulin management more complex, but modern long-acting insulin analogues with durations of action longer than 24 hours have made life easier.

DIABETES IN SPECIAL SITUATIONS

Diabetes in early adulthood

More than 1 million children have diabetes worldwide with approximately 132 600 new cases diagnosed annually. The incidence has been steadily rising over the past 50 years. Most children with diabetes have type 1 diabetes, although type 2 diabetes is becoming more common in older children. As the child grows up, the responsibility for managing the diabetes will shift from parent to child. The period of transition between paediatric and adult services is challenging, and many young adults with diabetes lose contact with healthcare professionals if this process is not managed effectively (see Chapter 46). The physical transfer between paediatric and adult services is only a small component of transition, and the process can take a number of years as the paediatric team, working with the adult team, provides the young adult with the information and skills needs to negotiate an adult health service independently. Although many young adults move to adult services around the age of 18 to 19 years, the decision to transfer should be based on skills and competencies rather than chronological age.

Emerging adulthood is a new concept that describes the early years of adulthood when an individual may be entering the world of work and moving away from home for the first time, including going to university. As well as providing many new opportunities, it is often a time for risk-taking. Many centres have now developed young adult clinics to care for the specific needs of this age group.

Diabetes in older people and at the end of life

The prevalence of diabetes in older people is increasing dramatically because of an ageing population and age-related challenges in body composition and insulin resistance. The lifetime risk of developing diabetes is 22% for women and 19% for men from the age of 60 years. More than half of those with diabetes are aged older than 65 years. Approximately 25% of older people living in care homes or nursing homes have diabetes.

Diabetes places an additional burden on older people, who frequently have other chronic conditions, with up to 40% having three or more other co-morbidities. Diabetes increases the risk of dementia, and cognitive decline compromises diabetes management. Frailty, which is characterized by weight loss, weakness, decreased physical activity, exhaustion, and slow gait speed, is more common in older people.

The management of diabetes in an older individual should consider the health status and needs of the person with diabetes. A thorough assessment should identify co-morbidities. Older people with diabetes are a highly heterogeneous population ranging from those living independently in the community to frail individuals with multiple co-morbidities in care homes. Glycaemic targets should therefore be individualized by taking into consideration the person's overall health, life expectancy, cognitive decline, and co-morbidities (**Box 35.23**). Maximizing quality of life should always be the focus of care.

Box 35.23 Glycaemic targets for older people

Independent or robust	Dependent	Dependent dementia or frail	End of life
7.0%–7.5%	7.0%–8.0%	<8.5%	Avoid symptomatic hypoglycaemia
53–59 mmol/mol	53–64 mmol/mol	<70 mmol/mol

Box 35.24 Use of insulin in older people[a]

Insulin regimen	Independent or robust	Dependent frail	Dependent dementia	End of life
Basal insulin + oral antidiabetes agents	First choice	First choice	First choice	First choice but consider withdrawal
Premix insulin	Alternative first choice			
Basal-bolus insulin	Second-line choice	Avoid	Avoid	Avoid

[a]Choose the appropriate device, usually a prefilled pen.

Dunning T, Sinclair A, Colagiuri S. New IDF Guideline for managing type 2 diabetes in older people. Diabetes Res Clin Pract. *2014;103(3):538–540.*

When possible, drugs that avoid hypoglycaemia are preferred because the associated co-morbidities, geriatric syndromes, polypharmacy, and long duration of diabetes and the increased prevalence of hepatic and renal dysfunction increase the risk of hypoglycaemia. Insulin regimens should be simplified (**Box 35.24**). Furthermore, hypoglycaemia can be less easily recognized and is often misdiagnosed because of reduced autonomic symptoms.

As people approach the end of life, the goals of treatment shift from the prevention of long-term complications to the avoidance of symptomatic hyper- and hypoglycaemia, acute metabolic decompensation, and drug-related adverse events. Glycaemic targets should be relaxed with the aim of keeping the glucose between 6 and 15 mmol/L (110–270 mg/dL) to minimize the risk of hypoglycaemia and other drug-related adverse events. Insulin should usually be continued. It is important to take care to avoid foot ulceration in bedbound individuals.

Inpatient diabetes

Having diabetes more than doubles the risk of being hospitalized for any given condition. In 2019, the UK National Diabetes Inpatient Audit showed that 18.1% of hospital inpatients had diabetes. In the majority, diabetes was not the cause for their admission, but poor management of diabetes lengthens hospital stay and increases the risk of developing complications, such as hospital-acquired infection, or dying. This applies equally to medical and surgical inpatients.

Although the stress of acute illness can worsen hyperglycaemia, hypoglycaemia is also associated with increased morbidity and mortality. Because there is a lack of robust evidence demonstrating that intensive glucose management improves outcomes, the general consensus is that the main priority is to avoid hypoglycaemia, and diabetes treatments need to be adjusted accordingly.

Because people with diabetes may be less able to self-manage their diabetes while in hospital, it is important the diagnosis of diabetes is clearly identified in the medical records and glucose and HbA_{1c} measured on admission. Errors in insulin prescribing are common, and one-third of all fatal inpatient medical errors that cause death within 48 hours of the error involve insulin administration. An emphasis on insulin safety, particularly when an i.v. insulin is being used, is essential. There is an increasing move for people with insulin-treated diabetes to self-manage when they are able on the grounds that they know how to do so much better than many hospital staff.

Many hospitals have specialized diabetes inpatient teams that take responsibility for diabetes management, but all staff caring for people with diabetes should be appropriately trained and competent in the management of inpatient diabetes (**Box 35.12**).

Intravenous insulin is required for a number of specific conditions because this mode of administration provides the greatest flexibility to meet rapidly changing insulin requirements (**Box 35.25**). Intravenous insulin is usually administered as a variable rate infusion, but the insulin rate is fixed when treating DKA. Variable-rate or fixed-rate i.v. insulin infusion is preferred to the old but more ambiguous terminology 'sliding scale'. To maintain patient safety, the glucose should be monitored frequently.

Box 35.25 Indications for intravenous insulin in hospital

Variable rates intravenous insulin infusion

- Critical care illness
- Acute coronary syndromes
- Stroke
- 'Nil by mouth' status when more than one meal will be missed (type 1 diabetes)
- General preoperative, intraoperative, and postoperative care
- Stroke
- Hyperglycaemia during high-dose corticosteroid therapy
- Labour and delivery
- Other acute illness for which prompt glycaemic control is judged important for recovery

Fixed rates intravenous insulin infusion

- Diabetes emergencies:
  - Diabetic ketoacidosis
  - Hyperosmolar hyperglycaemic syndrome

Management of diabetes during an admission for surgery

Both hyperglycaemia and hypoglycaemia in the postoperative period worsen surgical outcomes by increasing the risk of infection, myocardial infarction, and death and are associated with an increased duration of stay on the intensive care unit and in hospital.

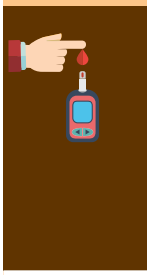
The patient journey begins in primary care and general practitioners should help optimize glucose management in the preoperative period. This reduces the likelihood of the surgery's being cancelled or postponed owing to hyperglycaemia. The preoperative assessment provides a further opportunity to improve diabetes management and allows the patient to be placed at the beginning of a morning list when possible to minimize the period of fasting and subsequent metabolic disturbance.

For people treated with insulin, unless the period of fasting is less than one missed meal, a variable-rate i.v. insulin infusion is needed to manage the glucose perioperatively. The long-acting insulin should be continued because it will prevent rebound hyperglycaemia when the i.v. insulin is stopped. Oral drugs that can cause hypoglycaemia should also be stopped for the dose immediately before surgery but can be resumed after the patient is eating and drinking normally. Metformin should be stopped if i.v. contrast is used.

Before discharge, a clear follow-up plan is needed, which should be communicated to the person with diabetes and their primary care team.

Diabetes in pregnancy

Diabetes is one of the most common medical conditions in pregnancy, with 15.8% of live births in 2019 being affected by some



form of diabetes in pregnancy. Approximately 85% of women with diabetes in pregnancy have gestational diabetes with the remainder having pre-existing diabetes. The epidemiology of pre-existing diabetes in pregnancy is changing as women are delaying pregnancy to an older age, and the prevalence of obesity and type 2 diabetes is increasing in women of childbearing age. Whereas 25 years ago, type 2 diabetes was rare in pregnant women, the latest UK national audit has indicated that there are now more pregnant women with type 2 diabetes than type 1 diabetes.

Adverse effects of diabetes in pregnancy

Before the discovery of insulin, pregnancy with diabetes was invariably fatal for both the mother and fetus. Even in the era up to the 1960s, pregnancy remained a risky enterprise, with perinatal mortality rates of up to 40%. However, with an understanding that maternal hyperglycaemia was the major cause of fetal loss, management changed to ensure as near normoglycaemia as possible, and outcomes began to improve. Nevertheless, pregnancy outcomes in women with diabetes still remain worse than for women without diabetes.

Diabetes in pregnancy is associated with risks to both the woman and to the developing fetus. Women with pre-existing diabetes may find it harder to conceive and in the first trimester have higher rates of miscarriage and congenital anomalies. The frequency of many developmental abnormalities, including cardiac and skeletal malformations, is increased. Although rare, the risk of caudal regression syndrome appears to be specifically increased in women with diabetes. Towards the end of pregnancy, women with either pre-existing diabetes or gestational diabetes have a higher risk of preterm labour, hypertension, and pre-eclampsia.

The risks to the fetus include higher rates of macrosomia and associated shoulder dystocia and birth injury, polyhydramnios, stillbirth and perinatal mortality, and impaired postnatal metabolic adaptation leading to higher rates of neonatal jaundice and respiratory distress. After birth, neonatal hypoglycaemia may occur as maternal glucose crosses the placenta but insulin does not; this leads the fetal islets to hypersecrete insulin to combat the rising hyperglycaemia, and rebound hypoglycaemia may occur when the umbilical cord is cut. In the longer term, offspring of mothers with diabetes have a higher risk of obesity and diabetes in adulthood.

Management of diabetes during pregnancy

As the adverse effects of diabetes are largely mediated by hyperglycaemia, the major aim of management in diabetic pregnancies is to maintain normoglycaemia by avoiding pre- and postprandial hyperglycaemia without causing severe hypoglycaemia. This is a demanding process, so pregnant women with diabetes should be in contact with a specialist multidisciplinary team jointly led by a physician and obstetrician at least every 2 weeks.

Preconception care

Pregnancy management should begin well before conception; because pregnancy can only be diagnosed a minimum of 2 weeks after conception, it is important that optimal glycaemic levels are achieved before conception. This requires planning on the part of both the woman with diabetes and the diabetes team. From puberty, girls with diabetes need to know about the importance of pregnancy planning and contraception until they are ready to start a family.

When a woman expresses a desire for pregnancy, referral to a specialist diabetes preconception clinic improves the pregnancy outcomes. This provides an opportunity to review diabetes management, discuss the need for high dose folic acid (5 mg daily) to reduce the risk of neural tube defects, ensure that microvascular screening is up to date, stop medications that are contraindicated in pregnancy, and check that the woman has been immunized against rubella.

The optimal target preconception HbA_{1c} is below 48 mmol/mol (6.5%) when this can be achieved safely, and women should be advised not to become pregnant if their HbA_{1c} is above 86 mmol/mol (10%). Target fasting plasma glucose levels are 5 to 7 mmol/L (90–126 mg/dL) and 4 to 7 mmol/L (70–126 mg/dL) before meals at other times of the day. This is challenging for women, and they should be offered the opportunity to attend structured education if they have not done so already. When necessary, insulin analogues should be used because they appear to convey advantages over human insulin. Metformin may be used while preparing for pregnancy, but other oral antidiabetes drugs and GLP-1 receptor agonists should be stopped. ACE inhibitors, angiotensin II receptor antagonists, and statins should be stopped before conception.

Antenatal management

The need for optimal glycaemic management continues when a female becomes pregnant; the target glucose levels are less than 5.3 mmol/L fasting (95 mg/dL), less than 7.8 mmol/L (140 mg/dL) 1 hour after meals, and less than 6.4 mmol/L (115 mg/dL) 2 hours after meals. Women need to monitor their glucose levels by capillary blood testing; when available, CGM is now preferred because it increases the time that women spend in the target glucose range and is associated with improved fetal outcomes.

These stringent glycaemic targets are made harder to achieve because pregnancy changes the insulin requirement; this tends to fall in the first trimester, partly as a result of the hormonal changes in pregnancy but also because pregnancy-associated nausea and vomiting can reduce appetite. This increases the risk and severity of hypoglycaemia; for reasons that are not entirely clear, early pregnancy is associated with impaired awareness of hypoglycaemia, further increasing the likelihood of hypoglycaemia. Women and their partners need to know about the risk and how to manage it. Interestingly, fetuses tolerate maternal hypoglycaemia relatively well.

During the second and third trimesters, pregnancy induces a state of insulin resistance, which typically increases insulin requirements by 50% to 100% in the latter half of pregnancy. Towards the end of pregnancy, insulin absorption is delayed, so women may need to increase the length of time between the short-acting insulin injection and eating in the third trimester.

Ketoacidosis in pregnancy carries a 50% fetal mortality rate, so if it occurs in pregnancy, it should be diagnosed and managed rapidly. To expedite the diagnosis, women should be taught to monitor blood ketones at the outset of pregnancy.

As pregnancy can accelerate the progression of retinopathy, pregnant women should be screened in the first and third trimesters and in the second trimester if any retinopathy is present at the outset.

Low-dose aspirin (150 mg daily) from the 12th week of pregnancy lowers the risk of hypertension and pre-eclampsia.

Enhanced fetal surveillance is needed and a detailed ultrasound scan for fetal anomalies including a four-chamber view of the fetal heart and outflow tracts should be offered at 18 to 20 weeks of gestation. Growth scans and other tests of fetal wellbeing should be performed during the third trimester.

Birth

Most babies of women with diabetes are born before term after an induction of labour or elective caesarean section to reduce the risk

of stillbirth. Glycaemic management during labour is usually maintained by a variable rate i.v. insulin infusion, but pumps are being increasingly used as an alternative in some centres.

Postnatal care

After birth, maternal insulin requirements drop rapidly to preconception levels within hours of the birth and may even be lower if a woman chooses to breast-feed. Because the neonate is at increased risk of hypoglycaemia, early feeding should be encouraged with breast-feeding being the preferred option, and the baby's blood glucose should be checked regularly until it is clear that the pre-feeding glucose levels are being maintained in the normal range.

Gestational diabetes

Gestational diabetes is defined as diabetes occurring for the first time in pregnancy that is clearly not overt diabetes before pregnancy. It is usually diagnosed in the second and third trimesters of pregnancy after a 75-g OGTT. Gestational diabetes occurs in women whose pancreatic β cells are unable to secrete sufficient insulin to meet the pregnancy-induced insulin resistance. The risk factors for gestational diabetes are the same as for type 2 diabetes, so gestational diabetes can be regarded as an early revelation of the metabolic abnormality brought on by the demands of pregnancy. Not all diabetes presenting in pregnancy is gestational. Screening may identify women with previously undiagnosed type 2 diabetes or monogenic diabetes, and in a few cases, gestational diabetes may unmask pre-clinical type 1 diabetes.

Diagnosis of gestational diabetes

There is a lack of international agreement regarding the diagnosis with varying diagnostic cut-off values and number of abnormal values needed between recommendations (**Box 35.26**). Universal screening for diabetes is recommended in many countries but in the UK, NICE recommends screening only women with risk factors for gestational diabetes; the advantage of the latter approach is that many low-risk women do not need the screening test. This costs less but it risks missing gestational diabetes in a significant proportion of women (**Box 35.27**).

Management of gestational diabetes

Glucose targets are the same as for pre-existing diabetes, but management begins with health behaviour modification, similar to the management of type 2 diabetes (see Chapter 48). If health behaviour modification does not achieve adequate maternal glycaemia within 1 to 2 weeks, pharmacological therapy is indicated. Although insulin is still widely used, studies have suggested that metformin or glibenclamide (a sulphonylurea) is an acceptable alternative.

Women with gestational diabetes have a 20%–50% chance of developing diabetes within 10 years of the pregnancy. The diabetes antenatal team should discuss this risk and the measures needed to reduce the likelihood of developing diabetes before discharge after the birth. An annual HbA_{1c} or glucose test is recommended to diagnose asymptomatic diabetes. At present, the uptake of postnatal interventions and screening is low, and more research is needed to find out how to manage this risk more effectively.

ORGANIZATION OF DIABETES CARE

The diabetes care team involves a multidisciplinary group of healthcare professionals who are available to support the person with diabetes (**Fig. 35.10**). Because the amount of time that each person with diabetes spends with a healthcare professional is small—on average, less than 6 hours a year—it is important that every contact counts and provides appropriate medical and psychosocial support. To ensure that the person with diabetes derives the maximum benefit from the time spent with their diabetes team, whether in a hospital or community setting, the consultation should be collaborative, patient-centred, and goal-focused and with clear aims. As well as traditional clinic visits, people with diabetes may access diabetes care virtually through phone, email, or Internet contact or through educational sessions.

Box 35.27 Risk factors for gestational diabetes: NICE recommendations for a 75-g oral glucose tolerance test

NICE recommends undertaking a 75-g OGTT at 24–28 weeks of gestation in females with the following risk factors:

- Body mass index >30 kg/m^2
- Previous macrosomic baby weighing ≥4.5 kg
- Previous gestational diabetes[a]
- First-degree relative with diabetes
- Family origin with a high prevalence of diabetes: South Asian, Black Caribbean, or Middle Eastern

[a]Women with a previous history of gestational diabetes should be offered a 75 g 2-hour oral glucose tolerance test (OGTT) as soon as possible after booking (whether in the first or second trimester), and a further 75 g 2-hour OGTT at 24 to 28 weeks of gestation if the results of the first OGTT results are normal.

Much of care is focused towards minimizing the long-term complications while avoiding adverse effects from treatment. Diabetes UK has described the 15 essentials of diabetes care (**Box 35.28**) that should be assessed and discussed at least once a year.

The majority of diabetes care takes place in a primary care setting, but people with diabetes with complex medical or psychological needs require management and support in a specialist setting for some or all of their care. A close collaboration between primary and secondary healthcare professionals and among specialists is essential to ensure that care is integrated and coordinated across the wide range of disciplines involved.

People with diabetes need to be involved in decisions about their care because this improves outcomes and the likelihood that a specific management plan will be followed. It is good practice to provide the person with diabetes with copies of any letters written about them so that all decisions are clear, and it is easier to review the management plans at subsequent contacts.

CORE SKILLS AND KNOWLEDGE

Inherited metabolic diseases (IMDs) are individually rare, although as a group, they are not altogether uncommon.

Many patients with IMDs are diagnosed in childhood, and transition in adulthood to the care of metabolic medicine specialists in tertiary referral centres, supported by dieticians and other healthcare professionals. However, they may also present for the first time as adults to general services or require general or emergency management in non-specialist settings (e.g., when a metabolic emergency is triggered by starvation, dehydration, or intercurrent illness). All doctors therefore must have at least a basic awareness of these conditions.

Key skills in this area include:

- Knowing when to suspect an IMD and understanding the principles of tailored therapy for rare diseases
- Recognizing the acute presentations of such conditions and knowing core steps in management of these emergencies.

Opportunities for learning in this specialty include observing clinics in specialist metabolic medicine centres and attending specialist conferences, courses, and workshops.

BACKGROUND

Inherited metabolic diseases (IMDs), previously known as inborn errors of metabolism, are a heterogeneous group of complex monogenic disorders that occur because of an impairment in the activity of an enzyme involved in one or more metabolic pathways. Hundreds of disorders exist, with the number of known disorders increasing yearly. The International Classification of Inborn Metabolic Disorders currently includes 1450 disorders. Thus, although individually rare, collectively, they are not that uncommon, with reported prevalence ranging from 1 in 800 to 1 in 2500 live births. IMDs are commoner in populations where consanguinity occurs. Specific founder mutations are found in societies derived from small original ancestral populations, where intermarriage and genetic drift further increase the prevalence of specific IMDs, especially in geographically or culturally isolated populations.

Clinical signs and symptoms occur because of accumulation of substrate precursors or deficiencies of enzyme products. The majority of IMDs present in childhood or are picked up through neonatal screening programmes. With early diagnosis and specific treatments, life expectancy is improved considerably, and patients may transition to adult metabolic services in late adolescence. Their risk of other common medical problems may be higher than that of patients in the general adult population.

Up to 40% of IMDs may be diagnosed in adults, with presentations that may differ from those seen in children. Patients may present to the emergency department with acute metabolic decompensation or to any specialist outpatient clinic with problems related either to a previously diagnosed IMD or an as-yet undiagnosed IMD.

APPROACH TO THE PATIENT

History

An IMD should be considered:

- In patients presenting with symptoms associated with particular IMDs, including encephalopathy, rhabdomyolysis or unexplained high creatine kinase (CK), acidosis or persistently high lactate of unknown aetiology, hypoglycaemia, or stroke
- When there is multisystem involvement
- When there is a history of metabolic triggers
- When there is a family history of similar symptoms, early death, or consanguinity
- When an alternative more common diagnosis is not forthcoming

It is important not to miss a diagnosis because the prognosis is often good after early institution of simple therapy or diet modulation.

A confirmed diagnosis also has implications for the extended family, who may benefit from early intervention and reproductive counselling.

Examination

Patients with IMD may have signs relating to their clinical presentation such as focal neurological symptoms, encephalopathy, retinopathy, or hearing impairment. In some of the storage diseases, hepatosplenomegaly (sometimes massive) or dysmorphia can be demonstrated.

Investigations

Patients with IMDs may require measurement of metabolites, including ammonia, lactate, glucose, organic acids, and amino acids in serum, urine, and cerebrospinal fluid. Basic and additional tests, including the role of genetic testing, are described in **Box 36.1**.

Special considerations

Patients with IMDs may have specific risks related to pregnancy, surgery, or anaesthesia. Hence, any pregnancy or surgery should be discussed with a specialist metabolic physician well in advance to enable a personalized birth or surgical treatment plan to be drawn up.

Genetic testing, including multigene panels and whole-exome and whole-genome sequencing, is becoming an almost first-line diagnostic tool and is likely to widen the spectrum of IMDs both in terms of phenotypic presentations and new diseases. Genetic testing is discussed in greater detail in Chapter 5.

ACUTE PRESENTATIONS OF INHERITED METABOLIC DISEASES

Patients with known or undiagnosed IMDs can present acutely to the emergency department as a result of metabolic decompensation precipitated by metabolic triggers, including:

- Catabolic states such as intercurrent illness or an inability to tolerate food and drink
- Labour and the postpartum period
- Non-compliance with IMD treatment
- Drugs (therapeutic or recreational), including alcohol
- Change in diet

Known inherited metabolic disease

Patients at risk of decompensation often carry with them an emergency management plan provided by their specialist metabolic centre. For many patients with inherited disorders of glucose, lipids, and protein metabolism, this may include a basic oral ***emergency regimen*** (ER) to use when unwell. This usually comprises 200 mL of 25% glucose polymer drink every 2 hours (50 g of carbohydrates or 200 kcal) with instructions to attend hospital for intravenous (i.v.) treatment and further management if they are unable to tolerate oral ER or fail to improve despite it. Intravenous ER for these conditions is usually an infusion of 10% glucose i.v. at 2 mL/kg per hour. The oral or i.v. glucose provides adequate calories and increases

Box 36.1 Basic and additional tests in known or suspected inherited metabolic diseases

Investigation	Timing of investigation and clinical significance
Basic metabolic screen	
FBC, renal, liver and bone profiles, CRP, ammonia, lactate, glucose, ketones (beta-hydroxybutyrate and free fatty acids), venous blood gases, CK, urate	At presentation Laboratories servicing emergency departments should return results for these tests within the hour, at any time of day or night, to enable prompt treatment.
Tests of vitamin B_{12} metabolism, preferably including active vitamin B_{12} (transcobalamin and methylmalonic acid), homocysteine, and folate	At presentation Abnormalities may be suggestive of IMDs in cobalamin and folate metabolism that are eminently treatable.
Two bottles of 5-mL lithium heparin preservative samples for plasma amino acids and acyl-carnitines	At presentation
Urine collected in a 15-mL universal container for urine organic acids	At presentation
Additional tests to consider	
If the patient is undergoing a lumbar puncture and IMD is suspected, send: • 1 aliquot of CSF in a fluoride–oxalate tube for lactate and glucose • 1 aliquot of CSF in a plain tube to the laboratory to be saved for further investigations if needed Paired plasma fluoride–oxalate and lithium heparin samples should be sent along with the CSF samples. CSF results can only be interpreted by comparison with serum and plasma levels.	Preferably discuss with a metabolic centre before taking samples. If unable to contact centre, take and send to the laboratory to be saved. Ensure prior consent taken as per local guidelines.
Consider sending two 5-mL EDTA preservative whole-blood samples for DNA analysis and WBC extraction.	Preferably discuss with a metabolic centre before taking samples. If unable to contact centre or if patient perimortem, take and send to laboratory to be saved. Ensure prior consent taken as per local guidelines.
Skin biopsy: DNA can be extracted from fibroblasts grown from a skin biopsy (even taken up to 24 hours postmortem if sterile); a postmortem diagnosis of individuals dying of a suspected IMD may allow screening of other family members, as well as confirm the cause of death.	Preferably discuss with a metabolic centre before taking samples. If unable to contact centre or if the patient is perimortem or immediate postmortem, take and send to the laboratory to be saved. Ensure prior consent taken as per local guidelines.
Tissue biopsy (if indicated): muscle, liver, renal, and cardiac	Preferably discuss with a metabolic centre before taking samples. If unable to contact centre or if the patient is perimortem or immediate postmortem, take and send to the laboratory to be saved. Ensure prior consent taken as per local guidelines.

CK, Creatine kinase; *CRP,* C-reactive protein test; *CSF,* cerebrospinal fluid; *EDTA,* ethylene-diamine-tetra-acetic acid; *FBC,* full blood count; *IMD,* inherited metabolic disease; *WBC,* white blood cell.

endogenous insulin production, and both help reverse the catabolic state. ER prevents or mitigates acute metabolic decompensation caused by a catabolic state, resulting in endogenous protein breakdown, lipolysis, and possible hypoglycaemia.

Emergency departments should ensure these patients are triaged as emergencies and that treatment and investigations are instituted without delay as per their emergency management plan. Although prompt treatment is often associated with good prognosis, a delay can lead to permanent significant neurological sequelae or death.

Patients should also be investigated and treated for metabolic triggers of acute decompensation. ERs for common metabolic conditions are available online, for example, on the British Inherited Metabolic Disease Group's (BIMDG) website (see Further reading). Every effort should be made to contact the patient's metabolic centre for advice as soon as possible, ideally within the first hour. (Many metabolic centres, including in the UK, offer a 24/7 on-call advice.)

Situations when an inherited metabolic disease should be suspected

An IMD should be suspected in patients presenting with one of the clinical syndromes described next, particularly if there is no obvious alternative diagnosis, if there is a suggestive family history, one or more metabolic triggers, a history of aversion to certain food groups (e.g., proteins), or a recent history of exclusion diets (low-carbohydrate, high-fat, high-protein diets). A basic metabolic screen should be sent off. Abnormalities in biochemistry may only be apparent during an acute episode, so samples for a basic acute metabolic screen (**Box 36.1**) should be taken at presentation. Specialist advice should be sought and emergency treatment initiated as soon as possible if an IMD is suspected.

Clinical presentations in which an IMD should be suspected include the disorders described next.

Encephalopathy and urea cycle disorders

Patients with a known and an as-yet undiagnosed IMD can present for the first time in adulthood with encephalopathy. Specific findings on brain imaging and electroencephalography may point towards a metabolic encephalopathy, which most commonly occurs secondary to hyperammonaemia. Plasma ammonia levels must therefore be measured urgently in all patients presenting with undiagnosed encephalopathy.

Ammonia is a by-product of protein catabolism (**Fig. 36.1**). It is detoxified by conversion to urea via the urea cycle in the liver (**Fig. 36.2**), and urea is subsequently excreted by the kidneys. A diagnosis of a urea

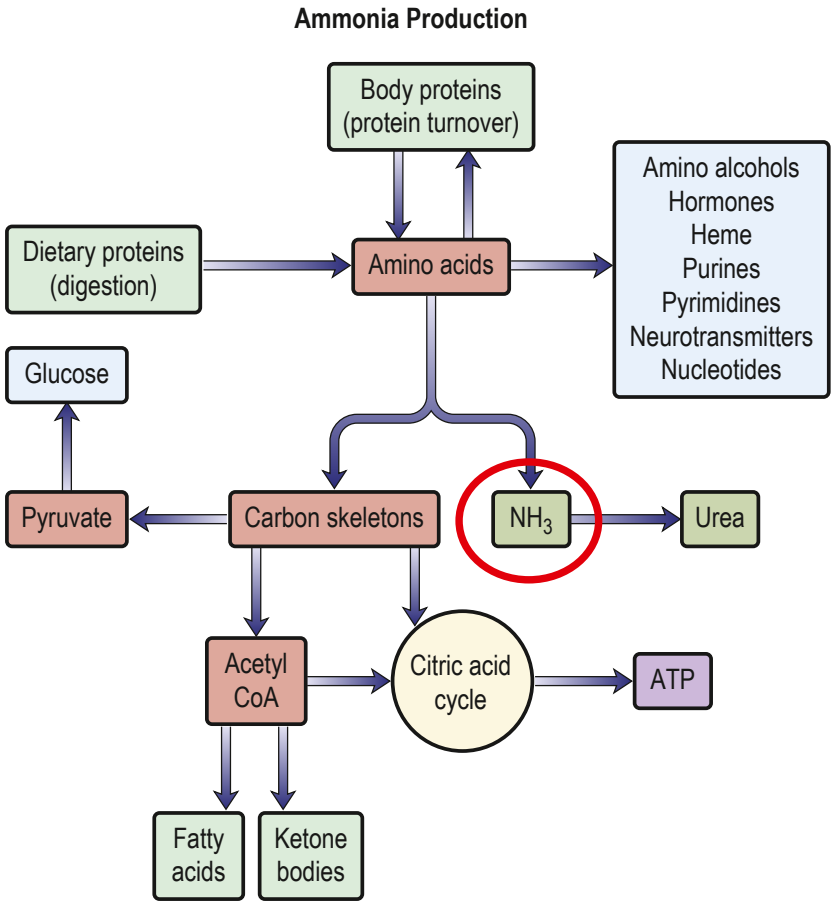

Fig. 36.1 Much of the body, including structural components, enzymes, and receptors, is made of proteins. Dietary proteins are broken down to constituent amino acids and then used for synthesis of body proteins. Amino acids derived from excess dietary protein, and during times of increased energy demands, from breakdown of body proteins, are used as metabolic fuel through decomposition to hydrocarbons skeletons and ammonia. Hydrocarbons are converted to pyruvate and acetyl CoA, which are in turn metabolized to glucose and fatty acids or ketones, respectively. Ammonia is converted to urea via the urea cycle in the liver and subsequently excreted in the urine. *ATP,* Adenosine triphosphate.

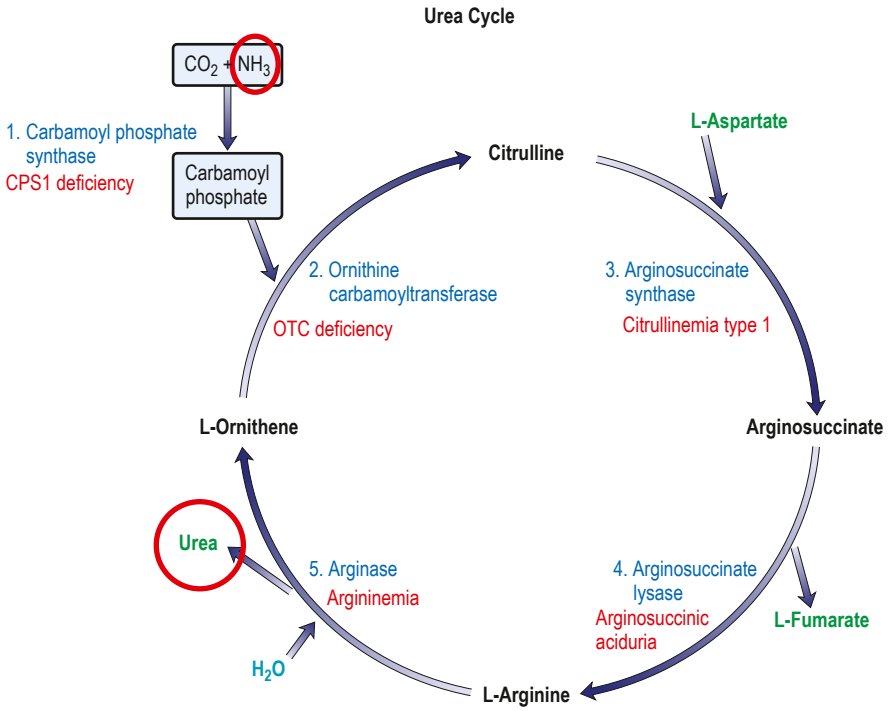

Fig. 36.2 Ammonia is detoxified by conversion to urea through the urea cycle in the liver hepatocytes. The urea cycle is a set of cytosolic and mitochondrial enzymatic reactions that convert ammonia (NH_3) and carbon dioxide (CO_2) to urea (enzymes are highlighted in blue). Briefly, carbamoyl phosphate synthetase 1 (CPS1) *(1)* catalyzes the condensation of NH_3 and CO_2 to carbamoyl phosphate, which in turn combines with ornithine in the presence of ornithine carbamoyltransferase *(2)* to citrulline. Citrulline is bound to aspartate by arginosuccinate synthetase *(3)* to form arginosuccinate. Arginosuccinate is split by arginosuccinate lyase *(4)* to form arginine and fumarate. Arginine is hydrolyzed by arginase *(5)* to the end products urea and ornithine, which are recycled back into the urea cycle. Inherited deficiencies in any of the enzymes in the urea cycle are collectively known as urea cycle disorders, labelled in red. *1,* CPS1 deficiency; *2,* ornithine transcarbamylase (OTC) deficiency; *3,* citrullinemia type 1; *4,* arginosuccinic aciduria; *5,* argininemia.

cycle defect, one form of IMD, should be sought in patients in whom other more common causes of hyperammonaemia such as decompensated liver disease and drugs have been excluded. Prolonged hyperammonaemia is associated with permanent neurological deficit and death. Ammonia should be included in the first-line screening investigations for all patients presenting with encephalopathic symptoms.

Ammonia samples are unstable and should be collected on ice and dispatched promptly to the laboratory. If hyperammonaemia is confirmed, treatment can and should be started promptly before the precise details of the IMD causing hyperammonaemia is known.

The main principles of treatment are to:

- Prevent catabolism by giving i.v. ER. (This can be done before ammonia levels are known if index of suspicion high.)
- Lower plasma ammonia levels as quickly as possible. This is most effectively done using haemofiltration or haemodialysis in symptomatic patients.
- Decrease protein load by temporarily stopping all external natural protein intake. (This can be done before ammonia levels are known if index of suspicion high.) Total protein restriction should not continue beyond 48 hours.
- Use ammonia scavengers such as sodium benzoate and phenylbutyrate as soon as available.

Published guidelines ('Urea cycle defects—acute emergency management') are available on the BIMDG's website (see Further reading). Advice from a specialist IMD centre should be sought for ongoing management and further investigations immediately on finding a high ammonia level.

Rhabdomyolysis

Although trauma and drugs are the commonest causes of rhabdomyolysis, IMDs such as glycogen storage disorder (GSD) type 5 (see **Box E36.3**; the eBoxes can be found in our ebook, please use the PIN code on the inside cover of the book for access) or disorders of fatty acid metabolism (see **Box E36.4**) should be considered in patients with recurrent episodes or a suggestive history. Send samples for an acute metabolic screen, including CK. In addition to standard treatment for rhabdomyolysis, patients with IMD-related rhabdomyolysis benefit from i.v. ER.

Stroke

Thrombotic strokes in younger adults or a cerebral sinus thrombosis should prompt measurement of plasma homocysteine levels to exclude homocysteine and folate metabolism disorders, particularly as they are treatable (see primary homocystinuria; see **Box E36.1**).

IMDs such as mitochondrial disorders and Fabry's disease should also be considered in patients with strokes who are young or in whom symptoms or imaging is inconsistent with a defined

vascular territory. The risk of stroke can be up to 12 times higher in young males with Fabry's disease than in the general population

Hypoglycaemia

Although hypoglycaemia is a common neonatal and childhood presentation of GSDs (see **Box E36.3**) and fatty acid oxidation disorders (FAODs) (see **Box E36.4**), presentations among adults are rare. Nevertheless, there are isolated reports of patients with IMDs such as glucokinase-activating mutations presenting for the first time in adulthood with hypoglycaemia. Because this is eminently treatable, the diagnosis should be considered and excluded. Insulin and C-peptide measurements and an acute metabolic screen at the time of hypoglycaemia provide important diagnostic clues.

Acidosis

A raised unexplained anion gap may be suggestive of an IMD. Hyperlactatemia, hyperammonaemia, or ketosis without hyperglycaemia may all be diagnostic clues. Clinicians should send samples for an acute metabolic screen, including blood gases, bicarbonate, glucose, and lactate, at presentation if an IMD is suspected.

GENERAL PRINCIPLES OF MANAGEMENT OF INHERITED METABOLIC DISEASES

There are several common mechanisms by which IMDs may cause symptoms, for instance, via accumulation of metabolic precursors or toxic waste products. These suggest general management principles applicable to the specific conditions described later in the chapter:

Dietary manipulation to bypass 'metabolic block'

'Metabolic block' describes accumulation of upstream precursors and deficiency of downstream products of a defective metabolic enzyme.

The principle of management of these conditions is to institute dietary changes to decrease the availability of the precursors and replace any crucial important products.

For example, amino acid metabolism disorders (described later) are generally managed by varying degrees of protein restriction. In phenylketonuria (PKU) and maple syrup urine disease (MSUD), this restriction may be severe (less than 10 g of protein a day). To prevent severe protein deficiency and micronutrient deficiencies as a result of food restriction, patients need supplementation with amino acid mixtures that contain all other essential amino acids other than the specific precursor (phenylalanine in those with PKU and leucine in those with MSUD). Patients should also be advised to have regular adequate calorie intake and avoid fasting to prevent endogenous protein breakdown and build-up of precursor amino acids.

Adult Refsum's disease and long-chain fatty acid disorders (covered later) are examples of diseases in which symptoms are caused by increase in circulating levels of long or very long-chain fats. Treatment principles here are similar and include restriction of very long- or long-chain fats in the diet and adequate calorie intake to prevent lipolysis.

Maintenance of regular and adequate calorie intake

Patients with disorders of glycolysis, glycogenolysis, or gluconeogenesis (e.g., GSD 1 and 3) are treated with regular and adequate calorie intake in the form of slow-release carbohydrates, or glucose, or both. Although patients with GSD 1 are unable to use fats and proteins as energy sources because of impaired gluconeogenesis, patients with conditions such as GSD 3 benefit from alternative energy sources such as protein and fats in the diet. Patients with glucose transporter 1 deficiency are unable to adequately transport glucose for brain energy metabolism; these patients benefit from alternative fuel sources such as ketone bodies produced endogenously when on a ketogenic diet.

Supplementation with vitamins, minerals, and co-factors

Vitamins and minerals are important co-factors for a number of intermediary energy metabolism pathways. A number of IMDs are related to impaired absorption, transport, or metabolism of these vitamins and minerals. Some of these disorders are managed with high-dose vitamins, often resulting in normalization of biochemistry and mitigation of symptoms.

Examples include pyridoxine responsive homocystinuria, vitamin B_{12}–responsive methylmalonic aciduria, and sapropterin responsive PKU.

Enzyme replacement therapy

Enzyme replacement therapy (ERT) is becoming available for patients with a number of conditions, most notably for lysosomal disorders. A range of 'orphan drugs' are available via government subsidy schemes that cover the pharmaceutical costs of development of drugs that would otherwise not be profitable to manufacturers because of low patient numbers. Examples include recombinant alpha-galactosidase (e.g., agalsidase alpha and beta) for use in Fabry's disease, or recombinant glucocerebrosidase (e.g., imiglucerase) for use in Gaucher's disease. Some of the main challenges for ERT are the need for regular lifelong parenteral administration, variable bioavailability, and development of antibodies to the drugs.

Newer therapies

Gene, mRNA, and oligonucleotide-based therapies for a number of IMDs are currently undergoing clinical trials. Advances in this field of emerging therapies are likely to have a significant positive impact on the prognosis and outcomes in patients with IMDs in the future and may even offer the prospect of a complete and lifelong cure.

Supportive management and surveillance

Despite recent advances in specific therapies, management of many IMDs remains largely supportive. Patients must be followed up regularly to ensure early detection and management of co-morbidities such as cardiomyopathy, diabetes, neurological or skeletal abnormalities, learning difficulties, and mental health problems. The spectrum of phenotype is wide, even within a single IMD, and therefore management plans and surveillance must be personalized to ensure best possible quality of life outcomes.

SPECIFIC INHERITED METABOLIC DISEASES

Mitochondrial diseases

Mitochondrial function is regulated by the interplay between nuclear, chromosomal genes and the 37 mitochondrial genes that together code for nearly 1500 mitochondrial proteins (see Chapter 5). Thus,

mitochondrial diseases (MDs) can be caused by maternally inherited defects in the mitochondrial genome (see Fig. 5.6 in Chapter 5) or by Mendelian inherited nuclear genome defects. *De novo* mutations are also known to occur.

Every nucleated cell in the body contains between 100 and 10 000 mitochondria that are responsible for adenosine triphosphate (ATP) generation through oxidative phosphorylation. Hence, mitochondrial dysfunction leads to clinical manifestations secondary to cellular dysfunction and premature cell death as a result of an energy deficit. MDs are not especially uncommon, with a reported incidence of 1 in 4300 in the UK. MDs presenting in adulthood were traditionally thought to be caused by mutations in the mitochondrial genome; however, it is now increasingly apparent that roughly 25% of MDs presenting for the first time in adulthood may be secondary to mutations in the nuclear genome.

Patients can present with a variable phenotype with one or more clinical features associated with MD, varying in severity and chronology (**Box 36.2**). Patients may sometimes present with well-defined clinical syndromes that are associated with a particular nuclear or mitochondrial mutation (**Box 36.3**). Investigation profiles should include glucose, lactate, acyl-carnitines, CK, muscle biopsy, and genetics.

Diagnosis

Although biochemistry may be indicative, confirmatory diagnosis requires specialist investigations, including tissue (most often muscle) biopsy and genetic testing.

Management

Although clinical trials are ongoing, specific therapies for patients with MD are currently not available in the clinical setting. Management is largely supportive, including surveillance for and treatment of MD-associated co-morbidities such as diabetes and cardiac disease. Patients should be offered genetic counselling, and a detailed pedigree history should be taken to ensure appropriate cascade testing of at-risk relatives. With the option of mitochondrial donation now becoming available, reproductive options should also be discussed.

Box 36.2 Clinical features that should prompt consideration of a mitochondrial disease[a]

System	Clinical feature
Neurological	Ataxia or stroke-like episodes (predominantly occipital), seizures, myoclonus, neuropathy, myopathy, migraines, encephalopathic symptoms, magnetic resonance imaging changes suggestive of mitochondrial disease
Cardiac	Cardiomyopathy, conduction defects, Wolff–Parkinson–White syndrome
Endocrine	Diabetes, particularly in patients with a strong maternal history of diabetes, sensorineural hearing loss or a phenotype, biochemistry not typical of insulin resistance
Eyes	Non-fatigable ptosis, ophthalmoplegia, pigmented retinopathy, cataracts, optic atrophy
Sensorineural hearing loss	Early onset, bilateral, with strong maternal family history
Gastrointestinal	Dysmotility presenting as vomiting or constipation
Other biochemistry	May have raised plasma lactate or creatine kinase

[a]Unless otherwise explained.

Disorders of protein metabolism

Phenylketonuria

PKU (incidence, 1 in 20 000 globally) is an autosomal recessive amino acid metabolism disorder caused by a bi-allelic mutation in the phenylalanine hydroxylase gene. It is the most common IMD encountered in specialist metabolic centres in Europe, where the incidence is highest (1 in 5000 to 15 000 in white babies of European descent). It is characterized by elevated levels of phenylalanine in the blood, and if treatment is delayed, it can result in severe intellectual disability. Early treatment within the first few days of life results in normal development. Many countries, including those in the UK, offer newborn screening for PKU, with the aim of starting therapy within the first 2 weeks of life. The aim of treatment is to maintain phenylalanine levels below therapeutic targets, which may vary slightly among countries. The mainstay of treatment is a diet restricted in natural proteins, combined with supplements (phenylalanine-free protein, vitamins, and minerals) and specialist low-protein foods available on prescription. More recently, more specific therapies, including enzyme and co-factor replacement therapy, have become available in some countries. High phenylalanine levels during pregnancy in patients with PKU can result in microcephaly, significant intellectual disability, cardiac defects, and growth retardation in the baby. Females with PKU are therefore

Box 36.3 Some well-described mitochondrial disease syndromes

Syndrome	Inheritance	Key feature	Additional features
Spastic paraplegia type 7 (SPG7) (6 in 100 000)	AR	Spastic paraparesis	Dysarthria, dysphagia, nystagmus
Progressive external ophthalmoplegia	AD or AR Mitochondrial Sporadic	Ophthalmoplegia, ptosis	Dysphagia, myopathy, exercise intolerance
Optic atrophy type 1	AD	Optic atrophy, ophthalmoplegia	Sensory neural hearing loss, ataxia, neuropathy
Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes	Mitochondrial	Diabetes, sensory neural hearing impairment, lactic acidosis, encephalopathy	
Leber's hereditary optic neuropathy	Mitochondrial	Optic atrophy in early adulthood	Movement disorders, tremors, cardiac conduction defects

AD, Autosomal dominant; *AR*, autosomal recessive.

advised against unplanned pregnancies and require close monitoring by specialist centres because target phenylalanine levels during pregnancy are much lower than baseline adult targets. Unplanned pregnancy in a female with PKU is a medical emergency and should be referred to a metabolic centre to enable treatment to be started or options discussed within 24 hours. Pregnancy-related hyperemesis in females with PKU needs aggressive and prompt management because if it is left untreated, it can lead to a rise in phenylalanine levels because of reduced calorie intake.

Some other common protein metabolism IMDs are listed in **Box E36.1**. They all have autosomal recessive inheritance, except for ornithine transcarbamylase deficiency, which is X-linked. All the conditions other listed in **Box E36.1** other than alkaptonuria can present acutely.

Lysosomal storage disorders

Lysosomes play an important role in cell turnover. Their main functions are to break down complex macromolecules to simple monomers and to transport these monomers out of the lysosome into the cytosol for recycling. Any disruption to this process results in lysosomal storage disease (LSD). Genetically inherited LSDs are some of the commonest IMDs encountered in metabolic centres treating adult patients, with Gaucher's and Fabry's disease being the most common among these. A number of these conditions can present for the first time in adulthood. The prognosis is variable, depending on residual enzyme activity. Specific therapies are now available for a number of LSDs, and hence it is important that clinicians consider LSDs in patients presenting with suggestive symptoms. A few common LSDs with specific therapies are listed in **Box E36.2**. All LSDs listed in the table have an autosomal recessive inheritance except for Fabry's disease, which has an X-linked inheritance.

Disorders of carbohydrate metabolism

Glycogen storage disorders

GSDs are a group of IMDs in which either glucose utilization (glycolysis) or glycogen mobilization (glycogenolysis or glycogen transport) is impaired. Glycogen is a glucose polymer stored most abundantly in the muscle and liver. Patients present with symptoms related to decreased availability of glucose for ATP generation (e.g., resulting in hypoglycaemia), abnormal glycogen accumulation (causing hepatosplenomegaly), and impairment in other linked metabolic pathways. Effective treatments for a number of GSDs exist, and early treatment significantly improves the prognosis. GSDs can be classified broadly based on the most affected organs. Some of the principal GSDs are listed in **Box E36.3**. A few other treatable IMDs of carbohydrate metabolism are listed in **Box E36.4**.

Disorders of fatty acid oxidation defects

The fatty acid oxidation pathway provides an important alternative fuel source by using fats in situations such as fasting, exercise, or illness in which the glucose supply may be inadequate. Briefly, it involves the following:

- Conversion of fatty acids to fatty acyl CoA on entry through the plasma membrane
- Entry of fatty acyl CoAs into the mitochondria via the carnitine shuttle
- Beta-oxidation of fatty acyl CoAs to acetyl-CoA by dehydrogenases in the mitochondria
- Transfer of electrons by dehydrogenases to the respiratory chain via electron carriers. Acetyl CoA is used either to generate ketone bodies (an alternate fuel for the brain) or for direct ATP production via Krebs cycle (e.g., in skeletal muscle).

Defects in any step in the pathway result in a FAOD. Characteristic features of FAODs include hypoketotic hypoglycaemia, cardiomyopathy, and myopathy with or without rhabdomyolysis. Although most present in childhood, some FAODs can present for the first time in adulthood (**Box E36.5**) with myopathy or rhabdomyolysis. Unlike in GSD 5 (McArdle's disease), symptoms usually occur after prolonged exercise, during a prolonged fast, or during an intercurrent illness that results in a catabolic state after glycogen reserves are depleted. When the diagnosis is known, management to avoid crisis is relatively simple (see **Box E36.5**). As with all other IMDs, symptoms may be unmasked (with catastrophic consequences) by a recent change in diet (e.g., a ketogenic diet) in addition to all the other metabolic triggers already described.

Porphyrias

Porphyrias are a group of disorders caused by defects in the haem synthesis pathway, and symptoms occur because of an accumulation of toxic metabolites. Whereas a block in the early stages of synthesis leads to accumulation of porphyrin precursors, including porphobilinogen (PBG) and α-aminolaevulinic acid (ALA), a block in the late stages results mainly in accumulation of porphyrins (**Fig. 36.3**). Porphyrin precursors are neurotoxic, but porphyrins themselves induce a photosensitive blistering rash. Thus, presentations may include acute neurovisceral crisis (in conditions such as acute intermittent porphyria in which there is a block in the early stages of haem synthesis) or non-acute cutaneous disease (in conditions such as porphyria cutanea tarda in which there is block in the late stages of haem synthesis). A block in the intermediate stages cause cutaneous and neurovisceral symptoms (e.g., in variegate porphyria and hereditary coproporphyria).

Acute porphyrias have an autosomal dominant inheritance; however, penetrance is incomplete. They almost always present in late childhood or adulthood. The prevalence is 5 per 1 000 000 in Europe, but it is much higher prevalence in South Africa (3 in 1000). Clinical features include abdominal pain, vomiting, neuropsychiatric symptoms, hypertension, seizures, hyponatraemia, and fever. In addition to the usual triggers for metabolic decompensation in IMDs, anaesthesia and drugs (including cytochrome P450 enzyme inducers) can precipitate an acute attack. Porphyria occurs more often in females, particularly in the luteal phase of the menstrual cycle and pregnancy. Symptoms may mimic an acute abdomen, and anaesthesia during an acute attack can be catastrophic. It is treatable, so a diagnosis of porphyria should be considered and sought early in the emergency department if symptoms are suggestive. The diagnosis is made by measuring ALA and PBG in a fresh urine sample (in a plain bottle with no preservatives and always protected from light). Normal levels exclude acute porphyria, and an alternative diagnosis for symptoms should be sought.

If porphyria is confirmed or likely, management should be initiated immediately.

- Remove all precipitating causes, including any triggering drugs (www.drugs-porphyria.org).
- Give supportive therapy for symptoms and an i.v. infusion for hydration and correction of electrolyte imbalance.
- Ensure a high carbohydrate intake of at least 600 g/day.
- Administer heme arginate (i.v.).
- Contact a porphyria reference centre for further advice. Published emergency management guidelines are available on the BIMDG's website. Recurrent severe attacks may merit consideration for liver transplantation.

Box E36.1 Common inherited metabolic diseases of protein metabolism

Urea cycle defects (A)[a]	Mutations in one of six urea cycle enzymes or two transporters (CPS1, OTC,[a] ASS1, ASL, ARG1, NAGS, SLC25A15, SLC25A13; most common, OTC deficiency) Incidence: 1 in 8000–45 000 Presentation in adulthood may be triggered by a change in diet (e.g., ketogenic diet, intercurrent illness, extreme metabolic stress). Progressive encephalopathy, cyclical vomiting, non-specific neuropsychiatric symptoms Diagnosis and biochemistry: characteristic abnormalities in AA or OA; when unwell: hyperammonaemia, genetics Management: as for hyperammonaemia in acute setting, lifelong protein restriction +/– ammonia scavengers or arginine, citrulline; liver transplant; gene therapy clinical trials ongoing Prognosis: good if treated promptly, fatal or catastrophic sequelae if diagnosis and treatment are delayed
Tyrosinaemia type 1A[a]	Fumaryl-acetoacetate hydroxylase deficiency Incidence: 1 in 100 000 More common in Quebec, Canada, because of founder mutation Presentation: liver failure, Fanconi's syndrome, tubulopathy, renal rickets, acute porphyria, gastrointestinal bleeding Guillain-Barré syndrome–like acute neurogenic crisis Hepatocellular carcinoma Diagnosis and biochemistry: raised tyrosine in serum AA and raised succinylacetone in urine OA, genetics Management: nitisinone (NTBC), tyrosine restriction, tyrosine-free amino acid supplementation Liver transplantation: less needed now because of success with nitosinone Prognosis: good if treated early If the patient is not compliant with medication or untreated, can present in adulthood with any of clinical features described
Alkaptonuria (A)	Homogentisate 1,2-dioxygenase deficiency Incidence: 1 in 250 000 Presentation: more often in adulthood (third to fifth decades of life); large joint arthritis, ochronotic pigmentation (sclera, ears), valvular heart disease Urine turns black on standing, black nappies in children Diagnosis and biochemistry: raised homogentisic acid on OA, genetics Management: nitisinone (NTBC) improves biochemical profile Prognosis: chronic progressive disease with variable prognosis
Classical homocystinuria (A)	Classical homocystinuria Cystathionine β synthase deficiency Incidence: 1 in 40 000–250 000; Qatar: 1 in 1800 Presentation: thromboembolic events (stroke or arterial or venous occlusive disease) Acute lens dislocation, visual loss, neuropsychiatric symptoms Developmental delay, seizures; acute, subacute, or chronic neurological deterioration; marfanoid habitus; osteoporosis Diagnosis and biochemistry: raised plasma homocysteine, (particularly if >50 μmol/L); raised plasma methionine; reduced plasma cysteine Management: pyridoxine, betaine, vitamin B_{12}, folic acid Methionine-restricted diet in pyridoxine-non-responsive homocystinuria with added vitamin supplements Genetic analysis may be useful in predicting response to pyridoxine in addition to confirming diagnosis Prognosis: variable depending on severity; early treatment (in neonatal period or early childhood) results in normal IQ and decreased risk of long-term morbidity Note: Folate or vitamin B_{12} deficiencies or other inherited metabolism defects in the folate–vitamin B_{12} pathway can also cause a rise in homocysteine levels; these must be excluded
Defects in metabolism of branched-chain amino acids Maple syrup urine disease (MSUD) Propionic aciduria (PA) Methylmalonic aciduria (MMA) (A)	MSUD: branched-chain α-ketoacid dehydrogenase deficiency PA: propionyl CoA carboxylase deficiency MMA: genetically heterogenous disorder Incidence: MSUD, 1 in 185 000; 1 in 200 in Old Order Mennonite population; PA, 1 in 100 000; more common in Saudi Arabians; MMA, 1 in 100 000 Presentation: first presentation in adults very unusual, although there have been a few reported cases in the literature Acute decompensation: encephalopathy, acidosis, hyperammonaemia, developmental delay, abnormal neurology, cardiomyopathy (PA > MMA), pancreatitis (MMA, PA), renal failure (more often in MMA; occasionally, adults with milder forms of MMA may present with just renal impairment) Diagnosis and biochemistry: metabolic acidosis with high anion gap; hyperammonaemia during acute decompensation Characteristic abnormalities on AA or OA and AC profiles Management: natural protein restriction, avoid catabolism liver transplantation (MSUD, PA), renal or combined liver and renal transplantation (MMA), carnitine supplementation (PA, MMA) BCAA-free supplements (MSUD) Prognosis: variable depending on severity; acute decompensations can be fatal

[a]Acute presentation.

A, Adult presentation reported (including first presentation in adulthood); *AA*, amino acid; *AC*, acylcarnitine profile; *BCAA*, branched-chain amino acids; *OA*, organic acid; *OTC*, ornithine transcarbamylase.

Box E36.2 Lysosomal storage disorders

Gaucher (A)	Beta-glucocerebrosidase (GBA) deficiency Incidence: panethnic, 1 in 75 000; AJ population, 1 in 850 Presentation: 94% of patients have non-neuronal disease (type 1) characterized by hepatosplenomegaly, bone marrow involvement, cytopaenia, and skeletal symptoms such as severe bone pain and avascular necrosis. Presentation can occur in adulthood, frequently with asymptomatic splenomegaly. The neuronopathic form is much rarer (6% of patients). Acute (1%) (type 2) presentation almost always at younger than 1 year of age and includes severe progressive neurological deficit leading to early death. Chronic (5%) (type 3) presentation includes mild to severe neurological and skeletal symptoms and organomegaly. Intermediate forms occur, as can late neurological presentations in adulthood with neurological symptoms including a supranuclear horizontal gaze palsy Acute complications: avascular necrosis of bone and splenic infarcts Heterozygous mutations may increase risk of Parkinson's syndrome Diagnosis and biochemistry: deficient GBA activity in leukocytes or fibroblasts, 'Gaucher cells' on biopsy; genetic conformation Management: supportive, enzyme replacement therapy (ERT) using recombinant GBA
Fabry (A, X)	Alpha-galactosidase A (α-GLA) deficiency Incidence: 1 in 40 000 Presentation: late onset of milder forms is much more common; acroparesthaesia (burning or numbness in the hands and feet), cornea verticillate, angiokeratomas, gastrointestinal symptoms (classical phenotype, most common presenting symptoms in paediatric population); adults more often present with end-organ disease; arrhythmia, cardiac fibrosis, hypertrophic cardiomyopathy; proteinuria, renal impairment; stroke; decreased exercise tolerance, fatigue, depression, and acroparesthesia worsened by stress, heat, or exercise Females can also be symptomatic because of lyonization of the X chromosome but often experience end-organ symptoms usually a decade later than males Wide phenotypic spectrum in both males and females based on residual enzyme activity levels Diagnosis and biochemistry: deficient (α-GLA) activity in white blood cells; activity can be normal in 60% of affected females; genetic confirmation is therefore needed Management: supportive, ERT
Niemann-Pick disease (A)	Acid sphingomyelinase deficiency Incidence: 1 in 250 000; 1 in 40 000 in AJ Presentation: age of presentation and severity are variable; can present for the first time in adulthood; splenomegaly, hypersplenism; hepatomegaly, hepatic fibrosis, cirrhosis; dyslipidaemia (high low-density lipoprotein cholesterol and triglycerides); osteoporosis; storage facies; cherry-red macular spot (25%); lung fibrosis causing restrictive lung disease Niemann-Pick A: severe neurodegenerative form; usually fatal in early childhood Diagnosis and biochemistry: deficient enzyme activity in leukocytes, genetic confirmation Management: supportive, ERT
Tay–Sachs disease (A)	Beta-hexosaminidase (isoform A) deficiency Incidence:1 in 250 000; 1 in 25 (vs 1 in 250 in the general population) carrier frequency in AJ; actual incidence in Jewish populations has now significantly decreased in many countries because of effective counselling Presentation: childhood disease is fatal with rapidly progressive neurology, visceromegaly, dysmorphia, and increased startle response Late-onset adult disease: age of onset and severity vary; cerebellar and motor neurone dysfunction causing tremor, dysarthria, chorea, and dystonia Diagnosis and biochemistry: deficient enzyme activity in leukocytes, genetic confirmation Management: supportive
Pompe's disease (GSD type 2) (A)	Acid alpha-glucosidase (acid maltase) deficiency Incidence: 1 in 40 000 Presentation: adult with Pompe's disease are usually symptomatic in the third to fourth decades of life with limb girdle muscle weakness and respiratory insufficiency secondary to diaphragm weakness, which is often major cause of death acute decompensation related to respiratory failure Classical infantile form: more severe presentation in the first few months of life Diagnosis and biochemistry: deficient enzyme activity in leukocytes; vacuolated lymphocytes; vacuolar myopathy on muscle biopsy; pulmonary function test (>20% change in vital capacity between sitting and supine position) Management: supportive, ERT

A, Adult presentations reported; *AJ,* Ashkenazi Jewish population; *X,* X-linked inheritance.

i Box E36.3 Common glycogen storage disorders

GSDs affecting mainly muscle GSD 2 (Pompe's disease) (A) GSD 5 (McArdle's disease) (A)[a]	See **Box E36.2** Myophosphorylase deficiency Incidence: 1 in 100 000 Presentation: first presentation in adults not unusual; exercise intolerance; pain within 5–10 min of starting exercise ('second wind' phenomenon, i.e., symptoms improve within a few minutes if able to continue with exercise); rhabdomyolysis Diagnosis and biochemistry: raised CK, flat lactate with an exaggerated rise in ammonia on non-ischaemic exercise test, genetic testing, PAS staining vacuolar myopathy (although muscle biopsy should not normally be needed for diagnosis) Management: supportive with aerobic conditioning exercise programmes and dietary advice to improve exercise tolerance and avoidance of unaccustomed strenuous exercise; oral glucose (for e.g., glucose polymer drink with 25% glucose) 5 min before exercise
1a (glucose-6-phosphatase deficiency) and 1b (glucose-6-phosphatase translocase deficiency)[a] GSD IIIA[a]	Incidence: 1 in 100 000 Presentation: hypoglycaemia, ketosis, and lactic acidosis in infancy; growth retardation massive hepatomegaly; renal impairment; hepatic adenomas; and hepatocellular carcinoma (GSD 1b can present with neutropenia and features similar to inflammatory bowel disease); no cognitive impairment if hypoglycaemia is avoided; with improved treatment, most transition into adulthood; unlikely to present for the first time in adulthood; isolated case reports of first presentation in adults; adults are much more likely to present with complications related to cardiac or liver involvement rather than hypoglycaemia Diagnosis and biochemistry: enzymology and genetic testing for diagnosis; secondary abnormalities include hyperuricemia, ketosis, lactic acidosis, and hypertriglyceridaemia Management: dietary therapy with regular doses of slow-release cornstarch to maintain normoglycaemia, ER; most severe cases may need continuous feed through gastrostomy; patients with GSD 1b need management of neutropenia and inflammatory disease; SGLT2 inhibitors decrease the incidence and severity of neutropenia in patients with GSD 1b Debrancher enzyme deficiency Incidence: 1 in 100 000; 1 in 5400 in North African Jewish ancestry Presentation: less severe than GSD 1; fasting hypoglycaemia less severe than GSD 1; ketosis but no lactic acidosis; mild hyperlipidaemia; childhood presentation with hypoglycaemia and hepatomegaly; kidneys not involved; hepatic adenomas less common; muscle weakness with raised CK may occur; cardiac complications, including ventricular hypertrophy Diagnosis and biochemistry: enzymology and genetic testing for diagnosis; may have raised CK Management: dietary therapy with regular doses of slow-release cornstarch to maintain normoglycaemia; ER

[a]Emergency presentations reported.

A, Adult presentations reported; *AR,* autosomal recessive; *CK,* creatine kinase; *ER,* emergency regimen; *PAS,* periodic acid-Schiff; *SGLT2,* sodium–glucose transporter 2.

i Box E36.4 Other inherited metabolic diseases affecting carbohydrate metabolism

Galactosaemia	Most commonly galactose-1-phophate uridyltransferase deficiency Incidence: 1 in 40 000 Presentation: neonatal presentation on ingestion of galactose (milk or formula) with failure to thrive, liver disease, cataract, and renal tubular dysfunction; treated adults can have developmental delay, neurological deficits, or premature ovarian failure Adult presentation rare; however, exclude the diagnosis in patients with premature ovarian failure ± cataracts ± neurological disease Diagnosis and biochemistry: elevated levels of galactose-1-phosphate in RBCs Management: immediate removal of galactose from the diet as soon as suspected without awaiting diagnostic confirmation; galactose restriction for life; supportive therapy, including options to freeze eggs before onset of premature ovarian failure
Glucose transporter 1 (GLUT-1) deficiency (AD)	GLUT-1 deficiency Incidence: 1 in 90 000 Presentation: symptoms secondary to decreased facilitated glucose transport into brain via GLUT-1; symptoms include seizures, developmental delay, and complex movement disorder; symptoms worse a few hours postprandial Diagnostic and biochemistry: lumbar puncture after a 4- to 6-hour fast; paired CSF-to-blood glucose ratio <0.45 suggestive; confirmation with genetics and RBC glucose uptake studies Management: ketogenic diet imitates metabolic state of fasting so brain uses ketones as alternative fuel; ketogenic diet for life; antiepileptic medication
Hereditary fructose intolerance	Aldolase B deficiency Incidence:1 in 20 000 Presentation: ingestion of fructose, sucrose, or sorbitol causes acute illness (within minutes) of abdominal pain, vomiting, and diarrhoea More severe symptoms, including hypoglycaemia, seizures, and coma, can occur Persistent exposure leads to liver steatosis, fibrosis, or failure and renal tubular disease or Fanconi's syndrome; patients may go undiagnosed or have the diagnosis delayed until adulthood because of self-restricted fructose intake and thus symptom prevention Diagnostic and biochemistry: enzymology now replaced by genetic testing Management: withdrawal of all enteral and parenteral sources of fructose medications, infusions, and supplements should be checked for fructose; supplementation with vitamin C and other vitamins Prognosis good if all fructose is avoided

AD, Autosomal dominant inheritance; *CSF,* cerebrospinal fluid; *RBC,* red blood cell.

Box E36.5 Fatty acid oxidation disorders

Medium-chain acyl-CoA dehydrogenase deficiency (MCADD)	Incidence: 1 in 17 000; more common in people of north European descent Diagnosis and biochemistry: characteristic profile on AC or OA, genetics; newborn screening in the UK and a number of countries Presentation: in adults, first presentation with rhabdomyolysis, most often triggered by excess alcohol intake; paediatric presentation: hypoketotic hypoglycaemia, encephalopathy, liver dysfunction, cot death Management: avoid fasting, regular meals No specific dietary modifications needed other than avoiding foods that have very high medium-chain fat content; ER
Carnitine palmitoyltransferase 2 (CPT2) deficiency	Incidence: exact frequency not known (>300 cases reported in the literature) Presentation: as above + myopathy in paediatric presentation Diagnosis and biochemistry: characteristic profile on AC and OA, genetics Management: avoid fasting, regular meals No specific dietary modifications needed in milder adult presentation; more severe paediatric presentations may require restriction of long-chain fats in the diet; medium-chain fat supplements may be used to supplement calories; ER
VLCADD: very long-chain acyl-CoA dehydrogenase deficiency	Incidence: 1 in 40 000 Presentation: as in CPT2 + neuromuscular weakness, cardiomyopathy in paediatric presentation Diagnosis and biochemistry: characteristic profile on AC/OA, genetics Management: as for CPT2 deficiency, need cardiac surveillance and restriction of long-chain fatty acids depending on severity both in adult and paediatric presentations; medium-chain fat supplements may be used to supplement calories; ER

AC, Acylcarnitine profile; *ER*, emergency regimen; *OA*, organic acid profile.

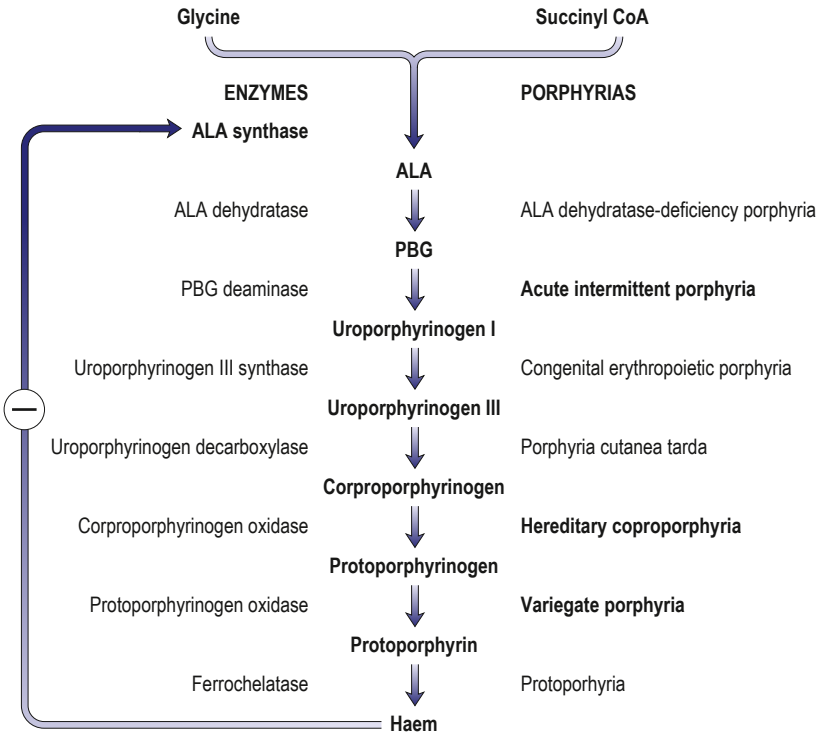

Fig. 36.3 Haem synthesis involves eight enzymes and occurs mainly in the bone marrow and liver. Inherited deficiencies of each of the enzymes result in distinct disease phenotypes collectively known as the porphyrias. Acute porphyrias include acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, and delta-aminolevulinic acid (ALA) dehydratase deficiency porphyria. *PBG,* Porphobilinogen.

Peroxisomal diseases

Peroxisomes have a role in lipid metabolism, processing reactive oxygen species, and oxidation of specific biomolecules.

X-Adrenoleukodystrophy

Being X-linked, presentation is more severe in males, who present with the cerebral form. Symptoms usually begin between 4 and 10 years of age with behavioural and neuropsychiatric problems; cognitive decline; and variable progressive neurological decline, which is fatal. The presentation may be delayed into adulthood and even into the third or fourth decade of life. Patients also often develop adrenal insufficiency, which may precede development neurological symptoms. Although no treatment exists for symptomatic patients, presymptomatic patients may be amenable to treatment with bone marrow transplant or a clinical trial of gene therapy. Therefore, X-adrenoleukodystrophy (ALD) should be excluded in all patients with adrenal insufficiency in whom no other cause is found. Female carriers and adult males may also present with adrenomyeloneuropathy, resulting in spastic paraparesis of the lower limbs and bladder disturbances. Cerebral ALD and adrenal insufficiency almost never occur in female carriers. Adult physicians should exclude ALD in patients with suggestive symptoms because a positive diagnosis will initiate cascade testing to find any presymptomatic relatives.

Adult Refsum's disease

Adult Refsum's disease is a recessive disease that results in phytanic acid accumulation in tissues and plasma secondary to mutations in the *PHYH* or *PEX7* gene. The diagnosis should be excluded in patients presenting with retinitis pigmentosa, which (along with anosmia) is present in almost all patients with adult Refsum's disease. These two features often precede development of other features such as ataxia, peripheral neuropathy, and cataract by several years. One-third of patients may have bony abnormalities such as shortened fourth metatarsals. Cardiac arrhythmias may occur, particularly when phytanic acid levels are high. Treatment includes a phytanic acid–restricted diet and avoidance of fasting or rapid weight loss. Plasmapheresis may be needed at times of acute decompensation. Without treatment, there is gradual progressive deterioration. Elevated plasma phytanic acid levels with low pristanic acid levels are diagnostic.

CORE SKILLS AND KNOWLEDGE

Obesity is a complex, chronic disease that adversely impacts the patient's quality of life and life expectancy. Significant contributors to death and disability in people living with obesity include cardiovascular disease, cancer, chronic kidney disease, diabetes mellitus, and musculoskeletal disorders.

Global obesity rates are rising sharply. There are many biopsychosocial drivers, including increased intake of energy-dense foods and sedentary time, in modern societies. Addressing these challenges requires highly skilled, empathic clinicians working in partnership with people living with obesity. On a broader societal level, effective policies across sectors such as urban planning, food marketing, education, and others are vital.

A substantial body of evidence demonstrates that effective obesity care can make a difference. Across a population, it has the potential to reduce the burden of diabetes, hypertension, cardiovascular disease, liver disease, and obstructive sleep apnoea (OSA). A variety of lifestyle, pharmacological, and surgical interventions have been shown to be effective in reducing weight. For individuals, communities, and the local health economy, the effects of good obesity care are transformative.

Key skills within obesity include:

- Developing a compassionate, non-judgemental consulting style; negotiating with patients about the best interventions; and using motivational interviewing techniques
- Understanding the physiology of weight gain and its effects on multiple body systems
- Working with multidisciplinary teams to address all aspects of obesity care
- Understanding the social determinants of health and developing leadership skills to advocate for appropriate public health measures and effective obesity services.

BACKGROUND

Prevalence

Obesity is a complex, chronic disease with multisystem impact. It is defined by the World Health Organization (WHO) as abnormal, excessive fat accumulation that presents a risk to health. Worldwide obesity rates have nearly tripled since 1975 and continue to rise. Currently, 2 billion adults are living with overweight, and of them, 650 million are living with obesity (body mass index [BMI] ≥30 kg/m^2).

Obesity does not affect a population equally. For example, adults in the most deprived regions have almost double the prevalence of obesity than those living in more affluent regions, a trend that begins in childhood in poorer populations. There are also sex disparities: females are twice more likely to gain weight and develop obesity-associated complications.

Obesity is responsible for 4.7 million premature deaths each year, and life expectancy decreases as BMI increases. Definitive and coordinated action is needed to address the obesity epidemic. A key step is to recognize obesity as a disease and work to challenge the stigma and bias experienced by patients.

Obesity was recognized as a disease as far back as 1948 in the WHO's International Classification of Disease, although this has not been consistently visible in clinical practice. The concept of obesity as a disease is now endorsed by many global organizations, supporting delivery of effective, responsive care for people living with obesity and working to reduce bias.

Aetiology

The aetiology of obesity is complex, and previous assertions including 'eat less, move more' have failed to address globally rising obesity rates. This simple narrative fails to explain why people respond

differently to obesogenic environments and respond differently to different interventions for obesity.

Current thinking acknowledges the principle of energy balance but also presents evidence for multiple other factors that promote and sustain obesity.

The landmark Foresight report published by the UK government in 2007 combined expertise from across society to map the complex factors contributing to obesity. This report comments that 'causes of obesity are extremely complex encompassing biology and behaviour, but set within a cultural, environmental and social framework' (**Box 37.1**).

Obesogenic environment

The obesogenic environment has strong sociocultural, economic, and policy drivers. Food environment includes the immediate eating environment (distractions, atmosphere, time of day) as well as the food itself (presentation, portion size, serving style).

People make an estimated 200 food choices daily, including food type and quantity. A host of neurobiological processes plays a role in this decision-making, which extend beyond simple 'willpower'. Most choices are subconscious and strongly responsive to environmental influences.

Persuasive food marketing plays a key role in promoting highly processed foods, typically with high sugar, high fat, and low fibre content. These foods are usually affordable and highly palatable. Many people also eat from widely distributed and easily accessible food outlets where food has higher caloric value and fewer micronutrients. These outlets often open for extended hours and may offer a food delivery service. This is further compounded by increasing sedentary behaviour linked to limited green spaces; unsafe, polluted public areas; and increased opportunities for working from home.

Biology: genetics and obesity

There are marked variations in how individuals respond to the obesogenic environment described. It is widely accepted that genetics and related biological differences have a powerful influence, interacting with environmental factors to result in the obesity phenotype. Twin studies demonstrate that the heritability of body weight (the percentage attributed to genetics) is similar to that of height.

Initially, candidate genes were identified in mice displaying severe obesity and hyperphagia. Reverse genetic techniques uncovered that mutations in the *ob* or obese gene (encoding for adipocyte-produced hormone leptin) resulted in severe obesity. Leptin is a hormone that provides the sensation of satiety and regulates appetite. This seminal body of work has broadened thinking and enabled the biological basis of obesity to gain acceptance.

Further research identified the central role of leptin-related pathways in food intake, reward, and preference. In addition to congenital leptin deficiency, mutations were also uncovered in genes encoding the leptin receptor (LEPR) and other components of the melanocortin pathway (**Fig. 37.1**). Genome-wide association studies have now highlighted more than 1000 other genes and hundreds of single nucleotide polymorphisms that affect feeding behaviour and contribute to obesity.

Epigenetics in obesity

Although crucial in our understanding of obesity, genetics does not fully explain the variance observed in the population. A solely genetic explanation also does not account for rising obesity rates over the timespan observed. Here, 'epigenetic modifications' have emerged as an important phenomenon. This refers to changes in gene expression mediated by mechanisms such as DNA methylation, histone modification, and non-coding RNA-associated gene silencing. Epigenetic modifications change how DNA is transcribed without altering the actual DNA sequence. These changes may be physiological but also arise in response to environmental stimuli.

An example of epigenetic change resulting in obesity is the hypomethylation of the agouti viable yellow *(Avy)* gene in mice. As a result, there are reduced methylation and aberrant expression of a protein binding to the melanocortin-4 receptor (MC4R) in the hypothalamus, a critical regulator of energy homeostasis and appetite. This results in hyperphagia (insatiable appetite). Feeding affected mice (*Avy* gene mutation) with food rich in folate and methionine (both acting as methyl donors for DNA) improved their body weight and insulin resistance.

Box 37.1 Summary of aetiological factors in obesity

Category	Aetiological factor (examples)
Biology	• Genetic predisposition • Level of satiety • Low resting metabolic rate • Ethnicity • Parental obesity
Early life	• Intrauterine environment (diet, weight, glucose tolerance) • Breast-feeding (reduces childhood obesity)
Individual activity	• Sedentary behaviour (e.g., television viewing) • Reduced outdoor activity in childhood • Sedentary occupation • Reductions in walking and cycling • Reduced fitness impairing ability to engage in exercise
Environmental factors	• Financial costs of physical exercise (e.g., gym membership fees) • Perceived danger in the environment • Walkability of the living environment • Cultural values associated with activity patterns • Lack of outdoor activities (reduced green spaces, parks, and playgrounds) • Endocrine disrupting chemicals: molecules present in food and cosmetics (e.g., bisphenol A and phyto-oestrogens) that interfere with the endogenous hormonal milieu and affect weight • Reduced diversity in the gut microbiome
Individual psychology	• Mixed feelings and beliefs about health lifestyle choices • Self-esteem • Stress, distractions • Level of food literacy • Level of parental control and family dynamics • Difficulty translating intention into action
Food consumption	• Increased variety and low cost of food • Surplus of energy-dense food • Larger portion sizes • Easy availability of low-cost ultra-processed foods
Food production	• Pressure for increased palatability of food • Low market prices of ultra-processed foods • Higher cost of ingredients for fresh cooking
Societal influences	• Social acceptability of weight • Importance of ideal body size image • Food education • Food advertising

Adapted from Tackling obesities: Future choices report.

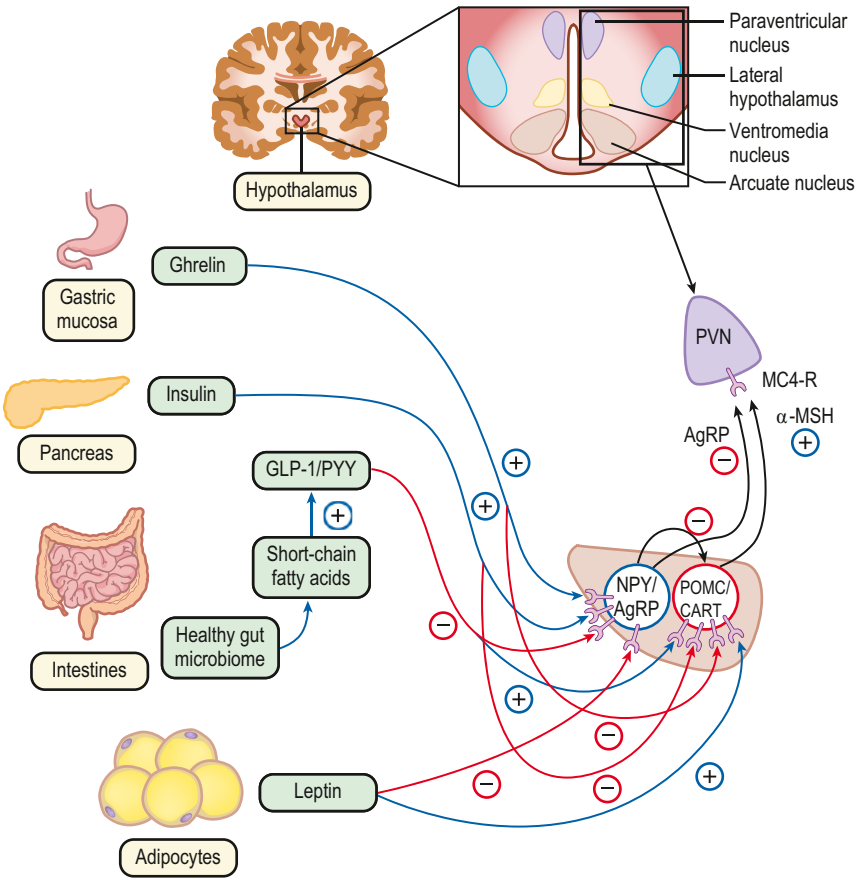

Fig. 37.1 Appetite is regulated by various peripheral peptides which act on nuclei in the hypothalamus. The main peripheral peptides which act on these neurons [neuropeptide Y (NPY)/agouti-related protein (AgRP)] and [pro-opiomelanocortin (POMC)/CART (cocaine and amphetamine regulated transcript)] to regulate appetite include: (a) ghrelin: secreted by the stomach, acts on GHS-R1a receptors on NPY/AgRP to stimulate appetite and inhibit POMC/CART neurons; (b) insulin: secreted by endocrine pancreas, acts on insulin receptors on NPY/AgRP and POMC/CART to inhibit appetite; (c) GLP-1 (glucagon like peptide 1): secreted by the distal ileum and colon, acts on GLP-1 receptors; delay gastric emptying, stimulate insulin and somatostatin secretion and inhibition glucagon secretion. They inhibit NPY/AgRP neurons and stimulate POMC/CART neurons to suppress appetite. A healthy gut microbiome produces more short chain fatty acids which increase secretion of GLP-1 and PYY. (d) PYY (peptide YY): secreted by the ileum, colon, and rectum, acts on Y2 receptors on NPY neurons to inhibit them and Y2 receptors on POMC/CART neurons to stimulate them and suppress appetite; (e) leptin: secreted by adipocytes, acts on leptin receptor (LEPR) on NPY/AgRP to inhibit them and on POMC/CART neurons to stimulate them thereby suppressing appetite. Disorders with leptin deficiency and leptin resistance leads to hyperphagia (insatiable appetite) and obesity. The hypothalamic nuclei involved in appetite regulation include the paraventricular, ventromedial, and arcuate nuclei. The arcuate nucleus consists of two main types of neurons mentioned above regulating food intake and energy expenditure. These include: (1) NPY/AgRP neurons which **increase appetite** (orexigenic) via agouti-related protein (AgRP). (2) POMC/CART neurons which **reduce appetite** (anorexigenic) via α-melanocyte stimulating hormone (α-MSH) and increase energy expenditure. Upon activation, NPY/AgRP neurons secrete AgRP which inhibit MC4-R receptors on the paraventricular nucleus (PVN) and increase appetite. In contrast, activated POMC/CART neurons produce α-MSH which stimulate MC4-R receptors on the PVN and reduces appetite. MC4-R mutations also lead to hyperphagia and obesity as with leptin deficiency and resistance. These pathways are actively regulated via conscious and subconscious signals from the brain as food intake results in activation of reward pathways in the brain. *(Diagram by Beenish Masood.)*

Epigenetic modifications are part of 'developmental programming' that occur *in utero* or during early life in response to an adverse environment (e.g., starvation or food scarcity). These adaptations prepare the fetus or child to survive in the presence of food scarcity later in life. If, however, these individuals grow up in a food-replete environment, these epigenetic modifications function as a catalyst for weight gain and promote obesity. Most epigenetic markers are erased during early development, although some of these markers persist and are passed on to offspring.

Physiological mediators of obesity

Energy balance is a key principle. There are two interrelated yet distinct mechanisms:

- *Continuous positive energy balance* in which energy intake exceeds energy expenditure
- *Reset of the body weight* to a higher setpoint so that a higher body weight is actively defended by the body itself through a variety of mechanisms

In humans, energy intake is from food and drink ingested. Energy expenditure is the sum of the energy expended for:

1. **Basal metabolic rate:** This is the energy required for sustaining basic functions of life at rest, which is determined by body size and lean body weight. This accounts for 50% to 70% of total energy expenditure and varies significantly between individuals with obesity despite similar weight. People with lower metabolic rates struggle to lose weight.

2. **Physical activity and digestion:** This is the most variable component of the daily expenditure, depending on patterns of behaviour.
3. **Nutrient absorption (diet-induced thermogenesis):** This is the amount of energy required to digest, absorb, and store ingested nutrients and is much higher for certain food constituents (e.g., proteins) than for others (e.g., dietary fats and carbohydrates). It accounts for 10% of total daily energy expenditure.

Fig. 37.1 presents a model of energy flow within the human body. The brain is the primary organ regulating our weight. It integrates external and internal signals to influence food intake and energy balance (subconsciously). The initial stimulatory input *(green arrow)* is from the environment and food intake. From there, hormones (including insulin) relay signals that have an impact on food intake. Weight gain causes ectopic lipid distribution within organs.

Control of appetite

The control of appetite is complex but elegantly orchestrated. Feeding behaviour and energy intake are driven by the metabolic need to eat to alleviate discomfort (drive reduction) or by food reward (fulfilment by eating).

Certain hypothalamic neurons are crucial in controlling feeding behaviour (Fig. 37.1). After a meal, gastric and duodenal distension and the release of many substances (peripherally and centrally) cause satiety and signal to stop eating.

These substances include cholecystokinin, bombesin, glucagon-like peptide 1 (GLP-1), enterostatin and somatostatin (released from the small intestine), and glucagon and insulin (from the pancreas). The lateral hypothalamic area, and the paraventricular and arcuate nuclei play a key role in integrating signals involved in appetite and body weight regulation. The control of appetite is illustrated in Fig. 37.1, and key peripheral hormones are described below.

Peptide YY (PYY)* is a rapid and short-acting signal produced by the L cells of the large bowel and distal small bowel shortly after food intake. It is released in proportion to the energy ingested. PYY reduces appetite through inhibition of the appetite-stimulating pathway (NPY/AgRP-expressing neurones). There are numerous other peripheral appetite-suppressing signals, including GLP-1 and oxyntomodulin, which, like PYY, are produced by the gut in a nutrient-dependent manner.

Ghrelin* is a 28-amino-acetylated peptide produced by the oxyntic cells of the fundus of the stomach that activates the central appetite-stimulating pathway. Levels are high before a meal and reduce rapidly after ingestion of a meal or glucose (in contrast to PYY, which increases after a meal). It also acts as a long-term signal because its circulating concentration in weight-stable individuals is inversely related to BMI. Ghrelin is also increased in several situations in which there is a negative energy balance, such as long-term exercise, very-low-calorie diets, anorexia nervosa, and both cancer and cardiac cachexia. (An exception is vertical banded gastric bypass surgery, in which its concentration is low rather than high.) Obestatin is a peptide produced by the same gene that encodes ghrelin and counteracts the increase in food intake induced by ghrelin.

The endocannabinoid system is also involved in the control of food intake and energy balance. There are two receptors, endocannabinoid (CB1) in the brain and CB2 in the periphery. CB1 receptors are in the cerebral cortex, cerebellum, and hippocampus.

Tumor necrosis factor (TNF) and interleukin-2 are cytokines that are elevated in inflammatory and traumatic conditions and also suppress appetite; exact pathways are unclear. Appetite inhibitors include dopamine, serotonin, and γ-aminobutyric acid, and appetite stimulators include opioids.

The gut–brain axis

The gastrointestinal (GI) tract and the central nervous system communicate via immune, neural, and endocrine pathways. Relevant messengers include bacterial metabolites, gut hormones, and neuroactive substances.

The gut microbiome impacts nutrient metabolism and energy expenditure. Its role in obesity is via its effects on the permeability of the GI mucosa and fermentation and absorption of polysaccharides. Animal studies report that the gut microbiome in obesity is less diverse than in lean individuals and impacts appetite and energy consumption.

Hedonic hunger

This is a nonhomeostatic hunger caused by excess hedonic drive (to feel better) rather than caused by a true metabolic need (as in starvation). Thus, individuals eat without being hungry despite large fat reserves. Neuroimaging revealed that when fasting humans viewed pictures of high-calorie and low-calorie foods, the former increased neural activity in the orbitofrontal cortex, ventral striatum, amygdala, and anterior insula (i.e., brain reward areas). Hence, specific foods activate brain reward and determine food preference. Eating is stimulated by a metabolic need, hedonic hunger, or a combination of the two (Fig. 37.2).

CLINICAL APPROACH TO OBESITY

The clinical assessment of obesity should focus on establishing *why* a person has obesity and *how* it is affecting them and lay the foundations to consider the *best treatment plan*. Assessment should be done is a sensitive and non-judgemental way and undertaken when the individual is ready (Box 37.2).

The 'making every contact count' approached promoted in the UK encourages all clinicians to take opportunities presented in every clinical encounter to prompt patients towards positive health behaviours. There may be opportunities in an obesity clinic to suggest non–weight-related lifestyle measures (e.g., smoking cessation). Clinicians in other settings should look for opportunities to talk about weight reduction in people living with overweight or obesity in an appropriate way even if this is not the main focus of the clinical encounter.

Clinicians should be mindful that many people will have struggled with their weight for years and encountered stigma and bias both in society and within healthcare settings. It is not uncommon to hear that people have relayed negative messages to themselves internally. In this context, **language matters** and can have a significant impact on how an individual reacts to the discussion and

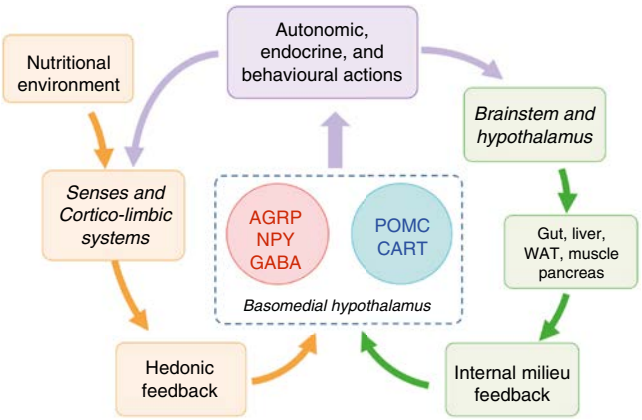

Fig. 37.2 Internal and external appetite regulation. Agouti-related protein (AgRP), neuropeptide Y (NPY), and gamma-aminobutyric acid (GABA) neurons (hunger neurons) integrate metabolic and hedonic signals and translate them, so a person feels hungry (similar to the accelerator of a car). Proopiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART) neurons control this hunger, like a brake pedal. *WAT,* White adipose tissue. (*From Blaming the brain for obesity: Integration of hedonic and homeostatic mechanisms*.)

Box 37.2 Principals of caring for patient with obesity

In caring for people living with obesity, it is critical to recognize:

- The person living with obesity is the expert in their condition and best understands personal barriers and potential solutions to treatment.
- Stigma impacts quality of life and reduces engagement.
- One of the most important roles of an obesity specialist is to create an empathic environment where a patient's story can be heard without judgement.
- A deeper understanding of an individual's obesity phenotype supports personalized care.
- Multidisciplinary working is key to effective care delivery.

advice provided. To build rapport and minimize stigma, it is especially important to use clear, person-first language and adopt a neutral, non-judgemental tone (**Box 37.3**).

Motivational interviewing

Motivational interviewing (MI) is a valuable tool to support empowerment and elicit an individual's intrinsic motivation and is a key approach developed to help encourage behaviour change and new habit forming. People often have a strong desire to change, but complex biopsychosocial factors can impair their progress. In this context, directive advice, 'education', and messages such as 'eat less and move more' are largely unhelpful.

MI uses a variety of evidence-based strategies to develop an empathic environment and encourage rapport between the patient and clinician. Within this space, individuals are guided to harness their own intrinsic motivation and drive change to support improvement. The ethos of MI or 'spirit' recognizes individual autonomy and expertise while emphasizing strengths rather than deficits. Advice is offered but not imposed. Clinical staff require initial training as well as ongoing coaching and supervision in the skills and strategies of MI to increase their competency in the method. The 'OARS' nemonic summarizes the principles and basic skills for MI (**Box 37.4**).

History

A comprehensive medical history for a person living with obesity is a key step. It enables a deeper understanding and supports the development of a personalized treatment strategy, aligning with personal goals. A comprehensive obesity-focused history is described in **Box 37.5**.

This may begin by trying to understand changes in a patient's weight throughout their life and in particular in relation to different life events and previous efforts to lose weight (**Fig. 37.3**). Medication may be a key driver of weight gain and may inhibit attempts to lose weight (**Box 37.6**).

Validated questionnaires may be used to complement the history. Examples include the Binge Eating Scale or the Food Frequency questionnaire for assessing eating habits, the generalized anxiety disorder screening (GAD-7) or patient health questionnaire-9 (PHQ-9) scores for assessing mood, and the Epworth and STOP-BANG scores for assessing sleep hygiene and risk of OSA, see Chapter 20 ('Obstructive sleep apnoea' section).

Examination

Physical examination of a person living with obesity has four main aims:

1. Identify obesity-related co-morbidities.
2. Consider the impact of obesity on existing co-morbidities.
3. Consider secondary causes of obesity.
4. Obesity phenotyping and profiling.

To do this effectively, it is important to ensure the dignity and comfort of the individual. There should be privacy and space and specialist settings equipped with appropriately sized chairs and weighing and monitoring equipment. For example, larger cuffs should be available to measure blood pressure (BP) because standard cuffs may overestimate the BP of a person with obesity. Key aspects of the physical examination in a patient with obesity are included in **Fig. 37.4**.

Anthropometric measurements

Waist-to-height ratio

Central fat distribution increases morbidity and mortality risk. Measuring waist-to-height ratio (**Fig. 37.5**) can identify individuals at greater risk.

Skinfold measurements

This is useful for individuals who may be housebound or unable to step onto scales. It is measured with callipers over the middle of the

Box 37.3 Examples of preferred language and language to avoid when consulting with people living with obesity

Seeking to be more…	Examples
Empathic	It sounds as though your weight is really hard to manage at the moment.
Empowering and inclusive	What changes do you believe are needed right now?
Respectful	I appreciate you being open to talk about this.
Trust building	I will have a conversation with the team and feed back to you.
Person centred	What thoughts have you had yourself about your eating?
Encouraging and positive	I can see the effort you are putting in; keep up the great work!
Clear	Yes, your weight has not come down yet.
Reassuring	It is not unusual for people not to lose weight immediately; it's hard work that your body is fighting.
Understanding	Now doesn't sound the best time to be concentrating on your weight.
Exploring	What makes you say, 'I feel like a failure'?
Environmentally aware	Make sure that your clinic and waiting room are appropriate for people who are of a larger size.
Collaborative	Let's talk together about the different options and then see what you think would suit you best.
Helpful and supportive	Offer specific help when appropriate, such as a referral, or a dedicated appointment to set goals and make plans.
Congruent words and behaviours	Looking at the person when welcoming or asking questions.
Culturally competent	Explore individuals' cultural, religious or faith, and spiritual beliefs.
Seeking to be less…	**Examples**
Stigmatizing	You're in denial.
Shaming or blaming	It's being so overweight that is causing you to have all these problems.
Authoritarian	You must not eat any of these foods.
Demanding	Before you come to see me, I want you to complete this food chart so I can check what's going wrong.
Disapproving	You aren't meant to eat that.
Discriminating	I don't think they'd get much from the exercise class.
Stereotyping	People from this background often prefer high-fat foods.
Assumptive	I think you just need to go for an operation; you won't cope with the other options.
Prejudging	No one in that family has ever taken much notice of their weight; they will be the same.
Judgemental	That's the wrong choice; it'll never work.
Threatening	If you don't lose weight, you will end up with your leg chopped off or just plain dead

Obesity UK. Summary of language matters guide.

Box 37.4 The OARS approach in motivational interviewing

O: open-ended questions	• How do you feel about your health right now? • How would you like things to be different?
A: affirmations	• You handled yourself really well in that situation. • I know how challenging this is, and you have made a lot of positive changes already.
R: reflections	• I see that you understand a lot about how weight is related to your health, and you really want to be in more control. • You're wondering if…
S: summarizing	• Here is what I've heard. Tell me if I've missed anything. • Let me see if I understand so far. I am wondering what you think your next step should be.

triceps muscle. Normal values are less than 20 mm in male adults and less than 30 mm in female adults.

Neck circumference

This is measured with a standard tape measure by starting at the Adam's apple and then bringing the tape around to the starting point (with care taken not to pull too tight) (Fig. 37.5). More than 43 cm in male adults and 41 cm in female adults indicates a high risk for sleep apnoea.

Bioelectrical impedance analysis

Some centres have access to bioelectrical impedance analysis technology, which can provide information about body composition (i.e., body fat mass, segmental body fat, visceral fat, muscle mass, total body water, basal metabolic rate, and metabolic age). These deeper insights into a body type can help guide conversations and management. Serial measurements are useful for motivation.

Body mass index and obesity diagnosis

BMI defines and classifies obesity severity (Box 37.7). It is calculated by dividing an adult's weight in kilograms by their height in metres squared. A lower cut-off is used for certain ethnicities to reflect higher visceral adiposity and increased cardiometabolic risk.

BMI has many advantages on the population level: it is inexpensive and simple to measure (without highly specialized equipment and training). However, at an individual level, it may not always provide an accurate picture or fully define risk. For example, because muscle is denser than fat, muscular individuals may be classified by BMI as 'obese'.

BMI also does not account for gender, age, or fat distribution and does not necessarily correlate with health risk. Certain individuals may be of an obese range BMI but considered 'metabolically healthy', but others may develop type 2 diabetes mellitus at a non-obese range of BMI. In case of the latter, a popular hypothesis is that everyone has a 'personal fat threshold' that determines their personal capacity to accumulate fat. After this threshold, they deposit visceral fat (e.g., liver, pancreas). This then triggers insulin resistance, type 2 diabetes, and other complications.

In view of these complexities and to obtain a more personalized profile of an individual living with obesity, measurements such as body composition and waist circumference are useful

Box 37.5 Components of an obesity-focused medical history

Age	• Consider physiological age and frailty • Digital literacy (relevant to care delivery) may vary with age • Specific factors relevant to young adults (see 'Obesity through the life course' section)
Sex	• Sex differences in obesity prevalence and risk • Sex-specific variations relating to obesity such as bone health, reproductive health, and body composition • Sex specific co-morbidities (e.g., polycystic ovarian syndrome, erectile dysfunction) • Transgender considerations (with specialist support)
Ethnicity	• Ethnic-specific criteria exist for access to certain interventions • Perspectives on weight management and dietary changes may also vary with ethnicity
Occupation	• Employed people spend one-third of their day in the workplace • Working environment influences sedentary time, food environment, and stress levels • Insufficient sleep and circadian misalignment secondary to shift work contribute to weight gain
Weight history	• Use open questioning and active listening to identify the reason why someone is seeking help • BMI is used to classify severity, but this may not be the main reason for a person to seek help • Assess the person's view of their weight and possible reasons for weight gain • Ask about weight at different stages of life (including birth weight) • Ask about minimum and maximum weight through life • Identify life events that may have resulted in weight changes; a visual representation (e.g., lifestyle events body weight graph) can support reflection and insights (see **Fig. 37.6**) • Identify previous attempts at weight loss and modalities used, as well as outcomes and learning from these experiences • Type and perception of hunger • Describe weight pattern (e.g., rapid onset versus gradual gain over years); rapid onset of weight gain points to a secondary cause • Adaptive behaviours relating to weight, e.g., excessive exercise, insulin misuse, or purging (vomiting or laxative use); it is a sensitive area, and clinicians should obtain relevant training and gain local awareness of support agencies for signposting (e.g., eating disorder unit) • Consider pointers toward monogenic genetic obesity: early-onset severe obesity, hyperphagia, learning disability, syndromic features, central endocrine abnormalities, increased severity; resistance to treatment
Past medical history	• Enquire specifically about obesity-related co-morbidities including diabetes, heart disease, OSA, renal impairment, and hypertension • For mental health diagnoses and eating disorders, clarify treatment modality and stability; restrictive diets can lead to a flare-up of binge-eating disorder • For diabetes mellitus, ask about duration of disease, glycaemic control, and related complications; diabetes onset <5 years has higher likelihood of remission with significant weight loss; ensure their diabetes treatment supports weight loss (see **Box 37.6**) • Enquire about suitability for bariatric surgery: previous general anaesthetic, reflux, hiatus hernia, previous abdominal surgery • Consider diagnoses that hinder weight loss (e.g., untreated OSA, which can lead to stress, fatigue and reduced exercise tolerance) • Ask about secondary causes for obesity such as Cushing's syndrome, hypothyroidism, or hypothalamic disorder or injury (this may be accompanied by hyperphagia)
Drug history	• Identify previous obesity pharmacotherapy and outcomes • Enquire specifically about drugs causing weight gain (**Box 37.6**) and corticosteroids
Family history	• Review if weight consistent with family trends
Social history	• Physical activity: type of occupation, day-to-day mobility, sedentary time, barriers to mobility (physical, psychosocial), structured activity (e.g., exercise classes, swimming) and level of exertion, experience and interest in digital or wearable technology, self-perceived level of fitness • Diet history, including food diary, speed of eating and eating environment, autonomy in meal preparation, and external influences • Sleep hygiene and quality • Functional status: see staging above • Economic status: deprivation is strongly associated with obesity, and food poverty or cost of living challenges can have an impact on food choices and quality • Smoking history • Alcohol intake (remember the calorie intake) • Support network • Who in the household prepares meals and will support with weight loss attempts? • Identify social isolation, which maybe a barrier to change

BMI, Body mass index; *OSA*, obstructive sleep apnoea.

to measure in addition to BMI. Adiposity-based chronic disease (ABCD), a newer diagnostic term, has also been proposed (American Association of Clinical Endocrinology guidance). This goes beyond simple BMI measurements and identifies obesity as a chronic disease, outlines its pathophysiology, and reduces stigma.

Staging of obesity

Because of the limitations of a simple BMI-based approach, newer staging systems have been developed that include an assessment of the impact of obesity on multiple areas of function and lifestyle (**Fig. 37.6**). These staging systems have been shown to correlate with mortality rate, as well as quality of life and other health indicators

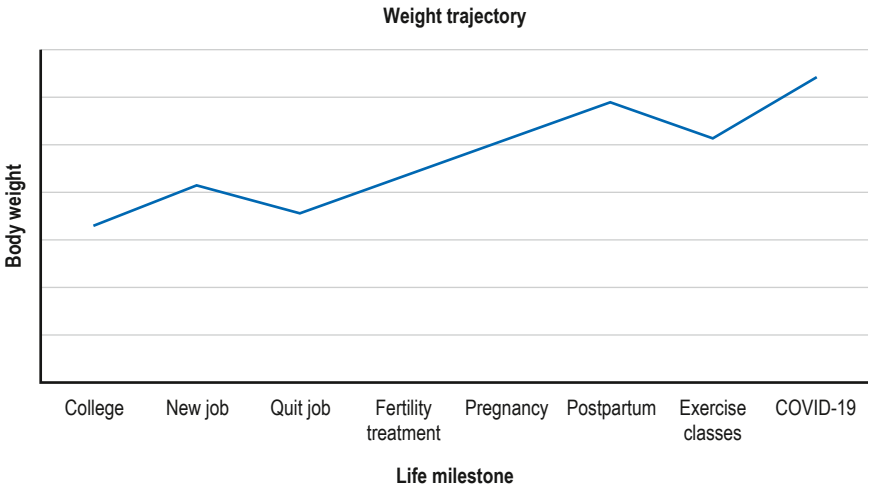

Fig. 37.3 **Lifestyle events: body weight graph.**

Box 37.6 **Common prescriptions and their impacts on weight**

Drug class	Weight loss	Weight neutral	Weight gain
Steroids			+ (e.g., prednisolone)
Hormonal contraceptives			+ (e.g., OCPs, DMPA)
Antihistamines			+ (e.g., cetirizine, fexofenadine, desloratadine)
β2-blockers			+ (e.g., atenolol, metoprolol)
α2-agonists			+ (e.g., clonidine)
Antidepressants		+ (e.g., escitalopram, duloxetine)	+ (e.g., amitriptyline, citalopram, fluoxetine, sertraline)
Atypical antipsychotics		+ (e.g., aripiprazole)	+ (e.g., olanzapine, clozapine, risperidone, quetiapine)
Anticonvulsants	+ (e.g., topiramate, zonisamide)	+ (e.g., levetiracetam, lamotrigine)	+ (e.g., valproate, carbamazepine, pregabalin)
Mood stabilizers			+ (e.g., lithium)
Antidiabetic medications			
Insulin			+
Biguanides	+		
SGLT2 inhibitors	+		
GLP-1RA	+		
DPP-4 inhibitors		+	
Sulfonylureas			+
Thiazolidinediones			+
Meglitinides	+		
α-glucosidase inhibitors		+	

DMPA, Depot-medroxyprogesterone acetate; *DPP-4*, dipeptidyl peptidase 4; *GLP-1 RA*, glucagon-like peptide 1 receptor agonist; *OCP*, oral contraceptive pill; *SGLT2*, sodium-glucose cotransporter-2.

and can be used to discuss with patients about weight reduction strategies.

Investigations

Investigations should consider:

- Underlying or secondary causes of obesity
- Severity of obesity and staging
- Associated co-morbidities of obesity
- Cardiovascular risk and metabolic syndrome
- Nutritional status
- Obesity profiling to guide future therapeutic options.

It is not uncommon to uncover silent conditions that may have a significant impact on the patient's health. These conditions may have unrecognized symptoms or be asymptomatic. Examples include liver disease, atrial fibrillation, OSA, and renal impairment. The investigation phase therefore presents an opportunity to 'make every contact count' and develop a clearer picture of the individual and their risk.

As with investigations in all areas of medicine, there should be careful thought. Excessive or unwarranted investigation carries the risk of unnecessary anxiety; expense; and in some cases, harm from radiation exposure. It is recommended that the clinical history and examination guide specialized investigations. Centres may

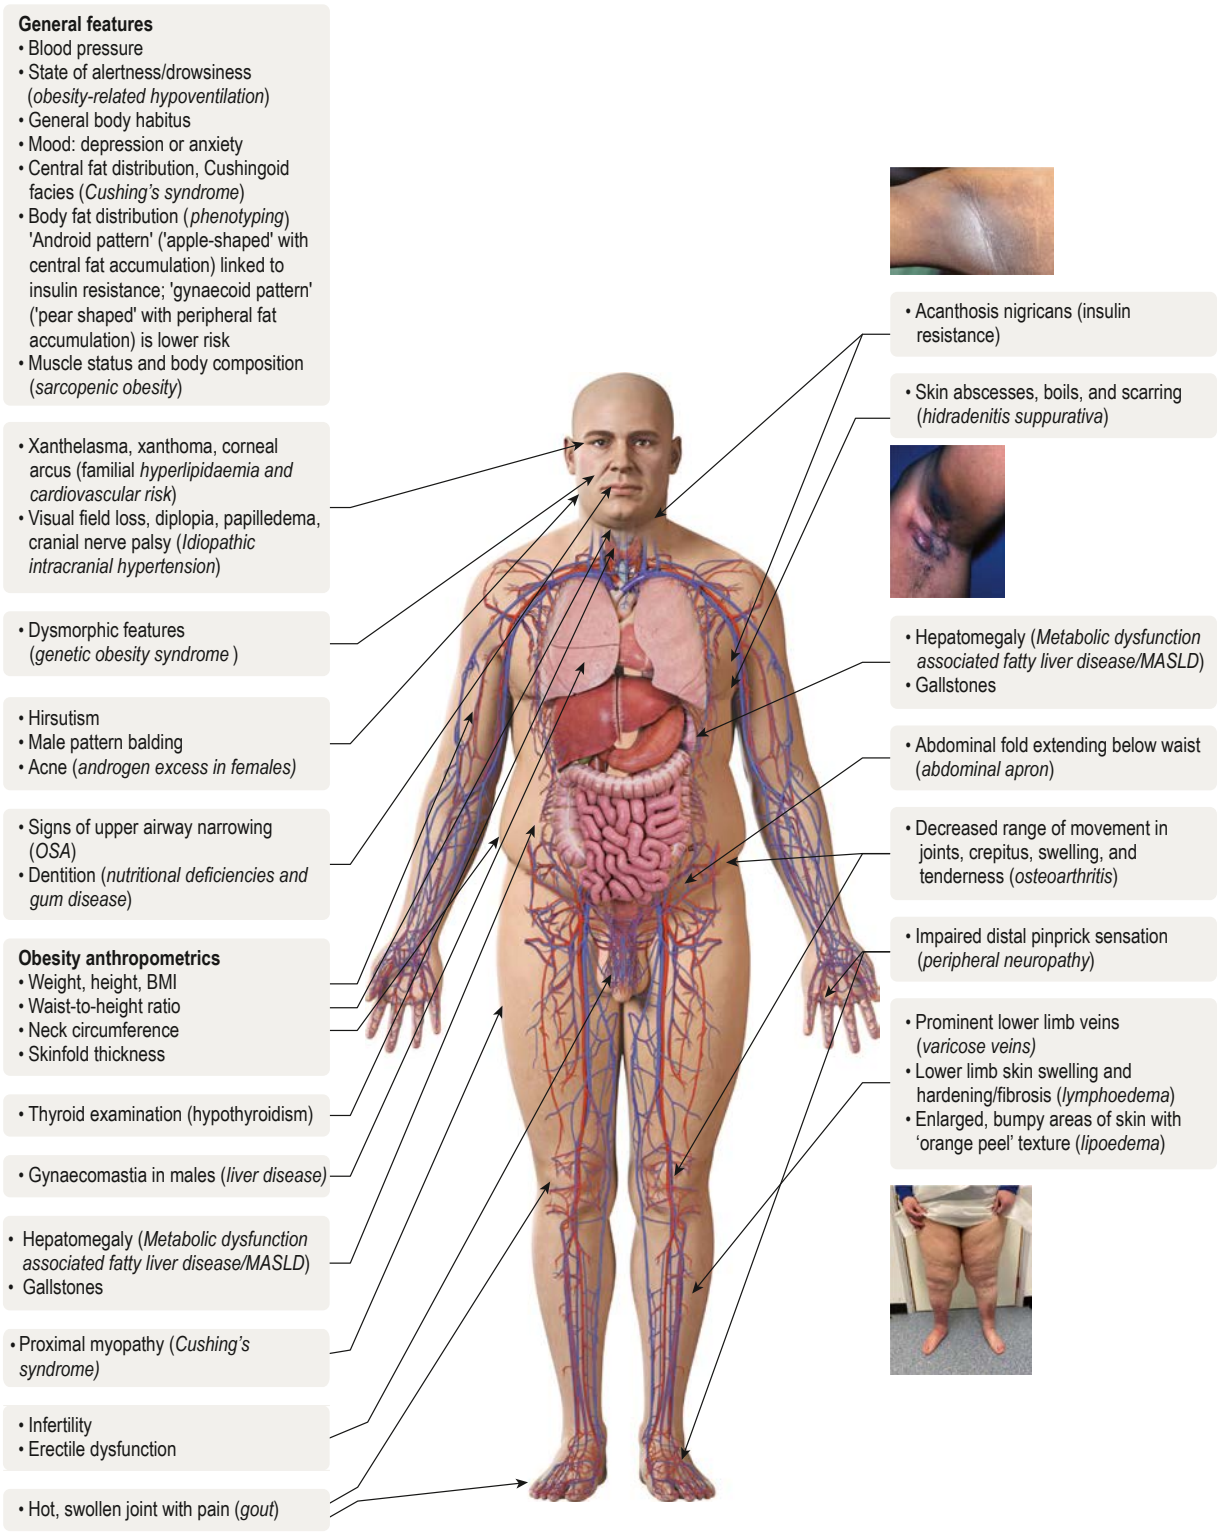

Fig. 37.4 Features to consider during examination of a person living with obesity. *BMI,* Body mass index; *MASLD,* metabolic dysfunction–associated steatotic liver disease; *OSA,* obstructive sleep apnoea.

adopt a 'standard panel' (**Box 37.8**) that is agreed on locally to reflect the local population and health service.

Specialist services should anticipate technical challenges and be well prepared with equipment such as larger scanners and beds. If this is not considered, it can lead to significant distress and embarrassment for both parties. Limitations of certain investigations (e.g., transthoracic echocardiogram that report 'limited views due to body habitus') should be addressed sensitively. It should also be anticipated that certain investigations may uncover unexpected or new diagnoses as well as create additional referral needs. Specialist pathways (e.g., to respiratory services) may need to be discussed and agreed.

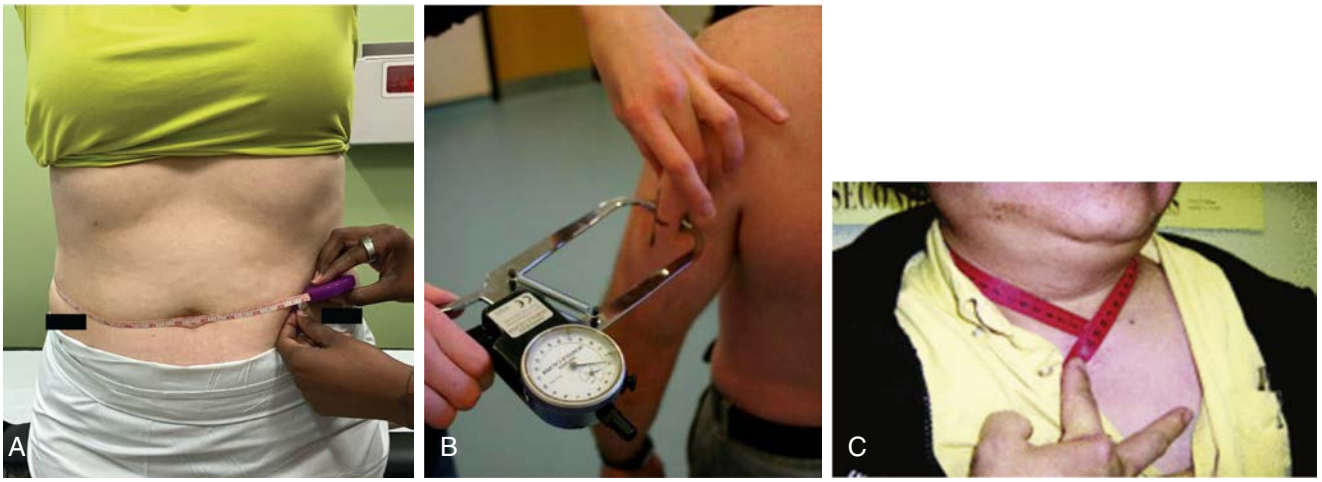

Fig. 37.5 Anthropometric measurement in obesity. (A) Waist-to-height ratio: To measure waist circumference, find a point midway between the lowest point of the ribcage and the iliac crest. Place a tape measure around the individual at this level, passing over the navel. Ask the patient to breath in and out, and measure at the end of expiration. **(B)** Skinfold: This is useful for individuals who may be housebound or unable to step onto scales. It is measured with calipers over the middle of the triceps muscle. Normal values are <20 mm in males and <30 mm in females. **(C)** Neck circumference: This is measured with a standard tape measure by starting at the Adam's apple and then bringing the tape around to the starting point (take care not to pull too tight). More than 43 cm in males and 41 cm in females indicates high risk for sleep apnoea.

Box 37.7 Classification using body mass index, including ethnic specific criteria

	General population BMI criteria (kg/m²)	Ethnicity-specific BMI criteria[a] (kg/m²)
Healthy weight	18.5–24.9	18.5–22.9
Overweight	25–29.9	23–27.4
Obesity class 1	30–34.9	27.5–32.4
Obesity class 2	35–39.9	32.5–37.4
Obesity class 3	>40	>37.5

[a]South Asian, Chinese, other Asian, Middle Eastern, Black African and African-Caribbean.
BMI, Body mass index.
(NICE guidance, CG189.)

Furthermore, specialist investigations maybe indicated depending on the clinical evaluation and proposed treatment plan. These may be considered when there is suspicion of a secondary cause of obesity (**Box 37.9**) or when additional tests are required to determine eligibility for specific treatment modalities (e.g., bariatric surgery) (**Box 37.10**).

Genetic investigations

Heritability is a feature in many patients with obesity; however, in some, the pattern of genetic association is the dominant aetiological factor. Features suggesting a genetic aetiology include early-onset obesity (aged 3–5 years); hyperphagia (extreme hunger); learning disabilities; hypothyroidism; difficulty losing weight; and, in some cases, weight regain after bariatric surgery. There is increasing awareness of monogenic obesity with the development of the novel licensed treatment setmelanotide, an MC4R agonist. Genetic testing is now accessible and performed in selected candidates. Testing requires training not only to take samples but also in genetic counselling and interpretation of the test results. It is best practice to link in with a centre of expertise and work with relevant specialists (e.g., learning disability teams, rare disease support groups).

COMPLICATIONS OF OBESITY

Obesity is a multisystem disease, and a full obesity assessment includes consideration of related conditions in multiple different organ systems.

Cardiovascular disease

Cardiovascular diseases are the main cause of death in people with obesity. Deposition of lipid-laden macrophages in vessel walls is accelerated by obesity and mediated via increased insulin resistance and inflammation. This promotes atherosclerosis, ***coronary artery disease, and structural heart changes (via fibrosis)***. Higher adiposity also results in increased total blood volume and increased cardiac output. This in turn results in ventricular hypertrophy and arrhythmias. Accompanying hypertension, dyslipidaemia and hyperglycaemia (metabolic syndrome) contribute to a higher prevalence of ***heart failure with preserved ejection***

	Stage 0	Stage 1	Stage 2	Stage 3
	'Normal health'	*'At risk of disease'*	*'Established disease'*	*'Advanced disease'*
Airways	Normal	Snoring	Requires CPAP	Cor pulmonale
Body mass index	<35	35–40	40–60	>60
Cardiovascular	<10% risk	10%–20% risk	Heart disease	Heart failure
Diabetes	Normal	Impaired fasting glycaemia	Type 2 diabetes	Uncontrolled type 2 diabetes
Economic	Normal	Expensive travel/clothes	Workplace discrimination	Unemployed due to obesity
Functional	Can manage three flights of stairs	Manages one or two flights of stairs	Requires walking aids or wheel chair	Housebound
Gonadal	Normal	PCOS	Infertility	Sexual dysfunction
Health perceived	Normal	Low mood or QoL	Depression or poor QoL	Severe depression
Body image	Normal	Dislikes body	Body image dysphoria	Eating disorder with purging (drug use or vomiting)

Fig. 37.6 Modified King's obesity staging criteria. *CPAP,* Continuous positive airway pressure; *PCOS,* polycystic ovary syndrome; *QoL,* quality of life.

Box 37.8 A typical panel of diagnostic tests for use in an obesity service

Standard obesity panel example:

- Full blood count
- Urea, creatinine, and electrolytes
- Glycated haemoglobin or HbA_{1c},
- Lipid profile
- Liver biochemistry (with calculation of a 'fibrosis-4' index based on age, ALT, AST, and platelet count to assess the likelihood of MASLD)
- Thyroid function tests
- Ferritin folate, vitamin B_{12}, vitamin D
- Urinalysis for protein

ALT, Alanine transaminase; *AST,* aspartate transaminase; *MASLD,* metabolic dysfunction–associated steatotic liver disease.

fraction. Any of these cardiac conditions in isolation or combination may lead to sudden cardiac death. Other complications include ***obesity-associated cardiomyopathy, left ventricular hypertrophy, cor pulmonale, pulmonary hypertension of obesity, and lymphoedema***.

Respiratory disease

Anatomic and neuromuscular changes in obesity are key factors in sleep-related breathing disorders. ***OSA*** (Chapter 20, 'Obstructive sleep apnoea' section) is caused by progressive expiratory narrowing in the retropharyngeal area, which results in a negative collapsing pressure during inspiration. ***Obesity hypoventilation syndrome*** is associated with chronic type 2 respiratory failure caused by diminished respiratory drive: maximal inspiratory and expiratory pressures are reduced, and there are reduced ventilation in the lower pulmonary lobes and hypercapnia. Possible mechanisms for this are leptin resistance, genetic predisposition, and sleep-disordered breathing. There is also a higher incidence of respiratory infections, asthma exacerbations, and pulmonary emboli in people living with obesity.

A striking association was seen between obesity and ***COVID-19–related death*** during the pandemic. Large-scale studies were conducted in England, the USA, and other countries revealing that people with obesity were more severely affected by COVID-19. One study showed that 77% of people hospitalized were either overweight (29%) or obese (48%). This is likely due to immune dysregulation and the low-grade inflammation of obesity predisposing to severe infection.

Box 37.9 Secondary causes of obesity

Obesity is a prominent feature of the following conditions and syndromes:

Polycystic ovarian syndrome: weight gain, irregular periods, hirsutism, subfertility

Hypothyroidism: tiredness, hair loss, feeling cold, constipation, dyslipidaemia, bradycardia, mood changes, dry skin and hair, menstrual irregularity

Cushing's syndrome: proximal muscle weakness, wasting of the extremities, wide purplish striae, easy bruising, supraclavicular fat; hypertension and glucose intolerance may also be present (high suspicion, sensitivity)

Prader-Willi syndrome: infants and toddlers present with hypotonia and failure to thrive; older children and adults manifest hyperphagia, intellectual disability, behavioural concerns, short stature, and hypogonadism

Bardet-Beidl syndrome: intellectual disability, retinitis pigmentosa, polydactyly, hypogonadism, deafness, and renal disease

Albright hereditary osteodystrophy (pseudohypoparathyroidism type 1a): short stature, short metacarpals and metatarsals, hypocalcaemia, precocious puberty, cognitive deficit

Alström syndrome: blindness, deafness, acanthosis nigricans, type 2 diabetes mellitus, cirrhosis, hypogonadism, renal disease

Hypothalamic obesity: abnormal weight gain caused by structural destruction of the hypothalamus characterized by rapid weight gain, hyperphagia, decreased energy expenditure, hypopituitarism, reduced quality of life

Liver disease

Metabolic dysfunction–associated steatotic liver disease (MASLD) is a newer term for non-alcoholic fatty liver disease. It is particularly prevalent in people with obesity. MASLD is related to chronic caloric excess, leading to fat accumulation in liver, especially of triglycerides. This is now one of the leading causes of cirrhosis in developed societies (Chapter 23, 'Metabolic dysfunction–associated steatotic liver disease' section).

Gastrointestinal disease

Obesity is linked to various disorders, including reflux disease, erosive oesophagitis, Barrett's esophagitis, oesophageal adenocarcinoma, erosive gastritis, gastric cancer, diarrhoea, colonic diverticular disease, colonic polyps and cancer, cholelithiasis, cholecystitis, acute pancreatitis, and pancreatic cancer. Aetiological factors include altered peristalsis, changes in sphincter pressures, chronic intestinal inflammation, increased colon transit time, increased permeability of the GI mucosa, changes in GI hormone

Box 37.10 Specialist tests considered for the investigation of obesity as directed by clinical assessment

Specialist tests considered for the investigation of obesity as directed by clinical assessment
Testosterone
Luteinizing hormone
Follicle-stimulating hormone
Sex hormone–binding globulin
B-type natriuretic peptide (false-negative results are more frequent in patients with obesity)
Investigations for Cushing's syndrome
Genetic obesity screening (next-generation sequencing)
Spirometry
Polysomnography or overnight sleep oximetry
Venous bicarbonate
Continuous positive airway pressure compliance report
Liver elastography
Electrocardiography
Echocardiography
Ultrasonography of the abdomen
Upper gastrointestinal endoscopy
Transvaginal ultrasonography
Dual-energy X-ray absorptiometry (bone density scan)

secretion (increased resistin and visfatin, reduced leptin), and altered bile acid absorption.

Endocrine disease

Obesity-associated endocrine dysfunction is linked to pro-inflammatory adipokines secreted by adipose tissue. Disorders include ***insulin resistance, prediabetes, type 2 diabetes mellitus, dyslipidaemia, hypothyroidism, and hypercortisolemia***.

In people with central obesity, there is ***functional hypercortisolism***. 11-β steroid dehydrogenase type 1 present in adipose tissue converts cortisone to cortisol. Therefore, an increase in adipose tissue results in increase in cortisol. This is accompanied by increased nocturnal Adrenocorticotropic hormone and cortisol levels, increased urinary free cortisol, and adrenal gland enlargement. The type of disturbance in the hypothalamic–pituitary–adrenal axis depends on adipose tissue distribution and individual stress response.

Reproductive system disease

Reproductive dysfunction occurs in both males and females living with obesity as a result of changes in sex hormone metabolism. Adipose tissue has increased aromatise cytochrome 450 activity, which converts testosterone to oestradiol. Higher oestradiol downregulates Glucose transporter type 4 receptors and worsens insulin resistance. This in turn reduces sex hormone–binding globulin and results in raised free testosterone. High oestradiol also reduces gonadotropin release from the pituitary, which reduces ovulation in females and spermatogenesis in males. In females, there are higher incidences of ***precocious puberty, polycystic ovarian syndrome, anovulation, infertility, sexual dysfunction, and hyperandrogenism***. Males with obesity experience a higher rate of ***low testosterone, decreased libido, and subfertility***.

Neurological disease

Idiopathic intracranial hypertension is caused by increased brain water content and excess cerebrospinal fluid production. It is triggered by weight gain, hormonal changes, increased cerebral venous pressure, and other factors. Inflammation in the brain may contribute to the higher rates of ***cognitive impairment*** and ***dementia*** seen in those with obesity. Other neurological complications include higher incidences of ***stroke, dementia,*** and ***polyneuropathy***.

Renal disease

Obesity predisposes to ***chronic kidney disease*** via associated conditions such as hypertension or diabetes as well as directly through glomerulosclerosis. Stress incontinence is another complication commonly seen in females with obesity.

Musculoskeletal disease

Musculoskeletal symptoms are common in patients living with obesity. These may relate to ***osteoarthritis*** and mechanical factors or muscle inflammation and impaired tissue healing in the context of chronic inflammation. Obesity is a risk factor for ***osteoporosis*** with contributions from inactivity, sarcopenia, and vitamin D deficiency.

Surgical

It is well recognized that obesity predisposes to increased perioperative risk. Weight reduction is often advised before procedures such as joint replacement and organ transplantation to support access and outcomes.

Psychological

There is a complex, bidirectional relationship between obesity and mental health. People living with obesity report a high prevalence (between 20% and 60%) of conditions such as depression and anxiety. These conditions are often exacerbated by factors that include weight bias, social isolation, and medication side-effects.

Obstetric and perinatal

Females who conceive when at a higher BMI are more likely to develop ***pregnancy-related hypertension, pre-eclampsia, postpartum infections, and gestational diabetes*** and their babies are more likely to be born preterm and via ***caesarean section***.

Skin

Dermatological complications associated with obesity include hidradenitis suppurativa, hirsutism, acanthosis nigricans, psoriasis, cellulitis, venous stasis ulcers, and cellulitis.

Pathophysiology of obesity complications

Inflammation

Obesity is a state of chronic low-level inflammation. Abundant immune cells in adipose tissue and macrophage aggregates increase proportionally with the degree of obesity.

Around 50 pro-inflammatory adipokines, including TNF-α, interleukin-6, adiponectin, resistin, and visfatin, are secreted by visceral adipose tissue. This causes disruptions of endocrine and nervous signals. Changes may be seen from early childhood.

Inflammation is proposed to be a central mechanism linking obesity to metabolic and vascular complications and increased risks of cancer and infectious disease. Evidence suggests that effective obesity care can reduce this inflammation.

The Krebs cycle and obesity

Abnormalities of the Krebs cycle and its components are implicated in inflammation. This is also emerging as an important concept in obesity linking metabolic stress to inflammation.

Fumarate hydratase deficiency has been linked to elevated levels of hypoxia-inducible factor-1 and other cytotoxic and oncogenic substrates. Tumours deficient in fumarate dehydrogenase have very high growth-differentiation factor 15 levels, linked to cellular stress and conditions such as obesity, diabetes mellitus, and liver disease. This discovery has led to novel therapeutic targets and is promising for future obesity research.

MANAGEMENT

General principles of management

An effective treatment strategy should be:

- Tailored to specific phenotype (based on clinical evaluation)
- Mindful of personal goals and barriers
- Effective for the severity of obesity and complications
- Sustainable within the context of lifestyle, support network, and affordability
- Evidence based and in line with local guidance and resource.

In designing a management strategy, a personalized care plan document (digital or paper) can add value and offer a reference point. The 'five As of obesity care' (**Box 37.11**) also offers useful framework.

Sensitive exploration of previous weight loss attempts and what has or has not worked provides valuable information. For example, a specific dietary strategy may have been classed as a 'failure', but this could be related to insufficient explanation around the weight loss trajectory or unrecognized binge eating disorder impairing progress. Information gleaned from these conversations can be used in the design of the current management strategy. This can enhance the chance of success.

Interventions can range from 'doing nothing' to bariatric surgery. It is helpful to describe the severity of obesity and associated risk (using staging systems as needed) to an individual to support their decision-making. Ideally, a range of choices would be presented. Suitability as well as eligibility should be considered by the individual and the multidisciplinary team. For example, a patient may meet criteria for bariatric surgery but live within a chaotic situation and may be actively self-harming. In this case, there is a significant risk associated with a bariatric intervention, and care for the person's mental health should take precedence.

Other considerations

Ethos

- Obesity is a chronic disease; discussions should cover relapse and potential strategies.
- It is important to remember that obesity is a complex, heterogeneous disorder. There is no single solution. Identifying the root cause of obesity by considering 'why' rather than simply 'how' will enable clinicians to plan an effective strategy.

Box 37.11 The five A's of obesity care

Ask	Ask for permission to explore weight. Explore readiness to change.
Assess	Assess body mass index class and stage. Assess for drivers, complications, and barriers.
Advise	Advise on obesity risks. Discuss the benefits of modest weight loss. Discuss treatment options.
Agree	Agree of realistic weight loss expectations. Focus on behavioural goals (Specific, Measurable, Attainable, Relevant, Time-bound [SMART]) and health outcomes. Agree on a treatment plan.
Assist	Assist in addressing drivers and barriers. Assist in accessing resources and programmes. Refer to appropriate provider. Arrange follow-up.

Adapted from Elaine A. Sherson, Elizabeth Yakes Jimenez, Nikki Katalanos, A review of the use of the 5 A's model for weight loss counselling: differences between physician practice and patient demand, Family Practice, *Volume 31, Issue 4, August 2014, Pages 389–398, https://doi.org/10.1093/fampra/cmu020.*

Approach

- Adopt a holistic approach and consider biopsychosocial factors. In preparing an individual to change, questions such as 'What would make you feel more ready?' can prompt self-reflection and ignite intrinsic motivation.

Communication

- There is heterogeneity in response to all strategies. Individuals should be counselled for nonresponse as well as response and appreciate that this is not a personal failure.
- Information should be provided on the fact that weight loss is rarely linear.
- Management strategies should be presented with information on predicted (average) weight loss. This will support managing expectations in line with goals.
- Repercussions of significant weight loss (i.e., loose skin, psychological impact on body image, relationships) should be considered and discussed.

Principles of management

- Multidisciplinary delivery is central to obesity care.
- Interventions should be considered as tools rather than solutions.
- Ineffective strategies should be promptly reviewed and adjusted.
- Identify high-risk individuals who require expedited care (e.g., those with declining renal function).
- The most appropriate management strategy may be watchful waiting. For example, for some it may not be the right time to engage with an obesity service (e.g., after recent bereavement). For these patients, gently guide them to return for support when able and if they would wish to.
- Management may include signposting to internal or external services and treatment of conditions within the expertise of the team, typically including metabolic conditions and nutritional deficiencies.
- The goal of management is to achieve clinically meaningful weight loss; evidence shows this starts from 5%.

Weight management goals

It is important to ascertain an individual's weight loss goals before embarking on a treatment strategy. If these have been

suggested from an external source (e.g., a surgical team to access another procedure), then it is important to review this in line with available and suitable interventions and individual circumstances. Realistic and personalized goal setting is key. A reasonable strategy is to:

- Prevent further weight gain
- Reduce body weight
- Maintain this lower weight for the long term.

Potential therapeutic strategies

- Lifestyle interventions are first-line treatment but generally result only in modest weight loss (5%–10%). Weight maintenance can be challenging because of physiological compensations.
- Remission of co-morbidities and cardiovascular risk reduction requires greater weight loss (10%–25%) (Fig. 37.7). This may be achievable with newer medical therapies.
- Bariatric surgery currently offers the greatest sustainable weight loss (for suitable candidates), in the region of more than 25%.
- It is important to map the weight loss against predicted and appreciate that individuals will respond differently. A poor or no response should prompt an alternative strategy.
- After successful weight loss, there is an expected shift in appetite-related hormones, increased appetite for palatable food, and a decrease in resting energy expenditure, which are thought to contribute to weight regain. This physiological response should not be attributed to lack of motivation, and adequate support should be provided.

The multidisciplinary team in obesity care

It is best practice to work with a multidisciplinary team to deliver care to people living with severe and complex obesity (Fig. 37.8). High-quality training in obesity care is available to allow professionals in different fields to become specialists in this area.

In the UK, a tiered approach is used in which basic obesity care is delivered in primary care, and more specialist interventions such as surgery is offered in secondary care in tier 3 and 4 services (Fig. 37.9).

Obesity through the life course

Obesity impacts individuals at every stage of their lives, including early childhood. Tailoring the approach and resources to the individuals' age and maturity is likely to add value:

- **Pregnancy and fetal outcomes:** Strong evidence links obesity to adverse maternal and fetal outcomes. Prenatal counselling is valuable. Fertility often improves as weight falls and should be considered in counselling for new drugs and bariatric surgery.
- **Young adults:** Leaving home, starting a new job, marriage, and parenthood are key transition points and may combine cost of living pressures with increased responsibility, triggering weight gain. The psychological burden on a young adult with obesity should be considered. Often this has persisted through childhood and involved adverse childhood events (including abuse and bullying). It may have resulted in social isolation. Psychology assessment is important. E-health strategies may support engagement. Complications begin silently at this stage, so vigilance is required to maintain awareness of genetic obesity.
- **Adults and middle age:** This is a key phase in the disease because co-morbidities usually begin to manifest. Care requires coordination with a range of specialists. People often have tried many strategies by this stage so require specific attention to novel strategies, rapport, and engagement.
- **Later life and older adults:** Sarcopenic obesity occurs with age because of low skeletal mass in combination with increased fat mass. This can exacerbate the age-related decline in physical function and contribute to frailty. Weight maintenance may be an appropriate strategy rather than weight loss.

Lifestyle interventions

Lifestyle intervention is the foundation of all obesity management strategies. It includes diet; physical activity; and other parameters such as sleep hygiene, alcohol moderation, and stress management. Also linked are measures to reduce cardiovascular risk in obesity such as smoking cessation. Lifestyle management should be underpinned by robust behaviour change theory and delivered in a manner that resonates with the individual, such as face-to-face consults, digital options, and group sessions. Outcomes vary, and studies suggest many of the effects of lifestyle intervention are short-lived, with weight rising after the intervention period has finished.

Dietary strategies

Obesity has been described as 'a normal condition in an abnormal environment'. There are many challenges to consuming a healthy, balanced diet within an obesogenic environment. Highly palatable foods high in fat, salt, and sugar with large portion sizes have become increasingly prevalent and accessible across the world. Food insecurity, economic crises, and many differing consumer messages create a landscape that can be extremely challenging to navigate.

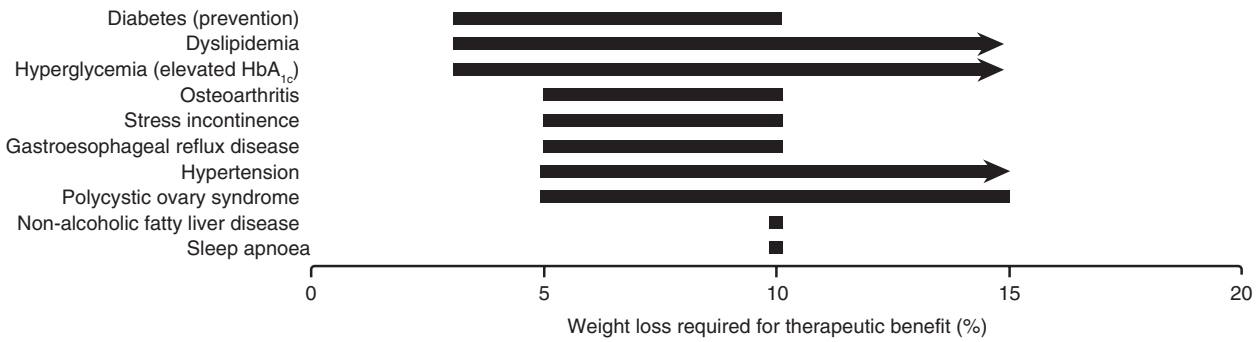

Fig. 37.7 Weight loss required for therapeutic benefit. *(Adapted from Cefalu, W. T., Bray, G. A., Home, P. D., Garvey, W. T., Klein, S., Pi-Sunyer, F. X., … Ryan, D. H., et al. [2015]. Advances in the science, treatment, and prevention of the disease of obesity: Reflections from a diabetes care editors' expert forum.* Diabetes Care, *38[8], 1567–1582.)*

Dietetic advice for obesity care is specialized. Inappropriate or generic advice with insensitive delivery can be harmful and lead to attrition from services.

When planning a dietary approach with a patient:

- Gain understanding about previous dietary strategies and outcomes, as well as the patient's food knowledge.
- Explain that 'fad' diets typically lead to rapid weight loss (often lean body mass) but lack a sound evidence base and are often unsustainable. Aim to understand if a cycle of weight loss and regain has been experienced and promote alternative, evidence-based approaches.

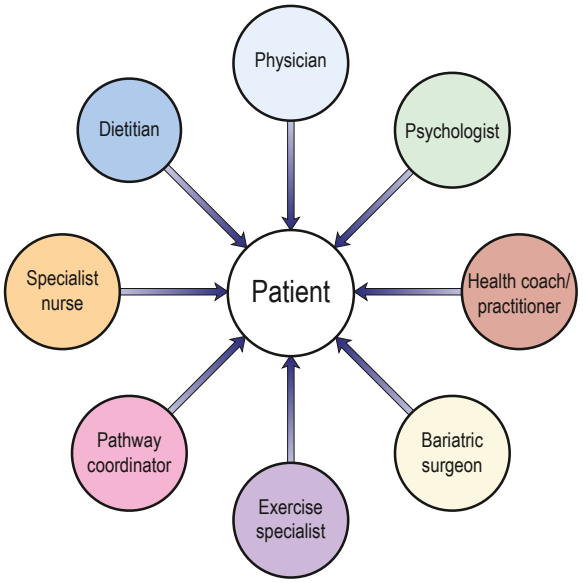

Fig. 37.8 **Multidisciplinary team example.**

- Perform a comprehensive dietetic assessment using validated tools (e.g., food diaries and food frequency questionnaires). Aim to understand typical dietary intake, meal timings, take-away consumption, and snack and fluid intake as well as drivers for these patterns, including mood.
- Understand if any co-morbidities may be having an impact on eating behaviour (e.g., hyperphagia in genetic obesity, preference for certain foods and patterns of eating in autism or attention-deficit hyperactivity disorder, trauma).
- Understand lifestyle factors, such as shift working, that have an impact on eating.
- Screen for disordered eating, which can be highly prevalent in obesity (up to 15%). This includes binge-eating disorder and night eating syndrome. Counsel and signpost accordingly.
- Before the implementation of a specific strategy, work on stabilizing eating behaviour, meal planning, and managing portion sizes. This can reduce unplanned, high-energy consumption and compensatory eating.
- Ask about consumption of sugar-sweetened beverages ('fizzy drinks'), which have been linked to disrupted physiological responses to feeding and reduced satiety, as well as poor dental health.
- Identify and track nutritional deficiency, which is common despite obesity.
- Encourage self-monitoring and weight tracking to support weight maintenance after weight loss. For example, a patient may be encouraged to monitor their weight at home and check in with the clinical team if their weight hits certain thresholds after an intervention (e.g., 2 kg as a red flag and 4 kg to return for intervention).

Specific dietary strategies

A range of specific dietary strategies can promote weight loss and other health benefits. Overarching aims should be to reduce

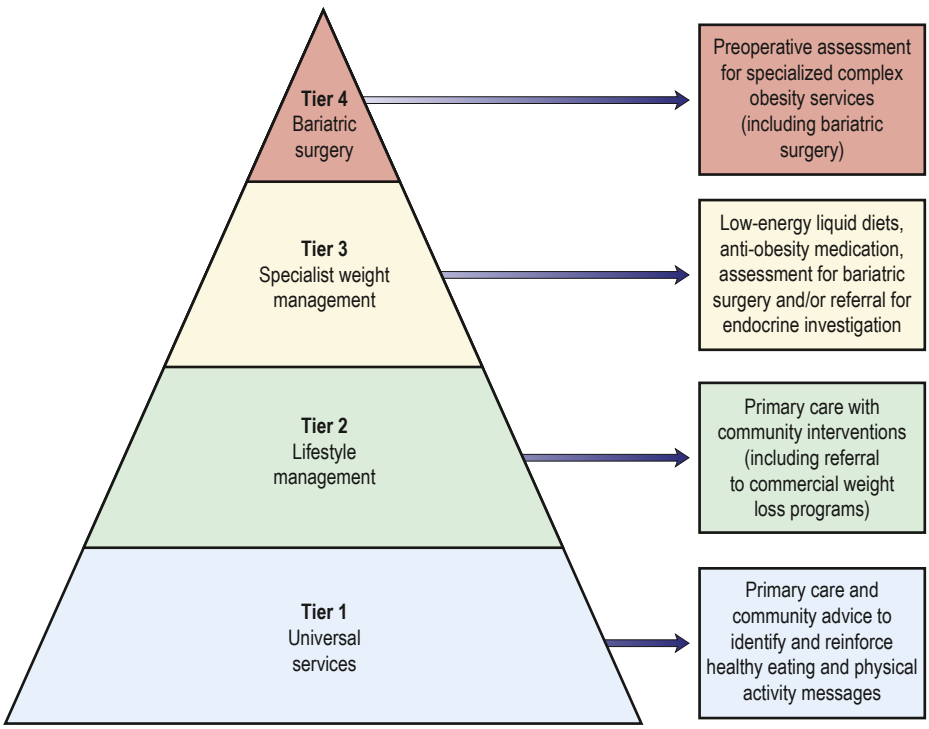

Fig. 37.9 **The tiered weight management system in England.**

energy intake while maintaining nutritional quality in a manner that is practical, sustainable, and evidence based. There is no 'right or wrong diet' as such, and a decision on strategy should be a shared decision.

A significant evidence base also demonstrates enhanced outcomes when a dietary intervention is combined with an effective lifestyle intervention. This is useful to convey in consultation. The Look AHEAD Trial study compared a 4-year intensive programme (including lifestyle counsellor, dietary interventions, portion-controlled meal plans, physical activity, and behavioural modification techniques) with usual medical care in people with diabetes. The intensive intervention group showed mean weight loss at 1 year of –8.6% versus –0.7%. This was sustained over 4 years with a mean weight loss of –6.15% in the intervention group. **Box 37.12** summarizes the main evidence-based dietary approaches for weight management.

Physical activity in obesity care

People living with obesity report lower levels of physical activity than those of normal body weight. They are also more likely to be sedentary (expending <1.5 metabolic equivalents in a sitting or lying position). Physical activity increases energy expenditure.

A strong body of evidence links increased physical activity to health benefit including cardiovascular disease. This guides national recommendations (**Fig. 37.10**).

There are, however, many reasons why these goals may not be easily attainable in people with obesity:

- Co-morbidities affecting mobility or fitness and lack of tailored support to be active
- Limited knowledge on exercise intensity and how this is perceived (e.g., breathlessness is to be expected with moderate intensity activity but may be experienced as pathology in those with co-morbid obesity who have not received a graduated programme with counselling)
- Stigma and bias having an impact on confidence to be active in public spaces
- Fear that gym equipment may not be the appropriate size
- Deprivation and health inequalities linked with obesity and physical inactivity.

With these factors, the national recommendations may seem unattainable and demoralizing. Yet people living with obesity who are sedentary may, in fact, have the most to gain from becoming active (**Fig. 37.11**).

Substantial evidence exists for the benefits of physical activity in obesity care:

- Increased efficacy and sustainability for other weight loss interventions
- Preservation of lean body mass during weight loss, particularly when rapid
- Improvements in cardiovascular risk factors and lower all-cause mortality
- Improved cardiorespiratory function in preparation for bariatric surgery
- Improvements in depression and anxiety (various meta-analyses).

Box 37.12 Dietary approaches for weight management and related evidence

Dietary strategy	Description	Evidence/phenotype
DASH (Dietary Approaches to Stop Hypertension) diet	Foods including vegetables, fruits, wholegrains, and low saturated fat. The diet limits sodium intake but is rich in potassium, calcium, and magnesium.	Evidence for hypertension, CVD risk, lipid profile Impact on body weight: 1.4 kg (systematic review).
Mediterranean diet	Emphasis on monounsaturated fats (extra-virgin olive oil, vegetables, nuts) and unrefined cereals. Reduced intake of processed meat and refined sugars.	Substantial body of evidence for improved CVD risk (e.g., PREDIMED study). Mean weight loss, 1.75 kg, enhanced to 4 kg when combined with lifestyle measures.
Low- calorie and very-low-calorie diets	Low-calorie diets are those that restrict daily caloric intake to 1000–1200 kcal. Very-low-calorie diets restrict daily caloric intake to 800 kcal/day or less.	Usually closely supported within a structured programme. Selection and readiness are important. Valuable for rapid weight loss such as before bariatric surgery (e.g., the 'liver shrinkage' diet) or in preparation for a specific intervention (e.g., transplant). Landmark evidence from national studies (DIRECT, DROPLET).
Low-GI diet	GI describes the impact of carbohydrate on blood glucose levels. Lower GI foods tend to be higher in fibre (e.g., vegetables, pulses) and can improve satiety.	Weight reduction of 1.8 kg. Reduced cancer and mortality rate in association with higher fibre content (WHO).
Low-carbohydrate diet	Ranges between very low levels (ketogenic or 20–50 g/day) to higher levels of up to 230 g/day. In the context of significant consumption, may still equate to a reduced approach.	Improvements in diabetes mellitus with evidence for PCOS and MASLD. Improves triglycerides but may have an adverse impact on LDL. Up to 9-kg weight loss.
Intermittent fasting	Intermittent fasting is voluntarily refraining from eating during a certain time period and limiting the number of calories eaten during this period.	An umbrella review of meta-analyses of randomized clinical trials reported that there is moderate- to high-quality evidence of a positive association between intermittent fasting and 'anthropometric and cardiovascular' outcomes.
Time-restricted eating	Time-restricted eating similarly refers to abstinence from food during a specific period of time without limiting the number of calories eaten during this period.	The TREAT randomized clinical trial shows there was a considerable decrease in weight for the group with time-restricted eating compared with the group with consistent meal timing.

CVD, Cardiovascular; *GI,* glycaemic index; *LDL,* low-density lipoprotein; *MASLD,* metabolic dysfunction–associated steatotic liver disease; *PCOS,* polycystic ovarian syndrome; *WHO,* World Health Organization.

Fig. 37.10 National recommendations on physical activity. *(UK Chief Medical Officers' Physical Activity Guidelines 2019.)*

Implementation of physical activity in obesity care

In counselling, it is important to communicate that physical activity alone is unlikely to have a major impact on weight loss. This can set expectations. Additional benefits should be emphasized as well as the synergistic effect of activity with other interventions. In terms of modalities, aerobic, high intensity-interval training, and resistance programmes all have evidence for benefit. 'E-health' approaches (see next section) may help patients engage with regular exercise programmes.

E-health in obesity care

Information and communication technologies used to support healthcare are broadly referred to as e-health. Examples include smartphone applications or apps that provide lifestyle support and promote behaviour change. Some offer clinical facing portals and links to wearable technology. Benefits include flexibility, ease of access to care, personalization, and support for motivation and planning. Challenges include attrition rates, digital exclusion, and integration with clinical services.

Given the rising obesity rates and accumulating evidence, it seems likely that there will be strong interest in promoting e-health delivery at scale, for example, to support patients monitoring their weight, calculating the calory content of food, or recording and engaging with exercise programmes. As with any other intervention in obesity, it is worthwhile considering this as a tool rather than a solution. Given the complex psychological burden of obesity, it should not be a substitute for face-to-face delivery because often people with obesity benefit hugely from and value the rapport and support offered from face-to-face delivery. For people who cannot or prefer not to access e-health, alternatives should be presented.

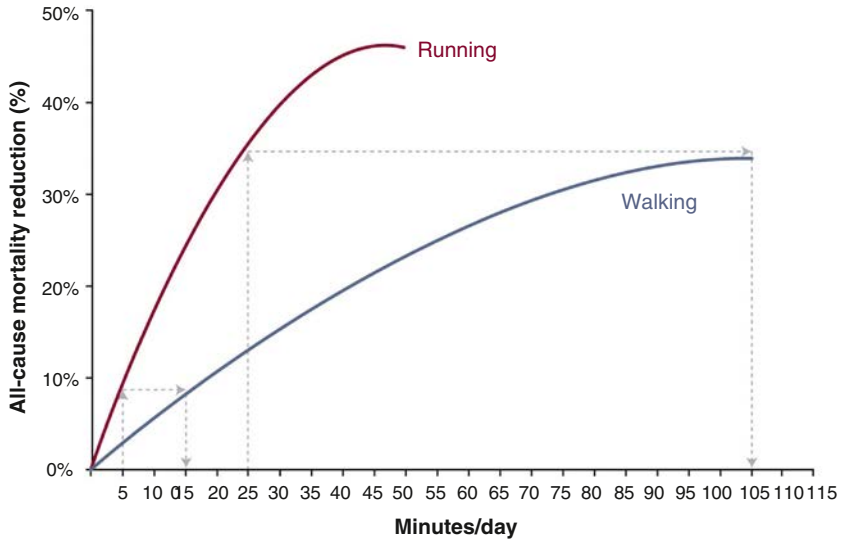

Fig. 37.11 Comparison of benefits between walking and running. A 5-min run generates the same benefits as a 15-min walk, and a 25-min run is equivalent to a 105-min walk. *(Minimal Amount of Exercise to Prolong Life: To Walk, to Run, or Just Mix It Up? August 2014* Journal of the American College of Cardiology *64[5]:482–484. https://doi.org/10.1016/j.jacc.2014.05.026.)*

Medical therapy

Compared with other disease areas, there has, until recently, been a limited range of options for the medical treatment of patients with obesity. Several agents have been withdrawn over the years for safety concerns (e.g., the cannabinoid-1 receptor blocker rimonabant). We are now in a promising new era.

As the pathophysiology of obesity has been elucidated in more detail, a range of therapeutic targets have emerged. Medical treatment for people with obesity is now one of the most highly publicized and exciting areas of drug development. This has led to increased social media traffic, media reports, and drug shortages. In this context, it is especially important to emphasize the medical intervention as a 'tool, not a solution'. Alongside medical therapy, patients should ideally be thoroughly reviewed by different members of the multidisciplinary team and undergo education about monitoring and likely side-effects, a detailed medication review, psychological support, and lifestyle coaching.

A medication review includes:

- Reviewing all existing medications and trying to remove those associated with weight gain, if appropriate and endorsed by specialist colleagues
- Reviewing drugs that will need to be deprescribed in the context of significant weight loss (e.g., bariatric surgery) such as antidiabetic or antihypertensive medications.

Vitamin D

There is strong evidence linking vitamin D deficiency with obesity and its associated diseases. However, whether this is a cause or a consequence remains to be determined. Whereas some studies suggest that vitamin D accumulates in adipose tissue, which leads to lower plasma levels, others suggest impaired 25-hydroxylation in the liver as the cause. Other studies suggest that low vitamin D predisposes to obesity by increasing pre-adipocyte differentiation into adipocytes. In either case, there appears to be a role for vitamin D replacement in obesity management.

Orlistat

Orlistat is an inhibitor of pancreatic and gastric lipases. It reduces dietary fat absorption by up to 30% and aids weight loss. In the UK, it is incorporated into obesity guidance and licensed for people with a BMI of 28 kg/m^2 or greater and obesity-related comorbidities or with a BMI of 30 kg/m^2 or greater. Because of its mechanism of action, orlistat can cause unpleasant side-effects (e.g., oily stools and faecal incontinence). This is in the context of relatively modest weight loss. For these reasons, it is frequently not tolerated. Counselling is important before prescription to support retention. Advice on lower fat diets may be beneficial. Orlistat is typically prescribed for 12 months but may be used for longer with support. A double-blind, randomized, controlled study (Xendos) reported 10.6-kg weight loss with the addition of lifestyle modification. Orlistat also has evidence in diabetes prevention (37% relative risk reduction), cardiovascular prevention, and renal failure.

Glucagon-like peptide 1 receptor agonists

Endogenous GLP-1 is a peptide consisting of 31 amino acids. It is secreted mainly by L-cells in the gut and ileum but also from the brain (nucleus tractus solitarius) in response to food intake. Receptors for GLP-1 are widely expressed across the body, resulting in a range of physiological effects (Fig. 37.12). In the context of weight management, effects such as increased satiety and reduced gastric emptying are clinically important.

The evidence base for GLP-1 receptor agonists is extensive and includes global, large-scale, randomized controlled studies (Fig. 37.13). In the SCALE trials of liraglutide, weight loss exceeded 5% of previous body weight in half of patients and exceeded 10% of previous body weight in 25%. There was also a significant reduction in the number of treated patients who developed diabetes. Semaglutide may offer even greater weight loss (10% weight loss in >70% of patients and 15% weight loss in >50% in the STEP clinical trial programme).

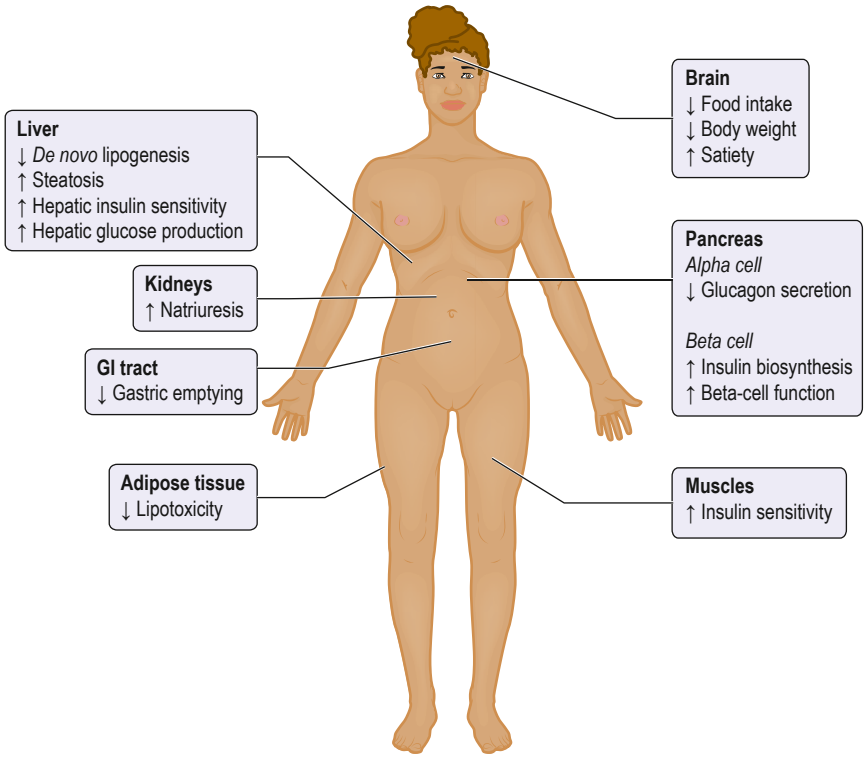

Fig. 37.12 Systemic effects of GLP-1 receptor agonists. *GI,* Gastrointestinal.

Clinical delivery of a glucagon-like peptide 1 agonist programme

GLP-1 agonists are given by daily or weekly subcutaneous injection. Phone prompts may be helpful in reminding patients when doses are due. Patient education and peer support are valuable. It is especially important to counsel people on common side-effects (e.g., headache, GI disturbance), how to manage these side-effects, and how the side-effects typically settle with time. This minimizes attrition.

Baseline and serial measurements of selected parameters (e.g., body composition, BP) can support with evaluation and programme retention. For example, scales may not immediately show weight loss, but body composition may change favourably. This insight can support motivation and retention.

Counselling should also cover:

- Indication
- Administration (important to check comfort, competence, and dexterity for injections)
- Titration schedule
- Side-effects and strategies for management (e.g., smaller meals, food diary)
- Clinical features of severe side-effects (e.g., pancreatitis, cholecystitis)
- Monitoring
- Cautions
- Expected benefits (note that weight loss may be less pronounced in certain groups)
- Review points and contact for the clinical team for support and questions
- Conception
- Concurrent lifestyle changes
- Variability in response.

Bupropion and naltrexone combination therapy

Bupropion is an antidepressant, and naltrexone is an opioid antagonist. The combination works synergistically to support weight loss as part of a multicomponent plan. The treatment works centrally with bupropion activating proopiomelanocortin (POMC) neurones in the hypothalamus, an effect is augmented by naltrexone. The overall impact is reduced appetite and cravings. There are numerous cautions, contraindications, and side-effects for this agent, and it should be used in centres with experience.

Phentermine and topiramate combination therapy

Phentermine is a sympathomimetic, and topiramate is a carbonic anhydrase inhibitor (used as an anticonvulsant). The combination acts to suppress appetite and increase satiety. This treatment is not recommended in patients with uncontrolled hypertension and significant cardiac disease. Careful monitoring is required.

Setmelanotide

Setmelanotide is a highly specialist drug indicated for a few specific monogenic forms of obesity only. Treatment is via subcutaneous injection and is typically available through selected centres with relevant genetic expertise. It is an MC4R agonist approved for monogenic obesity caused by POMC, proprotein convertase subtilisin/kexin type 1, or LEPR deficiency in individuals ages 6 years of age and older. The most common side-effects are GI effects, hyperpigmentation, and injection site reactions. Clinical trials are underway for further indications.

Diabetes medications

Type 2 diabetes and obesity often (but not always) coexist. International guidance supports the preferential use of agents that support weight loss in people living with obesity and diabetes (see Chapter 35).

Future therapies for obesity and areas of interest

Observations from bariatric surgery (in which the primary effects are thought to be mediated via altered concentrations of multiple gut hormones) have led to the development and study of novel combination therapies.

- ***Tirzeptide*** is a novel dual (glucagon-like peptide 1 [GLP-1] and gastric inhibitory polypeptide [GIP] receptor) agonist and first in class. It is currently licensed for type 2 diabetes in the USA, and significant weight loss outcomes have been reported (with 40%–69% achieving ≥10% weight loss in the SURPASS clinical trial programme). Tirzepatide is currently awaiting approval for obesity care.
- ***Retatrutide,*** an agonist of GLP-1, GIP, and glucagon receptors, causes substantial reductions in body weight.
- ***Orforglipron,*** an oral once-daily non-peptide GLP-1 receptor agonist, achieved a mean weight loss of 14.7% at 36 weeks in adults with obesity or overweight in phase 2 clinical trial.
- Use of a GLP-1 agonist with **glucagon**, which in addition to the well-recognized impact of increasing glucose levels also has favourable effects on energy balance, which supports weight loss. Additional areas of interest are also emerging from trial data, such as benefits on liver fibrosis.
- Use of a GLP-1 agonist with **amylin** (e.g., cagrilintide). Amylin is co-secreted with insulin and has a role in appetite regulation as well as reduced gastric emptying.
- Monoclonal antibody against the activin type II receptor. Activin is a protein complex with various biological effects, including regulation of the menstrual cycle and energy metabolism.

Bariatric surgery

Bariatric surgery (also known as metabolic surgery) is an effective and durable treatment for people with severe obesity, linked to improvements in obesity-related co-morbid conditions as well as all-cause mortality. A systematic review and

meta-analysis of 621 studies with 135 246 patients undergoing a range of bariatric procedures reported an overall average weight loss of 38.5 kg per patient, or 55.9% of excess body weight. This currently makes bariatric surgery the most potent treatment for obesity in appropriate candidates. A range of surgical options are available, and novel approaches show particular promise. In carefully selected and prepared individuals, surgery has a low mortality rate, minimal complication rate, and short lengths of stay. Some centres offer day case surgery or enhanced recovery protocols.

Remission of co-morbidities such as type 2 diabetes and OSA are realistic goals, but it is key to counsel patients that there are no guarantees. In the case of diabetes, validated scores such as DiaRem, which consider diabetes duration and treatment, can offer prediction scores for remission. In the postoperative period, glycaemic control often improves dramatically within a few days and before any significant weight loss.

Patient selection

The keys to the success of bariatric interventions are appropriate selection, work-up, and follow-up of individuals. People who wish to access bariatric surgery should commit to lifelong follow-up, modifications to their diet and lifestyle, and engagement with the service multidisciplinary team. Different models exist according to region, but typically, individuals are required to complete a comprehensive weight management programme before surgery, including medical and lifestyle elements. This is to ensure adequate preparation, selection, and understanding.

Unfortunately, uptake of this effective treatment can be limited, and in the UK, for example, it is estimated that fewer than 1% of eligible patients receive this intervention. There are various reasons for this, including cultural, economic, societal, and healthcare factors. In certain cases, individuals may choose to self-pay for surgery or travel overseas.

Preparation for surgery

In terms of **counselling and preparation** for bariatric surgery, the following are important:

- Identification of appropriate individuals based on individual preference, local criteria, and clinical phenotype. For example, people with recent-onset diabetes are more likely to achieve remission with surgery and should be considered for this approach if they are otherwise suitable and interested.
- Robust multidisciplinary assessment and combined discussion. Key members of the team include a specialist dietitian, psychologist, nurse, surgeon, physician, and anaesthetist. All should be happy to proceed as well as the individual. Certain high-risk cases may need dedicated meetings and more detailed discussion. Some individuals may need to be expedited (e.g., when bariatric surgery is required as a bridge to access organ transplantation).
- Counselling on risks of surgery. This includes standard risks as for all surgery (e.g., deep vein thrombosis) but also includes dumping syndrome, postbariatric hypoglycaemia, excess skin, anastomotic leak, strictures, internal hernias, and nutritional deficiencies.
- Psychological evaluation and readiness. Psychological instability may lead to postoperative deterioration (e.g., a switch of comfort eating to alcoholism or complications such as weight regain). It is important to explore body image, coping strategies, and partner and social support.
- Anaesthetic preparation. Relevant investigations include cardiac, metabolic, and sleep studies, as well as optimization of risk factors, including diabetes mellitus, hypertension, OSA, smoking, diet (a 'liver shrinkage diet'), and physical fitness using a 'prehabilitation' approach.
- Preconception counselling. Fertility is typically improved after bariatric surgery, but because of the dramatic weight and metabolic shifts in the postoperative period, females are advised to wait for at least 1 year before attempting conception.

Selection of bariatric procedure

Although bariatric surgery is an effective intervention with a strong evidence base, it is not without complications and is an arduous and risky process for those who are not effectively selected and prepared.

The type of procedure performed is a shared decision but should be guided by the views of the operating bariatric surgeon. Procedures may be classified as restrictive (reducing volume of digestive tract and reducing oral intake) or malabsorptive (reducing absorption of calories) and include the following.

Roux-en-Y gastric bypass

The Roux-en-Y gastric bypass (RYGB) is one of the most effective and widely performed procedures worldwide, typically performed laparoscopically under general anaesthetic. The stomach is reduced to a small pouch by stapling and then directly connected to the jejunum, thereby bypassing the small bowel (**Fig. 37.14**). It is a combined restrictive and malabsorptive procedure. After the procedure, the patient is provided with a tailored diet of thin fluids, gradually building up to solid food. They may be back at work in a matter of weeks.

Sleeve gastrectomy

This is a popular procedure and usually quicker to perform than the RYGB. The majority (85%) of the lateral aspect or curvature of the stomach is resected, leaving a tubular 'sleeve', which is typically less than 2 cm in diameter. It is important to identify people with reflux because higher intraluminal pressures can exacerbate symptoms.

Adjustable gastric banding

Adjustable gastric banding (AGB) is a restrictive procedure created through the placement of a silicone band at the upper aspect of the stomach. This band is connected to the skin via a filling port, which may then be adjusted as required. AGB gained popularity, particularly by those who perceived it as a reversible and less invasive procedure compared with other options. But trends have changed, and it is less commonly practised now because of comparatively lower weight loss outcomes, complication rate (e.g., band slippage, port infection, erosion), and follow-up burden (band adjustments). It is no longer offered within the UK National Health Service.

Other surgical techniques

'One anastomosis gastric bypass' is a newer, simplified form of the RYGB procedure reporting significant weight loss. The 'duodenal switch' procedure is a complex malabsorptive procedure with increased complications that is sometimes used as a second-step 'rescue' procedure.

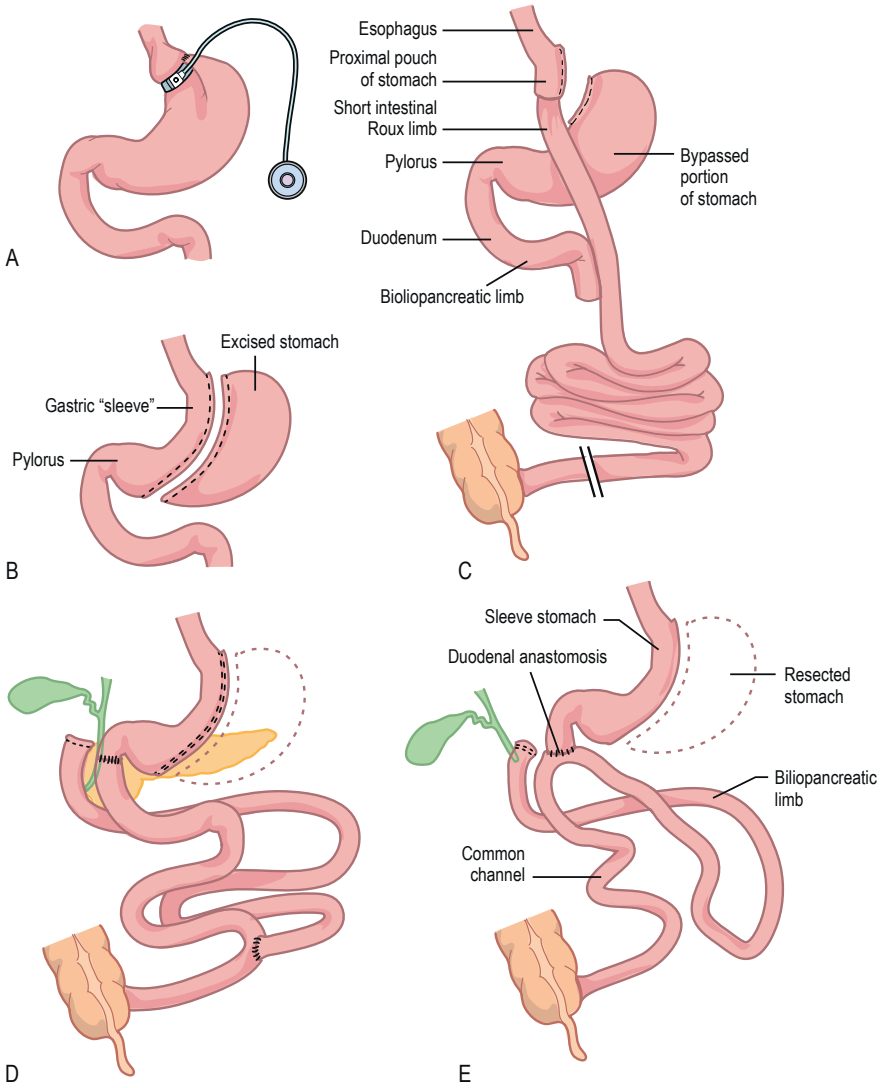

Fig. 37.14 **(A)** Adjustable gastric banding. **(B)** Sleeve gastrectomy. **(C)** Roux-en-Y gastric bypass. **(D)** Duodenal switch. **(E)** Single anastomosis duodeno-ileal bypass with sleeve gastrectomy.

Endoscopic procedures

A number of novel endoscopic procedures have been developed that tend to have a lower morbidity than surgery and that can, in some cases, be performed without anaesthetic. Long-term outcome data are awaited. Examples include:

- **Gastric balloon:** A small balloon (silicone or rubber) is inserted within the stomach. With inflation (500–750 mL of water), it offers restriction. There is a risk of deflation and migration of the balloon and minimal weight loss.
- **Endoscopic sleeve gastrectomy:** Using endoscopic access, suturing is placed inside the stomach to reduce the volume by up to 70%. Weight loss outcomes equivalent to the surgical sleeve gastrectomy have been reported.
- **Transoral outlet reduction endoscopy** is used in patients who have undergone gastric bypass surgery but have then regained weight. Endoscopically delivered suturing reduces the aperture of the anastomosis and aims to slow transit. It is also used to address postoperative complications, including dumping.

CORE SKILLS AND KNOWLEDGE

Haematologists treat patients with disorders of the blood. This chapter focuses on general haematology, including the investigation of anaemia and non-malignant white blood cell (WBC) and bleeding disorders, alongside the safe management of blood transfusion. Haematological malignancies (see Chapter 39) and thrombotic disease (see Chapter 40) are dealt with elsewhere.

The skills and responsibilities of haematologists extend beyond caring for the patients with specific haematological disorders and include ensuring that blood results reported by the laboratory analysers are accurate, establishing that blood used for transfusions is safe and available when and where it is needed, helping other specialties interpret results of laboratory tests, and guiding the use of blood products.

Key learning objectives for general haematology at undergraduate level include:

- Understanding anaemia: causes, investigation, and management
- Assessing whether disorders of WBCs and platelets are caused by primary haematological disease or secondary to other causes
- Understanding the way that blood transfusions are carried out and the mechanisms by which safety is ensured
- Understanding the mechanisms of disorders of haemostasis and thrombosis, as well as their investigation and management.

Specific opportunities for learning include attending ward rounds on inpatient haematology units, attending haematology clinics to understand the problems that cause patients to be referred from primary care, seeking out patients on a haematology day unit or medical admissions ward to understand the immediate and long-term management of haematological disorders, and attending laboratory 'morphology' meetings when laboratory science is correlated with individual patient care.

CLINICAL SKILLS

History

Symptoms of haematological disease tend to be caused by abnormalities in individual cell lines (Fig. 38.1).

Examination

Key clinical signs of haematological disease are included in Fig. 38.2. Most can be attributed to the effects of over- or under-production of different cell lineages or are features of underlying haematological disease processes (e.g., splenomegaly).

Investigations

Specific investigation of haematological disease generally begins with examination of the peripheral blood (Box 38.1). Bone marrow aspiration, with or without biopsy (Fig. 38.3), is a crucial investigation in the diagnosis and monitoring of many haematological disorders. These procedures allow determination of cellularity (increased or decreased?) as well as morphology (do the blood cell precursor cells look as they should?). The procedure and the cell lineages present in bone marrow are detailed in Fig. 38.3 and Box 38.2.

BACKGROUND

The formation of blood cells (haemopoiesis)

Blood consists of:

- Red blood cells (RBCs)
- White blood cells (WBCs)
- Platelets
- Plasma, in which the above elements are suspended.

Plasma is the liquid component of unclotted blood, which contains soluble fibrinogen. Serum is what remains after formation of the fibrin clot.

The haemopoietic system includes the bone marrow, liver, spleen, lymph nodes, and thymus. There is a huge turnover of cells, with RBCs surviving for approximately 120 days, platelets approximately 7 days, and granulocytes only 7 hours. The production of as many as 10^{13} new myeloid cells (all blood cells except for lymphocytes) per day in the normal, healthy state requires tight regulation according to the needs of the body.

Blood islands are formed in the yolk sac in the third week of gestation and produce primitive blood cells, which migrate to the liver and spleen. These organs are the chief sites of haemopoiesis from 6 weeks' to 7 months' gestation, when the bone marrow becomes the main source of blood cells. In childhood and adult life, the bone marrow is the only normal source of blood cells, apart from T lymphocytes, which are made in the thymus.

At birth, haemopoiesis takes place in the marrow of nearly every bone. As a child grows, the active red marrow is gradually replaced by fat (yellow marrow) so that haemopoiesis in the adult becomes confined to the central skeleton and the proximal ends of the long bones. Only if the demand for blood cells increases and persists do areas of red marrow extend. Pathological processes interfering with normal haemopoiesis may result in resumption of haemopoietic activity in the liver and spleen, which is referred to as ***extramedullary haemopoiesis***.

All blood cells are derived from pluripotent stem cells. These stem cells have two key properties:

1. ***Self-renewal:*** production of more stem cells
2. ***Proliferation and differentiation*** into progenitor cells, committed to one specific cell line

Pluripotent stem cells differentiate into mature blood cells through intermediate progenitor cells, which have lost the ability to self-renew but have high proliferative capacity. These progenitor cells can be broadly classified according to the blood cells that they are programmed to make (Fig. 38.3F). For example, the common lymphoid progenitor gives rise to T- and B-lymphoid cells; whereas the former are produced in the thymus, B-cell production primarily occurs in the bone marrow. The common myeloid progenitor gives rise to all non-lymphoid cells in the bone marrow via a series of intermediate progenitor cells. These cells cannot be identified in bone marrow biopsies but are recognized by their ability to form colonies (reflecting their high proliferative capacity) when haemopoietic cells are immobilized in a soft gel matrix, the so-called colony-forming unit (CFU).

These haemopoietic stem and progenitor cells interact closely with several components contained within the specialized microenvironment of the bone marrow, including non-haemopoietic stromal cells, blood vessels, and extracellular matrix, together creating a nurturing microenvironment for blood cell development. Central to this microenvironment are haemopoietic growth factors produced by stromal cells in the bone marrow and elsewhere, which are key regulators of blood cell production.

Haemopoietic growth factors

Haemopoietic growth factors are glycoproteins (GPs), which regulate differentiation and proliferation of haemopoietic progenitor cells and the function of mature blood cells. Some growth factors are present in the circulation, and other growth factors are produced within the bone marrow microenvironment by stromal cells such as fibroblasts, osteoblasts, or endothelial cells or at sites of inflammation by activated T cells, monocytes, and macrophages. Growth factors act on their respective cell surface receptors, expressed on haemopoietic cells at various stages of development, to maintain the haemopoietic progenitor cells and stimulate increased production of one or more cell types in response to stresses such as blood loss and infection (Fig. 38.3F).

These haemopoietic growth factors, including erythropoietin (EPO), interleukin (IL)-3, IL-6, IL-7, IL-11, IL-12, β-catenin, stem cell factor (Steel factor or C-kit ligand) and Fms-like tyrosine kinase 3, act

	Too many	Too few
Red cells	**Too many red blood cells** • Headache • Blurred vision • Could it be secondary? • Any hypoxia or dehydration? • Is there associated high white count, especially basophils? • Check JAK2 for primary polycythaemia	**Too few red blood cells** • Shortness of breath, fatigue • Chest pain: severe anaemia can exacerbate ischaemic heart disease and needs rapid treatment • Think about bone marrow failure • Are white cells low as well? • Look at trends over time – is this new or ongoing? • Ask about diet with haematinic deficiencies: vegans have poor intake of iron and B_{12}
White cells 	**Too many white cells** • Any recent infection? • High neutrophils are usually reactive • Is there a history of allergy, asthma, eczema? This raises eosinophil count • Remember to request a blood film so the morphology can be assessed • Immature white cells indicate malignant haematological disorders	**Too few white cells** • Any recent infection? This can be the cause or the effect of low white cells • Ask about mouth ulcers and family history • Benign neutropenia is seen in young females • Take a drug history: low white cells are a common side-effect • Make sure patients with neutrophils $<1 \times 10^9$ know who to call if they have a fever • Neutropenic sepsis is fatal if not treated rapidly with i.v. antibiotics
Platelets	**Too many platelets** • Headache, itching • Bleeding: very high platelet counts increase risk of bleeding • Is there evidence of infection or malignancy? • Secondary thrombocytosis is more common than primary • Look for splenomegaly: all myeloproliferative disorders are associated with this	**Too few platelets/abnormal clotting** • Bleeding: look for petechiae and blood blisters • Recent infection: immune thrombocytopenia often follows viral infection • Ask about rheumatological disorders • Take a drug history: low platelets are a common side-effect • Understand what platelet counts are safe for procedures • Platelet transfusions are rarely needed for immune thrombocytopenia • Bleeding history: ask about previous operations, labour, dental extractions, menstruation

Fig. 38.1 Key questions from the history and clinical signs are highlighted to guide the investigation of abnormal blood counts and common haematological presentations. *i.v.,* Intravenous; *JAK,* Janus kinase.

via specific receptors on cell surfaces to stimulate downstream signalling within the cell, such as the cytoplasmic Janus kinase pathway. This in turn activates signalling cascades within the cell, ultimately altering gene expression in the cell nucleus and thus influencing cell behaviour (e.g., to promote proliferation). Colony-stimulating factors (CSFs, with a prefix that indicates the cell type; Fig. 38.1), as well as ILs and EPO, regulate the lineage-committed progenitor cells.

Thrombopoietin (TPO) is produced in the kidneys, liver, and certain bone marrow stromal cells and acts to control platelet production, along with IL-6 and IL-11.

In addition to these factors, which stimulate haemopoiesis, there are other factors that inhibit the process including tumour necrosis factor (TNF) and transforming growth factor beta (TGF-β).

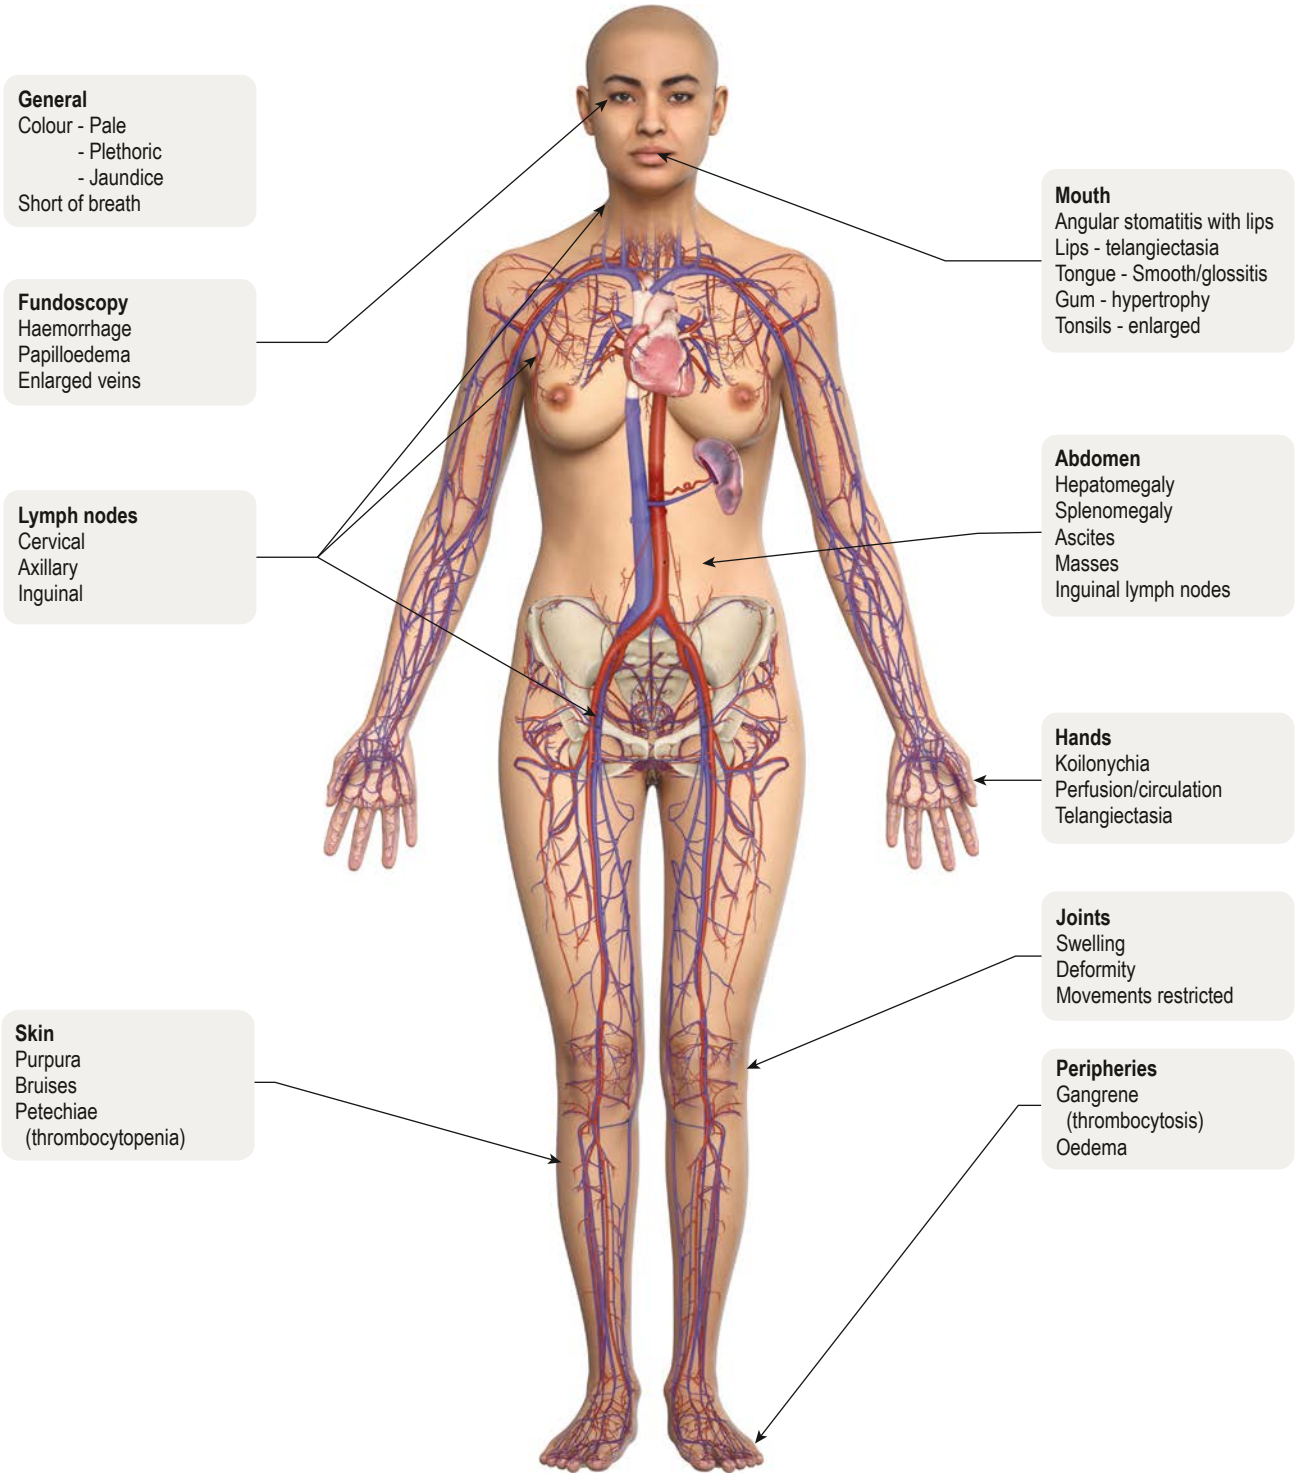

Fig. 38.2 **Clinical features of haematological disease**

Uses in treatment

Many growth factors have been produced by recombinant DNA techniques and are used clinically. Examples include:

- Granulocyte-colony-stimulating factor (G-CSF), used to accelerate haemopoietic recovery after chemotherapy and haemopoietic cell transplantation
- EPO, used to treat anaemia in patients with chronic kidney disease (CKD) and in patients with certain blood cancers
- TPO receptor agonists, used to treat patients with immune thrombocytopenic purpura (ITP).

Peripheral blood

Automated cell counters are used to measure the haemoglobin (Hb) concentration and numbers and sizes of RBCs, WBCs, and platelets (**Box 38.1**). Other indices can be derived from these values. A blood film examined by a professional experienced in blood cell morphology is an essential adjunct because definitive abnormalities of cells can be seen. This is particularly important in some haematological emergencies such as acute promyelocytic leukaemia (see Chapter 39) and thrombotic thrombocytopenic purpura (TTP;

Box 38.1 Reference values for peripheral blood

	Males	Females
Haemoglobin (g/L)	135–175	115–155
Packed cell volume (haematocrit; L/L)	0.4–0.54	0.37–0.47
Red blood cell count (10^{12}/L)	4.5–6.0	3.9–5.0
Mean corpuscular volume of red blood cell (fL)	80–96	
Mean corpuscular Hb (pg)	27–32	
Mean corpuscular Hb concentration (g/L)	320–360	
Red blood cell distribution width (%)	11–15	
White cell count (10^9/L)	4.0–11.0	
Platelets (10^9/L)	150–400	
Erythrocyte sedimentation rate (mm/h)	<20	
Reticulocytes	0.5%–2.5% (50–100 × 10^9/L)	

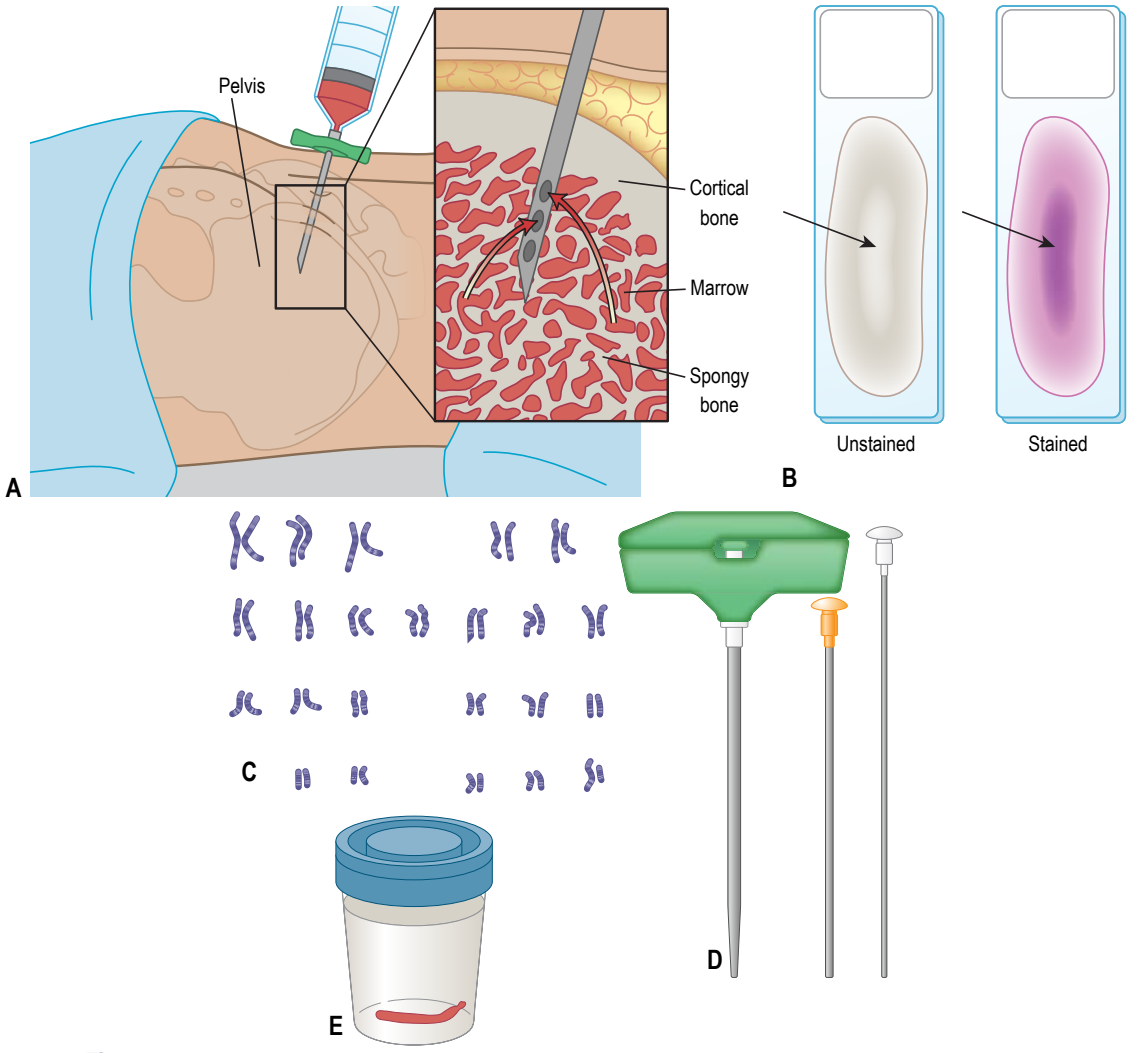

Fig. 38.3 Bone marrow aspiration and biopsy (trephine). **(A)** This is generally carried out as an outpatient procedure under local anaesthetic using aseptic technique. Informed consent is obtained. The skin overlying the superior posterior iliac crest is cleaned, and local anaesthetic is injected subcutaneously and around the periosteum, which is extremely well innervated. When the area is numb, an aspirate needle is used to obtain a liquid sample. **(B)** The sample is spread on a slide, stained, and examined under a microscope for morphology. **(C)** A sample is also sent for cytogenetic analysis, and a karyotype is generated, allowing identification of gross chromosomal rearrangements such as gain or loss of chromosomes or translocations. **(D)** A trephine needle is needed to obtain a bone biopsy. **(E)** The biopsy is a hard core of bone, which must be decalcified in chelating solution before being embedded in paraffin. Sections are then cut and stained, permitting the architecture of the marrow cells to be examined, and immunohistochemistry is carried out to detect abnormal cell populations.

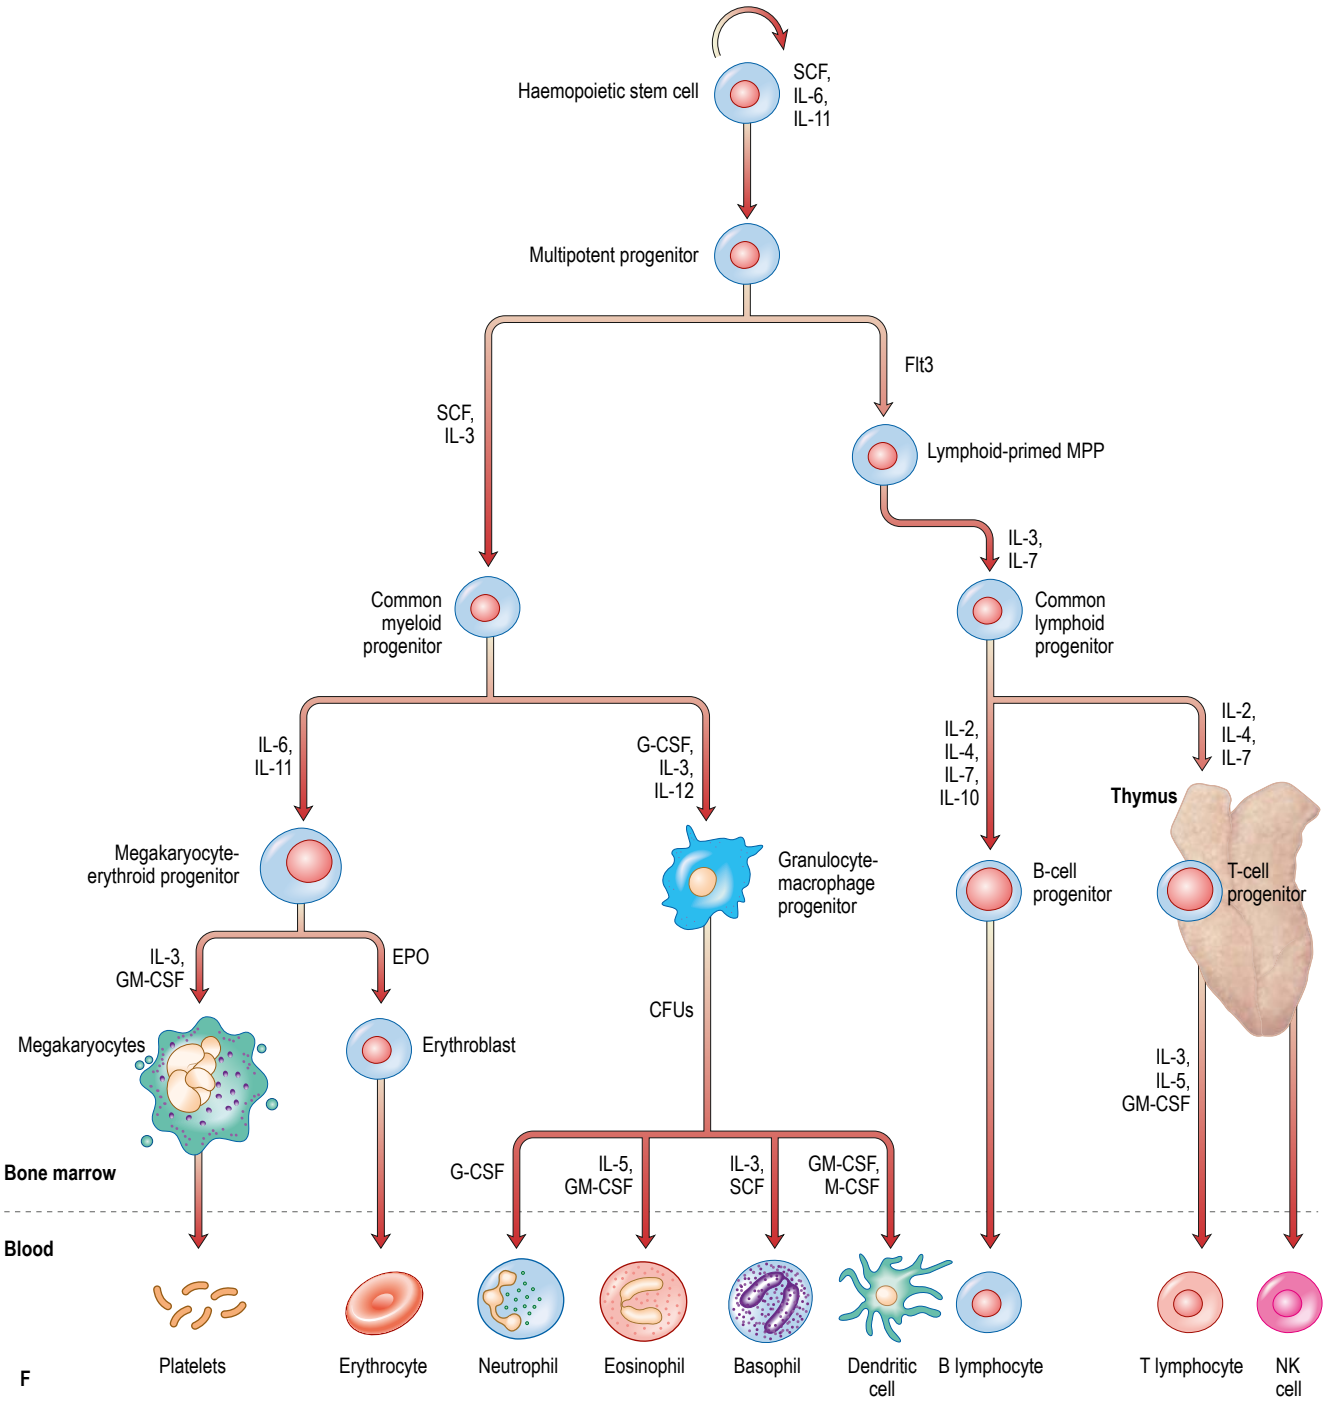

Fig. 38.3—Cont'd **(F)** Haemopoiesis arises from multipotent stem cells, which give rise to all different blood types according to the presence of internal and external regulatory molecules, hormones, and cytokines. As such, cell numbers are closely coordinated to respond rapidly to changes in requirements. *EPO,* Erythropoietin; *Flt3,* Fms-like tyrosine kinase 3; *G-CSF,* granulocyte-colony-stimulating factor; *GM-CSF,* granulocyte-macrophage-colony-stimulating factor; *IL,* interleukin; *MPP,* multipotent progenitor; *NK,* natural killer; *SCF,* stem cell factor; *TPO,* thrombopoietin.

see 'Thrombotic thrombocytopenic purpura' section), which require specific therapy within hours of diagnosis to prevent mortality.

- ***The mean corpuscular volume (MCV)*** of RBCs is a useful index in classification of anaemia (Fig. 38.4).
- ***The red cell distribution width (RDW)*** is a measure of variability in size of RBCs. An elevated RDW suggests increased variation in RBC size, e.g., anisocytosis in iron deficiency.
- ***The white cell count (WCC)*** (or white blood count [WBC]) gives the total number of circulating leucocytes. Differential counts specifically enumerate neutrophils, monocytes, lymphocytes, eosinophils, and basophils.
- ***Reticulocytes*** are young RBCs and usually make up less than 2.5% of all RBCs. The reticulocyte count gives a guide to erythroid activity in the bone marrow. An increased count is seen with

increased marrow activity (e.g., after haemorrhage or haemolysis) and during response to treatment with a specific haematinic. A low count in the presence of anaemia indicates an inappropriate response by the bone marrow and may be seen in bone marrow failure or deficiency of a haematinic.

- ***The erythrocyte sedimentation rate (ESR)*** is the rate of fall of RBCs in a column of blood and is a measure of the acute-phase response. A raised ESR reflects an increase in the plasma concentration of large proteins, such as fibrinogen and immunoglobulins. These proteins cause rouleaux formation, with RBCs clumping together and therefore falling more rapidly (Fig. 38.5). The ESR increases with age and is higher in females than males. Underlying pathology may be immunological, infective, ischaemic, malignant, or traumatic.
- ***Plasma viscosity*** is a measurement used instead of the ESR in some laboratories. It is also dependent on the concentration of large molecules such as fibrinogen and immunoglobulins and not affected by the concentration of Hb.
- ***C-reactive protein (CRP)*** is a protein produced in the acute-phase response. It is synthesized exclusively in the liver and rises within 6 hours of an acute event. CRP concentrations increase with fever (possibly triggered by IL-1, IL-6, TNF-α, and other cytokines), in inflammatory conditions, and after trauma. It follows the clinical state of the patient more rapidly than the ESR and is unaffected by the concentration of Hb but is less helpful than ESR or plasma viscosity in monitoring chronic inflammatory diseases such as systemic lupus erythematosus (SLE).

RED BLOOD CELLS

Erythropoiesis

RBC precursors pass through several stages in the bone marrow. The earliest morphologically recognizable cells are proerythroblasts. Smaller erythroblasts result from cell divisions, and precursors at each stage progressively contain less RNA and more Hb in the cytoplasm. The nucleus becomes more condensed and is eventually extruded from the late normoblast in the bone marrow when the cell becomes a reticulocyte.

- ***Reticulocytes*** contain residual ribosomal RNA and are still able to synthesize Hb. They remain in the marrow for about 1 or 2 days before release into the circulation, where they lose their RNA and become mature RBCs (erythrocytes) after another 1 or 2 days. Mature RBCs are non-nucleated biconcave discs.
- ***Late erythroblasts*** (nucleated RBCs) are not normally present in peripheral blood but are present in extramedullary haemopoiesis, cases of severe stress (e.g., severe infection, cardiac arrest), and some marrow disorders. About 10% of ***erythroblasts*** die in the bone marrow, even during normal erythropoiesis. Survival is dependent on erythropoietin (EPO) cell signalling. This 10% excess production of erythroblasts (ineffective erythropoiesis) ensures that a rapid drop in haemoglobin (e.g., acute haemorrhage or haemolysis) can lead to a rapid increase in terminally differentiated RBCs. Ineffective erythropoiesis is substantially increased in some anaemias, such as thalassaemia major and megaloblastic anaemia.
- ***EPO*** is a hormone that controls erythropoiesis. It is a heavily glycosylated polypeptide with a molecular weight of 30 400 Da produced in renal peritubular cells (90%) and in the liver (10%). Production is regulated mainly by tissue oxygen tension, increasing production in hypoxia (e.g., anaemia, cardiac or pulmonary disease). The *EPO* gene is one of several genes regulated by the hypoxic sensor pathway. The 3′-flanking region has a hypoxic response element necessary for induction of gene transcription in hypoxic cells. Hypoxia-inducible factor 1 is a transcription factor that binds to the hypoxia response element and acts as a master regulator of several genes responsive to hypoxia. EPO stimulates an increase in the proportion of bone marrow precursor cells committed to erythropoiesis by allowing a greater number of erythroid precursors to survive, and Colony Forming Unit-Erythroid (CFU-E) are stimulated to proliferate and differentiate. Increased production of EPO occurs in certain tumours such as renal cell carcinoma and when there is hypoxia, resulting in secondary erythrocytosis.

Haemoglobin synthesis

Hb performs the main functions of RBCs, carrying oxygen to the tissues and returning carbon dioxide from the tissues to the lungs. Each normal adult Hb molecule (HbA) has a molecular weight of 68 kDa and consists of two α- and two β-globin polypeptide chains ($\alpha_2\beta_2$). HbA makes up about 97% of the Hb in adults. Two other Hb types, HbA_2 ($\alpha_2\delta_2$) and HbF ($\alpha_2\gamma_2$), are found in adults in small amounts (1.5%–3.2% and <1%, respectively) (see Box 38.10).

Haem synthesis occurs in the mitochondria of the developing RBC (Fig. 38.6). The major rate-limiting step is the conversion of glycine and succinic acid to δ-aminolevulinic acid (ALA) by ALA synthase. Vitamin B_6 is a coenzyme for this reaction, which is inhibited by haem and stimulated by EPO. Two molecules of δ-ALA condense to form a pyrrole ring (porphobilinogen). These rings are then grouped in fours to produce protoporphyrins, and with the addition of iron, haem is formed. Haem is then inserted into the globin chains to form an Hb molecule. The structure of Hb is shown in Fig. 38.7.

Haemoglobin function

The biconcave shape of RBCs provides a large surface area for the uptake and release of oxygen and carbon dioxide. Hb becomes saturated with oxygen in the pulmonary capillaries, where the partial pressure of oxygen is high, and Hb has a high affinity for oxygen. Oxygen is released in the tissues where the partial pressure of oxygen is low, and Hb has a low affinity for oxygen.

In adult Hb, a haem group is bound to each of the four globin chains. Each haem group has a porphyrin ring with a ferrous atom, which can reversibly bind one oxygen molecule. The Hb molecule exists in two conformations, relaxed (R) and taut (T), corresponding to oxyhaemoglobin and deoxyhaemoglobin, respectively. The binding of one oxygen molecule to deoxyhaemoglobin increases the oxygen affinity of the remaining binding sites; this property is known as 'cooperativity' and is the reason for the sigmoid shape of the oxygen dissociation curve (Fig. 10.3). The binding of oxygen can also be influenced by secondary effectors such as hydrogen ions (acidity), carbon dioxide, and RBC bisphosphoglycerate (2,3-BPG). RBC metabolism produces 2,3-BPG from glycolysis. Binding of 2,3-BPG stabilizes the T conformation, reduces affinity for oxygen, and increases release of oxygen in the tissues. The P_{50} is the partial pressure of oxygen at which the Hb is 50% saturated with oxygen. When the primary limitation to oxygen transport is in the lungs (e.g., lung disease, high-altitude exposure), P_{50} is reduced to enhance oxygen loading. When the primary limitation is in the periphery (e.g., heavy exercise, anaemia) P_{50} is increased to enhance oxygen

unloading. Hydrogen ions and carbon dioxide added to blood also cause a reduction in the oxygen-binding affinity of Hb (Bohr effect), helping the exchange of carbon dioxide and oxygen in the tissues. A summary of normal RBC production and destruction is given in Fig. 38.8.

ANAEMIA

Anaemia is present when there is a decrease in Hb in the blood below age- and sex-specific reference limits (Box 38.1). Alterations in Hb concentration may occur because of changes in the plasma volume, as shown in Fig. 38.9. A reduction in plasma volume (e.g., dehydration) leads to a high Hb. An increase in plasma volume lowers the Hb concentration, even when this combined with a small increase in RBC volume, as occurs in pregnancy.

Anaemia can be classified in a variety of ways:

1. Decreased production or increased destruction
2. Inherited or acquired
3. By MCV (Fig. 38.4):
   - Hypochromic microcytic with a low MCV
   - Normochromic normocytic with a normal MCV
   - Macrocytic with a high MCV

Although there is some biological rationale for classification, some types of anaemia can present in more than one category.

Box 38.2 Techniques for obtaining bone marrow

Explain the technique to the patient and obtain consent.

Aspiration

- Site: usually the iliac crest
- Give local anaesthetic injection
- Use a special bone marrow needle (e.g., Salah)
- Aspirate marrow
- Make smear with glass slide
- Stain with:
  - Romanowsky technique
  - Perls' reaction (acid ferrocyanide) for iron

Trephine

Indications

- Better assessment of cellularity (e.g., aplastic anaemia)
- Better assessment of presence of infiltration or fibrosis

Technique

- Site: usually the posterior iliac crest
- Give local anaesthetic injection
- Use special needle (e.g., Jamshidi, which is longer and wider than for aspiration)
- Obtain core of bone
- Fix in formalin; decalcify (this takes a few days)
- Stain with:
  - Haematoxylin and eosin
  - Reticulin stain

Clinical features

Patients with anaemia may be asymptomatic. A slowly falling concentration of Hb allows for haemodynamic compensation and enhancement of the oxygen-carrying capacity of the blood. A rise in 2,3-BPG causes a shift of the oxygen dissociation curve to the right, so that oxygen is more readily given up to tissues. Where blood loss is rapid, more severe symptoms occur, particularly in older adults.

Symptoms

The symptoms of anaemia are non-specific and include breathlessness, fatigue, headaches, palpitations, and faintness (Fig. 38.1). Anaemia exacerbates cardiorespiratory problems (e.g., angina or intermittent claudication precipitated by anaemia). A good way to assess the effects of anaemia is to ask about breathlessness in relation to different levels of exertion such as walking on the flat or climbing a flight of stairs.

Signs

- Pallor
- Tachycardia
- Systolic flow murmur
- Cardiac failure

Specific signs seen in different types of anaemia include:

- Koilonychia: spoon-shaped nails seen in longstanding iron-deficiency anaemia
- Jaundice: haemolytic anaemia
- Bone deformities: thalassaemia major
- Leg ulcers: sickle cell disease

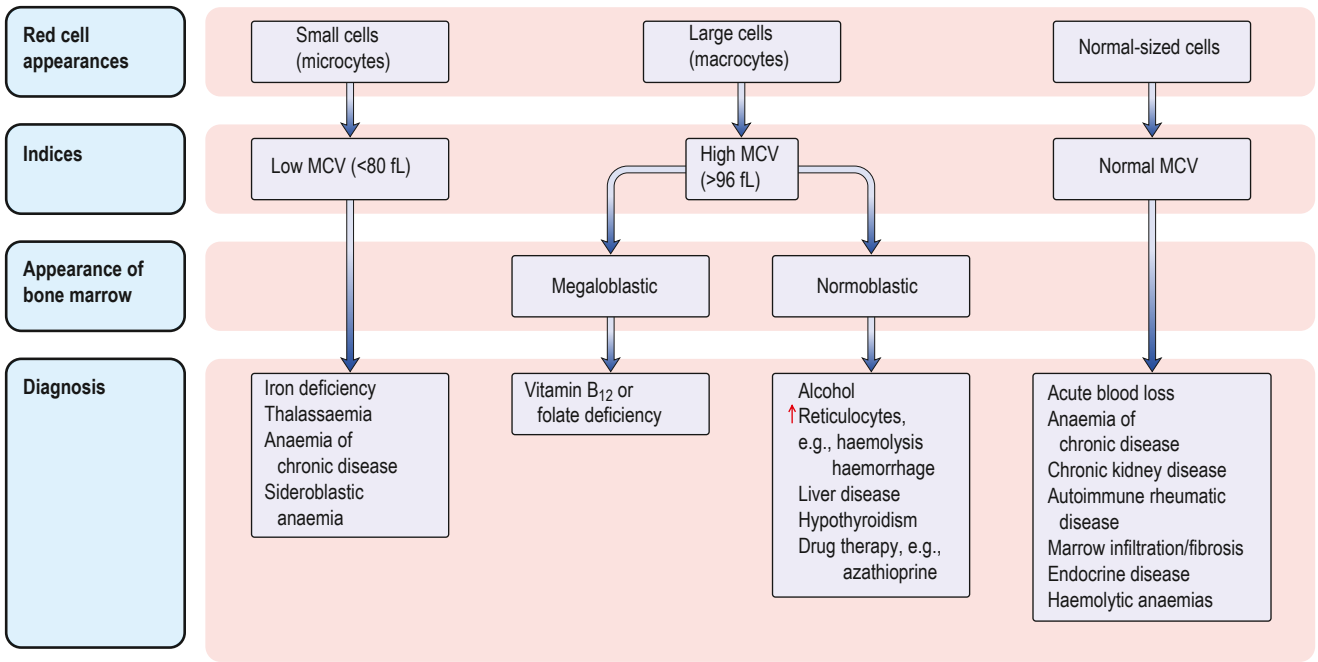

Fig. 38.4 Classification of anaemia. *fL,* Femtolitres; *MCV,* mean corpuscular volume; *RBC,* red blood cell.

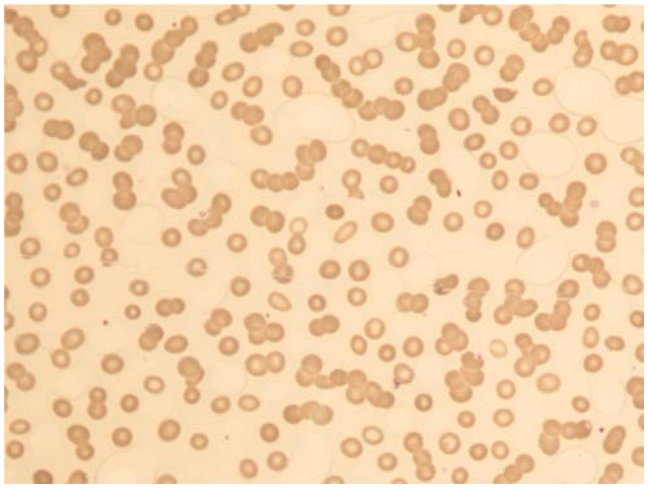

Fig. 38.5 Peripheral blood film (total magnification 400×) showing rouleaux formation in the red blood cells. In states of increased plasma protein concentration (e.g., infection, inflammation, paraprotein), the discoid red blood cells stack together like coins.

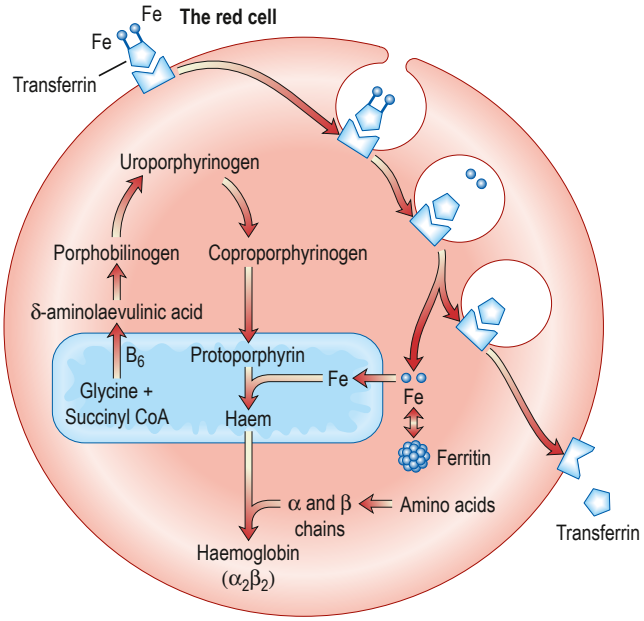

Fig. 38.6 Haemoglobin (Hb) synthesis. Transferrin attaches to a surface receptor on developing red blood cells. Iron is released and transported to the mitochondria, where it combines with protoporphyrin to form haem. Protoporphyrin itself is manufactured from glycine and succinyl CoA. Haem combines with α and β chains (formed on ribosomes) to make Hb.

Anaemia is not a final diagnosis. A cause should always be sought.

Investigations

Peripheral blood

A low Hb should be evaluated with:

- RBC indices
- WCC
- Platelet count
- Reticulocyte count (indicates marrow activity)
- Blood film: abnormal RBC morphology may indicate the diagnosis (Fig. 38.10).

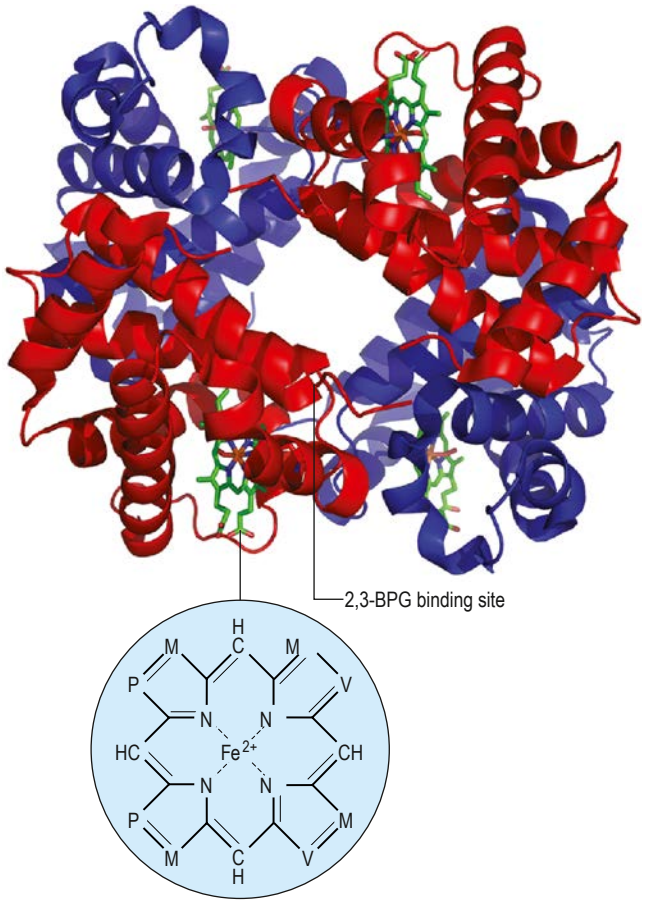

Fig. 38.7 Model of the haemoglobin molecule showing α *(red)* and β *(blue)* chains. Bisphosphoglycerate (2,3-BPG) binds in the centre of the molecule and stabilizes the deoxygenated form by cross-linking the β chains. *M,* Methyl; *P,* propionic acid; *V,* vinyl.

A dimorphic blood film is when two populations of RBCs are seen:

- 'Double deficiencies': e.g., combined iron and folate deficiency in coeliac disease or after treatment of anaemia with the appropriate haematinic when old RBCs exhibit the deficiency and new RBCs have a normal morphology
- After blood transfusion
- Inherited congenital sideroblastic anaemia (rare)

Bone marrow

Techniques for obtaining bone marrow are shown in Box 38.2. Bone marrow examination is performed to further investigate peripheral blood abnormalities:

- ***Aspiration:*** provides a film for microscopic examination of developing haemopoietic cell morphology. The liquid sample can also be used for immunophenotyping (assessment of the presence or absence of antigens on the surface of cells), cytogenetic investigations, assessment for molecular markers, or microbiological culture.
- ***Trephine:*** provides a core of bone that is processed as a histological specimen. It gives an overall view of bone marrow architecture, cellularity, and presence or absence of abnormal infiltrates. It can be also used for immunohistochemical investigations.

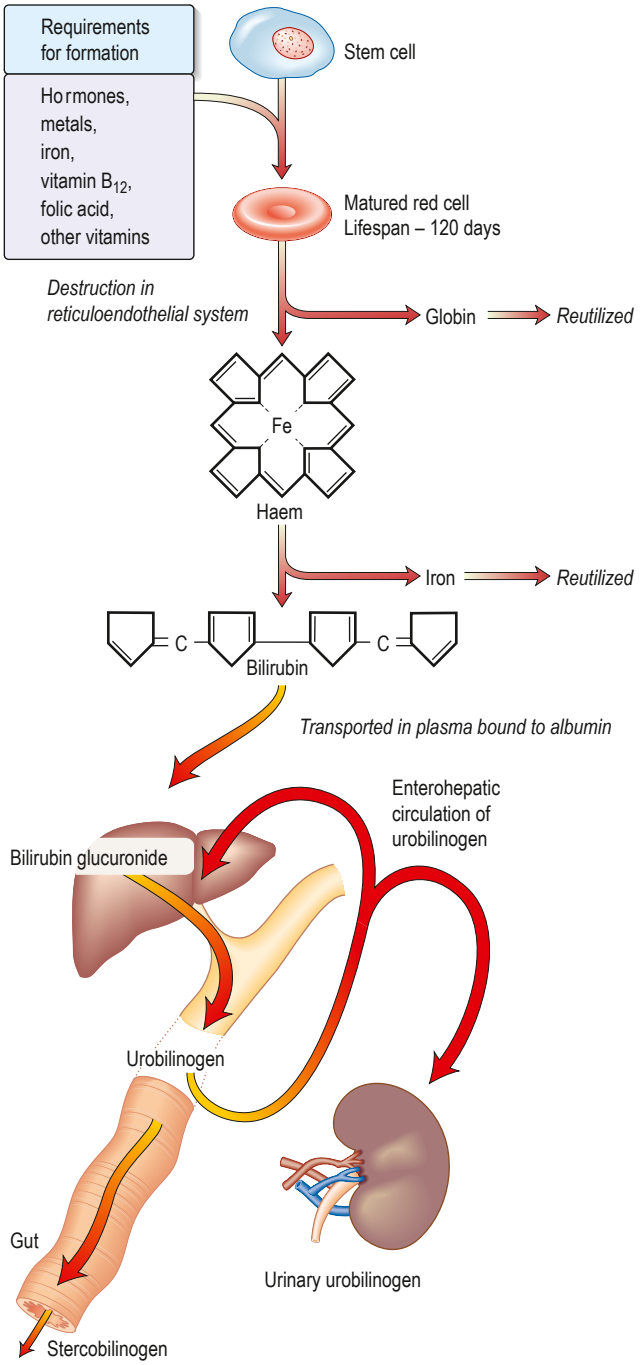

Fig. 38.8 **Red blood cell production and breakdown.**

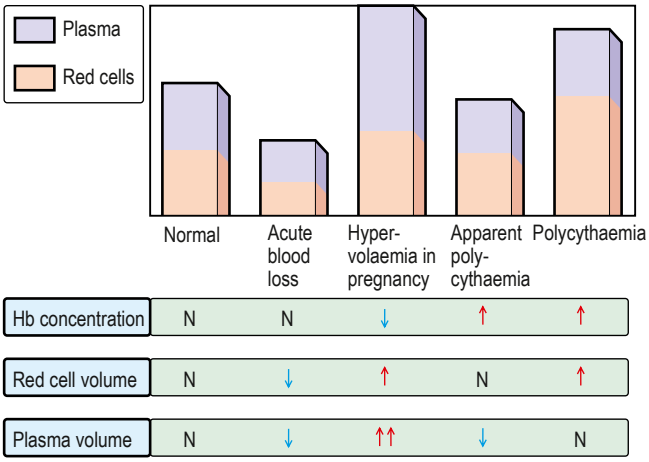

Fig. 38.9 **Alterations of haemoglobin (Hb) in relation to plasma.**

Fig. 38.10 **Hypochromic microcytic cells *(arrow)* on a blood film.** Poikilocytosis (variation in shape) and anisocytosis (variation in size) are seen.

The following are assessed:

- Cellularity of the marrow
- Type of erythropoiesis (e.g., normoblastic or megaloblastic)
- Morphology of all cell lines
- Cellularity of cell lines
- Infiltration of the marrow, e.g., presence of non-haemopoietic cells such as cancer cells
- Iron stores

MICROCYTIC ANAEMIA

Microcytic anaemia most commonly results from iron deficiency, the most common cause of anaemia globally, affecting 30% of the world's population. This occurs because of the body's limited ability to absorb iron and frequent loss of iron in bleeding. Although iron is abundant, most is in the insoluble ferric (Fe^{3+}) form, which has poor bioavailability. Ferrous (Fe^{2+}) iron is more readily absorbed. When anaemia of chronic disease is long-standing, iron restriction leads to microcytosis. Other causes of a microcytic hypochromic anaemia (Fig. 38.4) include defects in globin production (thalassaemia) or defects in haem synthesis, termed 'sideroblastic anaemia'.

Iron

Dietary intake

The average daily diet in the UK contains 15 to 20 mg of iron, although normally only 10% of this is absorbed. Absorption may be increased to 20% to 30% in iron deficiency and pregnancy. The main dietary iron is non-haem iron derived mainly from cereals commonly fortified with iron. Availability is affected by other dietary constituents such as calcium and tannins preventing absorption. Haem iron is derived from Hb and myoglobin in red or organ meats.

Absorption

Factors influencing iron and haem iron absorption are shown in Fig. 38.11 and Box 38.3.

Dietary haem iron is more rapidly absorbed than non-haem iron derived from vegetables and grains. Most haem is absorbed

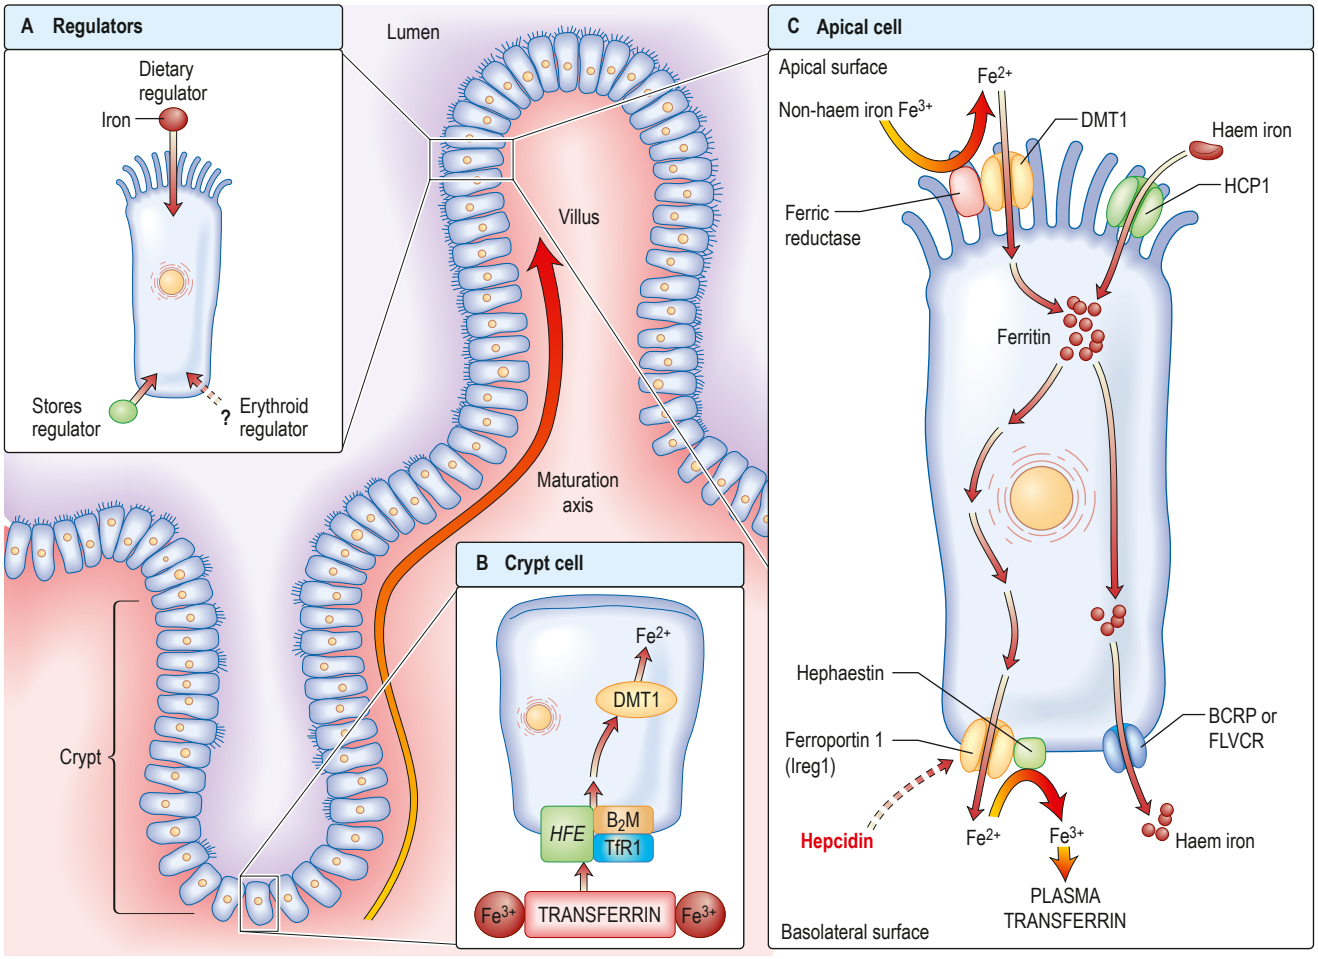

Fig. 38.11 Iron absorption. (A) *Regulation of the absorption of intestinal iron*. The iron-absorbing cells of the duodenal epithelium originate in the intestinal crypts and migrate toward the tip of the villus as they differentiate (maturation axis). Absorption of intestinal iron is regulated by at least three independent mechanisms. First, iron absorption is influenced by recent dietary iron intake *(dietary regulator)*. After a large dietary bolus, absorptive cells are resistant to iron uptake for several days. Second, iron absorption can be modulated considerably in response to body iron stores *(stores regulator)*. Third, a signal communicates the state of bone marrow erythropoiesis to the intestine *(erythroid regulator)*. **(B)** ***Duodenal crypt cells*** sense body iron status through the binding of transferrin to the *HFE/B_2M/TfR1* gene complex. Cytosolic enzymes change the oxidative state of iron from ferric (Fe^{3+}) to ferrous (Fe^{2+}). A decrease in crypt cell iron concentration upregulates the divalent metal transporter (DMT1). This increases as crypt cells migrate up the villus and become mature absorptive cells. **(C)** ***Apical cell***. Dietary iron is reduced from the ferric to the ferrous state by the brush border ferric reductase. ***DMT1*** facilitates iron absorption from the intestinal lumen. The export proteins (e.g., ferroportin 1, hephaestin) transfer iron from the enterocyte into the circulation, depending on hepcidin concentration. A second pathway absorbs intact haem iron into the circulation via breast cancer resistant protein (BCRP) and feline leukaemia virus subgroup C (FLVCR). *B_2M,* β_2-Microglobulin; *HCP1,* haem carrier protein-1; *HFE,* hereditary haemochromatosis gene; *TfR1,* transferrin receptor.

in the proximal intestine, with absorptive capacity decreasing distally. The intestinal haem transporter haem carrier protein 1 is highly expressed in the duodenum and is upregulated by hypoxia and iron deficiency. Some haem iron may be absorbed intact into the circulation via enterocytes by two exporter proteins, breast cancer resistant protein and feline leukaemia virus subgroup C (Fig. 38.11).

Non-haem iron absorption occurs primarily in the duodenum. Non-haem iron is dissolved in the low pH of the stomach and reduced from ferric to ferrous form by brush border ferric reductase. Cells in duodenal crypts sense the body's iron requirements and retain this information as they mature into cells capable of absorbing iron at the tips of the villi. Divalent metal transporter 1 (previously termed natural resistance-associated macrophage protein) transports iron and other metals across the apical (luminal) surface of the mucosal cells in the small intestine.

Inside the mucosal cell, iron may be transferred across the cell to the plasma or stored as ferritin. The body's iron status at the time the absorptive cell developed from the crypt cell is probably the crucial deciding factor. Iron stored as ferritin is lost into the gut lumen when mucosal cells are shed; this regulates iron homeostasis. Transport of iron across the basolateral surface of mucosal cells involves a transporter protein, ferroportin 1 through its iron-responsive element. This transporter protein requires hephaestin, an accessory multicopper protein (Fig. 38.11).

Box 38.3 Factors that influence iron absorption

- Haem iron is absorbed better than non-haem iron.
- Ferrous iron is absorbed better than ferric iron.
- Gastric acidity helps to keep iron in the ferrous state and soluble in the upper gut.
- Formation of insoluble complexes with phytate or phosphate decreases iron absorption.
- Iron absorption is increased with low iron stores and increased erythropoietic activity (e.g., bleeding, haemolysis, high altitude).
- Absorption is decreased in iron overload, except in hereditary haemochromatosis, in which it is increased.

The body iron content is closely regulated by control of iron absorption. There is no physiological mechanism for eliminating excess iron. The key molecule regulating iron absorption is ***hepcidin***, a 25-amino acid peptide synthesized in the liver. Hepcidin regulates the iron-exporting activity of ferroportin by binding to it causing internalization and degradation, thereby decreasing iron efflux from iron-exporting tissues into plasma. High concentrations of hepcidin that occur in inflammation states via inflammatory cytokines (e.g., IL-6) destroy ferroportin and limit iron absorption. Low concentrations of hepcidin in anaemia, low iron stores, and hypoxia encourage iron absorption. In haemochromatosis (Fig. 23.27), mutations in the genes *HFE, HJV,* and *TfR2* interrupt hepcidin synthesis. A deficiency of hepcidin in intestinal cells leads to less bound ferroportin and more iron release into the plasma, which accumulates in an uncontrolled fashion into target organs such as the liver, pancreas, heart, and endocrine glands.

Anaemias characterized by ineffective erythropoiesis (e.g., thalassaemia) are associated with excessive and inappropriate iron absorption. This is caused by down-regulation of hepcidin and up-regulation of ferroportin, mediated by a newly identified hormone, erythroferrone, produced by developing erythroblasts.

Transport in the blood

Normal serum iron concentration is about 13 to 32 μmol/L; there is diurnal variation, with higher concentrations in the morning. Serum iron is not used clinically for assessing iron status. Iron is transported in the plasma bound to transferrin, a protein synthesized in the liver. Each transferrin molecule binds two atoms of ferric iron and is normally one-third saturated. Most iron bound to transferrin comes from macrophages in the reticuloendothelial system and not from iron absorbed by the intestine. These recycle the iron obtained from senescent RBCs when Hb is broken down, a process that mostly occurs in the spleen. Transferrin-bound iron attaches by specific receptors to erythroblasts and reticulocytes in the marrow and the iron is removed (Fig. 38.6). In an average adult male, 20 mg of iron, chiefly obtained from RBC breakdown in the macrophages of the reticuloendothelial system, is incorporated into Hb every day.

Iron stores

About two-thirds of total body iron is in the circulation as Hb (2.5–3.0 g in a normal adult male). The rest is stored in reticuloendothelial cells, hepatocytes, and skeletal muscle cells (0.5–1.5 g). About two-thirds of this is stored as ferritin and one-third as haemosiderin. Small amounts of iron are found in plasma (~4 mg bound to transferrin), with some in myoglobin and enzymes.

Ferritin is a water-soluble complex of iron and protein. It is present in small amounts in plasma, proportional to the degree of iron loading. It is also an acute-phase protein and rises with infection and inflammation. It is more easily mobilized than haemosiderin for Hb formation.

Haemosiderin is an insoluble iron–protein complex found in macrophages in the bone marrow, liver, and spleen. Unlike ferritin, it is visible on light microscopy in tissue sections and bone marrow films after staining by Perls' reaction.

Requirements

Each day, 0.5 to 1.0 mg of iron is lost in faeces, urine, and sweat. Menstruation results in the loss of 30 to 40 mL of blood per cycle, an average of about 0.5 to 0.7 mg of iron per day. Menstrual blood loss more than 100 mL usually results in iron deficiency because increased iron absorption from the gut cannot compensate. Demand for iron increases during growth (~0.6 mg/day) and pregnancy (1–2 mg/day).

Increases in the body iron content (haemochromatosis) are classified into:

- ***Hereditary haemochromatosis:*** a mutation in the *HFE* gene or other iron-controlling proteins causes uncontrolled increased iron absorption.
- ***Secondary haemochromatosis*** (transfusion siderosis): iron overload in conditions treated by regular blood transfusion.
- ***Non-transfusional iron overload:*** ineffective erythropoiesis drives uncontrolled iron absorption from the gut via erythroferrone, e.g., thalassaemia, sideroblastic anaemia, congenital dyserythropoietic anaemia.

Iron deficiency

Iron-deficiency anaemia develops when there is inadequate iron for Hb synthesis. The causes are:

- Increased loss: blood loss
- Increased demands (e.g., growth and pregnancy)
- Decreased absorption (e.g., post-gastrectomy, poor dietary intake).

Most iron deficiency is caused by blood loss, usually from the uterus or gastrointestinal (GI) tract. A common cause of iron deficiency worldwide is blood loss from the GI tract resulting from parasites (e.g., hookworm). A poor diet, predominantly containing vegetables, contributes to the high prevalence of iron deficiency in low-resource settings. Iron deficiency is not uncommon in infancy, when iron intake is insufficient for the demands of growth. It is more prevalent in preterm infants and when introduction of solid food is delayed.

Clinical features

Symptoms of anaemia are described earlier (see 'Anaemia' section). Features of longstanding iron deficiency include:

- Brittle nails
- Spoon-shaped nails (koilonychia)
- Atrophy of the papillae of the tongue
- Angular stomatitis
- Brittle hair
- A syndrome of dysphagia and glossitis (Plummer–Vinson or Paterson–Brown–Kelly syndrome).

The diagnosis of iron-deficiency anaemia requires a clinical history, including dietary intake, use of non-steroidal anti-inflammatory drugs (NSAIDs) associated with GI bleeding, and presence of blood in the faeces. In females, careful enquiry should be made about the duration of periods, the occurrence of clots, and the number of sanitary towels or tampons used (three to five per day is normal).

Box 38.4 Microcytic anaemia: differential diagnosis

	Iron deficiency	Anaemia of chronic disease	Thalassaemia trait (α or β)	Sideroblastic anaemia
MCV	Decreased	Low normal or normal	Very low for degree of anaemia	Decreased in inherited type but often increased in acquired type
Serum iron	Decreased	Decreased	Normal	Increased
Serum TIBC	Increased	Decreased	Normal	Normal
Serum ferritin	Decreased	Normal or increased	Normal	Increased
Serum soluble transfer receptors	Increased	Normal	Normal or increased	Normal or increased
Iron in marrow	Absent	Present	Present	Present
Iron in erythroblasts	Absent	Absent or decreased	Present	Ring forms

MCV, Mean corpuscular volume of red blood cells; *TIBC,* total iron-binding capacity.

Investigations

- ***Blood count and film*** (Fig. 38.10). RBCs are microcytic (MCV <80 fL) and hypochromic (mean corpuscular haemoglobin (MCH) <27 pg). There are poikilocytosis (variation in shape) and anisocytosis (variation in size).
- ***Transferrin saturation.*** Serum iron is not helpful in the assessment of clinical iron status. Transferrin saturation is a more accurate measure: iron deficiency is present when this decreases below 19% (Box 38.4).
- ***Serum ferritin*** concentration reflects stored iron. Reference values are 30 to 300 μg/L (11.6–144 nmol/L) in males and 30 to 200 μg/L (5.8–96 nmol/L) in premenopausal females. In simple iron deficiency, a low serum ferritin confirms the diagnosis. However, ferritin is an acute-phase reactant and concentrations increase in inflammatory or malignant diseases, and in liver damage. These can result in a normal or raised ferritin concentration in iron deficiency. Very high concentrations of ferritin may occur in hepatitis and haemophagocytic lymphohistiocytosis.
- ***Serum soluble transferrin receptors.*** The number of transferrin receptors released into the serum from bone marrow erythroblasts increases in iron deficiency and correlate with estimation of iron stores from bone marrow aspiration. This can help distinguish iron deficiency from anaemia of chronic disease (Box 38.4) and may avoid the need for bone marrow examination. It may be helpful in the investigation of complicated causes of anaemia. However, it is not readily available in routine clinical practice.
- ***Serum hepcidin concentrations*** are possible in research settings but are not routinely available because of a lack of standardization of assays.
- ***Other investigations*** as indicated by clinical history and examination. Investigations of the GI tract are often required to determine the cause of iron deficiency.

Differential diagnosis

Anaemia with microcytosis and hypochromia does not always indicate iron deficiency. The most common other causes are thalassaemia, sideroblastic anaemia, and anaemia of chronic disease. In these disorders, iron stores are normal or increased. The differential diagnosis of microcytic anaemia is shown in Box 38.4.

Management

The correct management of iron deficiency is to find and treat the underlying cause and to give iron to correct anaemia and replace iron stores. Taking iron increases the Hb concentration of patients with iron deficiency by approximately 10 g/L per week unless other factors, such as bleeding, are present.

Oral iron is all that is required in most cases. The best preparation is ferrous sulphate. A 200-mg tablet provides 60 mg of elemental iron. Emerging evidence supports a quick rise in serum hepcidin concentrations after an oral iron dose, suppressing the absorption of subsequent doses. Prescription of oral iron replacement should therefore be no more than once daily. Optimizing absorption includes taking the tablet 30 minutes before food with a small amount of orange juice. (Vitamin C helps convert ferric to ferrous iron, aiding absorption.) Tannins in tea inhibit iron absorption and should be avoided.

In low-income countries, distribution of iron tablets and fortification of food are the main approaches. However, iron supplementation programmes have been ineffective, mainly because of poor adherence. There are also concerns regarding an increased risk of infection in areas where malaria and other parasites are endemic.

Oral iron should be given for long enough to correct the Hb concentration and to replenish iron stores; this can take 6 months. The most common causes of failure to respond to oral iron are:

- Reduced adherence
- Ongoing blood loss
- Incorrect diagnosis e.g., thalassaemia trait.

These possibilities should be considered before parenteral iron is used. Parenteral iron is indicated in those with intolerance to oral preparations, severe malabsorption, and chronic disease (e.g., inflammatory bowel disease). Iron stores are replaced faster with parenteral iron than with oral iron, but the haematological response is no quicker. Parenteral iron can be given by slow intravenous infusion of low-molecular-weight iron dextran (requires a test dose because of a risk of anaphylactoid reactions), iron sucrose, ferric carboxymaltose, or iron isomaltoside 1000; oral iron should be discontinued when intravenous treatment is given.

Anaemia of chronic disease

One of the most common types of anaemia, particularly in hospitalized patients, is anaemia of chronic disease, occurring in chronic inflammatory diseases such as Crohn's disease, rheumatoid arthritis, SLE, polymyalgia rheumatica, and malignancy or with chronic infections such as tuberculosis (TB). There are decreased release of iron from the bone marrow to developing erythroblasts, an inadequate EPO response to anaemia, and decreased RBC survival.

Serum iron and total iron-binding capacity are low. Serum ferritin is normal or raised because of the inflammatory process. Serum soluble transferrin receptor concentration is normal

(Box 38.4). Stainable iron is present in the bone marrow, but iron is not seen in developing erythroblasts. Patients do not respond to oral iron therapy. Treatment is, in general, that of the underlying disorder, though intravenous iron may help. Recombinant EPO therapy is used in renal anaemia (see Chapter 26) and occasionally in inflammatory disease (rheumatoid arthritis, inflammatory bowel disease).

High concentrations of hepcidin expression play a key role (see earlier). Because numerous pathogens are dependent on iron for multiplication, responding to infection and inflammation by increasing hepcidin concentrations and sequestering iron from the circulation is evolutionarily advantageous; IL-6 production during infection is a potent driver of hepcidin expression. However, hepcidin concentrations lead to poor delivery of iron to the marrow and hence anaemia. Measurement of hepcidin concentrations is emerging as a useful test to help distinguish anaemia of chronic disease from iron-deficiency anaemia.

Sideroblastic anaemia

Sideroblastic anaemias are inherited or acquired disorders characterized by a refractory anaemia (that does not respond to haematinic supplementation), a variable number of hypochromic cells in the peripheral blood, and excess iron and ring sideroblasts in the bone marrow. The presence of ring sideroblasts is the diagnostic feature of sideroblastic anaemia. Accumulation of iron in the mitochondria of erythroblasts is caused by disordered haem synthesis, forming a ring of iron granules around the nucleus that can be seen with Perls' reaction. The blood film is often dimorphic; ineffective haem synthesis is responsible for the microcytic hypochromic cells. Sideroblastic anaemias can be inherited as an X-linked or autosomal recessive forms. A structural defect in δ-ALA synthase, the pyridoxine-dependent enzyme responsible for the first step in haem synthesis (Fig. 38.6), is responsible for the X-linked form. Acquired causes include myeloproliferative disorders and myeloid leukaemia. Primary acquired sideroblastic anaemia is one of the myelodysplastic syndromes and is responsible for most cases of sideroblastic anaemia in adults. It can also be caused by drugs (e.g., isoniazid), alcohol misuse, or lead toxicity and can occur in other disorders such as rheumatoid arthritis, carcinomas, and megaloblastic and haemolytic anaemias.

Management

Some patients respond when drugs or alcohol are withdrawn if these are the causative agents. In occasional cases, there is a response to pyridoxine, particularly in the X-linked inherited form. Treatment with folic acid may be required to treat accompanying folate deficiency.

NORMOCYTIC ANAEMIA

Normocytic, normochromic anaemia (Fig. 38.4) is seen in:

- Anaemia of chronic disease
- Endocrine disorders, e.g., hypopituitarism, hypothyroidism, and hypoadrenalism
- Haematological disorders, e.g., aplastic anaemia and some haemolytic anaemias
- Early blood loss
- Inherited causes, e.g., Diamond-Blackfan anaemia, which usually presents in the first year of life and is associated with an extremely low reticulocyte count.

MACROCYTIC ANAEMIAS

These can be divided into megaloblastic and non-megaloblastic types, depending on bone marrow findings.

Megaloblastic anaemia

Megaloblastic anaemia is characterized by the presence erythroblasts in the bone marrow with delayed nuclear maturation because of defective DNA synthesis (megaloblasts). Megaloblasts are large and have large immature nuclei. The nuclear chromatin is more finely dispersed than normal and has an open, stippled appearance (Fig. 38.12). In addition, giant metamyelocytes are frequently seen. These cells are about twice the size of normal cells and often have twisted nuclei. Megaloblastic changes occur in:

- Vitamin B_{12} deficiency and abnormal vitamin B_{12} metabolism
- Folic acid deficiency and abnormal folate metabolism
- Other defects of DNA synthesis
  - Congenital enzyme deficiencies in DNA synthesis, e.g., orotic aciduria
  - Drugs interfering with DNA synthesis, e.g., hydroxycarbamide (hydroxyurea), azathioprine
- Myelodysplasia caused by dyserythropoiesis.

Haematological findings

- The MCV is characteristically greater than 96 fL unless there is a coexisting cause of microcytosis, in which case there may be a dimorphic picture with a normal or low average MCV.

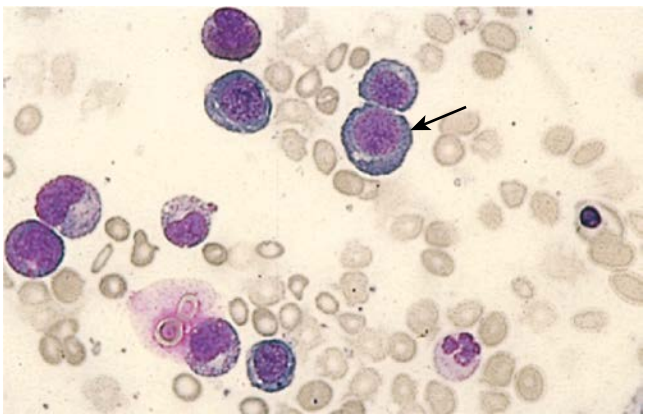

Fig. 38.12 Megaloblasts *(arrow)* in the bone marrow.

- The peripheral blood film shows oval macrocytes with hypersegmented polymorphs with six or more lobes in the nucleus (Fig. 38.13).
- If severe, there may be leucopenia and thrombocytopenia.
- Lactate dehydrogenase (LDH) is typically elevated, reflecting ineffective erythropoiesis.

Biochemical basis of megaloblastic anaemia

The key biochemical problem common to both vitamin B_{12} and folate deficiencies is a block in DNA synthesis owing to an inability to methylate deoxyuridine monophosphate to deoxythymidine monophosphate, which is used to build DNA (Fig. 38.14). The methyl group is supplied by the folate coenzyme methylene tetrahydrofolate (THF). Deficiency of folate reduces the supply of this coenzyme; deficiency of vitamin B_{12} slows the demethylation of methyltetrahydrofolate (methyl THF) and prevents cells from receiving THF for synthesis of methylene TFH polyglutamate.

Other congenital and acquired forms of megaloblastic anaemia are caused by interference with purine or pyrimidine synthesis, inhibiting DNA synthesis.

Vitamin B_{12} (cobalamin)

Vitamin B_{12} is synthesized by certain microorganisms. Humans are dependent on animal sources. It is found in meat, fish, eggs and milk but not in plants. Vitamin B_{12} is not usually destroyed by cooking. The average daily diet contains 5 to 30 μg of vitamin B_{12}, of which 2 to 3 μg is absorbed. The average adult stores 2 to 3 mg, mainly in the liver. It may take 2 years or more after absorptive failure before vitamin B_{12} deficiency develops because daily losses are small (1–2 μg).

Vitamin B_{12} consists of a small group of compounds, the cobalamins, which are composed of a planar group with a central cobalt atom (corrin ring) and a nucleotide set at right angles. Vitamin B_{12} was first crystallized as cyanocobalamin, but the main natural cobalamins have deoxyadenosyl-, methyl-, and hydroxocobalamin groups attached to the cobalt atom. Deoxyadenosylcobalamin is a coenzyme for the conversion of methylmalonyl CoA to succinyl CoA. Hence, measurement of methylmalonic acid was once used as a test for vitamin B_{12} deficiency, but this is no longer routine.

Absorption and transport

Vitamin B_{12} is liberated from protein complexes in food by gastric enzymes. It then binds to a vitamin B_{12}–binding protein ('R' binder) related to plasma transcobalamin I (TCI) and derived from saliva.

Fig. 38.13 Macrocytes and a hypersegmented neutrophil *(arrow)* on a peripheral blood film.

Vitamin B_{12} is released from the 'R' binder by pancreatic enzymes and then becomes bound to intrinsic factor. Intrinsic factor is a GP with a molecular weight of 45 kDa secreted by gastric parietal cells along with H^+ ions. It combines with vitamin B_{12} and carries it to a specific receptor on the surface of the mucosa of the ileum, cubilin. Vitamin B_{12} enters the ileal cells and intrinsic factor remains in the lumen and is excreted. Vitamin B_{12} is transported from the enterocytes to the bone marrow and other tissues by the GP transcobalamin II (TCII). Vitamin B_{12} bound to TCII is known as holotranscobalamin or 'active B_{12}' because this is the form taken up by cells. Although TCII is the essential carrier protein for vitamin B_{12}, the amount of B_{12} on TCII is low. Vitamin B_{12} in plasma is mainly bound to TCI (70%–90%). Only about 1% of an oral dose of B_{12} is absorbed 'passively' without the need for intrinsic factor.

Vitamin B_{12} deficiency

There are several causes of B_{12} deficiency and abnormal B_{12} metabolism (Box 38.5). The most common cause of vitamin B_{12} deficiency in adults is pernicious anaemia (PA). Malabsorption of vitamin B_{12} because of pancreatitis, coeliac disease, or treatment with metformin is mild and does not usually result in significant deficiency.

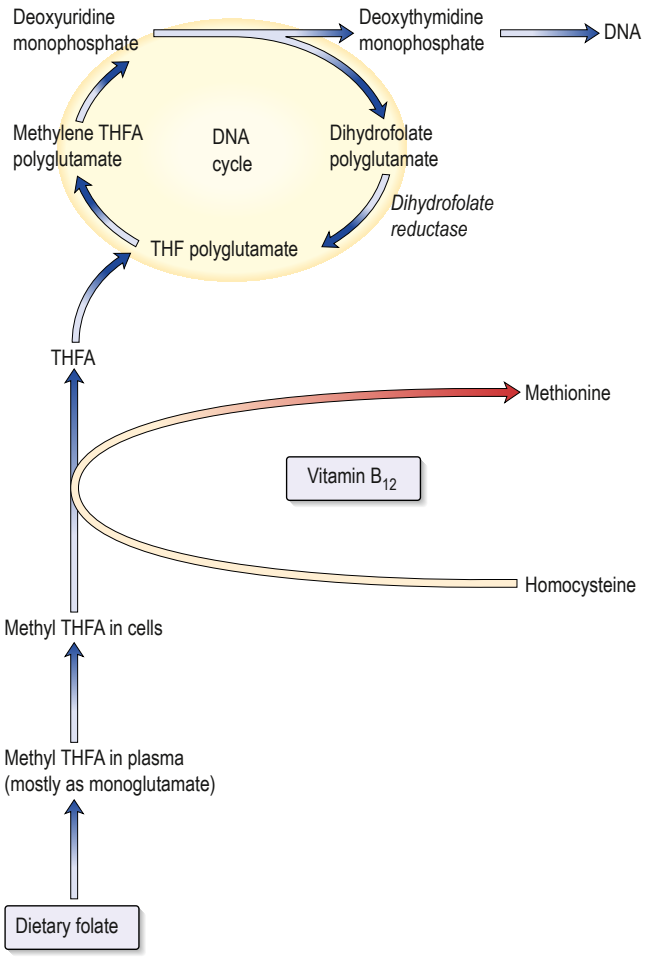

Fig. 38.14 Biochemical basis of megaloblastic anaemia. The metabolic relationship between vitamin B_{12} and folate and their role in DNA synthesis. Megaloblastic anaemia is characterized by erythroblasts with delayed nuclear maturation caused by defective DNA synthesis. *THFA,* Tetrahydrofolate.

Box 38.5 Vitamin B_{12} deficiency and abnormal B_{12} utilization

Low dietary intake
- Veganism

Impaired absorption

Stomach
- Pernicious anaemia
- Gastrectomy or bariatric surgery
- Congenital deficiency of intrinsic factor

Small bowel
- Ileal disease or resection
- Bacterial overgrowth
- Tropical sprue
- Fish tapeworm *(Diphyllobothrium latum)*

Abnormal utilization
- Congenital transcobalamin II deficiency
- Nitrous oxide (inactivates vitamin B_{12})

Pernicious anaemia

Pernicious anaemia (PA) is an autoimmune disorder with atrophic gastritis, loss of parietal cells in the gastric mucosa, consequent failure of intrinsic factor production, and vitamin B_{12} malabsorption. This disease is common in older adults: about 1 in 8000 aged older than 60 years are affected in the UK. It is seen in all ethnicities and is more common in females than males.

Pathogenesis

There is an association with other autoimmune diseases, particularly thyroid disease, Addison's disease, and vitiligo. Approximately 50% of all patients with PA have thyroid antibodies. There is a higher incidence of gastric carcinoma with PA (1%–3%) than in the general population.

Parietal cell antibodies are present in the serum in 90% of patients with PA but are also found in 10% of normal individuals. Conversely, intrinsic factor antibodies, although found in only 50% of patients with PA, are specific for this diagnosis.

Pathology

Fundal autoimmune gastritis is present, with plasma cell and lymphoid infiltration. The parietal and chief cells are replaced by mucin-secreting cells. Affected patients have achlorhydria and absent secretion of intrinsic factor. The histological abnormality can be improved by corticosteroid therapy, which supports an autoimmune basis for the disease.

Clinical features

The onset of PA is insidious, with progressively increasing symptoms of anaemia. Patients are sometimes said to have a lemon-yellow colour owing to a combination of pallor and mild jaundice caused by excess breakdown of Hb. A red, sore tongue (glossitis) and angular stomatitis are sometimes present.

Neurological changes, if left untreated for a long time, can be irreversible. Neurological abnormalities occur only with very low concentrations of serum B_{12} (<60 ng/L or 50 pmol/L) and occasionally in patients who are not clinically anaemic. The classical neurological features are those of a polyneuropathy progressively involving peripheral nerves and the posterior and eventually lateral columns of the spinal cord (subacute combined degeneration). Patients present with symmetrical paraesthesiae in the fingers and toes, early loss of vibration sense and proprioception, progressive weakness, and ataxia. Paraplegia may result. Dementia, psychiatric problems, hallucinations, delusions, and optic atrophy may also occur.

Investigations

- ***Haematological findings*** show features of a megaloblastic anaemia.
- ***Bone marrow*** shows typical features of megaloblastic erythropoiesis (Fig. 38.12), although it is frequently not sampled in cases of straightforward macrocytic anaemia with a low serum vitamin B_{12}.
- ***Serum bilirubin and LDH*** may be raised because of ineffective erythropoiesis. Normally, a minor fraction of serum bilirubin results from premature breakdown of newly formed RBCs in the bone marrow. In many megaloblastic anaemias, in which destruction of developing RBCs increased, serum bilirubin can be elevated.
- ***Serum vitamin B_{12}*** is usually well below 160 ng/L, which is the lower end of the reference range. Serum vitamin B_{12} can be assayed using radio-isotope dilution or immunological assays. Numerous factors can affect B_{12} concentrations, such as pregnancy and the oral contraceptive pill, which lower it.
- ***Holotranscobalamin*** is the 'active' fraction of cobalamin. Measurement may be a better marker for vitamin B_{12} deficiency than serum vitamin B_{12} concentration.
- ***Serum methylmalonic acid and homocysteine*** are raised in B_{12} deficiency, but testing is recommended only in complex cases (e.g., a strong suspicion of vitamin B_{12} deficiency with normal vitamin B_{12} concentration).

Absorption tests

Vitamin B_{12} absorption tests are no longer performed in the UK because radioactive vitamin B_{12} is not available.

Gastrointestinal investigations

In PA, there is achlorhydria. Intubation studies can be performed to confirm this but are rarely carried out in routine practice. Endoscopy or barium meal examination of the stomach is performed only if gastric symptoms are present.

Differential diagnosis

Vitamin B_{12} deficiency must be differentiated from other causes of megaloblastic anaemia, principally folate deficiency, but usually this is quite clear from blood concentrations.

PA should be distinguished from other causes of vitamin B_{12} deficiency by testing for intrinsic factor antibodies (Box 38.5). Patients negative for intrinsic factor antibodies with no other cause of vitamin B_{12} deficiency may still have PA.

Folic acid

Folic acid monoglutamate is not present in nature but occurs as polyglutamates. Folates present in food are polyglutamates in reduced dihydrofolate or THF forms. Polyglutamates are broken down to monoglutamates in the upper GI tract. During the absorptive process, these are converted to methyl THF monoglutamate, which is the main form in the serum. The first step in which methyl THF entering cells from the plasma is converted into folate polyglutamates involves methylation of homocysteine to methionine and requires both methylcobalamin and methyl THF as coenzymes. Intracellular polyglutamates are the active forms of folate and act as coenzymes in the transfer of single carbon units in amino acid metabolism and DNA synthesis (Fig. 38.14).

Dietary intake

Folate is found in green vegetables (e.g., spinach, broccoli) and offal (e.g., liver, kidney). Cooking loses 60% to 90% of folate. The minimal daily requirement is about 100 μg.

Folate deficiency

Causes of folate deficiency are shown in **Box 38.6**. The main cause is poor intake, which may occur alone or in combination with excessive utilization or malabsorption. The body's reserves of folate are about 10 mg. In a deficient diet, folate deficiency develops over the course of about 4 months, but folate deficiency may develop rapidly in patients who have both a poor intake and excess utilization (e.g., critical illness).

Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce the incidence of neural tube defects. In the USA and Canada, mandatory fortification of grain products, such as bread, flour, and rice, has substantially improved folate status and been associated with a significant reduction in neural tube defects. There is controversy about the role of folate supplementation in the reduction of cardiovascular and cerebrovascular disease by lowering homocysteine concentrations.

Clinical features

Patients with folate deficiency may be asymptomatic or may present with symptoms of anaemia or the underlying cause. Glossitis can occur. Unlike with vitamin B_{12} deficiency, neuropathy does not occur.

Investigations

The haematological findings are those of a megaloblastic anaemia.

Blood measurements

Serum folate reflects recent folate status and intake. It is usually measured by immunological methods; a concentration below 3 μg/L (7 nmol/L) is indicative of deficiency. The amount of folate in the RBCs is a measure of tissue folate over the lifetime of RBCs; a concentration below 150 μg/L (340 nmol/L) is consistent with folate deficiency, however, serum folate concentration, rather than red cell folate, is usually sufficient for the diagnosis of folate deficiency.

Further investigations

In many cases, the cause is not obvious from the clinical picture or dietary history. Occult GI disease should then be suspected, and appropriate investigations, such as small bowel biopsy, may be performed.

Box 38.6 Causes of folate deficiency

Nutritional (major cause)

Poor intake
- Poor social conditions
- Starvation
- Alcohol excess (also causes impaired utilization)
- Cancer

Gastrointestinal disease
- Partial gastrectomy or bariatric surgery
- Coeliac disease
- Crohn's disease

Antifolate drugs
- Anticonvulsants
  - Phenytoin
  - Primidone
- Methotrexate
- Pyrimethamine
- Trimethoprim

Excess utilization

Physiological
- Pregnancy
- Lactation

Pathological
- Haematological disease with excess red blood cell production (e.g., haemolysis)
- Malignant disease with increased cell turnover
- Inflammatory disease
- Metabolic disease (e.g., homocystinuria)
- Haemodialysis or peritoneal dialysis

Malabsorption
- Small bowel disease (minor effect compared with inadequate intake)

Management and prevention of megaloblastic anaemia

Treatment depends on the type of deficiency. Blood transfusion is not usually indicated in patients with chronic anaemia; indeed, it can be dangerous to transfuse older adult patients because heart failure may be precipitated. Folic acid may produce a haematological response in vitamin B_{12} deficiency but may aggravate the neuropathy. Large doses of folic acid alone should therefore not be used to treat megaloblastic anaemia unless the serum vitamin B_{12} concentration is known to be normal. In severely ill patients, it may be necessary to treat with both folic acid and vitamin B_{12} while awaiting serum concentrations.

Management of vitamin B_{12} deficiency

Hydroxocobalamin 1000 μg is given intramuscularly to a total of 5 to 6 mg over the course of 2 weeks followed by 1000 μg every 3 months for the rest of the patient's life. Clinical improvement may occur within 48 hours. A reticulocytosis can be seen 2 to 3 days after starting therapy, peaking at 5 to 7 days. Improvement of the polyneuropathy may occur over 6 to 12 months, but longstanding spinal cord damage is irreversible. Hypokalaemia can occur, and if severe, supplements should be given. Iron deficiency often develops in the first few weeks of therapy. Hyperuricaemia also occurs, but clinical gout is uncommon. In patients who have had a total gastrectomy or an ileal resection, vitamin B_{12} should be monitored; if concentrations are low, prophylactic intramuscular vitamin B_{12} should be given. Oral treatment with vitamin B_{12} may be used (e.g., in vegans), but good adherence is required.

Management of folate deficiency

Folate deficiency can be corrected by giving 5 mg of folic acid daily. The same haematological response occurs as with treatment of vitamin B_{12} deficiency. Treatment should be given for about 4 months to replace body stores. Any underlying cause, such as coeliac disease, should be treated.

Prophylactic folic acid (400 μg daily) is recommended for all females planning a pregnancy and in early pregnancy to reduce neural tube defects. Females who have had a child with a neural tube defect should take higher dose (5 mg) folic acid daily before and during subsequent pregnancies.

Prophylactic folic acid (5 mg/day or weekly), is given to patients with chronic haematological disorders in which there is rapid cell turnover and to those undergoing renal dialysis.

Macrocytosis without megaloblastic changes

A raised MCV with macrocytosis on the peripheral blood film can occur with a normoblastic rather than a megaloblastic bone marrow.

A common ***physiological*** cause of macrocytosis is pregnancy. Macrocytosis may also occur in the newborn. Common ***pathological*** causes are:

- Alcohol excess
- Liver disease
- Reticulocytosis (e.g., caused by haemolysis)
- Hypothyroidism
- Some haematological disorders (e.g., aplastic anaemia, myelodysplasia, pure RBC aplasia, multiple myeloma)
- Drugs (e.g., hydroxycarbamide, azathioprine)
- Cold agglutinins caused by autoagglutination of RBCs (the MCV decreases to normal with warming of the sample to 37°C).

In all these conditions, concentrations of vitamin B_{12} and folate are normal. Exact mechanisms in each case are uncertain, but in some, there is increased lipid deposition in the RBC membrane. An increased number of reticulocytes also leads to a raised MCV because they are large cells. High alcohol consumption is a frequent cause of a raised MCV and can be used as a surrogate marker for monitoring excess alcohol consumption. Megaloblastic anaemia can also occur in alcohol excess because of a toxic effect of alcohol on erythropoiesis or dietary folate deficiency.

ANAEMIA CAUSED BY MARROW FAILURE (APLASTIC ANAEMIA)

Aplastic anaemia is defined as pancytopenia with hypocellularity (aplasia) of the bone marrow; there are no leukaemic, cancerous, or other abnormal cells in the peripheral blood or bone marrow. It is usually an acquired condition but may rarely be inherited.

Aplastic anaemia is caused by a reduction in the number of pluripotent stem cells (**Fig. 38.3F**), together with either a fault in those remaining or an immune reaction against them so they are unable to repopulate the bone marrow. Failure of only one cell line may also occur, resulting in isolated deficiencies such as the absence of RBC precursors in pure RBC aplasia. Evolution to myelodysplasia, paroxysmal nocturnal haemoglobinuria (PNH), or acute myeloid leukaemia occurs in some cases, probably owing to the emergence of an abnormal clone of haemopoietic cells.

Aetiology

Causes of aplasia are shown in **Box 38.7**. Immune mechanisms are probably responsible for most cases of idiopathic acquired aplastic anaemia and play a part in the persistence of many secondary cases. Activated cytotoxic T cells in the blood and bone marrow are responsible for the bone marrow failure.

Many drugs may cause marrow aplasia. Cytotoxic drugs such as busulfan and doxorubicin are expected to cause transient aplasia with therapeutic use. However, some individuals develop aplasia due to sensitivity to non-cytotoxic drugs such as chloramphenicol, gold, carbimazole, chlorpromazine, phenytoin, ribavirin, tolbutamide, NSAIDs, and many others for which aplasia is reported as a rare side-effect.

? Box 38.7 Causes of aplastic anaemia

Primary
- Inherited e.g., Fanconi anaemia
- Idiopathic (67% of cases)

Secondary
- Chemicals e.g., benzene, toluene, glue sniffing
- Drugs
  - Chemotherapy
  - Antibiotics e.g., chloramphenicol, gold, penicillamine, phenytoin, carbamazepine, carbimazole, azathioprine
- Insecticides
- Ionizing radiation
- Infections
  - Viral e.g., hepatitis, Epstein–Barr virus, human immunodeficiency virus, erythrovirus
  - Other e.g., tuberculosis
- Paroxysmal nocturnal haemoglobinuria
- Miscellaneous e.g., pregnancy

Inherited aplastic anaemias are rare. Multiple gene mutations have been identified in genes involved in DNA repair, ribosomal processing, and telomere maintenance. Fanconi anaemia is an autosomal recessive condition with skeletal, skin, eye, renal, and central nervous system abnormalities. It usually presents between the ages of 5 and 10 years and is associated with an increased risk of malignancies.

Clinical features

The clinical manifestations of marrow failure from any cause are anaemia, bleeding, and infection. Bleeding is often the predominant initial presentation of aplastic anaemia with bruising on minimal trauma or blood blisters in the mouth. Physical findings include ecchymoses, bleeding gums, and epistaxis. Mouth infections are common. Lymphadenopathy and hepatosplenomegaly are rare in aplastic anaemia.

Investigations

- Pancytopenia
- The virtual absence of reticulocytes
- A hypocellular or aplastic bone marrow with increased fat spaces (**Fig. 38.15**)

Differential diagnosis

Aplastic anaemia must be differentiated from other causes of pancytopenia (**Box 38.8**). A bone marrow trephine is essential for assessment of the bone marrow cellularity.

Management and prognosis

Treatment of patients with aplastic anaemia depends on the underlying cause and the likelihood of spontaneous recovery of blood counts. Careful attention to supportive care is essential while awaiting bone marrow recovery. In some cases, specific treatment can be used to accelerate marrow recovery.

The main risk is infection and stringent measures should be undertaken to avoid this. Any suspicion of infection in a severely neutropenic patient (neutrophil count $<0.5 \times 10^9$/L) should receive broad-spectrum parenteral antibiotics. Supportive care, including transfusions of RBCs and platelets, should be given as necessary. The cause of the aplastic anaemia must be eliminated if possible.

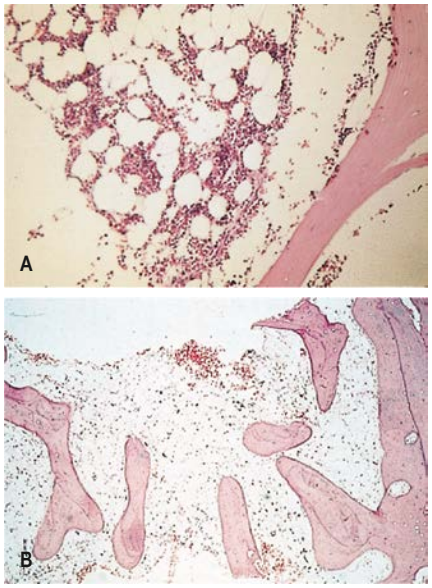

Fig. 38.15 Bone marrow trephine biopsies in low-power view. **(A)** Normal cellularity. **(B)** Hypocellularity in aplastic anaemia.

Box 38.8 Causes of pancytopenia

- Aplastic anaemia (Box 38.7)
- Drugs
- Megaloblastic anaemia
- Bone marrow infiltration or replacement
  - Hodgkin and non-Hodgkin lymphoma
  - Acute leukaemia
  - Myeloma
  - Bone metastases
  - Myelofibrosis
- Hypersplenism
- Systemic lupus erythematosus
- Disseminated tuberculosis
- Paroxysmal nocturnal haemoglobinuria
- Overwhelming sepsis

The course of aplastic anaemia can be variable, ranging from a rapid spontaneous remission to persistent, increasingly severe pancytopenia, which may lead to death through haemorrhage or infection. The most reliable prognostic factors are the number of neutrophils, reticulocytes, and platelets and the cellularity of the bone marrow.

Severe aplastic anaemia and a poor prognosis is associated with the presence of two of the following three features:

- Neutrophil count less than 0.5×10^9/L
- Platelet count less than 20×10^9/L
- Reticulocyte count less than 40×10^9/L.

Haemopoietic stem cells (allogeneic bone marrow transplantation) are the treatment of choice for patients with severe aplastic anaemia younger than the age of 40 years who have a human leucocyte antigen (HLA)-identical sibling donor, in whom it gives a 75% to 90% chance of long-term survival.

Immunosuppressive therapy is recommended for:

- Patients with severe disease older than the age of 40 years
- Younger patients with severe disease who do not have an HLA-identical sibling donor
- Patients who do not have severe disease but who are transfusion dependent.

Standard immunosuppressive treatment is antithymocyte globulin (ATG) and ciclosporin, which results in response rates of 60% to 80% and 5-year survival rates of 75% to 85%.

Stem cell transplantation using matched unrelated donors is an option for patients younger than the age of 50 years who have no matched sibling donor and who have failed to respond to immunosuppression. Results are improving (5-year survival rate, 65%–73%). The main problems are graft rejection, graft-versus-host disease, and viral infections.

Concentrations of haemopoietic growth factors (Fig. 38.3F) are normal or increased in most patients with aplastic anaemia, so these factors are ineffective as primary treatment.

Steroids should not be used to treat patients with severe aplastic anaemia except for those with serum sickness caused by ATG.

Adult pure RBC aplasia is associated with a thymoma in 5% to 15% of cases, and thymectomy occasionally induces a remission. It may also be associated with autoimmune disease or be idiopathic. Steroids, cyclophosphamide, azathioprine, and ciclosporin are effective treatments in some cases.

HAEMOLYTIC ANAEMIAS

Haemolytic anaemias are caused by increased destruction of RBCs. RBCs normally survive about 120 days, but in patients with haemolytic anaemias, survival times are considerably shortened. Breakdown of normal RBCs occurs in the macrophages of the bone marrow, liver, and spleen (Fig. 38.8).

Consequences of haemolysis

Shortening RBC survival does not always cause anaemia because there is a compensatory increase in RBC production by the bone marrow. If the RBC loss can be contained within the marrow's capacity for increased output, then haemolysis can exist without anaemia ***(compensated haemolytic disease)***. The bone marrow can raise its output by six to eight times by increasing the proportion of cells committed to erythropoiesis ***(erythroid hyperplasia)*** and by expanding the volume of active marrow. In addition, immature RBCs ***(reticulocytes)*** are released prematurely. These cells are larger than mature cells and stain with a light blue tinge on a peripheral blood film (termed ***polychromasia***) because of the presence of residual ribosomal RNA. Reticulocytes may be counted accurately as a percentage of all RBCs on a blood film using a supravital stain for residual RNA (e.g., new methylene blue).

Sites of haemolysis

Extravascular haemolysis

In most haemolytic conditions, RBC destruction is extravascular. The RBCs are removed from the circulation by macrophages in the reticuloendothelial system, particularly the spleen.

Intravascular haemolysis

When RBCs are rapidly destroyed within the circulation, Hb is liberated. This is initially bound to plasma haptoglobins, but these soon become saturated. Excess free plasma Hb is filtered by the

renal glomerulus and enters the urine, although small amounts are reabsorbed by the renal tubules, broken down, and deposited as ***haemosiderin***. This can be detected in a spun sediment of urine using Perls' reaction. Some free plasma Hb is oxidized to ***methaemoglobin***, which dissociates into ***ferrihaem*** and globin. ***Plasma haemopexin*** binds ferrihaem, but if its binding capacity is exceeded, ferrihaem becomes attached to albumin, forming ***methaemalbumin***. On spectrophotometry of the plasma, methaemalbumin forms a characteristic band; this is the basis of ***Schumm's test***.

The ***liver*** plays a major role in removing Hb bound to haptoglobin and haemopexin and any remaining free Hb. Free Hb is toxic and scavenges nitric oxide, which is a critical signalling molecule for smooth muscle relaxation and control of pulmonary pressure.

Evidence for haemolysis

- Increased RBC production accompanies increased RBC breakdown (Fig. 38.16).
- Demonstration of shortened RBC lifespan: RBC survival can be estimated from ^{51}Cr-labelled RBCs given intravenously, but this test is rarely performed.
- Intravascular haemolysis: haemosiderinuria, very low or absent haptoglobins, and the presence of methaemalbumin (positive Schumm's test).

Various laboratory studies will be necessary to determine the exact type of haemolytic anaemia present. Causes of haemolytic anaemias are shown in Box 38.9.

INHERITED HAEMOLYTIC ANAEMIA

Red blood cell membrane defects

The normal RBC membrane consists of a lipid bilayer crossed by integral proteins with an underlying lattice of proteins (cytoskeleton), including spectrin, actin, ankyrin, and protein 4.1, attached to integral proteins (Fig. 38.17).

Hereditary spherocytosis

Hereditary spherocytosis (HS) is the most common inherited haemolytic anaemia in Northern Europeans, affecting 1 in 5000. It can be inherited in autosomal dominant or recessive manners and by spontaneous *(de novo)* mutation. In the absence of a family history,

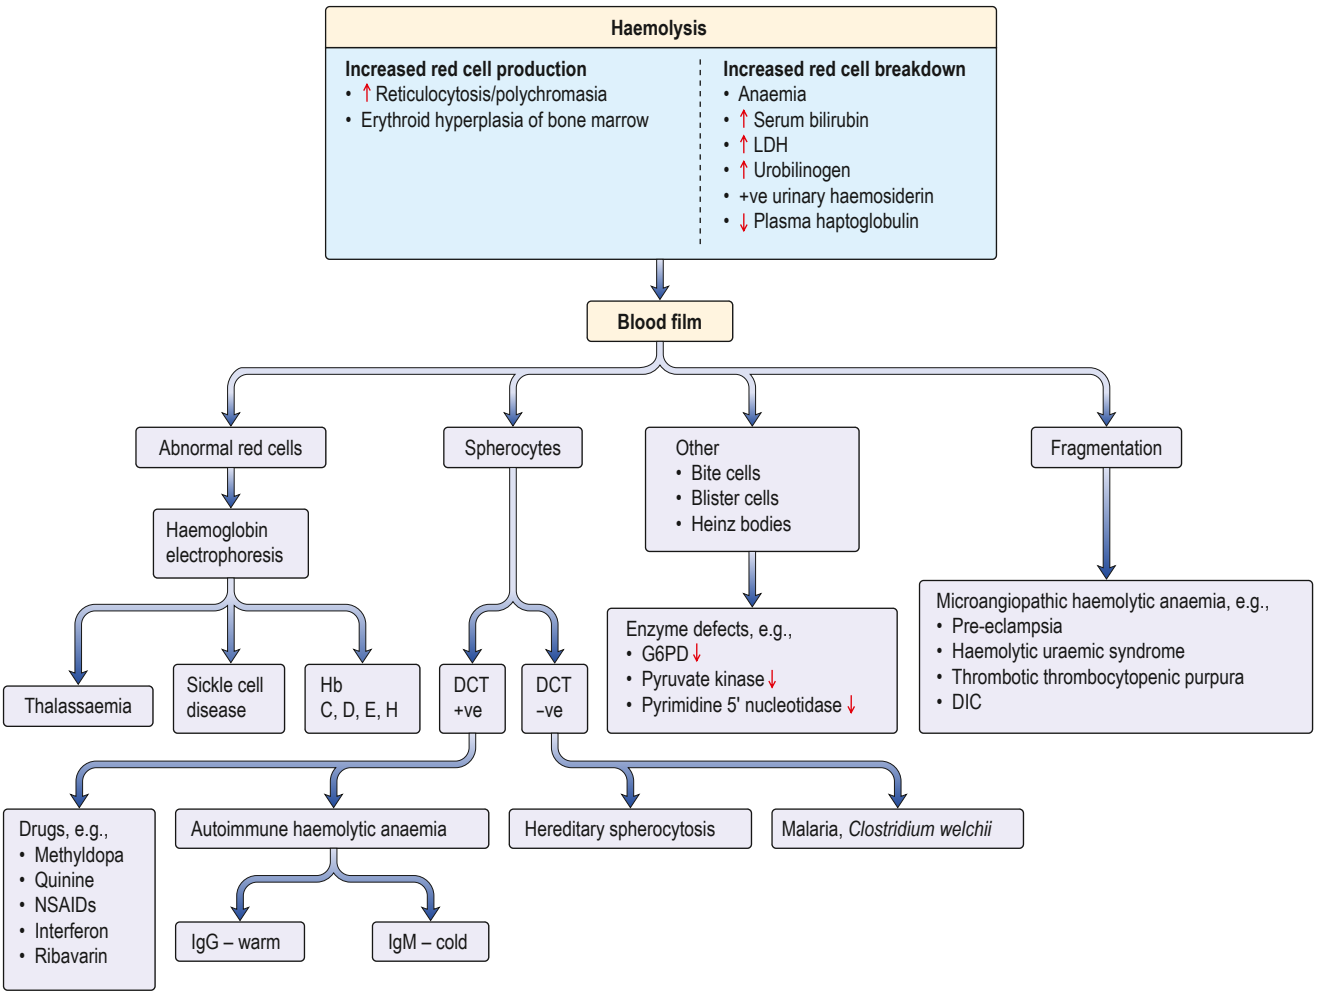

Fig. 38.16 Haemolysis: diagnostic and haematological features. *DCT,* Direct Coombs' test; *DIC,* disseminated intravascular coagulation; *G6PD,* glucose-6-phosphate dehydrogenase; *Hb,* haemoglobin; *Ig,* immunoglobulin; *LDH,* lactate dehydrogenase; *NSAIDs,* non-steroidal anti-inflammatory drugs; *RBC,* red blood cell.

the most important differential diagnosis is autoimmune haemolytic anaemia, which can usually be excluded by a negative direct antiglobulin test (DAT) result.

HS is caused by defects in RBC membrane proteins or the cytoskeleton, resulting in the cells losing part of the cell membrane as they pass through the spleen, possibly because the lipid bilayer is inadequately supported by the membrane skeleton. The best-characterized defect is a deficiency in the structural protein spectrin, but quantitative defects in other membrane proteins have been identified (Fig. 38.17), with ankyrin defects being the most common. The abnormal RBC membrane in HS is associated with an increased permeability to sodium. This requires an increased rate of active transport of sodium out of the cells, which is dependent on adenosine triphosphate (ATP), produced by glycolysis. The surface-to-volume ratio decreases, and cells become spherocytic. Spherocytes are more rigid and less deformable than normal RBCs. They are unable to pass through the splenic microcirculation so have a shortened lifespan.

? Box 38.9 Causes of haemolytic anaemia

Inherited

Red blood cell membrane defect
- Hereditary spherocytosis
- Hereditary elliptocytosis

Haemoglobin abnormalities
- Thalassaemia
- Sickle cell disease

Metabolic defects
- Glucose-6-phosphate dehydrogenase deficiency
- Pyruvate kinase deficiency
- Pyrimidine kinase deficiency

Acquired

Immune
- Autoimmune
  - Warm
  - Cold
- Alloimmune
  - Haemolytic transfusion reactions
  - Haemolytic disease of the newborn
  - After allogeneic bone marrow or organ transplantation
- Drug induced

Non-immune
- Acquired membrane defect: paroxysmal nocturnal haemoglobinuria
- Mechanical
  - Microangiopathic haemolytic anaemia
  - Valve prosthesis
  - March haemoglobinuria
- Secondary to systemic disease: kidney and liver failure
- Miscellaneous
  - Infections (e.g., malaria, mycoplasma)
  - *Clostridium perfringens (welchii)*, generalized sepsis
  - Drugs and chemicals causing damage to red blood cell membrane or oxidative haemolysis
  - Hypersplenism
  - Burns

Clinical features

The condition may present with jaundice at birth. However, jaundice can be delayed for many years. Some patients may go through life with no symptoms and are detected only during family studies. Patients may eventually develop anaemia; gallstones; splenomegaly; or, rarely, leg ulcers. As in many haemolytic anaemias, the disease course may be interrupted by aplastic, haemolytic, and megaloblastic crises. Aplastic anaemia usually occurs after infections, particularly with parvovirus, which infects developing erythroblasts and causes temporary abolition of RBC production, often requiring a blood transfusion for the patient to recover. Megaloblastic anaemia is the result of folate depletion caused by hyperactivity of the bone marrow. Chronic haemolysis leads to the formation of pigment gallstones.

Investigations

- ***Anaemia:*** usually mild but occasionally can be severe
- ***Blood film:*** spherocytes (Fig. 38.18) and polychromasia
- ***Haemolysis:*** raised serum bilirubin, urinary urobilinogen, and LDH (released by the destruction of RBCs)
- ***Osmotic fragility:*** RBCs placed in solutions of increasing hypotonicity take in water, swell, and eventually lyse. Spherocytes tolerate hypotonic solutions less well than normal biconcave RBCs. Osmotic fragility tests are infrequently carried out in routine practice but may be useful to confirm suspicion of spherocytosis on a blood film.

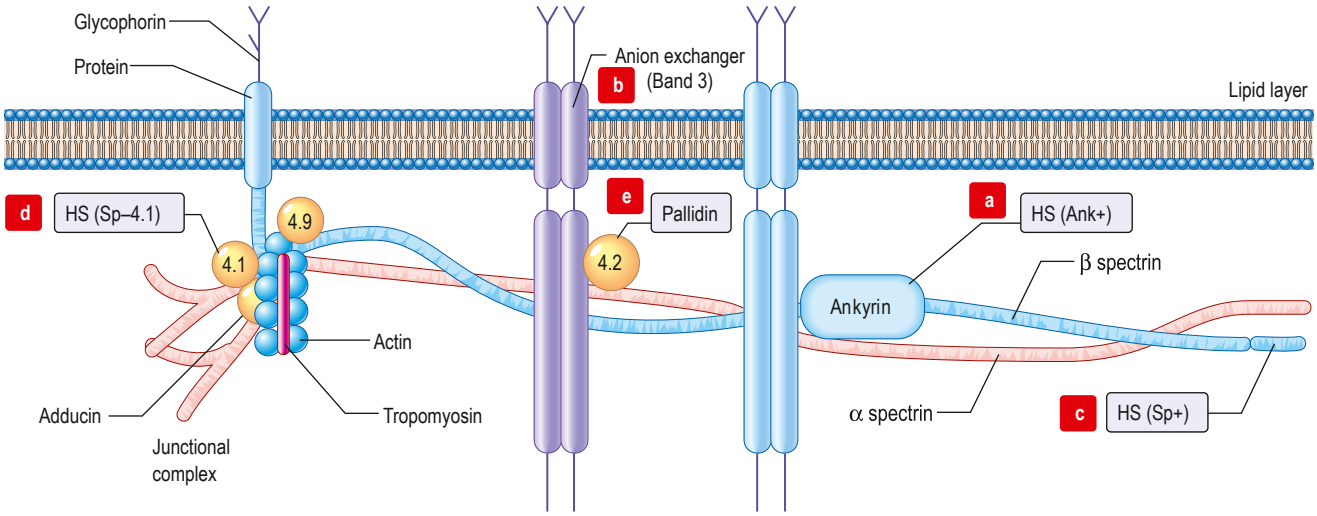

Fig. 38.17 Hereditary spherocytosis (HS) and hereditary elliptocytosis (HE): red blood cell membrane show the sites of the principal defects. Vertical interactions producing HS: **(a)** ***ankyrin mutation***, HS (Ank$^+$) producing deficiency (45% of cases); **(b)** HS ***band 3 deficiency*** (20%); **(c)** ***β-spectrin deficiency***, HS (Sp$^+$) (<20%); **(d)** ***abnormal spectrin/protein 4.1 binding***, HS (Sp–4.1); and **(e)** ***protein 4.2 (pallidin) deficiency***. These produce various autosomal dominant and recessive forms of the disease. Horizontal interactions producing HE: α-spectrin (80%), protein 4.1 (15%), and β spectrin (5%).

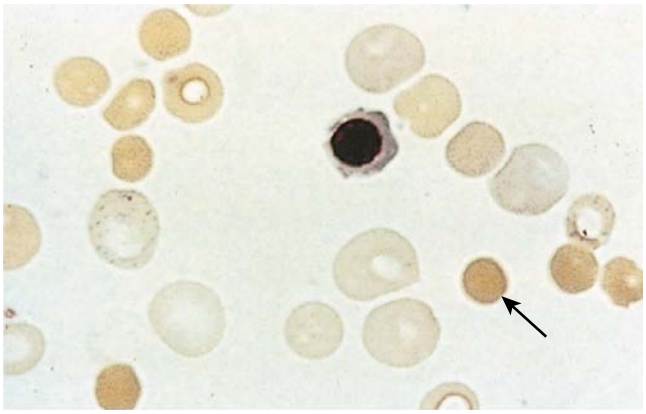

Fig. 38.18 Spherocytes *(arrow)*. This blood film also shows reticulocytes, polychromasia, and a nucleated erythroblast.

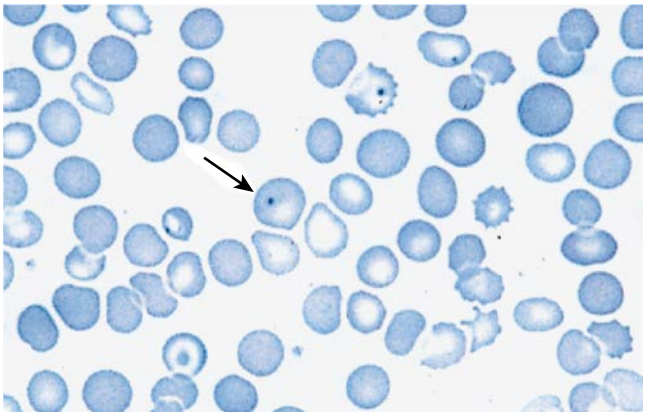

Fig. 38.19 Post-splenectomy film with Howell–Jolly bodies *(arrow)*. Target cells and irregularly contracted cells are also shown.

- ***Direct antiglobulin (Coombs') test:*** negative in HS, virtually ruling out autoimmune haemolytic anaemia in which spherocytes are also commonly present
- ***EMA dye binding.*** The dye eosin-5-maleimide binds to band 3, a RBC membrane protein. When assessed by flow cytometry, more than 20% reduced fluorescence is diagnostic of HS, providing a rapid diagnostic test.

Management

Most patients require no specific treatment. They may need occasional transfusions during pregnancy or intercurrent infections. Rarely, patients are transfusion dependent. For the remainder, splenectomy is indicated to relieve symptoms from anaemia or splenomegaly, reverse growth failure, and prevent recurrent gallstones. It is best to postpone splenectomy until after childhood because sudden overwhelming fatal infections, usually caused by encapsulated organisms such as pneumococci, may occur. Splenectomy should be preceded by appropriate immunization and followed by life-long penicillin prophylaxis. In addition to the well-known risk of bacterial infection, there is also a significant risk of adverse arterial and venous thromboembolic events after splenectomy, and this needs to be considered when deciding whether to proceed to splenectomy.

After splenectomy, spherocytes persist, but the Hb usually returns to normal because the RBCs are no longer destroyed. Other changes after a splenectomy include a raised WBC and platelet count, reticulocytosis, and the presence of Howell-Jolly bodies (nuclear remnants) on a blood film (Fig. 38.19).

Hereditary elliptocytosis

This disorder of the RBC membrane is inherited in an autosomal dominant manner and has a prevalence of 1 in 2500 in Whites. RBCs are elliptical because of deficiencies of protein 4.1 or the spectrin–actin–4.1 complex, which leads to weakness of horizontal protein interaction and the membrane defect (Fig. 38.17). Clinically, it is a similar condition to HS but milder. Only a minority of patients have anaemia, and only occasional individuals require splenectomy.

Rarely, HS or elliptocytosis may be inherited in a homozygous fashion, giving rise to a severe haemolytic anaemia sometimes necessitating splenectomy in early childhood (hereditary pyropoikilocytosis).

Hereditary stomatocytosis

Stomatocytes are RBCs in which the pale central area appears slit-like. Their presence in large numbers may occur in a hereditary haemolytic anaemia associated with a membrane defect, but excess alcohol intake is also a common cause. Although these hereditary conditions are very rare, a correct diagnosis is required; splenectomy is contraindicated because it may result in fatal thromboembolic events.

Haemoglobin abnormalities

In early embryonic life, haemoglobins Gower 1, Gower 2, and Portland predominate. Later, fetal haemoglobin (HbF), which has two α and two γ chains, is produced (Fig. 38.20). There is increasing synthesis of β chains from 13 weeks' gestation, and at term, there is 80% HbF and 20% HbA. Completion of the Hb switch from HbF to HbA occurs after birth, when the genes for γ chain production are further suppressed and there is rapid increase in synthesis of β chains. BCL IIA, a zinc finger protein, is one of several proteins that suppress γ gene expression and is a key genome editing target in the effort to reactivate HbF in adults with haemoglobinopathies. There is little HbF produced (normally <1%) by 6 months of age. The δ chain is synthesized just before birth, and HbA_2 ($\alpha_2\delta_2$) remains at a concentration of about 2% throughout adult life (Box 38.10).

A normal individual has four α-globin chain genes (Fig. 38.20), with two α-globin genes on each haploid genome (genes derived from one parent). These are situated close together on chromosome 16. The genes controlling the production of ε, γ, δ, and β chains are close together on chromosome 11. The globin genes are arranged on chromosomes 16 and 11 in the order in which they are expressed and combine to give different haemoglobins. Normal Hb synthesis is shown in Fig. 38.6. Understanding how globin chain production changes through fetal life and birth forms the basis of understanding how different genetic abnormalities lead to particular phenotypes.

Haemoglobinopathies

Abnormalities can occur in:

- Globin chain production: quantitative defect (e.g., thalassaemia)
- Structure of the globin chain: qualitative defect (e.g., sickle cell disease)
- Combined defects of globin chain production and structure (e.g., sickle cell β-thalassaemia, HbE).

The thalassaemias

The thalassaemias affect people throughout the world (Fig. 38.21), and at least 60 000 severely affected individuals are born every year. Normally, there is balanced (1:1) production of α and β chains. The defective synthesis of globin chains in thalassaemia leads to 'imbalanced' globin chain production, causing precipitation of the excess globin chains within the RBC precursors, resulting in ineffective erythropoiesis. Precipitation of globin chains in mature RBCs leads to haemolysis. This concept of globin chain imbalance is critical in understanding the relationship between genotype and phenotype (the greater the imbalance, the worse the phenotype), as well as understanding how novel therapies are used to ameliorate disease.

Beta-thalassaemia

In ***homozygous*** (identical mutations on both alleles) or ***compound heterozygous*** (different damaging mutations on both alleles) β-thalassaemia, either no normal β chains are produced (β^0) or β-chain production is very reduced (β^+). This leaves an excess of α chains, which precipitate in erythroblasts and RBCs, causing ineffective erythropoiesis and haemolysis.

In the carrier (heterozygous) state, excess α chains combine with δ and result in modestly increased quantities of HbA_2, which is used to screen for β-thalassaemia carrier status. Heterozygous β-thalassaemia carriers exhibit asymptomatic microcytosis with or without mild anaemia. Box 38.11 shows findings in the homozygote and heterozygote for the common types of β-thalassaemia.

Genetics

Molecular errors accounting for more than 200 genetic defects leading to β-thalassaemia have been characterized. Unlike in α-thalassaemia, the defects are mainly point mutations rather than gene deletions. The mutations result in defects in transcription, RNA splicing and modification, translation via frame shifts, and nonsense codons producing highly unstable β-globin that cannot be used.

Clinical syndromes

The terminology of clinical syndromes in thalassaemia have changed in recent years, moving away from the 'major' and 'minor' descriptions and now focusing on whether they are 'transfusion-dependent thalassaemias' (TDTs) or 'non–transfusion-dependent thalassaemias' (NTDTs) (Fig. 38.22). Patients who have NTDTs may require occasional blood transfusions (e.g., with infection, in pregnancy). Patients with NTDTs may be transferred to the TDT category if it is decided that regular transfusions would improve their growth, development, and wellbeing. 'Thalassaemia trait' is the term still used to describe the symptomless heterozygous carrier state.

Thalassaemia trait (carrier)

Heterozygous β-thalassaemia is asymptomatic. Anaemia is mild or absent. RBCs are hypochromic and microcytic with a low MCV and MCH, and the condition may be confused with iron deficiency. However, the two are easily distinguished because serum ferritin and iron stores are normal in thalassaemia trait (Box 38.4). The RDW is usually normal. Hb electrophoresis usually shows a raised HbA_2 and often a slightly raised HbF (Fig. 38.23). Iron should not be given in the absence of proven coincidental iron deficiency.

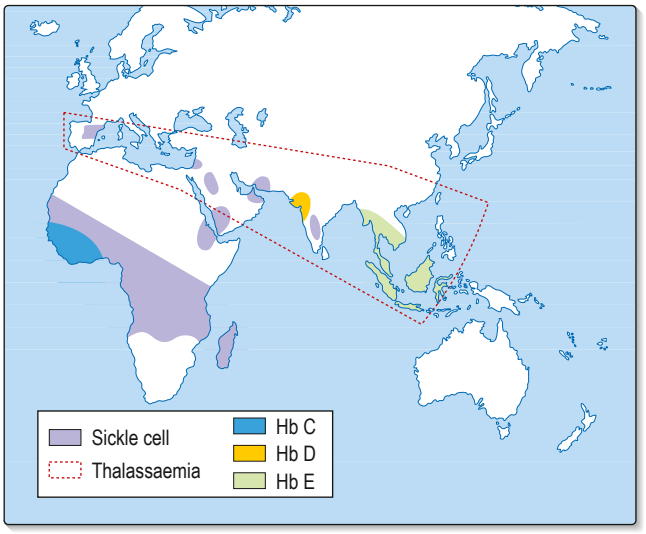

Fig. 38.21 Major haemoglobin (Hb) abnormalities: geographical distribution. Map lines delineate study areas and do not necessarily depict accepted national boundaries.

Box 38.11 Usual findings in β-thalassaemia

Type of thalassaemia	Homozygous or compound heterozygous phenotype	Heterozygous phenotype
β^+ (very reduced β-chain production)	**Transfusion-dependent anaemia** HbA (10%–30%) HbF (70%–90%) HbA_2 variable	**Mild reduction in Hb** HbA (90%–95%) Increased HbA_2 (3.6%–4.2%)
β^0 (no β-chain production)	**Transfusion-dependent anaemia** HbF (95%–98%) HbA_2 variable	**Mild reduction in Hb** HbA (90%–95%) Increased HbA_2 (4%–5%)

Hb, Haemoglobin.

Non–transfusion-dependent thalassaemia

This condition was previously referred to as 'thalassaemia intermedia'. Patients are symptomatic with moderate anaemia (Hb 70–100 g/L), but do not require regular transfusions.

NTDT occurs in patients in whom the effects of the excess α-globin chains are attenuated. This can be caused by a reduced production (co-inheritance of α-thalassaemia) or the α-chains being 'mopped up' by γ chains. Although there is usually very little γ-chain production after birth, some patients may co-inherit 'hereditary persistence of fetal Hb', in which γ-chain production is increased, sometimes to substantial amounts. By reducing α-chain production or increasing that of γ chains, there is less excess α-chain precipitation, thus helping to reduce the degree of globin imbalance and causing a consequent reduction in ineffective erythropoiesis and haemolysis.

NTDT may also arise from the inheritance of a heterozygous β^+ mutation with an excess of α-chain genes (e.g., triplicated α-chain genes). The more α-chain genes inherited, the greater the imbalance and the more severe the phenotype.

Patients with NTDTs may have splenomegaly and bone deformities. Recurrent leg ulcers, gallstones, and infections are also seen. Patients may be iron overloaded despite a lack of regular blood transfusions caused by excessive iron absorption resulting from the underlying dyserythropoiesis that drives Erfe production, suppressing hepcidin to undetectable concentrations.

Transfusion-dependent thalassaemia

This condition was previously referred to as 'thalassaemia major'. Most children affected by homozygous or compound heterozygous β-thalassaemia present during the first year of life with:

- Failure to thrive and recurrent bacterial infections
- Severe anaemia from 3 to 6 months, when the switch from γ- to β-chain production should normally occur
- Extramedullary haemopoiesis that leads to hepatosplenomegaly and bone expansion, giving rise to the classical thalassaemic facies (Fig. 38.24A).

Skull X-rays show the characteristic 'hair-on-end' appearance of bony trabeculation because of expansion of the bone marrow into cortical bone (Fig. 38.24B). Expansion of bone marrow can also be seen in plain films of the hand (Fig. 38.24C).

The classic features of untreated thalassaemia major are generally observed only when there is an absence of good blood transfusion support.

Management of symptomatic thalassaemia

The aims of treatment are to suppress ineffective erythropoiesis; prevent bony deformities; and allow normal activity, growth, and development.

- ***Long-term folic acid*** supplements are required.
- ***Regular transfusions*** should be given to keep the Hb above 100 g/L. Blood transfusions may be required every 4 to 6 weeks.
- ***Splenectomy*** was previously used to reduce transfusion requirements. However, these are associated with the development of

pulmonary hypertension and should be used only rarely and after discussion with a wide multidisciplinary team to ensure that the likely benefits outweigh risks. Splenectomy is usually delayed until after the age of 6 years because of the risk of infection; prophylaxis against infection is required (see 'The spleen' section).

- ***Iron overload*** caused by repeated transfusions (transfusion haemosiderosis) may lead to damage to the endocrine glands, liver, pancreas, and myocardium by adolescence if inadequate iron chelation results from a lack of adherence or access to chelators. Cardiomyopathy and associated cardiac tachyarrhythmias are the leading causes of morbidity and mortality. Magnetic resonance imaging (MRI) is useful for monitoring iron overload; both the heart (myocardial T_2-relaxation time) and the liver can be monitored. Iron chelation using the once-daily oral iron chelator deferasirox is now standard where it is available and economically accessible. Elsewhere, desferrioxamine remains the standard chelator, although it must be administered parenterally as an overnight subcutaneous infusion on 5 to 7 nights each week. Ascorbic acid 200 mg/day increases urinary excretion of iron in response to desferrioxamine. Deferiprone, an oral iron chelator, is usually used for cardiac iron overload or in combination with another chelator.
- ***Intensive treatment with desferrioxamine*** has been reported to reverse damage to the heart in patients with severe iron overload, but excessive doses of desferrioxamine may cause cataracts, retinal damage, and sensorineural deafness. Infection with *Yersinia enterocolitica* occurs in iron-loaded patients treated with desferrioxamine. Iron overload should be periodically assessed by measuring serum ferritin and assessing hepatic iron stores by MRI.
- ***Bone marrow transplantation*** has been used in young patients with HLA-matched siblings. It has been successful in suitable patients with a 3-year mortality rate of less than 5%, but there is a high mortality (>50%) in patients in poor condition with iron overload and liver dysfunction. Only 25% of patients have a sibling-matched donor.
- ***Prenatal diagnosis*** is discussed in the 'Prenatal screening and diagnosis of severe haemoglobin abnormalities' section.
- ***Gene therapy*** is detailed in Chapter 5.

Thalassaemia carrier	NTDT	TDT
Thalassaemia trait	'Thalassaemia intermedia'	'Thalassaemia major'
No transfusions	Intermittent transfusions	Transfusion dependence
Heterozygous for one of: • 1 or 2 deletions of α globin • β^0-globin mutation (no β globin produced) • β^+-globin mutation (small amount of β globin produced)	• HbH disease (3 α gene deletions) • HbE/β-thalassaemia • β-thalassaemia trait with co-inherited multiple copies of α globin • β-thalassaemia major with co-inherited hereditary persistence of fetal haemoglobin or α-thalassaemia	Homozygous or compound heterozygous for either: • β^0-globin mutation (no β globin produced) • β^+-globin mutation (small amount of β globin produced)

Fig. 38.22 Clinical syndromes in thalassaemia. The terms 'thalassaemia intermedia' and 'thalassaemia major' have been replaced by 'non–transfusion-dependent thalassaemia' (NTDT) and 'transfusion-dependent thalassaemia' (TDT). Patients can fluctuate between these categories, depending on their life circumstances. The phenotype of affected individuals is influenced by modifying factors such as the reactivation of γ globin or the co-inheritance of changes in the number of α-globin genes.

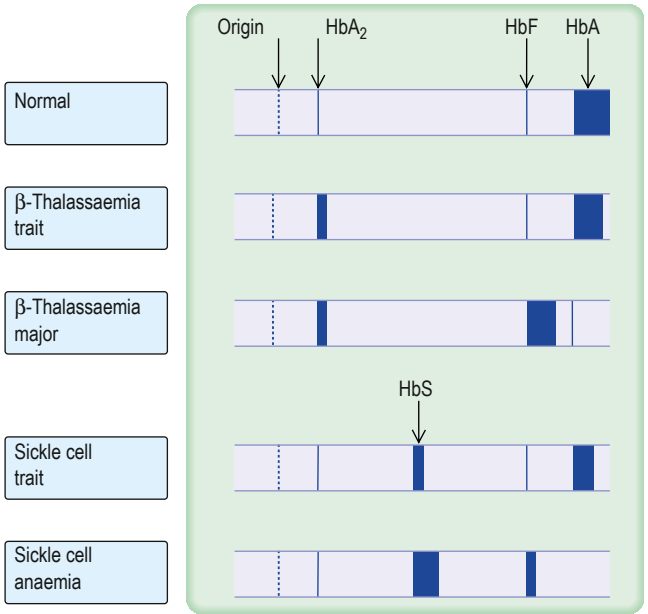

Fig. 38.23 Patterns of haemoglobin (Hb) electrophoresis.

Alpha-thalassaemia

Genetics

In contrast to β-thalassaemia, α-thalassaemia is often caused by gene deletions, although mutations of the α-globin genes may also occur. The gene for α-globin chains is duplicated on chromosome 16, meaning that a normal person has a total of four α-globin genes. Deletion of one α-chain gene (α^+) or both α-chain genes (α^0) on each chromosome 16 may occur (**Box 38.12**). The former is most common. Deletions arise during meiosis because of unequal crossover during non-homologous recombination, one of the main ways in which genetic variability arises. Although one of the gametes has a missing alpha gene, the other will have an excess of alpha genes, a term called 'triplicated alpha' (**Fig. 38.25A**). The risk to subsequent generations is more significant in α^0 than α^+ as depicted in **Fig. 38.25B**.

- ***Four-gene deletion*** (deletion of both genes on both chromosomes). There is no α-chain synthesis, and only Hb Barts (γ4) is present. Hb Barts cannot carry oxygen. This is incompatible with life (**Boxes 38.10 and 38.12**). Fetuses are pale and oedematous with enormous livers and spleens, a condition called 'hydrops fetalis'. If this is detected *in utero*, intrauterine transfusions can be given so that the fetus can grow and survive until term, at which point the baby will have TDT.
- ***Three-gene deletion.*** The severe reduction in α-chain synthesis results in HbH disease, which is common in parts of Asia. HbH has four β-chains, although patients may also have low concentrations of HbA and Hb Barts. HbA_2 is normal or reduced. HbH does not transport oxygen and precipitates in erythroblasts and erythrocytes. These patients have moderate anaemia (Hb 70–100 g/L) and splenomegaly (previously referred to as thalassaemia intermedia). The patients usually have NTDT.
- ***Two-gene deletion*** (α-thalassaemia trait). There is microcytosis with or without mild anaemia. HbH bodies may be seen on blood film staining with brilliant cresyl blue.

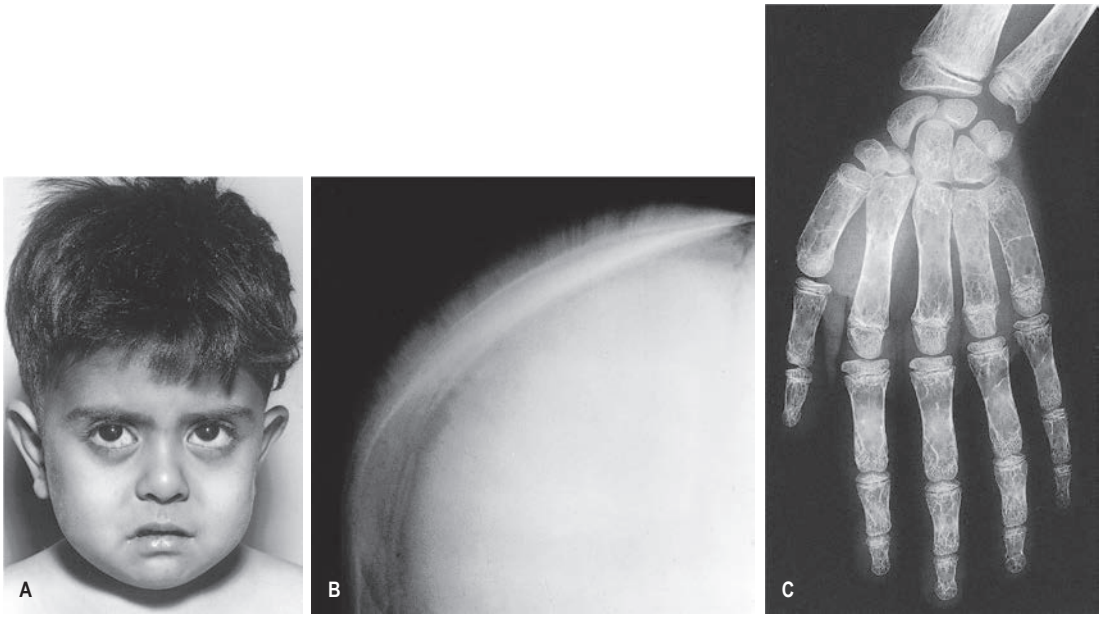

Fig. 38.24 Thalassaemia. (A) ***Child with thalassaemia*** showing the typical facial features. (B) ***Skull radiograph*** of a child with β-thalassaemia showing a 'hair-on-end' appearance. (C) ***Radiograph of a hand*** showing expansion of marrow and a thinned cortex.

Box 38.12 The α-thalassaemias

Number of α-globin genes deleted	Genotype[a]	Hb type	Clinical picture
4	−−/−−	Hb Barts (γ4)	Hydrops fetalis
3	−−/−α	HbH (β4)	Moderately severe anaemia Splenomegaly
2	−α/−α	HbA	Mild anaemia
	Or	Some HbH bodies	
	−−/αα		
1	αα/−α	HbA	Very mild/no anaemia

[a]The normal α-globin genotype is αα/αα (i.e., four α-globin genes present).
Hb, Haemoglobin.

- ***One-gene deletion.*** The blood picture is usually normal, but there microcytosis may be present.

Globin chain synthesis studies for the detection of a reduced ratio of α to β chains may be necessary for the definitive diagnosis of α-thalassaemia trait, although standard DNA analysis using gene sequencing can detect the most common deletions that lead to α-thalassaemia trait.

Sickle syndromes

Sickle cell Hb (HbS) results from a single-base mutation of adenine to thymine, which produces a substitution of valine for glutamic acid at the sixth codon of the β-globin chain ($\alpha_2\beta_2^{6glu\rightarrow val}$). In the homozygous state ***(sickle cell anaemia)***, both genes are abnormal (HbSS), whereas in the heterozygous state (***sickle cell trait***, HbAS), only one chromosome carries the abnormal gene. Because the synthesis of HbF is normal, the disease usually does not manifest itself until the HbF decreases to adult concentrations at about 6 months of age.

The sickle gene is most common in Africans (up to 25% gene frequency in some populations) but is also found in India, the Middle East, and Southern Europe. Its distribution mirrors that of malaria infestation.

Pathogenesis

Deoxygenated HbS molecules are insoluble and polymerize. The flexibility of the cells is decreased; they become rigid and take up their characteristic sickle appearance (Fig. 38.26). This process is initially reversible, but with repeated sickling, cells eventually lose their membrane flexibility and become irreversibly sickled. This is due to dehydration, partly caused by potassium leaving the RBCs via a calcium-activated potassium channel called the Gardos channel. These irreversibly sickled cells are dehydrated and dense and do not return to normal when oxygenated. Sickling can produce:

- shortened RBC survival (haemolysis)
- impaired passage of cells through the microcirculation, leading to obstruction of small vessels and tissue infarction.

Sickling is precipitated by infection, dehydration, cold, stress, acidosis, and hypoxia. In many cases, the cause is unknown, but adhesion proteins on activated endothelial cells (vascular cell adhesion molecule 1) may play a causal role, particularly in vaso-occlusion when rigid cells are trapped, facilitating polymerization. HbS releases its oxygen to the tissues more easily than does normal

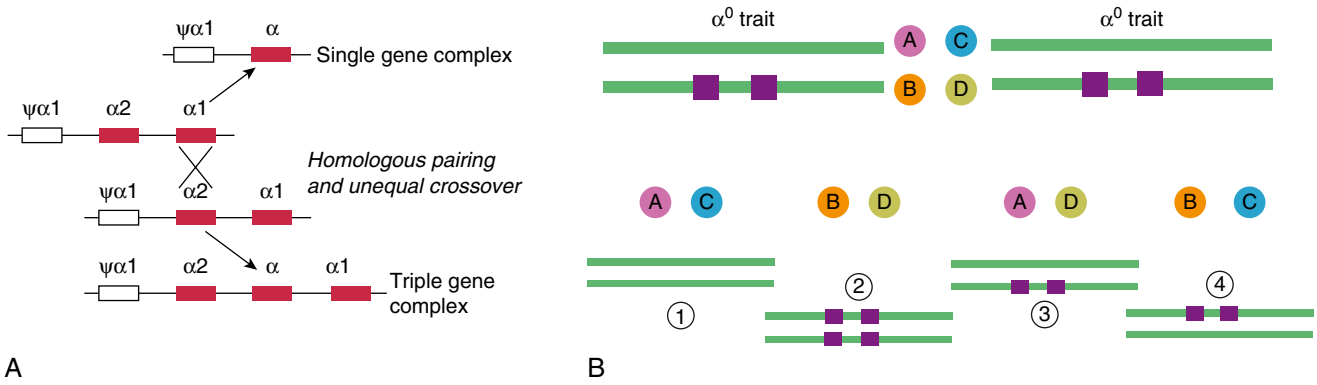

Fig. 38.25 Alpha-thalassaemia. **(A)** Deletions of α globin result from unequal crossover in the homologous recombination that occurs during meiosis. This also results in one allele with a triplicated α gene, which is of no clinical consequence in healthy individuals but can exacerbate the globin chain imbalance in individuals with reduced or abnormal β globin. **(B)** Possible outcomes from a pairing of two individuals with α^0 thalassaemia. Antenatal screening is needed because of a 25% risk of hydrops fetalis in the fetus. There is a 50% chance that the offspring will be an α^0 carrier and a 25% chance that the offspring will have all four α-globin chains.

Fig. 38.26 Sickle cells *(arrow)* and target cells.

Hb, and patients therefore feel well despite being anaemic (except, of course, during crises or complications).

Depending on the type of Hb chain combinations, three clinical syndromes occur:

- ***Homozygous HbSS*** patients have the most severe disease. Patients with co-inheritance of HbS and β-thalassaemia can have equally severe disease.
- ***Combined heterozygosity (HbSC) for HbS and C*** (see later) causes intermediate symptoms.
- ***Heterozygous HbAS (sickle cell trait)*** has no symptoms.

Sickle cell anaemia

Clinical features

Vaso-occlusive crises

An early presentation may be acute pain in the hands and feet (dactylitis) owing to vaso-occlusion of the small vessels. Severe pain in other bones, including the femur, humerus, vertebrae, ribs, and pelvis, occurs in older children and adults. Attacks vary greatly in frequency from patient to patient and sometimes in the same patient from year to year. Patients can be moderately asymptomatic or require multiple hospital admissions because of painful vaso-occlusive crises. Overall, 25% of patients with sickle cell disease report experiencing daily pain. Fever often accompanies pain.

Acute chest syndrome

This occurs in up to 30%, and pulmonary hypertension and chronic lung disease are the most common causes of death in adults with sickle cell disease. The acute chest syndrome is caused by infection, fat embolism from necrotic bone marrow in a vaso-occlusive crisis, or pulmonary infarction caused by sequestration of sickle cells. It consists of shortness of breath, chest pain, pyrexia, hypoxia, and new chest radiograph changes because of consolidation. The presentation may be gradual or very rapid, carrying a risk of death in a few hours. Management is with pain relief, high-flow supplemental oxygen, and antibiotics (cefotaxime and clarithromycin), which should be started immediately. If there is no improvement, exchange transfusion will reduce the amount of HbS to less than 30%. Continuous positive airways pressure may be necessary. Infections can be caused by *Chlamydia* and *Mycoplasma* spp., as well as *Streptococcus pneumoniae*. Use of an incentive spirometer to encourage deep breathing in patients admitted with vaso-occlusive crises reduces the risk of developing the acute chest syndrome.

Pulmonary hypertension

Pulmonary hypertension (defined as mean pulmonary artery pressure of >25 mmHg by right heart catheterization) is a known consequence of sickle cell anaemia, occurring in approximately 10% of patients. Its mechanism is not understood, but hypothesized contributory factors include sickle cell vasculopathy, damage from repeated chest crises, repeated thromboembolism, and intravascular haemolysis, which affect reactive oxygen species and concentrations of scavenging nitric oxide. Development of pulmonary hypertension increases the risk of hypoxaemia and worsening sickle cell crises and is an independent risk factor for death in patients with sickle cell anaemia. Diagnosis of pulmonary hypertension in patients with sickle cell anaemia should prompt consideration of therapies to reduce concentrations of HbS (see later) and referral to a pulmonary hypertension specialist.

Anaemia

Chronic haemolysis produces a stable Hb concentration, usually in the 60 to 80 g/L range, but an acute fall in Hb can occur owing to:

- Splenic sequestration
- Bone marrow aplasia
- Further haemolysis caused by drugs, acute infection, or associated glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Splenic sequestration

Vaso-occlusion produces an acute painful enlargement of the spleen. There are splenic pooling of RBCs and hypovolaemia, leading in some to circulatory collapse and death. The condition supervenes in childhood before multiple splenic infarctions have occurred, eventually leading to a fibrotic, non-functioning spleen. After an episode of sequestration has occurred, it is likely to recur and be life-threatening. In some cases, surgical splenectomy is required to prevent recurrence. Liver sequestration can also occur.

Bone marrow aplasia

This most commonly follows infection with parvovirus B19, which invades proliferating erythroid progenitors. There is a rapid fall in Hb with no reticulocytes in the peripheral blood because of the failure of erythropoiesis in the marrow. Patients may require transfusion until their bone marrow recovers.

Long-term problems

- ***Growth and development.*** Young children are short but regain their height by adulthood. However, they remain below the normal weight. Sexual maturation is often delayed and may require hormone therapy.
- ***Bones.*** Bones are a common site for vaso-occlusive episodes, leading to chronic infarcts. Avascular necrosis of the hips and shoulders, compression of vertebrae, and shortening of bones in the hands and feet occur. Osteomyelitis is more frequent in sickle cell disease and is caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, and salmonella. Occasionally, hip or knee joint replacement may be required at a young age.
- ***Infections.*** Infections are common in tissues susceptible to vaso-occlusion, such as the bones, lungs, and kidneys.
- ***Leg ulcers.*** These occur spontaneously (vaso-occlusive episodes) or follow trauma. They are usually found over medial or lateral malleoli. They often become infected and are quite resistant to treatment; blood transfusion may facilitate ulcer healing.
- ***Cardiac problems include*** cardiomegaly, arrhythmias, and iron overload cardiomyopathy. Myocardial infarctions are caused by thrombotic episodes, not secondary to atheroma.
- ***Neurological complications*** occur in 25% of patients and include transient ischaemic attacks, fits, cerebral infarction, cerebral haemorrhage, and coma. About 11% of patients younger than 20 years of age have strokes without a stroke prevention programme. The most common finding is obstruction of a distal intracranial internal carotid artery or a proximal middle cerebral artery. About 10% of children without neurological signs or symptoms have abnormal blood-flow velocity indicative of clinically significant arterial stenosis; such patients have a very high risk of stroke. It has been demonstrated that if children with stenotic cranial artery lesions, as demonstrated on transcranial Doppler ultrasonography, are maintained on a regular RBC transfusion exchange programme designed to suppress erythropoiesis so that no more than 30% of the circulating RBCs are their own, about 90% of strokes in such children are prevented. Whether they need to remain on these transfusions for life remains to be determined. Silent infarcts, seen on MRI but not manifesting clinically, are common in children with sickle cell disease and associated with poor educational attainment.
- ***Cholelithiasis.*** Pigment stones occur as a result of chronic haemolysis.
- ***Liver complications.*** Chronic hepatomegaly and liver dysfunction are caused by trapping of sickle cells.
- ***Renal complications.*** Chronic tubulointerstitial nephritis occurs (see Chapter 26), and 10% of patients develop CKD requiring long-term kidney replacement therapy.
- ***Priapism.*** An unwanted painful erection occurs because of vaso-occlusion and can be recurrent. This requires urgent treatment because it may result in impotence. Treatment is with an α-adrenergic blocking drug, analgesia, and hydration. When this is not successful, aspiration or shunts may be required.
- ***Eye complications.*** Background retinopathy, proliferative retinopathy, vitreous haemorrhages, and retinal detachments all occur. Annual eye checks are required.
- ***Pregnancy.*** Impaired placental blood flow causes spontaneous abortion, intrauterine growth restriction, pre-eclampsia, and fetal death. Painful episodes, infections, and severe anaemia occur. Pregnancy requires monitoring by a combination of haematologists and high-risk obstetricians.

Investigations

- ***Blood count.*** The concentration of Hb is in the range of 60 to 80 g/L, with a high reticulocyte count (10%–20%).
- ***Blood film.*** This shows features of hyposplenism (Fig. 38.19) and sickling (Fig. 38.26).
- ***Sickle solubility test.*** A mixture of HbS in a reducing solution such as sodium dithionite gives a turbid appearance because of precipitation of HbS, whereas normal Hb gives a clear solution. Commercial kits, such as Sickledex, are available for rapid screening for the presence of HbS (e.g., before surgery and in the emergency department).
- ***Hb electrophoresis*** is needed to confirm the diagnosis. There is no HbA, 80% to 95% HbS, and 2% to 20% HbF (Fig. 38.23).
- ***Parents.*** The parents of affected children show features of sickle cell trait.

Management

Precipitating factors (see earlier) should be avoided or treated quickly. Complications that require inpatient management are shown in Box 38.13.

Acute painful attacks require supportive therapy with intravenous fluids and adequate analgesia. Oxygen and antibiotics are given if indicated. Crises can be extremely painful and require strong, usually narcotic, analgesia. Morphine is the drug of choice. Milder pain can sometimes be relieved by codeine, paracetamol, or NSAIDs. Use of incentive spirometry is recommended for patients hospitalized for a vaso-occlusive crisis.

Infection prophylaxis includes penicillin 500 mg/day and vaccination with polyvalent pneumococcal, meningococcal, and *Haemophilus influenzae* type b vaccines because of functional hyposplenism.

Folic acid is given to all patients with haemolysis.

Anaemia

Blood transfusions should be given only when there are clear indications. Patients with steady-state anaemia, those having minor surgery, and those having painful episodes without complications should not be transfused. Transfusions (top-up or exchange) should be given acutely for acute chest syndrome and acute anaemia associated with splenic sequestration or an aplastic crisis, aiming for an Hb of 100 g/L and HbS below

Box 38.13 Complications of sickle cell disease requiring inpatient management

- Pain uncontrolled by non-opiate analgesia
- Swollen, painful joint(s)
- Acute sickle chest syndrome or pneumonia
- Mesenteric sickling, bowel ischaemia
- Splenic or hepatic sequestration
- Central nervous system deficit
- Cholecystitis (pigment stones)
- Cardiac arrhythmias
- Renal papillary necrosis resulting in colic or haematuria
- Hyphaema, retinal detachment
- Priapism

30%. Before elective operations, top-up transfusions are given to increase the Hb to 100 g/L and reduce risk of perioperative complications. During pregnancy, repeated transfusions may be used to reduce the proportion of circulating HbS to below 30% to prevent sickling and improve placental function. Regular exchange transfusions are given to children with a history of stroke (secondary prevention) or a high risk of stroke as assessed by transcranial Doppler (primary prevention). Exchange transfusions may be necessary in patients with severe or recurrent crises and before emergency surgery. RBCs for transfusion should be matched for Rhesus (Rh) and Kell blood groups to minimize the risk of alloimmunization, which arises from the mismatch between blood donors and recipients. Ideally, patients requiring long-term transfusion, such as those with sickle cell anaemia and thalassaemia, should undergo molecular blood group typing before their first transfusion.

Hydroxycarbamide (hydroxyurea) is widely used as therapy for sickle cell anaemia. It acts, at least in part, by increasing HbF concentrations. Hydroxycarbamide has been shown in trials to reduce episodes of pain, acute chest syndrome, and the need for blood transfusions, as well as to increase lifespan. It has been shown to be safe and effective and probably reduces long-term complications such as kidney dysfunction. It is now offered to almost all patients with sickle cell disease from the age of 12 months. Blood counts must be carefully monitored for neutropenia, which is a side-effect of treatment.

Novel therapies include crizanlizumab (anti–P-selectin antibody administered as a monthly intravenous infusion) and Voxelotor (a tablet that stabilizes oxygenated HbS). Their use is currently limited because not enough clinical trials have shown benefit, but they provide new avenues for treatment.

Stem cell transplantation has been used to treat patients with sickle cell anaemia but in lower numbers than for thalassaemia. Children and adolescents younger than 16 years of age who have severe complications (strokes, recurrent chest syndrome, or refractory pain) and an HLA-matched donor are the best candidates for transplantation.

Counselling and psychological support are important parts of improving long-term outcomes for people living with chronic illnesses. A multidisciplinary team should be involved, with regular clinic appointments to build up relationships. Adolescents require careful counselling including psychosocial aspects of care and contraception.

Prognosis

Some patients with HbSS die in the first few years of life from either infection or episodes of sequestration. However, there is marked variation in disease severity, and some patients have a relatively normal lifespan with few complications. In most, the length and quality of life are adversely affected, and regular monitoring is important to prevent long-term complications.

Sickle cell trait

These individuals have no symptoms unless extreme circumstances cause anoxia (e.g., flying in a non-pressurized aircraft). At a population level, sickle cell trait confers some protection against *Plasmodium falciparum* malaria, and the sickle cell gene has been seen as an example of a balanced polymorphism: the advantage of malaria protection in the heterozygote is balanced by the mortality of the homozygous condition. However, for an individual, the presence of sickle cell trait does not obviate the need for antimalarial prophylaxis. Typically, there is 60% HbA and 40% HbS. It should be emphasized that unlike thalassaemia trait, the blood count and film of a person with sickle cell trait are normal. The diagnosis is made by a positive sickle test or Hb electrophoresis (Fig. 38.23).

Other structural globin chain defects

There are many Hb variants, and most are not associated with any clinical manifestations. However, some Hb variants may interact with HbS; for example, compound heterozygosity for HbC and HbS gives rise to HbSC disease. The clinical course of HbSC disease is generally somewhat milder than that of HbSS disease, but there is an increased likelihood of retinopathy and thrombosis, which may lead to thrombosis in pregnancy.

Combined defects of globin chain production and structure

Abnormalities of Hb structure (e.g., HbS, HbC) can occur in combination with thalassaemia. The combination of β-thalassaemia trait and sickle cell trait (sickle cell β-thalassaemia) resembles sickle cell anaemia (HbSS) clinically.

HbE ($\alpha_2\beta_2^{26glu\rightarrow lys}$) is the most common Hb variant in South-east Asia and the second most prevalent Hb variant worldwide. HbE heterozygotes are asymptomatic; Hb concentration is normal, but RBCs are microcytic. Homozygous HbE causes a mild microcytic anaemia, but the combination of heterozygosity for HbE and β-thalassaemia produces a variable anaemia, which can be as severe as TDT (β-thalassaemia major).

Prenatal screening and diagnosis of severe haemoglobin abnormalities

Of the offspring of parents who both have either β-thalassaemia or sickle cell trait, 25% have TDT or sickle cell anaemia, respectively. Recognition of heterozygous states in parents and family counselling provide a basis for antenatal screening and diagnosis. Pregnant persons with either sickle cell trait or thalassaemia trait are identified at antenatal booking either by selective screening of high-risk groups or by universal screening of all pregnancies. Beta-thalassaemia trait can be detected by a low MCV and MCH and confirmed by Hb electrophoresis. However, sickle cell trait is undetectable from a blood count and needs a specific request to screen for sickle cell trait.

If a Hb defect is detected in pregnancy, the partner should be tested. Antenatal diagnosis is offered if both are affected, and there is a risk of a severe fetal Hb defect, particularly TDT. Fetal DNA analysis can be carried out using amniotic fluid, chorionic villus sampling, or fetal blood samples. Termination of pregnancy

is discussed if the fetus is found to be severely affected. Chorionic villus biopsy has the advantage that it can be carried out in the first trimester, thus avoiding the need for second-trimester termination.

Metabolic disorders of the red blood cell

Red blood cell metabolism

A mature RBC has no nucleus, mitochondria, or ribosomes and is therefore unable to synthesize proteins. RBC enzymes maintain the viability and function of the cells, but the lifespan of these enzymes is limited because there is no nucleus to replenish them after they become defective. Energy is required in the form of ATP to maintain flexibility of the membrane and the biconcave shape to allow passage through small vessels and for regulation of sodium and potassium pumps to ensure osmotic equilibrium. In addition, it is essential for Hb to be maintained in the reduced state.

The enzyme systems responsible for producing energy and maintaining a reduced state (Fig. 38.27) are:

- ***The glycolytic (Embden–Meyerhof) pathway:*** Glucose is metabolized to pyruvate and lactic acid with production of ATP.
- ***The hexose monophosphate (pentose phosphate) pathway:*** This provides reducing power for the RBCs in the form of NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate).

These biochemical processes are understandably complex; however, it is possible to focus on relevant aspects that lead to a clinical phenotype. For example, pyruvate kinase (Fig. 38.27, highlighted in *orange*) is the last enzyme in the glycolytic pathway. When this is defective, less ATP is formed, and less energy is available to the RBCs for their needs. RBCs use ATP to maintain the correct concentrations of solutes inside the cytoplasm by driving ion pumps; without enough ATP, these ionic gradients cannot be maintained, and cell survival is shortened.

About 90% of glucose is metabolized by the glycolytic pathway, and 10% goes through the hexose monophosphate shunt whose main function is to maintain glutathione in a reduced state. Glutathione is necessary to combat oxidative stress to the RBCs, and failure of this mechanism may result in:

- ***Rigidity*** caused by cross-linking of spectrin, which decreases membrane flexibility (Fig. 38.17) and causes 'leakiness' of the RBC membrane
- ***Oxidation of the Hb molecule***, producing methaemoglobin and precipitation of globin chains as Heinz bodies localized on the inside of the membrane; these bodies are removed from circulating RBCs by the spleen.

2,3-BPG is formed from a side-arm of the glycolytic pathway labelled the 'Rappaport-Luebering shunt' in Fig. 38.27. It binds to the central part of the Hb tetramer, fixing it in the low-affinity state. A decreased affinity with a shift in the oxygen dissociation curve to the right enables more oxygen to be delivered to the tissues. 2,3-BPG therefore has a role in modulating the severity of these disorders.

Glucose-6-phosphate dehydrogenase deficiency

The G6PD enzyme occupies a vital position in the hexose monophosphate shunt highlighted in *yellow* in Fig. 38.27. It oxidizes glucose-6-phosphate to 6-phosphoglycerate with the reduction of NADP to NADPH. The reaction is necessary in RBCs, where it is the only source of NADPH, which is used via glutathione to protect the RBCs from oxidative damage. G6PD deficiency is a common condition that presents with a haemolytic anaemia and affects millions of people throughout the world, particularly in Africa, the Mediterranean, the Middle East (~20%), and South-east Asia (up to 40% in some regions).

The gene for G6PD is localized to chromosome Xq28 near the factor VIII gene. Deficiency is therefore more common in males than females. However, female heterozygotes can also have clinical problems because of lyonization whereby, because of random X-chromosome inactivation, female heterozygotes have two populations of RBCs: a normal one and a G6PD-deficient one.

There are more than 400 structural types of G6PD, and mutations are mostly single amino acid substitutions (missense point mutations). The World Health Organization has classified variants by the degree of enzyme deficiency and severity of haemolysis. The most common ones with normal activity are called type B^+ (present in almost all Whites and ~70% of Black Africans) and type A^+ (present in about 20% of Black Africans). There are many variants with reduced activity but, only two are common:

- African (A–type). Deficiency is mild and more marked in older cells. Haemolysis is self-limiting because young RBCs newly produced by the bone marrow have nearly normal enzyme activity.
- Mediterranean type. Both young and old RBCs have very low enzyme activity. After an oxidant shock, the Hb concentration may fall precipitously; death may follow unless the condition is recognized and the patient is transfused urgently.

Clinical syndromes

- Acute drug-induced haemolysis (Box 38.14): usually dose related
- Favism: haemolysis after ingestion of fava beans
- Chronic haemolytic anaemia
- Neonatal jaundice
- Infections and acute illnesses precipitating haemolysis
- Mothballs containing naphthalene can also cause haemolysis

Clinical features are caused by rapid intravascular haemolysis with symptoms of anaemia, jaundice, and haemoglobinuria.

Investigations

- The blood count is normal between attacks.
- ***During an attack***, the blood film may show irregularly contracted cells, bite cells (cells with an indentation in the membrane), blister cells (cells in which the Hb appears to have become partially detached from the cell membrane; Fig. 38.28), Heinz bodies (RBC inclusions composed of denatured Hb, best seen on films stained with methyl violet), and reticulocytosis.
- ***Haemolysis*** is evident (see Fig. 38.16 and 'Evidence for haemolysis' section).
- ***Screening tests*** include demonstration of the decreased ability of G6PD-deficient cells to reduce dyes and direct assay of enzyme concentration. Immediately after an attack, test results

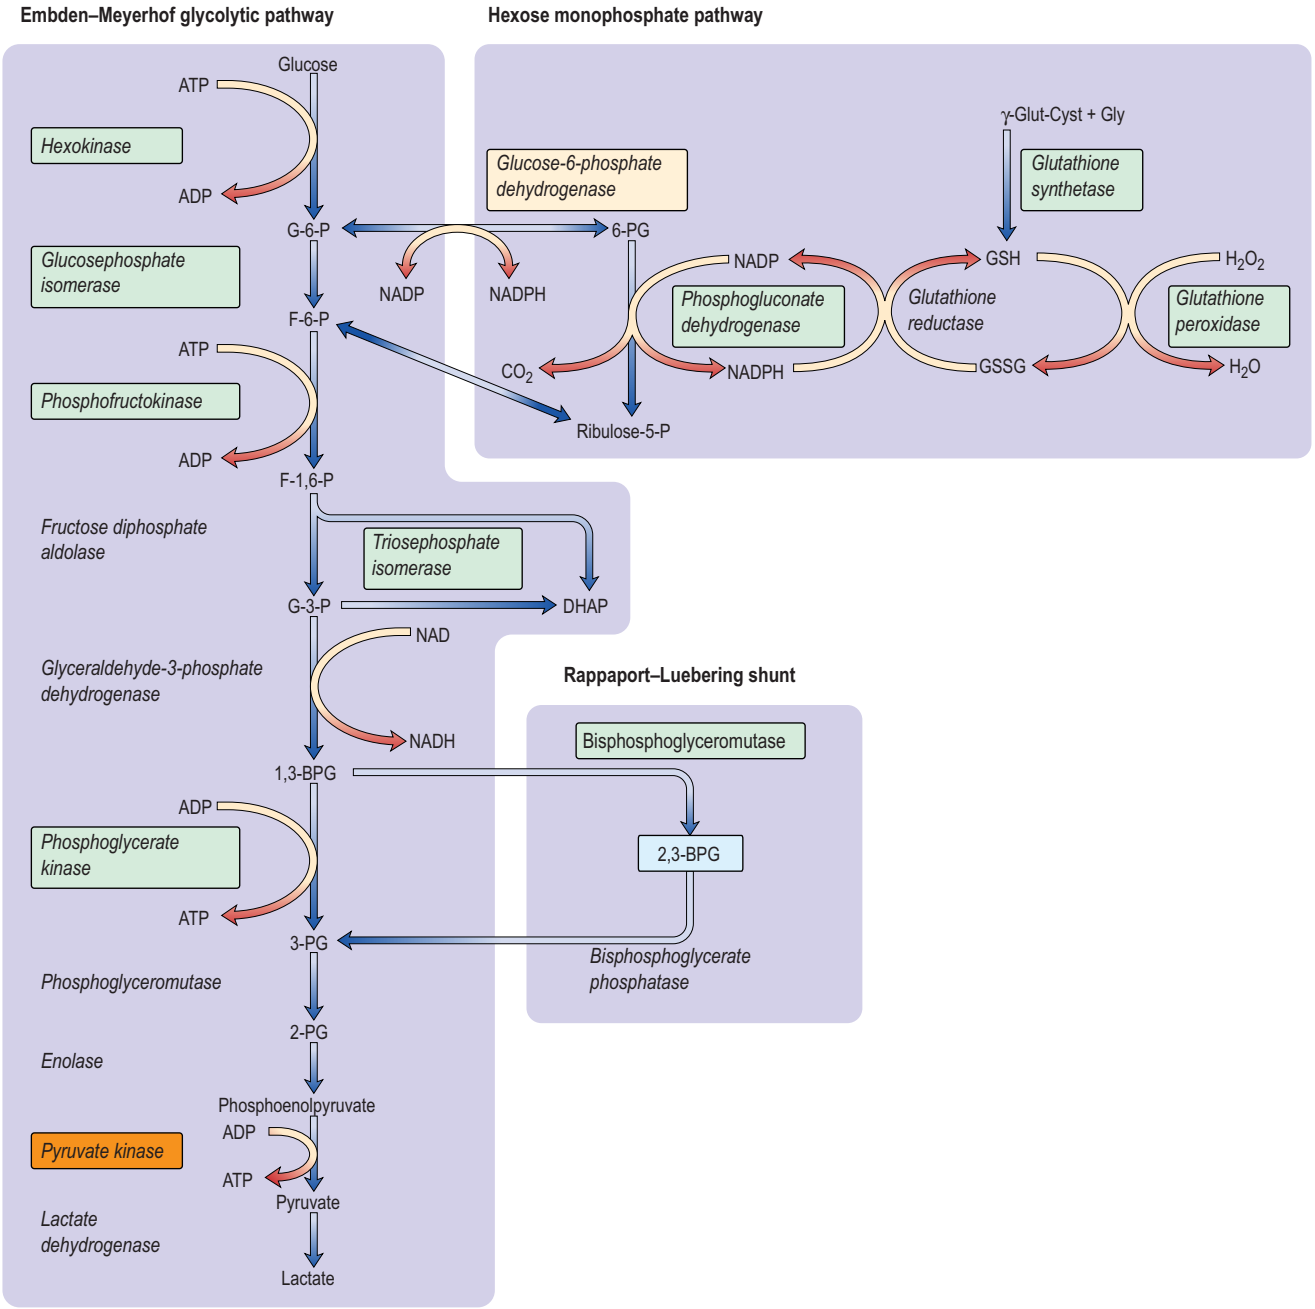

Fig. 38.27 Glucose metabolism pathways. may be normal because the oldest RBCs with least G6PD activity are destroyed selectively. Diagnosis of heterozygous females may be difficult because the enzyme concentration may range from very low to normal, depending on Lyonization. However, the risk of clinically significant haemolysis is minimal in patients with borderline G6PD activity.

Management

- Stop the offending drugs.
- Treat the underlying infection.
- Blood transfusion may be life-saving.
- Splenectomy is not usually helpful.

Pyruvate kinase deficiency

This is the most common defect of RBC metabolism after G6PD deficiency; it affects thousands rather than millions of people worldwide. The site of the defect is shown in *orange* in Fig. 38.27. Production of ATP is reduced, causing rigid RBCs. It is inherited as an autosomal recessive condition. Homozygotes have haemolytic anaemia and splenomegaly. Interestingly, with a dysfunctional pyruvate kinase

Box 38.14 Examples of drugs causing haemolysis in glucose-6-phosphate dehydrogenase deficiency

Analgesics
- Aspirin
- Phenacetin (withdrawn in the UK)

Antimalarials
- Primaquine
- Pyrimethamine
- Quinine
- Chloroquine
- Pamaquine

Antibacterials

- Nitrofurantoin
- Chloramphenicol
- Quinolones

Miscellaneous
- Dapsone
- Vitamin K
- Probenecid
- Quinidine
- Dimercaprol
- Phenylhydrazine
- Methylene blue

Fig. 38.28 'Blister' cells *(arrow)* in glucose-6-phosphate dehydrogenase deficiency.

enzyme, 2,3-BPG accumulates (highlighted in *blue* in Fig. 38.27), causing a right shift in the oxygen dissociation curve. This reduced Hb affinity for oxygen means that more oxygen is released to the tissues and partly compensates for the degree of anaemia.

Investigations

- ***Anaemia*** of variable severity (Hb 50–100 g/L). The oxygen dissociation curve is shifted to the right because of the rise in intracellular 2,3-BPG, which reduces severity of symptoms caused by anaemia.
- ***Blood films*** show distorted ('prickle') cells and a reticulocytosis.
- ***Pyruvate kinase activity*** is low; affected homozygotes have concentrations of 5% to 20%.

Management

Blood transfusions may be necessary during infections and pregnancy. Splenectomy may improve the clinical condition and is usually advised for patients requiring frequent transfusions. Novel drugs that stabilize the enzyme in RBCs have been shown to reduce haemolysis in clinical trials and may become available for clinical use.

Pyrimidine 5′ nucleotidase deficiency

This autosomal recessive disorder is the third most common RBC enzyme disorder after G6PD and pyruvate kinase, causing a haemolytic anaemia with basophilic stippling of the RBCs. The enzyme degrades pyrimidine nucleotides to cytidine and uridine, which feed into the pathway responsible for degradation of RNA in the reticulocytes. Lack of the enzyme results in accumulation of partially degraded RNA, which shows as basophilic stippling in mature RBCs. The enzyme is also inhibited by lead; therefore, basophilic stippling is also seen in lead poisoning (see Chapter 15). The hereditary form can be diagnosed by measuring the enzyme in erythrocytes. A screening test using the ultraviolet absorption spectrum of RBCs is available.

In addition to the G6PD, pyruvate kinase and pyrimidine 5′ nucleotidase deficiencies described here, specialist investigation of other rarer enzyme deficiencies highlighted in *green* in Fig. 38.27 also occurs.

ACQUIRED HAEMOLYTIC ANAEMIA

These anaemias may be divided into those that have immune, non-immune, or other causes (Box 38.9).

Aetiology

Causes of immune destruction of red blood cells

- Autoantibodies
- Drug-induced antibodies
- Alloantibodies

Causes of non-immune destruction of red blood cells

- Acquired membrane defects (e.g., PNH, see 'Paroxysmal nocturnal haemoglobinuria' section)
- Mechanical factors (e.g., prosthetic heart valves or microangiopathic haemolytic anaemia [MAHA]; see 'Mechanical haemolytic anaemia' section)
- Secondary to systemic disease (e.g., kidney and liver disease)

Miscellaneous causes

- Various toxic substances (e.g., arsenic, toxins produced by *Clostridium perfringens [welchii]*) can disrupt the RBC membrane and cause haemolysis.
- Malaria frequently causes anaemia owing to the combination of reduced RBC survival and reduced production of RBCs.
- Hypersplenism results in reduced RBC survival, which may also contribute to the anaemia seen in those with malaria.
- Extensive burns lead to denaturation of RBC membrane proteins and reduced RBC survival.
- Some drugs (e.g., dapsone, sulfasalazine) cause oxidative haemolysis with Heinz bodies.
- Some ingested chemicals (e.g., weedkillers such as sodium chlorate) can cause severe oxidative haemolysis, leading to acute kidney injury.

Autoimmune haemolytic anaemias

Autoimmune haemolytic anaemias (AIHAs) are acquired disorders resulting from increased RBC destruction caused by

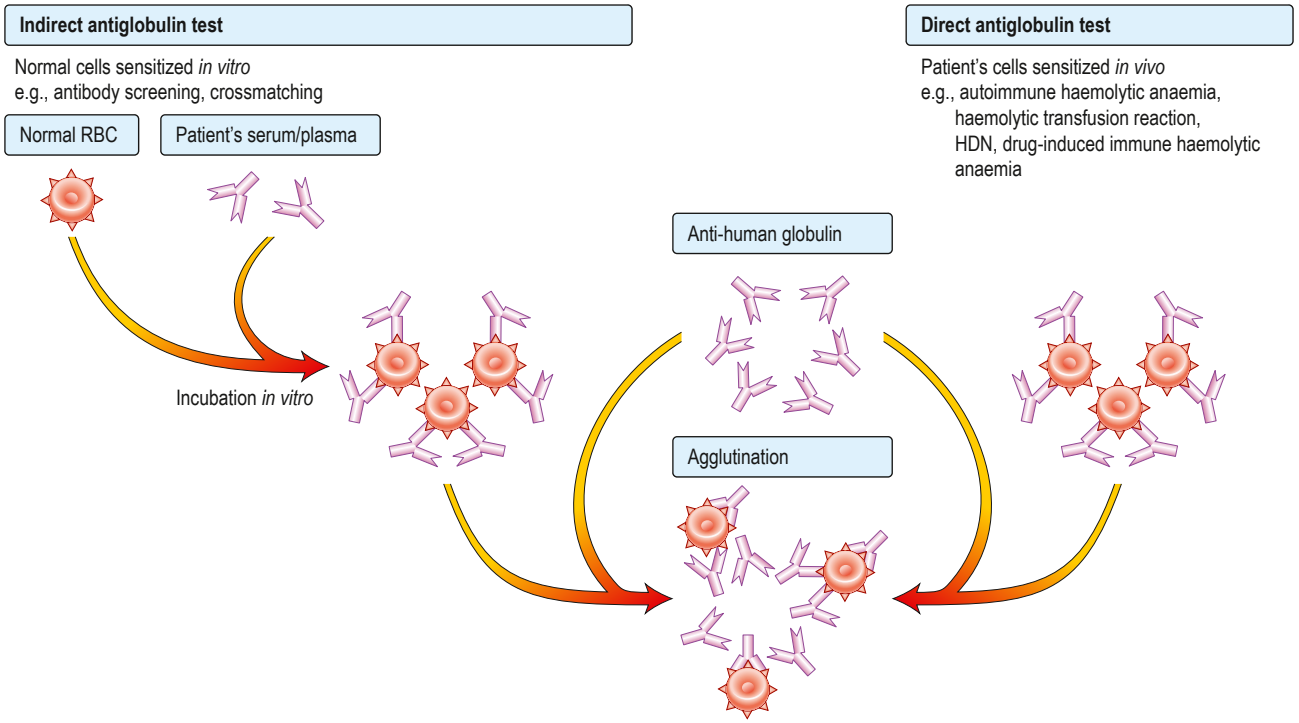

Fig. 38.29 Antiglobulin (Coombs') tests. The anti-human globulin forms bridges between the sensitized cells, causing visible agglutination. The direct test detects patients' cells sensitized *in vivo*. The indirect test detects normal cells sensitized *in vitro*. *HDN,* Haemolytic disease of newborn; *RBC,* red blood cell.

RBC autoantibodies. These anaemias are characterized by the presence of a positive direct antiglobulin (Coombs') test result, which detects evidence of the presence of autoantibody (immunoglobulin [Ig] G, or complement) on the surface of the patient's RBCs (Fig. 38.29).

AIHA is divided into 'warm' (65%), 'cold' (30%), and mixed (5%) types, depending on whether the antibody attaches better to the RBCs at body temperature (37°C) or at lower temperatures. The major features and the causes of these two forms of AIHA are shown in Box 38.15. In warm AIHA, IgG antibodies predominate, and the result of the DAT is positive with IgG alone, IgG and complement, or complement only. In cold AIHA, the antibodies are usually IgM. They easily elute off RBCs, leaving complement, which is detected as C3d.

Immune destruction of red blood cells

IgM and IgG RBC antibodies that fully activate the complement cascade cause lysis of RBCs in the circulation and intravascular haemolysis.

The majority of IgG antibodies do not activate complement, and the coated RBCs undergo extravascular haemolysis (Fig. 38.30). They either are completely phagocytosed in the spleen through an interaction with Fc receptors on macrophages or lose part of the cell membrane through partial phagocytosis and circulate as spherocytes until they become sequestered in the spleen.

Some IgG antibodies may partially activate complement, leading to deposition of C3b on the RBC surface, and this may enhance phagocytosis as macrophages also have receptors for C3b.

IgM antibodies, which are non-complement binding, are rare and have little or no effect on RBC survival. IgM antibodies, which partially rather than fully activate complement, cause adherence of RBCs to C3b receptors on macrophages, particularly in the liver, although this is an ineffective mechanism of haemolysis. Most of the RBCs are released from the macrophages when C3b is cleaved to C3d and then circulate with C3d on their surface, which is not relevant clinically but allows them to be detected by the DAT.

'Warm' autoimmune haemolytic anaemias

Clinical features

These anaemias occur at all ages and in both sexes, although they are most frequent in middle-aged females. They can present as a short episode of anaemia and jaundice, but they often remit and relapse and may progress to an intermittent chronic pattern. The spleen may be palpable. Infection or folate deficiency may provoke a profound fall in Hb concentration. AIHAs are primary (50%) or secondary to an associated disorder (50%). The most common underlying cause is a lymphoproliferative disorder (Box 38.15).

Investigations

- ***Haemolytic anaemia*** is evident (see 'Haemolytic anaemias' section).
- ***Spherocytosis*** is present as a result of RBC damage.
- The ***DAT*** result is positive, with IgG alone (35%), IgG and complement (56%), or complement alone (9%) found on the surface of the RBCs.
- ***Autoantibodies*** may have specificity for the Rh blood group system (e.g., for the e antigen).
- ***Autoimmune thrombocytopenia*** or neutropenia may also be present (***Evans syndrome***).
- ***Abdominal computed tomography (CT)*** should be carried out to detect abdominal lymphoma.

Box 38.15 Causes and major features of autoimmune haemolytic anaemias

	Warm	Cold
Temperature at which antibody attaches best to red blood cells (°C)	37	<37
Type of antibody	IgG	IgM
Direct Coombs' test	Strongly positive	Positive
Causes of primary condition	Idiopathic	Idiopathic
Causes of secondary condition	Autoimmune (e.g., SLE) Chronic lymphocytic leukaemia Lymphomas Hodgkin lymphoma Carcinomas Drugs: many, including methyldopa, penicillins, cephalosporins, NSAIDs, quinine, interferon	Infections (e.g., infectious mononucleosis, *Mycoplasma pneumoniae*, other viral infections [rare]) Lymphomas Paroxysmal cold haemoglobinuria (IgG)

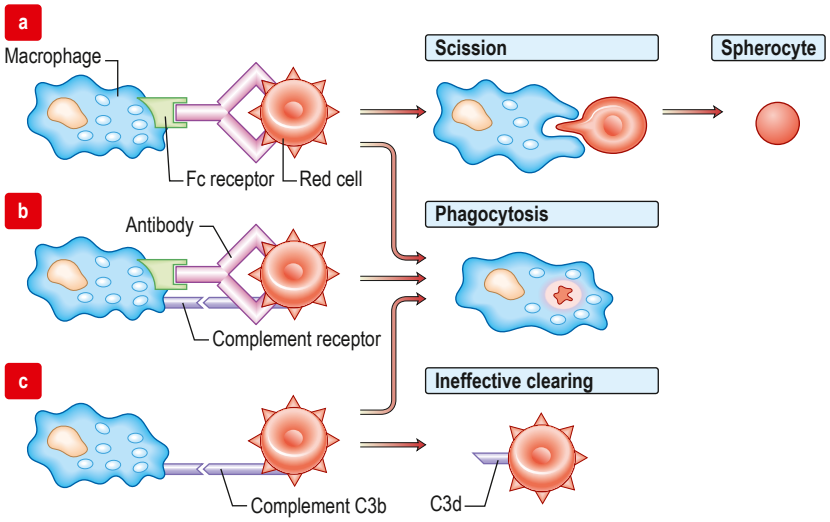

Fig. 38.30 Extravascular haemolysis. This is caused by interaction of antibody-coated cells with cells in the reticuloendothelial system, predominantly in the spleen. **(a)** Spherocytosis results from partial phagocytosis. **(b)** Complete phagocytosis may occur and is enhanced if there is complement as well as antibody on the cell surface. **(c)** Cells coated with complement only are ineffectively removed and circulate with C3d or C3b on their surfaces. *RBC,* Red blood cell.

Management and prognosis

Corticosteroids (e.g., prednisolone 1 mg/kg daily) are effective in inducing a remission in about 80% of patients, although only 30% to 40% have a sustained remission after 1 year. Steroids reduce both production of the RBC autoantibodies and destruction of antibody-coated cells. Rituximab (anti-CD20) is recommended as second-line therapy for patients who fail to respond to steroids or relapse after the dose is reduced. The conventional dosage is 375 mg/m^2 administered as four weekly cycles, but lower doses seem to be equally effective. Response rates of 70% have been reported with a median time to response of 3 to 6 weeks. Splenectomy is effective for patients failing to respond to steroids and rituximab, but many patients prefer to avoid it because of the lack of a guaranteed successful outcome, potential complications, and the need to take antibiotic prophylaxis. Blood transfusion may be necessary if there is severe anaemia, although compatibility testing is complicated by the presence of RBC autoantibodies.

'Cold' autoimmune haemolytic anaemias

Low titres of IgM cold agglutinins reacting at 4°C are normally present in plasma and are harmless. At low temperatures, these antibodies can attach to RBCs and cause their agglutination in the cold peripheries of the body. In addition, activation of complement may cause intravascular haemolysis when the cells return to the higher temperatures in the core of the body. After certain infections, including mycoplasma, cytomegalovirus (CMV), or Epstein–Barr virus (EBV), increased production of *poly*clonal cold agglutinins may occur producing a mild to moderate transient haemolysis.

Chronic cold haemagglutinin disease

Chronic cold haemagglutinin disease usually occurs in older adults, with a gradual onset of haemolytic anaemia owing to the production of *mono*clonal IgM cold agglutinins. After exposure to cold, the

patient develops an acrocyanosis similar to Raynaud's syndrome as a result of RBC autoagglutination.

Investigations

- ***RBCs*** agglutinate in the cold or at room temperature. Agglutination is sometimes seen in the sample tube after cooling but is more easily observed on a peripheral blood film made at room temperature, which is less than body temperature. The agglutination is reversible after warming the sample. Agglutination may cause a spurious increase in MCV.
- ***Cold agglutinin test:*** The titre is elevated to more than 1:512.
- The ***DAT*** result is positive with complement (C3d) alone.
- ***Monoclonal IgM antibodies*** have specificity for the Ii blood group system, usually for the I antigen but occasionally for the i antigen. Developing fetuses and newborns express i antigen until around 13 to 20 months after birth, when I antigen starts to be expressed instead.

Management

Any underlying cause should be treated, if possible. Patients should avoid exposure to cold. Steroids, alkylating agents (chemotherapy), and splenectomy are usually ineffective. Rituximab results in responses in 45% to 60%, but complete responses are unusual. Complement inhibition with sutimlimab, a humanized monoclonal antibody selectively targeting the C1s protein, has been reported to produce rapid responses halting haemolysis with increased Hb concentrations and reduction in fatigue. Blood transfusion may be necessary, and if so, the patient should be in a warm environment; compatibility testing may be difficult because of the cold agglutinin.

Paroxysmal cold haemoglobinuria

Paroxysmal cold haemoglobinuria is a rare condition associated with common childhood infections such as measles, mumps, and chickenpox. Intravascular haemolysis is associated with polyclonal IgG complement-fixing antibodies. These antibodies are biphasic, reacting with RBCs in the cold in the peripheral circulation, with lysis occurring due to complement activation when the cells return to the central circulation. The antibodies have specificity for the P RBC antigen. The lytic reaction is demonstrated *in vitro* by incubating the patient's RBCs and serum at 4°C and then warming the mixture to 37°C (Donath–Landsteiner test). Haemolysis is self-limiting, but RBC transfusions may be necessary. Even though the antibody has specificity for P, transfusion with P-negative RBCs is not necessary.

Drug-induced immune haemolytic anaemia

Drug-induced immune haemolytic anaemias are rare, although more than 100 drugs have been reported to cause immune haemolytic anaemia. Testing for drug-dependent RBC antibodies is not routinely available, and rechallenge with the drug to confirm the diagnosis of drug-induced immune haemolytic anaemia is not advisable. Confirmation of the diagnosis requires:

- A temporal association between administration of a drug and haemolytic anaemia
- A positive DAT result
- Recovery after withdrawal of the drug.

Alloimmune haemolytic anaemia

Antibodies produced in one individual react with the RBCs of another. This situation occurs in haemolytic disease of the newborn (HDN); in haemolytic transfusion reactions (see 'Red blood cell complications: haemolytic transfusion reaction' sections); and after allogeneic bone marrow, kidney, liver, cardiac or intestinal transplantation when donor lymphocytes transferred in the allograft ('passenger lymphocytes') produce RBC antibodies against the recipient and cause haemolytic anaemia.

Haemolytic disease of the newborn

HDN is caused by fetomaternal incompatibility for RBC antigens. Maternal alloantibodies against fetal RBC antigens pass from the maternal circulation via the placenta into the fetus, where they destroy fetal RBCs. Only IgG antibodies are capable of transplacental passage from the mother to the fetus. The most common type of HDN is that caused by ABO incompatibility, in which the mother is usually group O and the fetus group A.

HDN caused by ABO incompatibility is usually mild, and exchange transfusion is rarely needed. HDN caused by RhD incompatibility has become much less common in high-income countries since the introduction of anti-D prophylaxis (see later). HDN may be caused by antibodies against antigens in many blood group systems (e.g., other Rh antigens such as c and E, Kell, Duffy, and Kidd).

Sensitization occurs as a result of passage of fetal RBCs into the maternal circulation (which most readily occurs at the time of delivery), so that first pregnancies are rarely affected. However, sensitization may occur at other times (e.g., after a miscarriage, ectopic pregnancy, or blood transfusion) or be caused by episodes during pregnancy that cause transplacental bleeding, such as amniocentesis, chorionic villus sampling, and threatened miscarriage.

Clinical features

These vary from a mild haemolytic anaemia of the newborn to intrauterine death with the characteristic appearance of hydrops fetalis (hepatosplenomegaly, oedema, and cardiac failure). Kernicterus occurs because of severe jaundice in the neonatal period, when the unconjugated (lipid-soluble) bilirubin exceeds 250 μmol/L and bile pigment deposition occurs in the basal ganglia. This can result in permanent brain damage, choreoathetosis, and spasticity. In mild cases, it may present as deafness.

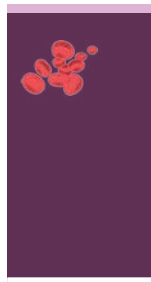
Investigations

All mothers should have their ABO and RhD groups determined and tested for atypical antibodies at antenatal booking and at 28 weeks' gestation. If an antibody is detected, blood group specificity should be determined, and the mother should be retested at least monthly. A rising antibody titre of IgG antibodies or a history of HDN in a previous pregnancy is an indication for referral to a fetal medicine unit.

Antenatal assessment and treatment

If a clinically significant antibody capable of causing HDN, such as anti-D, anti-c, or anti-K, is detected, the father's genotype provides useful information for predicting the likelihood that the fetus carries the relevant RBC antigen. If the father is heterozygous, the genotype of the fetus can be determined from fetal DNA from maternal plasma.

The severity of anaemia is assessed by Doppler flow velocity of the fetal middle cerebral artery; measurement of bile pigments in the amniotic fluid is no longer routine. If the infant appears to have severe anaemia on non-invasive monitoring, ultrasound-guided fetal blood sampling is used to confirm this directly. If necessary, an intrauterine fetal transfusion of RBCs is given.



Birth of an affected infant

A sample of cord blood is obtained at birth. This shows:

- Anaemia with a high reticulocyte count
- Aa positive DAT result
- A raised serum bilirubin

Postnatal management

In mild cases, phototherapy may be used to convert bilirubin to water-soluble biliverdin, which can be excreted by the kidneys. Bilirubin concentrations need to be monitored, and phototherapy may be needed for several days. In more severely affected cases, exchange transfusion may be necessary to replace the infant's antibody-coated RBCs with normal antigen-negative RBCs and to remove bilirubin. Indications for exchange transfusion include severe anaemia or a high or rapidly rising bilirubin concentration.

The blood used for exchange transfusions should:

- Be ABO-compatible with the mother and infant.
- Lack the antigen against which the maternal antibody is directed.
- Be fresh (no more than 5 days from the day of collection).
- Be irradiated to prevent transfusion-associated graft-versus-host disease (TA-GvHD) and be CMV seronegative to prevent transmission of CMV.

Avoidance of exchange transfusion is beneficial because of its risks. Antenatal administration of intravenous immunoglobulin (IVIG) to the mother significantly reduces the need for exchange transfusion.

Prevention of RhD immunization in the mother

Anti-D should be given after delivery when all of the following conditions are fulfilled:

- The mother is RhD negative.
- The fetus is RhD positive.
- There is no maternal anti-D detectable in the mother's serum (i.e., the mother is not already immunized).

The dose is 500 IU of IgG anti-D intramuscularly within 72 hours of delivery. The ***Kleihauer test*** assesses the number of fetal cells in the maternal circulation. A blood film prepared from maternal blood is treated with acid, which elutes HbA. HbF is resistant to this treatment and can be seen when the film is stained with eosin. If large numbers of fetal RBCs are present in the maternal circulation, a higher or additional dose of anti-D is necessary.

Prophylaxis may be required by RhD-negative females at times other than delivery if sensitization may occur, including after an ectopic pregnancy, threatened miscarriage, or termination. The doses of anti-D are 250 IU before 20 weeks' and 500 IU after 20 weeks' gestation. A Kleihauer test should be carried out after 20 weeks' gestation to determine whether more anti-D is required.

Of previously non-immunized RhD-negative females carrying RhD-positive fetuses, 1% to 2% became immunized by the time of delivery. Routine antenatal prophylaxis with anti-D reduces the incidence of immunization during pregnancy and is standard practice in the UK. It is given as two doses of anti-D immunoglobulin of either 500 IU or 1500 IU (one at 28 weeks' and one at 34 weeks' gestation) or as a single dose of 1500 IU either at 28 weeks' or between 28 and 30 weeks' gestation. In the UK in 2016, the National Institute for Care and Health Excellence recommended fetal D typing using maternal plasma to avoid the administration of anti-D to females carrying RhD-negative fetuses.

Non-immune haemolytic anaemia

Paroxysmal nocturnal haemoglobinuria

PNH is a rare form of haemolytic anaemia that results from the clonal expression of haemopoietic stem cells that have mutations in the X-linked gene *PIG-A*. These mutations cause impaired synthesis of glycosylphosphatidylinositol, which anchors many proteins, such as decay accelerating factor (CD55), to the cell surface, and membrane inhibitor of reactive lysis (CD59) to cell membranes. CD55, CD59, and other proteins are involved in complement degradation, and in their absence, the haemolytic action of complement continues.

Clinical features

The major clinical signs are intravascular haemolysis, venous thrombosis, and haemoglobinuria. Haemolysis may be precipitated by infection, iron therapy, or surgery. Characteristically, only the urine voided at night and on waking in the morning is dark, though the reason for this phenomenon is not clear. In severe cases, all urine samples are dark. Urinary iron loss may be sufficient to cause iron deficiency. Some patients present insidiously with signs of anaemia and recurrent abdominal pain.

Venous thrombotic episodes may occur at atypical sites and severe thromboses may be a feature, such as in hepatic (Budd–Chiari syndrome), mesenteric, or cerebral veins. The cause of the increased predisposition to thrombosis is not known but may be:

- Complement-mediated activation of platelets deficient in CD55 and CD59
- Haemolysis releases Hb in the plasma and lowers plasma nitric oxide.

Investigations

- ***Intravascular haemolysis*** is evident (see 'Intravascular haemolysis' section).
- ***Flow cytometric analysis*** of RBCs with anti-CD55 and anti-CD59.
- ***Bone marrow*** is sometimes hypoplastic (or even aplastic) despite haemolysis.

Management and prognosis

PNH is a chronic disorder requiring supportive measures such as blood transfusions, which are necessary for patients with severe anaemia. However, treatment with ***eculizumab*** has revolutionized therapy. The drug is administered intravenously every 7 days for the first 5 weeks and then fortnightly. It is a recombinant humanized monoclonal antibody that prevents cleavage of C5 and therefore formation of the membrane attack complex. It reduces intravascular haemolysis, haemoglobinuria and the need for transfusion, and it improves quality of life. Eculizumab also lowers risk of thrombosis, which was the leading cause of death in patients with PNH. The most serious risk of terminal complement blockade is infection with *Neisseria meningitidis*; thus, vaccination against *N. meningitidis* is recommended 2 weeks before commencing treatment.

PNH may transform into aplastic anaemia or acute leukaemia but may remain stable for many years; the PNH clone may even disappear. With appropriate treatment, the median survival time of patients with PNH is now similar to that of age-matched control participants.

Brodsky RA. How I treat paroxysmal nocturnal haemoglobinuria. *Blood* 2021; 137:21304–21309.

Mechanical haemolytic anaemia

RBCs may be injured by physical trauma in the circulation. Direct injury may cause immediate cell lysis or be followed by resealing of the cell membrane with the formation of distorted RBCs or 'fragments'. These cells may circulate for a short period before being destroyed prematurely in the reticuloendothelial system. Causes include:

- Damaged artificial heart valves
- March haemoglobinuria: damage to RBCs in the feet, associated with prolonged marching or running
- MAHA: fragmentation of RBCs occurs in an abnormal microcirculation (e.g., malignant hypertension, eclampsia, haemolytic uraemic syndrome, TTP, vasculitis, disseminated intravascular coagulation [DIC]).

POLYCYTHAEMIA

Polycythaemia (or erythrocytosis) is defined as an increase in Hb or haematocrit (Hct). Hct is a more reliable indicator of polycythaemia than Hb, which may be disproportionately low in those with iron deficiency. Relative erythrocytosis occurs when the RBC volume is normal but there is a decrease in the plasma volume.

Polycythaemia can be classified as primary or secondary. Primary polycythaemia (polycythaemia vera) is a neoplastic process. Secondary polycythaemia can be congenital or acquired. The latter is caused by either an appropriate increase in EPO in response to hypoxia or inappropriate ectopic EPO production by tumours, such as a renal carcinoma. The causes of polycythaemia are given in **Box 38.16**.

Secondary polycythaemias

Serum EPO concentrations are normal or raised in secondary polycythaemia.

Many high-oxygen affinity Hb mutants have been described that lead to increased oxygen affinity but decreased oxygen delivery to the tissues, resulting in compensatory polycythaemia. Chuvash polycythaemia is an autosomal recessive disorder caused by a defect in the oxygen-sensing EPO production pathway caused by a mutation of the von Hippel–Lindau *(VHL)* gene, resulting in increased production of EPO.

Rarely, the discovery of a high EPO concentration may be a clue to the presence of an EPO-secreting tumour.

Management

Treatment is of the precipitating factor (e.g., resection of renal or posterior fossa tumours). The most common cause is heavy smoking, which can produce as much as 10% carboxyhaemoglobin, leading to polycythaemia because of a reduction in blood oxygen-carrying capacity. Heavy smokers may also have respiratory disease.

Complications of secondary polycythaemia are distinct to those seen in polycythaemia vera. Although hyperviscosity symptoms and thromboembolic episodes can occur, management depends on the underlying cause. Complications from myeloproliferative disease, such as progression to myelofibrosis or acute leukaemia, do not develop. Venesection may be symptomatically helpful in certain patients with secondary polycythaemia, particularly if the Hct is above 0.54.

? Box 38.16 Causes of polycythaemia

Primary
- Polycythaemia vera

Congenital
- Mutations in erythropoietin receptor
- High-oxygen-affinity haemoglobins
- Mutations in hypoxia-sensing pathways (e.g., Chuvash polycythaemia mutation in von Hippel–Lindau gene)

Secondary

Increase in erythropoietin caused by hypoxia
- High altitude
- Chronic lung disease
- Cardiovascular disease (right-to-left shunt)
- Sleep apnoea
- Morbid obesity
- Heavy smoking

Caused by an inappropriate increase in erythropoietin
- Renal disease: renal cell carcinoma, Wilms' tumour
- Hepatocellular carcinoma
- Adrenal tumour
- Cerebellar haemangioblastoma
- Massive uterine leiomyoma
- Over-administration of erythropoietin
- Treatment with androgen preparations

Relative
- Stress or spurious polycythaemia
- Dehydration
- Burns

'Relative' or 'apparent' polycythaemia (Gaisböck's syndrome)

The RBC volume is normal, and there is relative polycythaemia because of decreased plasma volume. 'Relative' polycythaemia is more common than polycythaemia vera and typically occurs in middle-aged males, particularly in association with smoking, high alcohol intake, obesity, and high blood pressure. The condition may present with cardiovascular disease, including myocardial or cerebral ischaemia. For this reason, it may be justifiable to venesect selected patients. Management requires modification of lifestyle factors, including smoking and alcohol.

THE SPLEEN

The spleen is the largest lymphoid organ in the body and is situated in the left hypochondrium. There are two anatomical components:

- The red pulp, consisting of sinuses lined by endothelial macrophages and cords (spaces)
- The white pulp, which has a structure like that of lymphoid follicles.

Blood enters via the splenic artery and is delivered to the red and white pulp. During the flow, the blood is 'skimmed', with leucocytes and plasma preferentially passing to white pulp. Some RBCs pass rapidly through into the venous system, and others are held up in the red pulp.

Function

Sequestration and phagocytosis

Normal RBCs, which are flexible, pass through the red pulp into the venous system without difficulty. Old or abnormal cells are damaged by the hypoxia, low glucose, and low pH in the sinuses of the red pulp and are therefore removed by

phagocytosis along with other circulating foreign matter. Howell–Jolly and Heinz bodies and sideroblastic granules have their particles removed by 'pitting' and are then returned to the circulation. IgG-coated RBCs are removed through their Fc receptors by macrophages.

Extramedullary haemopoiesis

Pluripotential stem cells are present in the spleen and proliferate during severe erythroid stress, such as in haemolytic anaemia, thalassaemia major, and myelofibrosis. This occurs because of the presence of anaemia despite every available marrow cavity already being fully engaged in haemopoiesis. It is usually a feature of ineffective erythropoiesis.

Immunological function

About 25% of the body's T lymphocytes and 15% of B lymphocytes are present in the spleen. The spleen shares the function of production of antibodies with other lymphoid tissues.

Blood pooling

Up to one-third of the platelets are sequestrated in the spleen and can be rapidly mobilized. Enlarged spleens pool a significant percentage (up to 40%) of the RBC mass.

Splenomegaly

The spleen enlarges from under the left costal margin inferiorly and medially. It is dull to percussion, and it may be possible to palpate a notch along its leading edge, which further differentiates the mass from an enlarged left kidney. The spleen typically measures 11 cm in its longest dimension. An enlarged spleen is only palpable if it is 1.5 to 2 times the size of a normal spleen. Ultrasound or CT scanning may be used to confirm splenomegaly and may also provide other useful information, such as the presence of abdominal lymphadenopathy.

Aetiology

A clinically palpable spleen can have many causes:

- Infection:
  - Acute (e.g., septic shock, infective endocarditis, typhoid, infectious mononucleosis)
  - Chronic (e.g., TB, brucellosis)
  - Parasitic (e.g., malaria, kala-azar, schistosomiasis)
- ***Inflammation:*** rheumatoid arthritis, sarcoidosis, SLE
- ***Haematological factors:*** haemolytic anaemia, haemoglobinopathies, leukaemia, lymphoma, myeloproliferative disorder
- ***Portal hypertension:*** liver disease
- ***Miscellaneous:*** storage diseases (e.g., Gaucher's disease), amyloidosis, primary and secondary neoplasias, tropical splenomegaly.

Massive splenomegaly is seen in myelofibrosis, chronic myeloid leukaemia, chronic malaria, kala-azar or, rarely, Gaucher's disease.

Hypersplenism

This can result from splenomegaly of any cause. It is commonly seen with splenomegaly from haematological disorders, portal hypertension, rheumatoid arthritis (Felty's syndrome), or lymphoma. Hypersplenism produces:

- Pancytopenia
- Haemolysis caused by sequestration and destruction of RBCs in the spleen
- Increased plasma volume.

Box 38.17 Prophylaxis against infection after splenectomy or in splenic dysfunction

Vaccinate 2–3 weeks before elective splenectomy.

- 23-Valent unconjugated pneumococcal polysaccharide vaccine repeated every 5 years
- Meningococcal polysaccharide vaccine (ACWY)
- Meningococcus group B vaccination
- Annual influenza vaccine

Antibiotic prophylaxis

- Long-term penicillin V 500 mg 12-hourly (if allergic, use erythromycin)

Management

This is often dependent on the underlying cause; splenectomy is sometimes required for severe anaemia or thrombocytopenia. Splenectomy is performed mainly for:

- Trauma
- ITP (see 'Immune thrombocytopenic purpura' section)
- Haemolytic anaemias (see 'Haemolytic anaemias' section)
- Hypersplenism

Problems after splenectomy

An increased platelet count (usually 600–1000 × 10^9/L) may occur for 2 to 3 weeks with risk of thromboembolic phenomena. In the longer term, there is an increased risk of overwhelming infections, particularly pneumococcus.

Prophylaxis against infection after splenectomy or splenic dysfunction

See **Box 38.17** for prophylactic measures. All patients should be educated about the risk of infection and the importance of early recognition and treatment. They should be given an information leaflet and should carry a card, bracelet, or electronic health alert.

Post-splenectomy haematological features

- ***Thrombocytosis*** persists in about 30%.
- The ***WCC*** is usually normal, but there may be a mild lymphocytosis and monocytosis.
- ***Abnormalities in RBC morphology*** are most prominent and include Howell–Jolly bodies (basophilic nuclear remnants), Pappenheimer bodies (sideroblastic granules), target cells, and irregular contracted RBCs (**Fig. 38.19**). Pitted RBCs can be counted.

Splenic atrophy

This is seen in sickle cell disease because of infarction. Hyposplenism is also seen in a wide range of non-haematological diseases, including coeliac disease, dermatitis herpetiformis, and occasionally ulcerative colitis. Post-splenectomy haematological features are seen.

BLOOD TRANSFUSION

Cells and proteins in the blood express antigens that are controlled by polymorphic genes; a specific antigen may be present in some individuals but not in others. A blood transfusion may

immunize the recipient against donor antigens that the recipient lacks (alloimmunization), and repeated transfusions increase the risk. Similarly, the transplacental passage of fetal blood cells during pregnancy may alloimmunize the mother against fetal antigens inherited from the father. Antibodies stimulated by blood transfusion or pregnancy, such as Rh antibodies, are termed ***immune antibodies***. They are usually IgG, in contrast to ***naturally occurring antibodies*** such as ABO antibodies, which are made in response to environmental antigens present in food and bacteria and are usually IgM.

Blood groups

Blood group antigens are proteins, GPs, or carbohydrates attached to GPs on the surface of RBCs; more than 300 blood groups are recognized. The ABO and Rh systems are the two major blood groups, but incompatibilities involving many other blood groups (e.g., Kell, Duffy, Kidd) may also cause haemolytic transfusion reactions or HDN.

ABO system

This is the most important blood group system in transfusion practice because naturally occurring IgM anti-A and anti-B antibodies can produce rapid and severe intravascular haemolysis of incompatible RBCs.

The ABO system is under the control of three allelic genes, *A*, *B*, and *O*, producing the genotypes and phenotypes shown in **Box 38.18**.

The precursor for A and B antigens is the H antigen, which codes for an enzyme that attaches fucose to galactose on an oligosaccharide structure on the RBC membrane. The *A* and *B* genes control specific enzymes responsible for the addition to H of *N*-acetylgalactosamine for group A and D-galactose for group B (**Fig. 38.31**). The *O* gene is amorphic and does not transform H, so O is not antigenic. The A, B, and H antigens are present in most body cells. They are also found in soluble form in tissue fluids (e.g., saliva, gastric juice) in the 80% of the population who possess secretor genes.

Rh system

Development of IgG RhD antibodies after exposure of RhD-negative individuals to RhD-positive RBCs occurs frequently, causing HDN and haemolytic transfusion reactions.

This system is coded by allelic genes: *C* and *c*; *E* and *e*l and *D* and no *D*, signified as *d*. They are inherited as triplets on each chromosome 1, one from each pair of genes (e.g., *CDE*/*cde*). RhD-negative individuals have no D protein in the RBC membrane, which explains why it is so immunogenic when RhD-negative individuals are exposed to RhD antigen through transfusion or pregnancy. In those of White European ethnicity, the RhD-negative phenotype almost always results from a complete deletion of the *RhD* gene; in those of Black African ethnicity, it can also result from an inactive gene containing stop codons in the reading frame.

Procedure for blood transfusion in hospitals

The safety of blood transfusion in hospitals depends on meticulous attention to detail at each stage before and during transfusion. Avoidance of patient and blood sample identification errors at the time of sample collection for compatibility testing and at the time of transfusion would avoid most serious haemolytic transfusion reactions, almost all of which involve the ABO system.

Pre-transfusion compatibility testing

Blood grouping

The ABO and RhD groups of the patient are determined.

Antibody screening

The patient's serum or plasma is screened for atypical antibodies that may cause a significant reduction in survival of transfused RBCs. The patient's serum or plasma is tested against RBCs from at least two group O donors expressing a wide range of RBC antigens, for detection of IgM RBC alloantibodies (using a direct agglutination test of cells suspended in saline) and IgG antibodies (using an indirect antiglobulin test; **Fig. 38.29**). About 10% of patients have a positive antibody screening result. If this occurs, further testing using a comprehensive panel of typed RBCs to determine the blood group specificity of the antibody is performed. Clinically significant RBC antibodies are detected in about 20% of patients with positive antibody screen results.

Transfusion laboratory testing

Several systems for blood grouping, antibody screening, and cross-matching are available to hospital transfusion laboratories. Not all depend on the traditional agglutination of RBCs in suspension. Others work by differential passage of agglutinated and unagglutinated RBCs through a column of dextran gel matrix (e.g., DiaMed and Ortho Biovue systems) or on the capture of antibodies by RBCs immobilized on the surface of a microplate well (e.g., Capture-R solid phase system).

Selection of donor blood and compatibility testing

Selection procedures

Donor blood of the same ABO and RhD group as the patient is selected. Matching for additional blood groups is carried out for patients with clinically significant RBC antibodies (see later) and for patients who are likely to be multi-transfused and at high risk of developing antibodies (e.g., in sickle cell disease). Many hospitals routinely provide Kell-negative blood for females of childbearing age to minimize the risk of alloimmunization caused by anti-K and subsequent HDN.

Compatibility testing procedures

Timing of sample collection

The timing of sample collection for compatibility testing must take account of pregnancy or recent transfusion because both may

Box 38.18 The ABO system: antigens and antibodies

Phenotype	Genotype	Antigens	Antibodies	Frequency in the UK (%)
O	OO	None	Anti-A and anti-B	43
A	AA or AO	A	Anti-B	45
B	BB or BO	B	Anti-A	9
AB	AB	A and B	None	3

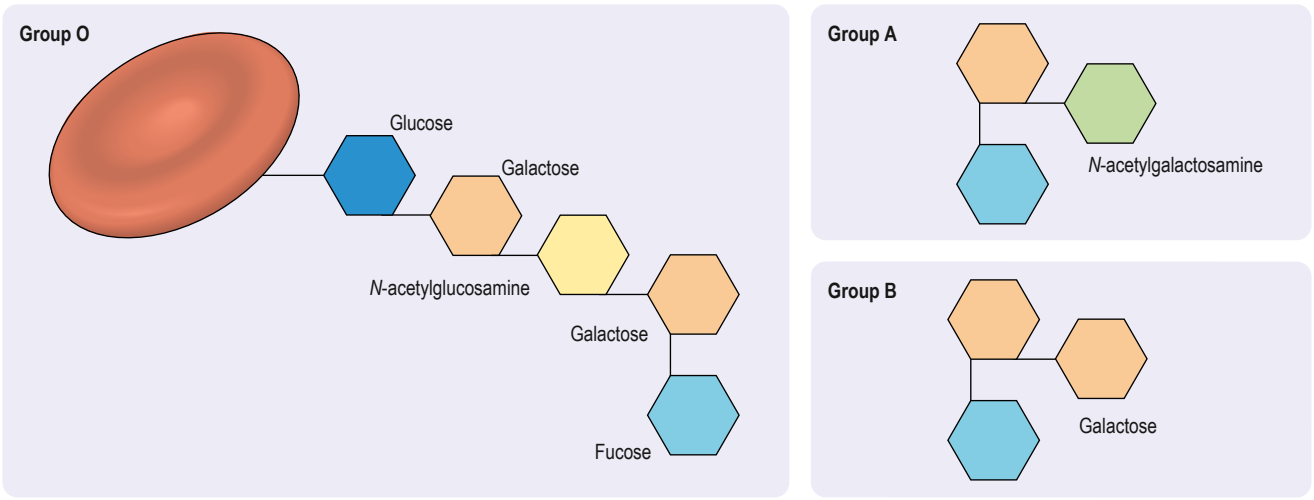

Fig. 38.31 Sugar chains in the ABO blood group system. See text ('ABO system' section).

stimulate antibodies that could cause a haemolytic transfusion reaction. Blood samples should be collected no more than 3 days before transfusion if the patient has been transfused or pregnant within the preceding 3 months.

Patients without atypical red blood cell antibodies

A full crossmatch involves testing the patient's serum or plasma against donor RBCs suspended in saline in a direct agglutination test and using an indirect antiglobulin test. In many hospitals, this serological crossmatch is now omitted because a negative antibody screen makes it highly unlikely that there will be any incompatibility with the donor. Error in collection or labelling of the patient sample or a mix-up of samples in the laboratory are much greater risks. When the antibody screen result is negative, laboratories can use their information system to check the patient records and authorize the release of ABO-compatible donor units ***(computer or electronic crossmatching)***.

Electronic issue can be extended to fridges remote from the main laboratory ***('remote blood issue')*** provided they are electronically linked to the blood transfusion laboratory's information system. The printing of compatibility labels for the blood and its collection are under electronic control, applying the same rules as electronic issue from the main laboratory. Issue of blood using this process reduces the time taken to provide blood for patients, particularly at hospitals without a blood transfusion laboratory, because transport of blood from the central laboratory is not required. There are good examples of centralized transfusion services in cities such as Oxford in the UK and Pittsburgh and Seattle in the USA, and this model is likely to be increasingly employed in the future.

Patients with atypical red blood cell antibodies

Donor blood should be selected that lacks the relevant RBC antigen(s) and is the same ABO and RhD group as the patient. A full crossmatch should always be carried out in case new antibodies have developed.

Blood ordering

Hospitals are increasingly relying on electronic systems for blood ordering; some include algorithms for appropriate use of blood, with 'alerts' if there is non-compliance with agreed blood count triggers for transfusion. Electronic systems also provide data on comparative use of blood for clinical teams and the documentation of consent to transfusion.

Elective surgery

Many hospitals have guidelines for ordering blood for elective surgery (maximum surgical blood ordering schedules). These are aimed at reducing unnecessary crossmatching, which increases the risk of blood eventually becoming outdated and wasted. Many operations in which blood is required only occasionally for unexpected high blood loss can be classified as ***group and save***; this means that when the antibody screen is negative, blood is not reserved but can be made available quickly if necessary—that is, in a few minutes—using the electronic crossmatch procedure described. However, if a patient has atypical antibodies and is undergoing any procedure or surgery that may result in the need for transfusion, compatible blood should be available; this may take several days if the patient has multiple or unusual antibodies.

Emergencies

There may be insufficient time for full pre-transfusion testing. Options include:

- Blood required immediately: 2 units of O RhD-negative blood ***(emergency stock)*** is used to allow additional time for the laboratory to group the patient.
- Blood required in 10 to 15 minutes: Blood of the same ABO and RhD groups as the patient is used ***('group compatible blood')***.
- Blood required in 45 minutes: Most laboratories are able to provide fully crossmatched blood within this time.

Complications of blood transfusion

Reporting schemes under the term ***haemovigilance*** have been established in many countries, including the Serious Hazards of Transfusion (SHOT) scheme in the UK, which produced its first report in 1997. SHOT reported 35 deaths from blood transfusion in its 2022 report of which 18 (51%) were caused by transfusion reaction and 17

Box 38.19 Complications of blood transfusion

Immunological

Alloimmunization and incompatibility

- Red blood cells
  - Immediate haemolytic transfusion reactions
  - Delayed haemolytic transfusion reactions
- Leucocytes and platelets
  - Non-haemolytic (febrile) transfusion reactions
  - TRALI
  - Poor survival of transfused platelets and granulocytes
  - Post-transfusion purpura
  - TA-GvHD
- Plasma proteins
  - Urticarial and anaphylactic reactions

Non-immunological

Transmission of infection

- Viruses
  - Hepatitis: A, B, C, E
  - HIV
  - CMV, HTLV-1, West Nile virus, Dengue, Zika
- Parasites
  - Malaria
  - Trypanosomiasis
  - Babesia
- Bacteria
- Prions

Transfusion-associated circulatory overload
Iron overload caused by multiple transfusions

Bleeding and electrolyte changes: may be caused by massive transfusion of stored blood

CMV, Cytomegalovirus; *HIV,* human immunodeficiency virus; *HTLV-1,* human T-cell leukaemia (or lymphotropic) virus 1; *TA-GvHD,* transfusion-associated graft-versus-host disease; *TRALI,* transfusion-related acute lung injury.

(49%) were caused by error. Transfusion-associated circulatory overload occurred in 8 (23%) patients (Fig. 38.32). Data from the SHOT reports indicating that ***'incorrect blood component transfused'*** is the most frequent type of serious incident with pulmonary complications the most frequent cause of morbidity and mortality. Errors in clinical areas, including collection of the blood sample for compatibility testing, collection of blood from the fridge, or the administration of blood, are more frequent than laboratory errors (Box 38.19).

Prevention of wrong blood transfusions

The potentially serious consequences of errors in transfusion emphasize the need for meticulous procedures. Good training of staff is essential, and regular reviews of practice to ensure compliance with standard procedures are required. New approaches include the use of barcode patient identification and new technology at the bedside. Handheld devices can prompt staff through the key steps and check that the barcode on the patient's wristband matches the barcode on the unit of blood (Box 38.20).

Immunological complications

Alloimmunization

Blood transfusion carries a risk of alloimmunization to the many 'foreign' antigens present on RBCs, leucocytes, platelets, and plasma proteins. Alloimmunization also occurs during pregnancy to fetal antigens inherited from the father and not shared by the mother.

Alloimmunization does not usually cause clinical problems (e.g., haemolytic transfusion reaction) with the first transfusion, but they may occur with subsequent transfusions. There may also be delayed consequences of alloimmunization, such as HDN and rejection of tissue or organ transplants.

Incompatibility

Transfusion of blood cells such as RBCs and platelets into a recipient who has antibodies against antigens on the cells may result in poor survival of the transfused cells and in harmful effects of the antigen–antibody reaction.

Red blood cell complications: haemolytic transfusion reaction (immediate)

This is the most serious and life-threatening complication of blood transfusion and is usually caused by ABO incompatibility. There is complement activation by the antigen–antibody reaction, usually caused by IgM anti-A or anti-B antibodies. Initial symptoms and signs (rigors, lumbar pain, dyspnoea, hypotension, and haemoglobinuria) begin a few minutes after starting the transfusion. Kidney failure may develop. Activation of coagulation occurs and bleeding caused by DIC is a bad prognostic sign. Emergency treatment for patients with shock is needed to maintain blood pressure and kidney function.

Diagnosis

This is confirmed by finding evidence of intravascular haemolysis (e.g., haemoglobinuria) and incompatibility between the donor and recipient. All documentation should be checked for errors such as:

- Failure to check patient identity when taking the sample for compatibility testing (i.e., sample from the wrong patient)
- Mislabelling of the blood sample with the wrong patient's name
- Labelling or handling errors in the laboratory
- Errors in the collection of blood, leading to delivery of the wrong blood to the ward or theatre
- Failure to perform proper identity checks before the blood is transfused (i.e., blood transfused to the wrong patient).

Investigations

To confirm where the error occurred, blood grouping should be carried out on:

- The patient's original sample (used for the compatibility testing)
- A new sample taken from the patient after the reaction
- The donor units.

At the first suspicion of any serious transfusion reaction, the transfusion should always be stopped and the donor units returned to the blood transfusion laboratory with a new blood sample from the patient to exclude a haemolytic transfusion reaction.

Red blood cell complications: haemolytic transfusion reaction (delayed)

This occurs in patients alloimmunized by previous transfusions or pregnancies. The antibody concentration is too low to be detected by pre-transfusion compatibility testing, but a secondary immune response is seen after the transfusion, resulting in destruction of the transfused cells, usually by IgG antibodies.

Haemolysis is usually extravascular because the antibodies are IgG. The patient may develop anaemia and jaundice about 1 week after the transfusion, although most episodes are clinically silent. The blood film shows spherocytosis and reticulocytosis. The DAT result is positive and detection of the antibody is usually straightforward.

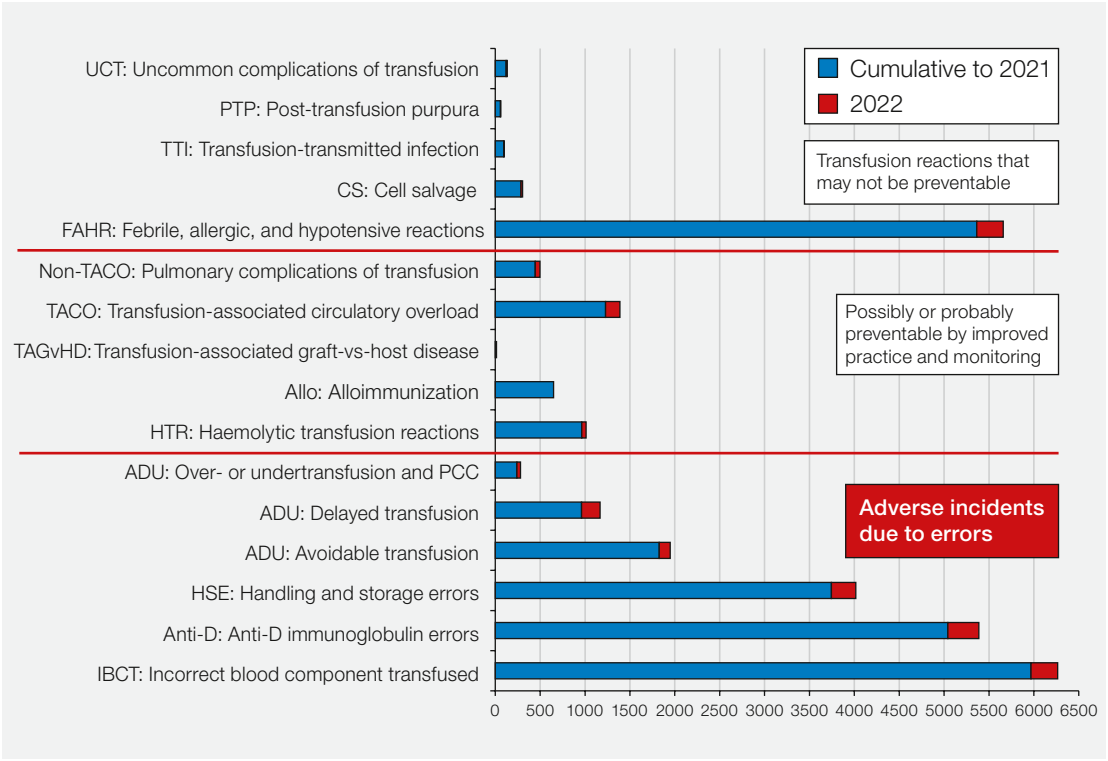

Fig. 38.32 Cumulative data for Serious Hazards of Transfusion categories 1996 to 2022 (*n* = 28877). The adverse events are divided into transfusion reactions that may not be preventable, those that are probably or possibly preventable, and those caused by mistakes. Those reported in 2022 are indicated in red at the *right-hand side* of each *bar*. *PCC,* Prothrombin complex concentrates. *(From Narayan S (ed), Poles D et al. on behalf of the Serious Hazards of Transfusion (SHOT) Steering Group. The 2022 Annual SHOT Report (2023). https://doi.org/10.57911/WZ85-3885. Resources from SHOT are reviewed and updated regularly so please refer to the SHOT website for up-to-date content.)*

Box 38.20 Bedside checks for blood unit compatibility

- Traditional (historical) pre-transfusion bedside checking
  - Two healthcare professionals
  - Multiple checks of written documentation
- Barcode technology
  - Prompts key steps
  - Scans patient's unique barcode ID
  - Including asking patient to state their full name and date of birth
  - Checks patient's details match those on the unit's compatibility label barcode after pre-transfusion testing
  - The unit's compatibility label barcode contains the unique number of the unit, which is matched with the unit number at the top left of the bag ensuring the blood bank has attached the right compatibility label to the bag

Leucocyte complications: non-haemolytic (febrile) transfusion reactions

The typical cause of febrile reactions after RBC transfusions is the presence of leucocyte antibodies in patients who have previously been transfused or pregnant. Antibodies against donor leucocytes lead to the release of pyrogens. The mechanism of febrile reactions is different after platelet transfusions, in which the release of cytokines from donor leucocytes is the most likely cause. Typical signs are flushing, tachycardia, fever (>38°C), chills, and rigors, which are uncomfortable but not life-threatening. Paracetamol may be used to reduce the fever, although it should not be given to patients with thrombocytopenia. The routine introduction of leucocyte-reduced blood in the UK to minimize the risk of transmission of variant Creutzfeldt–Jakob disease (vCJD) by blood transfusion (see later) has reduced the incidence of febrile reactions in the UK.

Transfusion-related acute lung injury

Potent leucocyte antibodies in the plasma of donors (usually multiparous females) may cause transfusion-related acute lung injury (TRALI) characterized by dyspnoea, fever, cough, and shadowing in the perihilar and lower lung fields on a chest radiograph. Prompt respiratory support is essential, and mechanical ventilation is frequently necessary. TRALI usually resolves within 48 to 96 hours but the mortality can occur. The avoidance of female plasma in the preparation of fresh-frozen plasma (FFP) and pooled platelets, and the testing of female plateletpheresis donors for leucocyte antibodies has been implemented in many high-income countries to reduce the risk of TRALI; the number of reported cases has fallen considerably.

Transfusion-associated graft-versus-host disease

Transfused donor lymphocytes that share HLA haplotype with the patient are not rejected and may recognize the patient as 'foreign' causing an acute GvHD reaction including pancytopenia. It is usually fatal. No cases have occurred in the UK for many years, probably because of the routine leucocyte reduction of blood components since 1999. However, certain groups of immunosuppressed patients at particular risk of TA-GvHD should receive irradiated blood to minimize the danger. Such

patients include those with congenital or acquired immunodeficiencies (e.g., individuals who have had treatment with purine analogue chemotherapy, patients with Hodgkin lymphoma, those who have undergone haemopoietic stem cell transplantation, and fetuses and neonates who have received intrauterine transfusions).

Platelet complications: post-transfusion purpura

A rare transfusion reaction characterized by severe thrombocytopenia, which can be life-threatening.

Plasma protein complications: urticaria and anaphylaxis

Urticarial reactions are often attributed to plasma protein incompatibility, but in most cases, they are unexplained. They are common but rarely severe; stopping or slowing the transfusion and administering chlorphenamine 10 mg intravenously are usually sufficient treatment.

Anaphylactic reactions occasionally occur; severe reactions are seen in patients lacking IgA who produce anti-IgA that reacts with IgA in the transfused blood. The transfusion should be stopped and ***adrenaline (epinephrine)*** 0.5 mg intramuscularly and ***chlorphenamine*** 10 mg intravenously given immediately; endotracheal intubation may be required. Patients who have had severe urticarial or anaphylactic reactions should receive washed RBCs. Blood from IgA-deficient donors is required for patients with IgA deficiency.

Immunosuppression

Transfusions are known to have a negative effect on the survival of later kidney allografts caused by transfusion-induced immunomodulation. The precise mechanism is unclear but may be associated with the transfusion of allogeneic leucocytes. Transfusion-induced immunosuppression, including an increase in postoperative infection and tumour recurrence, has been hypothesized but remains unproven.

Non-immunological complications

Transmission of infection

Although stringent measures are being taken to minimize the risk of transfusion-transmitted infection, it may never be possible to guarantee that donor blood is absolutely 'safe'. The current approach to the safety of blood components and plasma in the UK and other high-income countries is cautious, but it is not an absolute guarantee of safety. Clinicians should always consider the patient's requirement for transfusion carefully and only transfuse if clinically appropriate (see later).

Viral transmission

Donor blood in the UK is currently tested for hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis E virus (HEV), human immunodeficiency virus (HIV)-1, and human T-cell leukaemia virus 1. CMV-seronegative blood is given to fetuses and neonates and during pregnancy. Blood services continue a vigilant search for new infectious agents ('emerging' infections) that may be transmitted by blood transfusion and for methods to prevent their transmission, including donor screening, testing, and pathogen inactivation. Donor questionnaires record recent travel to exclude the possible risk of West Nile virus, the causal agent of meningoencephalitis, which has been transmitted by transfusion and transplantation in the USA, and Zika virus in light of the 2015 to 2016 epidemic.

The risk of transmission of viral infections by blood transfusion varies from country to country, depending on factors such as the underlying prevalence of transfusion-transmitted infections in the population and measures taken to minimize risk of transmission. Viral transmission via blood transfusion is still a major issue in low-income countries. In the UK, the risks of potentially infectious HBV, HCV, or HIV not being detected are very low at less than 1 per million donations tested. Various measures, including treatment with solvents and detergents, are used for inactivating viruses in plasma products such as coagulation factor concentrates and IVIG.

Bacterial transmission

Bacterial contamination of blood components is rare, but when it occurs, it is a frequent cause of death associated with transfusion. Some organisms, such as *Yersinia enterocolitica*, can proliferate in RBC concentrates stored at 4°C. Platelet concentrates stored at 22°C are a more frequent cause of contamination. Measures to avoid bacterial contamination have been implemented in most high-income countries, including strict donor arm cleansing, diversion of the initial blood collection to samples for testing rather than into the collection bag, and bacterial detection systems for platelet concentrate. Such systems were implemented in the UK in 2011, and there have been no cases of bacterial transfusion-transmitted infections since 2015.

Transfusion-transmitted syphilis is very rare. Spirochaetes do not survive for more than 72 hours in blood stored at 4°C, and each donation is tested using the ***Treponema pallidum haemagglutination assay***.

Variant Creutzfeldt–Jakob disease

In the UK, four transmissions of vCJD have occurred after a blood transfusion; the last one was reported in 2004. Measures taken to minimize risk included universal leucocyte reduction of blood components in 1999 because the prion protein was thought to be primarily associated with lymphocytes. Persons who have received a blood transfusion since 1980 are excluded from blood donation in the UK. A ban on the manufacture of blood products using UK donor plasma was lifted in 2020. Imported plasma mostly from the USA had been used to produce blood products such as albumin and immunoglobulins.

Other

- Transfusion associated heart failure due to volume overload
- Iron overload, e.g., from recurrent transfusions in transfusion dependent conditions.

Strategies for the avoidance of unnecessary transfusion

These include:

- Evidence-based criteria for the use of blood components and blood products including:
  - The threshold ('trigger') for transfusion (e.g., Hb concentration or platelet count)
  - The dose. Single-unit transfusions are often sufficient: 'Don't use two when one will do'.
- Discontinuing anticoagulants and antiplatelet drugs whenever possible preoperatively to reduce bleeding in surgical patients
- Identification and treatment of anaemia before surgery and in pregnancy

- Use of antifibrinolytic drugs (e.g., tranexamic acid in major surgery and trauma)
- Use of intraoperative cell salvage of blood in major surgery.

Artificial Hb and other blood substitutes have not yet been developed for routine clinical use. They generally have a short intravascular half-life, and a recent meta-analysis found a significant risk of mortality and myocardial infarction.

Autologous transfusion

An alternative to using blood from volunteer donors is to use the patient's own blood. There are three types of autologous transfusion:

- ***Predeposit.*** The patient donates 2 to 5 units of blood at approximately weekly intervals before elective surgery. There is limited evidence that it reduces blood requirements. In high-income countries, it is only used in rare cases when it is not possible to identify compatible blood because of multiple antibodies.
- ***Preoperative haemodilution.*** Immediately before surgery, 1 or 2 units of blood is removed from the patient and then retransfused to replace operative losses.
- ***Blood salvage.*** Blood lost during or after surgery is collected and retransfused. Several techniques of varying levels of sophistication are available. The operative site must be free of bacteria and bowel contents. Salvage was thought to be contraindicated in cancer surgery because of the risk of facilitating metastases, but many centres are using it with apparent safety. Intraoperative cell salvage is increasingly being used as a way of avoiding the use of donor blood.

In low-income countries, blood from relatives may be used because of a lack of donor blood.

Blood, blood components, and blood products

Most blood collected from donors is processed as follows:

- ***Blood components***, including RBC and platelet concentrates, FFP, and cryoprecipitate, are prepared from a single donation of blood by simple separation (e.g., centrifugation) and are transfused without further processing. Platelet concentrates are also prepared by plateletpheresis (see later).
- ***Blood products***, including coagulation factor concentrates, albumin, and immunoglobulin solutions, are prepared by complex processes using plasma from many donors as the starting material.

In most circumstances, it is preferable to transfuse only the blood component or product required by the patient ***(component therapy)*** rather than using whole blood. This is the most effective way of using donor blood, which is a scarce resource, and it reduces the risk of complications from transfusion of unnecessary blood components. However, there is emerging interest in using whole blood in trauma and other causes of major haemorrhage.

Patients should be provided with information about blood transfusion and alternatives to transfusion whenever possible. This discussion should be documented. Some patients, such as Jehovah's Witnesses, may refuse transfusion and need specialized management when they undergo surgery or receive medical treatments that usually require blood transfusion.

Whole blood

A unit of whole blood consists of 450 mL ± 10% of blood from a suitable donor plus 63 mL of anticoagulant, which is then leucocyte-reduced by filtration. Blood stored at 4°C is given a 'shelf-life' of 5 weeks in the UK (6 weeks in some other countries), when at least 70% of the transfused RBCs should survive normally. Whole blood is rarely used for transfusion, though there is renewed interest in considering its use in major haemorrhage.

Red blood cell concentrates

Virtually all plasma is removed. It is replaced with about 100 mL of an optimal additive solution, such as SAG-M, which contains sodium chloride, adenine, glucose, and mannitol. The mean volume is about 330 mL. The PCV is about 0.57 L/L, but viscosity is low because there are no plasma proteins in the additive solution; this allows fast administration, if necessary. RBC concentrates are used to increase oxygen-carrying capacity in major haemorrhage and to treat non-bleeding patients with severe anaemia. A threshold Hb of 70 g/L for transfusion in anaemia may be increased (e.g., to 80 g/L) in severe cardiovascular disease. Contemporary algorithms for the management of major haemorrhage highlight the need for the early transfusion of FFP and platelets to support haemostasis.

Washed red blood cell concentrates

These are preparations of RBCs suspended in saline, produced by cell separators that remove all but traces of plasma proteins. They are used in patients who have had severe recurrent urticarial or anaphylactic reactions.

Platelet concentrates

These are prepared from single donors either by centrifugation of whole blood or by plateletpheresis of blood using cell separators. They may be stored for up to 7 days at 22°C in the UK after confirmation of a negative bacterial culture result to minimize the risk of bacterial transmission. They are used to treat bleeding in patients with severe thrombocytopenia and prophylactically to prevent bleeding in patients with bone marrow failure when the platelet count is below 10×10^9/L.

Granulocyte concentrates

These are prepared from whole blood as pooled granulocyte products or from blood from single donors using cell separators. They are used for patients with severe neutropenia when there is evidence of bacterial infection. The numbers of granulocytes collected may be increased by treating donors with G-CSF and steroids. The half-life of granulocytes is of the order of a few hours only, so granulocytes need to be collected and transfused daily, making the practicalities of this treatment challenging. There is limited evidence for their effectiveness, and they are commonly associated with febrile and occasional pulmonary reactions.

Fresh-frozen plasma

FFP is prepared by freezing the plasma from 1 unit of blood to –30°C to maintain the concentration of coagulation factors. The volume is approximately 200 mL. FFP contains all the coagulation factors present in fresh plasma and is used mostly for replacement of coagulation factors in acquired coagulation factor deficiencies, such as massive haemorrhage and DIC. It may be treated by a pathogen-inactivation process to minimize the risk of bacterial and blood-borne viral disease transmission.

Prothrombin complex concentrates

These contain factors II, VII, IX, and X and are the recommended treatment for rapid reversal of warfarin toxicity in bleeding patients with an elevated international normalized ratio (INR). The have replaced FFP in this context because of superior efficacy and lower risks of allergic reaction and volume overload.

Cryoprecipitate

This is obtained by allowing the frozen plasma from a single donation to thaw at 4° to 8°C and removing the supernatant. The typical adult dose is two pools each containing 5 donor units. Cryoprecipitate contains factor VIII:C, von Willebrand factor (VWF), and fibrinogen. It may be useful in patients with DIC and other conditions when the fibrinogen concentration is very low. However, fibrinogen concentrates are now available and are increasingly used in preference to cryoprecipitate.

Specific coagulation factor concentrates

Specific factor concentrates are available for factors VII, VIII, IX, X, XI, XIII, and VWF. These are freeze-dried preparations of the specific factor prepared from large pools of plasma. All products come from plasma sources at low risk of vCJD and are virus-inactivated during manufacture with either heat or chemicals. They are used for treating patients with inherited coagulation factor deficiencies when recombinant coagulation factor concentrates are unavailable.

Albumin

There are two preparations:

- ***Human albumin solution 4.5%*** contains 45 g/L of albumin and 160 mmol/L of sodium. It is available in 50-, 100-, 250-, and 500-mL bottles.
- ***Human albumin solution 20%*** contains approximately 200 g/L of albumin and 130 mmol/L of sodium. It is available in 50- and 100-mL bottles.

Human albumin solutions are inappropriate fluids for acute volume replacement or the treatment of shock. However, they are indicated for treatment of management of liver cirrhosis–related complications and as the replacement fluid for plasma exchange.

Normal immunoglobulin

This is prepared from normal plasma. It is used to treat hypogammaglobulinaemia, prevent infections, and in high doses to treat patients with autoimmune disorders, such as ITP (see 'Immune thrombocytopenic purpura' section).

Specific immunoglobulins

These are obtained from donors with high titres of antibodies. Many preparations are available, such as anti-D, anti-hepatitis B, and anti-varicella zoster.

WHITE BLOOD CELLS

Leucocytes found in peripheral blood are:

- Granulocytes: neutrophils, eosinophils, and basophils (all called granulocytes)
- Non-granulocytes: lymphocytes and monocytes
- The development of these cells is shown in **Fig. 38.3F**.

Neutrophils

Precursors to neutrophils in the bone marrow include:

- Myeloblasts: large cells constituting up to 3% of nucleated cells in the bone marrow. The nucleus is large and contains two to five nucleoli. The cytoplasm is scanty and contains no granules.
- Promyelocytes: similar to myeloblasts but have primary cytoplasmic granules, containing enzymes such as myeloperoxidase.
- Myelocytes: smaller cells without nucleoli. The cytoplasm is more abundant and contains primary and secondary granules.
- Metamyelocyte: the indentation of the nucleus marks the change from myelocyte to metamyelocyte.

The mature neutrophil is a smaller cell with a nucleus that has two to five lobes, with predominantly secondary granules in the cytoplasm, which contain lysozyme, collagenase, and lactoferrin. Peripheral blood neutrophils are equally distributed into a circulating pool and a marginating pool lying along the endothelium of blood vessels. In contrast to the prolonged maturation time of about 10 days for neutrophils in the bone marrow, the half-life in the peripheral blood is extremely short: only 6 to 8 hours. In response to stimuli (e.g., infection, corticosteroid therapy), neutrophils are released into the circulating pool from both the marginating pool and the marrow. Immature WBCs are released from the marrow when a rapid response (within hours) occurs in acute infection (described as a 'shift to the left' on a blood film).

Function

The prime function of neutrophils is to ingest and kill bacteria, fungi, and damaged cells. Neutrophils are attracted to sites of infection or inflammation by chemotaxins. Recognition of foreign or dead material is aided by the coating of particles with immunoglobulin and complement (opsonization) because neutrophils have Fc and C3b receptors. The material is ingested into vacuoles, where it is subjected to enzymic destruction; this is either oxygen dependent with the generation of hydrogen peroxide (myeloperoxidase) or oxygen independent (lysosomal enzymes and lactoferrin). Leucocyte alkaline phosphatase is an enzyme found in leucocytes. It is increased when there is a neutrophilia caused by an acute illness. It is also raised in polycythaemia and myelofibrosis and is reduced in chronic myeloid leukaemia.

Neutrophil leucocytosis

A rise in the number of circulating neutrophils to more than 10×10^9/L occurs in bacterial infections and tissue damage. It may also be seen in pregnancy, during exercise, secondary to smoking, and after corticosteroid administration (**Box 38.21**). With any tissue necrosis, there is a release of various soluble factors, causing leucocytosis. IL-1 is released in tissue necrosis and causes a pyrexia. The pyrexia and leucocytosis that accompany a myocardial infarction are a good example of this and may be wrongly attributed to infection.

Box 38.21 Causes of a neutrophil leucocytosis

- Bacterial infections
- Tissue necrosis (e.g., myocardial infarction, trauma)
- Inflammation (e.g., gout, rheumatoid arthritis)
- Drugs (e.g., corticosteroids, lithium)
- Acute haemorrhage or haemolysis
- Administration of granulocyte colony-stimulating factor
- Haematological
  - Myeloproliferative disease
  - Leucoerythroblastosis
- Physiological (e.g., pregnancy, exercise)
- Malignant disease (e.g., bronchial, breast, gastric)
- Metabolic (e.g., kidney failure, acidosis)
- Congenital (e.g., leucocyte adhesion deficiency, hereditary neutrophilia)
- Smoking

A ***leucoerythroblastic blood film*** (an overproduction of WBCs, with many immature cells and nucleated RBCs) may occur in severe infection, TB, malignant infiltration of the bone marrow, and occasionally after haemorrhage or haemolysis and in severe haemolytic or megaloblastic anaemias.

Neutropenia and agranulocytosis

Neutropenia is defined as a circulatory neutrophil count of less than 1.5 × 10^9/L. The causes are given in **Box 38.22**. A virtual absence of neutrophils is called agranulocytosis. Note that patients from African and Caribbean backgrounds may have lower neutrophil counts, termed 'ethnic neutropenia'. This is caused by a greater proportion of the neutrophils residing close to the vessel walls and not by an absolute reduction in total neutrophil production or function.

Viruses are probably the most common causes of neutropenia. Chemotherapy and radiotherapy predictably produce neutropenia. Other drugs (e.g., anti-thyroid drugs such as carbimazole, some antibiotics) can produce an idiosyncratic cytopenia; a drug cause should always be considered.

Clinical features

Infections may be frequent, are often serious, and become more likely as the neutrophil count falls. An absolute neutrophil count of less than 0.5 × 10^9/L is regarded 'severe' and may be associated with life-threatening infections such as pneumonia and septicaemia. A characteristic glazed mucositis occurs in the mouth, and ulceration is common.

Investigations

The blood film shows marked neutropenia. The appearance of the bone marrow indicates whether the neutropenia is caused by depressed production or increased destruction of neutrophils. Neutrophil antibody studies are performed if an immune mechanism is suspected. Viral serology, including HIV, should be undertaken.

Management

Antibiotics should be given as necessary and according to local guidelines in acute severe neutropenia. Exposure to infections should be minimized.

If the neutropenia seems likely to have been caused by a drug, therapy should be stopped. Recovery of the neutrophil count usually occurs after about 10 days. G-CSF is used to decrease the period of neutropenia after chemotherapy and haemopoietic transplantation. It is also used successfully in the treatment of chronic neutropenia.

Box 38.22 Causes of neutropenia

Acquired

- Viral infection
- Severe bacterial infection (e.g., typhoid)
- Felty's syndrome (rheumatoid arthritis associated)
- Autoimmune neutropenia
- Pancytopenia from any cause, including drug-induced marrow aplasia
- Drug-induced agranulocytosis (e.g., carbimazole)
- Pure white blood cell aplasia

Inherited

- Ethnic (neutropenia is common in African and Caribbean ethnicities)
- Kostmann's syndrome: severe infantile agranulocytosis caused by mutation in the elastane 2 *(ELA2)* gene
- Cyclical: genetic mutation in *ELA2* gene with neutropenia every 2–3 weeks
- Others (e.g., Shwachman–Diamond syndrome, dyskeratosis congenita, Chédiak–Higashi syndrome)

Steroids and high-dose IVIG are used to treat patients with severe autoimmune neutropenia and recurrent infections, and G-CSF has produced responses in some cases.

Eosinophils

Eosinophils are slightly larger than neutrophils and are characterized by a nucleus, usually with two lobes, and large cytoplasmic granules that stain deep red. The eosinophil plays a part in allergic responses and in the defence against helminth and protozoal infections. Eosinophilia is defined as more than 0.4 × 10^9/L eosinophils in the peripheral blood. The causes of eosinophilia are listed in **Box 38.23**.

Basophils

The nucleus of basophils is similar to that of neutrophils, but the cytoplasm is filled with large black granules containing histamine, heparin, and enzymes such as myeloperoxidase. The physiological role of basophils is not known. Binding of IgE causes the cells to degranulate and release histamine and other contents involved in acute hypersensitivity reactions.

Basophils are usually few in number (<1 × 10^9/L) but are significantly increased in some myeloproliferative disorders, such as chronic myeloid leukaemia. Basophilia should prompt further investigations.

Monocytes

Monocytes are slightly larger than neutrophils. The nucleus has a variable shape and may be round, indented, or lobulated. The cytoplasm contains fewer granules than neutrophils. Monocytes are precursors of tissue macrophages and dendritic cells; they spend only a few hours in the blood but can continue to proliferate in the tissues for many years.

A monocytosis (>0.8 × 10^9/L) may be seen in chronic bacterial infections (e.g., TB, infective endocarditis); chronic neutropenia; and myelodysplasia, particularly chronic myelomonocytic leukaemia.

Lymphocytes

Lymphocytes form nearly half of circulating WBCs. They descend from pluripotent stem cells (**Fig. 38.3F**). Circulating lymphocytes are

Box 38.23 Causes of eosinophilia

Parasitic infestations:
- Ascaris
- Hookworm
- Strongyloides

Allergic disorders:
- Hayfever (allergic rhinitis)
- Other hypersensitivity reactions, including drug reactions

Skin disorders:
- Urticaria
- Pemphigus
- Eczema

Pulmonary disorders:
- Bronchial asthma
- Tropical pulmonary eosinophilia
- Allergic bronchopulmonary aspergillosis
- Eosinophilic granulomatosis with polyangiitis

Malignant disorders:
- Hodgkin lymphoma
- T-cell non-Hodgkin lymphoma
- Carcinoma
- Eosinophilic leukaemia
- Acute myeloid leukaemia
- Myeloproliferative diseases associated with platelet-derived growth factor rearrangements

Miscellaneous disorders
- Hypereosinophilic syndrome
- Sarcoidosis
- Hypoadrenalism
- Eosinophilic gastroenteritis

small cells, a little larger than RBCs, with a dark-staining central nucleus. There are two main types: T and B lymphocytes.

Lymphocytosis (lymphocyte count >5 × 10^9/L) occurs in response to viral infections (e.g., EBV, CMV, and HIV) and chronic infections such as TB and toxoplasmosis. It is also found in chronic lymphocytic leukaemia and in some lymphomas.

HAEMOSTASIS

The integrity of the circulation is maintained by blood flowing through intact vessels lined by endothelial cells. Haemostasis is the host defence mechanism that protects this integrity after injury to the vessel wall and tissue. It is a complex process that depends on interactions between vessel wall, leucocytes, platelets, and coagulation and fibrinolytic mechanisms. Haemostatic systems are normally quiescent, but after tissue injury, become rapidly activated. The formation of the haemostatic plug is shown in Fig. 38.33.

Vessel wall

The vessel wall is lined by endothelium, which in normal conditions prevents platelet adhesion and thrombus formation. This property is caused by:
- Its negative charge
- Thrombomodulin and heparan sulphate expression
- Synthesis of prostacyclin (prostaglandin I_2 [PGI_2]) and nitric oxide, which cause vasodilation and inhibit platelet aggregation
- Production of plasminogen activator.

Injury to vessels causes reflex vasoconstriction, and endothelial damage results in loss of antithrombotic properties, activation of platelets and coagulation, and inhibition of fibrinolysis (Fig. 38.33).

Platelets

Platelet adhesion

When the vessel wall is damaged, the escaping platelets come into contact with and adhere to collagen and subendothelial bound VWF. This adherence is mediated through GP Ib. GP IIb/IIIa is then exposed, forming a second binding site for VWF. Within seconds of adhesion to the vessel wall, platelets begin to undergo a shape change from a disc to a sphere, spread along the subendothelium, and release the contents of their cytoplasmic granules: dense bodies (containing adenosine diphosphate [ADP] and serotonin) and α-granules (containing platelet-derived growth factor, platelet factor 4, β-thromboglobulin, fibrinogen, VWF, fibronectin, thrombospondin, and other factors).

Platelet activation

The release of ADP leads to a conformational change in the GP IIb/IIIa complex (GPIIb/IIIa) on the surfaces of adherent platelets, allowing it to bind to fibrinogen (Fig. 38.34).

Platelet aggregation

Because fibrinogen is a dimer, it can form a direct bridge between platelets and binds platelets into activated aggregates (Fig. 38.33B) and further platelet release of ADP occurs. A self-perpetuating cycle of events is set up, leading to formation of a platelet plug at the site of the injury.

Coagulation

After platelet aggregation and release of ADP, exposed platelet membrane phospholipids are available for assembly of coagulation factor enzyme complexes (tenase and prothrombinase). The presence of thrombin encourages fusion of platelets, and fibrin formation reinforces the stability of the platelet plug. Central to normal platelet function is ***prostaglandin synthesis***, which is induced by platelet activation and leads to the formation of thromboxane A_2 (TXA_2) in platelets (Fig. 38.35). TXA_2 is a powerful vasoconstrictor that reduces cyclic adenosine monophosphate (AMP) concentrations and initiates the platelet release reaction. PGI_2 is synthesized in vascular endothelial cells and opposes the actions of TXA_2. It produces vasodilation and increases the concentration of cyclic AMP, preventing platelet aggregation on the normal vessel wall, as well as limiting the extent of the initial platelet plug after injury.

Coagulation and fibrinolysis

Coagulation involves a series of enzymatic reactions that lead to the conversion of soluble plasma fibrinogen to fibrin-based clot (Fig. 38.36). Roman numerals are used for most of the factors, but I and II are referred to as fibrinogen and prothrombin, respectively; III, IV, and VI are redundant. The active forms are denoted by 'a'. The coagulation factors are primarily synthesized in the liver and are either serine protease enzyme precursors (factors IX, X, and XI and thrombin) or co-factors (V and VIII), except for fibrinogen, which is polymerized to form fibrin.

Coagulation pathway

This enzymatic amplification system was traditionally divided into 'extrinsic' and 'intrinsic' pathways (Fig. 38.37). This concept is useful for the interpretation of clinical laboratory tests such as the prothrombin time (PT) and activated partial thromboplastin time (APTT),

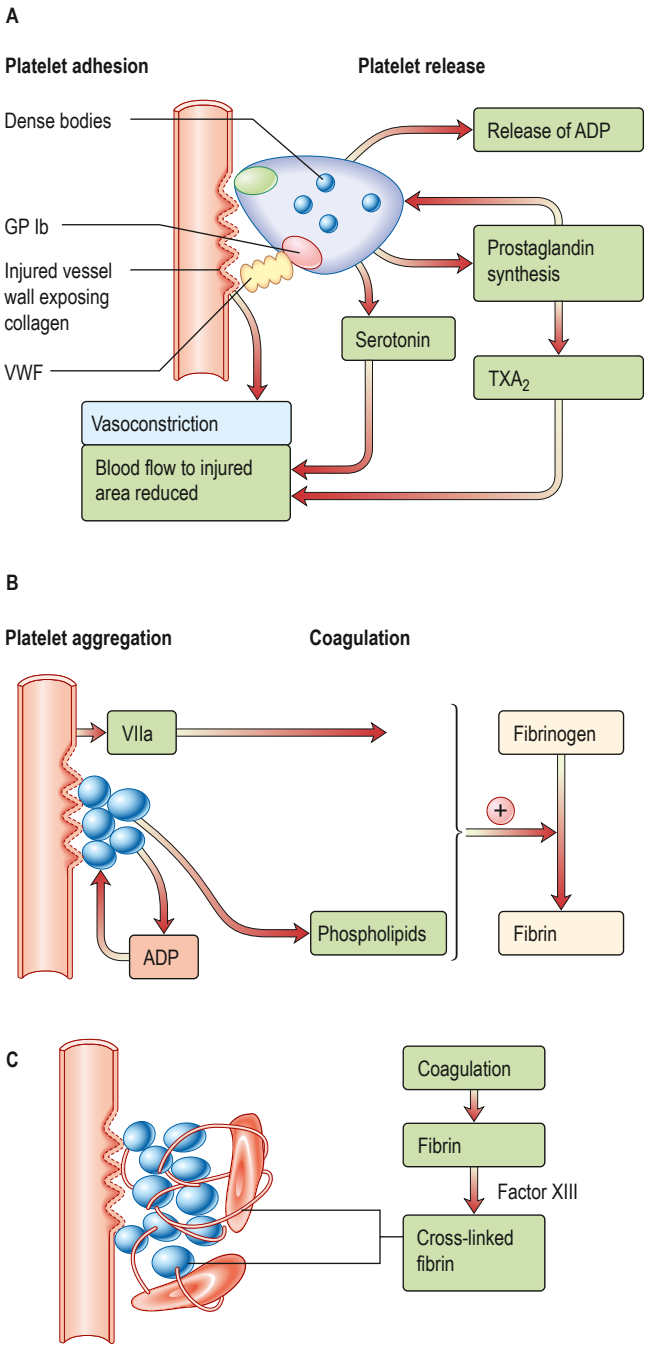

Fig. 38.33 Formation of the haemostatic plug: sequential interactions between the vessel wall, platelets, and coagulation factors. (A) ***Contact of platelets with collagen*** via the platelet receptor glycoprotein (GP) Ib and von Willebrand factor (VWF) activates platelet prostaglandin synthesis, which stimulates release of adenosine diphosphate (ADP) from the dense bodies. Vasoconstriction of the vessel occurs as a reflex and because of release of serotonin and thromboxane A_2 (TXA_2) from platelets. **(B)** ***Release of ADP from platelets*** induces platelet aggregation and formation of the platelet plug. The coagulation pathway is stimulated, leading to the formation of fibrin. **(C)** ***Fibrin strands are cross-linked by factor XIII*** and stabilize the haemostatic plug by binding platelets and red blood cells.

but it is unrepresentative and oversimplifies *in vivo* coagulation. Coagulation is initiated by tissue damage (Fig. 38.36):

- Tissue damage exposes tissue factor (TF), which binds to factor VII.
- The TF–factor VII complex directly converts factor X to active factor Xa and some factor IX to factor IXa.
- In the presence of factor Xa, tissue factor pathway inhibitor (TFPI) inhibits further generation of factor Xa and factor IXa.
- After inhibition by TFPI, the amount of factor Xa produced is insufficient to maintain coagulation. To allow haemostasis to progress to completion, further factor Xa can be generated only by the alternative factor IX–factor VIII pathway. However, enough thrombin exists at this point to activate factor VIII, which dramatically increases the activity of factor IXa (generated by TF–factor VIIa), so further activation of factor X can proceed. Without the amplification and consolidating action of factor VIII–factor IX, bleeding will ensue because generation of factor Xa is insufficient to sustain haemostasis.
- Similarly, thrombin activates factor V, dramatically enhancing conversion of prothrombin to thrombin by factor Xa.
- Thrombin hydrolyses the peptide bonds of fibrinogen, releasing fibrinopeptides A and B and allowing polymerization between fibrinogen molecules to form fibrin. At the same time, thrombin in the presence of calcium ions activates factor XIII, which stabilizes the fibrin clot by cross-linking adjacent fibrin molecules.

Factor VIII

Factor VIII is a key co-factor in the coagulation pathway. It is associated with its carrier protein VWF. When activated, factor VIII increases the conversion of factor X to Xa by factor IXa by approximately 200 000-fold. VWF functions to protect factor VIII from premature proteolytic breakdown and locates it to areas of vascular injury. Factor VIII:C (the antihaemophilic and procoagulant component of the factor VIII complex) has a molecular weight of about 350 kDa.

von Willebrand factor

VWF is a GP with a monomeric molecular weight of about 250 kDa, which readily forms multimers in the circulation with molecular weights of up to 20 000 kDa. It is synthesized by endothelial cells and megakaryocytes and stored in platelet granules and endothelial cells. The high-molecular-weight multimeric forms of VWF are the most biologically active. It has a primary role as an adhesive protein binding to platelets, surface GPs, and constituents of connective tissue. It also acts as a carrier protein for factor VIII (Fig. 38.38).

Factor V

Factor V is similar to factor VIII in that it is a non-enzymatic co-factor. In its thrombin-activated form, factor Va, it significantly enhances conversion of prothrombin to thrombin.

Physiological limitation of coagulation

Without a physiological system to limit blood coagulation, excessive thrombosis could ensue. The natural anticoagulant mechanism regulates and localizes thrombosis to the site of injury.

Antithrombin

Antithrombin, a member of the serine protease inhibitor (serpin) superfamily, is a potent inhibitor of coagulation. It inactivates the serine proteases by forming stable complexes with them and its action is greatly potentiated by heparin.

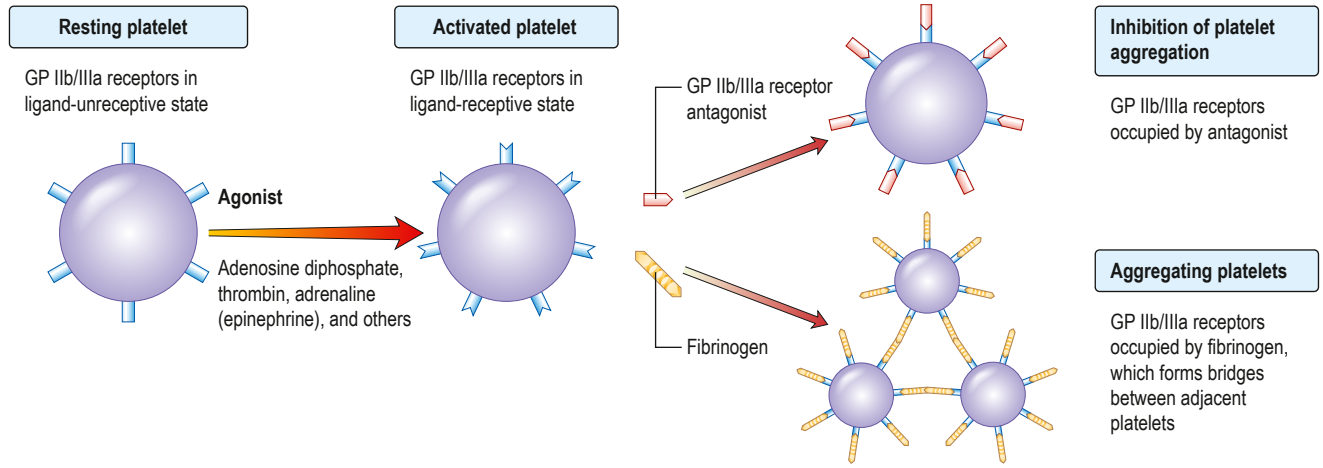

Fig. 38.34 The role of glycoprotein (GP) IIb/IIIa in platelet aggregation and inhibition of platelet aggregation by GP IIb/IIIa receptor antagonists.

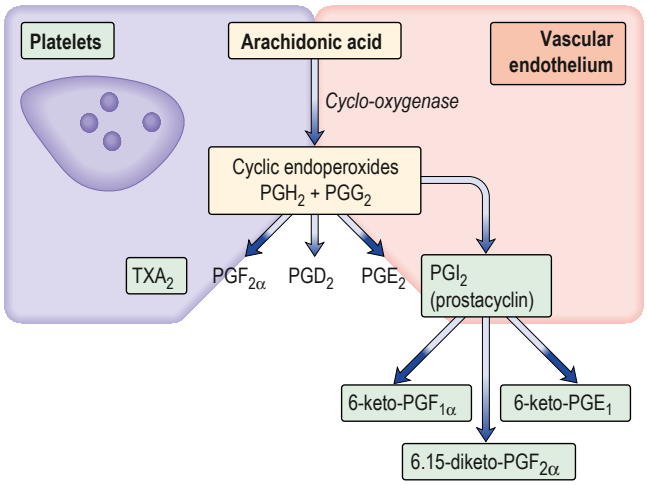

Fig. 38.35 Prostaglandin (PG) synthesis. *TXA_2,* Thromboxane A_2.

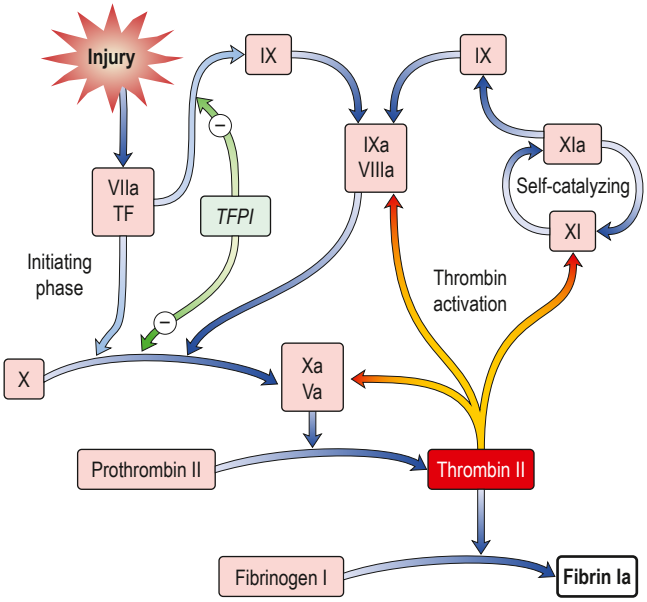

Fig. 38.36 Coagulation mechanism. The *in vivo* pathway begins with the tissue factor–factor VIIa (VIIa–TF) complex activating factor X (Xa) and amplifying factor IX (IXa). Thrombin activates factor XI (XIa), as well as factor IXa, VIIIa, and Va and Xa complexes. *TFPI,* Tissue factor pathway inhibitor.

Activated protein C

This is generated from its vitamin K–dependent precursor, protein C, by thrombin. Thrombin activation of protein C is greatly enhanced when thrombin is bound to thrombomodulin on endothelial cells (Fig. 38.39). Activated protein C inactivates factor Va and factor VIIIa, reducing further thrombin generation.

Protein S

This is a co-factor for protein C, which acts by enhancing binding of activated protein C to the phospholipid surface. It circulates bound to C4b binding protein, but about 30% to 40% remains unbound and active (free protein S).

Other inhibitors

Other natural inhibitors of coagulation include α_2-macroglobulin, α_1-antitrypsin, and α_2-antiplasmin.

Fibrinolysis

Fibrinolysis is a normal haemostatic response that helps to restore vessel patency after vascular damage. The principal component is the enzyme plasmin, which is generated from its inactive precursor plasminogen (Fig. 38.40). This is achieved principally via tissue plasminogen activator (t-PA) released from endothelial cells. Some plasminogen activation may also be promoted by urokinase, produced in the kidneys. Other plasminogen activators (factor XII and prekallikrein) have minor physiological importance.

Plasmin

Plasmin is a serine protease that breaks down fibrinogen and fibrin into fragments X, Y, D, and E, collectively known as fibrin (and fibrinogen) degradation products (FDPs). D-dimer is produced when cross-linked fibrin is degraded. Its presence in the plasma indicates that the coagulation mechanism has been activated.

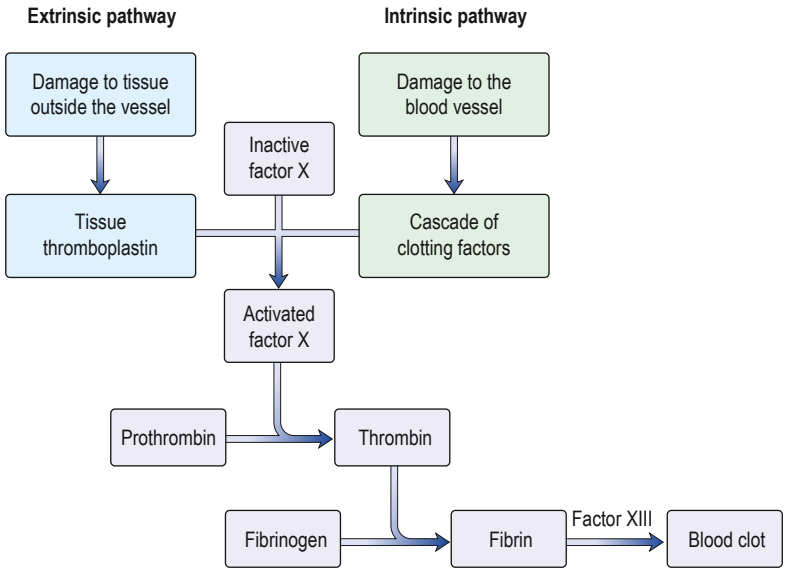

Fig. 38.37 The classic *in vitro* extrinsic and intrinsic coagulation cascade. See also Fig. 38.36. Initiation of coagulation differs significantly *in vitro* from *in vivo*.

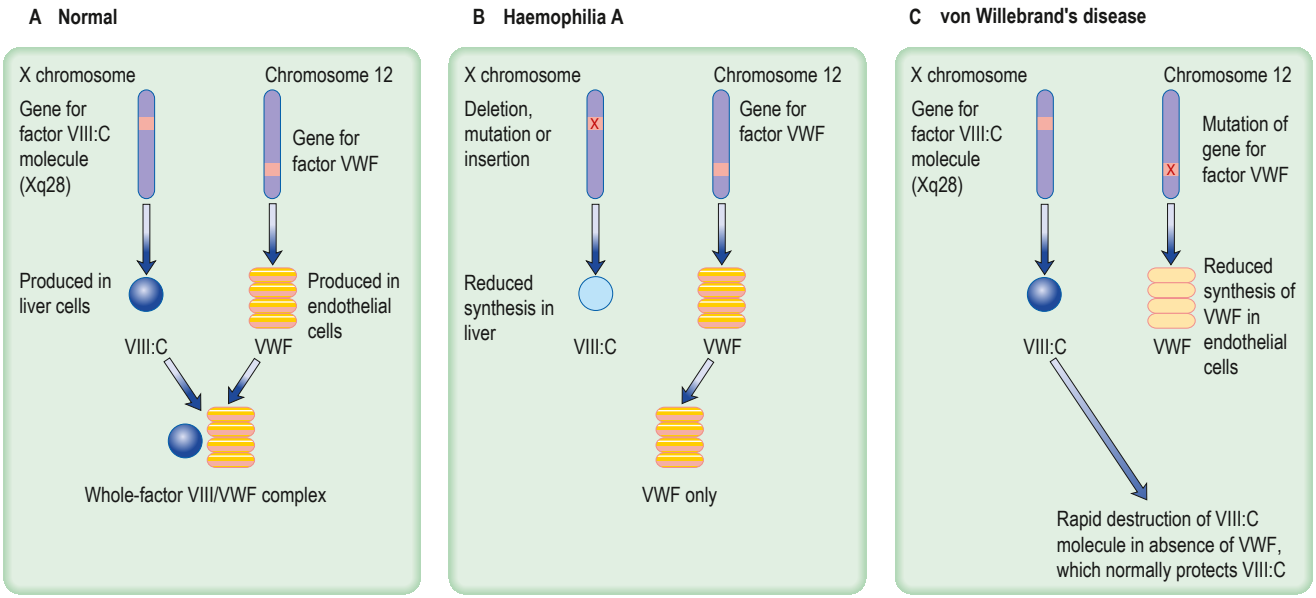

Fig. 38.38 Synthesis of factor VIII and von Willebrand factor (VWF) in inherited coagulation disorders. **(A)** Normal factor VIII synthesis. **(B)** Haemophilia A, showing defective synthesis of factor VIII:C. **(C)** von Willebrand's disease, showing reduced synthesis of VWF.

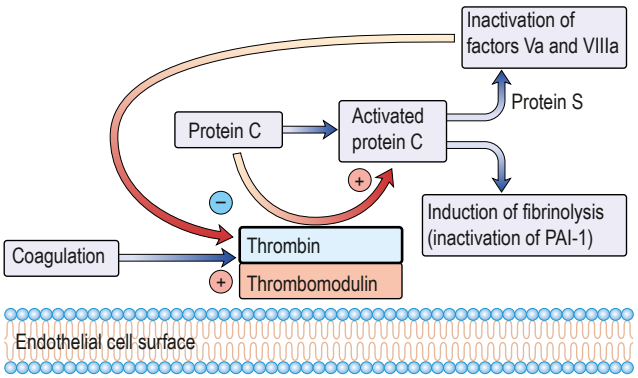

Fig. 38.39 Activation of protein C. *PAI-1,* Plasminogen activator inhibitor 1.

Fibrinolytic system

This is activated by the presence of fibrin. Plasminogen is specifically adsorbed to fibrin and fibrinogen by lysine-binding sites. However, little plasminogen activation occurs in the absence of polymerized fibrin, as fibrin also has a specific binding site for plasminogen activators, but fibrinogen does not (Fig. 38.41).

Tissue plasminogen activator

t-PA is inactivated by plasminogen activator inhibitor-1 (PAI-1). Activated protein C inactivates PAI-1 and therefore induces fibrinolysis (Fig. 38.39). Inactivators of plasmin, such as α_2-antiplasmin (Fig. 38.41) and thrombin-activatable fibrinolysis inhibitor, also contribute to the regulation of fibrinolysis.

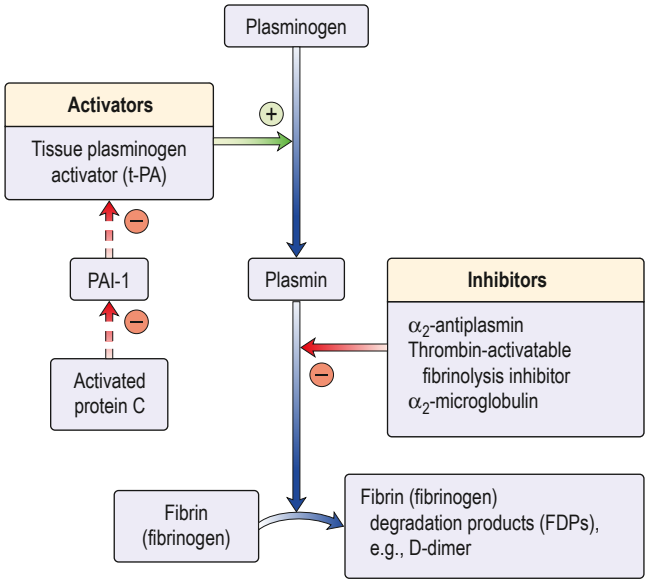

Fig. 38.40 Fibrinolytic system. *PAI-1,* Plasminogen activator inhibitor-1; *t-PA,* tissue plasminogen activator.

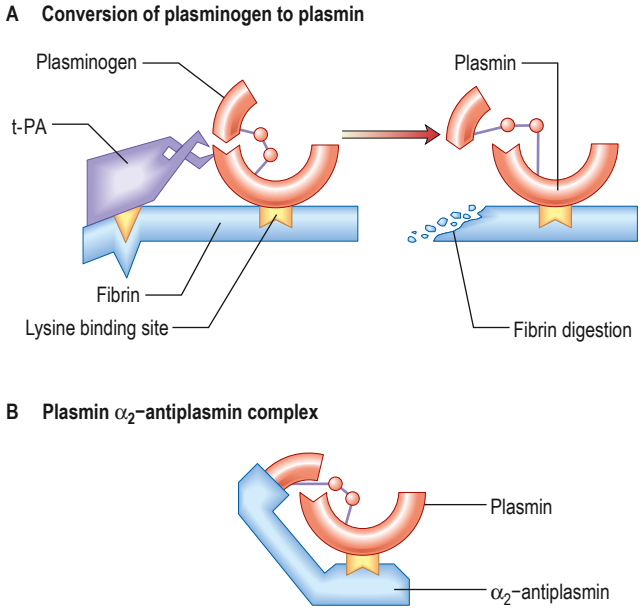

Fig. 38.41 Fibrinolysis. (A) ***The conversion of plasminogen to plasmin*** by tissue plasminogen activator (t-PA) occurs most efficiently on the surface of fibrin, which has binding sites for both plasminogen and t-PA. **(B) *Free plasmin in the blood is rapidly inactivated by α_2-antiplasmin*.** Plasmin generated on the fibrin surface is partially protected from inactivation. The lysine-binding sites on plasminogen are necessary for the interaction between plasmin(ogen) and fibrin and between plasmin and α_2-antiplasmin.

Investigation of bleeding disorders

Although the precise diagnosis of a bleeding disorder depends on laboratory tests, much information is obtained from a structured history and physical examination.

Is there a generalized haemostatic defect?

Supportive evidence includes bleeding from multiple sites, spontaneous bleeding, and excessive bleeding after injury.

Is the defect inherited or acquired?

A family history of a bleeding disorder should be sought. Severe inherited defects usually become apparent in infancy, sometimes at the time of birth with prolonged bleeding from the umbilical cord. Mild inherited defects may only come to attention later in life, such as with excessive bleeding after surgery, childbirth, dental extractions, or trauma. Some milder defects are revealed by routine coagulation screens performed before surgical procedures.

Is the bleeding suggestive of a vascular or platelet defect or a coagulation defect?

Vascular or platelet bleeding

This is characterized by easy bruising and spontaneous bleeding from small vessels. There is often bleeding into the skin. Purpura includes:

- Petechiae: small skin haemorrhages varying from pinpoint size to a few millimetres in diameter that do not blanch on pressure
- Ecchymoses: larger areas of bleeding into the skin

Bleeding also occurs from mucous membranes, especially the nose and mouth.

Coagulation disorders

These are typically associated with bleeding after injury or surgery. In more severe forms, there are haemarthroses and muscle haematomas. There is often a short delay between the precipitating event and overt haemorrhage or haematoma formation.

Laboratory investigations

Blood count and film

These show the number and morphology of platelets and any blood disorder, such as leukaemia or lymphoma. The normal range for the platelet count is 150 to 400 × 10^9/L.

Coagulation tests

These are performed on blood collected into citrate, which neutralizes calcium ions and prevents clotting.

- ***The PT*** is measured by adding tissue factor (thromboplastin) and calcium to patient plasma and establishing the length of time taken for the blood to clot. The normal PT is 11.5 to 13.5 seconds. When used to measure warfarin-based anticoagulation, the PT is expressed as the INR. The PT measures factors VII, X, and V, as well as prothrombin and fibrinogen (the classic 'extrinsic' pathway; Fig. 38.37) and is prolonged if any of these factors is low. It may also be abnormal in patients with liver disease or if the patient is taking oral anticoagulants, including warfarin, and direct oral anticoagulants that target factor Xa.
- ***The APTT*** is also sometimes termed PTT with kaolin. It is measured by adding a surface activator (e.g., kaolin, micronized silica, or ellagic acid), phospholipid (to mimic platelet membrane), and calcium to the patient's plasma. The normal APTT is 26 to 37 seconds and depends on the exact methodology. The APTT measures factors XII, XI, IX, VIII, X, and V, as well as prothrombin and fibrinogen (the classic 'intrinsic' pathway) and is prolonged in deficiencies of one or more of these factors. It is not dependent on factor VII.
- ***The thrombin time (TT)*** is measured by adding thrombin to the patient's plasma. A normal TT is 12 to 14 seconds. It is prolonged in fibrinogen deficiency, in qualitative defects of

Box 38.24 Vascular disorders associated with bleeding/bruising

Congenital
- Hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu disease)
- Connective tissue disorders: Ehlers–Danlos syndrome, osteogenesis imperfecta, pseudoxanthoma elasticum, Marfan's syndrome

Acquired

Severe infections
- Septicaemia
- Meningococcal infections

fibrinogen (dysfibrinogenaemia), and in the presence of inhibitors such as heparin or FDPs.

- ***Correction tests*** can be used to differentiate prolonged times in the PT, APTT, and TT caused by various coagulation factor deficiencies and inhibitors of coagulation. Prolonged PT, APTT, or TT caused by coagulation factor deficiencies can be corrected by addition of normal plasma to the patient's plasma. Failure to correct is suggestive of the presence of an inhibitor of coagulation.
- ***Factor assays*** are used to confirm coagulation defects, especially when a single inherited disorder is suspected.
- ***Special tests of coagulation*** will often be required to confirm the precise haemostatic defect. Such tests include estimation of fibrinogen and FDPs, platelet function tests such as platelet aggregation, and platelet granule contents.
- ***Bleeding time*** measures platelet plug formation *in vivo*. Classically, a sphygmomanometer cuff is inflated to 40 mmHg, and standardized incisions are made in the forearm. The time taken for bleeding to stop is recorded. Prolonged times are seen in platelet function defects and when the platelet count is less than 100×10^9/L. Nowadays, this test is very rarely done as it is painful and can scar.

VASCULAR DISORDERS

Vascular disorders can be characterized by easy bruising and bleeding into the skin (Box 38.24). Bleeding from mucous membranes sometimes occurs, but bleeding is rarely severe. Laboratory investigations, including the bleeding time, are normal.

Hereditary haemorrhagic telangiectasia

This is a rare disorder with autosomal dominant inheritance. In most cases, mutations occur in one of three genes—*ENG*, *ALK1*, or *SMAD4*—that encode components of the TGF-β signalling pathway involved in blood vessel development. Dilation of capillaries and small arterioles produces characteristic small red spots that blanch on pressure in the skin and mucous membranes, particularly the nose and GI tract. Recurrent epistaxis and chronic GI bleeding are the major problems that cause chronic iron-deficiency anaemia. Vascular malformations also occur in pulmonary, hepatic, cerebral, and spinal vasculature.

Box 38.25 Platelet count phenotypes

Platelet count ($\times 10^9$/L)	Clinical defect
>500	Haemorrhage or thrombosis
500–100	No clinical effect
100–50	Moderate haemorrhage after injury
50–20	Purpura Haemorrhage after injury
<20	Purpura common Spontaneous haemorrhage from mucous membranes Intracranial haemorrhage (rare)

Easy bruising syndrome

This is a common benign disorder often seen in otherwise healthy females. It is characterized by bruises on the arms, legs, and trunk with minor trauma, possibly because of skin vessel fragility. It may give rise to the suspicion of a serious bleeding disorder.

Senile purpura and purpura caused by steroids

These are both caused by atrophy of vascular supporting tissue.

Purpura caused by infections

This is mainly caused by damage to the vascular endothelium. The rash of meningococcal septicaemia is particularly characteristic.

Henoch–Schönlein purpura

This is mainly a disease of children. It is a type III hypersensitivity (immune complex) reaction that is often preceded by an upper respiratory tract infection. Purpura is seen mainly on the legs and buttocks. Abdominal pain, arthritis, haematuria, and glomerulonephritis also occur. Recovery is usually spontaneous, but some patients develop kidney failure.

Episodes of inexplicable bleeding or bruising

These may represent abuse, either self-inflicted or caused by others. The various forms of artificial or factitious purpura may be expressions of emotional or psychiatric disturbance.

PLATELET DISORDERS

Bleeding caused by thrombocytopenia or abnormal platelet function is characterized by purpura and bleeding from mucous membranes. Bleeding is uncommon with platelet counts of more than 50×10^9/L, and severe spontaneous bleeding is unusual with platelet counts greater than 20×10^9/L (Box 38.25).

Thrombocytopenia

This is caused by reduced platelet production in the bone marrow, excessive peripheral destruction of platelets, or sequestration in an

enlarged spleen (Box 38.26). The underlying cause may be revealed by history and examination, but a bone marrow examination will show whether the numbers of megakaryocytes are reduced, normal, or increased and will provide essential information on morphology. Specific laboratory tests may be useful to confirm the presence of conditions such as PNH or SLE.

Immune thrombocytopenic purpura

In ITP, thrombocytopenia is caused by immune destruction of platelets. The antibody-coated platelets are removed after binding to Fc receptors on macrophages.

Immune thrombocytopenic purpura in children

This occurs most commonly in the 2- to 6-year age group. ITP has an acute onset with mucocutaneous bleeding, and there may be a history of a recent viral infection, including varicella zoster or measles. Although bleeding may be severe, life-threatening haemorrhage is rare (~1%). Bone marrow examination is not usually performed unless there are atypical clinical or laboratory features.

Immune thrombocytopenic purpura in adults

The presentation is usually less acute than in children. ITP is characteristically seen in females and may be associated with other autoimmune disorders such as SLE, thyroid disease, and autoimmune haemolytic anaemia (Evans syndrome). It is also seen in patients with chronic lymphocytic leukaemia and solid tumours and after infections with viruses such as HIV. Platelet autoantibodies are detected in about 60% to 70% of patients. In the remaining patients, they are presumed to be present, although they are not detectable. The antibodies often have specificity for platelet membrane GPs IIb/IIIa or Ib.

Clinical features

Major haemorrhage is rare and is seen only in severe thrombocytopenia. Easy bruising, purpura, epistaxis, and menorrhagia are common. Physical examination is normal except for evidence of bleeding. Splenomegaly is rare.

Investigations

The only blood count abnormality is thrombocytopenia. The diagnosis is based on exclusion of other causes of thrombocytopenia using the history, clinical examination, blood count, and blood film. Normal or increased numbers of megakaryocytes are found in the bone marrow, but bone marrow examination is unnecessary unless there are unusual findings clinically or on blood film. The detection of platelet autoantibodies is not essential for confirmation of the diagnosis.

Management

Children

Children do not usually require treatment because the thrombocytopenia is short-lived. Treatment should be reserved for serious bleeding or urgent surgery. When treatment is necessary, corticosteroids and IVIG are effective in more than 80% of children and raise the count more rapidly than steroids alone. Chronic ITP is unusual in children and requires specialist management.

Adults

Patients with platelet counts of more than 30 × 10^9/L generally require no treatment unless they are about to undergo a surgical procedure. Those with even lower platelet counts may not require treatment unless they have spontaneous bruising or bleeding.

First-line treatment consists of oral corticosteroids (e.g., prednisolone 1 mg/kg body weight). Approximately two-thirds of patients respond to corticosteroids, but relapses are common when the dose is reduced. Only one-third of patients can expect a long-term response. Long-term remission is seen in just 10% to 20% of patients after stopping prednisolone. Patients who fail to respond to corticosteroids or require high doses to maintain a safe platelet count should be considered for alternative treatments. TPO receptor agonists such as romiplostim and eltrombopag have revolutionized management with high and durable response rates and a low level of adverse effects.

Other immune thrombocytopenias

Drugs

Many drugs have been reported to cause immune thrombocytopenia. The same drugs can be responsible for immune haemolytic anaemia, thrombocytopenia, or neutropenia in different patients.

Heparin-induced thrombocytopenia

See Chapter 40.

Neonatal alloimmune thrombocytopenia

This condition is due to fetomaternal incompatibility for platelet-specific antigens, usually for human platelet alloantigen 1a (HPA-1a). It is the platelet equivalent of HDN. The mother is HPA-1a negative and produces antibodies that destroy HPA-1a–positive

fetal platelets. Thrombocytopenia is self-limiting after delivery, but platelet transfusions may be required initially to prevent or treat bleeding associated with severe thrombocytopenia; platelets are prepared from HPA-1a–negative volunteers or the mother herself. Severe bleeding, such as intracranial haemorrhage, may occur *in utero*. Antenatal treatment of the mother, usually with IVIG, steroids, or both, has been effective in preventing haemorrhage in severely affected cases.

Post-transfusion purpura

Post-transfusion purpura (PTP) is rare, occurring 7 to 10 days after a transfusion of platelet-containing blood components, usually RBCs. PTP is associated with a platelet-specific alloantibody, usually anti–HPA-1a in an HPA-1a–negative individual. PTP always occurs in patients who have previously been immunized, either by blood transfusion or by pregnancy; hence, it is more common in females. The cause of the destruction of the patient's own platelets is not well understood, but they may be destroyed as 'bystanders' during the acute immune response to HPA-1a. PTP is self-limiting; IVIG is the treatment of choice if there is severe thrombocytopenia or bleeding.

Thrombotic thrombocytopenic purpura

TTP is a rare but very serious condition, in which platelet consumption leads to profound thrombocytopenia. There is a characteristic symptom complex of florid purpura, fever, fluctuating cerebral dysfunction, and MAHA with RBC fragmentation, often accompanied by acute kidney injury. The coagulation screen is usually normal, but LDH concentrations are markedly raised because of haemolysis. TTP stems from endothelial damage and microvascular thrombosis caused by a reduction in ADAMTS-13 (*a d*isintegrin-like *a*nd *m*etalloproteinase domain with *t*hrombospondin-type motifs), a protease that is normally responsible for regulating the size of VWF. ADAMTS-13 is needed to break down ultra-large von Willebrand factor multimers (UL VWFMs) into smaller, haemostatically active fragments that interact with platelets. Reduction in ADAMTS-13 results in the adhesion and aggregation of platelets to UL VWFMs and multiorgan microthrombi. In most sporadic cases, there is true deficiency of ADAMTS-13, associated with antibodies to ADAMTS-13. In some congenital cases, deficiency is caused by *ADAMTS-13* gene mutations. Secondary causes of acute TTP include pregnancy, oral contraceptives, SLE, infection, and drug treatment (including ticlopidine and clopidogrel). Such patients may have a variable ADAMTS-13 activity at presentation and may or may not have associated antibodies to ADAMTS-13.

Management

Plasma exchange is the mainstay of treatment. It provides a source of ADAMTS-13 and removes associated autoantibody in acute TTP. Cryoprecipitate and solvent-detergent FFP both contain ADAMTS-13. Pulsed intravenous methylprednisolone is given acutely; increasingly, rituximab is also a primary treatment of choice. Disease activity is monitored by measuring the platelet count and serum LDH. Platelet concentrates are contraindicated. The untreated condition has a mortality rate of up to 90%, but modern management has reduced this to about 10%. Recurrent and relapsing TTP occurs, often associated with a persistent lack of ADAMTS-13. In secondary TTP cases, identifiable precipitating drugs should be stopped. Caplacizumab is a single-variable-domain immunoglobulin directed to the A1 region of the VWF. It inhibits the VWF interaction with GP Ib and has recently been shown to lead to faster normalization of the platelet count and a lower rate of recurrent TTP.

Box 38.27 Causes of platelet dysfunction

Inherited

- ***Glanzmann's thrombasthenia:*** lack of platelet membrane GP IIb/IIIa complex, resulting in defective fibrinogen binding and failure of platelet aggregation
- ***Bernard–Soulier syndrome:*** lack of platelet membrane GP Ib/IX/V complex (the binding site for von Willebrand factor), causing failure of platelet adhesion and moderate thrombocytopenia
- ***Storage pool disease:*** lack of the storage pool of platelet dense bodies, causing poor platelet function

Acquired

- Myeloproliferative disorders
- Kidney and liver disease
- Paraproteinaemias
- Drug induced (e.g., NSAIDs [aspirin], platelet inhibitory drugs)

GP, Glycoprotein; *NSAID,* non-steroidal anti-inflammatory drug.

Platelet function disorders

Platelet function disorders (**Box 38.27**) are usually associated with excessive bruising and bleeding and, in some of the acquired forms, with thrombosis. The platelet count is often normal, but bleeding time is prolonged. Rare inherited defects of platelet function require more detailed investigations, such as platelet aggregation studies and factor VIII and VWF assays, because there is often a clinical overlap in symptoms with von Willebrand's disease (VWD).

If there is serious bleeding or if the patient is about to undergo surgery, drugs with antiplatelet activity should be withdrawn and any underlying condition should be treated if possible.

Platelet dysfunction can be a major component of bleeding in kidney disease. The degree of the platelet-related defect is broadly proportional to the serum urea concentration: platelet function is impaired by urea, guanidinosuccinic acid, and other phenolic metabolites that accumulate in those with CKD. Dialysis partially corrects platelet function. The Hct should be increased to over 0.30, and non-specific use of desmopressin may be helpful. Platelet transfusions may be required if these measures are unsuccessful or if the risk of bleeding is high.

Thrombocytosis

The platelet count may rise above 400 × 10^9/L as a result of:

- Splenectomy
- Malignant disease
- Inflammatory disorders (e.g., rheumatoid arthritis, inflammatory bowel disease)
- Major surgery and haemorrhage
- Myeloproliferative disorders
- Iron deficiency

Thrombocytosis is part of the acute-phase reaction. Platelet numbers are increased after splenectomy because of the loss of a major site of platelet destruction. ***Essential thrombocythaemia***, a myeloproliferative neoplasm, and other myeloproliferative conditions, such as polycythaemia vera, myelofibrosis, and chronic myeloid leukaemia, may also be associated with high platelet counts (Chapter 39).

A persistently elevated platelet count can lead to arterial or venous thrombosis. It is usual to treat the underlying cause of the

thrombocytosis but low-dose aspirin (75 mg) may also be given. In myeloproliferative diseases, the primary risk is thrombosis, and specific action is often taken to reduce the platelet count, usually with hydroxycarbamide (hydroxyurea). Paradoxically, there is also a risk of abnormal bleeding if the platelet count is very high.

INHERITED COAGULATION DISORDERS

Inherited coagulation disorders are uncommon and usually involve deficiency of one factor only. Acquired coagulation disorders occur more frequently and almost always involve several coagulation factors.

Isolated deficiencies of all factors have been described in patients with inherited coagulation disorders. Those leading to abnormal bleeding are rare, apart from haemophilia A (factor VIII deficiency), haemophilia B (factor IX deficiency), and VWD.

Haemophilia A

Haemophilia A is caused by a lack of factor VIII. VWF is normal in haemophilia (Fig. 38.38). The prevalence of haemophilia A is about 1 in 5000 of the male population. It is inherited as an X-linked disorder. If a female carrier has a son, he has a 50% chance of having haemophilia; a daughter has a 50% chance of being a carrier. All female offspring of males with haemophilia are carriers; male offspring are normal.

Although many different genetic defects have been found in the factor VIII gene, a common gene inversion in intron 22 is causative in approximately 50% of families with severe disease. There is a high mutation rate, one-third of cases being apparently sporadic with no family history of haemophilia.

Clinical features and investigations

The clinical features depend on the concentration of factor VIII. The normal concentration of factor VIII is 50 to 150 IU/dL.

- ***Severe haemophilia (<1 IU/dL):*** frequent spontaneous bleeding from early life, typically into joints and muscles. Without adequate treatment, recurrent bleeding into joints leads to joint deformity.
- ***Moderate haemophilia (1–5 IU/dL):*** severe bleeding after injury and occasional spontaneous bleeds.
- ***Mild haemophilia (>5 IU/dL):*** bleeding usually only after injury or surgery. Diagnosis in this group can be delayed until late in life.

With treatment, the life expectancy is very good. The most common causes of death are cancer and heart disease comparable to the general population, rather than bleeding, although cerebral haemorrhage is more frequent. The main laboratory features are shown in Box 38.28. The abnormal findings are an isolated prolongation of the APTT and a reduced concentration of factor VIII. The PT, bleeding time, and VWF concentration are normal.

Management

Patients with bleeding are treated by administration of ***factor VIII concentrate*** by intravenous infusion to achieve normalization of concentrations. Factor VIII concentrate is available as a plasma-derived or recombinant product. Recombinant products are the treatment of choice, but economic constraints often limit availability, particularly in low-income countries.

In severe haemophilia, the aim of treatment is to prevent recurrent bleeding into joints and subsequent joint damage. Such 'prophylaxis' is usually started in early childhood using factor VIII concentrates. Prophylaxis requires two to three infusions per week.

For those not on prophylaxis, patients are treated as and when they have a bleed ('on demand'). For surgery, concentrations should be kept to normal until healing has occurred; because factor VIII has a half-life of 12 hours, it is often administered twice daily to maintain the required concentration.

Bioengineered factor VIII products are increasingly replacing standard factor VIII products. They have a half-life approximately 1.5 to 4 times that of base factor VIII, depending on the degree of bioengineering, and can be used either to reduce the frequency of infusion or to improve the concentration of haemostatic protection.

Increasingly, bispecific antibodies that bind factor IXa and factor X to mimic the effect of factor VIII are used for provision of prophylaxis in those with severe and moderate haemophilia. These can be simply administered subcutaneously every 1, 2, or 4 weeks.

Gene therapy trials, using adeno-associated virus AAV to transfer a copy of a functional VIII gene, have recently shown promise in the potential management of severe haemophilia A.

In milder haemophilia, ***synthetic vasopressin*** (desmopressin, an analogue of vasopressin)—intravenous, subcutaneous or intranasal—produces a three- to fivefold rise in factor VIII and VWF concentrations. It is very useful in patients with a baseline concentration of factor VIII above 10 IU/dL. It avoids the complications associated with blood products and is useful for treating and preventing bleeding in mild haemophilia.

People with haemophilia should be registered at a comprehensive care centre, which takes responsibility for their medical care, including social and psychological support.

Complications

Up to 30% of people with severe haemophilia will develop antibodies to factor VIII that inhibit its action. Such inhibitors usually develop after the first few treatment doses of factor VIII. Inhibitors are relatively rare in moderate and mild haemophilia and are often associated with specific molecular defects.

Management of inhibitor patients has historically been very difficult because infused factor VIII is rapidly inactivated. Acute bleeding events require treatment with agents that can bypass factor VIII, such as recombinant factor VIIa or activated prothrombin complex concentrates. Bispecific antibodies have been shown to be highly

Box 38.28 Blood changes in haemophilia A, von Willebrand's disease, and vitamin K deficiency

	Haemophilia A	von Willebrand's disease	Vitamin K deficiency
Bleeding time	Normal	↑	Normal
Prothrombin time	Normal	Normal	↑
Activated partial thromboplastin time	↑+	↑±	↑
Factor VIII:C	↓++	↓	Normal
von Willebrand factor	Normal	↓	Normal

effective at preventing bleeding in haemophilia A with inhibitors because they are independent of factor VIII. They are widely used to provide prophylaxis in inhibitor patients.

In those recently identified as having developed an inhibitor, the long-term aim is to eradicate the inhibitory antibody. This is done using immune tolerance induction strategies, sometimes with additional immunosuppression, and is successful in around 80% of cases.

Although a historical legacy of plasma-derived concentrates, the risk of ***viral transmission*** has now been virtually eliminated. Historically, many patients died as a consequence of HIV and HCV infection, and a considerable number of patients remain who have HIV or HCV infection.

Carrier detection and antenatal diagnosis

Owing to lyonization (random inactivation of one X chromosome) in early embryonic life, some female carriers may have low concentrations of factor VIII, but others have normal concentrations. Definitive carrier detection therefore requires molecular genetic testing and mutation analysis. Antenatal diagnosis may be carried out by molecular analysis of chorionic villus biopsy at 11 to 12 weeks' gestation if selective termination is being considered or by third-trimester amniocentesis if not.

Haemophilia B (Christmas disease)

Haemophilia B is caused by a deficiency of factor IX. The inheritance and clinical features are identical to those of haemophilia A, but the incidence is only about 1 in 30000 males. The half-life of factor IX is longer than that of factor VIII, at 18 hours. Haemophilia B is treated with factor IX concentrates, recombinant factor IX being generally available, and prophylactic doses are given twice a week. Bioengineered factor IX concentrates have a half-life three to five times that of regular factor IX. Desmopressin is ineffective. Gene therapy for severe haemophilia B has offered hope for some time, and recent data have demonstrated achievement of durable near-normal factor IX concentrations using a variant factor IX gene with increased activity.

von Willebrand's disease

VWD is caused by a deficiency or abnormality of VWF (Fig. 38.38). Because VWF has a critical role as an adhesive protein in the platelet–vessel wall interaction, the absence of VWF leads to impaired platelet adhesion to the subendothelium. Reduced VWF concentrations also lead to factor VIII deficiency because factor VIII is not protected from premature degradation. VWF reduction in VWD therefore leads to a dual haemostatic defect.

The *VWF* gene is located on chromosome 12 and numerous mutations have been identified. VWD has been classified into three types:

- ***Type 1*** is partial quantitative deficiency of VWF. Significant type 1 VWD usually has autosomal dominant inheritance.
- ***Type 2*** is caused by a qualitative abnormality of VWF, usually with autosomal dominant inheritance.
- ***Type 3*** is recessively inherited, and patients have virtually complete deficiency of VWF. Parents are often phenotypically normal.

Many subtypes of VWD are described, particularly type 2 variants, which reflect specific qualitative changes in the VWF protein.

Clinical features

These are very variable. Patients with types 1 and 2 usually have relatively mild clinical features. Bleeding occurs after minor trauma or surgery, and epistaxis and menorrhagia often occur. Haemarthroses are rare. Patients with type 3 have more severe bleeding but rarely experience the joint and muscle bleeds seen in those with haemophilia A.

Characteristic laboratory findings are shown in Box 38.28. Classically, VWF activity is measured as its platelet-dependent function in the presence of ristocetin.

Management

Management depends on the severity of the condition and may be similar to that of mild haemophilia, including the use of desmopressin when possible. Although recombinant VWF is available, plasma-derived factor VIII concentrates that contain intact VWF are the mainstay of replacement therapy. These specific products are used to treat patients with bleeding or to cover surgery in patients who require replacement therapy, such as those with type 3 (severe) VWD and those who do not respond adequately to desmopressin. Cryoprecipitate could be used as a source of VWF, but this is avoided if possible because it is not virus inactivated.

ACQUIRED COAGULATION DISORDERS

Vitamin K deficiency

Vitamin K is necessary for the γ-carboxylation of glutamic acid residues on coagulation factors II, VII, IX, and X and on proteins C and S. Without it, these factors cannot bind calcium.

Deficiency of vitamin K may be caused by:

- ***Inadequate stores:*** HDN, severe malnutrition, especially when combined with antibiotic treatment
- ***Malabsorption of vitamin K:*** occurs in cholestatic jaundice owing to the lack of intraluminal bile salts preventing absorption of this fat-soluble vitamin
- ***Oral anticoagulant drugs:*** many are vitamin K antagonists.

The PT and APTT are prolonged (Box 38.28), and there may be bruising, haematuria, and GI or cerebral bleeding. Patients with minor bleeding are treated with phytomenadione (vitamin K_1) 10 mg intravenously. Some correction of the PT is usual within 6 hours, but it may not return to normal for 2 days.

Newborn babies have low concentrations of vitamin K and this may cause minor bleeding in the first week of life ***(classical haemorrhagic disease of the newborn)***. Vitamin K deficiency also causes ***late haemorrhagic disease of the newborn*** 2 to 26 weeks after birth and results in severe bleeding such as intracranial haemorrhage. Most infants with these syndromes have been exclusively breast-fed, and both conditions are prevented by administering 1 mg vitamin K intramuscularly to all neonates. Concerns about the safety of this strategy are unfounded.

Liver disease

Liver disease may result in defects in haemostasis:

- ***Vitamin K deficiency*** caused by intrahepatic or extrahepatic cholestasis
- ***Reduced synthesis*** of coagulation factors (including natural anticoagulant proteins) because of severe hepatocellular damage. The use of vitamin K does not improve the results of abnormal

coagulation tests, but it is generally given to ensure that a treatable cause of failure of haemostasis has not been missed
- ***Thrombocytopenia*** caused by hypersplenism associated with portal hypertension or from folic acid deficiency
- ***Functional abnormalities*** of platelets and fibrinogen are found in many patients with liver failure
- ***DIC*** occurs in acute hepatic failure.

Disseminated intravascular coagulation

DIC never occurs in isolation. Recognition that the patient has a clinical disorder that may result in DIC (Box 38.29) is the key to investigation and management. DIC arises because of systemic activation of coagulation either by release of procoagulant material such as tissue factor or via cytokine pathways as part of the inflammatory response. Such systemic activation leads to widespread generation of fibrin and deposition in blood vessels, leading to thrombosis and multiorgan failure. Because of widespread coagulation activation there is consumption of platelets and coagulation factors and secondary activation of fibrinolysis leading to production of FDPs and D-dimer. These further contribute to the coagulation defect by inhibiting fibrin polymerization (Fig. 38.42). The consequences of these changes are a mixture of initial thrombosis followed by a bleeding tendency due to consumption of coagulation factors and dysregulated fibrinolytic activation.

Box 38.29 Causes of disseminated intravascular coagulation

- Malignant disease
- Septicaemia (e.g., Gram-negative, meningococcal)
- Haemolytic transfusion reactions
- Obstetric causes (e.g., placental abruption, amniotic fluid embolism, pre-eclampsia)
- Trauma, burns, surgery
- Infection (e.g., *falciparum* malaria)
- Liver disease
- Snakebite

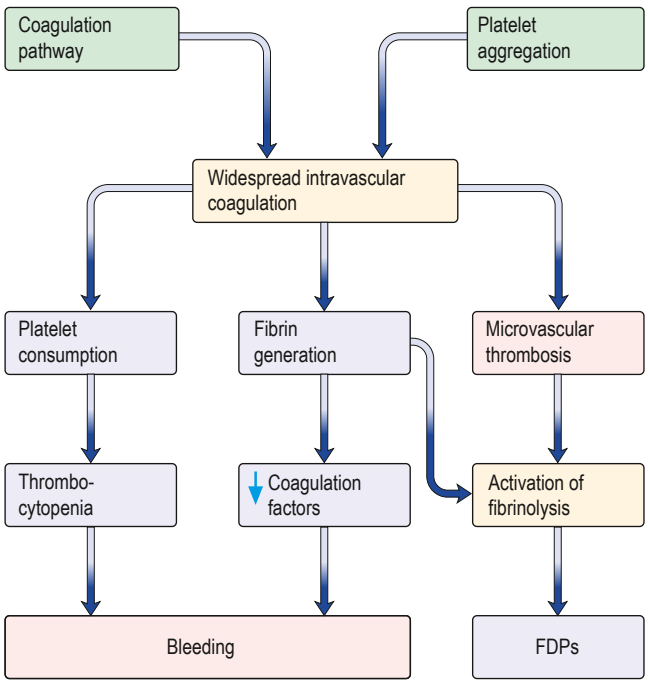

Fig. 38.42 Disseminated intravascular coagulation. *FDP,* Fibrin degradation product.

Clinical features

An underlying disorder is usually obvious. The patient is often acutely ill and shocked. The clinical presentation of DIC varies from no bleeding at all to profound haemostatic failure with widespread haemorrhage. Bleeding may occur from the mouth, nose, and venepuncture sites, and there may be widespread ecchymoses.

Thrombotic events occur as a result of vessel occlusion by fibrin and platelets. Any organ may be involved, but the skin, brain, and kidneys are most often affected.

Investigations

The diagnosis needs to encompass both clinical and laboratory aspects. It is often suggested by the underlying condition of the patient. If the patient has an underlying disorder known to be compatible with overt DIC, the International Society on Thrombosis and Haemostasis scoring system is a useful diagnostic tool and provides an objective assessment (Box 38.30).

In severe cases with haemorrhage:
- The PT, APTT, and TT are usually very prolonged, and the fibrinogen concentration is markedly reduced.
- High concentrations of FDPs, including D-dimer, are found, owing to the intense fibrinolytic activity stimulated by the presence of fibrin in the circulation.
- There is severe thrombocytopenia.
- The blood film may show fragmented RBCs.

Management

The cornerstone of management is treatment of the underlying condition and intensive support to manage hypoxia, acidosis, and organ failure. In those that are not bleeding, this is often all that is necessary. Transfusions of platelet concentrates, FFP, cryoprecipitate, and RBC concentrates are indicated in patients who are bleeding or to cover interventions. Transfusion of blood components based on coagulation tests alone is not required. Inhibitors of fibrinolysis, such as tranexamic acid, should not be used in patients with DIC because dangerous fibrin deposition may result. In cases with a dominant thrombotic component, the cautious use of unfractionated heparin should be considered. In critically ill, non-bleeding patients with DIC, thromboprophylactic doses of heparin are recommended.

Excessive fibrinolysis

Excessive fibrinolysis occurs in certain malignancies, such as acute promyelocytic leukaemia, and during surgery involving tumours of the prostate, breast, pancreas, and uterus owing to release of tissue plasminogen activators.

Primary hyperfibrinolysis is very rare. The clinical picture is like that of DIC, with widespread bleeding. Laboratory investigations are also similar, with a prolonged PT, APTT, and TT; a low fibrinogen concentration; and increased FDPs, although fragmented RBCs and thrombocytopenia are not seen because disseminated coagulation with widespread fibrin deposition is not present. If the diagnosis is certain, fibrinolytic inhibitors, such as tranexamic acid, can be given, but evidence for their efficacy is lacking.

Activation of fibrinolysis occurs in DIC as a secondary event in response to intravascular deposition of fibrin

Box 38.30 International Society on Thrombosis and Haemostasis diagnostic scoring system for disseminated intravascular coagulation

Parameter	Score[a]			
	0	1	2	3
Platelet count ($\times 10^9$/L)	>100	50 to <100	<50	
Elevated fibrin marker (e.g., D-dimer, fibrin degradation products)	No increase		Moderate increase	Strong increase
Prolonged prothrombin time (seconds)	<3	>3 to <6	>6	
Fibrinogen concentration (g/L)	>1	<1		

[a]A total score of ≥5 equals disseminated intravascular coagulation (DIC) if the score is associated with a clinical disorder known to cause DIC.

Massive transfusion

Few platelets and reduced concentrations of clotting factors are found in stored blood, although there are adequate amounts of the other coagulation factors. During massive transfusion (defined as transfusion of a volume of blood equal to the patient's own blood volume within 24 hours, e.g., >10 units in an adult), the platelet count, PT, and APTT should be checked at intervals. Transfusion of platelet concentrates, FFP, and cryoprecipitate should be given if thrombocytopenia or defective coagulation is thought to be contributing to continued blood loss. Other problems associated with transfusion are detailed in **Box 38.19**.

Inhibitors of coagulation

Factor VIII autoantibodies arise occasionally in patients without haemophilia but also with autoimmune disorders such as SLE, in older adult patients, with malignant disease, and sometimes after childbirth. There can be severe bleeding. Patients with immediate bleeding problems are managed with concentrates that bypass factor VIII activity (e.g., recombinant factor VIIa or activated prothrombin complex concentrates). Longer-term therapy aims to eliminate the autoantibody using immunosuppression (e.g., corticosteroids, cyclophosphamide, rituximab).

Lupus anticoagulant antibodies (see Chapter 40) are autoantibodies directed against phospholipids (antiphospholipid antibodies); they cause prolongation of phospholipid-dependent coagulation tests, particularly the APTT, but do not inhibit coagulation factor activity.

CORE SKILLS AND KNOWLEDGE

The haematological malignancies include leukaemias, the myeloproliferative neoplasms (MPNs), lymphomas, and myeloma. They are uncommon but not rare, with lymphoma being the fifth most common cancer in the UK.

Haemato-oncologists divide their time between inpatient care, outpatient clinics, chemotherapy day units, and diagnostic laboratories. In smaller centres, malignant haematology may comprise only one aspect of the work of a haematologist. In larger centres, specialist haematologists focus exclusively on the treatment of patients with malignant disease and are often engaged with clinical trials, medical education, and research.

Inpatient wards accommodate those requiring investigation and those receiving intensive chemotherapy in addition to patients requiring management of the acute complications caused by their disease or its treatment. Specialist units accommodate patients undergoing autologous or allogeneic stem cell transplantation (SCT).

Key to learning objectives for haemato-oncology include:

- Understanding acute leukaemia and the role of SCT
- Understanding lymphomas and myeloma and their different management strategies
- Having an appreciation of the key approaches to treatment with use of cytotoxics, immunotherapy, small molecules, and radiotherapy
- Managing emergencies in haemato-oncology, including leucostasis, hyperviscosity, tumour lysis syndrome (TLS), and spinal cord compression.

Specific opportunities for learning haemato-oncology include attending ward rounds on inpatient haemato-oncology wards and transplant units, spending time at haemato-oncology day units and becoming familiar with how chemotherapy is delivered, meeting patients presenting with haematological malignancy and following their diagnostic work-up, and attending haemato-oncology multidisciplinary team (MDT) meetings to review diagnostic material and discuss management options.

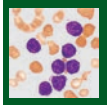
CLINICAL SKILLS

History

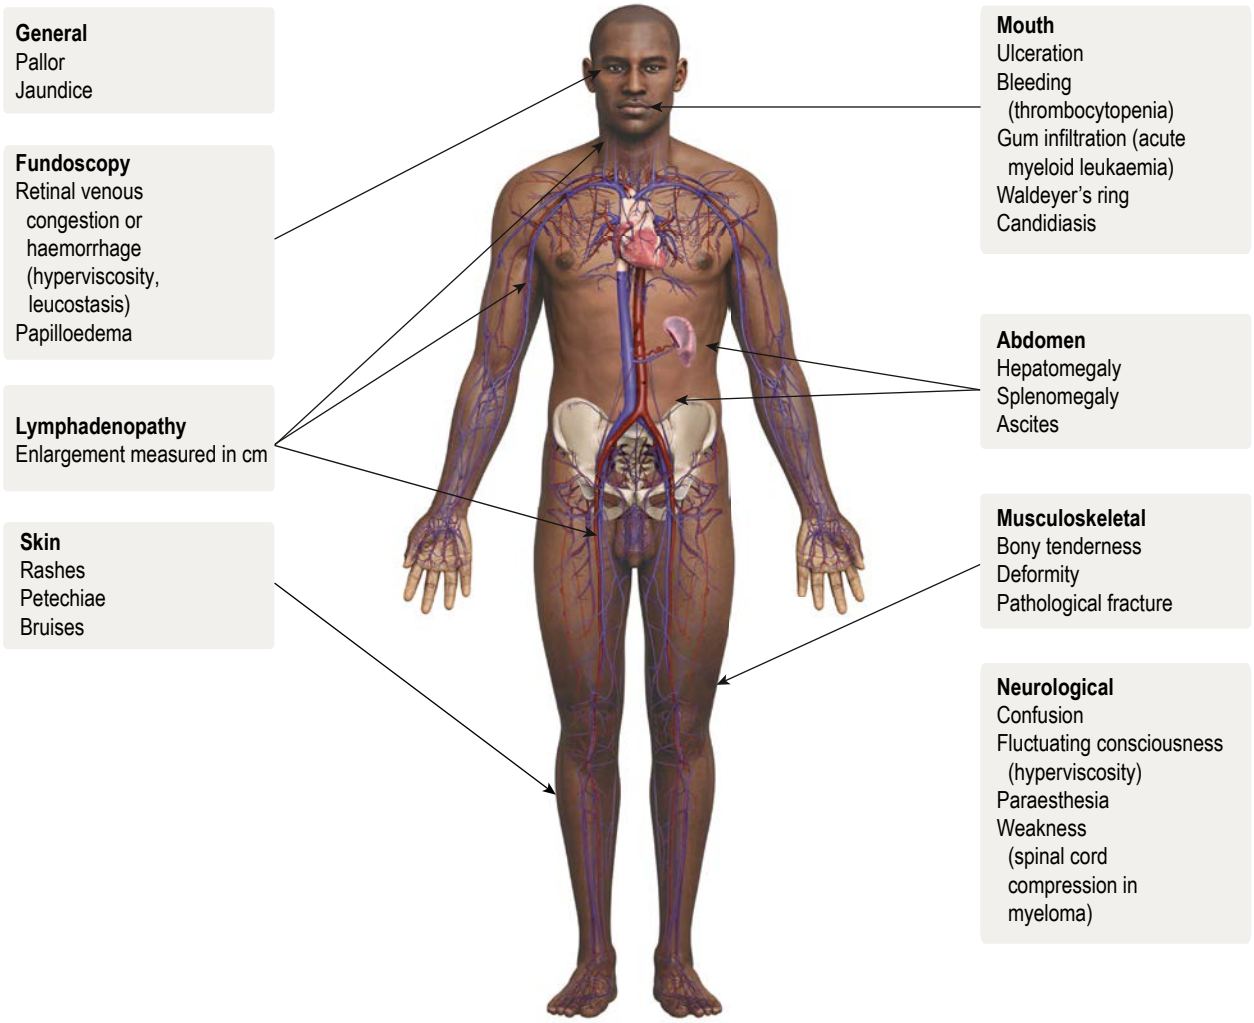
Symptoms of haematological malignancy can be acute or long-standing (Box 39.1). Patients can present with anything from an isolated lump to generalized symptoms. Aim to elicit specific symptoms, their duration, and their impact. Be alert to symptoms that may indicate an emergency presentation such as leukostasis or spinal cord compression. Always be sensitive to the challenges patients face in undergoing investigation and treatment for cancer.

Assessing suitability for treatment

A patient's ***performance status*** is a key determinant of how well they are likely to cope with intensive anticancer treatment, such as chemotherapy or SCT (see Box 41.13). Asking questions about various activities of daily living, including personal care (e.g., washing and dressing) and domestic tasks (e.g., shopping or preparing food), allows patients' performance status to be assessed and monitored over time.



Examination



Treatments

Treatment plans (Box 39.2) are guided by the large volume of clinical trial evidence that exists for all haematological malignancies, and patients can often be offered enrolment into clinical trials of novel agents.

Aims of treatment

Not all treatment intent is curative. In indolent disease, treatments are focused on slowing progression or managing symptoms and complications. Factors affecting treatment include:

- ***Patient factors.*** Performance status or frailty scores are helpful in estimating how well patients may tolerate a particular treatment. Open discussion with the patient is vital. Potential side-effects and complications of treatment must be balanced against the likelihood of a favourable outcome.
- ***Disease factors.*** Better understanding of pathophysiology has given us prognostic markers (e.g., FLT3 [FMS-like tyrosine kinase 3] in acute myeloid [or myeloblastic] leukaemia [AML]), and data gathered from large-cohort analyses inform scoring systems.
- ***Treatment factors.*** The expense of newer therapies results in restricted prescribing in most healthcare systems. Enrolment in clinical trials gives access before efficacy and cost-effectiveness have been completely evaluated.

BACKGROUND

Haematological malignancies cover a wide range of blood cancers, which can present in many ways. They can present with either ***circulating*** ('blood-based', 'leukaemic', or 'liquid') or ***solid*** disease, though often the clinical presentation is non-specific. Their diversity and nomenclature can be confusing. The updated 2022 World Health Organization (WHO) classification contains an increasing number of diagnostic entities, now well over 150. There is an increasing emphasis on underlying genetic and molecular abnormalities, as well as histology and immunophenotype. It is beyond the needs of generalists (and most haematologists) to be aware of all these conditions; however, some principles of clinical behaviour, diagnosis, as well as prognosis and treatment are helpful for all clinicians. They are discussed here.

Box 39.1 Taking a history in haemato-oncology

Symptoms of bone marrow failure
- Anaemia: fatigue, shortness of breath, reduced exercise capacity
- Thrombocytopenia: easy bruising or bleeding
- Leucopenia: recurrent infection

Symptoms caused by mass effect of malignant tissue
- Abdominal discomfort from splenic enlargement
- Neck, jaw, axillary, or groin swelling from enlarged lymph nodes

Systemic symptoms
- Malaise
- Fever: >38°C
- Sweats: particularly at night
- Weight loss: >10% unintentional weight loss over 6 months is considered significant

Family history
- Haematological disease or malignancy
- If allogeneic transplantation may be considered: health of potential donors

Risk factors
- Previous exposure to cytotoxins
- Previous exposure to ionizing radiation
- Viral infection

Fitness for treatment
- Medical co-morbidity that may influence treatment approach
- Performance status (see later)
- Impact on the individual
- Detailed social history to assess the implications of diagnosis and treatment

Box 39.2 Treatments in haematological malignancy

Cytotoxics
- Target rapidly growing cells
- Historically formed the basis of conventional anticancer chemotherapy and remain the backbone of most treatment regimens
- Classes: alkylating agents (e.g., cyclophosphamide), anthracyclines (e.g., doxorubicin), vinca alkaloids (e.g., vincristine), purine analogues (e.g., mercaptopurine, 6-MP)

Immunotherapy
- Monoclonal antibodies target a protein on the surface of the malignant cell (e.g., rituximab targets the CD20 molecule on B lymphocytes and triggers cell death). It is one of the most common monoclonal antibodies in haematological malignancy treatment.
- Drug–antibody conjugate: Antibodies target the tumour cell and act as a vector for toxins.
- Bispecific antibody therapies bind to an antigen on the tumour cell surface and also to T cells, linking the two cells and triggering cytotoxic activity.
- Chimeric antigen receptor T-cell therapy: modification of the patient's own T cells to express a receptor that will bind a particular tumour protein. The cells are expanded and re-infused to attack and destroy malignant cells.

Corticosteroid
- Synthetic high-dose corticosteroids (e.g., dexamethasone) induce cell death in malignant lymphoid cells.
- Treatment role alongside other anticancer treatments in all B-cell malignancies, including myeloma.

Molecular therapy
- Treatments targeting specific pathways:
  - FLT3 inhibitors (e.g., midostaurin) block abnormal cell signalling in acute myeloid leukaemia
  - Venetoclax blocks the mutated anti-apoptotic protein Bcl-2 in chronic lymphocytic leukaemia

Stem cell transplantation (SCT)
- Transfer of pluripotent stem cells from either the patient (autologous) or a donor (allogeneic) after myeloablative chemo- or radiotherapy.
- Generally performed after remission has been achieved with preceding chemotherapy regimens. An SCT will not treat the disease but is done to prevent disease recurrence.
- Transplanted cells permit bone marrow recovery.
- In allogeneic SCT, the patient's abnormal bone marrow is replaced with an alternative, normally functioning, haemopoietic system.

Radiotherapy
- Targets solid tumour masses (e.g., enlarged lymph nodes in early-stage lymphomas, plasmacytomas, and residual disease after other treatments).
- Surgery
- Although of limited use in treatment of patients with these conditions, surgery has a role, though rare, in obtaining diagnostic tissue through biopsy when image-guided biopsy is not feasible.
- Neurosurgery may relieve spinal cord compression, though steroids and radiotherapy are more frequently indicated.
- Orthopaedic fixation of pathological fractures may be required in patients with myeloma.

Aetiology

Like most cancers, haematological malignancies are mostly caused by the ***acquisition of genetic changes*** within a normal cell, leading to development of an abnormal population of cells. Most of these events are random, without a clear cause, although incidence generally ***increases with age***.

These changes may be large-scale chromosomal abnormalities (translocations, deletions, or duplications), which can be detected by cytogenetic analysis, or point mutations within a specific gene, which require DNA sequencing technology for analysis (Fig. 39.1). More and more cytogenetic and molecular changes are being identified. As highlighted in the 2022 WHO and European LeukemiaNet (ELN) 2022 guidelines, these changes can be diagnosis-defining and are continuously re-shaping the diagnosis, treatment, and prognosis of these malignancies.

Not all mutations necessarily lead to a malignancy. There is an increasing awareness of the accumulation of mutations as part of the normal ageing process. It can be a certain combination of changes, or *gene profile*, that leads to a haematological malignancy. It is important to know that a single finding is often not diagnostic of a type of malignancy because it can be found in people without cancer; interpretation of results should be done with caution, experience, and a knowledge of the clinical picture. Some changes are not diagnostic but carry a predisposition or risk of the patient's developing a certain haematological malignancy. Careful monitoring or intervention where appropriate might be indicated. For example, the t(14;18) translocation associated with follicular lymphoma (FL) can be found in up to 50% of healthy individuals' circulating lymphocytes.

Previous ***radiation exposure*** (usually as part of radiotherapy treatment for a previous cancer) and ***cytotoxic chemotherapy*** can cause genetic abnormalities and subsequent malignancy. This is seen most in myeloid malignancy, such as myelodysplastic syndrome (MDS) and AML, with the development of mutations that have a possible causal link with previous radiation or chemotherapy. However, the term 'therapy-related' MDS or AML is no longer being used and has been removed from classifications because these mutations can also be seen in patients without prior exposure.

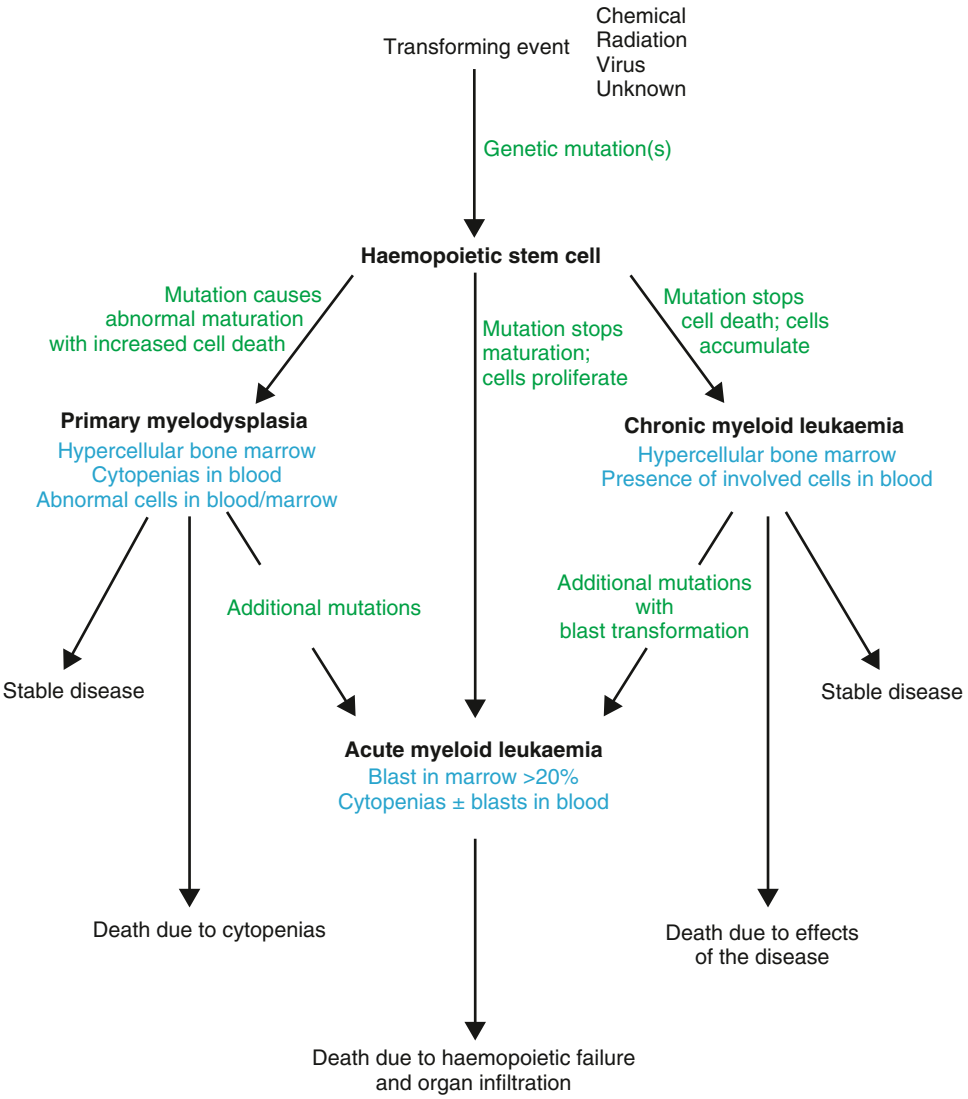


Fig. 39.1 Acquisition of clonal changes. *(Adapted from http://eclinpath.com/hematology/leukemia/transforming-aligorithm.)*

Viral infections are implicated as a possible cause of or contributor to the development of several haematological cancers. For example:

- Human T-cell leukaemia (or lymphotropic) virus type 1 (HTLV-1) in adult T-cell leukaemia/lymphoma (ATLL): Integration of viral DNA into regulatory T cells leads to malignant transformation.
- Epstein–Barr virus (EBV) plays a role in the aetiology of some lymphomas, including Hodgkin lymphoma (HL).
- Human immunodeficiency virus (HIV) infection predisposes to non-Hodgkin lymphoma (NHL) and HL development if not treated. This occurs primarily through immunosuppression, taking away essential normal immune-system control mechanisms in the development of abnormal haematopoietic cells, as well as risk of co-infection with other viruses such as EBV and human herpesvirus-8.

Immunosuppression caused by long-term use of systemic therapies can increase the risk of lymphoma, like that described in patients with HIV. This is most strikingly seen in post-transplant lymphoproliferative disorder, which can occur in patients receiving long-term immune-suppressive therapy after kidney or other transplants. In most of these cases, EBV infection or reactivation plays a significant role.

Congenital conditions that predispose patients to the development of haematological malignancy are rare, though possibly not as rare as previously thought. A small number of conditions do exist in which a germline genetic disorder increases the risk of leukaemias developing. These include Down's syndrome (trisomy 21), which can be associated with a transient myeloproliferative disorder in the neonatal period as well as an increased risk of both AML and acute lymphoblastic leukaemia (ALL) as well as and bone marrow failure syndromes such as Fanconi anaemia (see Chapter 38, 'Anaemia caused by marrow failure [aplastic anaemia]' section). In the myeloid malignancies MDS and AML, constitutional or germline mutations are increasingly identified and should be considered especially in patients in which a family history exists. If such a mutation is found, it can be challenging to determine who in a family, if any, might benefit from screening. It also has an understandable impact on donor selection when SCT is considered. These mutations remain very rare.

Pathogenesis

Haematological malignancies can be characterized based on the ***cell of origin***, the normal counterpart cell within the haemopoietic

Box 39.3 Classification of leukaemia and lymphoma

Timeframe	Myeloid (bone marrow)	Lymphoid (bone marrow)	Lymphoid (node)
Acute			
Immature cells predominate	Acute myeloid leukaemia	Acute lymphoblastic leukaemia	Lymphoma: 'high-grade', 'aggressive' (e.g., Burkitt lymphoma)
	Myelodysplastic syndrome	Myeloma	
Chronic			
Mature cells predominate	Chronic myeloid leukaemia Other myeloproliferative disorders	Chronic lymphocytic leukaemia	Lymphoma: 'low-grade', 'indolent' (e.g., follicular lymphoma)

system. For example, AML is derived from a haemopoietic stem cell (HSC) that has acquired mutations, leading to rapid proliferation of an abnormal, or ***malignant***, cell population. These are immature cells ***(blasts)*** that share some morphological and immunophenotypic appearances with normal myeloid precursor cells in the bone marrow, but their unchecked proliferation and inability to undergo differentiation lead to a neoplastic population. In contrast, in myeloma, the cell of origin is the plasma cell, a mature cell derived from a post-germinal centre B cell, whose normal function in producing antibodies is reflected in their malignant counterpart, in which an abnormal monoclonal paraprotein or light chain production is seen.

Haematological cancers can be broadly divided between ***myeloid*** and ***lymphoid*** lineages. Myeloid disorders arise from lineages within the marrow that produce granulocytes, red blood cells (RBCs), or platelets. Lymphoid disorders can arise from either B- or T-cell lineages. This classification is summarized in **Box 39.3**, and the specific subdivision of the lymphoid malignancies is illustrated in **Fig. 39.2**. This division may not, however, accurately represent or predict the cell of origin: for example, chronic myeloid leukaemia (CML) can undergo a myeloid transformation ***(blast crisis)*** into AML but can also transform into an ALL-like disease, reflecting the fact that the CML clone is derived from an HSC with both myeloid and lymphoid differentiation potential.

Early genetic changes

The number, type and sequence, and combination of acquired genetic mutations determines the phenotype of the condition. CML, for example, has a clear initiating event (the ***Philadelphia chromosome*** [Ph+] translocation) that defines the condition and has led to effective targeted therapy. Other malignancies have a wider variety of driver mutations, producing a more heterogeneous group of conditions with variable responses to different treatments and variable prognostic significance.

Cellular phenotypes

The pattern of mutations can lead to a ***dysplastic*** (abnormal appearance and function) or ***proliferative*** phenotype. The stem cell defect in MDS, for example, leads to dysplastic cells with a consequent reduction in normal haemopoiesis. AML, in contrast, is characterized by the rapid proliferation of large numbers of immature cells, which can move out of the bone marrow into the peripheral blood, causing a leukocytosis as well as failure of normal haemopoiesis often caused by extensive bone marrow infiltration.

Haematological malignancies can also be divided, based on the speed of disease evolution, into ***acute*** or ***chronic*** conditions. Whereas the most acute disorders (e.g., AML, Burkitt lymphoma) are rapidly progressive and invariably fatal within days to weeks if not treated, chronic disorders (e.g., CLL, FL) are typically indolent and slowly progressive with patients living with their conditions for long periods of time, often not even requiring treatment at diagnosis. In contrast to acute conditions, however, chronic malignancies are counter-intuitively less likely to be cured with standard treatments.

New mutational events

Additional mutational events can occur within the malignant populations, causing changes to the disease's behaviour ***(clonal evolution)***, with a subset of cells becoming dominant and leading to disease progression (**Fig. 39.3**). This can occur because of the 'selection pressure' of drug treatment, with resistant clones emerging over time, and this explains, for example, the loss of response to a drug after a period of remission. A sudden change in behaviour from a chronic to acute condition is often termed a ***high-grade transformation***, with examples including Richter's transformation of CLL to a high-grade lymphoma or blast crisis of CML to AML or ALL. High-grade transformation carries a poorer prognosis.

Leukaemic and lymphomatous presentations

A final division can be made between ***circulating*** or ***solid*** presentations, depending on whether there is primarily a marrow-based leukaemic presentation (with or without obvious circulating disease in the peripheral blood) or a nodal or extranodal lymphomatous presentation (in which soft tissue masses predominate). Often, though, these presentations are variations of the same disease. This can lead to confusing nomenclature for patients and clinicians alike.

Investigations

Full blood count

The full blood count (FBC) is the most fundamental test used to pick up most haematological cancers. This is an automated test available in all hospitals.

The basic results produced by an automated FBC are:

- Haemoglobin (Hb) concentration with RBC markers, mean corpuscular volume, and mean corpuscular haemoglobin
- White blood cell count (WCC) and proportions of cells in the different white blood cell (WBC) populations ***('differential')***
- Platelet count.

When an unexpected significant abnormal finding is detected, in either cell count or differential, a flag should be raised to laboratory staff. Often further investigation with a manual repeat with blood film (see later) is recommended. Increasingly, FBC interpretation is done automatically based on pattern recognition, though this should be interpreted with some caution. As with all laboratory tests, the FBC

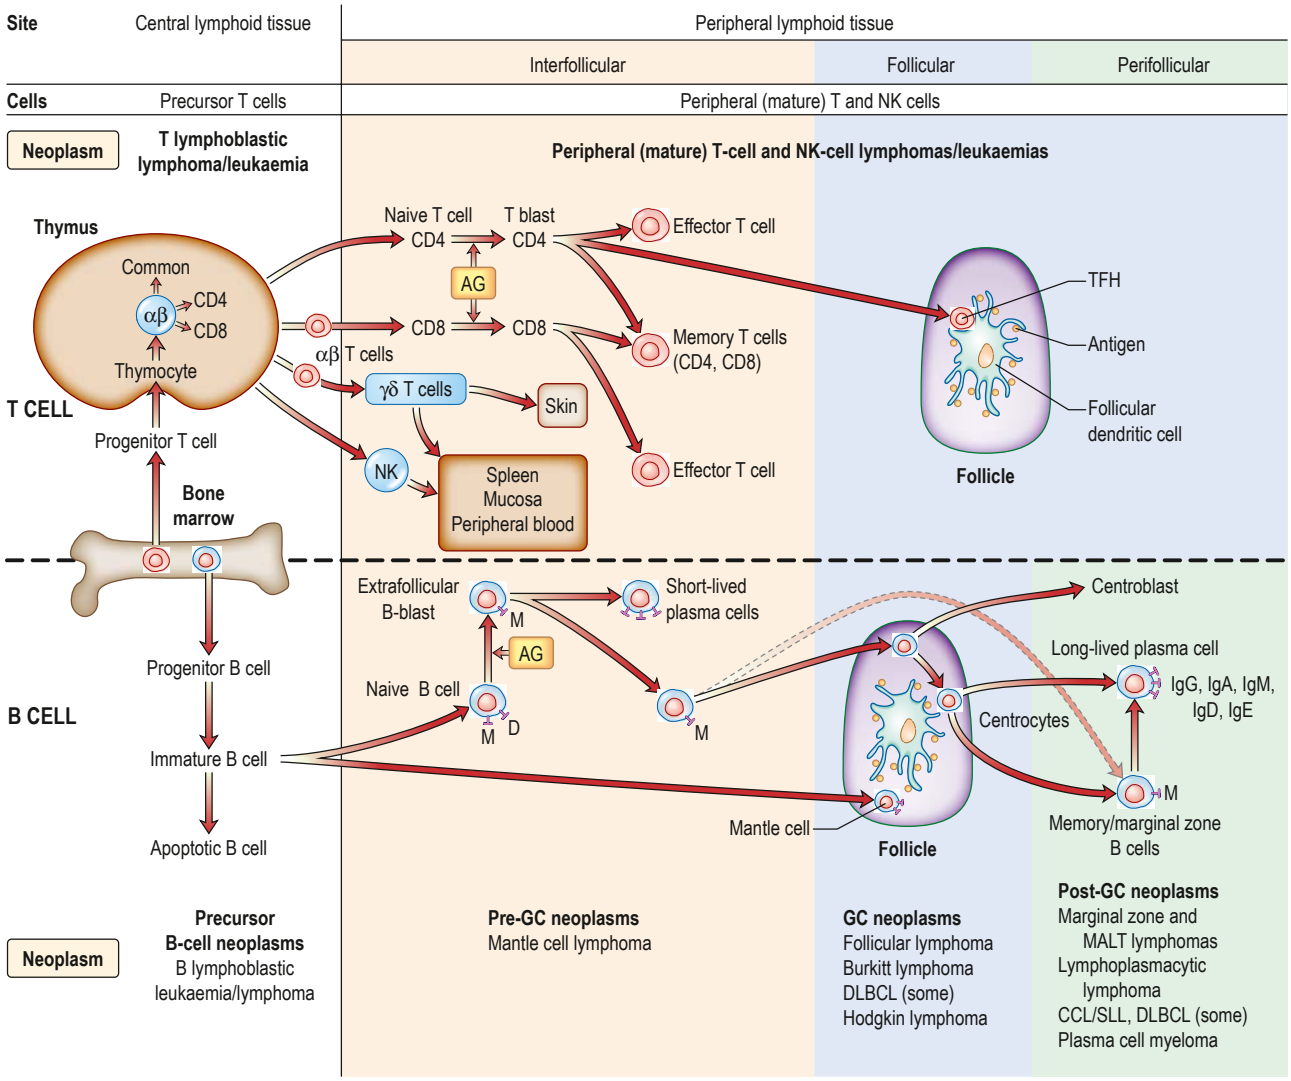

Fig. 39.2 Differentiation of T and B lymphocytes and their relationship to neoplasms. ***T-cell differentiation (above dotted line):*** Progenitor T cells from the bone marrow enter the thymus and develop into different naive T cells. αβ T cells leave the thymus, are exposed to antigen (AG), and undergo blast transformation. They then develop into CD4+ and CD8+ effector and memory T cells. CD4+ effectors cells include T regulatory cells and follicular helper T cells (TFHs) in the germinal centres (GCs). On antigenic stimulation, T-cell responses to antigenic stimulation pathways of natural killer cells (NK) and γδ T cells are unknown. ***B-cell differentiation (below dotted line):*** Precursor B cells mature in the bone marrow and undergo apoptosis or mature to naive B cells. After exposure to antigen and blast transformation, they develop into short-lived plasma cells or enter the GC. Somatic hypermutation and heavy chain class switching occur here (not shown). The transformed cells of the GC (centroblasts) undergo apoptosis or develop into centrocytes. Post-GC cells include long-lived plasma cells and memory or marginal cells. *CLL/SLL,* Chronic lymphocytic leukaemia/small lymphocytic lymphoma; *DLBCL,* diffuse large B-cell lymphoma; *Ig,* immunoglobulin; *MALT,* mucosa-associated lymphoid tissue. (*Redrawn from information in Swerdlow SH, Campo E, Harris NL et al. [eds].* WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, *4th edn. Geneva: WHO; 2008.*)

is subject to both internal and external quality assurance testing to ensure that all laboratories report results accurately and precisely.

Morphology

Blood film

Blood cells can be easily viewed by spreading a droplet of blood into a film on a microscope slide and staining it to reveal the appearance and number of the cells (Fig. 39.4). Certain conditions have morphological features that are characteristic (e.g., Auer rods in AML cells), and although definitive diagnosis usually requires additional tests (see later), expertise at blood film examination remains a key skill for all haematologists involved in diagnosis. The initial diagnosis of acute leukaemia, of whichever lineage, mainly in patients with higher WCCs, is made on blood film. This is a medical emergency even though patients can be clinically well.

Bone marrow aspirate

Although many leukaemias are visible in the peripheral blood, other blood cancers require examination of the cells within the bone marrow to make a formal diagnosis. Slide preparation and staining techniques

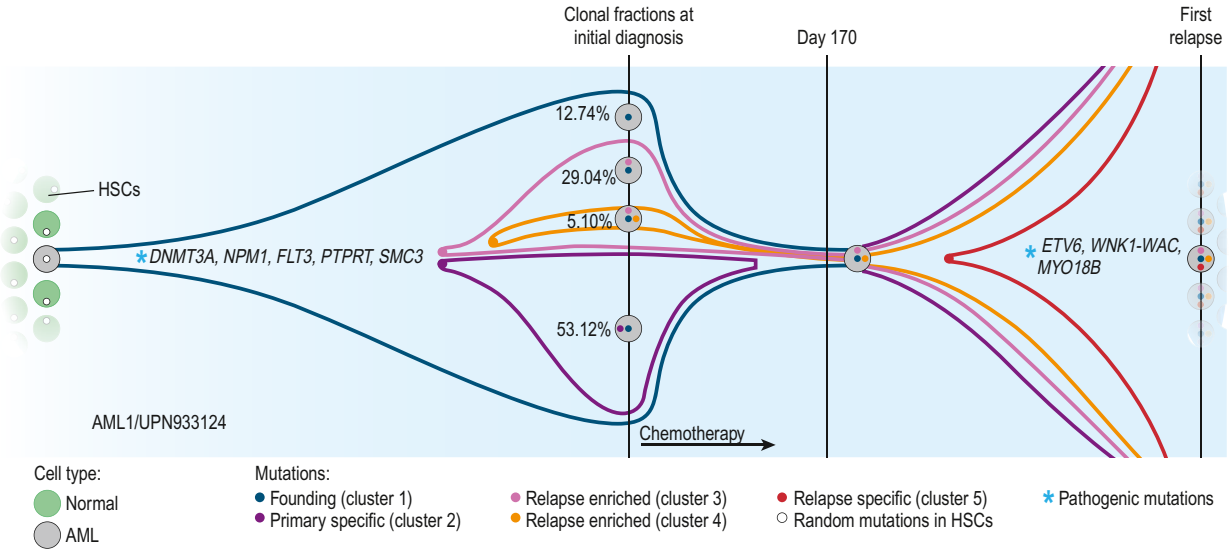

Fig. 39.3 Clonal evolution in a population of leukaemic cells from a patient with acute myeloid leukaemia (AML). The founding clone in the primary tumour contained somatic mutations in the genes *DNMT3A, NPM1, PTPRT, SMC3,* and *FLT3* that are all recurrent in AML and probably relevant for pathogenesis. One subclone within the founding clone evolved to become the dominant clone at relapse by acquiring additional mutations, including recurrent mutations in *ETV6* and *MYO18B* and a *WNK1-WAC* fusion gene. *HSC,* Haemopoietic stem cell. (*From Ding L, Ley TJ et al. Clonal evolution in relapsed acute myeloid leukaemia revealed by whole-genome sequencing*. Nature *2012;481:506–510.*)

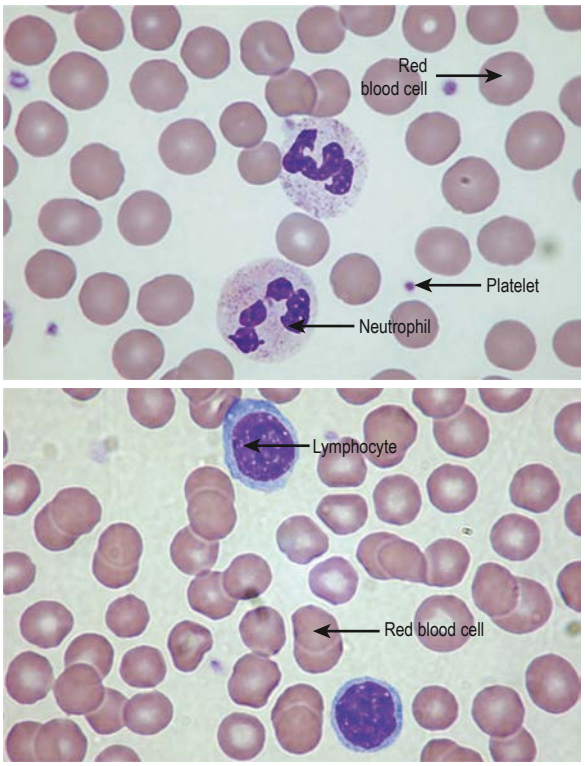

Fig. 39.4 Normal blood films.

Fig. 39.5 Normal bone marrow trephine.

are similar. The normal marrow aspirate shows a wide range of precursor cells at various stages of development.

Bone marrow trephine (trephine)

Histological examination can be performed on a bone marrow biopsy or trephine (from the Greek 'trypanon', meaning 'an instrument for boring'), which can provide an assessment of cellularity and fibrosis, tissue structure, and the presence and character of any malignant population (Fig. 39.5). Immunohistochemical staining can provide a specific diagnosis. The same staining techniques are also used on lymph node and other biopsies (e.g., in lymphomas). Time to results can vary because initial stains focus on the more likely or common diagnosis first, with stains added if no diagnosis is made. It is not that rare that repeat biopsy is required. This is essential if an accurate diagnosis cannot be made on the initial available material. This is especially seen with core biopsies, including endoscopic biopsies, in which the tissue samples obtained are small. It is for this reason that excision biopsy is recommended when possible.

Biochemistry

Routine biochemical testing is used to assess organ damage and tumour lysis. Specific tests (e.g., lactate dehydrogenase [LDH], beta-2-microglobulin [B2M]) are used in staging systems in myeloma and lymphoma.

Immunological assessment of paraproteins and serum free light chains is an essential part of the diagnosis and response assessment of myeloma and some other blood cancers (see later).

Immunophenotyping

Cell surface proteins act as markers that can be used to characterize and quantify malignant cell populations. ***Immunohistochemistry*** of solid samples (e.g., bone marrow trephines, lymph node biopsies) uses the same markers

Flow cytometry is performed on liquid samples (e.g., peripheral blood, bone marrow aspirate, cerebrospinal fluid [CSF]. In this process, cells are stained with fluorescently labelled antibodies and analyzed with specially designed analysers. The combination of cell size and appearance, together with the pattern of surface markers, identifies a profile or ***immunophenotype*** that is characteristic of a particular diagnosis (Fig. 39.6).

Immunophenotypic identification of malignant cell populations is an essential part of the diagnosis of almost all haematological malignancies. As an example, acute leukaemia cells may appear identical by morphology but have very different and specific immunophenotype profiles. It is the immunophenotype report, or ***flow***, that confirms or excludes a diagnosis; it is required before starting any treatment, except in extreme emergencies (Fig. 39.7). These results have a direct impact on treatment, different chemotherapy combinations being used for the different conditions. The markers identified can also in some cases be used to assess response to treatment or for monitoring.

Cytogenetics

Cancer is characterized by genetic abnormalities within the malignant cell populations, and these abnormalities can increasingly be detected in many haematological cancers, either to confirm a diagnosis or to act as biomarkers that can provide information on the likely timescale and behaviour of the disease ***(prognostic)*** or the likely response to a specific drug or treatment ***(predictive)***. Chromosomal abnormalities (translocations, insertions, deletions, inversions) may be detected by two major cytogenetic techniques:

- ***G-band karyotyping*** detects large structural abnormalities in chromosomes when they are condensed during metaphase. This technique detects the t(9;22) Ph+ translocation in CML (see Fig. 5.24) and many of the major structural abnormalities associated with AML prognosis (e.g., inv16, monosomy 7).
- ***Fluorescence in situ hybridization (FISH)*** assesses cells during interphase, so it is useful for slower-growing cancers; however, it only detects specific abnormalities using pre-designed fluorescently labelled probes. This technique is commonly used for detecting prognostically significant abnormalities in myeloma (e.g., t(4;14), 17p deletion) (Fig. 39.8).

Molecular genetics

Abnormalities in specific genes can be detected by DNA sequencing technologies, again providing important prognostic and predictive information. Gene mutations that are known to be of relevance may be specifically screened for. In CML, the T315I mutation in the *BCR-ABL* fusion gene, for example, is associated with poor response to standard therapy and may prompt a change to a specific tyrosine kinase inhibitor (TKI) with known activity in the presence of this mutation.

Use of high-throughput 'next-generation sequencing' (NGS) technologies allows for the investigation of several genes of interest in a single assay. These are increasingly being used as the number of known relevant mutations grows and advances in technology and bio-informatic analysis make this approach more cost-effective. As an example, *TET2*, *SF3B1*, and *ASXL1* are commonly mutated in MDS, and their detection can be helpful in making a diagnosis in unclear cases, as well as informing prognosis. With the development of novel drugs that have activity against specific mutations, the use of gene panels is likely to increase.

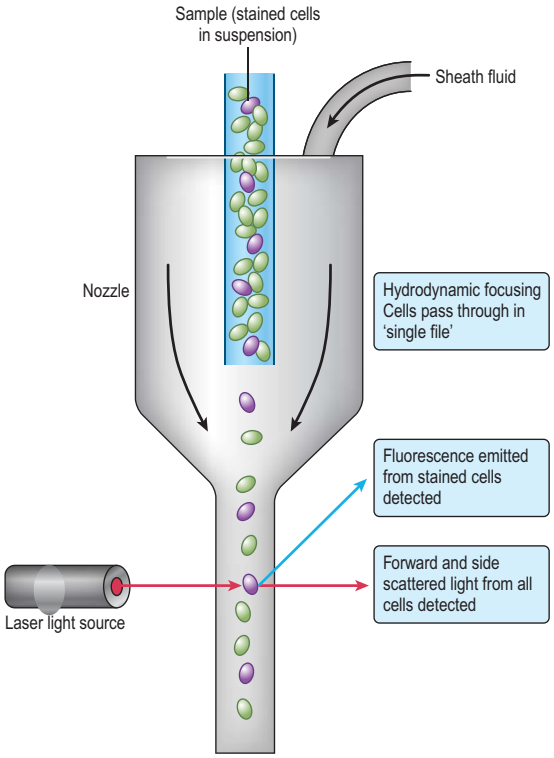

Fig. 39.6 Flow cytometer showing how cells are stained and then characterized with a laser light source and detectors. This method can produce detailed information on cell size, composition, and surface markers used to characterize both normal and malignant cell populations.

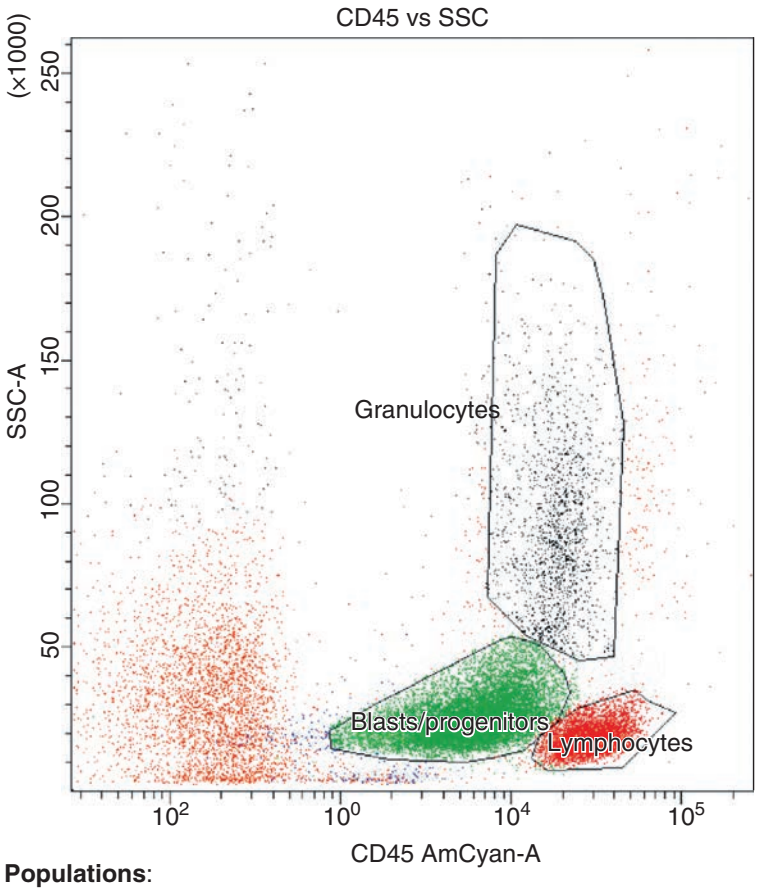
Minimal or measurable residual disease testing

Historically, the term '***minimal*** residual disease' was used. However, more appropriate is the term '***measurable*** residual disease', which is increasingly used. The presence of residual disease is far from a minimal finding because it has a significant prognostic importance and often a direct impact on treatment. It is for this reason that the authors support the use of '***measurable*** residual disease'. Flow cytometry and molecular technologies are increasingly being used to detect very low levels of malignant cells in so-called measurable residual disease (MRD) assays. An MRD-positive result can predict relapse before it is visible by morphology and may prompt an early change in treatment. Conversely, an MRD-negative result can provide confidence for de-escalating treatment or for not pursing further intensive treatments such as allogeneic transplant.

Two major methods are used for MRD testing:

- ***Flow cytometry.*** This uses the same methodology as immunophenotyping to detect low levels of malignant cells in the peripheral blood. Ideally, a sample at diagnosis is used to identify the distinctive immunophenotypic profile of the malignant cell population. This can then be used to look for persistence or early relapse of the same cell population.
- ***Quantitative polymerase chain reaction.*** This technique allows the amplification of a specific sequence of DNA or RNA,



Populations:
- Red: normal lymphocytes
- Black: granulocytes
- Green: progenitors (blasts)

Fig. 39.7 Flow cytometry plot from a patient with B lymphoblastic leukaemia. *SSC,* Side scatter. *(Courtesy of Timothy Farren, Barts Health NHS Trust, London, UK.)*

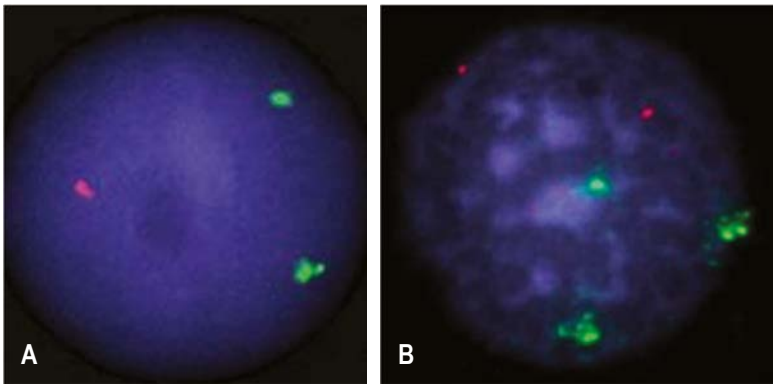


Fig. 39.8 Fluorescence *in situ* hybridization photomicrographs of a patient with chronic lymphocytic leukaemia. (A) 17p *(green probe)* shows two green signals (*TP53* deletion) and 11q *(red probe)* shows normal diploid complement of 11q. **(B)** Twelve centromere *(green probe)* shows three green signals (trisomy 12), and 13q14 *(red probe)* shows normal diploid complement of 13q. (*Courtesy of Debra Lillington, Barts and the London NHS Trust*.)

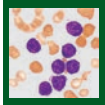
and it can be used to detect low levels of disease in several conditions:

- ***Gene fusions*** (e.g., *BCR-ABL* in CML)
- ***Immunoglobulin gene rearrangements*** in B-cell ALL
- ***T-cell receptor gene rearrangements*** in T-cell ALL

Tissue typing

For patients who may go on to allogeneic SCT, it is important to collect a blood sample for tissue typing at diagnosis so that potential donors may be identified. Testing identifies donors who match the patient's human leucocyte antigen (HLA) type and is done by



genetic testing, ideally at the HLA-A, B, C, DP, DQ, and DR loci. Testing packs can be sent out to siblings or potential haplo donors such as parents and children, to be returned for testing at the regional laboratory. If no related donors are identified, a search can be performed on national and international donor registries.

Radiological imaging

Although a tissue sample is required to make a diagnosis and commence treatment, radiological imaging plays a key role in the staging, response assessment, and investigation of haematological cancers, mainly the lymphomas and myeloma.

- Plain films are not routinely used for formal staging but may be helpful in initial investigation and assessment of complications (e.g., long bone fractures as a presenting symptom of myeloma).
- Ultrasonography assesses soft tissue masses (e.g., characterization of enlarged lymph nodes). Ultrasound-guided biopsies are a common method of making an initial lymphoma diagnosis, though excision biopsy is generally preferred.
- Computed tomography (CT) provide accurate imaging to stage tumours at diagnosis and assess response. Low-dose, non-contrast CT scans may be sufficient in myeloma, in which the main site of organ damage is the bones. Assessment of soft tissue masses (e.g., lymphoma) requires contrast. CT-guided biopsies are an effective method of obtaining tissue from deeper-lying areas. Positron emission tomography (PET) scans in combination with CT scans have become the standard in many centres.
- Nuclear medicine scans, such as fluorodeoxyglucose positron emission tomography (FGD-PET), are increasingly used in combination with CT (CT-PET) to visualize metabolically active disease. This technique is helpful for assessing response after therapy and to distinguish active residual tumour from fibrotic tissue after treatment.
- Magnetic resonance imaging (MRI) provides detailed views of organs and has benefits in a number of specific situations (e.g., bone marrow, brain, spinal cord). Diffusion-weighted MRI can provide functional information and is increasingly being used in myeloma assessment.

Specialist integrated haematological malignancy diagnostic service and multidisciplinary team

Several different techniques are used in establishing a diagnosis of a haematological cancer, as well as in providing relevant staging and prognostic information to guide treatment. Diagnostic reports can be integrated into a single document, incorporating all relevant pathological information. This is often carried out as part of a specialist integrated haematological malignancy diagnostic service, which may be run on a regional basis.

Review of all diagnostic information, choice of treatment, response assessment, and disease progression should (when possible) be done in the setting of an MDT. Emergency treatment should not be delayed and should be initiated as soon as possible with retrospective MDT discussion.

Bain BJ. *Blood Cells: A Practical Guide*, 5th edn. Oxford: Wiley–Blackwell.

LEUKAEMIA

There are four distinct subtypes of leukaemia: AML, ALL, CML, and chronic lymphocytic leukaemia (CLL).

The leukaemias are relatively rare diseases; the different subtypes have distinct diagnostic features. Though they can occur at any age, they tend toward an age distribution: ALL is mainly seen in childhood, but the median age at presentation for AML is 65 years; CML is seen across the ages, but CLL is almost exclusively a disease of older adults.

The diagnosis of leukaemia is remarkably straightforward on a routine blood film examination, available in every hospital, though confirmation of the diagnosis and subtype requires immunophenotyping, cytogenetics, molecular genetics, and a bone marrow investigation. The diagnosis is almost invariably unexpected and will worry both the clinician and patient. It is essential the patient is informed about the results in a timely manner.

Aetiology

In the majority of patients, the cause is unknown; however, several factors have been associated:

- ***Radiation.*** This can induce genetic damage to haemopoietic precursors; ALL, AML and CML have increased incidences in survivors of Hiroshima, Nagasaki, and Chernobyl and in patients treated with ionizing radiation.
- ***Chemicals and drugs.*** Exposure to benzene may lead to bone marrow damage. AML can also occur after treatment with chemotherapy drugs such as alkylating agents (e.g., melphalan) and topoisomerase-II inhibitors (e.g., etoposide). Historically, the term 'secondary AML' was used for AML after prior chemotherapy, though this entity is no longer present in the 2022 leukaemia classification.
- ***Genetic factors.*** Leukaemia risk is elevated in several germline conditions that result in genetic instability or bone marrow failure. These include Fanconi anaemia, ataxia telangiectasia, and Li–Fraumeni syndrome. The risk is also elevated some 30 times in Down's syndrome (trisomy 21), in which there is also a specific subtype in newborns. There is a high degree of concordance among monozygotic twins. Several genes have been associated with familial AML, including *CEBPA* and *RUNX1.* This remains an area of ongoing research.
- ***Viruses.*** ATLL is a rare type of leukaemia associated with HTLV-1, found particularly in Japan and the Caribbean. No other viral links are known.
- Lifestyle factors are not implicated.

Acute leukaemias

AML has a median age at presentation of 65 years and may arise *de novo* or against a background of myelodysplasia (MDS). The different subtypes within AML are increasingly defined by their cytogenetic and molecular findings, which in many cases carry clear prognostic value, as well as being potential treatment-targets.

ALL has a substantially lower median age at presentation; it is the most common malignancy in childhood. The genetic findings in ALL vary greatly between age groups, which explains the improved prognosis in children compared with the ongoing poor prognosis in adults.

A small number of acute leukaemias have an indeterminate immunophenotype between myeloid and lymphoblastic, labelled 'mixed phenotype leukaemia'. Genetic, molecular, histological, and clinical features determine the best treatment strategy.

Clinical features

Most patients with acute leukaemia, regardless of subtype, present with one or more of the following:

- Cytopaenia-related symptoms (Box 39.4) caused by inadequate haemopoiesis secondary to infiltration of the bone marrow by leukaemia
- Symptoms caused by tissue infiltration by leukaemic cells
- Clinical consequences of a high WCC in the circulation
- Symptoms caused by substance release from tumour cells.

Investigations

- ***Blood count.*** Hb and platelets are frequently low, though they can be deceivingly normal. The WCC is often raised, reflecting the proliferating population, but equally can be low if the leukaemic cells are confined to the bone marrow.
- ***Blood film.*** Blast cells are almost invariably seen (Fig. 39.9A). The lineage may be identified morphologically (e.g., the presence of Auer rods is pathognomonic for a diagnosis of AML). In emergencies, a blood film can suffice for diagnosis.
- ***Bone marrow aspirate.*** Increased cellularity (Fig. 39.9B), reduced erythropoiesis, and reduced megakaryocytes are usual. Replacement by blast cells traditionally had to be more than 20% for diagnosis. This diagnostic threshold has now been lowered to 10% in the presence of certain genetic abnormalities. Because AML is increasingly defined by its molecular and genetic basis, the presence of any change carries the most diagnostic weight, almost irrespective of blast percentage. Blast population and lineage is confirmed by immunophenotyping (see Fig. 39.7):
  - CD45: pan-leukocyte marker: defines presence of a blast population in both AML and ALL
  - AML: CD33 or CD13
  - B lineage ALL: CD10 and CD19
  - T lineage ALL: CD3

  Cytogenetic and FISH analysis, as well as molecular genetics, may be used for prognostication. NGS is increasingly used, though it is not available in all centres.
- ***Chest X-ray.*** Mediastinal widening is often present in T-lymphoblastic leukaemia.
- ***CSF examination.*** This should be done in all patients with ALL because the risk of central nervous system (CNS) involvement is high, though it is not indicated at diagnosis unless clear clinical concern is present. Intrathecal chemotherapy is part of standard ALL treatment regimens with its first administration usually around day 14 of treatment. CNS investigation is not routinely performed in AML unless there is a clinical concern.
- ***Coagulation profile.*** This is performed to exclude the presence of disseminated intravascular coagulation (DIC), particularly associated with acute promyelocytic leukaemia (APML), a specific AML subtype. Patients with DIC patients typically have

Box 39.4 Symptoms and signs of leukaemia

	Symptoms	Signs	Type
Marrow failure			
Anaemia	Breathlessness Fatigue Angina Claudication	Pallor Cardiac flow murmur	ALL or AML

a raised prothrombin time and activated partial thromboplastin time (APTT), reduced fibrinogen, and increased fibrinogen degradation products (D-dimers). Correction of clotting and platelet count during the initial few weeks of APML treatment is lifesaving.

- ***Biochemistry.*** This should include serum urate, kidney, and liver function tests.
- ***Cardiac function.*** Electrocardiography and echocardiography are used to assess cardiac function before intensive chemotherapy, which may include key cardiotoxic anthracycline drugs. In emergencies, treatment can start without an echo being available.
- ***HLA type and tissue type.*** These are performed to identify potential stem cell donors for allogeneic transplantation. They are recommended on appropriate family members in the first cycle of treatment for patients with AML and ALL. An allograft might not be indicated, but work-up for transplant can take a significant amount of time.
- ***HIV and hepatitis B screening.***

Management

If untreated, acute leukaemia is invariably fatal with a prognosis of weeks to months, though with best supportive care and early involvement of palliative care, this can be longer. If intensive chemotherapy is not appropriate, this should be discussed with the patient and their family at the earliest possibility.

Treatment with curative intent is appropriate in younger and fitter patients, generally those without significant co-morbidity or frailty. Cytogenetic results often define the patient's risk at diagnosis, and it is increasingly recommended, especially for those with AML, to wait for results before commencing treatment provided that a wait is clinically safe because results may determine the best treatment approach, as well as clinical trial entry. Leukaemia that does not respond to frontline treatment is termed 'refractory' leukaemia. Leukaemia that returns after a period of remission is termed 'relapsed' leukaemia. Both scenarios carry a poor prognosis.

At initial presentation, acute leukaemias range from being probably curable (e.g., childhood ALL) through to probably incurable (e.g., AML with adverse cytogenetic features such as p53 mutation). Because curative treatment carries considerable morbidity and potential mortality, it is essential for the risk-to-benefit ratio to be understood by both the physician and patient. In many cases with poor prognostic genetic features, cure requires allogeneic SCT.

The decision to treat with curative intent severely disrupts normal life for the patient and family for at least 6 months and often up to 1 year, if not beyond. In the short term, it may require transfer to another hospital, farther from the patient's home, because patients with acute leukaemias are treated in specialist centres. It is standard to admit the patients to hospital for the first cycle (AML) or phase (ALL) of treatment meaning at least 3 to 4 weeks in hospital. If response is favourable, this will be followed by further, partly predictable, lengthy admissions for further cycles or phases of treatment. It is a commitment that is daunting and hard for patients and relatives; though they should be aware of the longer-term treatment plan, it is advisable that the focus should be on one cycle or phase of treatment at a time because treatment is response dependent.

The decision to treat with curative intent implies that the chance of cure justifies the risks of the therapy. It does not imply that cure is guaranteed or expected.

Supportive care

This is integral, irrespective of treatment approach.

- ***Anaemia.*** Repeated transfusion of packed RBCs are given to keep Hb above 70 g/L. Irradiation of cells may be required (e.g., in patients who have received purine analogue drugs such as fludarabine).
- ***Thrombocytopaenia.*** Prophylactic platelet transfusion has been evaluated and remains superior to any alternative, certainly for patients with AML. Platelet count is maintained above 10×10^9/L in a patient that is stable or above 20×10^9/L if septic.
- ***Coagulation abnormalities.*** Fresh-frozen plasma is used to keep the APTT ratio and international normalized ratio below 1.5 times normal, with cryoprecipitate to keep the fibrinogen concentration above 1.5 g/dL. This is a particular risk in APML, which is associated with activation of the coagulation system (DIC).
- Norethisterone can be given to those who are menstruating to avoid menorrhagia during a thrombocytopenic phase.
- ***Infection*** (see **Box 11.98**)
  - ***Prophylaxis.*** Education of patients, relatives, and staff about diet, hand-washing, and isolation facilities should be done. Use of prophylactic antibiotics is controversial and varies greatly; local guidelines should be followed. Antiviral prophylaxis is recommended throughout. *Pneumocystis jirovecii* pneumonia prophylaxis should be considered, though the treatment itself can influence blood counts. Antifungal prophylaxis should be given to all patients during neutropaenic phases.
  - ***Therapeutic.*** All fevers should be managed following local 'neutropaenic sepsis' guidelines.
  - ***SARS-CoV-2.*** Vaccination is recommended, and all available treatments can be given.
- ***Control of hyperuricaemia (tumour lysis).*** This is achieved with hydration and prophylactic allopurinol. Rasburicase is used

for prophylaxis and treatment of patients with proliferative or high-count acute leukaemia.
- Indwelling venous devices, such as a peripherally inserted central catheter or Hickman line, are required to allow easy access to the blood for tests and administration of therapy.
- In patients of reproductive age, fertility preservation should be considered and offered, time and clinical circumstances allowing.
- Psychological support should be offered and available to all patients.

Intensive chemotherapy

For all acute leukaemias, the initial aim of therapy is to achieve remission, meaning the peripheral blood and bone marrow return to normal (complete remission [CR]). This 'induction chemotherapy' is tailored to the particular leukaemia and the individual patient's risk factors. Because treatments are not targeted, they also impair bone marrow function, which leads to a major risk of life-threatening infection, requiring a prolonged hospital admission.

Successful remission induction should always be followed by further treatment (consolidation) when possible. This consists of further cycles or phases of chemotherapy, which in some cases are subsequently followed by allogeneic SCT, when an appropriate donor is identified. Without consolidation treatment, recurrence is almost inevitable. Cytogenetics and molecular genetic techniques are now routinely used to identify residual leukaemia, not detected morphologically. This is termed 'detection of MRD'. The absence or presence of MRD is highly predictive of recurrence. In ALL, the importance of MRD and when to test are clearly understood and standardized because they have been an integral part of international trials for decades. In AML, this is less clear and standardized, though the role of MRD is clearly important.

Refractory and relapsed disease

Failure to achieve morphological CR with two cycles or phases of therapy ('refractory leukaemia') carries a poor prognosis. Salvage regimens exist in both acute leukaemias, though overall survival is significantly reduced. Salvage treatment only has a curative endpoint if remission is achieved and it is followed by an allogeneic stem cell transplant.

The treatment of patients with relapsed leukaemia, which also carries a poor prognosis, is identical.

Allogeneic stem cell transplant

Colloquially, the term 'bone marrow transplant' is used, though 'stem cell transplant' is correct. Whereas now stem cells are almost invariably collected ('harvested') from the peripheral blood, in the past, they were obtained via bone marrow aspirate. The terminology can be confusing for patients and doctors.

The decision on whether to proceed to allogeneic SCT is based on several factors:
- ***Relapse risk.*** This depends on cytogenetic and molecular risk factors at diagnosis. These have become increasingly defined and have even become part of the official diagnostic nomenclature in the most recent ELN classification (2022).
- ***Response to induction therapy.*** Allogeneic transplant can only proceed if the patient is in morphological remission. The prognosis of patients who have MRD going into allograft is significantly better than the prognosis of patients who have MRD. Further treatment to try to achieve an MRD result before transplant should be undertaken whenever possible.
- ***Transplant-related mortality.*** This varies, depending on frailty and co-morbidity, as well of the type of transplant and quality of the donor match.

Patients should proceed to transplantation only if the reduction in relapse risk outweighs the likely treatment-related mortality, leading to an improved overall survival. The Haematopoietic Stem Cell Transplant Comorbidity Index (HSCT-CI) is a useful tool that incorporates age, co-morbidities, and additional patient-related risk factors (e.g., obesity). All decisions for transplant should be made via an MDT.

Acute myeloid leukaemia

Prognosis

The prognosis depends on a range of key variables, mainly age, cytogenetics, specific gene mutations (Fig. 39.10), and the presence of MRD after initial therapy (Box 39.5).

Management

Treatment with intensive chemotherapy with curative intent is undertaken in most adults younger than the age of 70 years, provided there is no significant co-morbidity. Improved supportive care and reduced-intensity condition transplants have led to a steady increase in the upper age limit of patients considered for allograft. Treatment success reflects the cytogenetic pattern. A CR is achieved in about 80% of patients younger than the age of 70 years. Failure of treatment is caused by either resistant leukaemia (10%) or treatment-related mortality (10%), most commonly infection, sepsis, or haemorrhage. Approximately 50% of those entering CR will be cured (i.e., ~40% overall), although this varies from 60% to 70% in a favourable cytogenetic group to 10% to 20% in an adverse cytogenetic group.

Patients with 'favourable'-risk AML, depending on cytogenetic risk stratification, are treated with intensive combination chemotherapy. The usual approach is two cycles of induction chemotherapy (including an anthracycline) followed by two cycles of consolidation chemotherapy. Each cycle averages 3 to 4 weeks in hospital with a 1- to 2-week period at home in between. A large international AML trial more than a decade ago, which randomized patients to a total of either three or four cycles of chemotherapy, has yet to publish its results. Patients with favourable-risk disease do not benefit from allogeneic SCT during their first CR because the relapse risk is low. This group of patients have been termed as having 'good-risk' AML in the past, but using 'good' in the description of any AML subgroup seems a misnomer and should be avoided.

Patients with 'intermediate'-risk or 'standard'-risk AML are a heterogeneous and increasingly complex group. The initial treatment approach is the same as for those with favourable-risk disease when possible. In the past, most patients in this group were recommended to proceed to allogeneic transplant; however, in the past decade, MRD status has become a vital part of risk stratification. The confirmation of deep remission by MRD negativity is considered sufficient to remove the need for allogeneic transplant for most patients, though this should be assessed on a case-by-case basis. The shift of using MRD status to determine patients requiring allograft in first remission has led to overall 'poorer'-risk patients proceeding to allograft compared with historical approaches. This should be kept in mind when interpreting more recent allograft outcomes and comparing them with historical data.

Patients with 'adverse'-risk cytogenetics respond poorly to conventional induction and consolidation chemotherapy alone and have a high risk of relapse. If suitable, allogeneic SCT is

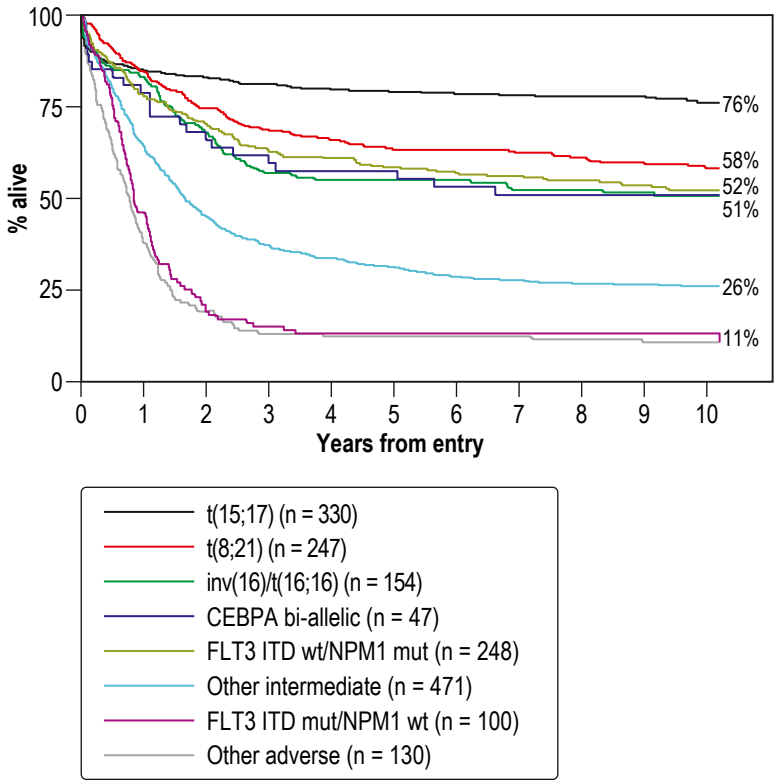

Fig. 39.10 Prognosis related to cytogenetics and molecular data in acute myeloid leukaemia (AML). Box 39.5 Risk factors in acute myeloid leukaemia

Good risk
- *De novo* disease
- Favourable cytogenetics: t(15; 17) t(8; 21) or inv(16) or its variant t(16; 16)
- *CEBPA* bi-allelic mutation
- *NPM1* mutation with FLT3 wild type

Poor risk
- Age older than >60 years
- Male gender
- Secondary disease (e.g., prior MDS or MPN)
- High WCC
- Adverse cytogenetics: –5, del(5q), –7, abnormal 3q26 or a complex karyotype
- FLT3 internal tandem duplication mutation
- MRD positivity post induction chemotherapy

FLT3, FMS-related tyrosine kinase-3; *MRD,* measurable residual disease; *MDS,* myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm; *WCC,* white blood cell count.

performed after they achieve a CR. In this strategy, allograft will often replace the fourth cycle of chemotherapy and occasionally the third.

Since 2020, the combination therapy of venetoclax and azacitidine has become another standard frontline therapy option. It is the first new option in frontline therapy for AML patients in more than 20 years. Though initially used in older and frailer patients not fit for intensive chemotherapy, there is emerging use in other patients as well. It allows more outpatient-based therapy. The role in refractory or relapsed patients is not clearly defined but may be significant.

Allografts, with many different conditioning regimens and protocols, as well as the vastly increased donor potential because of haplo-identical allografts becoming standard in recent years, fall outside the scope of this text.

The management of recurrence is undertaken on an individual basis because the overall prognosis is very poor, even though second remissions can be achieved. Long-term survival after recurrence is rarely achieved without allogeneic transplantation. The use of MRD monitoring may identify patients in CR who are in the early stages of relapse and need pre-emptive therapy before frank marrow relapse occurs.

Acute promyelocytic leukaemia

APML is a variant of AML, occurring in 10% to 15% of cases. It is characterized by the translocation t(15; 17), which produces a *PML-RARA* fusion gene with particular morphological features. There is an almost invariable coagulopathy, which remains a major cause of early death. The empirical discovery that all-*trans*-retinoic acid (ATRA) causes differentiation of promyelocytes and rapid reversal of the bleeding tendency was a major breakthrough. ATRA alone can achieve remission. If APML is suspected, ATRA should be commenced as soon as possible. Any coagulopathy and thrombocytopaenia should also be aggressively corrected for the initial few weeks. Intracranial haemorrhages occur frequently as a devastating and terminal event in the first few weeks of treatment. After remission is achieved,

prognosis is excellent, with relapses increasingly rare. There is therefore no need for allogeneic transplant in first remission.

APML has two curative treatment options in the front-line setting. Patients with high-risk APML patients (high WCC at diagnosis) are treated with ATRA and combination chemotherapy similar to chemotherapy outlined earlier. Those with low-risk APML (low WCC at diagnosis) are treated with ATRA and arsenic trioxide, a chemotherapy-free, mainly outpatient-based treatment. Both treatments have comparable outcomes.

Acute lymphoblastic leukaemia

This condition may present in leukaemic phase with significant marrow involvement (ALL) or as localized bulky disease, typically a mediastinal mass (lymphoblastic lymphoma). The tumour cells in each condition are indistinguishable, and similar therapies are therefore used.

Prognosis

Several clinical and laboratory features predict treatment response and survival in patients with ALL (**Box 39.6**). Increasingly, therapeutic strategies based on prognostic risk are used in management. MRD stratification is increasingly used to select patients who are at high risk (for treatment intensification) or low risk (for treatment de-escalation).

The prognosis of ALL in childhood is excellent: CR is achieved in almost all, with up to 80% being alive without recurrence at 5 years. Failure occurs most frequently in those with high presentation blast counts or patient with clearly defined adverse cytogenetics. Current treatment strategies de-escalate therapy for favourable-risk children to avoid some of the long-term consequences of therapy, such as avascular necrosis of bone, infertility, neurotoxicity, and cardiotoxicity.

The prognosis of ALL in adults remains very poor. Adverse cytogenetics are more commonly seen with advancing age. Co-morbidities further complicate the intense treatment approach. Long-term remission is only achieved in 25% to 30% of patients. Allogeneic SCT is recommended in almost all adults achieving a remission, though there are exceptions. Novel targeted immuno- and antibody therapies have led to improvement in patients achieving MRD status, allowing more patients to proceed to allograft. Their role in the relapse setting is less well defined. As with AML, most relapses occur within the first 2 years of initial treatment. Outcomes in those with relapsed ALL are extremely poor.

Management

As with AML, the overall strategy is to achieve an initial remission with induction chemotherapy followed by consolidation phases, an allogeneic transplant, or both. The drug combinations in ALL differ from those used in AML, with initial induction typically consisting of vincristine, a glucocorticoid, an anthracycline and Peg-asparaginase; different agents are used in the consolidation cycles. Every phase of ALL treatment is different, which makes the regimens appear very complex because they are not repeated. Different phases are also skipped or added depending on the patient route to transplant and the type of transplant being planned. To complicate things further, in patients not proceeding to allograft, the induction and consolidation phases are followed by lengthy maintenance phases to reduce the risk of disease recurrence, typically continuing for another 2 years.

A major difference between treatment for ALL and AML is the need for CNS-directed therapy in ALL because of the higher risk of CNS infiltration or relapse. Prophylaxis should be given with intrathecal chemotherapy (under platelet cover if necessary) as soon as blasts are cleared from the blood. The first planned intrathecal administration is usually around day 14 of the first induction phase. Cranial irradiation was used routinely in the past to reduce the risk of relapse within the CNS; however, this has been replaced by an intensification phase with high-dose methotrexate (which crosses the blood–brain barrier), usually after two induction phases. This phase was added to standard treatment, which historically included a number of intrathecal chemotherapy administrations; no randomized data exist comparing the two or a combination approach.

The presence of the t(9;22) Ph+ (see **Fig. 5.24**) has traditionally been associated with increased risk; however, the advent of imatinib and the other TKIs, originally developed for CML, have overcome this risk to some extent. These agents can be used in combination with intensive or non-intensive chemotherapy.

Chimeric antigen receptor T-cell (CAR T) therapy has rapidly become a treatment option for patients with relapsed ALL and for patients with no available donor. CAR T therapy comes with its own unique and potentially dangerous set of side-effects. An important difference between CAR T therapy and allogeneic SCT is that the patient does not need to be in remission to proceed to CAR T therapy. Indications for CAR T therapy will no doubt increase significantly in the coming years.

Chronic myeloid leukaemia and the myeloproliferative neoplasms

The MPNs are clonal stem cell disorders characterized by uncontrolled proliferation of one or more of the cell lines in the bone marrow, usually erythroid, myeloid, and/or megakaryocyte lines. Myeloproliferative disorders include:

- CML
- Polycythaemia vera (PV)
- Essential thrombocythaemia (ET)
- Primary myelofibrosis
- Chronic neutrophilic leukaemia
- Chronic eosinophilic leukaemia
- Juvenile myelomonocytic leukaemia
- MPN, not otherwise specified.

Chronic myeloid leukaemia

CML, which accounts for about 14% of all leukaemias, is a member of the family of MPNs. It is almost exclusively a disease of adults, with presentation between 40 and 60 years of age. It is defined by the presence of the Ph+ (see Fig. 5.24), which is demonstrated either by cytogenetic analysis alone (95%) or by FISH or reverse transcription polymerase chain reaction (RT-PCR) (5%). Unlike the acute leukaemias, which are rapidly fatal without urgent treatment, CML has a more slowly progressive course. If left untreated, the disease will evolve from the chronic phase to the blast phase. When it evolves, it can transform to an AML (75%) or an ALL (25%) with death in a median of 3 to 4 years. Fortunately, targeted therapy to arrest disease progression is highly effective, and the survival rate is excellent.

Clinical features

CML usually presents in the chronic phase, and some patients have no symptoms.

Symptoms

When present, symptoms include:

- Symptomatic anaemia (e.g., shortness of breath)
- Abdominal discomfort caused by splenomegaly
- Weight loss
- Fever and sweats in the absence of infection
- Headache (occasionally) or priapism caused by hyperleucocytosis
- Bruising and bleeding (uncommon)

Signs

- Pallor
- Splenomegaly, often massive
- Lymphadenopathy (uncommon; suggests blast crisis)
- Extramedullary soft tissue leukaemic deposit: 'chloroma' (indicates blast crisis)
- Retinal haemorrhage caused by leucostasis

Investigations

- ***Blood count.*** Hb is low (normochromic and normocytic) or normal; the WCC is high (usually >100 × 10^9/L); the platelet count can be low, normal, or high.
- ***Blood film.*** There is neutrophilia with the whole spectrum of mature myeloid precursors. Basophils and eosinophils are elevated. Increased numbers of blasts indicate evolution to blast crisis (Fig. 39.11).
- ***Bone marrow aspirate.*** Increased cellularity is seen, with greater numbers of myeloid precursors.

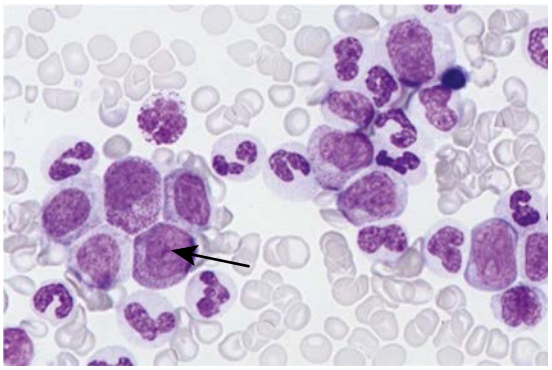

Fig. 39.11 Blood film showing blast cells *(arrow)* in chronic myeloid leukaemia.

- ***Cytogenetic analysis (G-banding).*** This reveals a t(9; 22) translocation (Ph+; Fig. 5.24).
- ***FISH or RT-PCR.*** These demonstrate the BCR:ABL fusion. These techniques are also used to quantify response to therapy.

Management

Most patients diagnosed with chronic-phase CML have a normal life expectancy. Treatment is with TKIs, which specifically block the enzymatic action of the BCR-ABL fusion protein. Imatinib is first-line treatment for patients in the chronic phase, although second-generation TKIs may be used. Imatinib produces a complete cytogenetic remission (no detectable Ph+ cells in the marrow) in 70% of patients. A significant proportion lose molecularly detectable BCR-ABL transcripts from the blood, achieving a molecular response (MR) of varying depths: MR3 (a log reduction of 3; <0.1%), MR4 (<0.01%), or MR5 (<0.001%). Side-effects of imatinib include nausea, headache, rash, and cytopenias. A goal of therapy is to achieve deep molecular response (DMR) to allow reduction and then stop treatment for a period of treatment-free remission (TFR). Discontinuation can be considered in those who respond optimally and achieve a sustained DMR (MR4). Patients need to be closely monitored, with around two-thirds able to remain off treatment without disease recurrence.

Resistance to imatinib as a single agent may develop as a result of secondary BCR-ABL kinase mutations beyond t(9; 22). If patients do not tolerate imatinib or have a suboptimal response, mutation analysis should be performed, and a second-generation TKI (e.g., dasatinib, nilotinib, bosutinib) should be commenced. Those who have developed a T315I mutation should be offered ponatinib.

In the blast phase, the approach is to combine a second-line TKI with intensive chemotherapy, as for acute leukaemia. SCT should then be considered with the aim of achieving a durable remission.

Other myeloproliferative disorders

The other myeloproliferative disorders are often characterized by a mutation in *JAK2*, calreticulin *(CALR)*, or thrombopoietin receptor *(MPL)*. These driver mutations cause proliferation of the myeloid cell lines. This is typically gradual, but all can transition to more aggressive forms, either myelofibrosis or AML, with the accumulation of secondary cytogenetic or molecular abnormalities.

Polycythaemia vera

The investigation of polycythaemia is covered in Chapter 38 (see 'Polycythaemia' section). Although it is important to exclude secondary causes of polycythaemia, the presence of a mutation of the

JAK2 gene is strongly suggestive of primary polycythaemia (PV). This is a clonal stem cell disorder in which there is an excessive proliferation of erythroid, myeloid, and/or megakaryocytic progenitor cells. Almost all patients with PV have acquired mutations of the *JAK2* gene. In 96% to 97% of patients, this is a point mutation that causes the substitution of phenylalanine for valine at position 617 (JAK2V617F). Most of the remainder have rarer *JAK2* exon 12 mutations. *JAK2* is a cytoplasmic tyrosine kinase that transduces signals, especially those triggered by haemopoietic growth factors such as erythropoietin (EPO), in normal and neoplastic cells. The discovery of the *JAK2* mutation in MPNs is significant for the diagnosis of PV and as a target for therapies.

Clinical features

The onset is insidious. PV is more common in patients older than 60 years of age and may present with fatigue, itching, vertigo, headache, and visual disturbance. These symptoms are common in the older population, so PV is easily missed. Increasingly, PV is detected on routine blood tests conducted for other reasons. Severe itching may occur after a hot bath or when the patient is warm. Gout caused by increased cell turnover may be a feature, and peptic ulceration occurs in a minority of patients. Thrombosis and haemorrhage are the major complications of PV.

The patient may be plethoric and have a dusky cyanosis and injection of the conjunctivae. The spleen is palpable in 70% and is useful in distinguishing PV from secondary polycythaemia. The liver is enlarged in 50% of patients.

Diagnosis

JAK2 mutation screening is routine in the investigation of polycythaemia and incorporated into diagnostic criteria. Although WHO criteria require a bone marrow biopsy for diagnosis in adults, current British guidelines do not mandate this in the presence of a confirmed *JAK2* mutation (**Box 39.7**).

The measurement of RBC mass and plasma volume is not routinely required or available. Measurement of serum ferritin can be useful to detect cases of iron-deficient PV. There may be a raised serum uric acid, leucocyte alkaline phosphatase, and raised serum vitamin B_{12} and vitamin B_{12} binding protein (transcobalamin 1).

Box 39.7 Recommended diagnostic criteria for polycythaemia vera (PV)

***JAK2*-positive PV (requires both criteria)**

- Haematocrit >0.52 in males, >0.48 in females, *or* raised RBC mass >25% above predicted
- Mutation in *JAK2*

***JAK2*-negative PV (requires A1–A4 plus another A or two B criteria)**

- A1: haematocrit ≥0.60 in males, ≥0.56 in females, *or* raised RBC mass >25% above predicted
- A2: absence of mutation in *JAK2*
- A3: no secondary cause of erythrocytosis
- A4: bone marrow histology consistent with PV
- A5: palpable splenomegaly
- A6: acquired genetic abnormality (excluding *BCR-ABL*) in haemopoietic cells
- B1: thrombocytosis (platelet count >450 × 10^9/L)
- B2: neutrophil count >10 × 10^9/L in non-smokers, ≥12.5 × 10^9/L in smokers
- B3: X-ray evidence of splenomegaly
- B4: low serum erythropoietin

Management

Course and treatment

Patients should be risk assessed for the likelihood of vascular events. Treatment is designed to prevent thrombotic complications of the disease and to reduce the long-term risk of progression and transformation. Additional modifiable cardiovascular risk factors should be actively addressed.

There are three types of specific treatment:

- ***Low-dose aspirin.*** Aspirin 75 mg/day is routinely used for patients with PV in the absence of contraindications to reduce the risk of cardiovascular complications.
- ***Venesection.*** During initial phases of treatment, the removal of 400 to 500 mL of blood weekly successfully relieves many of the symptoms of PV. Iron deficiency eventually limits erythropoiesis, and only infrequently is venesection required. Venesection is often used as the sole treatment, with the aim of maintaining a haematocrit below 0.45.
- ***Chemotherapy.*** Continuous or intermittent treatment with hydroxycarbamide (hydroxyurea) is used in patients who do not tolerate venesection or are at higher risk of thrombosis. It also helps those who have other poorly controlled disease features such as thrombocytosis, symptomatic splenomegaly, or thrombosis. Interferon-alfa is also effective; it is administered by subcutaneous injection but can cause unacceptable toxicity. Low-dose intermittent busulfan may be more convenient, but use must be weighed against potential long-term complications, such as the increased risk of leukaemia development.
- ***Ruxolitinib.*** This *JAK2* inhibitor can be used in patients who are intolerant or unresponsive to hydroxycarbamide.
- Iron replacement should be avoided in patients with iron-deficient PV because it can result in a dangerous rebound polycythaemia.

General measures

- ***Allopurinol.*** This can be given to block uric acid production.
- ***Avoiding very hot baths.*** This lessens pruritus.
- ***Surgery.*** Polycythaemia should be controlled before surgery. Patients with uncontrolled PV have a high operative risk. In an emergency, the haematocrit must be reduced by venesection and appropriate fluid replacement.

Prognosis

PV develops into myelofibrosis in 10% to 15% of cases by 10 years and into AML in 2% as part of the natural history of the disease.

Essential thrombocythaemia (ET)

ET is an MPN, closely related to PV, which is characterized by a persistently raised platelet count. Patients usually have normal Hb concentrations, although mild anaemia may occur. The WCC is high in some patients. At diagnosis, the platelet count is usually above 600 × 10^9/L and may be as high as 2000 × 10^9/L or rarely even higher.

Clinical features

ET presents either symptomatically with thromboembolic or bleeding (less common) or incidentally (e.g., at a routine medical check). Erythromelalgia (severe burning pain), erythema, and warmth of the extremities (primarily the feet and, to a lesser extent, the hands) may occur.

Investigations

The diagnosis of ET is based on a sustained platelet count of 450 × 10^9/L or more, in the absence of a possible reactive cause of thrombocytosis (Box 39.8) and of other haematological malignancy associated with thrombocytosis (e.g., PV, myelofibrosis). Mutations in *JAK2, CALR,* or *MPL* genes are detected in 50% to 60%, 25% to 30%, and 3% to 10% of cases, respectively. As a generalization, a person with a very high platelet count (>1000 × 10^9/L) who is clinically well with good health will most likely prove to have ET. In a patient who has a lower platelet count (e.g., 600 × 10^9/L) or infective or inflammatory conditions, the diagnosis can be more difficult.

Management

Because of the thrombotic risk, aspirin should be considered in all patients without contraindications, especially those with *JAK2-V617F* mutations or cardiovascular risk factors. Treatment to reduce the platelet count ('cytoreduction') is recommended for patients with any high-risk feature:

- Age older than 60 years
- Platelet count greater than 1500 × 10^9/L
- History of thrombosis or haemorrhage.

Treatment is usually with hydroxycarbamide (hydroxyurea) to control the platelet count to below 400 × 10^9/L. Alternative cytoreductive agents include anagrelide or busulfan. Interferon-alfa is also effective; it is administered by subcutaneous injection but can be difficult to tolerate because of side-effects. ET may eventually transform into PV, myelofibrosis, or acute leukaemia, but the disease may not progress for many years.

Secondary thrombocytosis

Other disorders that may give rise to reactive high platelet counts include iron deficiency, infection, inflammation, and malignancy. Individuals who have had a splenectomy often have high platelet counts.

? Box 39.8 Causes of thrombocythaemia

Primary ('haematological')

- Essential thrombocythaemia
- Polycythaemia vera
- Myelofibrosis
- CML
- Myelodysplasia with del(5q)
- MDS/MPN overlap syndromes (e.g., CMML, atypical CML)

Secondary ('reactive')

- Infection
- Inflammation
- Haemorrhage
- Postoperative
- Inflammatory conditions (e.g., IBD, RA)
- Haemolysis
- Hyposplenism: functional or surgical
- Iron deficiency
- Drug therapy (e.g., corticosteroids, thrombopoietin receptor agonists)
- Rebound after chemotherapy
- Solid malignancy

CML, Chronic myeloid leukaemia; *CMML,* chronic myelomonocytic leukaemia; *IBD,* inflammatory bowel disease; *MDS,* myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm; *RA,* rheumatoid arthritis.

Adapted from British Society for Haematology Thrombocythemia guidelines https://onlinelibrary.wiley.com/doi/full/10.1111/j.1365-2141.2010.08122.x.

Myelofibrosis

Myelofibrosis is an MPN characterized by clonal proliferation of megakaryocytes and abnormal myeloid cells in the bone marrow. It may be primary or develop late in the course of ET or PV. Abnormal megakaryocytes release fibroblast-stimulating factors such as platelet-derived growth factor, which cause reactive fibrosis in the bone marrow.

Clinical features

The disease presents with lethargy, weakness, and weight loss. Patients often experience a 'fullness' in the upper abdomen because of splenomegaly, which may be massive. Severe pain related to respiration may indicate perisplenitis secondary to splenic infarction, and bone pain and attacks of gout can complicate the illness. Extramedullary haemopoiesis can develop, typically in the spleen but also affecting other organs. Bruising and bleeding occur because of thrombocytopenia or abnormal platelet function.

Investigations

- ***FBC*** shows anaemia with leucoerythroblastic features. Poikilocytes and RBCs with characteristic teardrop forms are seen (Fig. 39.12). The WCC may be greater than 100 × 10^9/L, and the differential WCC may be very similar to that seen in CML; leucopenia may develop later. The platelet count may be very high but in later stages thrombocytopenia occurs.
- ***Bone marrow aspiration*** is often unsuccessful (a 'dry tap') owing to the fibrotic state of the bone marrow, which may give a clue to the presence of the condition. A bone marrow trephine is necessary to show the markedly increased fibrosis. Increased numbers of megakaryocytes may be seen.
- ***Cytogenetic and molecular analysis*** shows the absence of the Ph+ (*BCR-ABL* fusion gene); this helps to distinguish myelofibrosis from CML. A *JAK2* mutation is present in approximately 65% of cases, a *CALR* mutation in 25%, and *MPL* mutation in 8%.

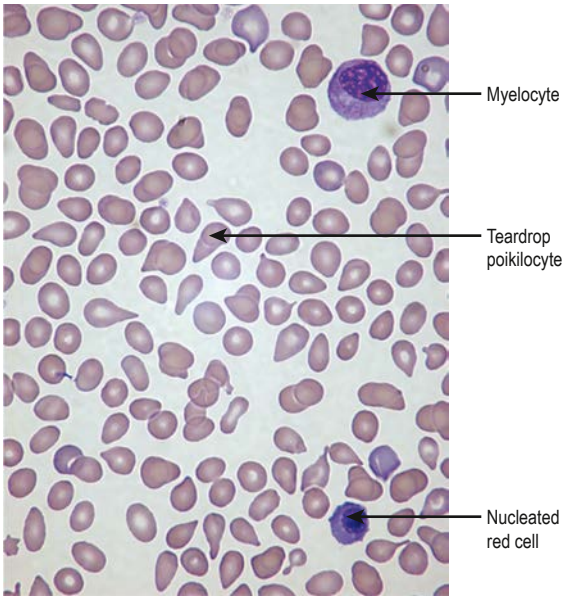

Fig. 39.12 Leucoerythroblastic blood film with teardrops in myelofibrosis.

Management

Myelofibrosis is incurable in all but the minority of patients who are fit enough to undergo allogeneic SCT. For most patients, treatment is aimed at managing symptoms of anaemia, splenomegaly, and constitutional symptoms. Prognostic scoring systems (e.g., international prognostic scoring system [IPSS] and dynamic international prognostic scoring system [DIPSS]) help estimate median survival.

JAK inhibitor treatments are now available to treat patients with myelofibrosis. Ruxolitinib results in substantial spleen reduction and improvement in symptoms in many patients with higher-risk myelofibrosis. Fedratinib improves spleen and symptom burden. Newer JAK inhibitor treatments are in the pipeline.

Anaemia is managed with transfusions, danazol, and EPO.

In the proliferative stages, hydroxycarbamide, interferon, and anagrelide can be used to control counts. Thalidomide and lenalidomide can improve cytopenias and reduce spleen size. Patients with massive splenomegaly can be treated with radiotherapy, but this has limited benefit in those with myelofibrosis.

Prognosis

Patients may survive for 10 years or more, though the median survival period is 4 to 5 years. Poor prognostic factors include cytopenias, the presence of circulating blast cells, constitutional symptoms, and the presence of poor-risk cytogenetics (e.g., monosomy 7) or molecular genetic mutations (e.g., *ASXL1* or *EZH2*). Death occurs in 10% to 20% of patients by transformation to AML, which is often resistant to intensive chemotherapy. The other most common causes of death are progressive bone marrow failure and infection.

Other myeloproliferative neoplasms

Rare MPNs include the following:

- ***Chronic eosinophilic leukaemia:*** associated with gene fusions that activate tyrosine kinase activity and may be treated with imatinib, as for CML
- ***Chronic neutrophilic leukaemia***
- ***'PMH, not otherwise specified'***

MYELODYSPLASIA

'Myelodysplastic neoplasms', or MDS, is the collective term for a group of acquired bone marrow failure disorders caused by a defect in haematopoietic stem cells. They are characterized by progressive bone marrow failure with quantitative and qualitative abnormalities in at least one of the three myeloid cell lines (RBCs, granulocyte/monocytes, and platelets). MDS covers a heterogeneous group of conditions with varying presentations and prognosis, for which there is a wide range of treatment approaches ranging from observation to allogeneic SCT. Although the natural history of MDS is variable, there is high morbidity and mortality owing to bone marrow failure and transformation to AML, which occurs in about 30% of cases. MDS and all its subtypes are considered malignancies.

The molecular and genetic discoveries during the past decade have had a huge impact on the understanding and classification of MDS and led to significant changes in treatment approaches. The classification of MDS has changed dramatically over the decades; often old terminology is used, which should be avoided. The latest classification by the WHO in 2022 identifies subtypes defined by their genetic abnormality (a trend that will likely continue in future classifications); it also lowers the blast percentage that defines AML from 20% to 10% in some subtypes. This is in keeping with the current clinical approach in which 'high-risk' MDS in younger or fitter patients is managed similar to AML as it is considered to be the same disease by most. The current WHO classification of MDS is shown in **Box 39.9**.

Clinical features

MDS occurs mainly in older adults and presents with symptoms of anaemia, infection, or bleeding because of thrombocytopaenia. MDS should be suspected in patients with otherwise unexplained cytopaenias or macrocytosis. Labelling a patient with MDS without absolute certainty should be avoided. If the diagnosis is in doubt, investigations, primarily of the bone marrow, should be repeated 3 to 4 months after the initial one.

Investigations

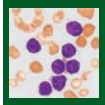
Serial blood counts show evidence of increasing bone marrow failure with anaemia, neutropenia, and thrombocytopenia, either alone or in combination.

A bone marrow investigation, both an aspirate and trephine, are required for diagnosis. The bone marrow cellularity can be increased, normal, or reduced, irrespective of the pancytopaenia. Dysplasia in one or more of the erythroid, granulocytic, and megakaryocytic lineages is usually present (**Fig. 39.13**). The description comes with an element of subjectivity, and an understanding of the clinical context is required. Patients who are otherwise unwell often have minor reactive dysplastic features. The percentage of blast cells in the bone marrow is important for classification and prognostic risk stratification in MDS. If the percentage rises above 20%, the diagnosis changes from MDS to AML. In some subtypes, this percentage has dropped to 10% in the presence of certain cytogenetic abnormalities, blurring the lines further between MDS and AML.

Cytogenetic abnormalities are common and increasingly important for prognostic stratification. The discovery of new cytogenetic abnormalities has greatly changed the classification and approach to treatment of patients with MDS. NGS has and will continue to identify further mutations with prognostic relevance. Any cytogenetic change can confirm a diagnosis of MDS if morphological changes are not sufficient. If there is diagnostic uncertainty, a repeat of investigations some months down the line can clarify whether a patient has MDS.

Management

MDS is a heterogeneous disease, and management is dependent on clinical and patient-dependent features, as well as the predicted prognosis estimated using international prognostic scoring systems incorporating blood counts, bone marrow blast percentage, and cytogenetics. Treatment strategy is based on the behaviour and clinical burden of the disease, the likely prognosis, and the frailty and co-morbidity of the patient. For example, an older patient may be managed with transfusion support alone, but a younger, fitter patient with high-risk disease may be considered for the higher-risk but potentially curative strategy of allogeneic SCT.



Box 39.9 Classification and defining features of myelodysplastic syndrome (MDS)

	Blasts	Cytogenetics	Mutations
MDS with defining genetic abnormalities			
MDS with low blasts and isolated 5q deletion (MDS-5q)	<5% BM and <2% PB	5q deletion alone, or with 1 other abnormality other than monosomy 7 or 7q deletion	
MDS with low blasts and *SF3B1* mutation[a] (MDS-SF3BI)		Absence of 5q deletion, monosomy 7, or complex karyotype	*SF3B1*
MDS with bi-allelic *TP53* inactivation (MDS-biTP53)	<20% BM and PB	Usually complex	Two or more *TP53* mutations or one mutation with evidence of *TP53* copy number loss or cnLOH
MDS, morphologically defined			
MDS with low blasts (MDS-LB)	<5% BM and <2% PB		
MDS, hypoplastic[b] (MDS-h)			
MDS with increased blasts (MDS-IB)			
MDS-IB1	5%–9% BM or 2%–4% PB		
MDS-IB2	10%–19% BM or 5%–19% PB or Auer rods		
MDS with fibrosis (MDS-f)	5%–19% BM; 2%–19% PB		

[a]Detection of >15% ring sideroblasts may substitute for *SF3B1* mutation. Acceptable related terminology: MDS with low blasts and ring sideroblasts.
[b]By definition, <25% bone marrow cellularity, age adjusted.
BM, Bone marrow; *cnLOH,* copy neutral loss of heterozygosity; *PB,* peripheral blood.

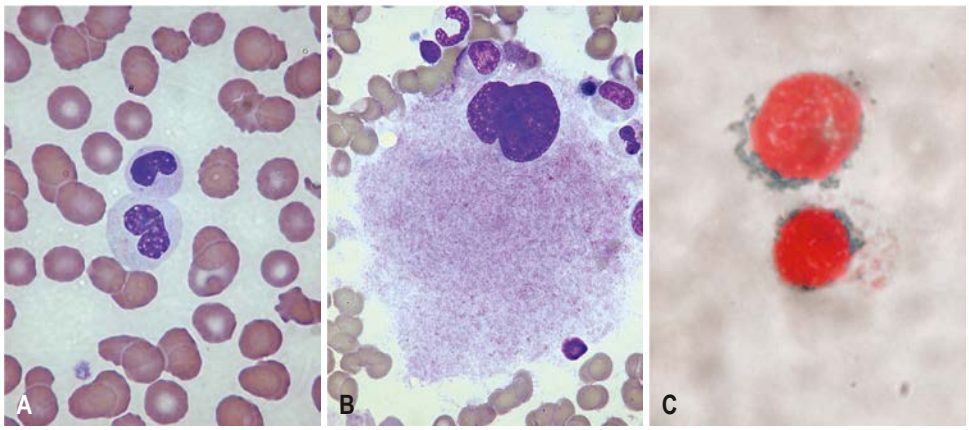


Fig. 39.13 Myelodysplastic syndrome. **(A)** Pseudo-Pelger neutrophil with bilobed nucleus. **(B)** Dysplastic megakaryocyte in the bone marrow. **(C)** Iron stain of the bone marrow showing 'ring sideroblasts'.

Treatment options include the following:

- ***Best supportive care*** is the mainstay for most patients with MDS and symptomatic low blood counts. It includes RBC and platelet transfusion and the prevention and treatment of MDS-associated bleeding and infection. Many patients with low-risk MDS can maintain a stable clinical picture for years.
- ***EPO*** can be used in selected patients with low-risk MDS, symptomatic anaemia, and inappropriately low endogenous EPO levels.
- ***Iron chelation*** should be considered for patients with good prognostic MDS who develop secondary iron overload (transfused >20 units of RBCs or serum ferritin >1000 μg/L).
- ***Hypomethylating agents*** (e.g., azacitidine, decitabine). Azacitidine, licensed in 2011, was the first MDS-specific treatment available. Significant clinical benefits are seen in half of patients with an improvement in quality of life mainly due to reduced transfusion requirements and a reduced risk of leukaemic transformation. It is a disease-stabilizing treatment, not a curative strategy.
- ***Immunosuppressive agents***, such as ciclosporin and antithymocyte globulin, may be used in selected patients with a hypocellular bone marrow. They are hypothesized to modify an immune driver in hypoplastic MDS, similar to aplastic anaemia.
- ***Intensive chemotherapy*** schedules used in AML should be considered in high-risk MDS. It is in many ways considered the same disease. Remission rates, however, are lower in patients with MDS, and more prolonged periods of pancytopaenia can be seen after treatment in this patient group.

- ***Lenalidomide*** (a thalidomide analogue) is successful in the treatment of early-stage MDS with a chromosome 5q deletion (the 5q– syndrome). This is a now clearly defined subtype of MDS.
- ***Allogeneic SCT*** carries the only possibility of cure in appropriate patients with MDS, similar to the case in AML. Patients (and donors) should be carefully selected. This treatment is restricted to patients with higher-risk MDS without major co-morbidities and frailty.

Myelodysplastic syndrome–myeloproliferative neoplasm overlap syndromes

This is a mixed group of conditions that have both dysplastic and proliferative features. It is often tricky to get to an accurate diagnosis. Repeat bone marrow biopsies may help elucidate the problem. It includes:

- Chronic myelomonocytic leukaemia
- Atypical chronic myeloid leukaemia (*BCR-ABL* negative)
- Juvenile myelomonocytic leukaemia
- MDS/MPN, unclassifiable.

Because of the rarity of these conditions, protocols are less well established. Treatment principles, however, are similar to those for MDS (e.g., supportive care for cytopaenias) and MPNs (e.g., cytoreduction for elevated blood counts). Similarly, more intensive approaches, including AML-type treatment and SCT, should be considered for selected patients. Patients with these conditions should be cared for in specialist centres.

LYMPHOMAS

The lymphomas are malignancies of the lymphoid ('lymphatic') system. They are a heterogenous group of malignancies that can arise anywhere in the body where lymphoid tissue is present. The overall incidence of lymphoma ranges 15 to 20 per 100 000 population; it is the fifth most common malignancy in the Western world. Clinical presenting features and symptoms can range wildly between the different types of lymphoma, from entirely asymptomatic to gravely ill patients. Most commonly, patients present with peripheral lymphadenopathy or symptoms caused by occult lymph nodes; however, approximately 20% of patients present with disease in extranodal sites. Only a small proportion of patients present with lymphoma-associated B symptoms: weight loss, fever, and night sweats (despite prominence in medical textbooks!). Significant disease can be present in the absence of these symptoms and vice versa. Although 'B symptoms' are important, they are non-specific and can be present in many other medical conditions. The natural history, clinical course, and treatment vary widely between lymphoma subtypes.

A significant proportion of patients are cured. However, in many types, the aim of treatment is control of the disease, which can be for many years.

The increasingly complex WHO classification of tumours of haemopoietic and lymphoid tissues primarily distinguishes HL from NHL, an umbrella term covering a multiply subclassified spectrum of B- and T-cell malignancies. It was last updated in 2022.

Overall management strategy common to all lymphomas

A suspected diagnosis of lymphoma should always be confirmed by an excision biopsy of the affected area to allow histological, immunological, and molecular analysis. Core biopsy is an acceptable substitute where excision is not possible. Fine-needle aspiration is not adequate and often leads to confusing reports unable to exclude lymphoma. Every histological diagnosis should be confirmed by an expert haemato-pathologist and be reviewed by an MDT. Use of steroids before biopsy should be avoided when clinically possible.

Investigations

After the diagnosis is established, the treatment strategy depends on the outcome of staging investigations that are common to all lymphomas (**Box 39.10**). These investigations allow the clinician and patient to better understand the extent of disease; staging can also determine treatments and inform prognosis, though not in all cases. The Ann Arbor classification is generally used, though historically, this was developed HL. When staging investigations would delay treatment to the detriment of the patient, common sense should be applied.

The tests listed in **Box 39.10** are essential for planning specific therapy. LDH and urate concentrations are helpful, particularly in lymphomas that carry a risk of TLS. An echocardiogram is recommended if anthracyclines are planned because these agents can be cardiotoxic. All patients should be screened for HIV and HBV, without exception. Staging PET/CT scans are recommended for all patients. Bone marrow investigations are recommended for staging in all NHLs but are performed less frequently in HL.

Treatment response, aside from obvious clinic change in symptoms, is assessed at standardized time points during treatment. In most cases, an end of treatment scan is recommended to assess treatment response but also to function as a new baseline scan for any possible future concerns. After treatment, patients with lymphoma should be followed up at regular intervals, which can decrease in frequency as time goes on. Most centres follow up with

Box 39.10 Investigation of the patient with lymphoma

Diagnosis

- Clinical history and examination
- Performance status
- Comprehensive geriatric assessment
- Chest radiograph for mediastinal widening (see **Fig. 39.15**)
- CT/PET scan (see **Fig. 39.16**)
- Bone marrow biopsy (if PET not used to assess bone marrow involvement)
- Blood count, differential, film

For planning specific therapy

- Electrolytes, kidney and liver function
- Serum uric acid
- Virology: HIV, hepatitis B and C
- Cardiac function: e.g., echocardiogram
- Respiratory function: e.g., lung function testing
- Referral for fertility preservation

CT, Computed tomography; *HIV,* human immunodeficiency virus; *PET,* positron emission tomography.

patients for 5 years (i.e., every 3 months for the first year, then every 4 months during the second year, 6 monthly in the third year, and then annually). Patients should be advised to contact the team if they have any concerns between appointments. ***Patient-initiated follow-up*** might be appropriate for certain patient groups.

Hodgkin lymphoma

HL has an incidence of 3 per 100 000 in the Western world. There is a slight male predominance of approximately 1.3 to 1.0. The majority of cases are diagnosed between the ages of 16 and 65 years, with a peak in the third decade of life. It is one of the most common cancers in teenagers. It has led to many countries providing more focused care and designated staff for teenagers and young adults with cancer.

Aetiology

The aetiology of HL is unknown. Positive antibody titres against EBV are found in 40%, providing evidence for an epidemiological link between the two in some cases. Other viruses have not been linked in the same way. Smoking and other lifestyle factors have not been linked, although environmental and occupational exposures to pathogens have been postulated. Large genetic studies have not found any predisposing or causal genetic changes linked to HL to date. It is not an inherited disease.

Diagnosis

HL is divided into subtypes, according to the WHO classification (Box 39.11):

- ***Classic Hodgkin lymphoma (cHL)***, the hallmark of which is the Reed–Sternberg cell (Fig. 39.14). cHL accounts for 90% to 95% of cases and is further subdivided into four distinct categories, with similar treatment strategies.
- ***Nodular lymphocyte-predominant HL (NLPHL)***, characterized by the lymphocyte-predominant or 'popcorn cell'. Reed-Sternberg cells are not seen in NLPHL.

Clinical features

Most patients are asymptomatic and well at diagnosis. The most common presentation of HL is painless lymphadenopathy, most often cervical. The lymphadenopathy has often been present for some time. Lymphadenopathy can be multiple or in other areas. Most disease has limited stage at diagnosis. More unusual presentations are caused by mediastinal lymph nodes and include cough, a feeling of 'pressure' in the chest, and shortness of breath (Fig. 39.15). Occasionally patients present with non-specific symptoms, including constitutional B symptoms or symptoms linked to hepatosplenomegaly. Rarer symptoms directly related to HL, but often not initially recognized as such, are pruritus and alcohol-related pain at the site of lymphadenopathy.

Box 39.11 World Health Organization pathological classification of Hodgkin lymphoma (HL)

Type	Histology classification	Proportion of HL (%)
Nodular lymphocyte-predominant HL		5
Classical HL	Nodular sclerosing	70
	Mixed cellularity	20
	Lymphocyte rich	5
	Lymphocyte depleted	Rare

Courtesy of WHO.

Investigations

These are summarized in Box 39.10. Baseline PET/CT is the gold standard to establish the extent and distribution of metabolically active sites of disease (Fig. 39.16). This enables staging according to the Cotswolds modification of the Ann Arbor classification (Box 39.12). Patients with early-stage disease are then categorized as having favourable or unfavourable disease depending on defined criteria (Box 39.13). The Hasenclever International Prognostic Score has been in use for decades for prognostication (Box 39.14). Stage and other prognostic factors divide patients with HL into three distinct groups (see Box 39.13). These groups determine clearly defined treatment paths for patients with HL.

Management

Principles of management

Patients with HL are invariably treated with a curative intent with a high success rate. In older or frailer patients, treatment modifications or alternative regimens should be reviewed on an individual basis by an experienced haematologist. Patients should be discussed by

Box 39.12 Cotswolds modification of Ann Arbor staging of Hodgkin lymphoma

Stage	Description
I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring) or involvement of a single extralymphatic site
II	Involvement of two or more lymph node regions on the same side of the diaphragm; localized contiguous involvement of one extranodal organ or site and lymph node region(s) on the same side of the diaphragm (IIE). The number of anatomical regions involved is indicated by a subscript (e.g., II_3)
III	Involvement of lymph node regions on both sides of the diaphragm, which may be accompanied by involvement of the spleen (IIIS), localized involvement of only one extranodal organ site (IIIE), or both (IIISE)
IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph node involvement
Designations applicable to any disease state	
A	No symptoms
B	Fever (temperature >38°C), drenching night sweats, unexplained loss of >10% of body weight within previous 6 months
X	Bulky disease (a widening of the mediastinum by more than one-third or the presence of a nodal mass with a maximal dimension >10 cm)
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site

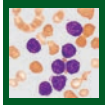
an expert MDT before treatment, clinical picture allowing. There is no change in treatment for patients living with HIV. NLPHL is often CD20+ on histology, hence rituximab should be added to standard chemotherapy. Patients with early-stage favourable disease are often treated with involved-field radiotherapy alone.

Treatment

Frontline treatment

Standard frontline treatment for all patients with cHL, irrespective of prognostic group and staging is with ABVD chemotherapy (doxorubicin, bleomycin, vinblastine, and dacarbazine) if patients



are fit enough to receive this. It is highly emetogenic, but the risks of infertility and secondary malignancy are low. The number of cycles of treatment required depends on staging and prognostic group at diagnosis. The biggest recent change is that HL treatment is now recommended to be response adapted: an early PET/CT scan is done after two cycles of treatment, and depending on the response, the treatment is appropriately adapted. Treatment is escalated where necessary and clinically appropriate, as well as de-escalated when a complete metabolic remission (CMR) is achieved. (Most guidelines recommend dropping the bleomycin from the regimen at CMR.) Depending on treatment response, two to six cycles of ABVD are recommended. Radiotherapy remains in use for localized stage 1 disease, as well as for bulky disease; however, the risks and benefits of radiotherapy should be individually assessed. Radiotherapy is used less now than in the past, mainly because of the superiority of PET/CT to assess response compared with CT. The cure rate is 90% for frontline therapy. For patients who are not fit enough for ABVD, alternative milder treatments are available, often also with significant responses, though cure is less likely.

In NLPHL, rituximab is added to ABVD to target CD20 positive B-cells. It is a different disease entity entirely. Many patients with NLPHL are asymptomatic, and their disease progression is often very slow. Expectant management is often recommended in early-stage, asymptomatic disease, though practices vary.

Salvage treatment

Although most cases patients are cured with frontline therapy, a number of patients either do not respond ('refractory') or relapse. Relapses are most common in the first few years after treatment, though late relapses also happen. Treatment for patients with refractory or relapsed HL remains treatment with a curative intent, though success rates are lower. Often salvage regimens require multiple elective hospital admissions to allow administration. Many different salvage regimens exist; the discussion of these falls outside of the scope of this text. No salvage regimens is clearly superior. Salvage treatment has greater toxicity and risk of late effects. When remission is achieved, strong consideration for consolidation with an autologous SCT (autograft) to achieve a lasting remission should be given to patients who are fit enough to undergo it. Peripheral blood stem cells are taken ('harvested') and stored. The removal of stem cells allows high dose therapy to be given, a treatment most patients would not naturally recover from if their stem cells were not re-infused at a clearly defined time point after high-dose therapy. Different high-dose therapy combinations are used in autografts, most commonly BEAM (carmustine, etoposide, cytarabine, and melphalan) or LEAM (Lomustine, etoposide, cytarabine, and melphalan). Outcomes of autologous SCTs are vastly improved in patients who are in a CR before transplant.

Novel and developing approaches

With such excellent first- and second-line therapies, the number of patients who experience treatment failure is small. However, this subset of patients has a very poor outcome and has been the topic of research, trials, and changing approaches. Brentuximab, an anti-CD30 immunoconjugate, can be used as a bridge to transplant when conventional chemotherapy regimens have failed. Likewise, the use of checkpoint inhibitors pembrolizumab and nivolumab should be considered. Allogeneic SCT (allograft) is only rarely required or considered in patients with HL. It is usually only considered where an autograft has failed. Remission is required before an allograft, which at this stage of disease can be extremely challenging.

Long-term follow-up

The risks of late effects of therapy, particularly second malignancy and cardiac and endocrine problems, require appropriate awareness and surveillance; this may be more significant for patients with HL because they are often at a younger age when diagnosed and treated.

Non-Hodgkin lymphoma (NHL)

The NHLs are a heterogenous, reflected in the WHO classification, last updated in 2022 (**Box E39.1**). A distinction is made between B-cell and T-cell lymphomas, depending on the cell of origin. Approximately 80% of NHL cases are of B-cell origin, with the remaining 20% is T-cell origin. Generally, B-cell lymphomas have a superior prognosis compared with T-cell lymphomas. It is essential a full histological diagnosis is made to inform patient information and treatment.

Aetiology

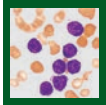
No clear aetiology is known for most NHL, including lifestyle factors. EBV is not clearly linked to NHL with the exception of endemic Burkitt lymphoma, a specific high-grade NHL subtype; sporadic Burkitt lymphoma has a less strong causal link with EBV. Another viral precipitant is HTLV-1 infection, which is casually linked to ATLL. Overall, NHL is seen more often in patients who are immunocompromised for a prolonged period, including patients living with HIV, patients on long-term immunosuppressive agents, and patients with inherited immune deficiency syndromes. Occasionally, bacterial infection may be linked (e.g., *Helicobacter pylori* in gastric mucosa-associated lymphoid tissue [MALT] lymphoma).

Pathogenesis

Lymphocytes develop in the bone marrow, the haematopoietic system, from the haematopoietic stem cells. They go through different stages of development in the bone marrow, and then they are released into the circulation, ultimately residing in the lymphoid tissue, where further maturation happens. Errors in development leading to malignant clonal expansion of lymphocytes can occur at any stage or in any site of a lymphocyte's development. Depending on where the error occurs, this will lead to the different subtypes of lymphoma (see **Fig. 39.2**). In general, neoplasms arising from more mature lymphocytes are more indolent, and those arising in earlier stages of cell development (e.g., lymphoblasts in the bone marrow) are more aggressive. The cell of origin (T or B lineage) and the stage of lymphocytic maturation at which the error occurs lead to the subclassification of NHL.

Genetic features

Unlike HL, multiple cytogenetic changes have been identified in certain NHL subtypes. Burkitt lymphoma was the first haematological malignancy in which a cytogenetic change was shown to involve the translocation of a specific gene: the *MYC* oncogene is translocated from chromosome 8 to near the immunoglobulin heavy chain gene (IGH) on chromosome 14. In most known cytogenetic changes in NHL, there is up- or downregulation of a specific regulator, inhibitor, or protein or pathway promotor in the cell cycle. Other cytogenetic abnormalities associated with NHL are t(14;18) in FL involving upregulation of *BCL2* and t(11; 14) in mantle cell lymphoma (MCL) involving upregulation of the cell cycle



Box E39.1 World Health Organization (WHO) classification of lymphoid neoplasms (2022)

WHO Classification, 5th edition	**Tumour-like lesions with T-cell predominance**
Tumour-like lesions with B-cell predominance	Kikuchi-Fujimoto disease

regulator cyclin D1. These changes become diagnostic for certain subtypes of NHL and are included in the WHO classification. They very often carry prognostic significance as well. Ongoing developments in gene expression profiling and NGS will continue to identify new molecular subclasses of lymphoma with prognostic significance, and any genetic change identified could also be a potential therapeutic target (Box 39.15).

Clinical features

The presentation can range from patients being completely well to patients with marked constitutional symptoms. Painless lymphadenopathy remains a common presentation (and cannot clinically distinguish between HL and NHL). Lymphoma identified in the CNS is almost invariably NHL and is likely to be a more clinically aggressive type. CNS lymphoma is exceedingly rare in HL.

The most common and clearly distinguished subtypes of NHL are described next.

B-cell lymphoma

See Fig. 39.17.

Diffuse large B-cell lymphoma

Diffuse large B-cell lymphoma (DLBCL) is the most common adult lymphoma worldwide (with increasing incidence with age) and the second most common lymphoma in childhood. It accounts for approximately 30% of all cases. Our understanding of DLBCL's molecular and genetic features has expanded exponentially in the past decade, leading to the description of different subgroups. Gene expression profiling has recognized germinal centre B cell–like (GCB) and activated B cell–like (ABC) subgroups, with the latter having an inferior clinical outcome. There is a focus of research into novel treatments to try to overcome this distinction (Fig. 39.18). Patients with a *MYC*, *BCL2*, and/or *BCL6* rearrangement represent a subtype of DLBCL that does considerably less well with conventional therapy. The increased understanding of variability within the disease may help to define groups of patients who are likely to do less well with conventional treatment and toward whom future targeted therapies may be directed. The development of new agents has happened alongside an understanding of molecular and genetic features that was not available for patients in the past, so historical trial data need to be interpreted with caution.

Clinical features

DLBCL is classed as one of the more aggressive subtypes, or 'high-grade' NHL. More patients have B symptoms, though asymptomatic patients remain common. Intra-abdominal disease presents with bowel symptoms caused by compression or infiltration of the gastrointestinal (GI) tract. In a small proportion, there

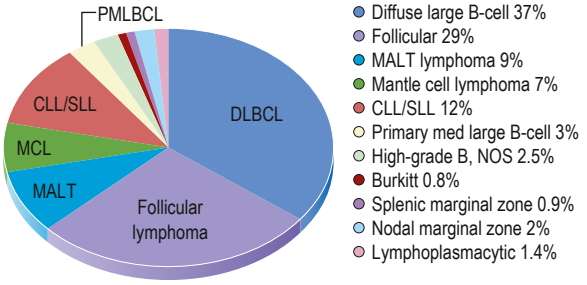

Fig. 39.17 Relative frequencies of B-cell lymphoma subtypes in adults. *CLL/SLL,* Chronic lymphocytic leukaemia/small lymphocytic lymphoma; *MALT,* mucosa-associated lymphoid tissue; *MCL,* mantle cell lymphoma; *NOS,* not otherwise specified; *PMLBCL,* primary mediastinal b-cell lymphoma. (*From Swerdlow SH, Campo E, Harris NL et al [eds].* WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, *4th edn. Geneva: WHO; 2008, with permission.*)

is a primary mediastinal presentation, with symptoms and signs akin to those of HL. DLBCL is often of higher stage at diagnosis than HL. DLBCL has a rapidly progressive disease course, and treatment when appropriate should be recommended as soon as investigations are complete. In rare cases patients are gravely ill. Patients presenting with life- or organ-threatening disease and initial results confirming NHL but no conclusive subtype should be treated as having DLBCL until proven otherwise, after clear explanation and discussion with the patient. LDH concentrations are often raised.

Management

First-line treatment

Treatment is with a curative intent in patients without significant co-morbidity. The revised International Prognostic Index (R-IPI) is used to inform prognosis and guide treatment (Box 39.16 and Fig. 39.19).

The age of the patient and co-morbidity are critical for both selection of treatment and prognosis.

Six cycles of R-CHOP (**r**ituximab, **c**yclophosphamide, **h**ydroxydaunorubicin, **O**ncovin [vincristine], and **p**rednisolone) have been standard treatment since the early 2000s when rituximab was added to CHOP chemotherapy. However, recently, substituting vincristine with polatuzumab (a CD79b-directed antibody–drug conjugate) has demonstrated superior outcomes for patients with R-IPIs greater than 2. This combination, R-PolaCHP, is now widely used.

In stage IA disease, three cycles of R-CHOP or R-PolaCHP followed by involved-field radiotherapy may be considered, though many centres give six cycles of R-CHOP.

The dose of the anthracycline and other cytostatic agents can be reduced in frail patients ('mini'-R-CHOP). In those with cardiac

ECOG, Eastern Cooperative Oncology Group.

impairment, R-GCVP can be considered, in which gemcitabine replaces the anthracycline, doxorubicin. R-maxi-CHOP, in which the cyclophosphamide and daunorubicin doses are increased, is used in patients with mantle cell lymphoma, a type of high-grade NHL. Radiotherapy to bulky disease should be considered on a case-by-case basis at the end of chemotherapy depending on the site and size of the radiotherapy field.

Involvement of the CNS, most often meningeal, is an uncommon but devastating complication with a very poor prognosis. Distinction should be made between primary CNS lymphoma and CNS relapse or involvement of systemic DLBCL. Patients with a high LDH and more than two extranodal sites of disease have a higher risk of CNS involvement and relapse and should be considered for CNS prophylaxis. Historically, three or four injections of intrathecal methotrexate, in addition to R-CHOP, were administered in the earlier treatment cycles. More recently, two or three cycles of high-dose methotrexate (which crosses the blood–brain barrier), alternating with R-CHOP, are preferentially given. Randomized controlled trials are lacking in this area.

Second (and subsequent) therapy

Although the patient may respond to alternative chemotherapy, the prognosis is poor after failure of initial therapy or subsequent progression. The major issues is whether treatment is to be undertaken with palliative or curative intent, and if the latter, what the chances of success are. The ***palliative approach*** involves both chemotherapy and irradiation. The ***curative approach*** involves re-evaluation followed by second-line (salvage) chemotherapy with an approach and regimens identical to salvage treatment for HL (see earlier). If response is achieved with salvage, it should be followed by high-dose therapy and autograft. The best prognosis is for those for whom a second CR can be achieved. When disease does not respond to salvage chemotherapy, clinical trials, including novel agents, should be considered. The prognosis remains poor. CAR T therapy is a rapidly evolving and promising new treatment.

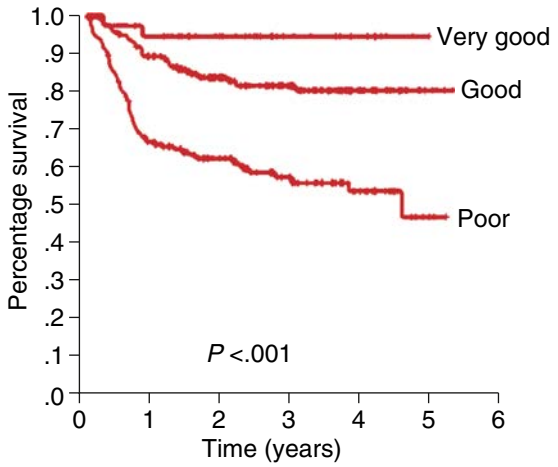

Fig. 39.19 Survival curves for the revised International Prognostic Index (R-IPI) in diffuse large B-cell lymphoma. (*Adapted from Sehn LH, Berry B, Chhanabhai M et al. The revised IPI is a better predictor of outcome than the standard IPI for patients with DLBCL treated with RCHOP*. Blood *109; 1857–1861*.)

Follicular lymphoma

FL is the second most common lymphoma and accounts for approximately 20% of lymphomas worldwide. It is classed as a 'low grade' and often 'indolent' NHL, though within FL, there are further subtypes, which can vary greatly in clinical phenotype. FL is further divided into different grades as defined by morphology (grade 1, grade 2, grade 3a, grade 3b). The grading often correlates with the clinical speed of expected progression. Grade 3b is the highest grade and is now considered equivalent in nature to DLBCL, with the same treatment. In rare cases, FL can transform to high-grade lymphoma; this is prognostically poor.

Clinical features and course

FL occurs in middle to late life; it is very rare in childhood. Most patients present with painless lymphadenopathy, which is often present at more than one site and may have been present for a long time. Results of bloods tests in this group are often normal,

including LDH. In a small proportion, clinical features might be more in keeping with high-grade NHL with the presence of B symptoms and raised LDH. Excision biopsy as with all lymphomas is essential to confirm the diagnosis and establish the grading (see later), and it may reveal transformation to DLBCL. Ideally, the largest lymph node or mass or the most ^{18}F-fluorodeoxyglucose avid on PET/CT should be biopsied if feasible. If a peripheral node is biopsied and shows FL, in the presence of a larger or more avid mass, transformation cannot fully be excluded. Clinical acumen and a repeat biopsy might be indicated in these cases. Bone marrow investigations are done less frequently but remain essential in FL and all low-grade NHL because potential upstaging has significant prognostic and treatment implications.

Most FLs progress very slowly, and in asymptomatic patients, expectant management should be adopted. This can be tricky to explain to the patient. It has been confirmed in large international trials that early treatment in this group of patients is equivalent to a 'watch-and-wait' approach. Treatment, if indicated, is with chemo-immunotherapy ('R-chemo'). FL is not considered a curable condition in most patients, often with a remitting–recurring after diagnosis. However, remissions can be for many years, if not decades. The advent of new combination therapies with favourable side-effect profiles have improved median survival, which is now greater than 10 to 15 years. In older or frailer patients, rituximab can be used as a single agent. The Follicular Lymphoma International Prognostic Index (FLIPI) continues to be used for prognosis and treatment, though it precedes advent of novel therapies (**Box 39.17**).

Management

General management

Asymptomatic patients without organ impairment, 'bulky disease', or evidence of rapid progression or transformation should be managed expectantly. This accounts for around 50% of patients at diagnosis. Up to 15% of patients require no treatment for more than 10 years from diagnosis. Indications for treatment of patients with low-grade NHL are shown in **Box 39.18**. It is vital that an experienced clinician and MDT are involved in the treatment decision. Careful thought should be given to alternative causes for the symptoms, as well as the anxiety of a 'watch-and-wait' approach, which can heighten symptom experience.

Box 39.17 Adverse prognostic factors in non-follicular lymphoma

- Haemoglobin <120 g/L
- More than four nodal sites involved
- Age older than 60 years
- Stage III or IV disease
- Elevated serum lactate dehydrogenase

Box 39.18 Indications for treatment of low-grade non-Hodgkin lymphoma at presentation or progression

- Stage I disease; possibly limited stage II disease
- Rapidly progressive disease
- Organ impairment bone marrow failure, urinary tract obstruction
- Bulky disease (i.e., lymph node mass >7 cm)
- Histological transformation
- Ascites or pleural effusion
- Shared decision-making between patient and healthcare professional

Frontline treatment: early disease

Patients with stage IA or IIA non-bulky disease are treated with involved field radiotherapy, with a possible curative intent. It has a high CR rate (50% of patients will be disease free after 10–15 years).

Frontline treatment: advanced disease (stages II–IV)

Chemo-immunotherapy including an anti-CD20 monoclonal antibody (rituximab or less commonly obinutuzumab) is the treatment of choice, often referred to 'R-chemo'. The combination regimen added to rituximab various widely across the world. R-CHOP and R-bendamustine are most often used. Consideration should be given to O-CHOP (obinutuzumab substituted for rituximab) and O-bendamustine if the FLIPI score is high. Rituximab is widely used with no evidence for a survival advantage between rituximab and obinutuzumab even though progression-free survival at 3 years appears improved with obinutuzumab. Continuing rituximab or obinutuzumab 'maintenance' every 2 months for 2 years improves the progression-free survival, although an overall survival benefit is also not seen. It should be considered that maintenance trials were done in the pre-PET/CT era; it has been postulated that the benefit of maintenance therapy may be greater with PET positivity after R-chemo. Single-agent rituximab is an option for frailer patients.

Second-line therapy and beyond

Patients are managed expectantly in the first instance as long as full re-evaluation, including repeat biopsy, reveals no evidence of transformation. Several options are available, determined by individual patient and the first-line therapy considerations. The same first-line therapy is not usually revisited. Further maintenance treatment (every 3 months) for another 2 years can be given. In second remission, high-dose treatment and autologous SCT should be considered for appropriate patients. Allogeneic HSCT is rarely considered but should not be forgotten as an option in unusually young and fit patients.

Prognosis

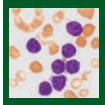
There has been a dramatic improvement in the overall survival of FL since anti-CD20 therapy addition to chemotherapy. The median survival time has been extended well beyond 10 years. Improvements in disease-free survival, after both initial and second-line therapy, are continuing to improve with novel targeted therapies and combinations.

Burkitt lymphoma

Burkitt lymphoma is the most rapidly proliferating lymphoma, with almost invariable, rapid clinical deterioration. It is the most common childhood malignancy worldwide, but it can occur at all ages, with a male-to-female ratio of approximately 3 to 1. There are three subtypes:

- Endemic Burkitt lymphoma is always EBV related and has a similar distribution to malaria. It occurs mainly in children and most frequently presents with a large jaw tumour.
- Sporadic Burkitt lymphoma is linked to EBV in 30% of cases and is the most common type in the Western world.
- Immunodeficiency-related Burkitt lymphoma is seen in patients living with HIV.

Extranodal disease is common at presentation, with renal and testicular disease frequently seen. Both the bone marrow and CNS are often involved; a staging bone marrow biopsy and lumbar puncture are required.



Management

Patients with Burkitt lymphoma are treated with curative intent when possible. The treatment approach is the same across the subtypes. Patients might not be well at diagnosis, though a treatment delay should be avoided because of the aggressive nature of the disease. Patients often have high LDH, with features of TLS before treatment has even started. Rasburicase prophylaxis (3 mg intravenously [i.v.] once a day for up to 7 days) should be given before treatment. The rasburicase treatment dosage (200 mcg/kg i.v. once a day for up to 7 days) should be given if any TLS features are present before starting treatment. Twice-daily monitoring of kidney function and electrolytes is recommended for the first few days of treatment.

The mainstay of treatment has been with alternating cycles of R-CODOX-M (**r**ituximab, **c**yclophosphamide, **O**ncovin [vincristine], **dox**orubicin, and **m**ethotrexate) and R-IVAC (**r**ituximab, **i**fosfamide, etoposide [**V**ePesid], and **C**ytarabine) for more than 2 decades. It is an intense, alternating, non–cross-resistant regimen. The number of cycles required, and whether both regimens are used and alternated depends on risk stratification at diagnosis. All patients should have prophylactic CNS therapy, either with intrathecal methotrexate or cytarabine or by adding high-dose methotrexate. (The i.v. dose of methotrexate in R-CODOX-M is not high enough for CNS penetration.)

Prognosis

In the Western world, the prognosis of Burkitt lymphoma has improved markedly in recent years, most likely because of better support measures and improved environmental factors. Cure rates are 90% for 'low-risk' patients and exceed 60% for 'poor-risk' patients, including those living with HIV, provided all treatment can be administered. Autologous or allogeneic SCT has no role in first remission. The prognosis is poor if remission is not achieved or relapse occurs. In relapsed or refractory Burkitt lymphoma, it is exceptionally difficult to achieve remission. Even if remission is achieved and autologous and/or allogeneic transplant is performed, the likelihood of success remains low.

Mantle cell lymphoma

MCL is one of the less common B-cell lymphomas. It is discussed here because of its specific diagnostic and clinical features (with aggressive and indolent clinical subtypes), as well as its unique treatment algorithm. MCL usually presents later in life and has a male-to-female ratio of 3 to 1. The most frequent presentation is with painless lymphadenopathy, often generalized. There may be non-specific symptoms of tiredness or GI symptoms. B symptoms occur in fewer than 50% of patients. Examination and standard investigation usually confirm generalized lymphadenopathy with or without hepatosplenomegaly. In patients with bowel symptoms, multiple lesions are frequently found on endoscopy. The bone marrow is usually involved, and analysis is recommended when MCL is suspected. Many patients with MCL, though not all, have circulating disease; a lymphocytosis can be the first and often an incidental finding that triggers further investigations.

Cytogenetically, MCL is characterized by a t(11; 14), with dysregulation of cyclin D1. *IGHV* gene mutations and expression of *SOX11* can identify a subtype of indolent disease that can be monitored without the need for immediate treatment. Given that most patients with MCL have an aggressive clinical course and rapid need for treatment, it is surprising there are patients with MCL with distinct low-grade features that might not require treatment for many years.

Management

In most patients, therapy is started after investigation has been completed. A prognostic index (Mantle Cell Lymphoma International Prognostic Index) is used to help determine the best treatment option for each patient. Older, less fit patients are treated with less intense chemo-immunotherapy combinations. In younger and fitter patients, the 'Nordic' regimen is used, an intensive chemo-immunotherapy protocol including alternating cycles of high-dose cytarabine and R-Maxi-CHOP with rituximab, followed by high-dose therapy and autologous SCT (autograft). Maintenance rituximab is commonly given for 2 years after autograft.

Second-line treatment is with a (Bruton's tyrosine kinase [BTK]) inhibitor. It is an oral agent that continues indefinitely or until progression; it is generally very well tolerated.

Historically, if patients progressed after autograft, allogeneic SCT (allograft) was considered, but since the availability of BTK inhibitors as a possible relapse treatment option in these patients, this is done less and less, and the role of allograft is less clear.

Prognosis

Untreated MCL has a natural history that lies between that of DLBCL and FL with features of high- and low-grade lymphoma. It is generally not considered a curable NHL, though if allogeneic SCT is considered, it is done so with curative intent. The prognosis used to be 8 to 12 years in patients well enough to tolerate intensive therapy. However, the advent of the first licensed BTK inhibitor for MCL, ibrutinib, in 2013 has improved the median prognosis, providing a valid treatment option in the relapse setting, also suitable for frailer patients.

Lymphoplasmacytic lymphoma

Lymphoplasmacytic (LPC) lymphoma is a relatively rare type of B-cell lymphoma, also known as ***Waldenström's macroglobulinaemia*** when associated with an immunoglobulin M (IgM) paraprotein. It usually occurs in later life. The presentation is often with cytopaenias related to bone marrow infiltration and the typical presence of a (mostly) IgM paraprotein. High levels of the IgM paraprotein can cause serum hyperviscosity symptoms, such as headaches, visual disturbance, dizziness, confusion, or seizures; they can be the presenting feature. Lymphadenopathy is typically minimal; splenomegaly is more common.

Management

Treatment depends on symptoms and cytopaenias. Many patients are asymptomatic and can be managed expectantly. In the presence of symptoms, rituximab-containing regimens are recommended. R-Bendamustine and DRC (dexamethasone, rituximab, and cyclophosphamide) are most commonly used. Caution should be given to using rituximab in the first cycle in patients with high tumour burden or high IgM paraprotein because there can be transient increase in the paraproteinaemia after treatment has been given. It is common to omit rituximab from cycle 1, adding it back in for subsequent cycles.

Although hyperviscosity is rare, it is an emergency, and patients should undergo urgent plasma exchange at the first instance.

Ibrutinib is used in patients with relapsed or refractory disease and continues indefinitely. The role of autograft should continue to be considered in second remission in appropriate patients, as should allogeneic transplant further down the line.

Prognosis

LPC lymphoma may also follow an indolent course for many years without therapy. It is usually chemotherapy and immunotherapy

sensitive. The 5-year survival rate is around 78%. The advent of BTK inhibitors will no doubt continue to improve prognosis.

Primary central nervous system lymphoma

Primary CNS lymphoma is histologically a diffuse large B-cell lymphoma. It occurs in patients that are immunocompetent (predominantly aged 55–70 years) and in patients that are immunosuppressed (mainly in the context of HIV infection or after solid organ transplantation). Its incidence has dramatically decreased since the introduction of highly active anti-retroviral therapy for patients with HIV. It presents with symptoms caused by single or multiple parenchymal mass lesions, often mimicking a stroke. The diagnosis is confirmed on a biopsy, particularly in those who are immunocompromised in whom an infectious aetiology, such as toxoplasmosis, is possible. A contrast-enhanced MRI scan is the first choice of imaging. CSF, if an LP is safe to perform, is usually normal. Further investigation is necessary to exclude generalized disease, hence staging PET/CT is recommended.

Management

Intensive inpatient chemotherapy is recommended for patients who are fit enough. It is given with curative intent. Different regimens are in use. Methotrexate is the key element of all regimens and needs to be given at a high enough dose to cross the blood–brain barrier. It is only since high-dose methotrexate has been used that cure rates are seen. Methotrexate is often given in combination with cytarabine and thiotepa, with rituximab routinely added. Consolidation with autologous SCT is recommended in those fit enough with adequate response to treatment. Whole-brain radiotherapy is used in less fit or relapsed patients.

Marginal zone lymphoma

This is an uncommon B-cell lymphoma associated with chronic inflammation or infection. (MALT is the commonest form of marginal zone lymphoma.) MALT of the salivary glands is linked with Sjögren's syndrome. Gastric MALT lymphoma is closely associated with *H. pylori* infection and presents with symptoms of gastric ulceration or a mass, indigestion, or bleeding; the diagnosis is made by endoscopic biopsy to include confirmation of both lymphoma and *H. pylori* status. Careful assessment of extranodal sites is required.

Management

Management depends on disease localization and symptoms. *Helicobacter* eradication therapy (see Chapter 22, 'Eradication therapy' section) is the treatment of choice for patients with 'low-grade' gastric MALT and almost invariably alleviates symptoms. Re-evaluation is carried out after 6, 12, and 24 months with endoscopy and repeat biopsies. In most patients, a conservative approach is followed because responses may take many months, and rapid progression is very unlikely. Failure is uncommon, but if it does occur, biopsy should be repeated. If the histology is unchanged after further *Helicobacter* eradication therapy, rituximab in combination with chemotherapy, single-agent rituximab, or low-dose involved-field radiotherapy is likely to be effective and possibly curative. Overall, the prognosis is very good, with a large proportion of patients being alive 10 years after diagnosis.

T-cell lymphoma

T-cell lymphomas can present in nodal, extranodal, cutaneous, or predominantly leukaemic forms (Fig. 39.20). They are a large group of rare diseases, less common than their B-cell counterparts, and varying in behaviour from indolent to aggressive. Many subtypes carry poor prognoses because of disappointing responses to treatment.

The two most common subtypes of nodal T-cell lymphoma are '*peripheral T-cell lymphoma, not otherwise specified (NOS)*' and '*angio-immunoblastic T-cell lymphoma*', which together account for about 50% of T-cell lymphomas. Both are rare at a young age. Most patients present with lymphadenopathy. In contrast to B-cell lymphomas, B symptoms are very common, and most patients have constitutional symptoms. Patients with angio-immunoblastic T-cell lymphoma can also present with inflammatory symptoms of fever, rash, and arthritis. *Anaplastic T-cell lymphoma* (ALCL), particularly when anaplastic lymphoma kinase (ALK) positive, has a better prognosis than other subtypes.

Management

After standard investigation, which usually reveals widespread disease, patients are treated with cyclical combination chemotherapy as for DLBCL. CD20 is not expressed on T cells, so rituximab is not used; as yet, there is no equivalent drug used routinely in T-cell lymphoma. The exception is the use of brentuximab vedotin, a CD30 antibody–drug conjugate, in combination with chemotherapy, in the treatment of patients with systemic ALCL, an aggressive subtype of T-cell lymphoma characterized by the uniform expression of CD30. Symptoms almost invariably resolve, although they may recur between cycles. Overall, the outcome of treatment is worse than for DLBCL in terms of quality of response, duration of response, and overall survival. Other than in ALK-positive ALCL, autologous SCT or indeed allograft should be considered in first remission. Second-line therapy is rarely satisfactory; patients should be considered for allogeneic SCT if a second remission is achieved, though this is rare.

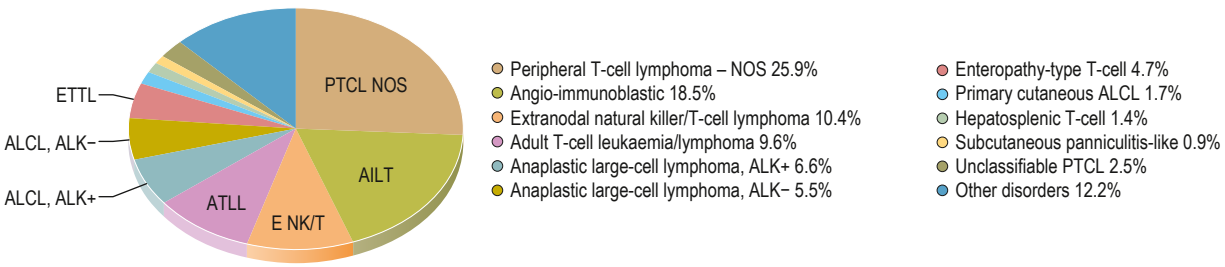


Fig. 39.20 Relative frequencies of T-cell lymphoma subtypes in adults. *ALCL,* Anaplastic large-cell lymphoma; *ALK,* anaplastic lymphoma kinase; *ETTL,* enteropathy-type T-cell lymphoma; *NOS,* not otherwise specified; *PTCL,* peripheral T-cell lymphoma. Mycosis fungoides and Sézary's syndrome

Mycosis fungoides is the most common cutaneous lymphoma. It predominantly arises in and is confined to the skin, spreading to other organs only later in the disease. The rare leukaemic variant is known as Sézary's syndrome. It has a long natural history, presenting with multiple erythematous lesions, plaques, and tumours. Often multiple skin biopsies are required to establish a diagnosis. A wide range treatments from topical to systemic treatments are used depending on the extent of disease. It is rare for patients to achieve a durable response, and the prognosis is poor. Patients with mycosis fungoides and Sézary's syndrome should be looked after in a specialist centre.

Chronic lymphocytic leukaemia

CLL is the most common type of leukaemia, increasing in incidence with age; the median age of presentation is around 70 years. CLL results from the clonal expansion of small, mature B lymphocytes with a characteristic immunophenotype. Most patients are asymptomatic and diagnosed after an incidental finding of a raised WCC on a blood test done for another indication. The WCC can be significantly raised. Some patients have symptoms of marrow failure or immunosuppression.

CLL most commonly presents in 'leukaemic phase', with bone marrow or blood involvement. It can also present in non-leukaemic form with isolated localized lymphadenopathy only, for which the terminology is small lymphocytic lymphoma (SLL), blurring the line between leukaemia and lymphoma. This terminology can be confusing. It is important to note that CLL and SLL are different clinical presentations of the same disease and are managed the same way. Most clinicians use the terminology CLL/SLL to reflect this and avoid confusion.

Nearly all cases of CLL are preceded by a monoclonal B-cell lymphocytosis (MBL) when there are fewer than 5×10^9/L circulating clonal B cells. However, this condition is also present in approximately 12% of the healthy population. The relationship between MBL and CLL is analogous to that between monoclonal gammopathy of uncertain significance (MGUS) and myeloma. MBL is not considered a neoplasm.

Although CLL is not considered a curable condition, the prognosis is good for most patients. Before the development and availability of many novel agents in the past decade, the median survival time was 10 years. Novel treatments and treatment approaches have no doubt improved the prognosis further (and will continue to do so), though mature data are not available yet.

Clinical features

Most patients are asymptomatic at presentation. If present, symptoms are non-specific. Common symptoms are:

- Recurrent infection caused by leukopenia and immune suppression: reduced immunoglobulins)
- Anaemia caused by marrow infiltration or haemolysis: often clinically obvious
- Painless small-volume lymphadenopathy: easily palpable and often present for long periods of time before diagnosis
- Splenomegaly related symptoms: left upper quadrant discomfort or early satiety.
- Constitutional symptoms: similar to B symptoms

Investigations

- ***FBC*** reveals a normal or low Hb, a raised WCC, (almost exclusively a lymphocytosis), and normal or low platelets.
- ***Blood film*** demonstrates small- or medium-sized mature and normal-appearing lymphocytes. Smudge cells may be seen *in vitro.* No immature forms (blasts) are evident, distinguishing CLL from ALL.
- ***Bone marrow*** reflects the peripheral blood findings. Often the marrow is heavily infiltrated with mature lymphocytes, with remarkable preservation of Hb and platelet count.
- ***Immunophenotyping*** shows a characteristic immunophenotype. The presence of specific markers give a score (the CLL score) that indicates the likelihood of CLL.
- ***Cytogenetics and FISH analyses*** can identify abnormalities, with known prognostic value. Abnormalities are seen in up to 90% of patients.
- ***DAT screen, direct Coombs test, and other haemolysis markers*** may be positive if there is haemolysis. CLL has a known association with (secondary) Evans syndrome, a rare disease condition presenting with a combination of autoimmune haemolytic anaemia and immune thrombocytopaenia.
- ***Immunoglobulins*** are low or normal.

Prognosis

The prognosis of CLL correlates with clinical stage at presentation (**Box 39.19**). Although different staging systems are used

Box 39.19 The Rai and Binet staging systems for chronic lymphocytic leukaemia[a]

Stage	Risk	Manifestations	Recommended treatment
Rai staging system			
0	Low	Lymphocytosis	Watch and wait
I	Intermediate	Lymphadenopathy	Treat only with progression[b]
II	Intermediate	Splenomegaly, lymphadenopathy or both	Treat only with progression[b]
III	High	Anaemia, organomegaly	Treat in most cases
IV	High	One or more of the following: anaemia, thrombocytopenia and organomegaly	Treat in most cases
Binet staging system			
A	Low	Lymphocytosis, <3 lymphoid areas enlarged[c]	Watch and wait
B	Intermediate	≥3 lymphoid areas enlarged[c]	Treat only with progression
C	High	Anaemia, thrombocytopenia, or both	Treat in most cases

[a]Lymphocytosis is present in all stages of the disease.
[b]Progression: weight loss, fatigue, fever, massive organomegaly, rapidly increasing lymphocyte count.
[c]Lymphoid areas include the cervical, axillary, and inguinal lymph nodes; spleen; and liver.

worldwide, key prognostic elements are not the presenting WCC but the speed at which it changes ('doubling time'), as well as the presence (or absence) of an associated anaemia or thrombocytopaenia. Several cytogenetic and molecular abnormalities also have prognostic significance; for example, the significant finding of a 17p deletion (which often coincides with a TP53 mutation) influences choice of therapy because it has a known association with rapid progression and poor response to certain treatments. NGS has recently identified additional gene mutations that influence prognosis.

Management

Asymptomatic patients with early-stage CLL should be managed expectantly. Up to 30% of CLL patients never require treatment. The most important decision is to know if or when to treat. Those with advanced-stage disease, either at diagnosis or if this develops during monitoring of the patient, should be treated. Although patient factors, such as age and fitness, play an important role, general indications for treatment are:

- Bone marrow failure with worsening anaemia or thrombocytopenia that is not autoimmune
- Massive or progressive splenomegaly or lymphadenopathy
- Progressive disease demonstrated by doubling of the lymphocyte count in less than 6 months
- Systemic symptoms: fever, night sweats, or weight loss
- Presence of haemolysis or other immune-mediated cytopaenias that are poorly responsive to steroids.

General and supportive measures

Patients with CLL with an associated autoimmune haemolytic anaemia should be treated with steroids in the first instance. Those with anaemia and thrombocytopenia caused by marrow infiltration should be treated with CLL-specific treatments.

Patients with infections should be treated as indicated; prophylactic antibiotic, antiviral, anti-*Pneumocystis*, and antifungal therapy should be considered for higher-risk patients during periods of treatment. Immunoglobulin replacement can be considered in patients with CLL with hypogammaglobulinaemia and recurrent infections, though availability of immunoglobulin products has dwindled in recent years. Pneumococcal, *Haemophilus influenzae* type B (Hib), influenza, and SARS-CoV-2 vaccinations are recommended. Live vaccines should be avoided. Allopurinol is given to prevent hyperuricaemia.

Treatments

The choice of therapy depends on patient-specific factors, including adverse prognostic features, anticipated response, and toxicities of therapy. The range of therapies has increased exponentially in the past decade. The availability of treatments and combinations is variable. Treatments are tailored to the patient's age, fitness, prior therapy, and co-morbidities.

- The ***BTK inhibitors*** ibrutinib and acalabrutinib, first approved in 2014, have greatly improved and forever changed the treatment approach for many patients with CLL. They are well-tolerated oral treatments that can often overcome poor prognostic cytogenetic findings. They are taken indefinitely.
- ***Fludarabine***, a purine analogue, in combination with cyclophosphamide and rituximab, was the standard first-line treatment for many years. Although novel therapies have superseded this for many patients, it may still be used for younger and fitter patients and remains a valid (and cheap) treatment option.
- ***Venetoclax***, a BCL-2 inhibitor, has incredible response rates and is often used as a second-line treatment option.
- ***'Old-fashioned'*** drugs, such as chlorambucil and bendamustine, continue to play a role, especially in refractory patients and in those intolerant of more novel agents.
- The role of allogeneic transplant in the era of novel therapies is slowly disappearing.

Richter's transformation

In rare cases, CLL can undergo transformation to high-grade lymphoma, usually DLBCL. Treatment is similar to that of DLBCL. This is a feared complication with a poor prognosis.

Hairy cell leukaemia

Hairy cell leukaemia (HCL) is a clonal proliferation of abnormal B (or very rarely T) cells, which accumulate in the bone marrow and spleen. It is a rare disease with a median age at presentation of 52 years. There is a male-to-female ratio of 4 to 1.

The name relates to the typical appearance of the WBCs down the microscope on both blood film and bone marrow.

HCL is almost always an indolent disease with a very slow course of disease progression. It can have a delayed diagnosis because findings on routine blood tests are minimal, with often only a minor neutropaenia in the first instance. Despite the striking features of the 'hairy cell', they are only present in low numbers on blood film and hence can easily be missed. Most patients are asymptomatic.

Clinical features

Clinical features can include anaemia, recurrent infections secondary to neutropaenia, and abdominal discomfort because of splenomegaly. Splenomegaly occurs in 80% of patients and can be massive. Constitutional symptoms and lymphadenopathy are rare. An unusual but typical finding in HCL is a peripheral blood monocytopaenia.

Management

The purine analogues cladribine and pentostatin have specific activity in this condition and are ideally given in combination with rituximab. A rituximab–cladribine combination is most used. It is a 5-day treatment, administered subcutaneously, leading to a CR in 95% of patients with just one cycle of treatment. Remissions can last for many years, and patients can be successfully retreated with the same treatment. Splenectomy is no longer routinely recommended.

MYELOMA AND OTHER PLASMA CELL DISORDERS

The classification of this group of related conditions is presented in **Box 39.20**; the most significant is myeloma.

Myeloma

Myeloma (or multiple myeloma) is a cancer of plasma cells. These cells usually produce immunoglobulin, but with malignant plasma cells, this is a non-functioning monoclonal paraprotein (or 'M band'). The paraprotein is usually an intact immunoglobulin, most commonly IgG (55%) or IgA (20%) and more rarely IgM or IgD. There is normally also an imbalance in free light chains (kappa or lambda),

Box 39.20 World Health Organization classification of plasma cell neoplasms (2017)

- Monoclonal gammopathy of undetermined significance
- Plasma cell myeloma
- Plasma cell myeloma variants:
  - Smouldering (asymptomatic) plasma cell myeloma
  - Non-secretory myeloma
  - Plasma cell leukaemia
- Plasmacytoma:
  - Solitary plasmacytoma of bone
  - Extraosseous plasmacytoma
- Monoclonal immunoglobulin deposition diseases
  - Primary amyloidosis (see Chapter 26)
  - Light chain diseases
  - Heavy chain diseases
    - Gamma (γ) heavy chain disease
    - Mu (μ) heavy chain disease
    - Alpha (α) heavy chain disease

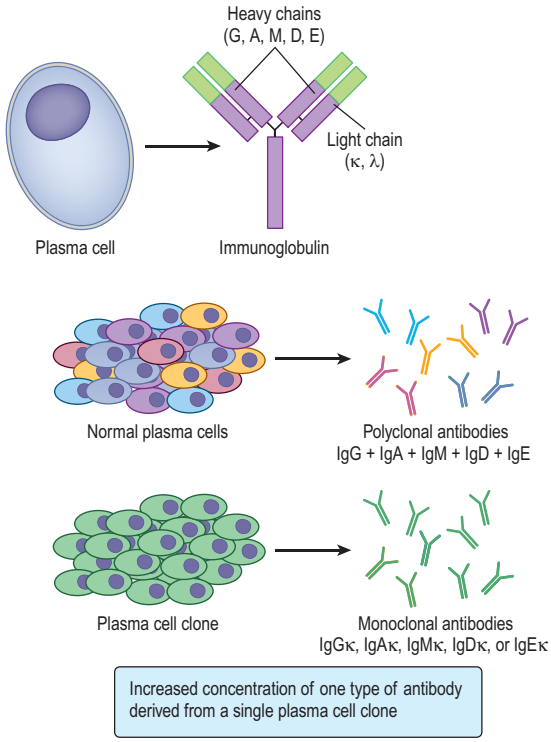

Fig. 39.21 Plasma cells produce immunoglobulins (Igs; antibodies) with different heavy- and light-chain combinations. A mixed population of plasma cells produces a polyclonal mixture of different immunoglobulins. In myeloma, the malignant plasma cell population is derived from a single clone, which produces a single type of Ig that can be detected by blood or urine assays.

which can be detected in the blood (serum free light chains [SFLCs]) and urine (Bence Jones protein) (Fig. 39.21). Around 15% of patients have no intact immunoglobulin and secrete an excess of light chain only, and 5% of cases are non-secretory.

Other conditions also produce paraproteins. B-cell lymphoproliferative disorders, such as low-grade B-cell NHL and CLL, can produce a paraprotein, and Waldenström's macroglobulinaemia is an IgM-producing lymphoplasmacytic lymphoma. Non-malignant disorders producing a paraprotein include poorly controlled HIV infection and autoimmune conditions, although the proteins are likely

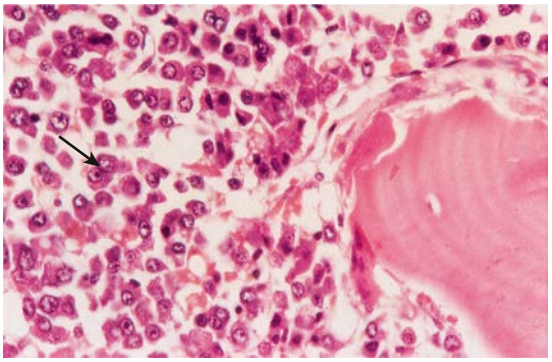

Fig. 39.22 Multiple myeloma. Histology shows replacement of the medullary cavity by abnormal plasma cells with some binucleate forms *(arrow)*. A residual bony trabeculum is present toward the *right*. (*Courtesy of Dr AJ Norton*.)

Box 39.21 Life-threatening complications of myeloma

- ***Kidney injury pr failure:*** requires urgent attention; renal replacement therapy may be indicated; haemodialysis
- ***Hypercalcaemia:*** treat with rehydration and bisphosphonates (e.g., pamidronate)
- ***Spinal cord compression:*** treat with dexamethasone followed by radiotherapy
- ***Hyperviscosity:*** caused by high circulating concentrations of paraprotein; can be managed with plasmapheresis

to be transient and should resolve with treatment of the underlying condition.

The abnormal plasma cell population can be identified on bone marrow aspirate or trephine biopsy, with the imbalance of kappa and lambda restricted plasma cells demonstrated by flow cytometry (aspirate) or immunohistochemistry (biopsy) (Fig. 39.22).

Myeloma is predominantly a disease of older adults, with the median age at presentation being older than 60 years. It is rare before 40 years of age. The annual incidence is 4 per 100 000, and disease is more common in males and in those of Black ethnicity.

Clinical features

The clinical features include:

- Bone pain: most commonly backache, owing to vertebral involvement (60%)
- Symptoms of anaemia
- Recurrent infections
- Symptoms of kidney failure (20%–30%)
- Symptoms of hypercalcaemia
- Rarely, symptoms of hyperviscosity or bleeding because of thrombocytopenia.

Patients can be asymptomatic, with abnormalities picked up on routine blood tests. Life-threatening complications are shown in Box 39.21.

The clinical features of myeloma are related to the underlying pathology:

- Bone marrow infiltration with plasma cells: anaemia, neutropenia, thrombocytopenia
- Paraprotein secretion. A reduction normal immunoglobulins (immune paresis) contributes to recurrent infections (Fig. 39.23). Very high paraprotein concentrations can cause symptoms of serum hyperviscosity, such as headaches, visual disturbance, dizziness, confusion, or seizures.

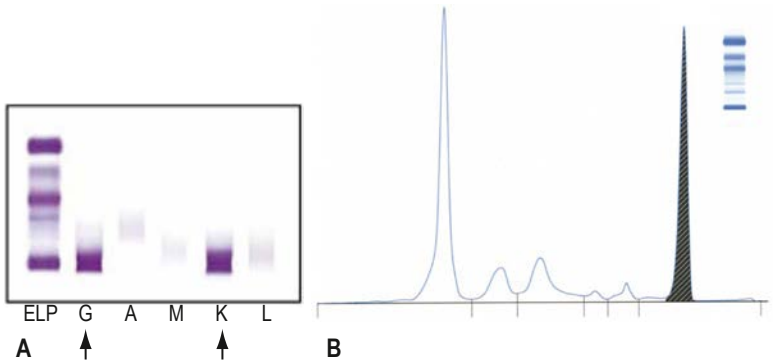

Fig. 39.23 Serum protein electrophoresis and immunofixation. **(A)** Immunofixation of immunoglobulin G (IgG) kappa monoclonal paraprotein in a patient with an IgG K paraprotein. The *column* on the *far left* is the total serum electrophoresis stained with anti-protein reagents. Albumin is at the *top* and the increased immunoglobulins at the *bottom*. These are shown to stain with anti-IgG and anti-kappa light chain reagents *(arrows)*. **(B)** Quantitation and serum electrophoresis of IgG paraprotein. The paraprotein is quantified *(right)* by calculating the area under the paraprotein spike and comparing it with the albumin concentration. *A,* Immunoglobulin A; *ELP,* electrophoresis; *G,* immunoglobulin G; *K,* kappa; *L,* lambda; *M,* immunoglobulin M.

- Free light chain secretion. This is often deposited in the renal tubules, causing kidney impairment by cast nephropathy. Other factors such as hypercalcaemia and (rarely) the deposition of AL amyloid can also contribute to kidney injury (see Chapter 26).
- Bone disease. Dysregulation of bone remodelling leads to typical lytic lesions, usually in the spine, skull, long bones, and ribs (Fig. 39.24). There is increased osteoclastic activity without increased osteoblast formation of bone, causing long bone fractures, vertebral collapse, and hypercalcaemia. Soft tissue plasmacytomas also occur and are the usual cause of spinal cord compression.

Diagnosis

The spectrum of plasma cell disorders is classified based on the degree of plasma cell infiltration and the presence of end-organ damage (Box 39.22). The presence of a paraprotein does not in itself make a diagnosis of myeloma. A diagnosis of myeloma requires more than 10% plasma cell infiltrate or a biopsy-proven bony or extramedullary plasmacytoma, together with at least one myeloma-defining event, which include 'CRAB' and biomarker criteria:

- Hyper***c***alcaemia: calcium greater than 2.75 mmol/L
- ***R***enal impairment: creatinine clearance less than 40 mL/min or serum creatinine greater than 177 μmol/L
- ***A***naemia: Hb less than 100 g/L or greater than 20 g/L below normal
- ***B***one involvement: one or more osteolytic lesions of 5 mm or larger on X-ray, CT, or PET scan

Biomarker criteria include:

- Involved-to-uninvolved (e.g., kappa–lambda) SFLC ratio of 100 or greater
- Bone marrow plasma cell infiltration of 60% greater than
- Two or more focal lesions on MRI scan.

Other related manifestations of end-organ damage (hyperviscosity, recurrent bacterial infections, AL (amyloid light chain) amyloidosis, peripheral neuropathy) are non-specific and not diagnostic of myeloma.

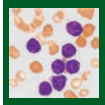
Investigations

General

- ***FBC:*** Hb, WCC, and platelet count are normal or low.
- ***Erythrocyte sedimentation rate*** is often high.

Fig. 39.24 Pathological fracture of long bone. A plain X-ray showing a spiral fracture through the right humerus.

- ***Blood film:*** rouleaux formation because of the paraprotein. Circulating plasma cells are present in the aggressive plasma cell leukaemia variant of myeloma.
- ***Serum creatinine and electrolytes:*** kidney injury (see earlier).
- ***Serum calcium:*** normal or raised. Serum alkaline phosphatase is usually normal.



Box 39.22 Classification and definitions of plasma cell disorders (IMWG, 2016)

	MGUS	Smouldering myeloma	Active myeloma
Clonal plasma cells in bone marrow (%)	<10	10–60	>10
Presence of myeloma-defining events	None	None	Yes
Likelihood of progression to myeloma	~1% per year	~10% per year	

IMWG, International Myeloma Working Group; *MGUS*, monoclonal gammopathy of undetermined significance.

- ***Total protein:*** normal or raised.
- B2M and LDH are used in prognosis. B2M is a marker of renal impairment and cell turnover.

Immunology

- ***Serum protein electrophoresis and immunofixation:*** characteristically shows a monoclonal band and immune paresis (see Fig. 39.23). The SFLC assay may show an abnormal ratio and an increased total amount of free kappa or lambda chains.
- ***Urine electrophoresis and immunofixation:*** assess light-chain excretion, although this is now superseded by the SFLC assay.

Radiology

- ***Skeletal imaging:*** CT, CT/PET, or whole-body MRI shows characteristic lytic lesions. Plain X-ray skeletal surveys are outdated because of poor sensitivity, although plain films may pick up a presenting pathological fracture.
- ***MRI of the spine:*** useful if there is back pain; it may show imminent compression or collapse. It can also pick up occult lesions not seen on CT (as per updated diagnostic criteria).

Histology

Bone marrow aspirate or trephine shows characteristic infiltration by clonal plasma cells (see Fig. 39.22).

Staging and prognosis

Patients can be risk stratified using the International Staging System (ISS) based on concentrations of albumin and B2M:

- ***ISS stage I:*** B2M less than 3.5 mg/L and serum albumin 35 g/L or greater
- ***ISS stage II:*** neither stage I nor stage III
- ***ISS stage III:*** B2M 5.5 mg/L or greater

Cytogenetic abnormalities can be detected via FISH in most cases of myeloma and have a bearing on prognosis. Hyperdiploidy is associated with a good prognosis, but some translocations affecting the IgH locus on chromosome 14 (e.g., t(4;14), t(14;16), t(14;20)) are associated with poor prognosis, as are other findings such as 17p–, 1q+, and 1p–. The most important of these, together with LDH concentrations, have been incorporated into a revised ISS staging system (R-ISS):

- ***R-ISS I:*** ISS stage I *and* normal LDH *and* no del(17p), t(4;14) or t(14;16) by FISH
- ***R-ISS II:*** neither stage I nor stage III
- ***R-ISS III:*** ISS stage III *and* elevated LDH *and/or* del(17p), t(4;14) or t(14;16) by FISH

This system is based on clinical trial data and clearly divides patients by overall survival: 10 years, 6 years, and 1.3 years for R-ISS groups I, II, and III respectively.

Management

Supportive therapy

- ***Anaemia:*** blood transfusion. In patients with very high paraproteins, there is a risk of precipitating or worsening symptoms of hyperviscosity.
- ***Hyperviscosity:*** plasmapheresis
- ***Hypercalcaemia and kidney injury:*** hydration, bisphosphonates, and high-dose steroids
- ***Infection:*** prompt treatment with antibiotics
- ***Bone pain:*** radiotherapy, high-dose dexamethasone, and systemic chemotherapy. NSAIDs are avoided because of the risk of acute kidney injury. Bisphosphonates such as zoledronate, which inhibit osteoclast activity, treat patients with hypercalcaemia and help reduce pathological fractures, cord compression, and bone pain.
- ***Pathological fractures:*** prevention by pinning of lytic bone lesions at critical sites such as the femoral shaft. Kyphoplasty and vertebroplasty may be useful in treating vertebral fractures.

Specific therapy

Although myeloma remains incurable for most patients, there are now a large number of drugs that can be used in combination and in sequence to prolong survival and reduce complications.

- ***Steroids.*** Dexamethasone and prednisolone are included in combination therapies and in initial management of acute complications.
- ***Cytotoxic chemotherapy drugs*** (e.g., melphalan and cyclophosphamide). Melphalan is used as high-dose therapy in autologous SCT.
- ***Proteasome inhibitors.*** Bortezomib was the first of these agents and is commonly given subcutaneously. Carfilzomib, an irreversible proteasome inhibitor, may have greater efficacy but can have cardiotoxic side-effects. Ixazomib is a newer oral agent.
- ***Immunomodulatory drugs.*** Thalidomide, lenalidomide, and pomalidomide act in conjunction with the cereblon protein to alter the transcriptional profile of myeloma cells, leading to cell death. They can be given over an extended period.
- ***Monoclonal antibodies.*** Daratumumab and isatuximab (anti-CD38), as well as elotuzumab (anti-SLAMF7), have anti-myeloma activity, particularly when given in combination with other agents.
- ***New and experimental immunotherapies.*** These include antibody–drug conjugates, bispecific T-cell engagers, and CAR T therapies. These are likely to be powerful tools in the future.

Anti-myeloma agents typically work most effectively when given in combination: daratumumab, bortezomib, thalidomide, and dexamethasone are highly effective when used together. Combinations are selected based on efficacy, side-effect profile, previous treatment history, and funding availability.

Younger patients who are fit enough for intensive chemotherapy will typically have an autologous SCT in their first and sometimes second remission to consolidate a good response to therapy. This typically increases the duration of remission. Low-level maintenance chemotherapy after high-dose therapy with stem cell rescue further extends the duration of response and overall survival. Myeloma inevitably relapses after each initial response, but there are now many effective treatments for patients with relapsed disease. Each subsequent remission tends to be less sustained with each treatment course as the cancer becomes more resistant to treatment.

Immunological therapies have the potential to cure a small subset of patients, with the use of allogeneic transplant sometimes considered for young patients with high-risk disease. Newer immunotherapies including CAR T, bispecifics, and antibody–drug conjugates are likely to transform future treatment algorithms.

Asymptomatic (smouldering) myeloma

In this condition, there is a significant paraprotein (IgG or IgA >30 g/L or urinary light chain excretion >0.5 g/day) or a marrow plasma cell infiltration of more than 10% but no end-organ damage or biomarkers of symptomatic myeloma. Most, but not all, patients eventually progress to symptomatic myeloma, with a median time to progression of about 5 years. The risk is highest for those with an elevated SFLC ratio, high bone marrow plasma cell infiltration, and paraprotein over 30 g/L. These patients need close monitoring in clinic.

Monoclonal gammopathy of undetermined significance

MGUS is an isolated finding of a monoclonal intact paraprotein or free light chain in serum or urine that does not fulfil the diagnostic criteria for asymptomatic or symptomatic myeloma. The risk of progression to myeloma is approximately 1% per year, with risk factors including and elevated SFLC ratio, paraprotein of more than 15 g/L and non-IgG subtype.

Solitary plasmacytoma

This is an isolated tumour of neoplastic plasma cells. It may be a solitary plasmacytoma within the skeleton or a soft tissue extramedullary plasmacytoma outside the marrow cavity. These can be treated curatively with radiotherapy, although a high proportion (especially bone plasmacytomas) will eventually progress to systemic myeloma.

Heavy-chain diseases

These rare conditions are characterized, as the name suggests, by the production of a heavy-chain-only paraprotein. They are usually caused by a B-cell lymphoproliferative condition.

Monoclonal gammopathies of clinical significance

There are several other conditions in which the clonal population is relatively small, but secondary clinical effects occur. These are discussed in more detail in the relevant organ-based chapters.

- ***AL amyloidosis*** involves organized fibrillary deposits in kidneys, heart, GI tract, skin, and nerves. It is usually caused by a lambda-light chain isotype. Other subtypes of amyloid (e.g., hereditary ATTR amyloid, and reactive AA amyloid) are not caused by a plasma cell disorder (see Chapter 26).
- ***Monoclonal gammopathies of renal significance*** is a group of renal pathologies caused by immunoglobulin deposition (see Chapter 26). Like AL amyloid, all of these may be treated with myeloma-directed therapies (e.g., bortezomib, cyclophosphamide, and dexamethasone).
- ***Plasma cell neoplasms with associated paraneoplastic phenomena (POEMS) syndrome*** is a rare disease characterized by ***p***olyneuropathy, ***o***rganomegaly, ***e***ndocrinopathy, ***m***onoclonal plasma cell disorder and ***s***kin changes (see Chapter 28). High concentrations of vascular endothelial growth factor are common and may be the mediating mechanism.

CORE SKILLS AND KNOWLEDGE

Venous thromboembolism (VTE) is common, affecting more than 5% of people during their lifetimes. The risk increases with age. VTE presents as an acute episode of deep vein thrombosis (DVT) or pulmonary embolism (PE) and is frequently recurrent.

Patients with a suspected episode of VTE may present to their general practitioners or directly to the hospital emergency department, or VTE may occur while care is being given to patients in hospital for other medical problems. Many clinical teams may therefore be involved in the initial diagnosis and management, but most commonly, acute physicians play a leading role. Haematologists often provide advice on acute management and frequently oversee long-term treatment, and some chest physicians have a particular interest in the management and long-term complications of PE.

Key learning objectives for VTE include:

- Being familiar with the main risk factors for VTE and recognizing its presenting clinical features
- Knowing how to manage suspected VTE
- Understanding the pharmacology of the different anticoagulants used to treat patients with VTE, their use in clinical practice, and the management of anticoagulant-related bleeding.

Opportunities for learning about VTE include observing the work of a DVT diagnostic service (linked in many hospitals to the emergency department or acute medical unit) or attending an outpatient anticoagulant service, overseen in many hospitals by the haematology department.

CLINICAL SKILLS

Diagnosis

In DVT, a history should be elicited of leg pain and swelling. In PE, the patient has breathlessness (sometimes only on exertion), chest pain (often pleuritic in nature), and haemoptysis or collapse or syncopal episodes. A personal or family history of VTE should be sought along with information about any current or past anticoagulant therapy, including adherence. Risk factors for VTE include recent surgery, hospital admission, trauma, immobility, cancer and its treatment, oestrogen therapy (contraception, hormone replacement, and pregnancy), and intravenous drug use. Pregnancy history includes current or recent pregnancy and history of pregnancy complications, including miscarriage, intrauterine death, and preterm delivery because of pre-eclampsia. Around 5% of patients presenting with an unprovoked DVT or PE have an underlying cancer, so note should be made of weight loss or other system-related symptoms.

Examination

Important features include tachycardia, reduced oxygen saturation (<95% while breathing room air), leg swelling (particularly if unilateral and the calf is at least 3 cm larger on the symptomatic side), tenderness along the deep veins, and pitting oedema affecting the symptomatic leg. A pleural rub might be heard on chest auscultation along with a split second heart sound. Haemodynamic instability characterized by a systolic blood pressure below 90 mmHg not caused by arrhythmia, hypovolaemia, or sepsis, and features of end-organ hypoperfusion (altered mental status; cold, clammy skin) is particularly concerning because it may indicate a high-risk PE and the need for urgent treatment escalation.

Investigation

These are dictated by whether a diagnosis of DVT or PE is considered and the likelihood of the diagnosis being present. If a DVT or PE is suspected, blood is typically taken for a full blood count (FBC); kidney and liver function tests; and a clotting screen, including D-dimer. Imaging for DVT is typically with ultrasonography. Most

often, computed tomography pulmonary angiography (CTPA) is performed if imaging is required for a possible PE. Patients presenting with chest pain also typically have an electrocardiogram and serum troponin performed. If a DVT or PE is confirmed, routine tests, including serum calcium, urinalysis, and a chest X-ray (if a CTPA has not been performed), should be undertaken, with further screening for an underlying cancer performed only if clinical features or routine investigations suggest the need to pursue this possibility. Thrombophilia testing is not indicated at the time of diagnosis, although testing for antiphospholipid antibodies might be considered, especially in those with an unprovoked episode because it might influence choice of anticoagulant. A pregnancy test should be considered if pregnancy is possible because it may influence treatment.

BACKGROUND

PE is the third most common cause of cardiovascular death after acute myocardial infarction and stroke. As well as leading to PE, DVT frequently results in the post-thrombotic syndrome (PTS), which is a major cause of long-term disability. 'VTE' is the term describing both conditions. It is multicausal, often arising as a result of transient provoking factors or in individuals with a heritable or acquired predisposition, although no cause can be established in up to 50% of patients.

Every clinician must be familiar with VTE because:

- It is common, particularly in those admitted to hospital, after surgery or trauma, or if there is another cause of reduced mobility.
- It is life-threatening.
- It is preventable. PE is the most common avoidable cause of death in patients admitted to hospital, and the single leading direct cause of death during pregnancy and the puerperium in the UK.
- It can be difficult to diagnose. Clinical features (Fig. 40.1) and routine initial investigations, particularly for PE, are often non-specific, leading to diagnostic delay with potentially serious consequences.
- Its treatment can be hazardous. Anticoagulant therapy, which may be long-term, is effective but carries the risk of major, even fatal, bleeding, and it can be particularly challenging in patients with co-morbidities.
- It is a significant cause of morbidity. Long-term sequelae are frequent and significantly impair quality of life.

PATHOGENESIS OF THROMBOSIS

Thrombosis is the pathological process by which a localized solid mass of blood constituents (a blood clot or ***thrombus***) forms within a blood vessel, mostly because of fibrin formation, with a variable contribution from platelets and other cells. This differentiates it from physiological haemostasis in which a fibrin-rich blood clot occurs outside the vessel-wall lining (endothelium) as a result of injury. Thrombi form on and are attached to the vessel wall, but fragments ***(emboli)*** may break off and occlude downstream vessels.

Arterial and venous thrombosis

Thrombosis can occur in both arteries and veins. For example, the usual cause of myocardial infarction is thrombosis within a coronary artery. The pathogenesis of thrombosis in these two sites is different, reflecting the different shear stresses in arteries and veins and the contribution that rupture of atheromatous plaques makes

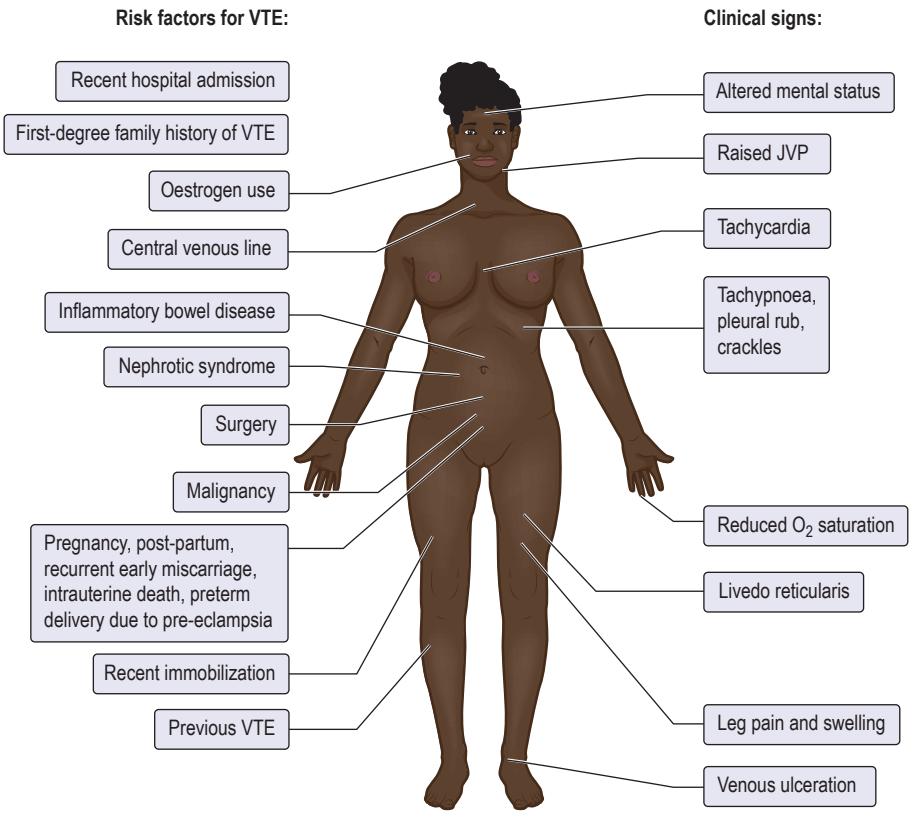

Fig. 40.1 Diagnosis of venous thromboembolism. *JVP,* Jugular venous pressure; *VTE,* venous thromboembolism.

to initiation of arterial thrombosis. Arterial clots are described as white thrombi, reflecting the contribution that platelets as well as fibrin make, and venous clots as red thrombi because of red cells and fibrin. Thrombosis is thought to be the cause of about 25% of deaths worldwide.

Factors influencing thrombosis

Thrombosis is considered to arise from the interplay between the three factors that make up Virchow's triad:

- Changes in blood flow (stasis or turbulence)
- Vessel wall dysfunction
- Changes in blood components, leading to hypercoagulability

The importance of the individual components of Virchow's triad varies between arterial and venous thrombosis:

- ***Turbulence*** and ***vessel wall dysfunction*** caused by atheromatous plaques are factors in arterial thrombosis.
- ***Stasis*** and ***hypercoagulability*** are more relevant in the pathogenesis of venous thrombosis.

ACUTE VENOUS THROMBOEMBOLISM

Definitions, epidemiology, clinical features, and the diagnosis and primary management of VTE are detailed in Chapter 11.

LONG-TERM MANAGEMENT OF VENOUS THROMBOEMBOLISM

Anticoagulation needs to continue for a minimum of 3 months in all patients with proximal DVT or PE because earlier discontinuation is associated with a higher risk of recurrence. After 3 months, the decision to stop treatment or continue long-term anticoagulation for secondary prevention should be made on an individual patient basis, taking account of the risks of recurrent thrombosis, bleeding, and the person's own views.

Anticoagulants reduce the relative risk of recurrent thrombosis by 80% to 90% but carry a 1% to 3% absolute risk per year of major bleeding. Both recurrent thrombotic episodes and anticoagulant-associated major bleeding carry significant risks of morbidity and mortality. Therefore, the benefits of long-term anticoagulation potentially outweigh the risks of major bleeding in those with a higher risk of recurrent thrombosis, but in others, the risks of long-term treatment potentially outweigh the benefits.

Across all patients receiving anticoagulation for VTE, if anticoagulation is stopped after a minimum of 3 months, the risk of recurrent thrombosis is about 5% in the next year. It has been suggested that if recurrence risk is greater than this, continuation of anticoagulation should be considered, and if the recurrence risk is less than 5%, anticoagulation should stop. If anticoagulation has been continued for at least 3 months, a longer duration of treatment does not appear to reduce the risk of recurrent thrombosis further on stopping anticoagulation.

Higher recurrence risks (~10% at 1 year and 30% at 5 years) are seen in patients with unprovoked VTE episodes and in those with persisting risk factors, including active cancer or antiphospholipid syndrome (APS). Lower recurrence risks are seen in those with transient provoking risk factors, and the stronger the transient provoking factor, the lower the recurrence risk (providing the transient provoking factor is no longer present). Recurrence risks are higher in males than in females, in those with second events, and in those with PE or proximal DVT as opposed to distal DVT. The risk of recurrent PE is higher in those whose initial presentation is with PE rather than with DVT. Because the case fatality rate of PE is higher than that of DVT, this suggests that the threshold for continuing anticoagulation might be lower in patients presenting with PE. Also relevant is the individual patient's cardiopulmonary reserve because those with impaired reserve are less able to compensate for the acute circulatory effects of PE.

Prediction of recurrent venous thromboembolism

Several prediction rules have been devised to assist in determination of risk of VTE recurrence after stopping anticoagulation in those with unprovoked VTE. These consider several clinical features and often the measurement of D-dimer after discontinuation of anticoagulation. Prediction scores for risk of major bleeding on anticoagulant therapy for VTE have also been evaluated, and National Institute for Health and Care Excellence (NICE) suggests the HAS-BLED score (initially developed for patients with atrial fibrillation (AF), though NICE now recommend the ORBIT score in those with AF; see Chapter 17) might be used for assessment, with discontinuation of anticoagulation discussed with those with a score of 4 or more that cannot be modified. However, the decision to continue or stop anticoagulation should not be based solely on existing risk prediction tools. In the UK, long-term anticoagulation is considered in patients with unprovoked proximal DVT or PE and a low bleeding risk.

Patients with risk factors for recurrence should be considered for continuation of anticoagulation if the risk factor persists. For example, the risk of recurrent thrombosis is very high in patients with cancer-associated DVT or PE in whom cancer remains active, but stopping anticoagulation after 6 months might be considered if the cancer is in remission, recurrence is unlikely, and cancer treatment has been completed.

The risk of recurrence is lower after isolated calf vein thrombosis than in proximal DVT or PE. In practice, most patients with symptomatic distal DVTs are treated for 3 months, and anticoagulation is then stopped. In those with a low risk of recurrence (e.g., because of a transient provoking factor that has now resolved and a high risk of bleeding), it may be reasonable to reduce the treatment duration to 6 weeks.

Treatment of patients with upper limb DVT follows the same principles as for those with leg vein thrombosis. Many episodes are associated with indwelling central venous lines; anticoagulation should generally continue for a minimum of 3 months, longer if the line remains *in situ*.

Complications

Death

After VTE is diagnosed and treatment commenced, the short-term mortality rate is lower in patients presenting with DVT than with PE. In those presenting with PE, the mortality rate is around 5% by 1 month, although at least half of these deaths are caused by associated co-morbidities rather directly caused by PE. Nevertheless, compared with those without VTE, the mortality rate remains elevated in both the short and longer term, with observed mortality rates of 10% to 20% at 1 year; cancer is the leading cause of death.

Cancer

Cancer-associated thrombosis, the initial description of which is often attributed to Trousseau in the 19th century (Trousseau's syndrome), is common, and 10% to 20% of all episodes of VTE are diagnosed in people with cancer. The pathogenesis is multifactorial and includes:

- Hypercoagulability caused by cancer
- Surgery or systemic therapy
- Reduced mobility
- Indwelling central venous catheters leading to catheter-associated thrombosis.

The combination of cancer and thrombosis carries a particularly poor prognosis. Up to 5% of patients who present with a seemingly unprovoked episode of VTE are diagnosed with cancer within 12 months. However, current evidence does not support extensive investigations for an unknown cancer unless indicated by history and examination, FBC, liver and kidney function tests, serum calcium, chest X-ray, and urinalysis.

Post-thrombotic syndrome

Post-thrombotic syndrome (PTS) can affect long-term quality of life after VTE. It occurs in about 40% of people after a proximal DVT. It causes symptoms of variable severity in the affected leg, including pain, swelling, heaviness, venous claudication on exercise, itching, and discoloration. Symptoms may be persistent or intermittent and reduce physical functioning and mobility. At its most severe, it leads to permanent skin damage with redness, hyperpigmentation, venous ectasia, and skin fibrosis (lipodermatosclerosis), and 5% to 10% of patients develop leg ulceration that is difficult to treat and tends to recur (Fig. 40.2).

PTS results from:

- Proximal venous occlusion with outflow obstruction
- Damage to the venous valves that normally allow blood flow from superficial to deep and distal to proximal
- Development of a collateral circulation
- Venous hypertension
- Capillary leakage
- Localized inflammation.

The role of knee-length, graduated compression stockings providing at least 24 mmHg of support at the ankle in the reduction of risk of PTS is controversial. Those who develop PTS sometimes benefit symptomatically from graduated compression stockings, but others find them difficult to put on and uncomfortable to wear. A multidisciplinary approach is necessary in patients who develop venous ulceration. With residual ilio-femoral vein occlusion, a vascular surgery opinion should be sought because some patients may benefit from venous stent insertion.

Fig. 40.2 Venous ulceration of the ankle. This patient has an ulcer with local venous-type staining of local skin caused by poor venous drainage from the lower leg. Immobility, previous deep vein thrombosis, and varicose veins contribute to development. *(From Cross SS.* Underwood's Pathology: A Clinical Approach, *7th edn, Elsevier Ltd, 2019, Fig. 13.17.)*

Pulmonary hypertension

After PE, up to 5% of patients remain persistently breathless because of chronic thromboembolic pulmonary hypertension. In this condition, there is incomplete resolution of pulmonary emboli. The diagnosis should be suspected in those with persisting symptoms supported by follow-up perfusion lung scanning or CTPA showing evidence of residual occlusion and echocardiography suggesting pulmonary hypertension. Assessment is undertaken by respiratory specialists. Some patients can be successfully treated surgically with pulmonary endarterectomy, but a much greater proportion have post-PE syndrome with persisting breathlessness, impaired exercise intolerance, and impaired quality of life. Cardiopulmonary exercise testing and assessment by experienced clinicians can be helpful in defining the cause, including the contribution of deconditioning and mental health symptoms, and approaches to management.

INVESTIGATION AFTER VENOUS THROMBOSIS

General investigations

All patients with newly diagnosed, unprovoked VTE should undergo physical examination and have the following general tests to ensure safety of anticoagulation and to look for occult malignancy and other co-morbidities:

- FBC
- Kidney function tests
- Liver function tests
- Serum calcium

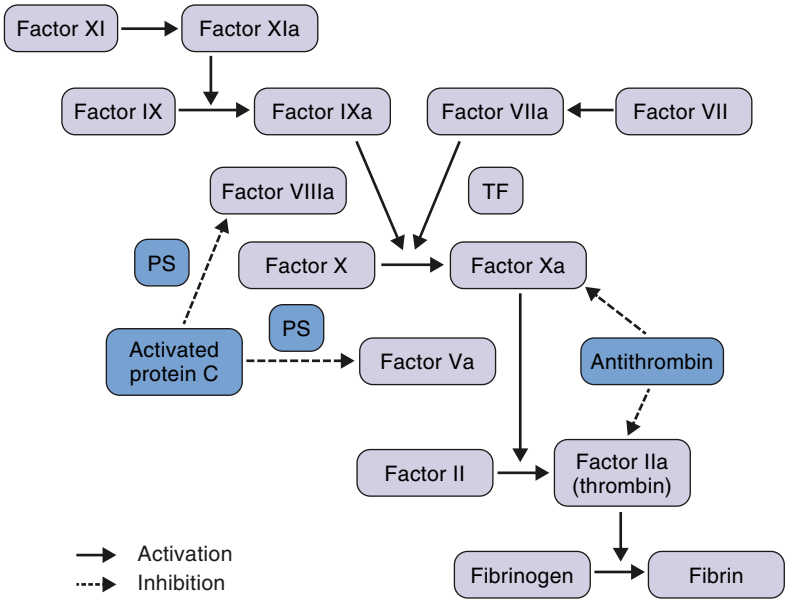

Fig. 40.3 Outline of the coagulation system, highlighting sites of action of the naturally occurring inhibitors of coagulation. Naturally occurring anticoagulants are shown in *blue*. Activated protein C results from activation of protein C by thrombin (not shown). *PS,* Protein S; *TF,* tissue factor. *(From MacCallum P, Bowles L, Keeling D. Diagnosis and management of heritable thrombophilias.* BMJ *2014; 349:g4387.)*

- Clotting screen
- Chest X-ray
- Urinalysis for both proteinuria and microscopic haematuria

Thrombophilia testing

Thrombophilia testing is often considered in patients with VTE, but indications remain controversial. In this context, the term 'thrombophilia' applies to a thrombotic tendency that can be identified in the laboratory. Thrombophilic tendencies can be either heritable or acquired.

Heritable thrombophilias

Heritable thrombophilias can be identified in about 20% of cases of VTE. They do not play a significant role in arterial thrombosis. They can be divided into variants that cause either gain of function of procoagulants or loss of function of anticoagulants.

Gain of function of procoagulants

Factor V Leiden results from a variant in clotting factor V that causes activated clotting factor V (factor Va) to be resistant to inactivation by activated protein C and thereby leads to an increase in thrombin generation. Heterozygous factor V Leiden is present in about 5% of individuals of European or Mediterranean origin but is not found in other ethnic groups such as those from eastern Asia. It increases the risk of VTE fivefold throughout life and interacts synergistically with acquired risk factors such as oestrogen-containing contraceptives and pregnancy. Thus, the risk of thrombosis is increased about 30-fold in heterozygous V Leiden carriers taking the combined oral contraceptive pill compared with non-carriers not taking the combined oral contraceptive pill. However, because the absolute risk of VTE is low in young females, even a 30-fold increase in risk remains significantly below 0.5% per year for any individual. Overall, factor V Leiden is present in about 20% of cases of VTE. Individuals who are homozygous for factor V Leiden are less common, but their risk of thrombosis is about 10-fold higher than those who are heterozygous.

A ***variant in the 3′ untranslated region of the prothrombin gene*** *(G20210A)* causes levels of prothrombin to rise and increases the risk of VTE two- to threefold throughout life. It is present in about 2% of Caucasians and in about 5% of people with VTE.

Loss of function of anticoagulants

The sites of action of the naturally occurring anticoagulants are shown in Fig. 40.3.

Antithrombin is a serine protease inhibitor (serpin) that functions as an anticoagulant by inhibiting predominantly thrombin and factor Xa reactions that are catalysed by heparin. Reduced antithrombin activity therefore leads to increased thrombin generation and activity, thereby predisposing to thrombosis. Heterozygous antithrombin deficiency is rare in the population but increases the risk of VTE about 10-fold. The disorder is identified by measurement of antithrombin activity rather than by genetic testing because multiple genetic mutations (some reducing synthesis and others reducing function) are described. Laboratory diagnosis is not straightforward because low antithrombin concentrations can also be acquired, for example, after acute illness, after surgery, with heparin therapy, in liver disease, and in nephrotic syndrome. Those with antithrombin deficiency often present at a young age and are more likely to have recurrent events. Because antithrombin is required for the action of heparin, those with antithrombin deficiency may be relatively resistant to heparin.

Protein C and protein S are vitamin K–dependent, naturally occurring anticoagulants. Together, they inhibit activated forms of clotting system co-factors, factor Va and factor VIIIa. Deficiency leads to an increase in thrombin generation and a predisposition to thrombosis. Heterozygous deficiencies of protein C and protein S are uncommon in the population and increase the risk of venous thrombosis at least fivefold. As with antithrombin deficiency, multiple genetic mutations have been described that affect either synthesis

or function. Diagnosis is based on measurement of activity or protein concentration and is often difficult because reduced levels can also be acquired because of for example, acute illness; liver disease; warfarin or vitamin K deficiency; or in the case of protein S, pregnancy or oestrogen therapy. Very rarely, homozygous protein C or protein S deficiency may occur and present as neonatal purpura fulminans.

Management of heritable thrombophilias

In general, the more common heritable defects cause a milder clinical picture than those that are rare, such as antithrombin deficiency. The acute management of VTE is not affected by the presence or absence of heritable thrombophilia, and diagnosis of antithrombin, protein C, and protein S deficiencies is problematic in the setting of acute VTE because levels of these proteins are often reduced either by the thrombosis itself or by the anticoagulants used in treatment. Moreover, for the most part, identification of a heritable thrombophilic defect does not influence the long-term management because most defects do not influence the risk of recurrent VTE. Therefore, if a heritable thrombophilia is to be sought, it should preferably be after the acute stage is over, when the patient has completed a minimum of 3 months of anticoagulation, and when their course of treatment either has finished or can be safely interrupted to allow measurement of naturally occurring anticoagulant levels.

Testing for heritable thrombophilias might be considered in:

- Those with unprovoked VTE who are planning to stop anticoagulation, particularly if they have a family history
- Those who present with VTE younger than 40 years of age
- Females of reproductive age for assistance with management of future pregnancies
- Those with unusual-site thromboses.

Acquired thrombophilias

Many risk factors for thrombosis cause an acquired hypercoagulable state, but from a laboratory angle, the main acquired thrombophilia is APS. Other prothrombotic conditions considered in this section are myeloproliferative neoplasm (MPN) and SARS-CoV-2 infection. Heparin-induced thrombocytopenia (HIT) is considered later in this chapter (see 'Heparin-induced thrombocytopenia' section).

Antiphospholipid syndrome

APS is an acquired prothrombotic disorder that has specific clinical and laboratory features. See 'Antiphospholipid syndrome' section in Chapter 32 for a full description, including diagnostic testing.

The diagnosis of APS should be considered in patients presenting with:

- ***VTE if unprovoked, or provoked by a minor risk factor***
- ***Unusual-site venous thrombosis***
- ***Recurrent episodes of venous thrombosis***, particularly if anticoagulants are being given
- ***Arterial thrombosis*** at a young age (younger than 50 years) that is otherwise unexplained
- ***Pregnancy-related morbidity*** with one or more of the following:
  - Three consecutive miscarriages before 10 weeks' gestation after exclusion of other causes such as chromosomal abnormalities
  - One or more otherwise unexplained fetal deaths after 10 weeks' gestation
  - Birth of a morphologically normal baby before 34 weeks' gestation because of severe pre-eclampsia, eclampsia, or placental insufficiency.
- ***Incidentally detected abnormalities of clotting screens.*** The activated partial thromboplastin time (APTT) is typically prolonged; less often, the prothrombin time is prolonged. Although this suggests a bleeding tendency, in practice, a thrombotic tendency is observed.

APS is associated with an increased risk of recurrent thrombotic episodes. This may influence decisions on duration of anticoagulation after an episode of VTE. The oral factor Xa inhibitors appear to be less effective than warfarin in the prevention of recurrent thrombosis, in APS, particularly arterial events such as strokes.

Management of patients with APS presenting with arterial thrombosis is controversial, and there is ongoing debate as to the best approach, including anticoagulation with warfarin at either standard intensity (international normalized ratio [INR], 2.0–3.0) or higher intensity (INR, 3.0–4.0) and/or antiplatelet therapy.

Obstetrical APS in the absence of a thrombotic history is usually managed with low-dose aspirin and a prophylactic dose of low-molecular-weight heparin (LMWH) through the pregnancy.

People with a **myeloproliferative neoplasm (MPN)** (see Chapter 39) have an increased risk of thrombosis, particularly in unusual sites such as splanchnic vein or cerebral venous sinus thrombosis. Hence, when thrombosis occurs in an unusual location or is unexplained with abnormalities in the FBC, an MPN screen is warranted.

Patients admitted to hospital with **SARS-CoV-2** have a high incidence of thromboembolic events, particularly if admitted to intensive care. The pathogenesis of thrombosis in SARS-CoV-2 is complex with coagulopathy (illustrated typically by raised D-dimer concentrations), platelet activation, and endothelial perturbation leading to a thrombo-inflammatory process that includes VTE, arterial thrombosis, and formation of capillary microthrombi. The short-term risk of thrombosis is also increased, albeit to a lesser extent, in those not requiring hospital admission.

Vaccine-induced immune thrombotic thrombocytopenia (VITT) is a rare but life-threatening thrombotic complication of the AstraZeneca and Johnson & Johnson adenoviral vaccines against SARS-CoV-2. Recognition of this side-effect resulted in some national authorities, including those in the UK, recommending alternative vaccines, particularly for those aged under 50 years in whom the risk of VITT was greater. Affected individuals typically present 5 to 30 days after their first vaccine with DVT, PE, unusual-site thrombosis (cerebral venous sinus thrombosis or splanchnic vein thrombosis), or arterial thrombosis and thrombocytopenia. The D-dimer concentration is usually considerably elevated. The diagnosis is confirmed by the presence of antiplatelet factor 4 (PF4) antibodies. Management of VITT includes anticoagulation with a non–heparin-based anticoagulant and immunosuppression with corticosteroids, intravenous immunoglobulin, and/or plasma exchange. The increased risk of thrombosis in SARS-CoV-2 infection is much greater than the approximately 1 in 50 000 or greater risk of VITT.

PREVENTION

Between one-third and half of all episodes of VTE are provoked by surgery or admission to hospital, with most diagnosed in the

3 months after discharge. Studies of routine postoperative screening for venous thrombosis after major orthopaedic or cancer surgery report an asymptomatic DVT incidence as high as 50%. PE is the most common preventable cause of hospital-related death. Clinical trials have shown that thromboprophylaxis to prevent symptomatic VTE in patients undergoing major surgery and in high-risk medical inpatients is beneficial and cost-effective. All adults admitted to hospital in the UK require formal assessment of their risks of VTE and of bleeding. The factors included in the UK Department of Health risk assessment tool are shown in **Box 40.1**.

VTE prophylaxis can be mechanical or pharmacological. Pharmacological prophylaxis is considered for patients at risk of VTE without significant bleeding risk, with or without additional mechanical measures. Those who have a significant bleeding risk are considered for mechanical prophylaxis.

Box 40.1 UK Department of Health risk assessment tool for venous thromboembolism (VTE) and bleeding

Patients at risk of VTE
- Medical patients expected to have ongoing reduced mobility relative to normal state
- Surgical patients

Thrombosis risk factors
- Patient-related
  - Active cancer or cancer treatment
  - Age older than 60 years
  - Dehydration
  - Known thrombophilia
  - Obesity (body mass index >30 kg/m^2)
  - One or more significant medical co-morbidities (e.g., heart failure, acute infectious diseases, inflammatory conditions)
  - Personal history or first-degree relative with a history of VTE
  - Oestrogen containing medication
  - Varicose veins with phlebitis
  - Pregnancy or <6 weeks postpartum
- Admission-related
  - Significantly reduced mobility for ≥3 days
  - Hip or knee replacement
  - Hip fracture
  - Total anaesthetic and surgical time >90 minutes
  - Pelvic or lower limb surgery with total anaesthetic and surgical time >60 minutes
  - Acute surgical admission with inflammatory or intra-abdominal condition
  - Critical care admission
  - Surgery with significant reduction in mobility

Bleeding risk
- Patient related
  - Active bleeding
  - Acquired bleeding disorder (e.g., acute liver failure)
  - Concurrent use of anticoagulants known to increase bleeding risk (e.g., warfarin with international normalized ratio >2)
  - Acute stroke
  - Thrombocytopenia (platelets <75 × 10^9/L)
  - Uncontrolled hypertension (≥230/120 mmHg)
  - Untreated inherited bleeding disorders (e.g., haemophilia, von Willebrand's disease)
- Admission-related
  - Neurosurgery, spinal surgery, or eye surgery
  - Procedure with high bleeding risk
  - Lumbar puncture, epidural, or spinal anaesthesia expected within the next 12 hours
  - Lumbar puncture, epidural, or spinal anaesthesia within the previous 4 hours

Mechanical prophylaxis

Mechanical prophylaxis measures include:
- Early mobilization
- Elevation of the legs
- Use of anti-embolic stockings of knee or thigh length (not in peripheral arterial disease, stroke, or situations when they could result in skin damage)
- Intermittent compression devices during surgery or on bed rest to improve blood flow

Pharmacological prophylaxis

This involves anticoagulants in lower doses than those used in the treatment of VTE. Most often, LMWH is used during hospital admission, and in some groups (e.g., those undergoing major abdominal surgery for cancer), this is continued for a period after discharge. Oral factor Xa and thrombin inhibitors at reduced dose have been approved for VTE prevention after major hip and knee replacement surgery, and these are continued for 2 to 5 weeks after surgery. Though traditionally not thought to be of benefit in VTE, aspirin has been shown to reduce the risk of venous thrombosis after hip or knee replacement surgery.

Prophylactic LMWH should be offered as soon as possible after VTE risk assessment to young people and adults admitted to hospital with SARS-CoV-2. NICE recommend a treatment dose of LMWH is considered in young people and adults who need low-flow oxygen and who do not have an increased bleeding risk.

ANTICOAGULANT AGENTS

The physiological purpose of the coagulation system is to generate the enzyme (or serine protease) thrombin rapidly and locally. This converts soluble circulating plasma fibrinogen into insoluble fibrin in response to vascular injury, and secures ***haemostasis***. This is achieved through a complex series of reactions on exposed cell surfaces and activated platelets, in which inactive circulating clotting factors become locally activated in a coordinated and sequential manner. Initiation follows the binding of circulating factor VII to tissue factor, a receptor expressed on subendothelial and adventitial cells, and leads to the generation of activated factor X (traditionally referred to as the ***extrinsic system***; see **Fig. 38.37**). This in turn results in initial thrombin generation and subsequent amplification of the process through activation of the ***intrinsic system***, leading to further activation of factor X and thrombin generation. Venous thrombosis is characterized by the pathological formation of a localized fibrin-rich clot. Anticoagulants work by inhibiting the generation or activity of thrombin in different ways (**Figs. 40.4 and 40.5**).

Parenteral anticoagulants

The main pharmacological properties of parenteral anticoagulants used in the treatment and prevention of VTE are summarized in **Box 40.2**.

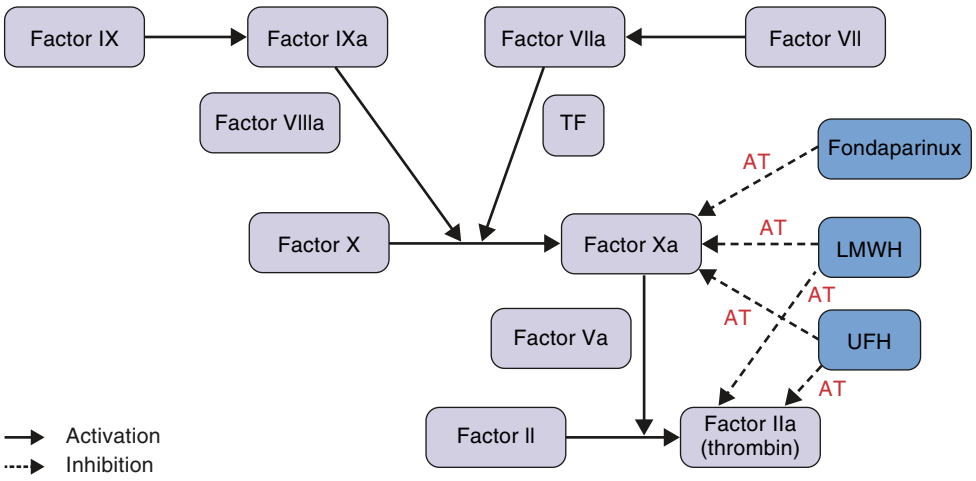

Fig. 40.4 Sites of action of parenteral anticoagulants used in the treatment and prevention of venous thromboembolism. *AT,* Antithrombin; *LMWH,* low-molecular-weight heparin; *TF,* tissue factor; *UFH,* unfractionated heparin.

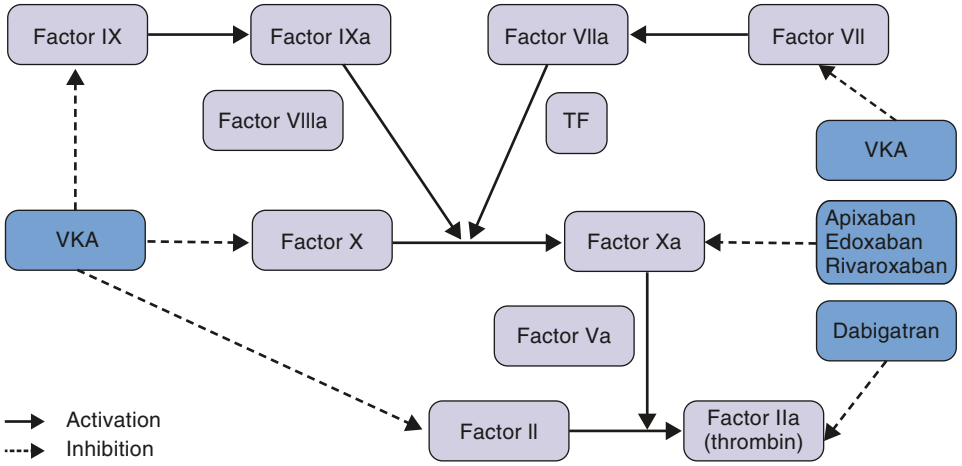

Fig. 40.5 Sites of action of oral anticoagulants used in the treatment and secondary prevention of venous thromboembolism. *TF,* Tissue factor; *VKA,* vitamin K antagonist (e.g., warfarin).

Box 40.2 Pharmacological properties of parenteral anticoagulants

	Unfractionated heparin	Low-molecular-weight heparin	Fondaparinux
Source	Biological	Biological	Synthetic
Molecular weight (Da)	3000–30 000	2000–9000	1500
Target (via antithrombin)	Xa = IIa	Xa > IIa	Xa
Half-life	1 h	4 h	18 h
Monitoring test	APTT	Anti–factor Xa (not usually required)	Anti–factor Xa (not usually required)
Renal excretion	No	Yes	Yes
Antidote	Protamine sulfate	Protamine sulfate (partial reversal)	None

APTT, Activated partial thromboplastin time.

Heparin

Heparin is not a pure substance but a mixture of polysaccharides of different molecular weights of biological origin. In the UK, all heparins are derived from processed porcine gut mucosa. Heparins are destroyed in the stomach and must be administered parenterally. Heparin is an indirect anticoagulant because it does not work directly but by binding through a specific pentasaccharide sequence to naturally occurring antithrombin in plasma and inducing a conformational change that increases the inhibitory activity of antithrombin at least 1000-fold. The result is more rapid inhibition of several of the activated serine protease coagulation factors, particularly thrombin (factor IIa) and factor Xa. Heparins are classed as LMWH or unfractionated heparin (UFH).

Unfractionated heparin

For many years, UFH was the only form of heparin available for the treatment and prevention of VTE. In VTE treatment, it is usually administered as an immediate-acting bolus injection followed by an initially weight-based intravenous infusion. It is difficult to use in practice because it is necessary to monitor its effect on the APTT regularly and to adjust the rate of infusion to maintain the APTT ratio (APTT of patient sample compared to midpoint of the normal range) within a target range: typically, an APTT ratio of 1.5 to 2.5. UFH has a short half-life of 1 hour and, if necessary, can be rapidly reversed with a protamine sulfate. It is not excreted through the kidneys. It carries a small but significant risk of major bleeding and of an uncommon but important immunologically mediated, prothrombotic adverse drug reaction, ***HIT*** (see later). Its use nowadays in the treatment of patients with VTE is largely restricted to particular high-risk settings in which its short half-life, reversibility, and lack of renal excretion are advantageous properties. UFH is rarely used for thromboprophylaxis because its short half-life means that it needs to be given two or three times daily by subcutaneous injection.

Low-molecular-weight heparin

LMWHs are the main type of heparin given because of favourable pharmacokinetic properties. LMWH is produced by the chemical or enzymatic degradation of UFH and results in polysaccharide chains of shorter length and molecular weight than UFH. Whereas long chains with at least 18 saccharides are required for inhibition of thrombin by antithrombin, factor Xa is inhibited by shorter chains; therefore, LMWHs inhibit factor Xa to a greater degree than thrombin compared with UFH. LMWH is administered by subcutaneous injection, and peak activity is seen by 4 hours. The half-life of LMWH is longer than that of UFH at 4 hours. LMWH is renally excreted, and caution is required in kidney impairment. Because of its better bioavailability than UFH, it has the major advantage of fixed, weight-based dosing, without the need for laboratory monitoring. As a result, the majority of patients with DVT and many with PE can be treated as outpatients without hospital admission. LMWH is at least as safe and effective as UFH and carries a lower risk of HIT. However, LMWH is only partially reversed by protamine sulfate.

In VTE treatment, standard practice for many years has been to give an initial subcutaneous injection of LMWH while awaiting confirmation of the radiological diagnosis of DVT or PE. LMWH is then switched to an oral agent for ongoing treatment to avoid the need for daily injection, which is usually self-administered by the patient. Warfarin generally requires continuation of LMWH for at least 5 days until it can provide sufficient anticoagulation for LMWH to be stopped. In certain groups, longer-term LMWH is preferred over oral anticoagulants:

- LMWH is used throughout pregnancy because it does not cross the placenta and is therefore not fetotoxic.
- In patients with cancer-associated thrombosis, LMWH is more effective than warfarin and non-inferior to oral factor Xa inhibitors. If the patient has an increased bleed risk because of having (multiple) surgical interventions or is on an interacting medication, LMWH is preferred over oral options.

LMWH is widely used as thromboprophylaxis in patients admitted to hospital or undergoing surgery and has the advantages over UFH of once-daily administration and lower risk of HIT. LMWH (or an alternative anticoagulant) may also be used to reduce morbidity and mortality in patients with acute coronary syndrome, in whom it is usually given twice daily.

Heparin-induced thrombocytopenia

An uncommon but important adverse effect of heparin administration is HIT. Thrombocytopenia typically increases the tendency to bleed, but in HIT, thrombocytopenia is associated with a strong prothrombotic tendency caused by activation of both platelets and the coagulation system. The disorder usually occurs 5 to 14 days after heparin exposure, with a greater than 30% fall in platelet count occurring over 1 or 2 days. The thrombocytopenia is usually mild to moderate, and it is rare for the platelet count to fall below 20 × 10^9/L. HIT is immunologically mediated, with the development by the patient of immunoglobulin G (IgG) antibodies to a complex of heparin and PF4 that is found in and released from platelet granules. Without prompt diagnosis and treatment, the risk of thrombosis, which can be either venous or arterial, is 50% over the next few days. The diagnosis is based on the clinical features, supplemented by laboratory confirmation of IgG antibodies to the heparin–PF4 complex.

If HIT is suspected or confirmed:

- Specialist advice should be sought.
- All heparins should be discontinued (including that used, e.g., to flush indwelling lines).
- The allergic reaction should be noted on the drug chart.
- An alternative, non-heparin anticoagulant should be administered in view of the high rate of thrombosis.

The most common alternative anticoagulants used in this setting are ***danaparoid*** (a heparinoid), ***argatroban*** (an intravenously administered direct thrombin inhibitor), and ***fondaparinux***. Patients who develop HIT should not be re-exposed to heparin in the future without consultation with a haematologist.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide. It binds to antithrombin, and because of its short chain length, it inhibits only factor Xa and not thrombin. It is administered by subcutaneous injection and has a longer half-life than heparin at around 18 hours. It is renally excreted and cannot be used in those with significant kidney impairment. Its effect is not reversed by protamine sulfate.

Oral anticoagulants

All patients commencing oral anticoagulants should be counselled by a qualified healthcare professional covering topics, including correct dosing, the importance of adherence, bleeding risks and features to look out for, lifestyle factors (including avoidance of contact sports), possible future pregnancy, management around the time of clinical procedures, and the need for periodic checks of kidney function when medications are renally cleared.

Oral factor Xa and thrombin inhibitors

- Three oral factor Xa inhibitors (***apixaban, edoxaban,*** and ***rivaroxaban***) and one oral thrombin (factor IIa) inhibitor ***(dabigatran)*** are currently licensed for the treatment of patients with VTE in the UK (**Box 40.3**). Unlike heparin and warfarin, they directly inhibit their target substrates. Peak concentrations are seen about 2 hours after ingestion. They are variably eliminated through the kidneys and have a half-life of around 12 hours. Pharmacological advantages of these agents include:
- A wider therapeutic index than warfarin
- No interaction with dietary factors or alcohol
- Limited interaction (compared with warfarin) with other drugs

Box 40.3 Pharmacological properties of oral anticoagulants

	Warfarin	Apixaban	Edoxaban	Rivaroxaban	Dabigatran
Target	II, VII, IX, X	Xa	Xa	Xa	IIa
Peak effect	5 days (variable)	2 hours	2 hours	2 hours	2 hours
Approximate half-life	40 hours	12 hours	12 hours	9 hours	15 hours
Renal elimination	No	25%	50%	33%	80%
Drug interactions	Multiple	P-gp, CYP 3A4	P-gp	P-gp, CYP 3A4	P-gp
Diet or alcohol interactions	Yes	No	No	No[a]	No
Monitoring	Yes	No	No	No	No
Measurement	INR	Anti-Xa	Anti-Xa	Anti-Xa	Dilute thrombin time
Reversal	Vitamin K, PCC	Andexanet (licensed for life-threatening GI bleeding)	Andexanet (not currently licensed)	Andexanet (licensed for life-threatening GI bleeding)	Idarucizumab

[a]Rivaroxaban should be taken with food to improve bioavailability.
CYP 3A4, Cytochrome P450 3A4; *GI,* gastrointestinal; *INR,* international normalized ratio; *PCC,* prothrombin complex concentrate; *P-gp,* P-glycoprotein.

- Fixed dosing with no monitoring (a major advantage for patient convenience compared with warfarin).

Clinical trials have shown they are as effective as heparin and warfarin in the treatment and secondary prevention of VTE. Overall, they carry a similar or lower risk of major bleeding, with a reduced risk of intracranial haemorrhage, partly offset by an increased risk of gastrointestinal (GI) haemorrhage. Their use in the acute treatment of VTE has already been outlined. The combination of efficacy, safety, simplified dosing, and avoidance of monitoring has led to a rapid increase in their clinical use for VTE treatment and secondary prevention. Collectively the oral factor Xa and thrombin inhibitors are referred to as DOACs (direct oral anticoagulants) or NOACs (non-vitamin K antagonist oral anticoagulants). For edoxaban and dabigatran, after an initial period of at least 5 days of LMWH, a switch can be made to these oral drugs. For rivaroxaban and apixaban, initial LMWH is not required.

Special circumstances

The oral factor Xa and thrombin inhibitors cross the placenta and should not be used in pregnancy or in those trying to conceive. They are also avoided in breast-feeding because of an absence of lactation safety data. The oral factor Xa inhibitors are licensed for VTE treatment down to a creatinine clearance of 15 mL/min, although data are still limited in patients with a creatinine clearance of less than 30 mL/min, the lower limit for dabigatran. Significant interactions with certain drugs such as protease inhibitors and many antiepileptics preclude their use in some patients. They are also contraindicated in those with mechanical heart valve replacements or moderate or severe mitral stenosis. Recent trials suggest that the oral factor Xa inhibitors are as effective as LMWH in the treatment of patients with cancer-associated thrombosis. However, they increase the risk of GI bleeding, and LMWH remains the preferred option in patients with cancers in whom this is a risk. Oral factor Xa inhibitors are not recommended in patients with thrombotic APS because of an increased risk of arterial thrombosis (especially stroke) compared with warfarin in clinical trials.

Management of bleeding on oral factor Xa and thrombin inhibitors

Management of ***major bleeding*** follows established principles:

- The oral factor Xa or thrombin inhibitor should be stopped.
- Supportive therapy, such as intravenous fluids and blood components, should be administered as appropriate.
- Consideration should be given to targeted intervention (e.g., endoscopy).

In the event of ***life-threatening bleeding***, specific antidotes are emerging as additional options. In the case of dabigatran, a monoclonal antibody, ***idarucizumab***, that rapidly binds and completely reverses dabigatran is now available and can also be used to reverse dabigatran before urgent surgery. An antidote to apixaban and rivaroxaban, ***andexanet alfa***, is approved by NICE for use in those with life-threatening or uncontrolled GI bleeding. Other national regulators have licensed its use for reversal of oral factor Xa inhibitors in intracranial haemorrhage. In the absence of an antidote, prothrombin complex concentrate (PCC) administration should be considered.

Vitamin K antagonists

These agents are indirect anticoagulants that inhibit the final stage of the synthesis of vitamin K–dependent proteins in the liver: clotting factors II (prothrombin), VII, IX, and X and the naturally occurring anticoagulants protein C and protein S. The main vitamin K antagonist used in the UK is ***warfarin***. The full anticoagulant effect of warfarin takes at least 5 days because it affects only synthesis of new proteins; those already circulating or fully formed in hepatocytes are unaffected and decline as a function of their half-lives, which vary from 6 hours (factor VII) to 60 hours (prothrombin). Therefore, in the setting of VTE treatment, in which an immediate anticoagulant effect is desired, it is necessary to commence with a quick-acting anticoagulant such as heparin and to continue until warfarin is providing sufficient anticoagulation on its own.

The anticoagulant effect of vitamin K antagonists is measured using the ***prothrombin time (PT)***, which measures the extrinsic and common pathways of the coagulation system. Because different laboratories use different reagents with different sensitivities and normal ranges to measure the PT, a system has been devised to standardize assessment of the degree of anticoagulation by the vitamin K antagonists. In this system, the PT for each patient test (compared with the normal PT of the general population not on anticoagulants) is converted to a standardized ratio, the ***INR***. This enables comparison between results in different laboratories, and target ranges defined in clinical trials can be adopted into clinical

practice. The higher the INR, the greater the anticoagulation. For most patients taking warfarin for VTE treatment, the target INR is 2.0 to 3.0. A small proportion of patients (e.g., those who have a recurrent VTE episode while the INR is in the target range or with high-risk mechanical heart valve replacements) need to be more intensively anticoagulated, and the target range may be set at 3.0 to 4.0, reflecting greater prolongation of the PT.

Warfarin is metabolized in the liver and has a half-life of about 36 hours. It has a narrow therapeutic index and a wide range of interactions with dietary factors, alcohol, and other medications. Drug interactions can be either ***pharmacokinetic*** or ***pharmacodynamic***. The former include drugs that either induce or inhibit warfarin metabolism by the cytochrome P450 system, thereby reducing or increasing warfarin concentrations and the resulting INR. The latter are exemplified by aspirin and clopidogrel, which do not affect warfarin concentrations but increase the bleeding risk of warfarin through antiplatelet effects. For reasons that are partly genetic, there is considerable variation between individuals in the warfarin dose required for the same effect on the INR.

Monitoring warfarin therapy

During the initial period of anticoagulation with warfarin and heparin, it is necessary to measure the INR frequently (almost daily) so that the dose of warfarin can be adjusted and heparin can be discontinued when the INR is in the target range for 2 consecutive days. After this initial period, the frequency of INR monitoring can be reduced, but it remains necessary on a long-term basis at least every 8 to 12 weeks in patients whose INR control is stable and more frequently in those with unstable INRs to allow appropriate dose adjustment. that is, a dose increase if the INR is below target and a dose reduction and/or omission if the INR is too high. INR monitoring is usually done either in hospital-based anticoagulant clinics or in general practice, with emerging availability for self-testing of INRs at home using point-of-care coagulometers.

Pregnancy and breast-feeding

In general, warfarin should not be used in pregnancy because it crosses the placenta and is teratogenic between the 6th and 12th weeks of pregnancy, as well as causing fetal bleeding later in pregnancy. It does not cross into breast milk and therefore is safe during breast-feeding.

Risks of warfarin therapy

The main risk of warfarin is bleeding. Most bleeds are not major. The risk of major bleeding is around 2% per year, and about 0.25% patients per year will have a fatal bleed, usually caused by intracranial haemorrhage. Most bleeds occur when the INR is within the therapeutic range, but the higher the INR is, the greater the risk of a major bleed. Management of high INRs and of bleeding on warfarin is shown in **Box 40.4**.

Peri-procedural management of anticoagulation

Given the increasing number of people taking oral anticoagulants for AF, VTE treatment and secondary prevention, and mechanical heart valve replacements, management around the time of operations and procedures is a common clinical concern. The British Society for Haematology and other national specialty societies have produced guidelines, and most hospitals have adapted these for local use.

Anticoagulant management around the time of procedures depends on the bleeding risk of the procedure (high, low, or negligible), the thrombotic risk during anticoagulant interruption (high or low), the anticoagulant used (warfarin vs an oral factor Xa or thrombin inhibitor), and whether the procedure is elective or emergency.

Box 40.4 Management of high international normalized ratios (INRs) and bleeding in patients taking warfarin

INR >5.0, no bleeding

1. Withhold warfarin.
2. Reduce maintenance warfarin dose.
3. Investigate cause of elevated INR.

INR >8.0, no bleeding or minor bleeding

1. Withhold warfarin.
2. If no bleeding, give 1–5 mg ***p.o.*** vitamin K.
3. If minor bleeding, give 1–3 mg ***i.v.*** vitamin K.
4. Recheck INR within 24 hours.

Major bleeding

1. Withhold warfarin.
2. Give four-factor PCC 25–50 u/kg. (Give FFP 15 mL/kg only if PCC is not available.)
3. Give 5 mg i.v. vitamin K.
4. Recheck INR after administration of PCC.
   In the event of bleeding, investigate a local anatomical cause.

FFP, Fresh-frozen plasma; *i.v.,* intravenous; *PCC,* prothrombin complex concentrate; *p.o.,* oral; *u,* units.
From Keeling D, Baglin T, Tait C et al. and British Committee for Standards in Haematology. Guidelines on oral anticoagulation with warfarin—fourth edition. Br J Haematol *2011; 154:311–324.*

Elective procedures

Some procedures have a negligible bleeding risk, and anticoagulation can continue uninterrupted. Others carry a significant bleeding risk, and anticoagulation must be stopped in advance and only reintroduced when safe to do so after the procedure.

Because of their short half-life, this is generally straightforward for the oral factor Xa and thrombin inhibitors. Oral factor Xa inhibitors need to be discontinued at least 48 hours before procedures with a high bleeding risk (72 hours if creatinine clearance <30 mL/min) and at least 24 hours before procedures with low bleeding risk (48 hours if creatinine clearance <30 mL/min). Because of the predominant renal excretion of the oral thrombin inhibitor dabigatran, these times are extended in those with moderately impaired kidney function (creatinine clearance 30–50 mL/min) and even more so in those with significantly impaired kidney function (creatinine clearance <30 mL/min). The re-introduction of oral factor Xa and thrombin inhibitors after the procedure may have to be delayed by 2 to 3 days if the bleeding risk is high. Standard thromboprophylaxis should be considered in the interim.

Because of its long half-life, warfarin needs to be stopped for 5 days before procedures associated with a bleeding risk, assuming the INR is in the therapeutic range at the outset. Patients at high risk of thrombosis during this interruption are considered for bridging therapy with therapeutic dose of LMWH starting 48 to 72 hours after the last warfarin dose and with the last dose given at least 24 hours before the procedure to give it time to clear. LMWH and warfarin are resumed when safe to do so after the procedure, generally at least 48 hours later in those with a high bleeding risk with thromboprophylaxis considered in the interim. Patients who are at high thrombotic risk and considered for bridging during warfarin interruption include those with:

- A VTE episode within the previous 3 months or recurrent episode on anticoagulants
- AF with a stroke or transient ischaemic attack within the previous 3 months or with a CHA_2DS_2-VASc score of 5 or more

- A mechanical heart valve replacement (excluding a bileaflet aortic valve and no other risk factors).

Consideration should be given to deferring elective procedures in those with a VTE episode within the previous 3 months.

Emergency procedures

Multidisciplinary discussion is often necessary when patients taking oral anticoagulants present needing urgent surgery. For patients taking oral factor Xa inhibitors, which have no available antidote, a decision is required on whether it is preferable to proceed with emergency surgery or delay by 12 to 24 hours or more to allow the drug to clear. The time the drug was last taken, measurement of kidney function, and drug concentration (if available) should be considered. PCC should be available if surgical bleeding occurs.

For patients taking dabigatran, idarucizumab is licensed for reversal before emergency surgery or urgent procedures. A multidisciplinary discussion should therefore involve whether to proceed to emergency surgery with or without idarucizumab administration or delay until the drug had cleared naturally.

Because of its long half-life, warfarin reversal is usually necessary before urgent surgery. The INR should be checked. PCC reverses warfarin coagulopathy almost immediately by replacing the vitamin K–dependent clotting factors. The effect wears off over a number of hours, and a small dose of vitamin K is generally given to extend the period of warfarin reversal. If surgery is urgent but will wait 12 to 24 hours, it may be reasonable to administer vitamin K alone to reverse the coagulopathy. After surgery, warfarin can be re-introduced when safe to do so, generally with administration of LMWH at prophylactic or treatment dose until the INR reaches a therapeutic level when warfarin can continue alone.

CORE SKILLS AND KNOWLEDGE

In high-income countries, nearly half of the population will develop cancer at some time during their lives, and it is second only to cardiovascular disease as a cause of death. Many advances have been made in recent years in terms of both the molecular understanding and the targeted treatments of different cancers.

Patients are diagnosed with cancer in a number of different settings: by screening, via their general practitioners, as an emergency admission, or in a routine hospital outpatient or inpatient encounter. Many professionals are involved in the care of patients with cancer, and management decisions are made at multidisciplinary team (MDT) meetings (usually tumour site specific), with input from surgeons, oncologists, radiologists, pathologists, palliative care physicians, clinical nurse specialists, and allied health professionals.

Oncologists are trained to deliver radiotherapy and systemic therapy. They must combine clinical skill and knowledge with empathy and excellent communication skills because they often see patients when they are at their most vulnerable.

Key learning outcomes in malignant disease include:

- Understanding the biology of cancer, including its presentation and natural history
- Understanding the goals of treatment (cure, prolonging life expectancy, and palliation) and the principles underlying the main classes of cancer intervention (surgery, chemotherapy, radiotherapy, hormonal therapy, targeted therapy, and immunotherapy)
- Being able to assess patients with malignant diseases, understanding where patients are in the course of their disease and treatment, and communicating likely outcomes
- Managing emergencies caused by the cancers themselves (e.g., spinal cord compression) or by anticancer treatment (e.g., neutropenic sepsis).

Opportunities for learning about malignant disease include reviewing patients undergoing urgent investigation for malignant disease (e.g., in urgent referral outpatient clinics), attending cancer MDT meetings, visiting chemo- and radiotherapy day units, attending clinics with treating clinicians, and shadowing clinical nurse specialists.

CLINICAL SKILLS

History

The history needs to be tailored to the clinical setting: in a patient being investigated for malignant disease, diagnostic questions are crucial, as is patient's functional status.

In a patient already undergoing active therapy, questions about treatment-related symptoms and general fitness are more relevant. At all stages, it is necessary to consider how the patient is coping with the emotional challenges of confirmed or suspected malignancy and to adopt an empathetic and caring approach.

The questions in **Box 41.1** are grouped into different sections that can be brought together according to the clinical setting. Patients often present with non-specific systemic symptoms such as weight loss, malaise and lethargy, pains all over, and 'not feeling great'; for these patients, it can be worth using 'review of systems' questions to slowly tease out specific system-based problems.

Investigations

Cancers require both radiological and histological evaluation for a complete diagnosis (**Box 41.2**). The findings are used to establish histological grade and radiological staging, according to internationally agreed systems specific to each type of malignancy.

Formulating a management plan

A diagnosis of cancer can have different implications for a patient. After seeing patients with a confirmed or suspected malignancy, it is crucial to establish where they are in the disease process. Are they previously fit and well but recently diagnosed with a potentially curable disease? Or are they into their third cycle of chemotherapy for metastatic malignancy, with few additional treatment options left? Asking the questions in **Box 41.3** will shed light on the patient's perspective, and the answers can then be supplemented by reviewing medical records for investigation results and details of MDT discussions.

i Box 41.1 Taking a history in malignant disease

General symptoms of malignancy

- Weight loss
- Anorexia, loss of appetite
- Malaise, weakness, and tiredness
- Paraneoplastic syndromes

Common site-specific symptoms

- Brain: seizures, any focal neurological symptoms, personality change
- Lung: cough, haemoptysis, chest wall pain (if invasive), breathlessness
- Oesophagus and stomach: mechanical dysphagia, early satiety, regurgitation, symptoms of anaemia caused by occult blood loss
- Hepatobiliary tract: upper abdominal pain and heaviness, jaundice
- Colon and rectum: altered bowel habit, rectal bleeding, tenesmus, symptoms of anaemia from blood loss
- Breast: breast lump, skin changes, nipple discharge
- Prostate: obstructive lower urinary tract symptoms
- Ovary: abdominal discomfort and bloating
- Cervix and endometrium: postmenopausal, intramenstrual, or postcoital bleeding
- Thyroid: neck swelling, thyrotoxicosis
- Urinary tract: painless haematuria
- Bone: dull bony pain, pathological fractures, back pain
- Mouth and throat: non-healing ulcer, voice change, hoarseness
- Skin: progressive moles or ulcers
- Metastases: may present with any of the above symptoms and are most common to the long bones, spine, liver, lung, and brain

Risk factors

- Smoking
- Obesity
- Air pollution
- Industrial exposure: asbestos, chemicals, dyes, dusts
- Viral infection: hepatitis viruses, human immunodeficiency virus, human papillomavirus, Epstein–Barr virus
- Lack of engagement with screening: breast, cervix, bowel

Common chemotherapy related side-effects

- Nausea and vomiting
- Oral mucositis
- Anorexia, loss of appetite
- Diarrhoea
- Peripheral neuropathy
- Fever: if present, always consider neutropenic sepsis, which is a medical emergency

i Box 41.2 Investigation of malignant disease

Radiology

- Typically, a CT scan of the chest, abdomen, and pelvis is performed to assess the local tumour site for the size of the tumour and for signs of localized invasion.
- ^{18}FDG-PET/CT scanning may be used if there is evidence of lymphadenopathy to assess whether lymph nodes are metabolically active, which may suggest malignant spread.
- Other forms of imaging are used if symptoms are suggestive of malignancy (e.g., a contrast-enhanced CT scan of the head to look for brain metastases, a radiolabelled technetium bone scan to assess for bony metastases).

Histology

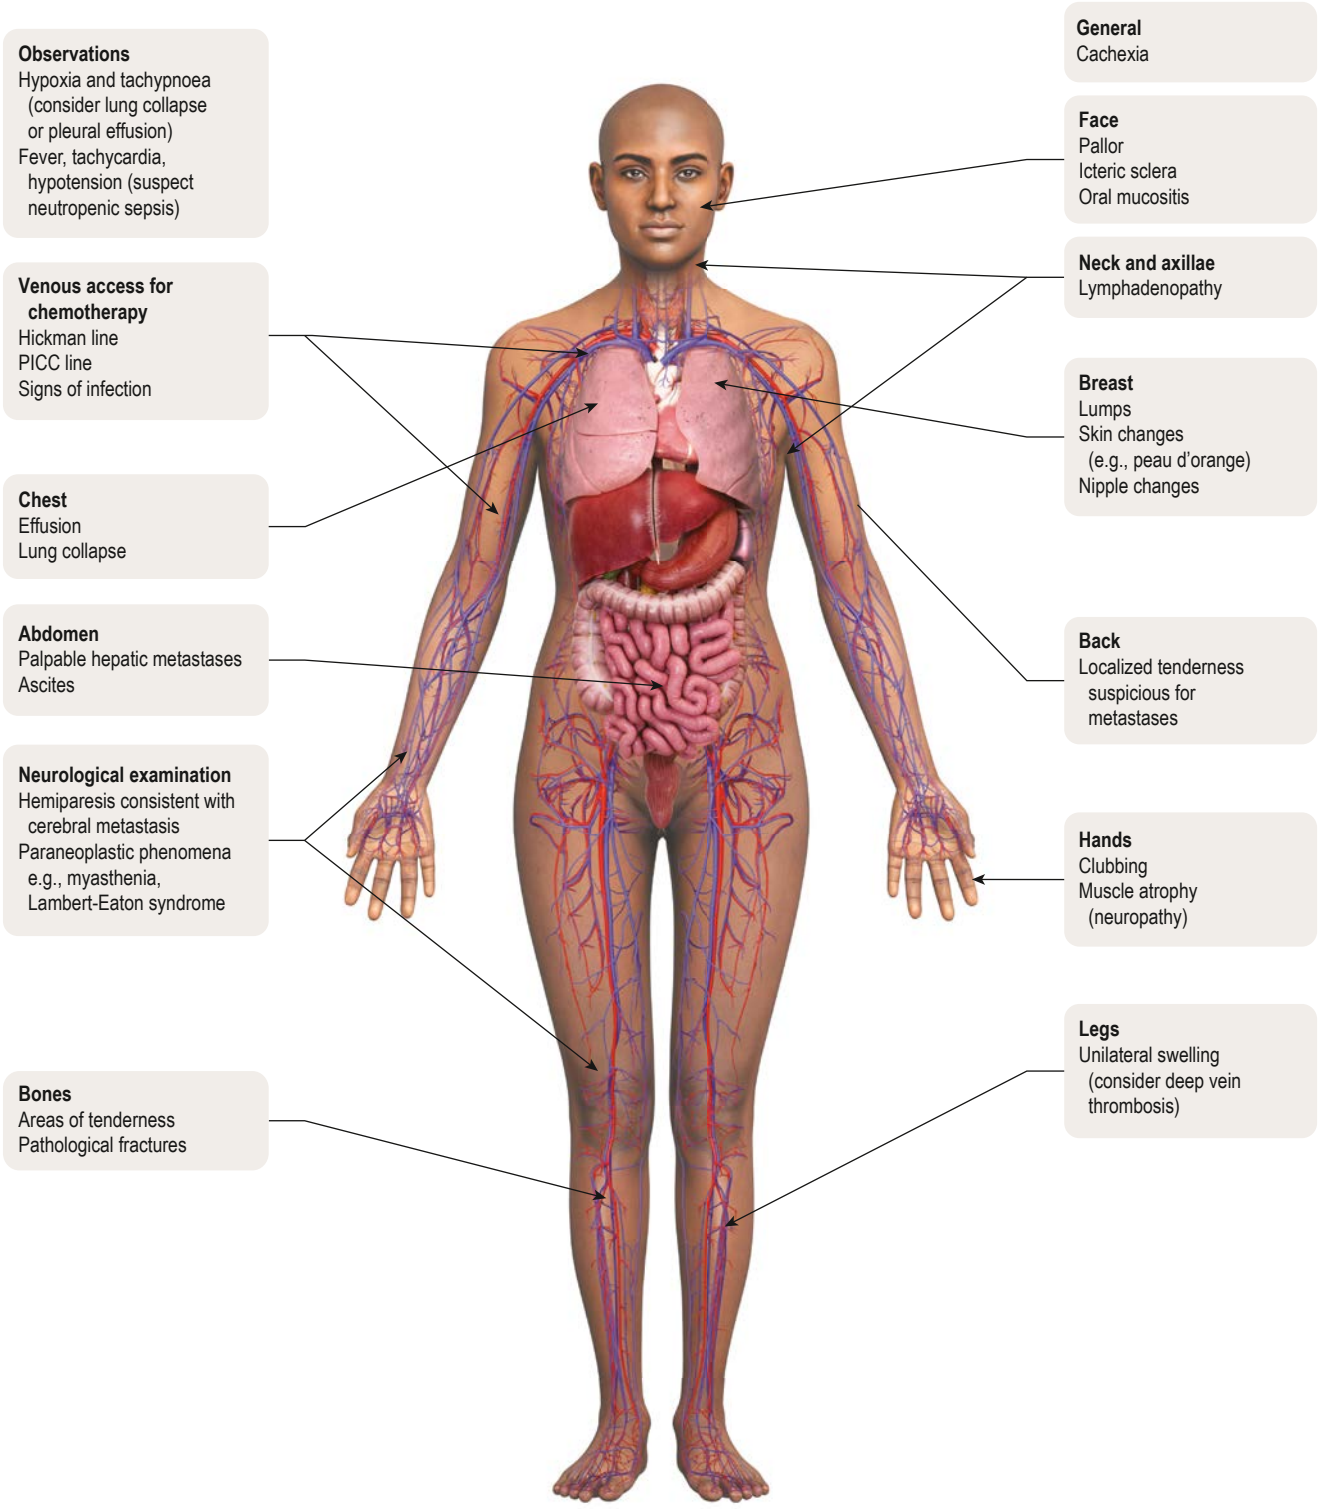
- Tissue biopsy is generally required for all forms of malignancy before treatment is considered.
- Basic histology confirms the tumour type (classified by the original cell type (e.g., adenocarcinoma from glandular epithelium), the degree of differentiation (poor differentiation is a bad prognostic sign), and local neurovascular invasion.
- More advanced techniques may look for expression of cell-surface molecules predictive of response to treatment (e.g., the oestrogen receptor in breast cancer).
- Genetic sequencing of tumour material has the potential to allow therapeutic regimens to be designed that target the particular genetic abnormalities in the malignant cells present.

CT, Computed tomography; *^{18}FDG*, ^{18}fluorodeoxyglucose; *PET*, positron emission tomography.

Box 41.3 Implications of a cancer diagnosis for the patient

- When was the patient diagnosed?
- What do they understand about the condition?
- Have they been offered surgery, chemotherapy, radiotherapy, or other forms of treatment?
- What do they understand about the aims of the treatment—cure or palliation?
- What do they understand about the likely outcomes of their disease?
- How do they feel about further courses of treatment?
- Who is supporting them through their disease, and what other sources of support (e.g., social networks, religious faith) do they have?
- Do they have late effects from their curative treatment?

Examination



BACKGROUND

Cancer is on the rise globally, driven by a range of factors, including obesity, urbanization, air pollution, tobacco smoking, and increasing life expectancy in the developing world. The Global Cancer Observatory predicts that the worldwide incidence of cancer will rise by 56% between 2020 and 2040. In the UK, the number of new cases of cancer continues to increase, with more than 375 000 new cancers registered between 2016 and 2018, equivalent to 1000 new cases a day. Of these, more than 50% were accounted for by breast (15%), prostate (14%), lung (13%), and colorectal (11%) malignancies, although globally, there is significant variation in the pattern of malignant disease, reflecting differences in environmental risk factors. The global burden of different types of cancer is shown in Fig. 41.1. Cancer is a disease of older people, with those older than 75 years accounting for 36% of total registered cancers.

Data from the UK suggests that although most patients with cancer are diagnosed after presenting to primary care with symptoms of malignancy, about 25% are diagnosed in the context of an emergency presentation requiring hospital attendance or admission. Patients diagnosed in an emergency situation tend to have worse outcomes because their cancers are more aggressive or more advanced at presentation.

An appreciation of the genetic and biological basis of cancer is crucial in understanding how the disease progresses and how different modalities of treatment work.

PRINCIPLES OF ONCOLOGY

THE BIOLOGY OF CANCER

Most human neoplasms are clonal in origin: that is, they arise from a single population of precursor or cancer stem cells. This process is typically initiated by genetic aberrations within this precursor cell that may be inherited (germline) or acquired (somatic). Cancer

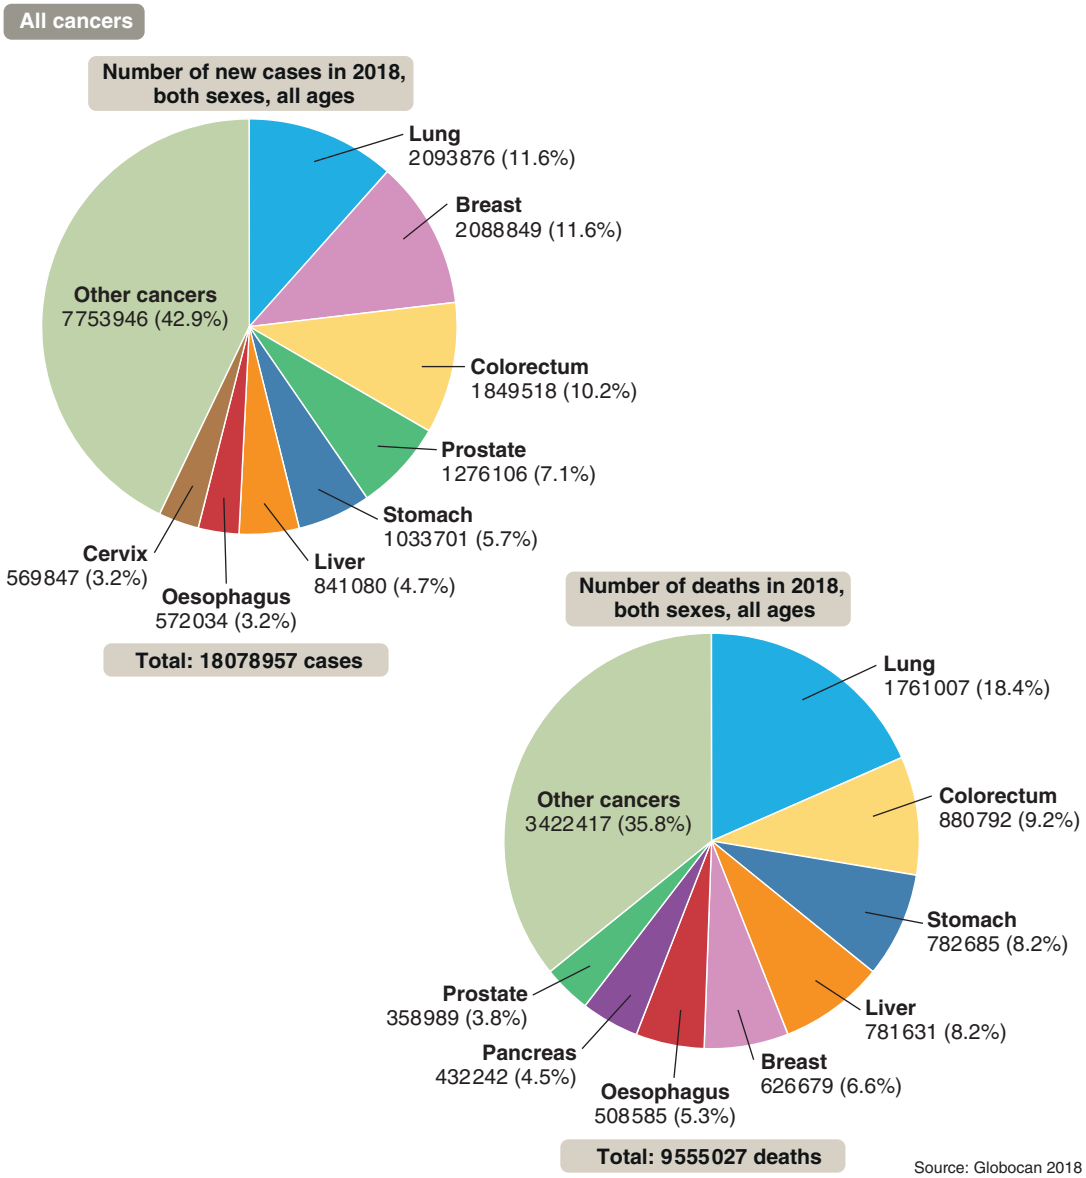


Fig. 41.1 The worldwide burden of cancer: new cases and deaths in 2018. (*GLOBOCAN 2018 Graph production: IARC [http://gco.iarc.fr/today]. World Health Organization.*)

becomes increasingly common with increasing age and can be related to a time-dependent accumulation of DNA damage that is not repaired by the normal mechanisms of genome maintenance, damage tolerance, and checkpoint pathways. The hallmark areas of loss or gain in function in developing cancer are shown in **Fig. 41.2**.

Whole-genome sequencing experiments are now identifying significant clonal genetic heterogeneity within tumours, including 'passenger' (inactive) and 'driver' (active) mutations. This heterogeneity is a potential source of treatment-resistant clones and is temporally variable, so that, at relapse, the predominant founder clone that has not been eradicated is seen to have acquired new mutations on its return; alternatively, a subclone, selected out by treatment pressure, has gained further mutations and led to a recurrence. A fuller description of the genetic basis of cancer is found in Chapter 5.

Evading growth suppression

Tumour cells are usually not recognized and killed by the immune system for two main reasons:

- There is a failure to express molecules such as human leucocyte antigen and co-stimulatory B7 molecules that are required for activation of cytotoxic, or 'killer', T lymphocytes.
- Tumours may also actively secrete immunosuppressive cytokines and cause a generalized immunosuppression.

Successful strategies for tumour vaccines that overcome these obstacles are developing in renal cancer and prostate cancer. The monoclonal antibody (MAb) ipilimumab, which works against the inhibitory cytotoxic T lymphocyte–associated antigen 4 (CTLA4) molecule expressed after T-cell activation, is used in patients with melanoma and renal cell carcinoma. Multiple tumours respond to immunotherapy targeting the programmed death pathway (PD/PD-ligand), a checkpoint inhibitor (see Fig. 6.8) that negatively affects the immune response. Blocking of either programmed death protein 1 (PD-1) (on T cells) or its ligand, programmed death ligand 1 (PDL-1), which is present in some tumours, has been associated with an immune response capable of producing durable tumour shrinkage. Common tumours, such as breast, lung, head and neck, gastrointestinal (GI), and transitional cell carcinomas (TCCs), have all shown response to PD-1– or PD-L1–targeted immunotherapy. This class of anticancer therapies, commonly known as immunotherapies, now has a role in tumours from common endometrial cancers to rare Merkel cell carcinomas and are likely to be commonly encountered in the acute medical setting as their use increases. They present a unique set of challenges because their side-effect profiles differ from those of conventional chemotherapy agents.

Inducing angiogenesis

As a tumour grows larger, its rate of growth progressively slows down. This occurs for many reasons, but outgrowing the blood supply to the tumour is a crucial factor. New vessel formation (angiogenesis) is stimulated by a variety of peptides produced both by tumour cells and by host inflammatory cells, such as basic fibroblast growth factor, angiopoietin 2, and vascular endothelial growth

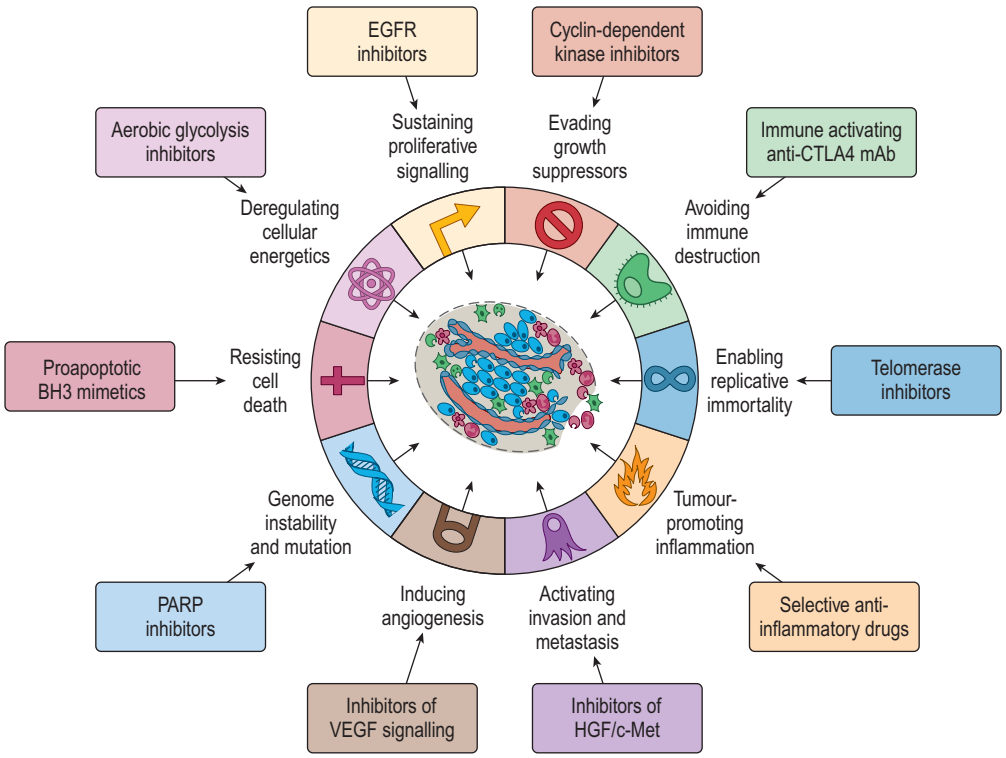

Fig. 41.2 The hallmarks of cancer. Ten biologically damaging capabilities are acquired during the multistep development of human tumours. Different colours indicate different actions of malignant cells, as depicted in the circle. Each of these can be targeted by anticancer drugs, as shown by the different-coloured rectangular boxes. In multitargeting, toxicity to normal healthy tissue is a major challenge. *BH3,* Member of bcl2 family of proteins/homologue BH3; *CTLA4,* cytotoxic T lymphocyte–associated antigen; *EGFR,* epidermal growth factor receptor; *HGF/c-Met,* hepatocyte growth factor/c-Met receptor complex; *PARP,* poly-ADP ribose polymerase; *VEGF,* vascular endothelial growth factor. (*From Hanahan D. The cancer wars 2: rethinking the war on cancer.* Lancet *2014; 383:558–563, with permission. Adapted from Hanahan D, Weinberg PA. The hallmarks of cancer: the next generation.* Cell *2011; 144:646–474*).

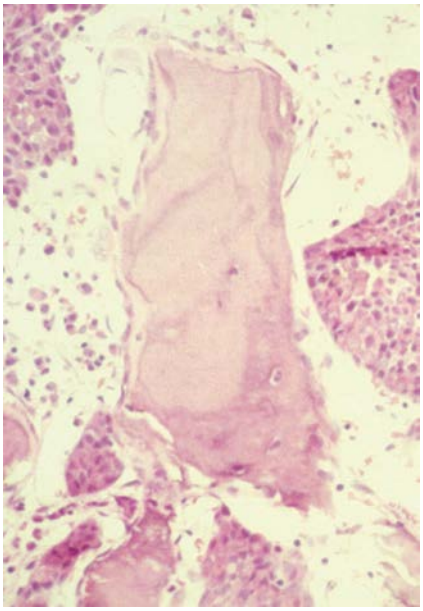

Fig. 41.3 Bone metastasis with osteoclast and osteoblast activation.

factors (VEGFs), which are stimulated by hypoxia. The anti-VEGF receptor MAb bevacizumab has had some success in the treatment of GI, cervical, and ovarian cancers. Alternatively, small molecules that target post-receptor response (tyrosine kinase inhibitors [TKIs]) may be used; examples include sunitinib and pazopanib.

Invasion and metastasis

Solid cancers spread by both local invasion and distant metastasis (Fig. 41.3), through the vessels of the blood and lymphatic systems. Infiltration into surrounding tissues is associated with loss of cell–cell cohesion, which is mediated by active homotypic cell adhesion molecules. Epithelial cadherin (E-cadherin) is expressed by many carcinomas and mutated in some, such as familial gastric carcinoma.

Invasion is also determined by the balance of activators and inhibitors of proteolysis. The matrix metalloproteinases and their tissue inhibitors are involved in tumour growth, invasion, metastasis, and angiogenesis and are being targeted by new therapeutic drugs for cancer treatment.

Dissemination of tumour cells occurs through intravasation into the vascular and lymphatic vessels and dissemination to distant sites, partly by chance but also because of specific interactions between receptors and cytokines found on stromal and tumour cells, such as tumour necrosis factor (TNF), interleukin 6 (IL-6), and chemokines.

AETIOLOGY AND EPIDEMIOLOGY

In most patients, the cause of cancer is unknown, probably representing a multifactorial interaction between individual genetic predispositions and environmental factors.

? Box 41.4 Some causative factors associated with the development of cancer

Causative factor	Neoplasms
Smoking	Mouth, pharynx, oesophagus, larynx, lung, bladder, lip
Obesity	Breast, bowel, pancreas, gynaecological, oeseophageal, thyroid
Alcohol	Mouth, pharynx, larynx, oesophagus, colorectal
Iatrogenic	
Alkylating agents	Bladder, bone marrow
Oestrogens	Endometrium, vagina, breast, cervix
Androgens	Prostate
Radiotherapy (e.g., mantle radiotherapy)	Breast, bronchus
Diet	
High-fat diet, obesity	Colorectal
Environment, occupation	
Air pollution	Lung
Vinyl chloride	Liver (angiosarcoma)
Polycyclic hydrocarbons	Skin, lung, bladder
Aromatic amines	Bladder
Asbestos	Lung, mesothelium
Ultraviolet light	Skin, lip
Radiation	Leukaemia, thyroid cancer
Aflatoxin	Liver
Biological agents	
Hepatitis B virus	Liver (hepatocellular carcinoma)
Hepatitis C virus	Liver (hepatocellular carcinoma)
Epstein–Barr virus	Nasopharyngeal carcinoma
Human papillomavirus types 16 and 18	Cervix
	Oral (type 16)
Schistosoma japonicum	Bladder
Helicobacter pylori	Stomach

Aetiology

Genetic factors

These are outlined in Chapter 5 ('The genetic basis of cancer' section).

Environmental factors

A wide range of environmental factors has been identified as being associated with the development of malignancy (Box 41.4) and may be amenable to preventive action, such as smoking cessation, dietary modification, and antiviral immunization (Box 41.5). Environmental factors interact with genetic predisposition. For example, subsequent generations of people moving from countries with a low incidence of breast or colon cancer to those with a high incidence acquire the cancer incidence of the country to which they have moved, and Northern Europeans exposed to strong ultraviolet (UV) radiation have the highest risk of developing melanoma.

Tobacco

Since the mid-1990s, the incidence of lung cancer, in both males and females, has increased dramatically worldwide but is falling in many high-income countries. The association of smoking with lung cancer is indisputable, and causative mechanisms have been identified;

Box 41.5 Key messages for a healthy lifestyle and the prevention of cancer

- Stop smoking.
- Consume alcohol in moderation.
- Maintain a healthy weight.
- Take moderate exercise.
- Eat healthily (fruit and vegetables; high fibre; low fat, salt, and sugar).
- Limit sun exposure.
- Minimize occupational risk.
- Minimize radiation exposure.
- Vaccinate against hepatitis B and human papillomavirus.

cigarette tobacco is responsible for one-third of all deaths from cancer in the UK. Smoking not only causes lung cancer but also is associated with cancer of the head and neck, GI tract, kidney, cervix, and bladder. Smoking cessation is discussed in Chapter 20 ('Smoking cessation' section).

Obesity

Obesity has been identified as the second largest cause of cancer in the UK after tobacco smoking. It has been associated with increased incidents of many types of tumour, including tumours of the GI and biliary tract, breast, uterus, ovary, and thyroid. Cancer risk is related to the degree and duration of obesity and reduces with successful weight loss. Causative mechanisms identified include DNA damage through chronic inflammation, metabolic stress as a result of insulin resistance, and increased growth stimulus on cells mediated by high serum levels of growth hormone and sex steroids.

Alcohol

Alcohol is associated with cancers of the upper respiratory and GI tracts, and it also interacts with tobacco in the aetiology of these tumours. It may be associated with an increased risk of breast cancer.

Diet

One-third of cancer deaths have been attributed to dietary factors, although it is often difficult to differentiate these from other epidemiological causes. For example, whereas the incidence of stomach cancer is particularly high in the Far East, breast and colon cancers are more common in Western high-income countries. Many associations have been observed without a causative link being identified between the incidence of cancer and the consumption of food constituents, including dietary fibre, red meat, saturated fats, salted fish, vitamin E, vitamin A, and many others.

Ultraviolet light

UV light is known to increase the risk of skin cancer (basal cell, squamous cell, and melanoma). The incidence of melanoma is therefore particularly high in the White Anglo-Celtic populations of Australia, New Zealand, and South Africa, where exposure to UV light is combined with a genetically predisposed population.

Arsenic contamination

Arsenic contamination of water supplies has been linked to a high incidence of lung and colon cancers in South-east Asia, particularly where boreholes are the main water source.

Occupational factors

In 1775, Percival Pott described the association between carcinogenic hydrocarbons in soot and the development of scrotal epitheliomas in chimney sweeps. The principal causes nowadays are ***asbestos*** (lung and mesothelial cancer) and ***polycyclic hydrocarbons*** from fossil fuel combustion (skin, lung, and bladder cancers). ***Organic chemicals***, such as benzene, may cause the development of bone marrow conditions, such as myelodysplastic syndrome and acute myeloid leukaemia.

Infectious agents

The geographical distribution of some rare malignancies led to the discovery that cancer may be caused by infective agents. Chronic persistent infection provides growth stimulation, and many viruses contain transforming viral oncogenes.

T-cell leukaemia, seen almost exclusively in residents of the southern island of Japan and in the West Indies, is caused by infection with the locally endemic retrovirus human T-cell leukaemia (or lymphotropic) virus type 1 and integration of the oncogene *TAX* into the cellular genome.

Hepatocellular carcinoma (HCC) occurs in patients with hepatitis B and C virus infections, and Burkitt's lymphoma and nasopharyngeal carcinoma are associated with the Epstein–Barr virus (EBV). EBV is also linked with Hodgkin lymphoma (see Chapter 39).

Patients with human immunodeficiency infection or immunosuppression from organ transplantation have an increased incidence of EBV-related lymphoma and herpesvirus-8-associated Kaposi's sarcoma.

Human papillomavirus (HPV) infection types 16 and 18, for which an effective vaccine is available, is an established cause of a rise in cervical cancer among sexually active females; it has also been associated with an increase in head and neck cancers. Bacterial infection with *Helicobacter pylori* predisposes to the development of gastric cancer and gastric lymphoma, and *Schistosoma japonicum* infection predisposes to the development of squamous cell carcinomas (SCCs) in the bladder.

Medication

Oestrogens have been implicated in the development of vaginal, endometrial, and breast carcinoma. Certain cytotoxic drugs, such as those given for Hodgkin lymphoma (see Chapter 39), are associated with an increased incidence of secondary acute myeloid leukaemia and bladder and lung cancers. Androgens have been linked with both benign and malignant liver tumours.

Radiation

Accidental

The nuclear incidents at Hiroshima, Nagasaki, and Chernobyl led to an increased incidence of leukaemia after 5 to 10 years in the exposed population, as well as greater incidences of thyroid and breast cancer. Radiation workers are at a higher risk of malignancy because of occupational exposure unless precautions are taken to minimize the danger by using personal and environmental shielding and to record and limit the amount of personal exposure.

Therapeutic

Long-term survivors who have been treated with radiotherapy, such as those with Hodgkin lymphoma, for which patients were historically treated with wide radiation fields, have an increased incidence of cancer, particularly at the radiation field margins. These patients should have regular surveillance follow-up, for example, for the early identification of breast cancer in the previously treated Hodgkin lymphoma cohort of patients.

Diagnostic

Imaging procedures involving radiation exposure are associated with an increased risk of cancer. This risk is cumulative, dose dependent, and time dependent, so children are at higher risk than

Box 41.6 Radiation exposure from common diagnostic radiological procedures[a]

Procedure	Radiation exposure (mSv)
Chest X-ray	0.02
Chest CT	7
Abdomen CT	8–10
Whole-body CT	20
Percutaneous coronary intervention	15
Myocardial perfusion imaging	15.6

[a]UK background radiation is 2.6 mSv per year. 1 mSv carries a lifetime cancer risk of 1 in 17 500, and 5 mSv carries a risk of 1 in 3500.
CT, Computed tomography.
Modified from Smith-Bindman R, Lipson J, Marcus R et al. Radiation dose associated with common computed tomography examinations and the associated lifetime attributable risk of cancer. Arch Intern Med *2009; 169:2078–2086 and Fazel R, Krumholz HM, Wang Y et al. Exposure to low-dose ionizing radiation from medical imaging procedures.* N Engl J Med *2009; 361:849–857.*

adults. The cancer risk of various common investigations is shown in **Box 41.6**. All doctors should strive to minimize diagnostic exposure to radiation where possible by using alternative modalities such as ultrasonography or magnetic resonance imaging (MRI). Good documentation of radiation doses is required, particularly in children and pregnant females.

Epidemiology

Geographical distribution

The incidence of cancer across the world depends on local environmental factors, diet, and the genetics of the local population (see interactive maps at the International Agency for Research on Cancer: https://gco.iarc.fr/today/en/dataviz/pie?mode=population&group_populations=0, and **Fig. 41.4**). Age is also a factor because most cancers occur in those older than the age of 65 years, who make up 3.3% of the population in Africa compared with 15.2% in Europe. Reproductive patterns influence the incidence of breast cancer. Migrating individuals often take on the risks associated with local environmental factors.

Other factors

Incidence and mortality rates are closely linked for cancers for which treatment has yet to make significant improvements, such as lung, pancreas, stomach, and liver cancers. However, in countries with effective screening programmes, there are increasing incidences but decreasing mortality rates for breast, cervix, bowel, and prostate cancers.

SCREENING AND INVESTIGATIONS

Asymptomatic detection through screening

Most common cancers start as focal microscopic clones of transformed cells, and diagnosis becomes likely only when sufficient tumour bulk has accumulated to cause symptoms or signs. To make an earlier diagnosis and enhance the curative possibility, an increasing number of screening programmes are being developed that either target the asymptomatic or pre-invasive stages of the cancer, as in cervix, breast, lung, and colon cancers, or use serum tumour markers, as in prostate cancer. 'Circulating tumour DNA' (ctDNA) is a subtype of serum cell-free DNA derived from cancer cells that contains mutations known to associate with malignancy. It is a promising biomarker that may allow early diagnosis of cancer from a single blood test.

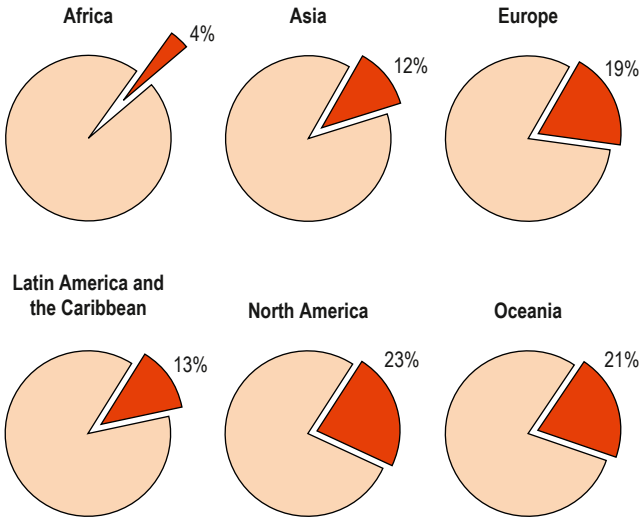

Fig. 41.4 Percentage of all deaths from cancer in different regions of the world. *(From https://gco.iarc.fr/today/en/dataviz/pie?mode=population&group_populations=0.)*

Genetic screening can be used to target screening to those groups at most risk of developing cancer, such as *BRCA1*-positive individuals who may develop breast or ovarian cancer (**Box 41.7**).

The aim of screening programmes is to improve individual or population survival by detecting cancer in its very early stages when patients are asymptomatic. This strategy depends on finding tests that are sufficiently sensitive and specific, using detection methods that identify cancer before it has spread, and having curative treatments that are practical and consistent with maintenance of a normal lifestyle and quality of life.

In the UK, population screening is provided for breast, cervical, and colon cancers. Lung cancer screening is available in certain parts of the UK and is gaining momentum. Prostate cancer can be detected using a simple blood test available to individuals via annual check-ups, but a screening programme has not been instituted in the UK because of a lack of evidence that the benefit outweighs the risks.

Unfortunately, earlier diagnosis does not necessarily mean longer survival times, and randomized trials of screening programmes are necessary to prove benefit. With lead-time bias, patients diagnosed via screening may merely be treated at an earlier date, so survival appears longer; death may still occur at the same time from the point of genesis of the cancer (**Fig. 41.5**). With length-time bias, a greater number of slowly growing tumours are detected when asymptomatic individuals are screened, which may lead to a false impression of an improvement in survival times.

The characteristics of effective screening programmes are shown in **Box 41.8**.

Symptomatic patients with cancer

Patients may offer information about predisposing conditions and family history that alerts the clinician to the likelihood of a cancer

Box 41.7 Familial cancer syndromes for which genetic screening may be relevant

Syndrome	Gene	Neoplasms
Autosomal dominant		
Retinoblastoma	*RB1*	Eye
Wilms' tumour	*WT1*	Kidney
Li–Fraumeni	*p53*	Sarcoma, brain, leukaemia
Neurofibromatosis type 1	*NF1*	Neurofibromas, leukaemia
Familial adenomatous polyposis	*APC*	Colon
Lynch's syndrome (previously hereditary non-polyposis colon cancer)	*MLH1* and *MSH2*	Colon, endometrium
Hereditary diffuse gastric cancer syndrome	E-cadherin	Stomach
Breast, ovary families	*BRCA1*	Breast, ovary
	BRCA2	
	p53	
Melanoma	*p16*	Skin
Von Hippel–Lindau	*VHL*	Renal cell carcinoma, haemangioblastoma
Multiple endocrine neoplasia type 1	*MEN1*	Pituitary, pancreas, parathyroid
Multiple endocrine neoplasia type 2	*RET*	Thyroid, adrenal medulla
Autosomal recessive		
Xeroderma pigmentosa	*XP*	Skin

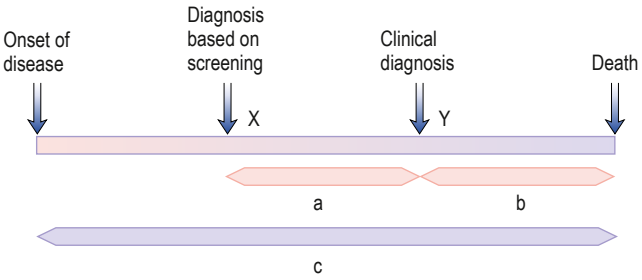

Fig. 41.5 Lead-time bias. Earlier diagnosis, at X, made by screening tests before the clinical diagnosis, at Y, suggests an increased survival time of a + b. The actual survival time (c) remains unchanged.

diagnosis. Many patients present with a history of tumour site–specific symptoms, such as pain, and physical signs, such as a mass, which readily identify the primary site of the cancer (Box 41.9). However, some patients seek medical attention only when more systemic and non-specific symptoms occur, such as weight loss, night sweats, fever, fatigue, recurrent infections, and anorexia. These usually indicate a more advanced stage of disease except in some paraneoplastic and ectopic endocrine syndromes. Other patients are diagnosed only on discovery of established metastases, such as the abdominal distension of ovarian cancer, the back pain of metastatic prostatic cancer, or the liver enlargement of metastatic GI cancer.

Box 41.8 Characteristics of an effective screening programme

- It must be affordable for the healthcare system.
- It must be acceptable to all social groups so they attend for screening.
- It must have a good discriminatory index between benign and malignant lesions.
- It must show a reduction in mortality rate from the cancer.

Paraneoplastic syndromes are indirect effects of cancer (Box 41.10 and Fig. 41.6) that are often associated with specific types of cancer and may be reversible with treatment of the cancer. The effects and mechanisms can be very variable. For example, in Lambert–Eaton syndrome (see Chapter 28, 'Lambert–Eaton myasthenic syndrome' section), there is cross-reactivity between tumour antigens and the normal tissue acetylcholine receptors at neuromuscular junctions.

The ***coagulopathy of cancer*** may present with thrombophlebitis, deep vein thrombosis, and pulmonary emboli, particularly in association with cancers of the pancreas, endometrium, lung, stomach, kidney, brain, and bladder. Some 18% of patients with recurrent pulmonary embolus will be found to have an underlying cancer, and many patients with cancer are at increased risk of venous thromboembolism (VTE) after diagnosis. All patients with active cancer admitted to hospital are at high risk of VTE and should be given prophylaxis with, for example, subcutaneous low-molecular-weight heparin in the absence of any contraindications (see Chapter 40).

Other cancer symptoms may be related to peptide or hormone release, such as in carcinoid or Cushing's syndrome.

Cachexia of advanced cancer is thought to be attributable to systemic effects, including the release of chemokines such as TNF, or local pressure effects, in which certain cancers may impair the patient's ability to swallow or may cause early satiety. The unexplained loss of more than 10% of a patient's body weight should always act as a red flag and be investigated.

Cancer-associated immunosuppression can lead to reactivation of latent infections such as herpes zoster (Fig. 41.7) and tuberculosis.

Serum tumour markers

Tumour markers are intracellular proteins or cell-surface glycoproteins released into the circulation and detected by immunoassays. Examples are given in Box 41.11. Values in the normal range do not necessarily equate with the absence of disease and a positive result must be corroborated by histology because these markers can be seen in many benign conditions. They are most useful in the serial monitoring of response to treatment. MicroRNA may be more tumour specific and offer the possibility of increased sensitivity compared with classical tumour markers.

Cancer imaging

Radiological investigation is required at various stages, including at initial diagnosis and staging of the disease, during the monitoring of treatment efficacy, at the detection of recurrence, and for the diagnosis and treatment of complications. See Chapter 8 for a fuller discussion of the role of imaging in malignant disease.

Contrast agents are used for increased structural discrimination in cross-sectional imaging and can be further enhanced with functional specificity for metabolically active tissue with ^{18}fluorodeoxyglucose (^{18}FDG) positron emission tomography (PET)/computed tomography (CT) scan, although these specialist scans are generally not done for early-stage disease and should generally be requested only after recommendation by a cancer specialist or MDT meeting.

Box 41.9 Symptoms and signs of malignant disease

Degree of spread	Anatomical location	Examples of clinical problems
Local	Mass	Thyroid nodule, pigmented naevus, breast lump, abdominal mass, testicular mass
	Local infiltration of the skin	Dermal nodules, peau d'orange, ulceration
	Local infiltration of a nerve	Neuropathic pain and loss of function, Horner's syndrome, cord compression, Pancoast tumour, focal CNS deficit, hypopituitarism
	Local infiltration of a vessel	Venous thrombosis, tumour emboli, haemorrhage (e.g., gastrointestinal)
	Obstruction of the viscera or duct	Small or large bowel obstruction, dysphagia, SVC obstruction, obstructive uropathy, acute kidney injury, urinary retention, stridor, lobar collapse, pneumonia, cholestatic jaundice
Nodal	Peripheral	Supraclavicular fossa, Virchow's node, lymphoedema
	Central	Mediastinum: SVC obstruction; porta hepatis: obstructive jaundice, para-aortic nodes, back pain
Metastatic	Lung	Pleuritic pain, cough, shortness of breath, lymphangitis and respiratory failure, recurrent pneumonia
	Liver	RUQ pain, anorexia, fever, raised serum liver enzymes, jaundice
	Brain	Headache and vomiting of raised intracranial pressure, focal deficit, coma, seizure
	Bone	Bone pain, cord compression, fracture, hypercalcaemia
	Pleura	Effusion, pain, shortness of breath
	Peritoneum	Ascites, Krukenberg tumours
	Adrenal	Addison's disease (hypoadrenalism)
	Umbilicus	Sister Mary Joseph's nodule

CNS, Central nervous system; *RUQ,* right upper quadrant; *SVC,* superior vena cava.

Box 41.10 Paraneoplastic syndromes

Syndrome	Tumour	Serum antibodies
Neurological		
Lambert–Eaton syndrome	Lung (small-cell) carcinoma	Anti-VGCC
Peripheral sensory neuropathy	Lung (small-cell), breast, ovary, lymphoma	Anti-Hu
Cerebellar degeneration	Lung (particularly small-cell) lymphoma	Anti-Yo
Opsoclonus or myoclonus	Breast, lung (small-cell)	Anti-Ri
Stiff person syndrome	Breast, lung (small-cell)	Anti-amphiphysin
Limbic, hypothalamic, or brainstem encephalitis	Lung	Anti-Ma protein
	Testicular	Anti-NMDAR
Endocrine or metabolic		
SIADH	Lung (small-cell)	
Ectopic ACTH secretion	Lung (small-cell)	
Hypercalcaemia	Renal, breast, myeloma, lymphoma	
Fever	Lymphoma, renal	
Musculoskeletal		
Hypertrophic pulmonary osteoarthropathy	Lung (non–small-cell)	
Clubbing	Lung	
Skin		
Dermatomyositis or polymyositis	Lung and upper gastrointestinal	
Acanthosis nigricans	Mainly gastric	
Velvet palms	Gastric, lung (non–small-cell)	
Hyperpigmentation	Lung (small-cell)	
Haematological		
Erythrocytosis	Renal cell carcinoma, hepatocellular carcinoma, cerebellar haemangioblastoma	
Thrombocytosis	Ovarian cancer	
Migratory thrombophlebitis	Pancreatic adenocarcinoma	
DVT	Adenocarcinoma	
DIC	Adenocarcinoma	
Renal		
Membranous nephropathy (frequently presenting with nephrotic syndrome)	Lung, stomach, and colon cancers	
Amyloidosis (presenting with nephrotic syndrome)	Myeloma	

ACTH, Adrenocorticotrophic hormone; *DIC,* disseminated intravascular coagulation; *DVT,* deep vein thrombosis; *NMDAR,* N-methyl-D-aspartate receptors; *SIADH,* syndrome of inappropriate antidiuretic hormone secretion; *VGCC,* voltage-gated calcium channels.

Fig. 41.6 Paraneoplastic peripheral neuropathy. There is wasting of the small muscles of the hands.

Fig. 41.7 Reactivated herpes zoster (shingles).

Radionuclide imaging of sentinel lymph nodes is used to guide lymphatic surgery in many cancers. Tumour-targeted contrast agents can improve detection rates; examples include the radiolabelled MAb rituximab for lymphoma and radiolabelled small molecules such as octreotide for neuroendocrine tumours. Research into the use of reporter agents that become visible only on activation within the tumour environment holds the promise of greater sensitivity and specificity in the future.

Biopsy and histological examination

A diagnosis of cancer may be suspected by both the patient and doctor, but advice about treatment can usually be given only on the basis of a tissue diagnosis. This may be obtained by endoscopic, radiologically guided, or surgical biopsy or sometimes by cytology (e.g., lung cancer may be diagnosed by sputum cytology). Malignant lesions can be distinguished morphologically from benign ones by the pleomorphic nature of the cells; increased numbers of mitoses; nuclear abnormalities of size; chromatin pattern and nucleolar organization; and evidence of invasion into surrounding tissues, lymphatics, or vessels. The degree of differentiation of the tumour has prognostic significance: generally speaking, well-differentiated tumours have a better prognosis than poorly differentiated or anaplastic ones. In some tumours, diagnosis and treatment may be combined within a single surgical procedure, with the exact nature of the procedure being carried out varying depending on the presence of malignancy. An intraoperative provisional histological opinion can be rapidly obtained with a tissue sample processed using 'frozen section' techniques, rather than having the sample paraffin embedded, which takes more than a day.

Immunocytochemistry using MAbs against tumour antigens is very helpful in differentiating between lymphoid and epithelial tumours and between some subsets of these (see **Box 41.18**). However, there is much overlap in the expression of many of these ***tissue tumour markers***, and some adenocarcinomas and squamous carcinomas do not bear any distinctive immunohistochemical markers that are diagnostic of their primary site of origin.

Molecular markers of genetic abnormalities have long been available in haematological cancers and are increasingly available in solid cancers. For example, ***fluorescence in situ hybridization*** (see Chapter 39) can be used to look for characteristic chromosomal translocations, as in lymphoma and leukaemia, as well as deletions or amplifications, as in breast cancer (see Chapter 47, 'Breast cancer' section). The development of the new targeted MAbs and TKIs has been guided by increasing use of mutation analysis of common oncogenes, such as *RAS* and *RAF* in colon cancer and melanoma. ***Tissue microarrays*** can identify patterns of multiple genomic alterations and single nucleotide polymorphisms, as in breast cancer and lymphoma (see Chapter 39, 'Lymphomas' section), and ***RNA assays*** with reverse transcriptase polymerase chain reaction can be used to identify tissue of origin with prognostic and predictive relevance.

Genomics and proteomics have been used to guide the use of novel therapies, such as imatinib in gastrointestinal stromal tumours (GISTs); trastuzumab, pertuzumab, and lapatinib in breast cancer;

Box 41.11 Serum tumour markers

Serum tumour marker	Neoplasms
α-Fetoprotein (AFP)	Hepatocellular carcinoma and non-seminomatous germ cell tumours of the gonads
β-Human chorionic gonadotrophin (β-hCG)	Choriocarcinomas, germ cell tumours (testicular), and lung cancers
Prostate-specific antigen (PSA)	Carcinoma of the prostate
Carcinoembryonic antigen (CEA)	Gastrointestinal cancers
CA-125	Ovarian cancer
CA19-9	Gastrointestinal cancers, particularly pancreatic cancer
CA15-3	Breast cancer
Osteopontin	Many cancers, including mesothelioma
Calcitonin	Medullary carcinoma of the thyroid
Thyroglobulin	Papillary and follicular thyroid cancer

osimertinib and crizotinib in lung cancer; and cetuximab and bevacizumab in colon cancer.

PRINCIPLES OF CANCER TREATMENT

Aims of treatment

Optimal cancer treatment is delivered by an MDT that coordinates the delivery of the appropriate anticancer treatment, supportive and symptomatic care, and psychosocial support.

Establishment of agreed patient pathways has enabled more effective and timely delivery of care and post-treatment rehabilitation. Central to this endeavour is the involvement of the patient through education about the nature of their disease and the treatment options available.

A curative approach

For many solid tumours, local control is necessary, but not sufficient, for cure because of the presence of systemic (microscopic) disease. Improvement in the rate of cure of most cancers is thus dependent on earlier detection to increase the success of local treatment and effective systemic response. The likelihood of cure of the systemic disease rests on the type of cancer and its expression of appropriate treatment targets, its drug sensitivity, and tumour bulk (microscopic or clinically detectable). A few rare cancers are so chemosensitive that even bulky metastases can be cured (e.g., gonadal germ cell tumours and choriocarcinoma). For most common solid tumours, such as lung, breast, and colorectal cancers, there is no current cure of bulky (clinically detectable) metastases, but micrometastatic disease treated by adjuvant systemic therapy after surgery can be cured in 10% to 20% of patients.

Adjuvant therapy for solid tumours

Micrometastatic spread by lymphatic or haematological dissemination often occurs early in the development of the primary tumour and can be demonstrated by molecular biological methods capable of detecting the small numbers (1 in 10^6) of circulating cells. Studies correlating prognosis with histological features of the primary cancer, such as differentiation, invasion of blood vessels or regional lymph nodes, and molecular markers such as human epidermal growth factor receptor 2 (HER2) in breast cancer, enable risk stratification and increasing individualization of therapy.

- ***Adjuvant therapy*** is defined as treatment given, in the absence of macroscopic evidence of metastases, to patients at risk of recurrence from micrometastases after treatment given for the primary lesion.
- ***Neoadjuvant therapy***, alternatively, is given before primary surgery, both to shrink the tumour to improve local excision and to treat any micrometastases as soon as possible.

The success of adjuvant treatment across many tumour types relies on careful selection of patients according to defined risk criteria and reduction of treatment toxicity to reach a balanced risk-to-benefit ratio. However, the majority of patients who receive such treatment do not benefit, either because they were already cured or because the cancer is resistant to the treatment. Better tests, such as gene arrays and circulating tumour cells, are being developed to identify those with micrometastases, who really do benefit from treatment.

A palliative approach

When cure is not possible, palliation—that is, relief of tumour symptoms, preservation of quality of life, and prolongation of life—is possible in many cancers in proportion to their drug and radiation sensitivity. There is, on average, a 2- to 18-month prolongation in median life expectancy with treatments for solid tumours; individuals with the most responsive tumours experience the greatest benefit. In addition, through early assessment during treatment, it is possible to stop if no evidence of benefit is demonstrable early on so as to minimize exposure to toxic and unsuccessful treatment.

Assessment before treatment

Staging

Before a decision about treatment can be made, not only does the type of tumour need to be established but also its extent and distribution (**Box 41.2**). Various 'staging investigations' are therefore performed before a treatment decision is made. To be useful clinically, the staging system must subdivide the patients into groups with different prognoses, which can guide treatment selection. The TNM (tumour, node, metastases) classification (see **Box 41.12**) can be adapted for application to most common cancers.

Performance status

In addition to anatomical staging, the person's age and general state of health need to be taken into account when planning treatment. The latter has been called 'performance status' and is of great prognostic significance for all tumour types (**Box 41.13**). Performance status reflects the effects of the cancer on the patient's functional capacity. An alternative performance rating scale is provided by Karnofsky. With a performance status of 2 or more, response to and survival after treatment are greatly reduced for most tumour types.

Assessment of the benefits of treatment

A measurable response to treatment can serve as a useful early surrogate marker when deciding whether to continue a given treatment for an individual patient. Trials to assess response to treatment in advanced disease have identified active agents for use in the more curative setting of adjuvant treatment of patients with early-stage disease.

Response to treatment can be subjective or objective.

- ***A subjective response*** is one perceived by the patient in terms of, for example, relief of pain and dyspnoea or improvement in appetite, weight gain, or energy. Such a subjective response is a major aim of most palliative treatments. Quantitative measurements of these subjective symptoms (patient-reported outcome measures) form a part of the assessment of response to chemotherapy, especially in situations when cure is not possible and when the aim of treatment is to provide prolongation of good-quality life. In these circumstances, measures of quality of life enable an estimate of the balance of benefit and side-effects to be made.
- ***An objective response*** to treatment is assessed clinically and radiologically (**Fig. 41.8**). The term 'remission' is often used

Box 41.12 Staging and survival of colorectal cancers: TNM and Dukes' systems

TNM classification	Description	Notation	Modified Dukes' classification	5-year survival rate (%)
Stage I (N0, M0)	Tumours invade submucosa Tumours invade muscularis propria	T1 T2	A	90
Stage IIA (N0, M0) **Stage IIB**	Tumours invade into subserosa Tumours invade directly into other organs	T3 T4	B	70 65
Stage III (M0) **Stage IIIB**	T1, T2 + one to three regional lymph nodes involved T3, T4 + one to three regional lymph nodes involved	N1 N1	C	60 35
Stage IIIC	Any T + four or more regional lymph nodes	N2	C	25
Stage IV	Any T, any N + distant metastases	M1	D	7

M, Metastasis; *N,* node; *T,* tumour.

Box 41.13 Eastern Cooperative Oncology Group performance status scale

Status	Description
0	Asymptomatic, fully active, and able to carry out all pre-disease performance without restrictions
1	Symptomatic, fully ambulatory but restricted in physically strenuous activity and able to carry out performance of a light or sedentary nature (e.g., light housework, office work)
2	Symptomatic, ambulatory, and capable of all self-care but unable to carry out any work activities; up and about >50% of waking hours; in bed <50% of the day
3	Symptomatic, capable of only limited self-care, confined to a bed or chair >50% of waking hours but not bedridden
4	Completely disabled, cannot carry out any self-care, totally bedridden

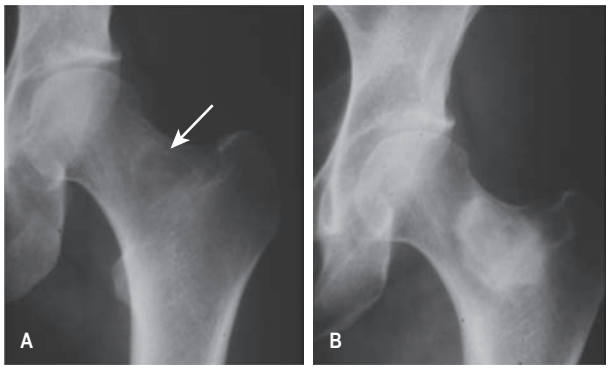

Fig. 41.8 Radiological response to chemotherapy and radiotherapy. X-rays showing response to chemotherapy and radiotherapy. **(A)** The *arrow* points to lytic bone metastasis. **(B)** Bone metastasis showing response to chemotherapy and radiotherapy with sclerotic new bone formation.

synonymously with 'response', which, if complete, means an absence of detectable disease without necessarily implying a cure of the cancer. The terms used to evaluate the responses of tumours are defined in Box 41.14. For a complete response, all previous clinical abnormalities should have resolved, and this needs to be confirmed by clinical examination or sampling of the primary disease site or by detection of serum tumour markers. Radiological response can be quantified through use of the Response Evaluation Criteria in Solid Tumours convention, although this is mainly used for patients in clinical trials.

The increasing use of PET/CT has meant that metabolic responses (i.e., reduction in tracer avidity with or without a reduction in the size of the mass) may predict long-term outcome more accurately and is the imaging modality of choice for surveillance in some cancers.

The final assessment of treatment outcome is the impact of the therapy on remission duration and survival, that is, the **cure rate**. Such survival figures are increasingly incorporating quality-of-life assessments and a health economic assessment to calculate the number of quality-adjusted life years gained for the cost of the treatment to guide judgements about health system affordability (see Chapter 9, 'Health economics' section).

Principles of chemotherapy

Cytotoxic chemotherapy uses systemically administered drugs that directly damage cellular DNA (and RNA). It kills cells by promoting apoptosis and sometimes frank necrosis. Different cytotoxic drugs work at different stages in the cell cycle (Fig. 41.9).

There is a narrow therapeutic window between doses necessary for effective treatment of the cancer and those that cause normal tissue toxicity because cytotoxic drugs are not cancer specific (unlike some of the targeted biological agents), and the increased proliferation in cancers is often not much greater than in normal tissues. The dose and schedule of the chemotherapy are limited by normal tissue tolerance, especially in the more proliferative tissues of the bone marrow and GI tract mucosa. All tissues can be affected, however, depending on the pharmacokinetics of the drug and its affinity for particular tissues (e.g., heavy metal compounds for kidneys and nerves).

The therapeutic effect on the cancer is achieved by a variety of mechanisms that seek to exploit differences between normal and transformed cells. Although most drugs in the past (e.g., alkylating agents) have been derived by empirical testing of many different compounds, new molecular biology is leading to targeted approaches to particular genetic defects in the cancer (see 'Targeted therapies' section).

Toxicity to normal tissue can be mitigated in some instances by concurrent measures, including supplying growth factors such as granulocyte colony-stimulating factor (G-CSF). The use of more specific targeted biological agents with relatively weak pro-apoptotic effects, in combination with general cytotoxics, has also

Box 41.14 RECIST criteria for assessing response to treatment in solid tumours

Criterion	Description
Complete response	Disappearance of all target lesions
Partial response	≥30% decrease in the baseline sum of the longest diameters of all target lesions
Progression	≥20% increase in the sum of the longest diameters of all target lesions compared with the smallest recorded sum since treatment started, or the appearance of any new lesions
Stable disease	All values between partial response and progressive disease
Target lesions	Measurable lesions up to 5 per organ and 10 in total, selected on size and replicable measurement
Non-target lesions	Non-measurable lesions recorded as present or absent at baseline and on follow-up
Measurable	Lesions with the longest diameter in one dimension of ≥2.0 cm or ≥1.0 cm if assessed by spiral CT scan
Non-measurable	e.g., Bone lesions, meningeal disease, ascites, pleural effusion, inflammatory breast cancer, lymphangitis cutis and pulmonis, cystic lesions

CT, Computed tomography; *RECIST,* Response Evaluation Criteria in Solid Tumours.

improved the therapeutic ratio (e.g., trastuzumab and breast cancer; see 'Breast cancer' section). Certain cytotoxic therapies may also be administered into the pleural space, peritoneum or cerebrospinal fluid (CSF), or into the arterial supply of a tumour.

Most tumours rapidly develop resistance to single agents given on their own through changes in membrane transport and DNA repair pathways. For this reason, the principle of intermittent combination chemotherapy was developed. Several drugs are combined, chosen on the basis of differing mechanisms of action and non-overlapping toxicities. These drugs are given over a period of a few days followed by a rest of a few weeks, when the normal tissues have the opportunity for regrowth. If the normal tissues are more proficient at DNA repair than the cancer cells, it may be possible to deplete the tumour while allowing the restoration of normal tissues between chemotherapy cycles (Fig. 41.10).

In many experimental tumours, it has been shown that there is a log-linear relationship between drug dose and number of cancer cells killed, and that the maximum effective dose is very close to the maximum tolerated dose at which dose-limiting toxicity is reached. With a chemosensitive tumour, relatively small increases in dose may have a large effect on tumour cell kill. It is therefore apparent that when cure is a realistic option, the dose administered is critical and may need to be maintained despite toxicity. When cure is not a realistic possibility and palliation is the aim, a sufficient dose to exceed the therapeutic threshold but not cause undue toxicity is required because the short-term quality of life becomes a major consideration.

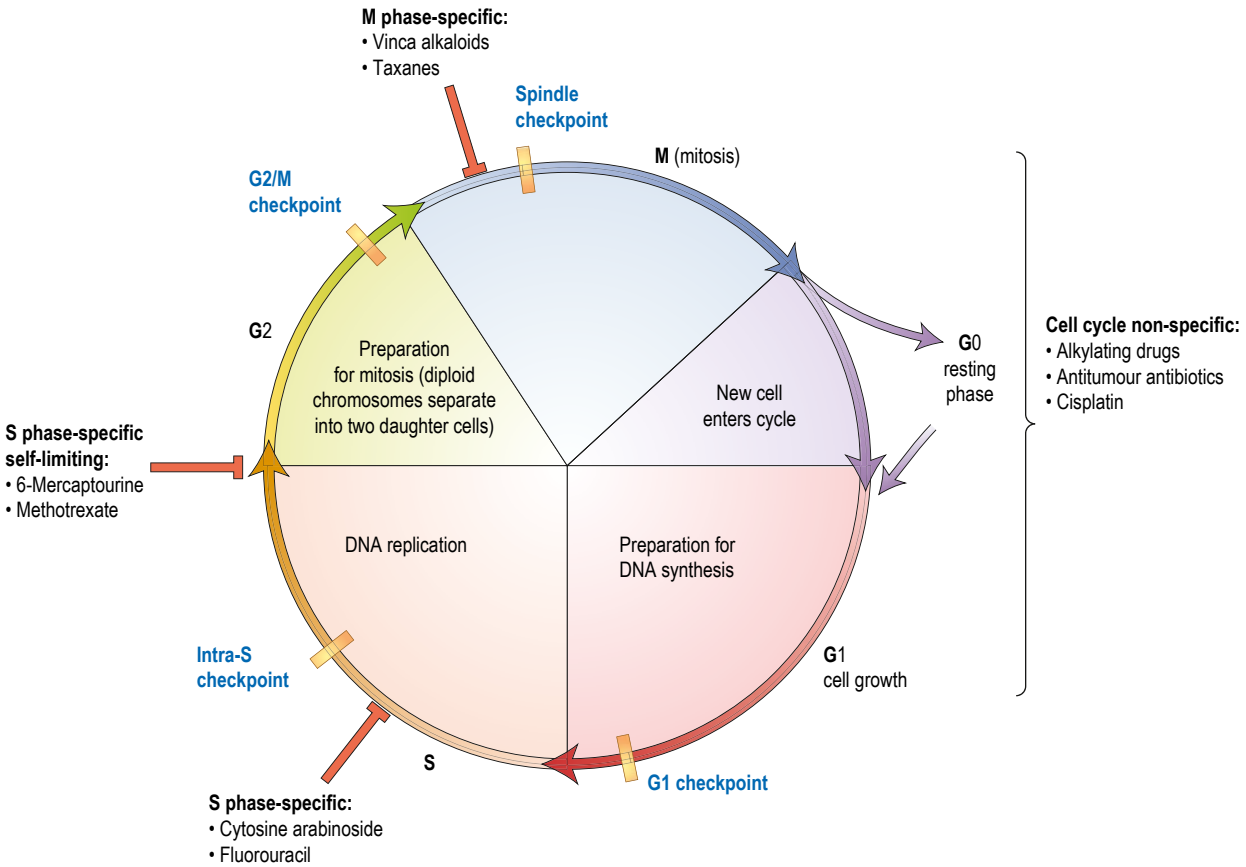

Fig. 41.9 **Cell cycle and chemotherapy drugs.**

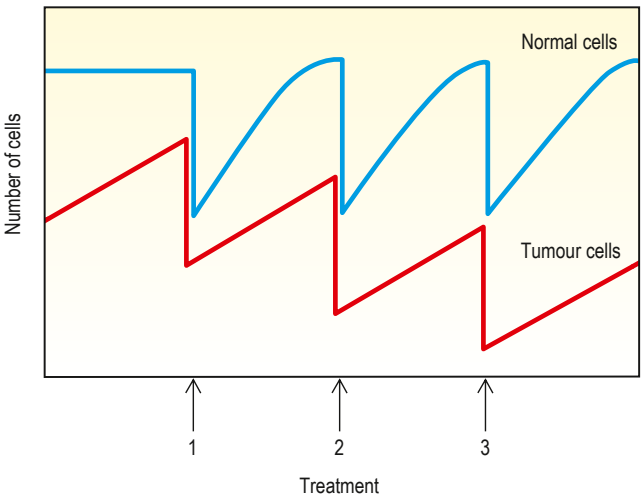

Fig. 41.10 Effects of multiple courses of cytotoxic chemotherapy. The decrease in the number of cells with each course is shown.

Classification of cytotoxic drugs

See **Box 41.15**.

DNA-damaging drugs

Alkylating agents

These act by covalently binding alkyl groups. Their major effect is to cross-link DNA strands, interfering with DNA synthesis and causing strand breaks. Examples include bendamustine and cyclophosphamide.

Platinum compounds

Cisplatin, carboplatin, and oxaliplatin cause interstrand cross-links of DNA and are often regarded as non-classical alkylating agents. They have transformed the treatment of patients with testicular cancer (cisplatin) and play a major role against many other tumours.

Antimetabolites

Antimetabolites are usually structural analogues of naturally occurring metabolites that interfere with normal synthesis of nucleic acids by falsely substituting purines and pyrimidines in metabolic pathways.

Folic acid antagonists

This class includes methotrexate, which is structurally very similar to folic acid and binds preferentially to dihydrofolate reductase, the enzyme responsible for the conversion of folic acid to folinic acid. It is used widely in the treatment of solid tumours and haematological malignancies. Folinic acid is often given to 'rescue' normal tissues from the effects of high doses of methotrexate. A related drug, pemetrexed, targets the enzyme thymidylate synthase, as well as glycinamide ribonucleotide formyltransferase.

Pyrimidine antagonists

5-Fluorouracil (5-FU) consists of one uracil molecule with a substituted fluorine atom. It acts by blocking thymidylate synthase, which is essential for pyrimidine synthesis. Oral capecitabine is metabolized to 5-FU, as is tegafur with uracil.

Arabinosides

Arabinosides inhibit DNA synthesis by inhibiting DNA polymerase. Cytarabine is used almost exclusively in the treatment of patients with acute myeloid leukaemia, in which it remains the backbone of therapy.

Purine antagonists

This class includes 6-mercaptopurine and 6-tioguanine, which are both used almost exclusively in the treatment of patients with acute leukaemia.

DNA repair inhibitors

Epipodophyllotoxins

These are semisynthetic derivatives of podophyllotoxin, which inhibit the topoisomerase enzymes that allow unwinding and uncoiling of supercoiled DNA and maintain DNA strand breaks.

Cytotoxic antibiotics

The anthracyclines act by intercalating adjoining nucleotide pairs on the same strand of DNA and by inhibiting topoisomerase-II DNA repair. They have a wide spectrum of activity in haematological and solid tumours.

Antitubulin agents

Vinca alkaloids

Drugs such as vincristine, vinblastine, and vinorelbine act by binding to tubulin and inhibiting microtubule formation during mitosis (see **Fig. 41.10**). They are associated with neurotoxicity because of their antimicrotubule effect and must never be given intrathecally because this is lethal.

Taxanes

Paclitaxel and docetaxel bind to tubulin dimers and prevent their assembly into microtubules.

Side-effects of chemotherapy

Chemotherapy carries many potentially serious side-effects and should be used only by trained practitioners; however, an appreciation of its common potential side-effects is necessary for all general physicians who are called to see patients with cancer who

Box 41.15 Chemotherapy: some cytotoxic drugs

DNA-damaging agents
- Free radicals:
  - Alkylators (e.g., cyclophosphamide, melphalan, chlorambucil, ifosfamide)
  - Nitrosoureas (e.g., carmustine [BCNU], bendamustine, lomustine [CCNU], busulfan)
  - Tetrazines (e.g., dacarbazine, temozolomide)
- DNA cross-linking—platinum (e.g., cisplatin, carboplatin, oxaliplatin)

Antimetabolites
- Pyrimidine synthesis (e.g., 5-fluorouracil, capecitabine, cytarabine, fludarabine, gemcitabine, cladribine, clofarabine, nelarabine, azacitidine)
- Purine synthesis (e.g., mercaptopurine, tioguanine)
- Antifolates (e.g., methotrexate, pemetrexed)

DNA repair inhibitors
- Topoisomerase-I inhibitors (e.g., irinotecan)
- Topoisomerase-II inhibitors (e.g., etoposide)
- Anthracyclines (e.g., daunorubicin, doxorubicin, epirubicin)

Antitubulin agents
- Tubulin-binding: alkaloids (e.g., vincristine, vinorelbine)
- Taxanes (e.g., paclitaxel, docetaxel)
- Eribulin, epothilones

Others
- Bleomycin, mitomycin

Box 41.16 Side-effects of chemotherapy

Common

- Nausea and vomiting
- Hair loss
- Myelosuppression
- Mucositis
- Fatigue

Drug specific

- Cardiotoxicity (e.g., anthracyclines)
- Progressive pulmonary fibrosis (e.g., bleomycin, busulfan)
- Neurotoxicity (e.g., cisplatin, vinca alkaloids, taxanes)
- Nephrotoxicity (e.g., cisplatin)
- Skin (e.g., anti-EGFR TKIs, immune checkpoint inhibitors)
- Skin: plantar–palmar dermatitis (e.g., 5-fluorouracil, liposomal doxorubicin)
- Gut: diarrhoea, mucositis (e.g., fluorouracil, methotrexate, etoposide, TKIs, immune checkpoint inhibitors)
- Sterility (e.g., alkylating agents, anthracyclines)
- Secondary malignancy (e.g., alkylating agents, epipodophyllotoxins, anthracyclines)
- Central nervous system (e.g., TKIs)

EGFR, Epidermal growth factor receptor; *TKI*, tyrosine kinase inhibitor.

Box 41.17 Some common chemotherapy regimens

Cancer	Abbreviation[a]	Regimen
Breast	AC	Adriamycin (doxorubicin) and cyclophosphamide
Lung	PE	Cisplatin and etoposide
Stomach	ECF	Epirubicin, cisplatin, and 5-fluorouracil
Colorectal	FOLFOX	Oxaliplatin, 5-fluorouracil, and folinic acid

[a]Some abbreviations are related to trade names.

are receiving chemotherapy. The five most common side-effects are vomiting, hair loss, tiredness, myelosuppression, and mucositis (Box 41.16). Side-effects are much more directly dose related than anticancer effects, and it has been the practice to give drugs at doses close to their maximum tolerated dose, although this is not always necessary to achieve their maximum anticancer effect. Common combination chemotherapeutic regimens are shown in Box 41.17.

Common side-effects

Extravasation of intravenous drugs

Cytotoxic drugs should be given only by trained personnel. They cause severe local tissue necrosis if leakage occurs outside the vein. If this occurs, the infusion should be stopped immediately, and local measures should be instituted; chemotherapy agents have specific extravasation protocols that should be followed. Antihistamines and corticosteroids may give symptomatic relief.

Nausea and vomiting

The severity of these common side-effects varies with the cytotoxicity and are particular problems with platinum analogues. They can be eliminated in 75% of patients by using modern antiemetics. A stepped policy, with antiemetics such as metoclopramide and domperidone, followed by 5-HT_3 (5-hydroxytrypamine, serotonin) antagonists (e.g., ondansetron, granisetron) combined with dexamethasone, should be used to match the emetogenic potential of the chemotherapy. ***Aprepitant***, a neurokinin receptor antagonist, is helpful in preventing acute and delayed nausea and vomiting. It is used with dexamethasone and a 5-HT_3 antagonist. Drugs such as cyclizine, olanzapine and levomepromazine, and benzodiazepines can be used to control persistent nausea.

Fig. 41.11 Nail growth cessation with each drug cycle (Beau's lines).

Effects on hair, skin, and nails

Many, but not all, cytotoxic drugs are capable of causing hair loss. Scalp cooling can sometimes be used to reduce hair loss, but in general, this side-effect can be avoided only by selection of drugs when it is possible. Hair regrows on completion of chemotherapy. Nails may demonstrate banding, reflecting periods of cessation of growth during each chemotherapy cycle (Fig. 41.11), and skin toxicity may be particularly pronounced with 5-FU, capecitabine, and docetaxel (Fig. 41.12).

Fatigue

Fatigue is often significant and may continue beyond completion of therapy. Other problems, such as anaemia or depression, may exacerbate fatigue. Attention should be paid to nutrition, hydration, sleep hygiene, gentle exercise, task prioritization, pacing, realistic target setting, and scheduling of rest within the day.

Bone marrow suppression and immunosuppression

Suppression of the production of red blood cells, white blood cells, and platelets occurs with most cytotoxic drugs and is a dose-related phenomenon (Fig. 41.13). Severely myelosuppressive chemotherapy may be required if treatment is to be given with curative intent, despite the potential for rare but fatal infection or bleeding. Anaemia and thrombocytopenia are managed by red cell or platelet transfusions. The risk of infective problems can be ameliorated by the use of prophylactic antimicrobials, such as ciprofloxacin, or the use of G-CSF as primary prophylaxis in chemotherapy regimens that carry a significant risk of febrile neutropenia (or in patients on less intensive therapies who are at higher risk because of age or co-morbidity).

Fig. 41.12 **Hands showing palmar–plantar skin toxicity.**

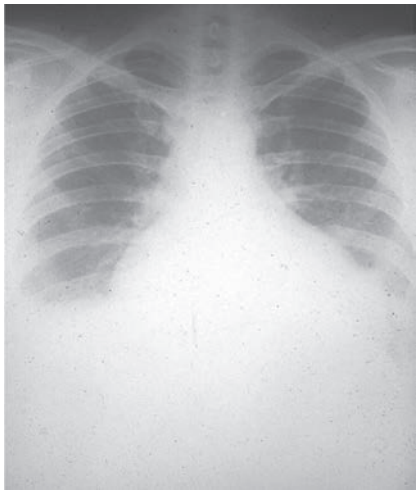

Fig. 41.14 **Anthracycline dilated cardiomyopathy with congestive heart failure.**

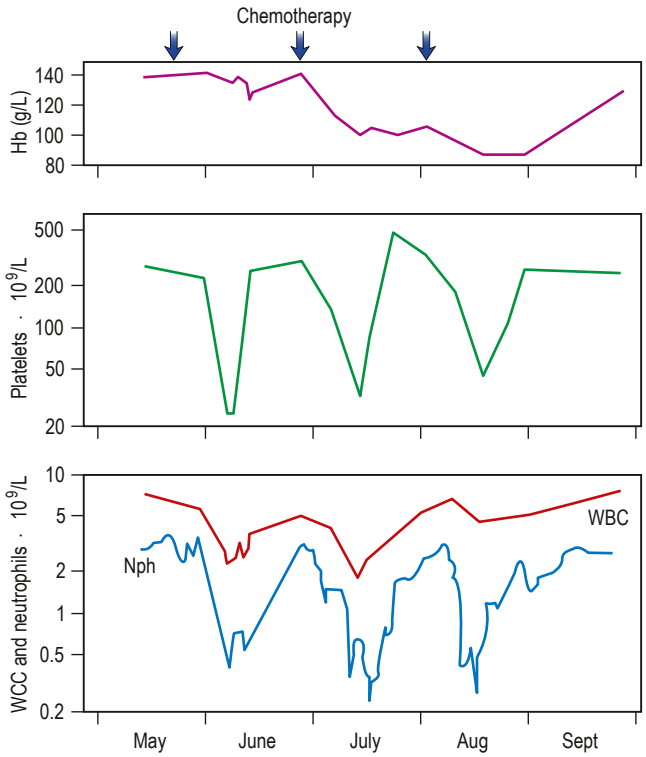

Fig. 41.13 **Cyclical myelosuppression from chemotherapy *(arrow)*.** *Hb,* Haemoglobin; *Nph,* neutrophils; *WCC,* white blood cell count.

Mucositis

This common side-effect of chemotherapy reflects the sensitivity of the mucosa to antimitotic agents. Mucositis causes severe pain in the oropharyngeal region and problems with swallowing and nutrition. It can be generalized throughout the intestinal tract and can cause life-threatening diarrhoea. Treatment is with antiseptic and anti-candidal mouthwash; if mucositis is severe, fluid and antibiotic support is required because the mucosa is a portal for entry of enteric organisms.

Other toxicities

Cardiotoxicity

This is a rare side-effect of chemotherapy and is usually associated with anthracyclines such as doxorubicin; effects can present as an acute arrhythmia during administration or cardiac failure due to cardiomyopathy after chronic exposure (Fig. 41.14). This effect is dose related and can largely be prevented by restricting the cumulative total dose of anthracyclines within the safe range (equivalent to 450 mg/m^2 body surface area cumulative doxorubicin dose). The risk of anthracycline cardiomyopathy is also dependent on other treatments, such as trastuzumab or radiotherapy, as well as other cardiac risk factors, such as hypertension, smoking, and hypercholesterolaemia. Cardiotoxicity can also be reduced by using the analogue epirubicin or by reducing peak drug concentrations through delayed-release preparations, such as liposomal doxorubicin. 5-FU and its prodrug, capecitabine, can cause cardiac ischaemia.

Neurotoxicity

This occurs predominantly with the vinca alkaloids, taxanes, and platinum analogues (but not carboplatin). It is dose related and cumulative. Chemotherapy is usually stopped before the development of a significant polyneuropathy, which, when established, is only partially reversible. *Vinca alkaloids, such as vincristine, must never be given intrathecally* because the neurological damage is progressive and fatal.

Nephrotoxicity

Cisplatin (but not oxaliplatin or carboplatin), methotrexate, and ifosfamide can potentially cause renal damage. This can usually be prevented by maintaining an adequate diuresis during treatment to reduce drug concentration in the renal tubules and by monitoring renal function.

Sterility and premature menopause

Some anticancer drugs, particularly alkylating agents but also anthracyclines and docetaxel, may cause gonadal damage, resulting in sterility and, in females, the loss of ovarian oestrogen production, which may be irreversible.

In males, storage of sperm before chemotherapy should be offered to the patient when chemotherapy is given with curative intent.

In females, collection of oocytes to be fertilized *in vitro* and cryopreserved as embryos for subsequent implantation is most successful; however, it is also possible to collect and freeze by vitrification of unstimulated oocytes. Cryopreservation of ovarian tissue and retrieval of viable oocytes for subsequent fertilization are still experimental. The recovery of gonadal function is dependent on the status before treatment; in females, this is mostly related to age since menarche, with those younger than 40 years of age having significantly more ovarian reserve.

Secondary malignancies

Anticancer drugs have mutagenic potential, and the development of secondary malignancies, predominantly acute leukaemia, is an uncommon but particularly unwelcome long-term side-effect in patients otherwise cured of their primary malignancies. The alkylating agents, anthracyclines, and epipodophyllotoxins are particularly implicated.

Principles of endocrine therapy

Oestrogens are capable of stimulating the growth of breast and endometrial cancers, and androgens can stimulate the growth of prostate cancer. Removal of these growth factors by manipulation of the hormonal environment may result in apoptosis and regression of the cancer. Endocrine therapy can be curative in a proportion of patients treated for micrometastatic disease in the adjuvant setting for breast and prostate cancer and provides a minimally toxic, non-curative (palliative) treatment in advanced or metastatic disease. The presence of detectable cellular receptors for the hormone is strongly predictive of response. However, this is also modified by the many molecular interactions between the activation pathways of, for example, epidermal growth factor receptor (EGFR), the androgen receptor (AR [see 'Endocrine therapy' section]) and oestrogen receptor (ER [see 'Oestrogen receptor–positive disease' section]).

Principles of biological and targeted therapy

Immunotherapy

Certain antigens that are specific to cancer cells, such as sequences of tumour immunoglobulin from melanoma antigens, have been used as tumour vaccines, together with manipulation of the immune system to overcome tolerance. Engineered chimeric antigen receptors that direct T cells to specific antigenic targets are emerging as a powerful potential tool in the treatment of a wide range of cancers.

Immune checkpoint inhibitors

These agents directly interfere with the relationship between T cells and antigen-presenting cells or tumour cells to overcome the common problems of immune tolerance and anergy (see **Fig. 6.8**).

Ipilimumab is a MAb that blocks the CD152 (CTLA4) receptor responsible for downregulating T-cell responses and is active in the treatment of melanoma. The inhibitors of the PD-1 receptor or its ligands, PD-L1 and PD-L2, on activated T cells, further reactivate tumour-specific cytotoxic T cells, so ipilimumab plus nivolumab (a PD-1 receptor blocker) double the response rate from 20% to 40% in metastatic melanoma. Many clinical trials are now examining these agents in the context of a variety of other cancers.

As the use of immunotherapies increases, physicians are likely to be increasingly exposed to patients receiving this therapy. Immunotherapies can present with many side-effects that are quite distinct to those of conventional chemotherapy, relating to excess immune system activity against healthy body tissues. Relatively mild symptoms can be a precursor to imminent life-threatening complications. Many of the side-effects of immunotherapy respond to high dose corticosteroid therapy. However, supportive medications such as antibiotics and corticosteroids may counter the beneficial effect of immunotherapies in cancer treatment and should ideally be avoided when safe to do so. Close liaison with oncology support services is required for patients on immunotherapy who present acutely unwell.

Common side-effects associated with immunotherapies include:

- Colitis
- Skin toxicities
- Hepatitis
- Endocrinopathies
- Neuropathies
- Nephritis

Immunomodulatory drugs: thalidomide, lenalidomide, and pomalidomide

This family of immunomodulatory drugs (IMIDs) is increasingly being used in a range of malignancies, such as myeloma, chronic lymphocytic leukaemia, and myelodysplastic syndrome, as well some solid tumours. They have anti-angiogenic functions, as well as effects on cytokine production, tumour–stromal interactions, and T-cell co-stimulatory functions. They are all considered teratogenic and should be avoided in females of reproductive potential unless extra precautions are taken against conception. There is increasing evidence that IMIDs work through binding of the E3 ligase protein cereblon, which acts to degrade two specific B-cell transcription factors, IKZF1 and IKZF3.

Interferons

Interferons are naturally occurring cytokines that mediate the cellular immune response. Interferon-alpha (IFN-α) has been used to treat patients with advanced melanoma and renal cell carcinoma.

Treatment with IFN has side-effects, most commonly, influenza-like symptoms, which tend to diminish with time, and fatigue, which generally does not and can be treatment limiting. IFN used to be given as a daily subcutaneous injection, but conjugation with polyethylene glycol (has led to a reduction in frequency of injection and severity of side-effects.

Interleukins

Interleukin 2 (IL-2), a recombinant protein, is used to activate T-cell responses, often in conjunction with IFN-stimulated B-cell activation. Anti-tumour activity has been observed in renal cell carcinoma and melanoma, with responses in 10% to 20% of patients, occasionally for prolonged periods. Toxicity is common; acutely, this includes the capillary leak syndrome with hypotension and pulmonary oedema; autoimmune thyroiditis and vitiligo occur later.

Targeted therapies

The fast-developing field of targeted therapies includes MAbs, receptor kinase inhibitors, and small molecule receptor blockers. Expression of a targeted molecule is insufficient to indicate that use of the corresponding drug will be therapeutic because it is also necessary for the drug to be able to interrupt a growth-critical pathway in that cancer.

Monoclonal antibodies

MAbs (**Box 41.18**) directed against tumour cell-surface antigens are 'humanized' by being genetically engineered to have a range of functions, including:

- Acting as a carrier molecule to target toxins or radioisotopes to the tumour cells (e.g., trastuzumab or trastuzumab emtansine for breast cancer)
- Acting as anti-growth factor agents added to chemotherapy by inhibiting dimerization of the extracellular receptor molecules.

Side-effects are those of hypersensitivity to the foreign protein and specific cross-reactivities, for example, trastuzumab for the myocardium, bevacizumab for the mucosa and renal tubule, and cetuximab for the skin follicles.

Intracellular signal inhibitors

Many cancer cells are transformed by the activity of the protein products of oncogenes that signal growth by phosphorylation of tyrosine residues on the intracellular portion of growth factor receptors. Small molecule inhibitors (**Box 41.19**) have many pharmacokinetic advantages over the MAb inhibitors. The first example was the TKI imatinib, which specifically inhibits the BCR-ABL fusion oncoprotein and c-Kit. This compound is an extremely effective treatment for chronic myeloid leukaemia and GISTs, which are characterized by the presence of the c-Kit target. Lapatinib, which inhibits HER2, has increased survival in breast cancer. The less specific TKIs sunitinib and pazopanib, which inhibit signalling by EGFR and vascular endothelial growth factor receptor (VEGFR), have proved effective in metastatic renal cancer, and afatinib, erlotinib, and gefitinib have shown activity in lung cancer. Vemurafenib is a kinase inhibitor and has a specificity for BRAF-V600, as used in patients with malignant melanoma (see 'Malignant melanoma' section). Many other similar molecules are in pre-clinical or early clinical development, but heterogeneity within a single tumour occurs, and genomic anomalies may not all be represented in a single biopsy specimen. Vandetanib, a combined VEGF and C-RET inhibitor, is useful in the treatment of patients with medullary thyroid cancer.

Proteasome inhibitors

The proteasome degrades redundant or damaged proteins that have been labelled by a process called ubiquitination. Such proteins include cyclins and cyclin-dependent kinases, as well as factors in the nuclear factor kappa-B pathway. Inhibition of the proteasome leads to apoptosis in cancer cells and is synergistic with other treatments such as steroids and chemotherapy. Bortezomib is the first of such inhibitors to reach clinical practice and is used in myeloma, as well as some types of non-Hodgkin lymphoma. There are also recent additions to this class, including carfilzomib and ixazomib.

i Box 41.18 Monoclonal antibodies in cancer

Gene therapy

Antisense oligonucleotides are short sequences of DNA bases that specifically inhibit complementary sequences of either DNA or RNA. As a result, they can be generated against genetic sequences that are specific for tumour cells. Their clinical development has been hampered by poor uptake by tumour cells and rapid degradation by natural endonucleases. However, one antisense sequence directed against the *Bcl-2* oncogene has been shown to have an anti-tumour effect in patients with non-Hodgkin lymphoma. Viral vectors for the transfection of tumour cells *in vivo* are being tested as a way of delivering specific replacement gene therapy in head and neck cancers.

Principles of radiation therapy

Radiation is an important modality for the treatment of patients with cancer and can be used with radical, adjuvant, or palliative intent. More than 50% of patients with a cancer diagnosis are treated with radiotherapy.

Radical radiotherapy aims to deliver a tumouricidal treatment dose to a well-defined target volume with curative intent, sparing the surrounding normal tissues as much as possible. It is usually given as a fractionated course over a number of weeks, with patients receiving daily treatment. Carcinoma of the cervix, for example, can be cured with 5.5 weeks of daily radiotherapy delivered Monday to Friday with concurrent cisplatin chemotherapy.

Adjuvant radiotherapy is used to reduce the risk of tumour recurrence after primary surgery. The aim of treatment is to eradicate occult micrometastatic disease that cannot be demonstrated on imaging, as occurs in a significant percentage of patients. In breast cancer, for example, a patient may have radiotherapy after wide local excision surgery, and this reduces the risk of recurrence to the same level as if they had had a mastectomy.

Palliative radiotherapy can be used to alleviate symptoms of local disease (e.g., haematuria) or distant metastases (e.g., bone pain). Treatment is usually given with a small number of fractions, and effective results can also be achieved with a single fraction of radiotherapy.

Theoretical background

Radiation, used therapeutically, exerts its effects through the ionization of intracellular molecules; the radiation can be electromagnetic or particulate. The two types of ***electromagnetic radiation*** used in radiotherapy are X-rays and gamma rays, and both of these can also be described by the term 'photon'. Gamma rays are produced from the nuclear decay of radioactive isotopes, whereas X-rays are produced artificially by electrical means, usually in a linear accelerator, accelerating electrons to a high energy and then stopping them abruptly in a heavy metal target. ***Particulate radiation*** consists of subatomic particles, including alpha particles, protons, and neutrons.

Interactions of X-rays with matter

The process by which photons are absorbed depends principally on their energy and the chemical composition of the absorbing material. The radiation effect depends on the intensity of the radiation source, measured as the linear energy transfer or frequency of ionizing events per unit of path, which is subject to the inverse square law as the energy diminishes with distance from the source. The depth of penetration of biological tissues by the photons depends on the energy of the beam. Low-energy photons from an 85-kV source are suitable for superficial treatments, whereas high-energy 15-mV sources produce a beam with deeper penetration, lower dose at the initial skin boundary (skin-sparing), sharper edges, and less absorption by bone. Superficial radiation may also be delivered by electron beams from a linear accelerator, from which the target electrode that generates the X-rays has been removed. The radiation dose is measured in Gray (Gy), with 1 Gy being equal to 1 joule (J) absorbed per kilogram of absorbing tissue. There are differing processes of energy absorption, depending on the energy of the photons delivered, but all share the fact that the photon causes excitation of electrons within the targeted tissue.

Biological effect

The resultant biological damage is caused in either an indirect or a direct way. X-rays and gamma rays mainly interact with target biological molecules in an indirect way. The interaction is initially with other atoms and molecules within the cells, producing free radicals, which are highly reactive molecules generated from water and oxygen. These free radicals exert a biological effect through the generation of single- and double-strand DNA breaks, inducing apoptosis of cells as they progress through the cell cycle.

The biological effect is dependent on the dose rate, duration, volume irradiated, and tissue sensitivity. Sensitivity to photon damage is greatest during the G2/M phase of the cell cycle (see **Fig. 41.10**) and is also dependent on the DNA repair capacity of the cell.

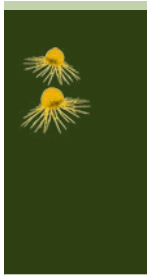
Radiobiology is the study of the actions of ionizing radiation on living things. The effects of radiation on normal and malignant tissues evolve through a series of steps. Classical radiobiology describes the 'five Rs' of the radiation response:

- ***Repair.*** This is the ability of cells to repair DNA damaged by ionizing radiation using different DNA repair mechanisms. Delivery of small daily doses of radiotherapy enables repair of DNA in the cells of normal tissues.
- ***Redistribution.*** When radiation is delivered, cells in the G2/M phase of the cell cycle are most radiosensitive. Cells in the more radioresistant phases (e.g., S phase) survive and progress through the cell cycle and are then in the more radiosensitive phase when the next fraction of radiotherapy is delivered.
- ***Reoxygenation.*** Oxygenated cells are more susceptible to DNA damage by radiation. Because of irregular blood supplies, tumour cells may be hypoxic. After radiation, the more oxygenated cells die, and the surviving hypoxic cells are reoxygenated as oxygen diffuses into these areas, making these cells more susceptible to radiation with the next fraction of treatment.
- ***Repopulation.*** During a course of fractionated radiotherapy, viable tumour cells continue to divide and repopulate the tumour. In some cancers (e.g., those of the head and neck or cervix), it is important not to extend the overall treatment time if there are gaps in treatment because the tumour will repopulate.
- ***Radiosensitivity.*** Some tumours are more sensitive to radiation than others. For example, SCCs and lymphomas are radiosensitive, whereas melanomas and brain tumours are radioresistant.

Clinical application of radiation therapy

Modern radiotherapy allows highly targeted radiation to maximize tumour dose while sparing normal tissue. Radiotherapy planning involves both detailed physics of the applied dose and detailed knowledge of the biology of cancer; it is also necessary to establish whether the intention is to treat the tumour site alone or to include the likely loco-regional patterns of spread. Normal tissue tolerance will determine the extent of the side-effects and therefore the total achievable dose to the tumour. A balanced decision is made according to the curative or palliative intent of the treatment and the likely early or late side-effects. The clinician outlines on the planning scan the areas that they wish to treat using all the clinical information available. They also delineate the critical structures that they do not wish to receive a dose. The physicist then uses planning algorithms to enable the best delivery of dose to the tumour, avoiding critical structures as far as possible. Depending on the site of the tumour, the patient is immobilized to allow reproducibility of position for each fraction of treatment. For example, if the brain is being treated, the patient will wear a mask that keeps them still on the treatment couch.

The cancers for which radiotherapy is usually used in a primary curative approach, when the tumour is anatomically localized, are listed in **Box 41.20**, along with those in which radiotherapy has



Box 41.20 Curative radiotherapy treatment

Primary modality	Adjuvant to primary surgery
• Retina	• Lung
• Central nervous system	• Breast
• Skin	• Uterus
• Pharynx and larynx	• Bladder
• Cervix and vagina	• Rectum
• Prostate	• Testis
• Lymphoma	• Sarcoma

Box 41.21 Palliative benefits of radiotherapy

- Pain relief (e.g., bone metastases)
- Reduction of headache and vomiting in raised intracranial pressure from central nervous system metastases
- Relief of obstruction of the bronchus, oesophagus, ureter, and lymphatics
- Preservation of skeletal integrity from metastases in weight-bearing bones
- Reversal of neurological impairment from the spinal cord or optic nerve compression by metastases

curative potential when added to surgery (adjuvant radiotherapy). Palliative treatments are frequently used to provide relief of symptoms and to improve the quality, if not duration, of survival (Box 41.21). Palliative treatment is usually given in as few fractions as possible over as short a time as possible.

Radiotherapy planning with CT guidance has been complemented by the introduction of three-dimensional planning and volumetric-modulated arc therapy, which can deliver curved dose distributions to improve the therapeutic ratio. This allows a greater differential in dose between the tumour and critical normal structures, in turn permitting dose escalation or a reduced risk of toxicity.

Four-dimensional radiotherapy planning is also becoming widely available. It varies the radiation dose over time (e.g., the respiratory cycle during lung cancer treatment).

Types of radiation therapy

Fractionated external-beam radiotherapy uses photons generated in a linear accelerator. The radiation dose is delivered in increments separated by at least 4 to 6 hours to try to exploit any advantage in DNA repair between normal and malignant cells.

Stereotactic radiosurgery or radiotherapy (Gamma Knife, CyberKnife, or linear accelerator–based treatment) can concentrate X-rays or gamma radiation from multiple sources on to a small volume to generate an ablative dose of radiation with rapid dose fall-off, minimizing the dose to surrounding tissues. Patients with small lung cancers can be treated in this way, allowing for the more aggressive treatment of cancer that has spread to the brain.

Proton-beam therapy is an alternative type of external-beam radiotherapy that uses charged proton particles. Because of their larger mass, the protons have little side scatter and so offer a much more focused beam with less dose to surrounding structures. Proton therapy is particularly recommended for the treatment of children, in whom radiotherapy can affect normal growth and development, and for tumours in close proximity to structures of the central nervous system.

Brachytherapy is the use of radiation sources in close contact with the tissue to provide intense exposure over a short distance to a restricted volume. Such techniques have been used to treat localized breast, prostatic, and cervical carcinoma.

Box 41.22 Side-effects of radiotherapy

Acute temporary side-effects depending on region being treated

- Anorexia, nausea, malaise
- Mucositis, oesophagitis, diarrhoea
- Alopecia
- Myelosuppression

Late side-effects

- Skin: ischaemia, ulceration
- Bone: necrosis, fracture, sarcoma
- Mouth: xerostomia, ulceration
- Bowel: stenosis, fistula, diarrhoea
- Bladder: fibrosis, frequency, incontinence
- Vagina: dyspareunia, stenosis
- Lung: fibrosis, breathlessness
- Heart: pericardial fibrosis, cardiomyopathy, vasculopathy
- Central nervous system: myelopathy
- Gonads: infertility, menopause
- Secondary malignancies (e.g., leukaemia, thyroid cancer)
- Other: carotid artery stenosis

Systemic radionuclides, such as ^{131}iodine- (in thyroid cancer) or radioisotope-labelled MAbs (e.g., anti-CD20 for lymphoma) and hormones (e.g., somatostatin for carcinoid tumours), can be administered by intravenous or intracavitary routes to provide radiation targeted to particular tissue uptake via surface antigens or receptors.

Radiotherapy in combination with systemic therapy

The local efficacy of radiotherapy can be increased by the simultaneous but not serial addition of chemotherapy with agents such as cisplatin, mitomycin, and 5-FU for cancers of the head and neck, lung, oesophagus, stomach, rectum, anus, cervix, and bladder. Reduced local recurrence rates have translated into survival benefits, and further research is investigating the concurrent use of biological agents (e.g., EGFR inhibitors) and immunotherapy with radiation. The ***abscopal effect*** occurs when localized radiotherapy induces the regression of non-irradiated metastatic lesions at a distance from the primary site of irradiation by a systemic immune-mediated response, which may be augmented by giving immunotherapy with the radiotherapy. This is an exciting area of oncology that is being explored in a number of tumour sites.

Side-effects of radiotherapy

Early radiotherapy side-effects may occur within days to weeks of treatment; at this point, they are usually self-limiting but associated with general systemic disturbance (Box 41.22). The side-effects depend on tissue sensitivity, fraction size, and treatment volume and are managed with supportive measures until normal tissue repair occurs. The toxicity may also be enhanced by exposure to other radiation-sensitizing agents, especially some cytotoxics, such as bleomycin, actinomycin, anthracyclines, cisplatin, and 5-FU.

Later side-effects occur months to years later and are unrelated to the severity of the acute effects because they have a different mechanism. Late effects reflect both the loss of slowly proliferating cells and a local endarteritis that produces ischaemia and proliferative fibrosis. The risks of late side-effects are related to the fraction size and total dose delivered to the tissue. Growth may be arrested if bony epiphyses are not yet fused and are irradiated, leading to distorted skeletal growth in later life.

Secondary malignancies after radiotherapy may appear 10 to 20 years after cure of the primary cancer. Haematological

malignancies tend to occur sooner than solid tumours from the irradiated tissues. The latter are very dependent on the status of the tissue at the time of treatment; for example, the pubertal breast is up to 300 times more sensitive to malignant transformation than the breast tissues of a female in her 30s. Patients who smoke are more liable to develop lung cancer. Treatment of these secondary cancers can be successful, provided there is normal bone marrow to reconstitute the haematopoietic system, or the whole tissue at risk can be resected (e.g., thyroid after mantle radiotherapy for lymphoma).

COMMON SOLID TUMOUR TREATMENT

Common cancer mortality rates are listed in **Box 41.23**; improvements in survival in recent years have stemmed from advances in prevention, diagnosis, and treatment. The presentation, diagnosis, and natural history of the common cancers are described in the relevant systems-based chapters of this book; staging and anticancer treatment is covered here. Haematological malignancy is presented in Chapter 39.

The decision to treat and the aim of the treatment, whether palliation or cure, require knowledge of the natural history of the disease, prognostic and predictive factors, the patient's performance status, and the potential efficacy of treatment. Management should be carried out by an MDT, which is usually led by an oncologist.

Box 41.23 Index of net survival of all cancers at 5 years after diagnosis

Cancer type	5-year survival rate (%)	
	Males	Females
Pancreas	3.6	3.1
Lung	8.4	11.6
Oesophagus	15.6	14.7
Stomach	19.5	17.7
Brain	17.8	19.5
Multiple myeloma	50	43.8
Ovary		46.4
Leukaemia	53.3	49.1
Kidney	56.7	55.6
Colon	59.2	57.3

LUNG CANCER

The presentation and diagnosis of lung cancer are covered more fully in Chapter 20. Current treatment reflects the fact that the majority of patients are diagnosed at an advanced stage with a poor prognosis; there are therefore many trials assessing different screening strategies to try to achieve an earlier diagnosis that would permit more curative treatment.

Prognosis

Lung cancer histology is divided into two main types (**Box 41.24**):

- ***Small-cell lung cancers (SCLCs)***, which derive from adenocarcinomas but develop neuroendocrine differentiation and tend to rapidly metastasize. They are sensitive to both chemotherapy and radiotherapy but frequently relapse after initially appearing to respond well.
- ***Non–small-cell lung cancers (NSCLC)***, which are more likely to be diagnosed in a localized form. As treatments have improved, it has become clear that what previously was simply called NSCLC to be separated into individual pathological entities because the management varies, and some therapies are effective only in particular subtypes.

Tumour stage and patient performance status are used in selecting treatment and predicting response and prognosis (**Box 41.25**). Although the overall 5-year survival rate has remained approximately 10%, treatment is beginning to have an impact in selected groups.

Box 41.24 Histological subtypes of lung cancer

Histological subtype	Percentage of all lung cancers
Small-cell lung cancer	15
Non–small-cell lung cancer	85
Adenocarcinoma	40
Squamous cell carcinoma	35
Large cell carcinoma	10

Based on data from Goldstraw P, Crowley J, Chansky K et al. The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (8th) edition of the TNM classification of malignant tumours. J Thorac Oncol *2016; 2:706–714.*

Staging

Where the technology is available, staging is normally based on PET/CT (Fig. 41.15). In the absence of distant metastases, further evaluation of local and regional lymph nodes is frequently undertaken if lymph nodes are enlarged but of low glucose avidity or lymph nodes do not appear enlarged but do show significant glucose avidity.

In these cases, confirmatory tests are required to yield histological samples, for example, endobronchial ultrasound and biopsy or, in the case of central nodes closer to the oesophagus, endoscopic ultrasound–based biopsy.

General approach to management

This is based on the stage of disease; the histological subtype; the presence of particular genetic mutations; the patient's performance status (see Box 41.13); and, crucially, the patient's own wishes.

- For ***stage 1 and 2 disease***, the treatment of choice is surgical resection by lobectomy or pneumonectomy, with stereotactic ablative radiotherapy when surgery is contraindicated. Increasingly, segmentectomies are offered and have been shown to reduce morbidity without an increase in local relapse rate. The use of neoadjuvant chemo-immunotherapy in patients with tumours larger than 40 mm in diameter with or without nodal involvement has been shown to reduce the risk of recurrence; increase the complete remission rate; and in patients with nodal involvement, to improve overall survival. It should be considered in these cases, and normally three cycles of platinum-based chemotherapy with a taxane, gemcitabine, or pemetrexed with nivolumab should be given before surgery.
- Selected patients with ***stage 3A disease*** can be managed surgically, but the alternative approach is a combination of chemotherapy and radiotherapy directed by histological subtype and molecular testing.
- For patients with ***more advanced disease***, a variety of agents can prolong survival, and specific palliative measures can relieve symptoms and improve quality of life.

Non–small-cell lung cancer

Staging of NSCLC is classified according to the TNM system (see Box 41.12 and Box 20.35); this system divides the disease into local, locally advanced, and advanced stages, with 5-year survival rates varying from 55% to 67%, 23% to 40%, and 1% to 3%, respectively.

Management

Surgery

Surgery can be curative in NSCLC (T1, N0, M0) but only 5% to 10% of all patients are suitable for resection; about 70% of these patients survive for 5 years. Preoperative assessment includes lung function testing and walking oximetry, which is used to predict postoperative potential. An active life after pneumonectomy is unlikely if the gas transfer is reduced below 50%.

Adjuvant radiotherapy and chemotherapy after surgery can improve prognosis in patients of good performance status, as shown by the International Adjuvant Lung Cancer Trial and a meta-analysis of 12 randomized controlled trials. Cisplatin-based combination chemotherapy induced a response in 60% of patients and produced a relative risk reduction of 11% with an absolute improvement in 5-year survival rate for stage II and IIIa disease of 4%, from 40.4% to 44.5%. This should be offered if patients have not had neoadjuvant chemo-immunotherapy. Patients who have high PDL-1 expression may be offered 1 year of adjuvant atezolizumab, and those with EGFR-mutated lung cancer should be offered 3 years of adjuvant osimertinib, which has been shown to improve survival.

Radiation therapy for cure

In patients who are fit and who have a stage 1 NSCLC, high-dose radiotherapy (65 Gy or 6500 rads) can result in a 27-month median survival time and a 22% 5-year survival rate. It is the treatment of choice if surgery is not appropriate; however, poor lung function can also be a relative contraindication to radiotherapy. ***Radiation pneumonitis*** (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10% to 15% of patients. ***Radiation fibrosis***, a fibrotic

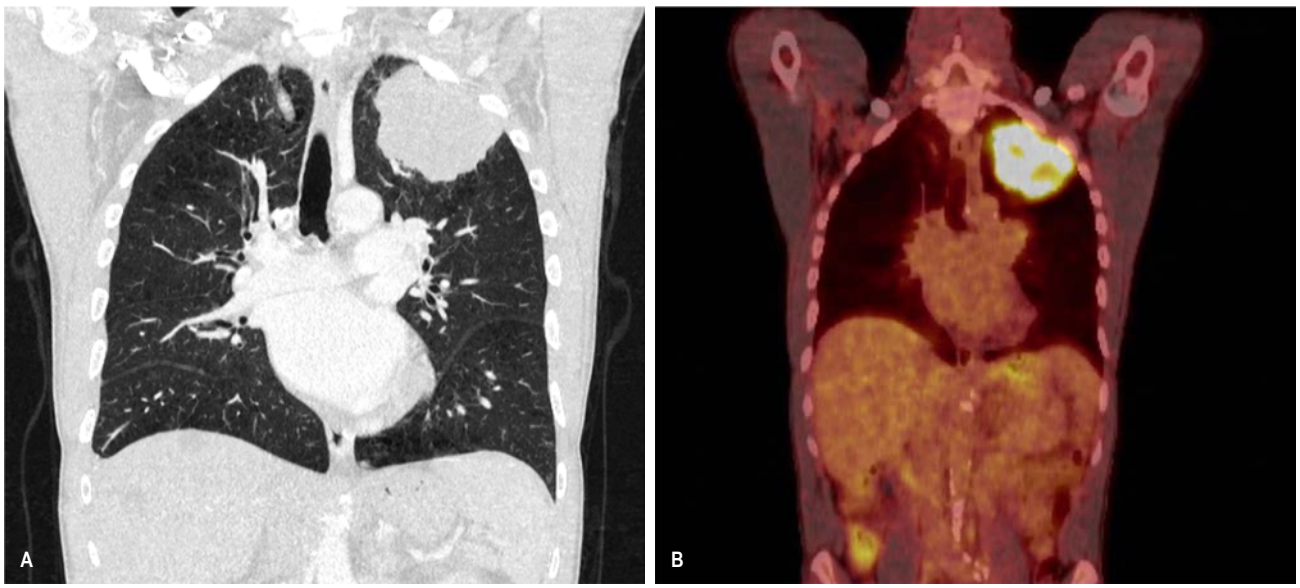

Fig. 41.15 **(A)** Coronal contrast-enhanced computed tomography (CT) scan showing a large left upper lobe primary lung malignancy. **(B)** Corresponding positron emission/CT scan show significant avidity with central necrosis. These findings are typical for a primary lung malignancy.

change occurring within 1 year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all patients but is usually asymptomatic.

Genetic profiling and tyrosine kinase inhibitors

Increasingly, tissue obtained at biopsy is investigated using next-generation sequencing (NGS; see Chapter 5, 'Next-generation sequencing' section) to seek the presence of specific oncogenic (activating) mutations (**Box 41.26**). These are more common in non-smokers, although they account for less than 5% of cases in unselected series. Where mutations are identified, targeting these driver mutations with an appropriate TKI is the first-line treatment (see **Box 41.19**); however, if the cancer is localized, standard radical options (surgery, radiotherapy) may still be preferred. In patients with more advanced disease, targeted drugs are preferable to cytotoxic chemotherapy in certain situations.

For EGFR mutants (with the exception of exon 20 insertions), osimertinib should be offered as first-line therapy. Currently, on progression, further treatment consists of combination chemotherapy, most often platinum and pemetrexed based with maintenance pemetrexed.

Other commonly targeted mutations are *ALK* and *ROS*. Alk mutations are most often treated with alectinib in the first instance with lorlatinib a useful second-line drug, and for ROS-1, mutations crizotinib is often the drug of first choice.

In other cases, cytotoxic chemotherapy is chosen first, and targeted drugs are used in the second-line setting (e.g., in *KRAS* mutations, in which the G12C variant is seen, sotorasib is a useful option). In RET fusions selpercatinib may be used, and in *NTRC* mutations, larotrectinib may be chosen. In all these cases, response rates of 40% to 70% may be seen with response durations between 5 and 12 months.

Immunotherapy

PDL-1 and its receptor, PD-1, are often overexpressed in patients with NSCLC, allowing cancer cells to evade destruction by the body's immune system. In patients who are PDL-1 positive (>50%) but lack the driver mutations described earlier, pembrolizumab (a MAb that acts as a PD-1 antagonist) is used alone, and in those with lower levels of expression, it may be combined with chemotherapy, with significant improvements in survival. The PDL-1 antagonist durvalumab, used every 2 weeks for 1 year alongside cisplatin-based chemotherapy, has been shown to raise the median time to progression or death from 16 to 28 months in patients with NSCLC in the setting of chemoradiotherapy.

Conventional chemotherapy

This is used in the absence of specific driver mutations. Cisplatin (or carboplatin) plus gemcitabine for squamous carcinoma and cisplatin and pemetrexed for adenocarcinoma remain the standard treatments. (An alternative, particularly in older patients, is carboplatin and paclitaxel.) Single-agent docetaxel with or without the targeted drug nintedanib may be offered as second-line therapy if patients are fit.

Box 41.26 Activating mutations seen in non–small-cell lung cancer

Squamous cell carcinoma in never smokers	Y	Y		Y		Y
Squamous cell carcinoma in smokers				Y		

Small-cell lung cancer

Prognosis

SCLC is an aggressive neuroendocrine tumour. It is staged in the same way as NSCLC, and patients with stage 1 tumours may benefit from surgery. For non-operable cases, disease is classified as limited- or extensive-stage disease.

Management

Limited-stage disease is confined to one anatomical area and is present in approximately 30% of patients. It is best treated with concurrent chemotherapy and radiotherapy using either cisplatin or carboplatin, with either etoposide or irinotecan, which increases the survival rate at 5 years from 15% to 25% compared with radiotherapy alone. Recurrence is usual within 6 to 12 months; for those who remain fit, further chemotherapy is appropriate. A similar degree of improvement can also be achieved with hyperfractionated radiotherapy. Prophylactic whole-brain radiation to prevent cerebral metastases can reduce symptomatic central nervous system disease and improve the overall survival rate by 5%.

For ***extensive disease***, concurrent chemoradiotherapy with carboplatin, etoposide, and the anti–PDL-1 MAb atezolizumab over four cycles followed by atezolizumab maintenance for up to 2 years is considered optimal. This can increase the median survival time from 10 to 12 months and the 18-month survival rate from 21% to 34% compared with chemotherapy alone. Second-line chemotherapy can provide further palliation for patients with good performance status.

Symptomatic care for patients with lung cancer

The prognosis for the majority of patients remains poor because the disease is diagnosed at an advanced stage, and the co-morbidity from other smoking-related diseases compromises treatment. Therefore, much of the treatment, whether symptomatic or anticancer, is delivered with palliative intent. (General palliative care is discussed in Chapter 50.) Specific issues for patients with lung cancer are the relief of bronchial obstruction and breathlessness. Options for dealing with these problems include:

- A ***neodymium-Yag laser*** passed through a fibreoptic bronchoscope can be used to vaporize inoperable fungating intraluminal carcinoma involving short segments of trachea or main bronchus. Benign tumours, strictures, and vascular lesions can also be treated effectively with immediate relief of symptoms.
- ***Cryotherapy*** is an endobronchial technique in which a cryoprobe is passed through the bronchoscope. The cryoprobe repeatedly freezes and thaws the tumour, which enables parts of it to be excised, restoring airway patency without causing bleeding. The excised tissue can be sent for histological analysis.
- ***Tracheobronchial stents*** made of silicone or in the form of expandable metal springs are available for insertion into strictures caused by tumour, external compression, or weakening and collapse of the tracheobronchial wall.
- Local radiotherapy can be used for the alleviation of local pain related to malignant infiltration of structures such as the pleura or chest wall.

Mesothelioma

Diagnosis of mesothelioma is discussed in Chapter 20 (see 'Mesothelioma' section). The treatment of patients with mesothelioma is currently not curative, although long-term survival is possible. There is no routine role for surgery either in the form of extrapulmonary pneumonectomy or radical decortication. Immunotherapy using checkpoint inhibitors (e.g., nivolumab and ipilimumab) as first-line therapy has been shown to improve survival compared with cisplatin and pemetrexed chemotherapy, with the median survival time increasing from 14 to 18 months and the 2-year rate survival from 27% to 41%.

Chemotherapy can be offered after treatment failure or when immunotherapy is contraindicated.

Metastases in the lung

Metastases are very common and usually present as round shadows (1.5–3.0 cm in diameter). They are usually detected on chest X-ray in patients already diagnosed as having cancers at other sites but may be the initial presentation of disease. Typical sites for the primary tumour include the kidney, prostate, breast, bone, GI tract, cervix, or ovary.

Metastases usually develop in the parenchyma or pleura and are often relatively asymptomatic even when the chest X-ray shows extensive disease. Rarely, metastases may develop within the bronchi and present with haemoptysis.

Metastatic carcinomas (particularly of the stomach, pancreas, and breast) can involve the mediastinal lymph nodes and spread along the lymphatics of both lungs ***(lymphangitis carcinomatosa)***, leading to progressive and severe breathlessness. Chest X-ray signs of hilar lymphadenopathy and basal shadowing are unreliable compared with the characteristic signs on CT scan of irregular thickening of the interlobular septa in a polygonal pattern around a thick-walled central vessel.

The differential diagnosis includes:

- Primary bronchial carcinoma
- Tuberculoma
- Benign tumour of the lung
- Hydatid cyst

Single pulmonary metastases can be removed surgically, but because CT scans usually show the presence of small metastases that remain undetected on chest X-ray, detailed imaging, including PET scanning and assessment, is essential before undertaking surgery.

BREAST CANCER

Breast cancer is the most common cancer in females in the UK. Breast cancer screening has improved the detection of early and curable breast cancer and is a model for other screening programmes. The diagnosis of breast cancer is covered in Chapter 47.

Improvements in multimodality treatment have increased overall cure rates. Breast-conserving surgery for selected patients with early disease has greatly ameliorated the psychosexual impact of the disease (Fig. 41.16).

When therapy is being planned, decisions are based on:

- The extent of the disease (staging)
- Histological features (grading)
- The presence or absence of three crucial cell-surface receptors: the ER, progesterone receptor (PR), and HER2.

Triple-negative disease tends to be the most aggressive disease, often requiring use of systemic chemotherapy regardless of stage and grade. ER positivity allow use of hormonal treatment such as tamoxifen, while HER2 is the target of trastuzumab. Younger patients and those with a family history of the disease should be genotyped for the *BRCA* gene because those who are positive may elect to undergo bilateral mastectomy to reduce risk of subsequent disease.

Management of early disease

Surgery

In early disease, surgical options include wide local excision and segmental mastectomy with breast conservation; simple mastectomy, with or without reconstruction, is used for larger, inflammatory, or multicentric tumours. The choice is dictated by the location, extent of the breast mass, and patient preference. Clear histological margins around the cancer are important for cure.

In the absence of clinical or ultrasound evidence of lymphadenopathy, surgery to the axilla can be minimized if sentinel lymph node–guided sampling excludes local spread; otherwise, axillary nodal dissection is required if there are clinically involved nodes to gain local control and provide prognostic information to guide adjuvant treatment. The greater the amount of axillary surgery, the greater the risk of postoperative lymphoedema.

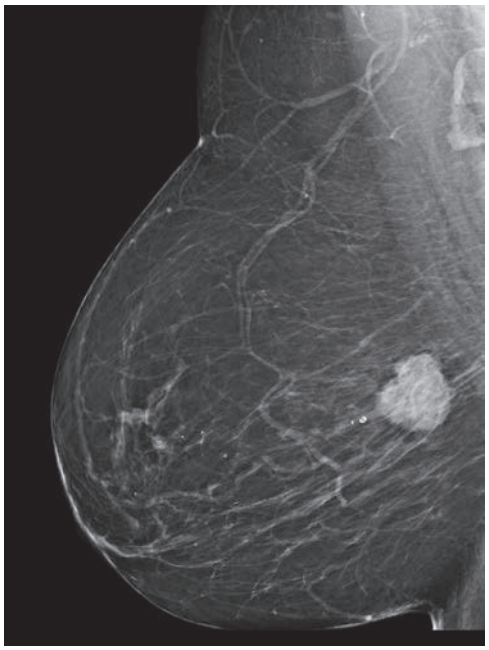

Fig. 41.16 A mammogram showing a 30-mm irregular mass in the upper-outer quadrant of the right breast, which is suspicious for carcinoma.

Box 41.27 Indications for adjuvant radiotherapy in breast cancer

- Breast-conserving surgery
- Large, high-grade primary tumour
- Proximity to surgical margins
- Lymph node metastases

Radiotherapy

All patients who undergo breast-conserving surgery for early breast cancer require postoperative radiotherapy to the breast to provide the security of local control equivalent to that conferred by mastectomy (Box 41.27). Those undergoing mastectomy who have disease close to resection margins also require radiotherapy to the chest wall. The axillary nodes are spared during radiotherapy if the axilla has been dissected (to avoid worsened lymphoedema), but supraclavicular nodes are included if there are four or more positive axillary nodes or one to three with high-risk features. Internal mammary node irradiation is occasionally given in selected higher-risk cases.

Systemic therapy

For locally advanced breast cancers, systemic therapy ***(neoadjuvant therapy)*** is sometimes given to downstage the cancer before locoregional treatment with surgery and radiotherapy. This may allow safe breast-conserving therapy in a patient with disease who, at presentation, would have required full mastectomy or to allow time for genetic testing. Neoadjuvant chemotherapy is also given in HER2-positive breast cancer, and patients with triple-negative breast cancer are treated with a combination of chemotherapy and immunotherapy. Pathological treatment response at surgery gives prognostic information for both HER2 and triple-negative breast cancer and directs adjuvant treatment options.

The term ***adjuvant therapy*** applies to systemic treatment that is given after definitive locoregional therapy in a patient who is perceived to have a significant risk of future relapse.

The aim of chemotherapy is to destroy microscopic residual disease that may have disseminated elsewhere in the body, and trials have shown benefit from both endocrine treatment and chemotherapy. Typical chemotherapy regimens are discussed later in the section 'Management of advanced disease'. In patients with triple-negative breast cancer, immunotherapy is often given to maintain treatment response after surgery if there has been a complete treatment response to neoadjuvant treatment.

Targeted therapy

A range of agents can be used, depending on the receptor status of the underlying disease.

HER2-positive disease

HER2 is overexpressed in 20% of all breast cancers and acts as an oncogene, 'driving' the cancer to grow. HER2-positive cancers tend to behave aggressively but respond to treatment with HER2 inhibitors such as trastuzumab and pertuzumab; endocrine therapy is used subsequently if tumours are also ER positive. If indicated, radiotherapy is usually given after systemic therapy, the logic being that systemic therapy is most likely to cure any microscopic disease when the tumour burden is lowest and that systemic therapy also treats regional disease and so should be given as soon as possible.

Oestrogen receptor–positive disease

For cancers that present a lesser risk and are ER positive, adjuvant endocrine therapy is delivered, for between 5 to 10 years after surgery. There are two strategies for endocrine therapy:

- ***ER blockade*** using tamoxifen (a competitive inhibitor of the oestrogen receptor) or fulvestrant (which also causes degradation of the oestrogen receptor)
- ***Oestrogen deprivation*** using aromatase inhibitors such as letrozole (which blocks non-ovarian oestrogen synthesis); aromatase inhibitors are not active in premenopausal females

In a head-to-head study, a slight advantage was proven for use of aromatase inhibitors as adjuvant therapy in postmenopausal females with ER-positive breast cancer compared with tamoxifen; consequently, this is now first-line endocrine therapy in this group. In premenopausal females with higher-risk ER-positive disease, there is an advantage for complete ovarian suppression (laparoscopic oophorectomy or luteinizing hormone-releasing hormone agonist therapy) plus aromatase inhibition.

In ER-positive breast cancer, the effector pathway that stimulates cellular proliferation is mediated via a cyclin D/cyclin-dependent kinase phosphorylating holoenzyme, which regulates the RB protein (a suppressor of G1- to S-phase progression). In patients with a high risk of recurrence, the addition of cyclin inhibitor (abemaciclib) to endocrine treatment significantly enhances the response rate and duration of this endocrine-based therapy in ER-positive breast cancer.

Bisphosphonates

For postmenopausal females at high-risk of recurrence, adjuvant bisphosphonate infusions given every 6 months for 3 to 5 years have been shown to reduce the incidence of metastatic breast cancer recurrence in bone.

Follow-up

After the end of therapy (or during ongoing adjuvant endocrine, anti-HER2 therapy, or immunotherapy), high-risk patients are reviewed clinically every 3 to 6 months by examination and enquiry into general wellbeing. Health economic studies have not supported the usefulness of proactive scanning in patients who have negative follow-up results based on these clinical assessments. However, an annual mammogram, both for the index breast and the contralateral side (where, irrespective of the genetics, there is an increased risk of a new cancer), is recommended for at least 5 years of follow-up. Low-risk patients are also followed up with 5 years of mammograms to both breasts.

Management of advanced disease

The management of patients presenting with metastatic disease depends on the extent and location of disease (Fig. 41.17).

Widespread visceral disease

Patients are advised to have systemic chemotherapy (with or without HER2-directed therapy) followed by endocrine therapy if the cancer is ER positive. Treatment is unlikely to be curative but may well improve prognosis by years, during which quality of life may be good.

The chemotherapy advised for this situation (and, indeed, the adjuvant therapy discussed earlier) is based on combinations of drugs, thereby reducing resistance (the same premise as is applied with multidrug antibiotic therapy for tuberculosis infection).

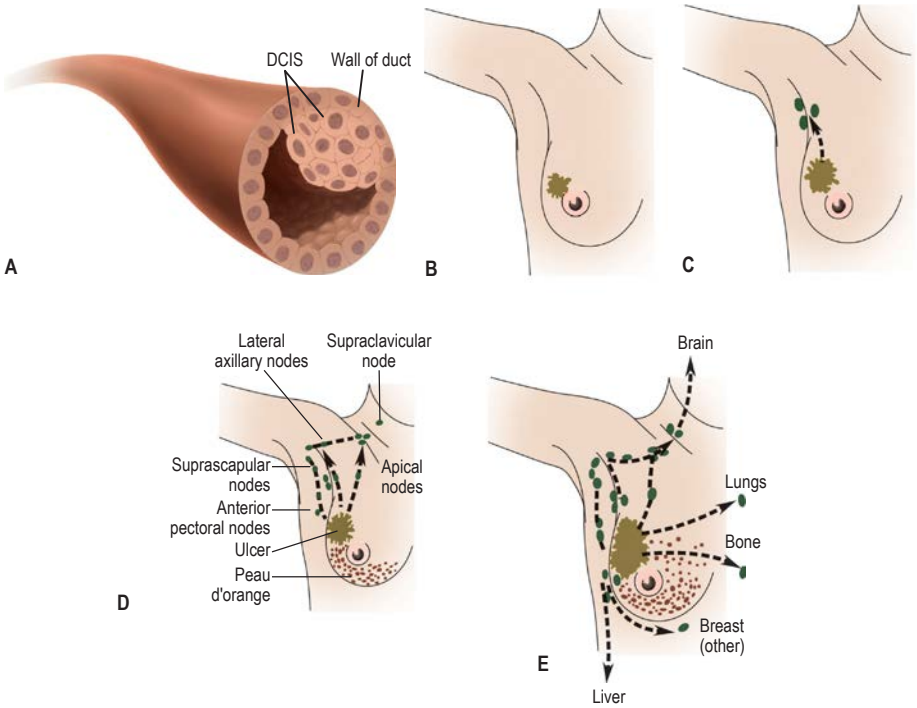

Fig. 41.17 Staging of breast cancer. **(A)** Carcinoma in situ. **(B)** Stage I: tumour is smaller than 2 cm with no nodal involvement. Stage IIa: cancer cells found in axillary lymph nodes, tumour is 2 cm or smaller with metastasis to axillary lymph nodes, or tumour is larger than 2 cm but not larger than 5 cm with no metastasis to axillary lymph nodes. **(C)** Stage IIb: tumour is larger than 2 cm but not larger than 5 cm with positive axillary lymph node involvement, or tumour is larger than 5 cm with negative axillary lymph node involvement. **(D)** Stage IIIa: tumour is 5 cm or smaller with metastasis to axillary lymph nodes that are attached to each other or to other structures or has spread to lymph nodes behind breastbone, or tumour is larger than 5 cm and has spread to axillary lymph nodes that are alone or attached to each other or to other structures or has spread to lymph nodes behind the breast bone. Stage IIIb: tumour of any size that has grown into the chest wall or skin of the breast, causing swelling of the breast or nodules in breast skin. **(E)** Stage IV: breast cancer that has spread to other parts of the body such as the bones, liver, or lung. *DCIS,* Ductal carcinoma *in situ*. (*From* Alexander's Care of the Patient in Surgery, *Seventeenth Edition*.)

Combinations of drugs are selected for their anti-tumour activity in breast cancer and their non-overlapping toxicities. Anthracyclines, taxanes, vinca alkaloids, capecitabine, and alkylating agents all feature in first-line regimens. For triple-negative breast cancer, immunotherapy and platins also have a role. Interestingly, the triple-negative group tends to carry a high mutational load, and this is the only group of breast cancers that respond well to immunotherapy.

Limited metastatic disease

For patients who present with one or only a few sites of metastatic disease (oligometastatic disease), there may still be a chance of cure. Aggressive treatment with ablative focal therapy to those oligometastatic sites (e.g., radiofrequency ablation, stereotactic radiation, or surgical metastasectomy) may be worth pursuing in a fit patient.

Indolent metastatic disease that is not immediately life-threatening

If the cancer is ER-positive, primary endocrine therapy may hold the disease at bay for long periods; usually with a CDK 4/6 inhibitor (e.g., ribociclib, abemaciclib, or palbociclib). Chemotherapy may be delayed until the cancer progresses despite this endocrine-based therapy. ER-positive breast cancers with a phosphoinositide 3-kinase escape pathway may also benefit from alpelisib when the cancer progresses.

Metastatic disease confined to regional lymph nodes

An aggressive regimen of neoadjuvant chemotherapy, surgery to breast and axillary nodes, regional radiotherapy, and long-term endocrine or HER2-directed therapy offers a chance of cure.

Relapsed disease after previous systemic therapy

The systemic therapy previously received has to be carefully considered before new therapy is instituted. The timing between the previous therapy and relapse is important because re-introduction of agents may be sensible only if the cancer has not been exposed to a particular group of drugs for a number of years. New agents (i.e., ones to which the cancer has not been exposed) are preferable, and eribulin is a chemotherapy agent that has value in this situation. In *BRCA*-driven cancer, the poly-ADP ribose polymerase (PARP) inhibitors (DNA repair inhibitors that seem to augment the defect of *BRCA* mutation in a lethal way) may enhance the efficacy of certain drugs, such as the platins, or be active as single agents. It is sometimes worth obtaining a biopsy at the time of relapse for

further genomic analysis of the 'new' tumour because the constant mutational events in a progressing cancer throw up new driver mutations, some of which can be blocked.

UPPER GASTROINTESTINAL CANCERS

Oesophageal cancer

Presentation and diagnosis are described in Chapter 22 (see 'Cancer of the oesophagus' section). Early diagnosis, as pioneered in Japan, where there is a particularly high incidence, has shown that it is possible to improve the prognosis of a disease that otherwise is typically diagnosed only when local metastases have already occurred.

Prognosis and management

Pretreatment histology, stage, age, and performance status are critical prognostic factors for treatment decisions, which should be made by an MDT in designated units with the surgical expertise to minimize treatment mortality. Although oesophageal SCC and adenocarcinoma are undoubtedly two different disease processes with independent tumour biology, the majority of trial data do not discriminate between the two. The influence of histology on treatment is therefore unclear and varies around the globe.

Treatment is dependent on the age and performance status of the patient and the stage of the disease, with approximately 40% of all patients still alive 1 year after diagnosis. The 5-year survival rates are 80% for stage 1 disease (T_1/T_2, N0, M0), 30% for stage 2, 18% for stage 3, and 4% for stage 4. Some 70% of patients present with stage 3 or greater disease, with 50% having distant metastases at the time of diagnosis and the majority of the remainder having regional spread into adjacent mediastinal structures, so the overall survival rates are 40% at 1 year and around 15% at 5 years.

Staging with endoscopic ultrasonography, CT, and PET/CT has improved the selection of patients of good performance status with truly localized disease, for whom curative treatment may be attempted.

Treatment of early-stage disease

Surgery provides the best chance of cure, particularly for tumours in the distal oesophagus, but it should be used as the primary modality only when imaging has shown that the tumour has not infiltrated outside the oesophageal wall (stage 1). Fewer than 40% of patients have potentially resectable disease at the time of presentation. Endoscopic mucosal resection may be appropriate for those with early mucosal disease.

Poor outcome data from surgery alone have challenged its role as monotherapy, and patients with locally advanced disease that is potentially resectable are recommended to have neoadjuvant chemotherapy with cisplatin/5-FU before surgery. Response to neoadjuvant therapy is a strong prognostic factor. Radical chemoradiotherapy alone is an alternative approach for patients with SCC of the thoracic oesophagus and avoids the morbidity associated with surgery. Those with adenocarcinoma of the oesophago-gastric junction can be treated with perioperative chemotherapy in a combination of docetaxel, oxaliplatin, fluorouracil, and leucovorin (FLOT).

Treatment of advanced or metastatic disease

This can be palliated with 5-FU or capecitabine chemotherapy in approximately 30%, increasing to 45% to 55% with the addition of oxaliplatin or irinotecan for a median duration of 6 to 8 months.

Palliative approaches

Distressing symptomatic problems with dysphagia can be partially relieved by endoscopic techniques, although dilation alone is only of short-term benefit, and the perforation risk is higher than for benign strictures. Combination of endoscopic dilation with laser or brachytherapy (see 'Types of radiation therapy' section) prolongs luminal patency and gives as good, if not better, functional results than stenting. Insertion of an expanding metal stent allows liquids and soft foods to be eaten, and percutaneous endoscopic gastrostomy tubes support liquid enteral feeding. The patient and family need considerable support and explanation to enable them to understand that feeding, including parenteral methods, does not improve survival beyond that dictated by the underlying cancer and may introduce its own complications with adverse effects on quality of life.

Gastric cancer

The presentation and diagnosis of gastric cancer are described in Chapter 22 (see 'Gastric tumours' section).

As with all cancers, treatment is discussed with an MDT.

Prognosis and management

The majority of patients are still diagnosed at an advanced stage, except in Japan, which has an active surveillance policy. Thus, in the West, the overall prognosis has not improved above 10% survival at 5 years. Selected groups may do much better and the histological grade and staging, with respect to the presence of serosal involvement (T3), nodal involvement (N1–2) and performance status, are the main factors in determining prognosis and selecting treatment.

Treatment of early-stage disease

Early non-ulcerated, mucosal lesions can be removed endoscopically by either endoscopic mucosal resection or endoscopic submucosal dissection.

Otherwise, surgery remains the most effective form of treatment if the patient is considered 'operable' in terms of lack of

direct invasion and nodal spread: selection based on operability has reduced the numbers undergoing surgery and significantly improved the overall surgical 5-year survival rates to around 30% or even 50% in those undergoing 'curative' operations. Perioperative chemotherapy with FLOT improves the 3-year overall survival rate in this patient group from 35% to 57%. If a patient has not had neoadjuvant treatment, adjuvant chemotherapy or chemoradiotherapy can be used.

Treatment of advanced disease

This may be palliated with chemotherapy, such as oxaliplatin and capecitabine combined with cisplatin and infusional 5-FU for patients with SCC, with a response in 40% to 50% for a median of 8 to 12 months in patients with good performance status (see 'Performance status' section). The addition of trastuzumab a and pertuzumab for tumours overexpressing HER2 (see 'HER2-positive disease' section) has improved the median time survival from 11 to 16 months. For patients with deficient mismatch repair, high levels of microsatellite instability (MSI), or PDL-1 overexpression, immune checkpoint inhibitors targeting PD-1 (pembrolizumab) have activity in this tumour type and may be considered in the future for patients who have relapsed. Trifluridine/tipiracil, which interferes with tumour DNA synthesis, may also have activity in the relapsed setting.

Palliative approaches

Supportive care for patients with upper GI cancers, more than cancers in any other site, must include attention to nutrition with the use of endoscopic stents to relieve obstruction, nasojejunal and percutaneous gastrostomy feeding tubes, and occasionally parenteral nutrition. When the disease progresses and active anticancer treatment is no longer appropriate, management of distressing obstructive symptoms can include octreotide to reduce secretions and, if necessary, a venting gastrostomy.

Gastrointestinal stromal tumours

GISTs are rare, slow-growing neoplasms that may arise in the stomach or small or large intestine. The prognosis depends on size, site, Ki-67 proliferation index (see Chapter 22, 'Gastrointestinal stromal tumours' section), and association with neurofibromatosis type 1 (see Chapter 28, 'Neurofibromatosis type 1 [von Recklinghausen's disease]' section). Immunohistochemistry for CD117 and DOG-1 (discovered on GIST-1) is usually positive; if negative, the diagnosis can be reached by analysis of the known mutational sites in *c-Kit* or *PDGFRA* oncogenes. These mutations predict response to TKIs such as imatinib (see Chapter 39, 'Chronic myeloid leukaemia and the myeloproliferative neoplasms' section). Surgery is potentially curative for patients with localized disease, and imatinib adjuvant therapy for 3 years prolongs survival. In metastatic disease, imatinib treatment should continue until relapse and can induce remissions in 50% to 80% of patients for a median of 2 years; further responses are possible with alternative TKIs such as sunitinib and nilotinib.

LOWER GASTROINTESTINAL CANCERS

Small intestinal cancer

Predisposing factors for small intestinal cancer and its presentation are described in Chapter 22. The principles of treatment are determined by extrapolation from management of the more common colorectal cancers (**Figs. 41.18 and 41.19**).

Colorectal cancer

The presentation and diagnosis of colorectal cancer are described in Chapter 22 (see 'Colorectal carcinoma' section).

Prognosis

The site of the disease (above or below the pelvic peritoneal reflection), TNM stage (see **Box 41.11**), surgical margins, and the patient's performance status (see **Box 41.2**) are the main clinical prognostic factors (**Box 41.28**). Gene expression profiling using Oncotype DX and Coloprint, for example, can identify prognostic subgroups but is not predictive of treatment benefit. High MSI predicts a better prognosis and can be used to identify low-risk patients for whom adjuvant therapy is unlikely to be of benefit. Mutations in *BRAF* occur in 6% to 8% of patients and indicate a poor prognosis, as do mutations with predictive effect in *KRAS* in 40% and *NRAS* in 10% to 15% of cancers.

Management

Management should be undertaken by MDTs working in specialist units. About 80% of patients with colorectal cancer undergo surgery (often laparoscopically), although fewer than half of them survive for more than 5 years. The operative procedure depends on the cancer site. Long-term survival is only likely when the cancer is completely removed by surgery with adequate clearance margins and regional lymph node clearance.

Surgery

- ***Total mesorectal excision (TME)*** is required for rectal cancers and removes the entire package of mesorectal tissue surrounding the cancer. A low rectal anastomosis is then performed. Abdomino-perineal excision, which requires a permanent colostomy, is reserved for very low tumours within 5 cm of the anal margin. TME combined with preoperative radiotherapy reduces local recurrence rates in rectal cancer to around 8% and improves survival. Pre- or postoperative chemotherapy reduces local recurrence rates but had no effect on survival in a recent study.
- ***Segmental resection*** and restorative anastomosis, with removal of the draining lymph nodes as far as the root of the mesentery, is used for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. When technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction, so surgery can be elective rather than emergency and is probably associated with a decrease in morbidity and mortality.
- ***Local transanal surgery*** is very occasionally used for early superficial rectal cancers.
- ***Surgical or ablative treatment of liver and lung metastases*** prolongs life when treatment is technically feasible and the patient is fit enough to undergo the treatment.
- ***Radiotherapy is not helpful*** for colonic cancers proximal to the rectum because of difficulties in delivering a sufficient dose to the tumour without excess toxicity to adjacent structures, particularly the small bowel.
- ***Adjuvant postoperative chemotherapy*** improves disease-free survival and overall survival in patients with stage III colon cancer. Those with stage II tumours and advanced features such as vascular invasion may also benefit. Genetic testing for *KRAS* mutations can help target appropriate chemotherapy regimens.

Neoadjuvant chemotherapy and radiotherapy

Neoadjuvant chemoradiation treatment of locally advanced rectal cancers, using 5-FU or capecitabine with 5 weeks of radiotherapy and then a 2-month wait, has increased the proportion of locally advanced tumours that can be resected with clear surgical margins and has improved the local control rate but has not had a beneficial effect on distant metastatic relapse and overall survival. Preoperative, rather than postoperative, treatment has reduced toxicity to the other pelvic structures because of preservation of the normal anatomical relations. Alternatives include short-course radiotherapy over 1 week with immediate or delayed surgery and total neoadjuvant treatment with chemotherapy before or after chemoradiotherapy in patients most at risk of metastatic disease, although this has not been proven in large randomized trials. In cases in which it is desirable to avoid radiation, preoperative chemotherapy alone can achieve similar response rates. In 20% to 30% of patients, there is a complete clinical and radiological response to treatment after chemoradiotherapy, and in these individuals, it may be possible to avoid surgery with stringent follow-up.

Adjuvant chemotherapy and radiotherapy

Adjuvant chemotherapy with oxaliplatin and 5-FU or capecitabine chemotherapy increases survival in patients with node-positive colorectal cancer, with a 5-year overall survival rate of 73%. Recent data have demonstrated that in those with lower-risk stage III disease, it is possible to give 3 months of adjuvant therapy rather than 6 months without reducing survival, sparing patients the neuropathy that is associated with oxaliplatin. Less benefit is seen with adjuvant treatment for stage II, node-negative patients. Those with higher-risk features can be considered for adjuvant single-agent capecitabine. If the tumour is deficient in one of the mismatch repair genes, adjuvant chemotherapy in this patient cohort has been shown not to be effective. Immunotherapy could be considered for these individuals in a trial setting.

Follow-up

In all patients who have surgery, a total colonoscopy should be performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second 'clearance' colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and carcinoembryonic antigen (CEA) measurements; rising levels of CEA suggest recurrence. CT scanning to detect operable liver metastases should be performed for up to 5 years after surgery.

Metastatic colorectal cancer

Patients with colorectal cancer may present with liver metastases. With appropriate selection of patients who have a good performance status and in whom MRI and PET/CT scans do not demonstrate disease elsewhere, local treatment can prolong good-quality survival. A variety of methods are used, including surgical resection, stereotactic body radiotherapy, radiofrequency ablation, cryoablation, or hepatic artery embolization. Small lesions can be ablated, but larger ones are best managed by partial hepatectomy or a

combination approach, so that embolization is followed by hepatic regeneration before final resection. Patient selection is critical; long-term survival without recurrence is reported in up to 20% at 5 years with a single lesion smaller than 4 cm amenable to resection presenting more than 1 year from initial diagnosis. More patients can be rendered suitable with perioperative chemotherapy, such as FOLFOX (oxaliplatin, 5-FU, and folinic acid) or FOLFIRI (irinotecan and 5-FU) with cetuximab if *RAS* is wild type. A similar approach is used for patients with lung metastases.

Untreated advanced colorectal cancer has an overall survival time of 5 to 6 months. With sequential chemotherapy regimens (including FOLFOX, CAPOX [oxaliplatin and 5-FU or capecitabine], FOLFIRI and LONSURF [trifluridine–tipiracil]), this can increase to more than 2 years. Patients without mutations in the *KRAS* gene can be considered for treatment with EGFR-targeted agents such as cetuximab and panitumumab. Immunotherapy can be of use in patients with loss of function of one or more of the mismatch repair genes.

Anal cancer

Patients with anal SCC are radically treated with chemoradiotherapy with mitomycin C and 5-FU or capecitabine. This is organ-preserving treatment, enabling the patient to avoid surgery that would result in a colostomy. Salvage abdominoperineal resection is possible if the tumour recurs. Patients with metastatic anal cancer are treated with carboplatin and paclitaxel chemotherapy. Immune checkpoint inhibitors may have activity in these tumours, as they do in SCC of the head and neck.

HEPATOBILIARY AND PANCREATIC CANCERS

Liver

Hepatocellular carcinoma

HCC (see 'Infectious agents' section) arises in cirrhotic livers in 95% of cases and can be screened and detected by cross-sectional imaging and a rise in serum α-fetoprotein (AFP).

Prognosis and management

Surgical resection of isolated lesions of less than 5 cm in diameter or up to three lesions of less than 3 cm in diameter is associated with a median survival of 5 years, although the remaining liver remains at risk of further recurrence. Liver transplantation offers the only opportunity for cure for patients with a small primary tumour, but is often limited by the underlying cause of the hepatitis and cirrhosis. Other focal treatments include transarterial embolization and chemoembolization, radioembolization, radiofrequency ablation, and stereotactic body radiotherapy in patients with small primaries and adequate liver function; these prolong survival, though less successfully than surgery.

In progressive disease, a combination of the immunotherapy atezolizumab and the VEGF inhibitor bevacizumab has shown median overall survival outcomes of 19.2 months and is considered the standard of care for appropriate patients. Second-line therapies include sorafenib and lenvatinib.

Biliary tract

Cancer of the biliary tract may be intra- or extrahepatic. These malignancies represent approximately 1% of all cancers. A number of associations have been identified, such as choledochal cyst and chronic infection of the biliary tract with, for example, *Clonorchis sinensis*. There are also associations with autoimmune disease processes, such as primary sclerosing cholangitis and inflammatory bowel disease.

Cholangiocarcinoma

Cholangiocarcinoma usually presents with jaundice and is detected by imaging: initially ultrasonography, and most important, magnetic resonance cholangiopancreatography. Spread is usually by local lymphatics or local extension. Cholangiocarcinoma of the common bile duct may be resectable at presentation, but local extension precludes such management in the majority of more proximal lesions. Localized disease justifies an aggressive surgical approach, including partial hepatic resection. Hepatic transplantation for selected stage 1 and 2 disease has achieved an 80% 5-year survival rate.

Palliative chemotherapy for patients with good performance status and advanced disease using gemcitabine and cisplatin effects a response in 50% with a median survival of 12 months. The addition of immunotherapy extends the median overall time survival by an additional 1.3 months and is considered in select cases. Chemoradiation has been used to treat patients with localized small hilar cholangiocarcinomas, and radiotherapy can provide good analgesia.

Pancreas

Pancreatic adenocarcinoma

The presentation and initial investigation of pancreatic cancer are covered in Chapter 24 (see 'Pancreatic cancer' section).

Prognosis

The 5-year survival rate for carcinoma of the pancreas is approximately 2% to 5%, with surgical intervention representing the only chance of long-term survival and 90% of patients having a cause of death directly related to the disease. Approximately 20% of all cases have a localized tumour suitable for resection, but in an older adult population, many individuals have co-morbid factors that preclude such major surgery.

Surgery

Surgical intervention represents the only chance of long-term survival. Assessment of the primary tumour and involvement of local vessels, including the coeliac artery, superior mesenteric artery and vein, portal vein, and hepatic artery, is critical in determining resectability. When treatment is considered to be of curative intent, a pancreatoduodenectomy ***(Whipple procedure)*** (Fig. 41.20) is required to remove tumours of the head and neck of the pancreas. Tumours of the body and tail are resected as part of a distal pancreatectomy, which is increasingly carried out by a laparoscopic approach.

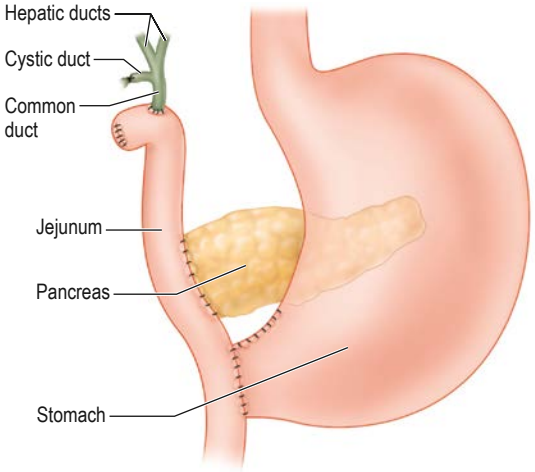

Fig. 41.20 Diagram of the aftermath of a Whipple's procedure, in which the pancreas, stomach, and jejunum are joined back together after a pancreaticoduodenectomy. (*From* Saunders Comprehensive Review for the NCLEX-PN® Examination, *Ninth Edition pii:B9780443112874000045X/f45-04-9780443112874*.)

Borderline-resectable tumours can be considered for neoadjuvant therapy to downstage the tumour, and a combination of chemotherapy followed by chemoradiotherapy before surgery has shown an improvement in overall survival over upfront surgery and the previous standard-of-care regimen of adjuvant gemcitabine and cisplatin chemotherapy. More intensive adjuvant chemotherapy in the form of combination fluorouracil, oxaliplatin, irinotecan, and leucovorin (FOLFIRINOX) has also led to better overall survival. The decision over whether to treat patients with a neoadjuvant or a more intensive adjuvant approach is individualized.

Advanced disease

In the majority of cases, management is palliative. Palliative chemotherapy for advanced disease can be managed with combination chemotherapy. First-line treatment for patients with a good performance status is FOLFIRINOX. This combination treatment was found to lead to a median overall survival time of 11.1 months. An alternative regimen for patients who are not fit enough for this treatment is gemcitabine and nab-paclitaxel (paclitaxel as albumin-bound nanoparticles).

Palliative interventions

- ***Pain*** is a debilitating feature in many cases. Management is best directed by dedicated pain teams. Opiates are a mainstay. There is some evidence that early intervention with coeliac axis block may have benefits.
- ***Nutritional deficit*** is a frequent feature at presentation and may be exacerbated by chemotherapy. Early dietetic support may alleviate this. Malabsorption is common with pancreatic cancer and can be managed by the introduction of pancreatic enzyme supplementation. The adverse metabolic effects of diabetes can be avoided by early detection and management.
- ***Obstructive jaundice*** will occur at some stage in 70% of cases and is frequently associated with anorexia and nausea, as well as pruritus. Endoscopic placement of endoprostheses (stents) offers excellent palliation (see Chapter 50).
- ***Duodenal obstruction*** is seen in up to 20% of cases, particularly when the tumour is situated in the head or uncinate process of the pancreas. Endoscopic stenting is the treatment of choice with excellent palliation. Surgical bypass is an option in selected cases.

UROLOGICAL CANCERS

Renal cancer

Clinical features and diagnosis

See Chapter 26 (see 'Renal cell carcinoma' section).

Investigations and management

At diagnosis, renal cancers are staged using CT, MRI, or both to assess operability and the presence or absence of metastases.

Disease confined to the kidney

A nephrectomy is performed unless bilateral tumours are present, in which case conservative surgery may be indicated. Preservation of as many nephrons as possible is beneficial in the long term, and a partial nephrectomy should be undertaken when possible.

Metastatic disease

For patients with metastatic disease, prognosis is predicted on the basis of the International Metastatic Renal Cell Carcinoma Database Consortium criteria. One point is scored for each of the following poor prognostic features:

- Impaired fitness (<80% on the Karnofsky performance status score)
- Haemoglobin below the lower limit of normal
- Neutrophils above the upper limit of normal
- Platelets above the upper limit of normal
- Serum calcium above the upper limit of normal
- Less than 12 months from diagnosis to the requirement for systemic chemotherapy

Those with no adverse prognostic factors have a 2-year survival rate of more than 75% and are considered to have a good prognosis, those with one or two factors are regarded as having an intermediate prognosis and have an approximately 50% chance of surviving for 2 years, and those with three factors or more have a poor prognosis and a 2-year survival rate of 7%. Patients with a good prognosis may benefit from a debulking palliative nephrectomy, which is sometimes followed by regression of metastases. Adjuvant therapy reduces the risk of progression, but the benefits must be weighed against toxicity.

Systemic therapy

The TKIs are the mainstay of therapy for metastatic disease. When the prognosis is good, either sunitinib or pazopanib is given as first-line treatment. For patients with an intermediate or poor prognosis but preserved performance status, the combination of the checkpoint inhibitor pembrolizumab (which targets PD-1) and the TKI axitinib increases survival compared to sunitinib (hazard ratio [HR], 0.53). Similar results have been seen with nivolumab and

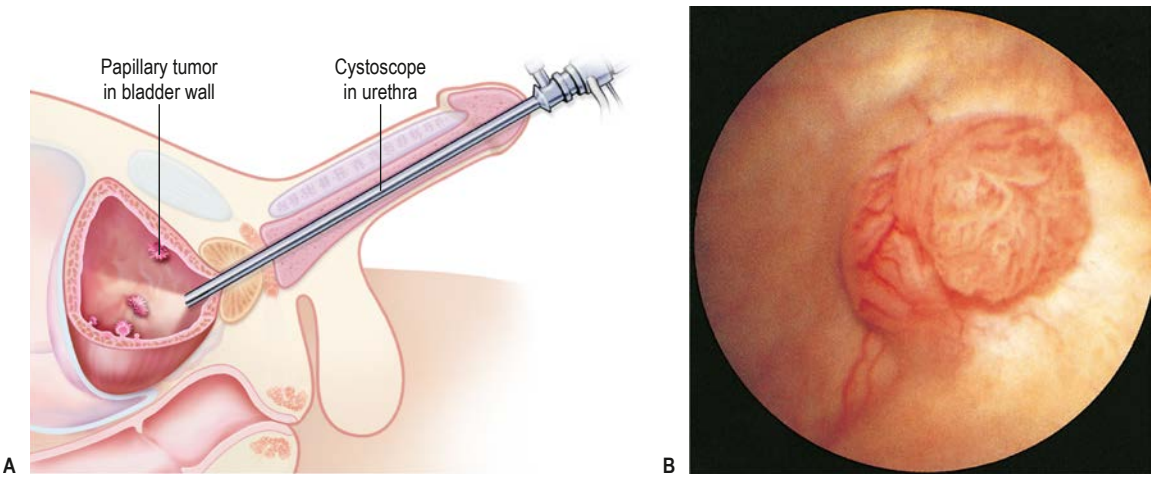

Fig. 41.21 Imaging of bladder cancer. **(A)** Cystoscope in typical male bladder. **(B)** Cystoscopic view of a cancerous growth (a transitional cell carcinoma) on the bladder wall. (The Human Body in Health & Disease, *Eighth Edition. pii:B9780323734165000293/f20-14-9780323734165*.)

cabozantinib and lenvatinib and pembrolizumab. The response rate to these regimens is 60% to 70%. An alternative in these patients is the combination of ipilimumab and nivolumab (HR, 0.69 compared with sunitinib for overall survival). This combination has a lower response rate than TKI based combinations but a greater proportion of durable responses. Good-risk patients may benefit from high-dose IL-2, which appears to increase the survival rate by 5% to 10%. Sequential use of other drugs, such as cabozantinib, lenvatinib, and everolimus, can produce further responses and improvement in disease control. Isolated metastases may be amenable to surgery or stereotactic irradiation.

Urothelial (bladder and ureteric) cancer

These cancers are usually TCCs, associated with smoking and exposure to a range of chemical agents, although SCCs are common in areas where schistosomiasis is endemic (Fig. 41.21). Their clinical presentation is described in Chapter 26 ('Tumours of the kidney and genitourinary tract' section).

Superficial cancers

Patients with superficial TCC of the bladder without invasion through the basement membrane may be treated by transurethral resection or local diathermy. The risk of recurrence varies according to the degree of differentiation, and follow-up check cystoscopies and cytological examination of the urine are required. Patients with recurrent superficial TCCs can be treated with bladder installation of the mycobacterium bacille Calmette–Guérin, which activates immune destruction of cancer cells; alternatively, a cytotoxic drug may be used (either gemcitabine or mitomycin).

Invasive bladder cancer

For invasive cancers, the strongest evidence is for neoadjuvant chemotherapy followed by either surgery (cystectomy) or chemoradiotherapy.

- ***Neoadjuvant chemotherapy*** is usually cisplatin based, most commonly with gemcitabine. It improves absolute survival by 10%, the prognosis ranging from a 5-year survival of 80% to 90% for lesions not involving bladder muscle to 5% to 10% for those presenting with metastases. If no neoadjuvant therapy has been offered, then postoperative adjuvant treatment is recommended.
- ***Surgical treatment*** involves cystectomy, generally followed by ileal conduit and stoma formation; in some cases, however, a neobladder can be constructed, allowing more normal micturition. This very much depends on the position of the tumour and the absence of extensive carcinoma *in situ.*
- ***Bladder preservation strategies*** for those with T1 with grade 3 histology or T2–T4 tumours can alternatively be offered with chemoradiotherapy using mitomycin and fluorouracil. In many patients, this can achieve complete disease response, bladder preservation with a good quality of life, and comparable long-term survival (30%–50% at 5 years) to cystectomy.

Metastatic urothelial cancer

Patients with metastatic disease may be palliated by chemotherapy (cisplatin or carboplatin based) or immunotherapy (using a PD-1/PDL-1 checkpoint inhibitor such as pembrolizumab or atezolizumab). Responses are seen in approximately 25% of patients with PDL-1 expression. In patients who have completed chemotherapy, maintenance avelumab for up to 2 years is indicated regardless of the degree of PDL-1 expression. Encouraging responses have been seen with the Mab enfortumab vedotin targeted against nectin 4. This has been shown to improve overall survival compared with chemotherapy (13 vs 9 months). Combining it with pembrolizumab may be particularly effective.

Upper tract tumours

Patients with early-stage tumours are treated by nephroureterectomy. The addition of adjuvant therapy with cisplatin and gemcitabine in the management of non-metastatic T2 tumours has been shown to reduce the risk of recurrence by half.

Prostate cancer

Clinical features and diagnosis

The pathogenesis, presentation, diagnosis, and initial investigation of prostate cancer are discussed in Chapter 47 (see 'Prostate cancer' section).

Prognosis

The histological appearances are graded and accorded a Gleason score (see Fig. 47.12). Together with the serum prostate-specific antigen (PSA) level, and accurate staging of the local extent of disease with pelvic MRI (dynamic contrast) and transrectal ultrasound examination, this score can identify prognostic groups. Treatment decisions must balance the age and performance status of the patient with the predicted behaviour of the cancer, which is becoming more objectively identifiable with advances in gene profiling. This allows the selection of patients with a good prognosis for no active treatment; they may reasonably choose to be kept under surveillance and die with, but not because of, their prostate cancer, as do 75% of males older the age of 80 years. In experienced hands, pre-biopsy MRI may allow targeted biopsy of the prostate and prediction of those who will have clinically significant prostate cancer (Fig. 41.22).

Management

Disease localized to the prostate

This can be managed by surgical resection, brachytherapy, radiotherapy, or watchful waiting with regular surveillance. The optimum approach depends on both features of the disease and the wider patient context.

Locally advanced disease

Patients with locally advanced prostate cancer (T3, N0) without distant metastases are best treated with combined androgen deprivation (see later) and radiotherapy; this improves the 10-year survival rate, compared with endocrine treatment alone, from 61% to 71%.

Endocrine therapy

Prostate cancer is the most hormone-sensitive malignancy, with the AR playing a critical role. However, prostate cancer tissue is able to trap circulating androgens so that tissue levels of androgens are maintained despite very low levels of circulating androgens. This means that resistance to endocrine therapy often develops over time, commonly involving receptor super-sensitivity and altered ligand binding, allowing other steroids to act as agonists and eventually bypassing the AR. A number of strategies are used to reduce or abolish androgen stimulation of cancer cells:

- ***Gonadotrophin-releasing hormone (GnRH) agonists*** (e.g., goserelin and leuprorelin) are as effective as orchidectomy at lowering circulating androgens and inducing responses in patients with prostate cancer. However, in the first week, GnRH agonists produce increases in luteinizing hormone and testosterone, which can result in a tumour flare in metastatic disease; they must therefore be combined with an antiandrogen (e.g., flutamide) in the initial phases. An alternative is to use a gonadorelin antagonist (e.g., degarelix). Physical castration, achieved by bilateral orchidectomy, achieves very effective androgen deprivation but is invasive, often unacceptable to patients, and generally unnecessary.
- ***Androgen receptor–targeted inhibitors*** (ARTIs): These include drugs such as bicalutamide and the more potent antagonists enzalutamide and darolutamide. They directly block the action of testosterone on prostate cancer cells.
- ***Androgen synthesis inhibitors***, such as abiraterone, act by inhibiting CYP17, a key enzyme in the testosterone production pathway.
- ***Corticosteroids and oestrogens*** may also be helpful in disease that has become refractory to castration.

Hormonal agents may also be used after chemotherapy for prostate cancer, and both enzalutamide and abiraterone have been shown to prolong life in this situation.

Non-hormonal therapy

Non-hormonal approaches are frequently used for metastatic disease:

- ***Conventional chemotherapy.*** The use of docetaxel in the early management of metastatic castration-sensitive disease has led

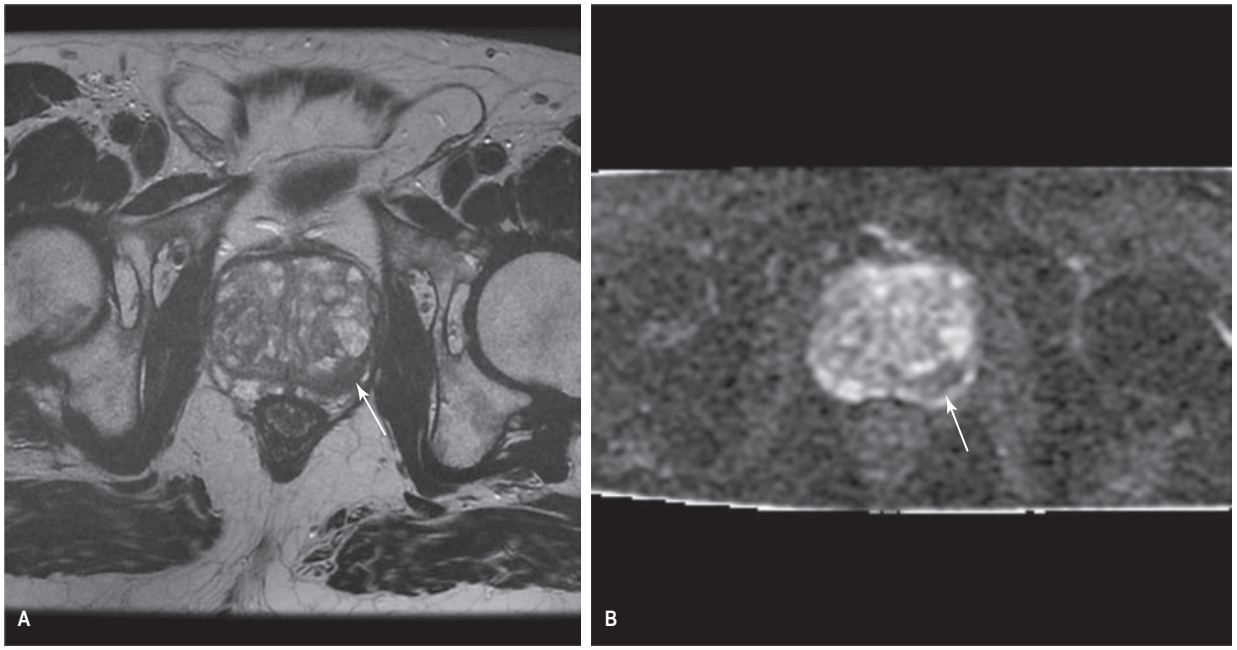

Fig. 41.22 **(A)** An axial slice of a T2-weighted magnetic resonance imaging scan demonstrating reduced signal intensity in the right peripheral zone midgland. **(B)** The corresponding diffusion-weighted sequence. The tumour is shown by the *arrow*.

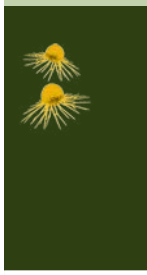

to an improvement in overall survival. The HR for benefit from docetaxel is constant, but when it is used early at a point when the survival rate is greater, this translates into a greater absolute benefit in overall survival than when it is used after failure of hormonal therapy. The timing of chemotherapy versus hormonal treatment is currently not clear in prostate cancer: early use of the androgen synthesis inhibitor abiraterone, as an alternative to docetaxel, in the management of metastatic castration-sensitive disease seems to confer similar benefits. If chemotherapy fails, a return to hormonal therapy may prolong disease control. Currently, there is no consensus as to whether chemotherapy should be deferred until all available hormonal therapy has failed or be used earlier in disease control.

- ***PARP inhibitors.*** It is clear that a proportion of prostate cancers have deficits in DNA repair, often associated with carriage of the *BRCA2* gene. These patients seem to respond to PARP inhibitors such as olaparib, which prevent repair of DNA strand breaks and cause the death of cancer cells.
- ***Bone-targeted therapy.*** Drugs such as alpharadin (^{223}radium), zoledronic acid, and denosumab, alongside palliative radiotherapy, can be used to target painful metastases.
- ***Radioligand therapy.*** Recently developed therapy using MAbs with a radionuclide payload (e.g., lutetium-labelled antibodies against prostate-specific membrane antigen [PSMA]) has been shown to be effective post docetaxel and an ARTI in metastatic, castration-resistant disease.

General approach to treatment

Profound androgen deprivation using ARTIs from the start (darolutamide or enzalutamide or abiraterone) leads to improved survival rates in the initial treatment of prostate cancer compared with docetaxel and a gonadorelin analogue alone and may become the treatment of choice for younger patients (and particularly those with high-volume disease). After the failure of an AR-targeted drug and docetaxel, alternatives include further hormone treatments (oestrogens and corticosteroids) or further chemotherapy (e.g., cabazitaxel).

Penile cancer

Penile cancer is described in Chapter 47 (see 'Penile cancer' section).

Testicular and ovarian germ cell tumours

The diagnosis of these conditions is dealt with in Chapter 47.

Management

- ***In males***, surgery involves radical inguinal orchidectomy to avoid spillage of highly metastatic tumour in the scrotum.
- ***In females***, surgery for diagnosis and staging should always be conservative, compared with the approach in epithelial ovarian cancer, with preservation of fertility because of the efficacy of chemotherapy.

Seminomas

Seminomas (in males) are very radiosensitive and chemosensitive. They are associated with raised serum lactate dehydrogenase (LDH) but only rarely mildly raised β-human chorionic gonadotropin (β-hCG) and never raised AFP. Stage I disease limited to the gonad is associated with a 10% to 30% 5-year risk of recurrence with surgery alone, so adjuvant therapy, with either chemotherapy or radiotherapy to the para-aortic lymph nodes, is preferred because it leads to a cure rate of more than 95% in patients with early-stage disease. Carboplatin is the first choice because of convenience, reduced acute side-effects, and absence of the long-term risks of secondary malignancy that are associated with radiotherapy. Alternatively, post-surgical surveillance can be undertaken, with treatment reserved for those who relapse; this approach carries an equally high cure rate because combination chemotherapy (e.g., cisplatin, etoposide and bleomycin [BEP]) cures more than 90% of those with visible metastatic disease. In females, the equivalent of the seminoma is the dysgerminoma, which is morphologically identical to seminoma and is managed similarly.

Non-seminomas

Early disease

The risk of relapse after surgery for stage I disease varies from 5% to 50%, depending on the prognostic factors of histological differentiation, presence of embryonal elements, and extent of local and vascular invasion. For those at moderate to high risk, adjuvant chemotherapy with a single cycle of BEP carries a 97% cure rate.

Metastatic disease

This commonly involves para-aortic lymph nodes and lungs but may spread rapidly (especially if trophoblastic, β-hCG–producing elements are present) and cause life-threatening respiratory or other organ failure. In males, rapid diagnosis can be made in the presence of gynaecomastia and a positive urinary pregnancy test result, allowing the institution of potentially life-saving treatment. About 80% of teratomas express either β-hCG or AFP, and almost all cases of metastatic disease are associated with an elevation of the less specific serum marker, LDH.

The percentage cure rate depends on the height of the tumour markers (AFP >10 000 ng/mL and β-hCG >100 000 IU/L) and the sites of metastases; it ranges from 60% to 95%. The most established regimen is BEP; three or four cycles are usually given. More intensive regimens appear to yield higher progression-free survival rates and may be preferred in some patients.

Relapsed disease

Patients who relapse after initial chemotherapy may well be cured by subsequent chemotherapy; this is most common with further cisplatin-based chemotherapy or high-dose chemotherapy, usually with carboplatin and etoposide, and a stem cell transplant. The timing of high-dose chemotherapy is uncertain: some clinicians prefer to defer it and use it only after standard-dose salvage treatment has failed. Others believe that the best results are seen if it is used on first relapse.

Although approximately 20% of males are infertile because of azoospermia at the time of diagnosis, the majority of the remainder retain their fertility after chemotherapy and are able to father children normally. Similarly, most females retain their fertility, although less is known about the association with infertility at presentation owing to the much lower frequency of germ cell tumours in females.

GYNAECOLOGICAL CANCERS

The main gynaecological cancers are those of the cervix, the body of the uterus (endometrium), and the ovary. The presentation and investigation of these cancers are introduced in Chapter 47. All are important, and enormous progress has been made in therapy.

Cervical cancer

A significant reduction in the incidence of cervical cancer has been achieved in high-income countries through vaccination against HPV and cervical screening, which may detect pre-malignant carcinoma intraepithelial neoplasm (CIN) (**Fig. 41.23**).

Management and prognosis

CIN is classified into three grades, according to the thickness of the cervical epithelium involved: CIN1, CIN2, and CIN3. Removal of abnormal cells is recommended in most CIN2 and all CIN3 disease and is most commonly achieved by a colposcopic loop electrosurgical excision procedure, also known as a large loop excision of the transformation zone.

Localized disease

Patients with early-stage cancer may be treated using limited surgical techniques that preserve the function of the cervix and are compatible with future fertility. More deeply invasive disease that remains non-metastatic is still highly curable by more major resection of the uterus, ovaries, and pelvic nodes (which are the first site of metastatic disease in most cases); this is termed the 'Wertheim hysterectomy'. When disease is more advanced or surgery is contraindicated for reasons of age or co-morbidity, pelvic radiotherapy (usually with concomitant chemotherapy with cisplatin and a transvaginal radiation brachytherapy boost to the cervix) is advised; this confers a similarly high chance of cure.

Metastatic disease

There are no curable options, but platin-based chemotherapy, often together with a taxane, with or without a VEGF Mab (bevacizumab), is recommended for fitter patients and delays progression for some time in many patients. In addition, immunotherapy can also be added in to improve disease control.

Endometrial cancer

Clinical features are discussed in Chapter 47. Endometrial cancers have been broadly categorized into two types: type I is the more

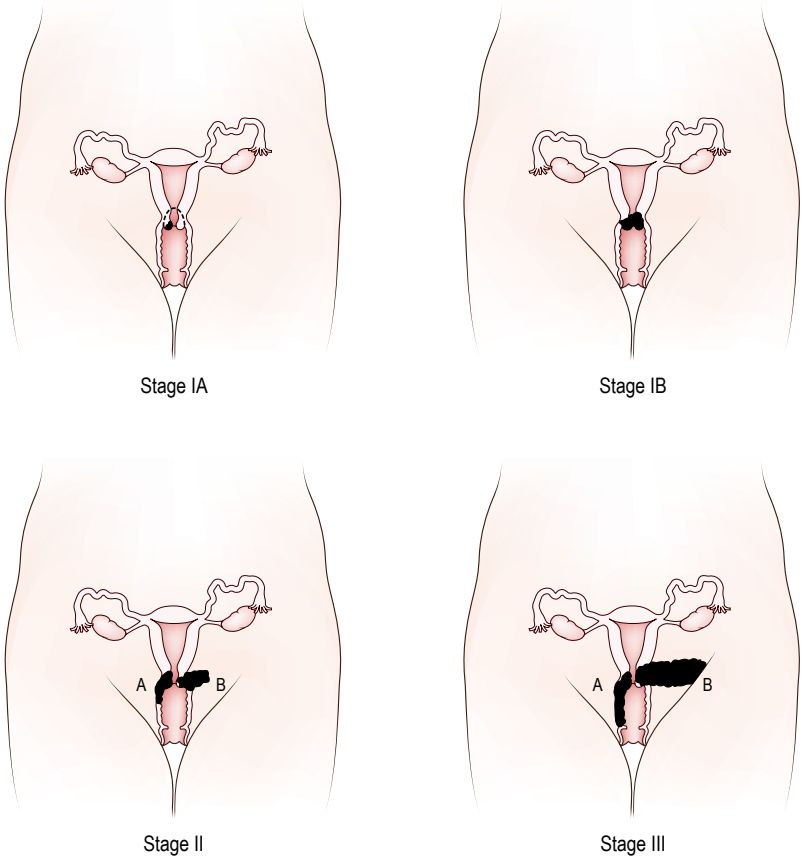

Fig. 41.23 Staging of cervical cancer: findings an examiner may appreciate on bimanual and rectovaginal examination. Stage IA: only microscopic cancer present. Stage IB: cancer is confined to the cervix. Stage II: the cancer extends beyond the cervix to involve nearby structures such as the vagina but is still confined to the pelvis. Stage III: the tumour extends to the lower part of the vagina or reaches the pelvic side wall. The *dotted line* in the stage IA diagram illustrates the line of resection for a cold-knife cone biopsy. The A and B substages for stages II and III disease are represented on the patient's right and left sides, respectively. (*From* Colposcopy Principles and Practice: An Integrated Textbook and Atlas, *Second Edition. pii:B9781416034056100149/gr13.*)

commonly seen endometrioid adenocarcinoma (80%–90%), and type II are non-endometrioid subtypes such as serous, clear-cell, and undifferentiated carcinomas (10%–20%).

Early disease

When the cancer is diagnosed at an early stage and is confined to the uterus, hysterectomy and bilateral salpingo-oophorectomy is the recommended treatment. The 5-year survival rate exceeds 90%.

Advanced and metastatic disease

When disease is more advanced, postoperative pelvic radiotherapy lowers the risk of local recurrence when the cancer has penetrated deep into the myometrium. For those with disease outside the uterus, chemotherapy (typically a doublet regimen including a platinum agent) may delay progression for some time. Progesterones have a small suppressive role for those with advanced disease and those who are too frail to benefit from systemic chemotherapy.

Ovarian cancer

Ovarian cancer arising from the surface epithelial cells ('epithelial ovarian carcinoma') is discussed in this section; other rarer cancers arising from the ovary include stromal cell tumours and germ cell tumours and are discussed earlier. The clinical features of all ovarian tumours are described in Chapter 47.

Prognosis

Histological subtype (clear cell and mucinous are worse), grade and differentiation, stage, extent of residual disease after surgery (macroscopic vs microscopic or none), and performance status are all significant independent prognostic factors for survival (**Box 41.29**).

BRCA mutation status should be assessed in patients with a positive family history (**Box 41.30**). *BRCA* status is also a predictive marker for increased sensitivity to platinum and anthracycline cytotoxics and to PARP inhibitors such as olaparib.

Management

Early disease

Curative treatment inevitably requires radical surgery (laparotomy with bilateral salpingo-oophorectomy, hysterectomy, and omentectomy). Because of the high risk of peritoneal dissemination, all but patients with very early, ovary-confined cancers benefit from postoperative adjuvant chemotherapy, which is given despite complete macroscopic resection of all visible disease. Clinical trials have shown that such postoperative chemotherapy reduces the chance of subsequent relapse when the subsequent relapse risk is high.

Advanced disease

In patents presenting with widespread peritoneal disease or metastatic disease beyond the abdomen and pelvis, neoadjuvant chemotherapy is usually used first to shrink the cancer down to minimal proportions before debulking surgery is attempted. Among the chemotherapy options used for treating patients with ovarian cancer (adjuvantly or for advanced disease), the platinum group includes the best single agents, and a taxane is usually the partnering cytotoxic. A good majority of advanced cancers respond to these agents. The VEGF inhibitor bevacizumab may be usefully added in cases of advanced disease.

Box 41.30 Familial patterns of breast and ovarian cancer with increased risk of inherited *BRCA* mutations

- A mother or sister diagnosed with breast cancer before the age of 40 years
- Two close relatives from the same side of the family diagnosed with breast cancer; at least one must be a mother, sister, or daughter
- Three close relatives diagnosed with breast cancer at any age
- A father or brother diagnosed with breast cancer at any age
- A mother or sister with breast cancer in both breasts, the first cancer diagnosed before the age of 50 years
- One close relative with ovarian cancer and one with breast cancer diagnosed at any age; at least one must be a mother, sister, or daughter
- A close relative of Ashkenazi Jewish origin with breast or ovarian cancer
- A close relative with pancreatic cancer and breast or ovarian cancer

Relapsed disease

Response to therapy may be assessed clinically, by scanning and by measurement of the useful ovarian tumour marker CA-125: a rising CA-125 suggests relapse. Drugs used for patients with relapsed disease include other cytotoxics, but new agents are also making an impact on therapy. The realization that ovarian cancer is driven by DNA repair faults and that the protein PARP1 is significant in this repair has led to the use of PARP inhibitors to treat patients with advanced ovarian cancer, particularly those with cancers that have a known DNA repair deficit such as *BRCA* or *PALB2* mutations. PARP inhibitors used in combination with a DNA 'toxin' that causes strand breaks, such as platin chemotherapy, achieves a 'synthetic lethality', a new concept in cancer therapy that made its first inroads in ovarian cancer. It is also predicted that immunotherapy will have a role for patients with advanced ovarian cancer.

Palliative approaches

Up to 30% of those with metastatic disease may be alive after 5 years, although this falls to 5% to 10% if it is not possible to debulk the cancer at operation or if it has spread outside the peritoneal cavity. Bulky disease in the peritoneum commonly causes progressive

bowel obstruction, which may require palliative surgery or expert palliative care support to manage the terminal phases of the illness.

BRAIN TUMOURS

The most common intracranial tumours are brain metastases, which can be solitary or multifocal. Primary brain tumours account for 3% of total cancer cases in the UK. The clinical presentation and initial investigation of brain tumours are discussed in Chapter 28 (see 'Brain tumours' section) (**Fig. 41.24**).

Brain metastases

Any cancer can metastasize to the brain, but the most common tumours to do so are those arising from the following:

- Lung
- Breast
- Skin (melanoma)
- Kidney

Metastases may occur anywhere in the brain and may be single or multiple.

Cerebral oedema commonly surrounds brain metastases; this oedema usually responds to steroid therapy, which is often the first measure to ameliorate the symptoms.

Many systemic therapies for the primary tumour do not cross the blood–brain barrier and therefore do not control brain metastases. In recent years, with better systemic control of cancers, brain metastases have become an increasingly important threat to life as a site of uncontrolled disease. There are various treatment approaches. For large metastases causing raised intracranial pressure, surgery is considered with urgency. An alternative, particularly for smaller or multiple metastases and where the metastases are not abutting radiosensitive structures (e.g., the optic chiasm, brainstem), focal radiation therapy (stereotactic radiation therapy) is commonly used for therapy, including Gamma Knife, CyberKnife. and linear accelerator–based therapy. In these techniques, focused high-dose radiotherapy is delivered to the small-volume metastases within the brain via multiple pencil-beam radiation portals from three dimensions, coinciding at the target. Hence, a very high obliterative dose is deposited on each metastasis with a steep external dose gradient such that the radiation dose 'falls off' very quickly at the edge of the targeted metastasis, thus sparing adjacent normal brain. There is still a role for whole-brain radiotherapy when there are large numbers of brain metastases or they are too large to treat with stereotactic radiotherapy. Occasionally, hydrocephalus causes raised intracranial pressure, and a shunt may need to be inserted before radiotherapy commences (particularly because the radiation may transiently worsen cerebral oedema notwithstanding anti-oedema therapy with high-dose steroids).

An increasing number of systemic therapies are active against brain metastases. Immunotherapy (checkpoint inhibitors) is often active against melanoma brain metastases, and osimertinib (a TKI active against lung cancer brain metastases driven by an activating mutation of the *EGFR* gene) has considerable success in treating the metastases in this subtype of lung cancer.

Primary brain tumours

Glioma

Gliomata arise from astrocytes, ependymal cells, or oligodendroglial cells. They can be low or high grade; this has an impact on prognosis, although low-grade tumours nearly always transform into high-grade tumours eventually. Survival is very limited for patients with high-grade glioma, and the worst prognosis of all is for the

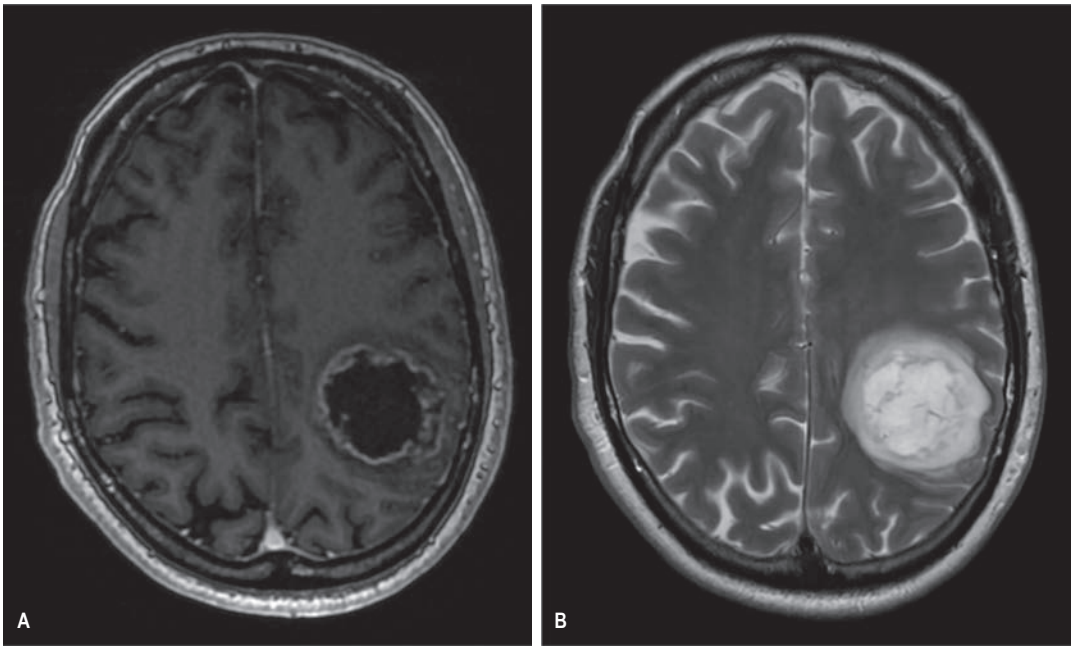

Fig. 41.24 **(A)** A T1-weighted, contrast enhanced magnetic resonance imaging scan with a large tumour in the left fronto-parietal lobe. **(B)** The corresponding T2-weighted sequence. Images are typical of a primary glioblastoma.

glioblastoma (grade 4) population of patients in whom survival (even after treatment with surgery, radiotherapy, and chemotherapy) is rarely beyond 2 years. However, the survival of patients with low-grade glioma may be well into the second decade from diagnosis.

Knowledge of molecular pathology can inform prognosis and predict response to treatment and may direct therapy in the future:

- ***Mutations in isocitrate dehydrogenase 1 or 2 (IDH1 or IDH2)*** indicate that a tumour may be slower growing. If they are found in a patient with a high-grade tumour, it may indicate that the tumour has transformed from a low-grade one rather than arising *de novo.*
- ***Loss of heterozygosity of* 1p *and* 19q *genes*** is associated with oligodendrogliomas and a better prognosis and response to treatment.
- ***Promoter methylation of the O6-methylguanine-DNA methyl-transferase* (MGMT) *gene*** causes inactivation of the gene and predicts a better response to temozolomide chemotherapy, conferring a better prognosis.

Management

The management of gliomas depends on the grade, the molecular pathology (if known), the genomics and epigenetics of the tumour, and the tumour site; the patient's performance status and their wishes (regarding the risks they are willing to accept) are also critical. Options include:

- ***Surveillance.*** Low-grade tumours were traditionally followed up with serial imaging alone, but a more proactive approach with earlier intervention is now also considered an option.
- ***Surgery.*** Craniotomy and maximum debulking surgery are carried out, if possible. This depends on the site of the glioma because it is not possible to resect a tumour in an area of the brain that would cause significant morbidity. Because gliomas spread along white matter tracts, full resection of a high-grade glioma is never possible. A stereotactic biopsy via a burr hole to inform diagnosis may be a preferable option to debulking surgery for critically situated tumours.
- ***Adjuvant treatment.*** Treatment after surgery can include radiotherapy with or without chemotherapy. The chemotherapy must cross the blood–brain barrier (e.g., temozolomide, an oral alkylating agent, which is commonly used both during radiotherapy in the case of high-grade tumours and after radiotherapy).

At relapse, further surgery, radiotherapy, or chemotherapy (temozolomide or procarbazine, lomustine and vincristine [PCV]) may all play a part. The role of immunotherapy in the treatment of patients with gliomas is still under investigation, with vaccine trials and other immunotherapy methods the subject of current trials. Targeted therapies include agents targeting *IDH1* (e.g., vorasidenib). Indeed, a recent trial of prescribing vorasidenib to patients with low-grade *IDH*-mutant gliomas has shown positive results in extending progression-free survival. PARP inhibitors may have a future role in therapy. More extensive genomics will be of always interest in the search of other targeted therapies and *BRAF, EGFR, H3,* and *VHL/HIF* are genes of interest in intracranial tumours; the quest is for inhibitors of actionable driving mutations.

Anti-angiogenic agents may also have a role in the relapse setting, particularly when there is a lot of widespread oedema resistant to steroids, but have not been shown to improve survival.

Meningioma

Meningioma arises from the arachnoid fibroblast and is usually a benign tumour with a slow growth rate, but it can cause damage because of pressure effects. Most are curable by surgical excision, Although the majority of meningiomata are low grade and as curable as just stated, not all behave in a 'benign' manner because they can cause significant disability to the patient, for instance, by causing mass effect, eroding adjacent structures, or obstructing the flow of CSF. Indeed, the rare grade 3 meningioma is a malignant cancer of sarcoma type. Methylation of meningioma tumour DNA also affects grading; this epigenetic phenomenon (as in other tumours) alters the growth of the tumour.

Surgery is the definitive treatment but may not be feasible because of the sensitive location of the tumour. There is a role for fractionated external-beam radiotherapy and stereotactic radiosurgery in the management of inoperable, recurrent, and residual meningiomas or in lieu of surgery. Meningiomas often carry hormone receptors, particularly PRs, and grow at an accelerated rate in pregnancy, and anti-hormonal drugs may be useful at retarding growth.

Neurofibroma and schwannoma

These benign tumours occur with different frequencies; the eighth or vestibular nerve (particularly in neurofibromatosis type 2) is the commonest site of origin, and patients present with ipsilateral hearing loss and often tinnitus. Neurofibromata arising from the other cranial nerves are less common Although surgery is curative if complete excision can be achieved, stereotactic radiosurgery is commonly used to treat patients with these tumours and prevent hearing loss.

HEAD AND NECK CANCER

The term 'head and neck cancer' generally describes SCCs arising from the mucosa lining the aerodigestive tract. See Chapter 21 for details on how these tumours may present and be diagnosed. Thyroid cancer is discussed in Chapter 34 (see 'Thyroid cancer' section).

Staging

Squamous head and neck cancer describes a group of cancers that spread 'logically': first to regional lymph nodes (the horizontal group—occipital, post-auricular, pre-auricular, facial, submandibular, and submental, or the vertical deep cervical chain) before spreading elsewhere, often to the lung. A considerable time frequently elapses before disease spreads beyond the primary site and nodes. This provides a greater chance for cure in the form of local and regional therapy, such as surgical resection with local radiotherapy. Most cases of early head and neck cancer are curable (Fig. 41.25).

Biopsy-proven cancer requires staging using the TNM system. Whereas PET scanning is often useful for staging distant disease, MRI is best for obtaining anatomical detail of local spread and depth of invasion. Viral status (HPV or EBV) may have implications for therapy. Genomic analysis and predictive tests for immunotherapy have roles in relapsed patients.

Management

Early disease

When early cases are easily operable with margins clear of disease, surgery is usually curative. Elective dissection of the deep cervical chain is sometimes indicated to treat 'one step ahead of the cancer's spread', that is, resecting the next most likely site to harbour microscopic disease. When surgical resection of the primary may lead to great morbidity (e.g., laryngectomy for early laryngeal

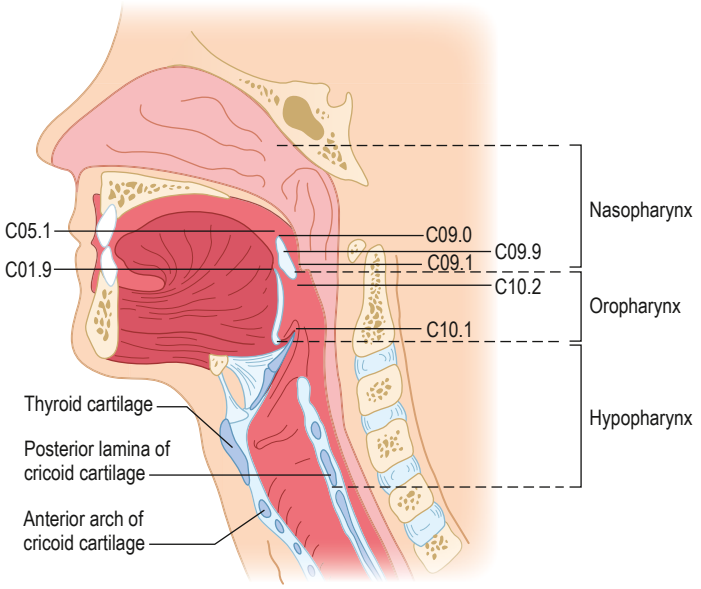

Fig. 41.25 Anatomy of head and neck cancers, showing subdivisions into distinct anatomical areas (nasopharynx, oropharynx, and hypopharynx). More than 95% of head and neck cancers arise from the mucosal surfaces of the upper aerodigestive tract. Specific anatomical sites are associated with unique aetiologies, including environmental and viral risk factors, and underpin modern staging systems and treatment paradigms. *(From* Goldman-Cecil Medicine, *Twenty Seventh Edition B9780323930383001763/f176-01-9780323930383.)*

cancer), radiotherapy (to which this type of cancer is sensitive) may have an equivalent chance of cure and be the preferred treatment choice. When the cancer is invading cartilage or bone, it is considered to be more radiotherapy resistant, and surgery may be the better option.

Locally advanced disease

In more locally advanced cases for which radiotherapy is chosen, chemotherapy (usually cisplatin) in conjunction with the radiotherapy enhances the radiation effect. The EGFR inhibitor cetuximab can be used to inhibit signal transduction within cancer cells, again in conjunction with radiotherapy, although this is generally reserved for patients unsuitable for chemoradiotherapy.

Metastatic disease

The lungs and bones are the most common sites for spread after local lymph node groups. Immunotherapy agents, such as the PD-1 inhibitor pembrolizumab, may have significant efficacy and can induce remarkable remissions in some patients, presumably because of the high mutational load and PDL-1 expression of these squamous cancers. The use of pembrolizumab is licensed as first-line therapy for metastatic head and neck cancers provided PDL-1 expression is positive. Chemotherapy agents such as 5-FU and cisplatin are reserved as second-line.

MALIGNANT MELANOMA

Management

In the UK, all people with suspected melanoma should be referred urgently (2-week wait pathway) to the local hospital's multidisciplinary skin cancer team. Clinical features and diagnosis are discussed in Chapter 45.

Surgery remains the definitive treatment for patients with primary melanoma, and early wide excision of thin tumours is usually curative. Suspicious lesions should be completely and promptly excised with a narrow (2-mm) margin for review by a dermatopathologist experienced in melanoma diagnosis. The pathological staging of the primary melanoma depends on the Breslow thickness of the melanoma (i.e., the depth of dermal invasion) and whether the tumour is ulcerated (Fig. 41.26).

Staging

The eighth ***American Joint Committee on Cancer (AJCC) melanoma staging system***, published in 2017, defines four broad categories of tumour, T1 to T4, ranging from T1a (<0.8 mm thickness without ulceration) to T4b (>4.0 mm with ulceration). These categories guide the margins of the subsequent wide local excision and the likely benefit from a sentinel lymph node biopsy (SLNB) to detect occult metastases in the adjacent lymph nodes. The latest National Institute for Health and Care Excellence guidelines recommend that SLNB should be offered to patients with stage 1B to 2C melanoma with a Breslow thickness of more than 1 mm. Patients with clinically evident lymphadenopathy or positive SLNB are further evaluated with PET/CT to detect distant metastases.

Treatment for patients with metastatic melanoma (stages 3 and 4) has been revolutionized in the past few years with the advent of targeted therapy. This includes the oral TKIs vemurafenib and dabrafenib and the MEK inhibitor trametinib for patients whose melanomas demonstrate the *BRAF V600* mutation. They are more effective than conventional chemotherapy when given in combination, but toxicity and tumour resistance are limitations. Immunotherapy with immune checkpoint-blocking agents, including CTLA4 antibody (ipilimumab) and PD-1 antibody (pembrolizumab, nivolumab), has led to significant improvements in survival for patients with advanced melanoma with tolerable toxicity.

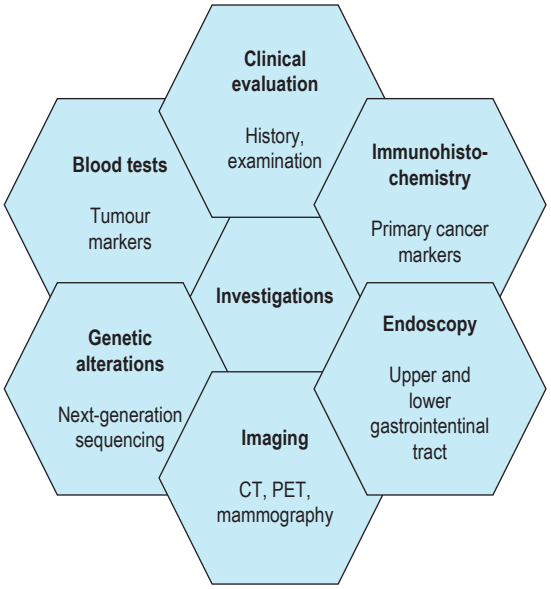

Fig. 41.27 Numerous tests may be indicated for patients presenting with a carcinoma of unknown primary. A non-exhaustive selection of these investigations is shown. *CT,* Computed tomography; *PET,* positron emission tomography.

METASTATIC CANCER OF UNKNOWN PRIMARY ORIGIN

Patients presenting with symptoms of metastases or with an incidental finding on imaging without a clinically obvious primary cancer after investigation represent a well-recognized clinical problem and make up 5% to 10% of patients in a specialist oncological centre. Clinical guidelines are based on several systematic studies, some with postmortem follow-up. Patients predicted to have a poor prognosis (based on performance status, histology, and site and extent of incurable disease) can be spared the discomfort of intensive investigation and be given appropriate palliative care (Fig. 41.27).

Diagnosis and investigation

The diagnosis requires histology first and foremost because it will lead to the identification of several distinct groups. If clinical examination does not give an obvious clue to the probable primary origin of the cancer, then a whole-body scan (usually FDG-PET body scan) is performed and usually gives the clue as to the site of origin. A biopsy follows for histological definition, whereafter staging and appropriate therapy is instituted.

- ***Squamous cancers*** may present with neck lymphadenopathy; 80% are associated with an occult head and neck primary, the majority remainder arising from the lung. Inguinal nodes usually point to a primary of the genital tract or anal canal. Treatment with radiotherapy and chemotherapy may have curative potential, especially in the head and neck area and even in the absence of an identifiable primary on pan-endoscopy.
- ***Poorly differentiated or anaplastic cancers*** include a number of potentially curable cancers, such as high-grade lymphomas and germ cell tumours, and should be suspected in all young patients with midline masses. They are sometimes identifiable by their immunocytochemistry and tumour markers. Gene markers, such as i12p for germ cell tumours in cancer of unknown primary, and BCL-2 for lymphomas, are increasingly available to aid diagnosis. Treatment and prognosis are as outlined for lymphoma (see Chapter 39) and germ cell tumours.
- ***Adenocarcinomas*** form the majority of cases of metastatic cancer of unknown primary. Their investigation should be guided by the desire to identify the most treatable options and the knowledge that the largest proportion will have arisen from the lung or pancreas, with relatively poor treatment prospects.

Investigations

Investigations should always start with a thorough review of the histology and appropriate imaging, such as FDG-PET scan (or indeed a tissue-specific PET, e.g., PSMA PET for prostate cancer and Dotatate PET for neuroendocrine tumours). CTs of the chest, abdomen, and pelvis are anatomic scans compared with PET scans, which assess function. In males, further investigations should include serum PSA and pelvic MRI to identify prostate cancers; in females, mammography and breast MRI and ultrasound examination should assess for breast cancer; pelvic MRI is used when gynaecological cancer is suspected (Box 41.31).

Circulating tissue-specific serum markers can be helpful (e.g., PSA, thyroglobulin, CEA, Ca153, CA-125, Ca 19-9, HCG, AFP) (Box 41.32), and increasingly, tumour genetics are able to identify the primary site of origin by gene expression microarray and polymerase chain reaction. Genomics of cancers are also very important with therapeutics in mind to search for actionable mutations that are driving the cancer's growth beyond physiologic or homeostatic cell reproduction. Not infrequently, mutations of transduction pathways are associated with cancer, and *RAS, RAF, PI3K,* and *mTOR* mutations are important in this regard because there are now specific inhibitors of these oncogenic driver mutation pathways. The

Box 41.31 Adenocarcinoma of unknown primary site: where to search for the primary is of therapeutic benefit

- Breast (e.g., isolated axillary lymphadenopathy)
- Ovary (e.g., peritoneal carcinomatosis)
- Prostate (e.g., pelvic lymphadenopathy)
- Colon (e.g., liver metastases)

Box 41.32 Carcinoma of unknown primary site

Immunohistochemistry marker	Most probable (but not exclusive) tissue of origin
Epithelial membrane antigen (EMA)	Epithelial
Leucocyte common antigen (LCA)	Lymphoid
Cytokeratin 7+ 20+	Pancreas, 65%; cholangiocarcinoma, 65%
	Gastric, 40%; transitional cell, 65%; ovarian mucinous, 90%
Cytokeratin 7+ 20–	Ovarian (except mucinous), 100%; breast, 90%; lung adenocarcinoma, 90%; uterus or endometrioid, 85%; transitional cell, 35%; pancreas, adenocarcinoma, 30%; cholangiocarcinoma, 30%; thyroid, 100%; mesothelioma, 65%
Cytokeratin 7– 20+	Colorectal adenocarcinoma, 80%; gastric adenocarcinoma, 35%; Merkel cell, 70%
Cytokeratin 7– 20–	Hepatocellular, 80%; carcinoid, 80%; lung small-cell and squamous, 75%; prostate, 85%; renal adenocarcinoma, 80%; adrenal, 100%; germ cell, 95%; squamous cancer of the head and neck and oesophagus, 70%; mesothelioma, 35%
Thyroid transcription factor 1 (TTF-1)	Lung, thyroid
Thyroglobulin	Thyroid
Oestrogen receptor (ER), progesterone receptor (PR), and HER2 receptor	Breast
Prostate-specific antigen (PSA)	Prostate, breast
Carcinoembryonic antigen (CEA)	Gastrointestinal
CDX2	Colorectal, small intestinal
Villin	Gastrointestinal
CA-125 peritoneal antigen	Ovarian, fallopian tube and primary peritoneal, and breast
WT1	Ovarian serous cancer, mesothelioma, desmoplastic tumours, Wilms' tumours
S100, melanin, and HMB45	Melanoma
Myosin, desmin, and factor VIII	Soft tissue sarcoma
Chromogranin and neurone-specific enolase (NSE)	Neuroendocrine
α-Fetoprotein (AFP)	Germ cell tumours, hepatocellular carcinoma
β-Human chorionic gonadotrophin (β-hCG)	Germ cell and trophoblastic tumours
CD117	Gastrointestinal stromal tumours

predictive test for success of immunotherapy (PDL-1 expression combined positive score [CPS] score), is also relevant to the work-up of many metastatic cancers, whatever their tissue of origin.

Immunohistochemical analysis of cytokeratin (CK) proteins may discriminate the likely site of origin of a carcinoma. For example, CK20 positivity is a strong indicator of a GI origin of a cancer, whereas CK7 positivity alone suggests urothelial origin. Thyroid transcription factor-1 (TTF-1) positivity correlates with either lung or thyroid cancer origin.

Management

If investigations have not identified a primary site, then surgery may be considered for unifocal adenocarcinoma of unknown primary metastases.

In females, an isolated axillary lymph node metastasis (biopsy demonstrating the characteristics of breast cancer) should be treated as for lymph node–positive breast cancer. Cytology-positive (adenocarcinoma) ascites in females should be treated with a trial of chemotherapy, as for primary peritoneal, fallopian tube, or epithelial ovarian cancer. The serum marker CA-125 is almost always very high in these instances. The prognosis for those responding to such a therapeutic trial is similar to that in disease of known primary origin.

For patients with metastatic disease at multiple sites yet no primary organ of origin is found, no genomics suggestive of containing actionable driver mutations and negative CPS score for PDL-1 expression, then chemotherapy is offered to patients with reasonable performance status.

Such cancers are often poorly differentiated but may still display some response to chemotherapy, although the overall prognosis is poor. When there is a targetable mutation or a high predictive CPS/PDL-1 score, immunotherapy or checkpoint inhibitor therapy may be worth a trial and offer improved survival.

CORE SKILLS AND KNOWLEDGE

Humans have evolved to have robust defences against infections, and this interplay has had a profound effect on our development. Consequently, most infections are self-limiting and either managed at home by the patient or cared for by community services. Hospital-based infection services manage patients with complicated or severe infections that require expertise from trained infection specialists in settings that vary from outpatient clinics (e.g., those that treat patients with chronic infections such as tuberculosis) to critical care units. Outpatient parenteral antimicrobial therapy (OPAT) services are now used to bridge the gap for patients who need intravenous therapy and close specialist oversight but are stable enough to be at home.

There are two main clinical infection subspecialties:

- ***Clinical microbiologists and virologists***, who predominantly provide advice on patients in the care of other doctors and manage the microbiology laboratory
- ***Infectious disease specialists***, who are often trained as general physicians and treat patients directly under their care or provide a 'liaison infection service' to other teams.

These differences are increasingly blurred because most UK trainees now gain skills in both bench and bedside medicine. A small number of tropical medicine specialists are concentrated in tertiary centres, such as the Hospital for Tropical Diseases in London, and many infection specialists are research active and hold joint academic appointments in the UK and overseas.

Key skills to master in infectious diseases include:

- Taking a comprehensive history from patients to draw up a thorough account of their presentation and risk factors
- Understanding the geographical distribution of different types of infectious agent and their varied clinical presentations
- Being familiar with the role of laboratory-based experts in interpreting complex microbiological investigations.

The best way to learn about infectious diseases is by following patients as the stories of their illnesses unfold. Assess patients in the clinical environment where they present (often the emergency department), review available and subsequent investigations, and discuss them with the healthcare professionals caring for these individuals. Reflect on whether the initial assessment, investigations, and management were appropriate in light of any problems that emerged (e.g., adverse drug reactions or the need to intensify therapy) and review the subsequent processes of care (e.g., de-escalation of antibiotic therapy) and the final infection diagnosis.

CLINICAL SKILLS

History

Many patients with infectious diseases present with symptoms that are obviously suggestive of a particular type of infection. Others do not and may present with non-specific symptoms (fever, malaise, vomiting, or a rash). In addition, various types of immunodeficiency alter the way that infections present in these groups of patients. Taking a full history is critical in reaching a diagnosis (**Box 42.1**). A detailed description of how to ask about different risk factors is given later in this chapter. As put simply by Sir Eldryd Parry, a pioneer of training in infectious diseases, *'why has this person, from this place, presented in this way, at this time?'* The figure a couple pages away shows pathogens commonly affecting different organ systems, allowing a move from a clinical syndrome to a likely microbiological diagnosis.

Box 42.1 Taking a history in infectious diseases

Patient

- Age
  - Children and very old adults are more susceptible than young adults to some types of infectious disease.
- Sex
  - Epididymo-orchitis or prostatitis in males.
  - Pelvic inflammatory disease or tampon-related toxic shock syndrome in females.
- Occupation
  - Contact with animals raises the possibility of zoonotic infections.
  - Healthcare workers may acquire infectious diseases from their patients.
- Co-morbidity and immunosuppression
  - Some infectious diseases (e.g., bacterial meningitis or pneumococcal pneumonia) can affect even previously fit and healthy individuals.
  - Most infectious diseases are more common in immunosuppressed individuals, although the presentation might be blunted or less severe.
  - Certain co-morbidities raise the risk of specific types of infection (e.g., incomplete bladder emptying in neurological disease raises the risk of urinary tract infection).
  - Significant immunosuppression (e.g., in organ transplant recipients or patients with significant bone marrow disease) increases the risk of infection by a wide range of atypical (opportunistic) pathogens, including fungi, low-pathogenicity viruses and non-tuberculous mycobacteria.
- Socio-economic status
  - Malnutrition, poor sanitation, homelessness, and overcrowding increase the risk of a number of 'diseases of poverty'.
- Activities
  - People who inject drugs are at risk of blood-borne viruses and bacterial bloodstream infection.
  - Unprotected sex presents the risk of developing body-fluid-borne viruses and various sexually transmitted infections (see Chapter 43).
  - Freshwater swimming is a risk factor for leptospirosis and (in certain regions) schistosomiasis.
  - Domestic pets can transmit disease, including cat-scratch fever or toxoplasmosis.
- Close contacts
  - Diseases that occur in outbreaks (e.g., food poisoning) may also present in household or other close contacts.
- Uncommon exposures
  - When the diagnosis is unclear, taking time to revisit the history and ask about any unusual activities or exposures is sometimes helpful. Activities that may not be common in a particular setting (e.g., caving, cleaning aquariums, art restoration, repairing air-conditioning systems) all carry risks for developing particular infectious diseases. Unless you ask, you may never find out.

Place

- A detailed travel history is essential
  - Travel to tropical and subtropical countries may be a risk factor for a wide range of infectious diseases, including malaria, dengue, and typhoid.
  - Chronic infectious diseases, such as tuberculosis and viral hepatitis, may have been acquired during a childhood spent in endemic regions and then present in adulthood.
  - Recent geographically localized epidemics, such as Middle Eastern respiratory syndrome or Ebola (Central Africa), should be borne in mind.
- Contact with healthcare settings
  - Nursing or residential home residents are at risk of developing infectious diseases that are usually associated with hospital inpatients (e.g., 'hospital-acquired pneumonia' or *Clostridioides difficile* infection).
- There are significant global differences in antibiotic resistance rates, so patients who have been inpatients in or travelled to other countries may present with multi-resistant organisms not usually seen in their country of residence.

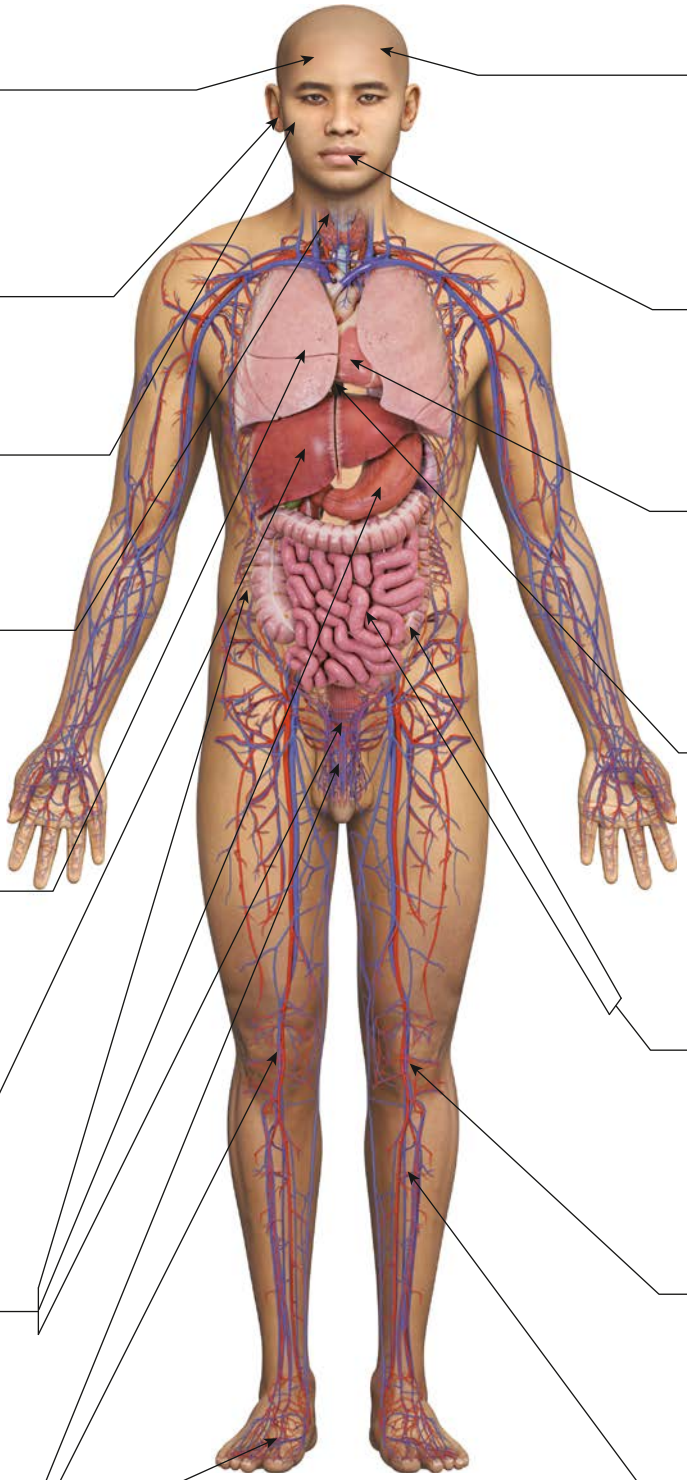
Time

- It is often helpful to produce a timeline describing the development (and perhaps resolution) of different symptoms over time.
- Symptoms of many acute viral and bacterial infectious diseases emerge over several days.
- Symptom duration of more than 2 weeks suggests chronic infection (e.g., tuberculosis, leishmaniasis, brucellosis, human immunodeficiency virus) or a non-infectious (e.g., autoimmune or malignant) disease process.
- An abrupt onset of severe symptoms suggests a highly virulent organism and may imply the need for urgent and empirical treatment before a diagnosis is made.
- Some diseases have characteristic time courses (e.g., the biphasic febrile response in dengue, or the initial 'Katayama fever' followed by haematuria seen in *Schistosoma haematobium* infection).

Symptoms

- Producing a clear account of the different general and organ-specific symptoms experienced by the patient is crucial.
- Sepsis is a physiological state that must not be missed because it always requires empirical antibiotic therapy (see Chapter 12).
- Some symptoms suggest the involvement of a particular anatomical site or organ system, such as localized pain, jaundice, or the bloody diarrhoea of dysentery.
- Other symptoms, such as headache and vomiting or watery diarrhoea, often occur non-specifically in various infectious and non-infectious diseases and should not be presumed to imply neurological or gastrointestinal disease, respectively.
- Some infectious diseases have unique pathological features that, if properly described, are highly suggestive of a particular diagnosis (e.g., the 'erythema migrans' rash of Lyme disease, the progressive phases of typhoid).

Common pathogens affecting different sites of the body



Sinuses/nose
Strep. pneumoniae
H. influenzae
Staphylococci (MSSA/MRSA)
Rhinoviruses
Polymicrobial infection
RSV
Other viruses

Outer ear
Staphylococci
Streptococci
Pseudomonas

Inner ear
Strep. pneumoniae
H. influenzae

Throat
Candida
Strep. pyogenes
MRSA (colonization)
Viruses, e.g., adenovirus
Anaerobic bacteria

Lungs
Strep. pneumoniae
H. influenzae
Staph. aureus
Gram-negative organisms
Tuberculosis
SARS-CoV-19

Liver
Viral hepatitis
Amoebiasis
Schistosomiasis
Strep. milleri

Kidney/bladder
Gram-negative organisms (from gut), especially *E. coli*

Cannula sites / skin
Staphylococci (MSSA/MRSA)
Streptococci
Candida

CNS
Meningococcus
Strep. pneumoniae
H. influenzae
Viruses, e.g., enterovirus, Herpes simplex
Listeria monocytogenes
Mycobacterium tuberculosis

Mouth
Staphylococci
Streptococci

Heart valves (endocarditis)
α-Haemolytic streptococci
Staph. aureus (e.g., right-sided valves in i.v. drug users)
Yeasts

Bloodstream infection (bacteraemia)
Staph. aureus
E. coli
Meningococcus
Strep. pneumoniae

Large and small intestine
Gram-negative organisms, e.g., *E. coli, Klebsiella*
Campylobacter
Salmonella
C. difficile
Bacteroides / anaerobes

Joints
Staphylococci
Streptococci
Neisseria gonorrhoeae
Haemophilus in children
Kingella in young children (≤5 years old)

Bones
Staphylococci
Salmonella
Streptococci
Gram-negatives

BACKGROUND

'Infection' is defined as the process of pathogenic organisms invading and multiplying in or on a host's tissues. The term should be reserved for situations in which this results in harm, or 'disease', rather than when a microorganism simply colonizes the host without ill effect. In some cases, pathogenic organisms have a dormant phase when they do not cause harm, for example, with latent TB or some herpes viruses. In fact, most microbes cause no harm, and the relationship between colonizing microorganisms and human health is increasingly being recognized in studies of the human microbiome. Some microbes, however (including some colonizing bacteria such as *Staphylococcus aureus*) have the potential to cause disease in the right circumstances.

Infectious agents

Novel infectious diseases continue to emerge around the world, and known diseases sometimes cause outbreaks in new areas (**Fig. 42.1**), making a patient's travel history a crucial risk factor in infectious disease. Up-to-date information on new outbreaks is maintained by the International Society for Infectious Diseases at http://promedmail.org.

The causative agents of infectious diseases can be divided into four groups:

Prions are the simplest infectious agents, consisting of a single protein molecule. They contain no nucleic acid and therefore no genetic information; their ability to propagate within a host relies on inducing the conversion of endogenous prion protein PrP^{c} into an abnormal protease-resistant isoform referred to as PrP^{Sc} or PrP^{Res}. Prion diseases are described in the 'Transmissible spongiform encephalopathies (prion diseases)' section.

Viruses contain both protein and nucleic acid, and so carry the genetic information for their own reproduction. However, they lack the apparatus to replicate autonomously, relying instead on 'hijacking' the cellular machinery of the host. They are small (usually <300 nm in diameter), and each virus possesses only one type of nucleic acid (either RNA or DNA).

Bacteria are usually larger than viruses. They are enclosed by a cell membrane and most have a cell wall (although some, e.g., *Mycoplasma* spp. have only a cell membrane, making them naturally resistant to cell-wall-acting antibacterial agents such as β-lactams).

Eukaryotes are the most sophisticated infectious organisms and include unicellular protozoa, fungi (which can be unicellular or filamentous) and multicellular parasitic worms. Other higher classes, such as the insects and the arachnids, also contain species that can envenom, injure or parasitise humans and cause disease.

CLINICAL APPROACH TO THE PATIENT WITH A SUSPECTED INFECTION

Fever is the cardinal feature of infection, but not all febrile illnesses are infections and not all infections present with a fever. **Fig. 42.2** provides an outline of the approach to the patient with acute (undifferentiated) fever of unclear cause. Fever is usually intermittent, so may not be present at the time of presentation, and occurs less commonly in elderly and newborn patients. Infection can also present with hypothermia (temperature <36°C), which is a poor prognostic sign. The biological behaviour of the pathogen and the consequent host responses are responsible for the clinical expression of disease, which sometimes allows for clinical recognition. Knowledge of the incubation period following exposure can be helpful (e.g., up to 21 days for chickenpox). The site and distribution of a rash may be diagnostic (e.g., shingles), while symptoms of cough, sputum and pleuritic chest pain may suggest lobar pneumonia. Fever and neck stiffness characterize meningitis but do not inform about the microbial cause or management.

The three critical points in the assessment and management of a patient with fever, suspected infection or sepsis are:

- ***Physiological assessment*** (severity of illness), predominantly based on systematic examination of key physiological markers at initial presentation and subsequently.
- ***Diagnostic assessment***, predominantly based on history-taking, examination and interpretation of those diagnostic tests available at presentation and subsequently performed in the context of the history and examination.
- ***Management assessment***, based on linking physiological and diagnostic assessments to key interventions. Decisions will be based on the seriousness of the underlying infection and the likely cause. Interventions may include:
  - The use of antimicrobials
  - Intravenous fluids or oxygen
  - Infection source control (e.g., drainage of an abscess)
  - Infection prevention and control measures
  - Use of advanced physiological support in a critical care setting.

A detailed history can be taken in a physiologically stable patient, but may need to be delayed until after a patient is stabilized in the presence of sepsis, or taken after isolating the patient if a highly transmissible infection is suspected. The recognition and management of sepsis are considered in Chapter 12.

Diagnostic assessment

History-taking, examination and investigations aim to identify the site(s) of infection and also the likely causative organism(s). **Boxes 42.2 to 42.4** outline the links between symptoms, risk factors, examination findings and potential infection diagnoses. **Box 42.5** shows the different components of an infection diagnosis and how and why these are ascertained.

History

The history is the most important component of diagnostic assessment. A detailed, systematic history is taken with specific questions about the nature, timing and periodicity of symptoms (see **Box 42.1**), in particular in relation to any infection exposures and other risk factors (see **Box 42.3**). If symptoms started after the upper limit of the incubation period of any potential transmissible infection exposure identified, the diagnosis is unlikely. Consideration of the incubation

Box 42.2 Linking symptoms elicited from the patient history to infection diagnoses

Element(s) in the symptom history of a patient with acute fever or possible infection	Example infection diagnoses
Acute headache, non-blanching rash, neck stiffness, photophobia	Meningococcal meningitis
Acute headache, neck stiffness, photophobia	Meningitis (bacterial, viral, fungal)
Acute agitation, confusion	Encephalitis
Ear pain with pus-like discharge	Otitis externa
Maxillary sinus area pain	Sinusitis
Sore throat, large neck glands (lymph nodes)	Tonsillitis, glandular fever syndromes
Sore, ulcerated mouth or throat with rash on the hands or feet	Hand, foot, and mouth (viral) infection; other viral infections (remember syphilis in patients with rashes on their hands or feet)
Cough, dyspnoea, pleuritic chest pain	Lower respiratory tract infection, pneumonia
Fever, shivers, rigors	Bloodstream infection (usually bacterial), malaria, viral infections (e.g., influenza), endocarditis, causes of fever or pyrexia of unknown origin (if history is ≥2 weeks); all may or may not be associated with other symptoms
Non-specific abdominal pains or cramps and diarrhoea	*Clostridioides difficile* infection, gastroenteritis
Right upper quadrant pain	Hepatitis, biliary tract infection, liver abscess, pneumonia adjacent to diaphragm
Left iliac fossa pain	Diverticulitis, left ovarian abscess
Renal angle pain with urinary symptoms	Pyelonephritis, renal abscess
Frequency, urgency, pain on micturition	Urinary tract infection
Pelvic pain	Pelvic inflammatory disease, ovarian abscess (if pain is unilateral)
Penile or vaginal discharge	Sexually transmitted infections, retained tampon (females)
Back pain	Discitis (with or without epidural abscess)
Red, swollen, hot joint	Septic arthritis (non-infection diagnoses such as gout and reactive arthritis should be considered; see Chapter 32)
Red, swollen, hot, painful limb	Cellulitis, soft tissue infection
Pain, redness, and discharge at the site of a prosthesis or invasive device	Prosthesis or invasive device infection

Box 42.3 Linking risk factors elicited from the patient history to infection diagnoses

Element(s) in the risk factor history of a patient with acute fever or possible infection	Example infection diagnoses
Alcohol abuse	Spontaneous bacterial peritonitis (if ascites), invasive pneumococcal disease (*Streptococcus pneumoniae*), tuberculosis, aspiration pneumonia
Diverticular disease	Diverticulitis, diverticular abscess
Gallstones	Biliary tract infection, pancreatitis
Immunosuppression or HIV	Opportunistic bacterial (e.g., nocardiosis), fungal (e.g., cryptococcosis) and viral infections (e.g., cytomegalovirus)
Intravenous drug use	Bloodstream infection, especially *Staphylococcus aureus*, blood-borne infections (e.g., HIV, hepatitis B and C)
Lung disease, smoker	Respiratory tract infections or pneumonia, e.g., with *Haemophilus influenzae* (chronic obstructive pulmonary disease) or *Pseudomonas aeruginosa* (in cystic fibrosis and bronchiectasis)
Prostheses or invasive devices	Prosthesis or invasive device infection
Recent abdominal surgery	Intra-abdominal infection or peritonitis, abscess(es), wound infection
Recent influenza	Secondary bacterial infection (e.g., with Lancefield group A streptococci or meningococcus)
Recent hospitalization	Healthcare-associated infections, e.g., pneumonia and urinary tract, surgical site and bloodstream infections; at higher risk of an antimicrobial-resistant pathogen
Recent new sexual partner	Chlamydia, gonorrhoea, HIV, syphilis, other sexually transmitted infections
School or university student, military service	Meningococcal disease, mumps, other infections based on local contemporaneous epidemiology
Splenectomy	Pneumococcal, *Haemophilus* spp., and meningococcal infections (vaccination and antibiotic prophylaxis reduce but do not eliminate risk)
Travel abroad	E.g., dengue, malaria, legionnaires' disease, leptospirosis, typhoid (depends on travel history)
Urinary tract problems (e.g., renal stone, benign prostatic hypertrophy)	Urinary tract infection, pyelonephritis

HIV, Human immunodeficiency virus.

period is irrelevant for many infections, however, for example, when the invading pathogen is often a colonizer of the host, such as in *S. aureus* bloodstream infections; when a specific exposure history cannot be identified; or when the patient's history and examination signs are not diagnostic.

Symptoms are often non-specific (e.g., a 3-day history of lethargy, loss of appetite, and shivers) but may lead to a diagnosis or differential diagnosis through careful interpretation and problem-solving (by linking the patient's symptoms to their exposures and risk factors and then to potential clinical infection diagnoses and causal pathogens; examination findings and any available test results also need to be considered).

In patients with sepsis, a full history should be obtained after, or at the same time as, initiating emergency medical management (see

Box 42.4 Linking examination findings to infection diagnoses

Examination finding(s) in a patient with fever or possible infection	Site of infection or diagnosis
Meningism, petechial rash	Meningitis (most likely meningococcal)
Cervical lymphadenopathy, enlarged tonsils	Tonsillitis (viral or bacterial), glandular fever syndromes (including HIV)
Tachypnoea, coarse focal crackles (can be bilateral)	Lower respiratory tract infection, pneumonia
Temperatures ≥37.8°C, new-onset regurgitant systolic murmur	Endocarditis
Right upper quadrant tenderness	Biliary tract or liver infection
Abdominal tenderness with rebound or guarding	Intra-abdominal infection (peritonitis)
Left iliac fossa tenderness	Diverticulitis or diverticular abscess, tubulo-ovarian abscess in females
Right iliac fossa tenderness	Appendicitis or appendix abscess, tubulo-ovarian abscess in females
Suprapubic tenderness(± catheter)	Urinary tract infection, pelvic inflammatory disease in females
Renal angle tenderness	Pyelonephritis, renal abscess
Red, hot, swollen limb	Cellulitis, soft tissue infection (consider necrotizing fasciitis if pain is out of keeping with examination appearances or if there is severe pain, rapidly progressing history and 'odd' examination appearance or findings)
Intravascular devices ± erythema, pus	Device infection, bloodstream infection, endocarditis

HIV, Human immunodeficiency virus.

Box 42.5 Components of the infection diagnosis and how and why these are ascertained

Diagnostic component	How?	Why?
Body organ(s) or system(s) involved	History (most important) Examination Non-microbiological investigations (e.g., WCC, CRP, CXR, other radiology)	Causal pathogens are relatively predictable (e.g., UTI vs pneumonia) Required intervention (e.g., drainage of abscess) Prognostic (e.g., mortality rate of meningitis vs cellulitis)
Microbiological or virological	Diagnostics (blood and urine culture, lumbar puncture, rapid diagnostics) Epidemiologically if diagnosis confirmed in other patients (e.g., outbreak of norovirus in a nursing home) (Clinical assessment if pathognomonic signs)	To avoid antibiotics (e.g., viral vs bacterial RTI) To target pathogen with optimal therapy Required investigation or intervention (e.g., need for TTE in *Staphylococcus aureus* BSI) Prognostic (e.g., viral meningitis vs bacterial) Epidemiology (for disease and resistance surveillance)
Prognostic (severity)	Physiology Age, co-morbidity, and so on Clinical or microbiological diagnosis (see earlier) if available	Dictates level of required intervention (i.e., sepsis vs self-limiting infection) Informs discussion with patient and relatives

BSI, Bloodstream infection; *CRP,* C-reactive protein; *CXR,* chest X-ray; *RTI,* respiratory tract infection; *TTE,* transthoracic echocardiogram; *UTI,* urinary tract infection; *WCC,* white blood cell count.

Chapter 12) to avoid therapeutic delay. If the patient is confused, the history may have to be obtained from a relative or friend. The time course of symptoms is one of the most relevant parts of the history:

- With some exceptions, patients with short, acute symptom histories are more likely to have infections caused by microbes that tend to cause acute presentations (e.g., *Streptococcus pneumoniae* infection in a patient with a 3-day history of shivers, cough with production of green sputum, and pleuritic chest pain).
- Patients with longer symptom histories are more likely to have infections caused by microbes that tend to cause chronic presentations (e.g., pulmonary TB in a patient with a 2-month history of sweats, weight loss, and cough productive of blood-stained sputum; a patient who has recently returned from living in sub-Saharan Africa).

Although this may seem obvious, it is often overlooked when it comes to requesting a battery of investigations.

Key diagnostic information in the patient's history should include the following.

Age

Older patients are more prone to some infections (e.g., *Clostridioides difficile* infection or pneumonia). Some infections (e.g., glandular fever, chickenpox) are less common in older adults but are sometimes more severe.

Sex

Some diagnoses are sex-specific, such as epididymo-orchitis, prostatitis, pelvic inflammatory disease, and tampon-related toxic shock syndrome (TSS).

Occupational history

The potential links between occupation and infection are sometimes significant. Healthcare workers may be exposed to certain infections, for example, by air-borne (e.g., chickenpox, TB), person-to-person (e.g., rotavirus), and needle-stick injury (e.g., blood-borne viruses) routes of transmission. Teachers may be exposed to the common infections of childhood. People who work with animals may be exposed to zoonoses.

Symptoms

See **Box 42.2** for examples of how symptoms can be linked to a diagnosis or differential diagnosis.

Human infection contact

Contact with others who have an infection diagnosis or symptoms of an infectious disease should be discussed. A patient with a new vesicular rash, for example, is asked about contact with chickenpox or shingles within the previous 21 days (the upper limit of the

incubation period). A patient with gastroenteritis is asked about contact with other people with similar symptoms, when that contact was with respect to the start of symptoms, and the social context of that contact. A patient with recurrent skin abscesses is asked about contact with other persons with recurrent skin infections (e.g., to assess the risk of transmission of Panton–Valentine–leukocidin (PVL) producing *S. aureus* skin infections).

Animal contact

Domestic (e.g., cats and *Toxoplasma gondii* infection), farm (e.g., sheep and *Coxiella burnetii* infection) and wild animal (e.g., bats and rabies) contact may be relevant.

Travel history

Some diseases are more prevalent in certain geographical locations. A detailed travel itinerary, including any flight stopovers, should be taken from anyone who is unwell after arriving from another country. Previous travel should also be covered because some infections may be chronic or recurrent (e.g., *Plasmodium vivax* malaria). It is necessary to find out not only which countries were visited but also the type of environment and length of stay; a prolonged stay in a remote rural village carries much higher health risks (for some conditions) than a short holiday in an air-conditioned coastal holiday resort, even in the same country. Food and water consumption, bathing and swimming, animal and insect contact, and contact with human illness need to be established. Enquiry should be made about sexual contacts, drug use, and medical treatment (especially parenteral). Patients who have spent time in hospitals elsewhere may be colonized with carbapenem-resistant organisms or *Candida auris*.

In some parts of the world, a high-proportion of professional sex workers are human immunodeficiency virus (HIV) positive, and hepatitis B and C (HBV and HCV) are common in some parts of Africa and Asia. Special tests may be needed, depending on the epidemiological risks and clinical signs, and a blood film is mandatory in anyone who is unwell up to 1 year after being in a malaria-endemic area. A reliable resource such as Travel Health Pro (see Further reading) or https://promedmail.org is consulted regarding current infectious disease alerts and endemic risks for the countries visited. Some of the more common causes of a febrile illness in returning travellers are listed in **Box 42.6**.

Food and drink history

Exposure to unclean water and uncooked, unpasteurized, or contaminated foods or drinks (e.g., *Listeria monocytogenes* infection from soft cheeses) should be asked about, and illness in other people also exposed.

Sexual activity

The sexual history is often omitted or poorly taken but is essential if diagnoses such as HIV infection are not to be missed. Sexual exposure is common in travellers, and routine testing of patients for blood-borne viruses is a simple and cost-effective solution. Sexually transmitted infections (STIs) are discussed in Chapter 42.

Pregnancy

Pregnant females may be more susceptible to some infections (e.g., malaria, HIV infection, and listeriosis) and may be at higher risk of severe infections (e.g., disseminated herpes simplex virus [HSV] infection, hepatitis E, influenza, malaria, measles).

Intravenous drug use and needle exposure

As well as blood-borne viruses (mostly HIV, HBV, and HCV), people who inject drugs are susceptible to a wide variety of bacterial and fungal infections, in particular those caused by *S. aureus* and *Streptococcus pyogenes* (group A streptococci [GAS]) as a result of contamination of the injecting equipment or inoculation from the patient's colonized skin. Abscesses (e.g., in the psoas or other muscles) and soft tissue infections at the site of injection are common, especially in the groin, and may involve adjacent vascular structures (forming pseudoaneurysms) and bones (osteomyelitis). Bloodstream and haematogenously spread infections, including endocarditis (often right-sided), spinal, and bone and joint infections, are also common. Other needle exposures, such as tattooing, body piercing, needle-stick injuries, and receipt of blood products are also risk factors for blood-borne infections, although this is much less common because the risks are better recognized and addressed.

Leisure activities

Certain pastimes (e.g., open-water swimming and leptospirosis) may predispose to water-borne infections or zoonoses.

Previous infections

Previous infections are reviewed, especially for the prior 12 months, for any pathogens isolated and associated antimicrobial susceptibilities. This is particularly useful in patients with a history of colonization or infection by meticillin-resistant *S. aureus* (MRSA) or other

? Box 42.6 Examples of causes of febrile illness in travellers returning from the tropics and other countries

The World Health Organization advises that fever occurring in a traveller 1 week or more after entering a malaria risk area and up to 3 months after departure is a medical emergency. A reliable travel health source is always consulted.

Low- and middle-income countries (mostly)

- Malaria
- Typhoid
- Leptospirosis
- Dengue
- Chikungunya
- Dysentery
- Hepatitis A
- Amoebiasis
- Schistosomiasis
- Tick typhus

Examples of specific geographical areas (see text)

- Ebola, Marburg, and Lassa fever
- Middle Eastern respiratory syndrome
- Zika
- Histoplasmosis
- Brucellosis

Worldwide

- Multidrug- and extensively drug-resistant Gram-negative infections
- Upper respiratory tract infection
- Pneumonia
- Influenza and other common viral infections
- Traveller's diarrhoea
- Tuberculosis

resistant microbes or of recurrent respiratory or urinary tract infection (UTI). Some infections, such as chickenpox, may rarely occur for a second time because of waning immunity, although chickenpox may recrudesce from latency in the form of shingles (zoster). Patients who are infected with dengue virus for a second time are at higher risk of developing severe forms of the infection.

Co-morbidities

The potential association between co-morbid illnesses and infections is considered (e.g., haematological malignancy and medication-related immune suppression are risk factors for invasive pneumococcal disease and opportunistic infections, such as *Pneumocystis jirovecii* infection).

Devices, prostheses, and implants

Symptoms relating to any recently inserted or longstanding devices, prostheses, or implants are discussed (e.g., increasing pain in a total hip replacement; swelling and warmth over a pacemaker insertion site).

Immunization history

Patients who have not received certain childhood (e.g., measles, mumps) or pre-travel (e.g., rabies) vaccines are at higher risk if exposed.

Medications

Some medications increase the risk of certain infections (e.g., proton pump inhibitors and histamine$_2$ antagonists may predispose to gastrointestinal [GI] infections, including, for example, *Salmonella* spp. gastroenteritis and *C. difficile* infection). Other drugs may be potent suppressors of immune function (e.g., ciclosporin or corticosteroids and cellular immunity; see later). The patient's recent antimicrobial exposure should also be ascertained; it is well known, for example, that individuals recently exposed to an antimicrobial are more likely subsequently to harbour microorganisms resistant to that antimicrobial (and possibly to other antimicrobials, too), and this may influence prescribing decisions.

Allergies and intolerances

The detailed nature of any prior allergies or intolerances should be determined with respect to antimicrobials or infection-related drugs (e.g., HIV medications). Most patients who report a penicillin allergy without clear recollection of events turn out not to be allergic to penicillin-based drugs. Some hospitals have introduced penicillin testing services, often run by infection specialists, to ensure a safe approach to penicillin allergy delabelling.

Infections in immunocompromised hosts

Increasing age and co-morbidity, as well as advances in medical treatment over recent decades, have led to a huge increase in the number of patients living with immunodeficiency states of varying degrees. Cancer chemotherapy; immunosuppressive drugs, including the increasing use of monoclonal antibody-based biologic therapy (e.g., infliximab); and the worldwide HIV epidemic have all contributed.

A patient's immunosuppression status is often multifactorial because of age, co-morbidity, and therapy, and an assessment of the patient's ***net state of immunosuppression*** is an important concept in determining the nature of the infections from which a patient is at risk. For example, an otherwise well 60-year-old patient taking low-dose maintenance prednisolone for polymyalgia rheumatica is considerably less immunosuppressed and hence at lower risk of infections than an 82-year-old patient with diabetes, rheumatoid arthritis, and a past history of a renal transplantation who is taking a variety of immunosuppressant and disease-modifying medications. The time course of immunosuppression is also relevant: patients within 6 months of solid organ transplantation are at higher risk of infection than those further out because this period corresponds to the most intense time of immunosuppression. Patients who do not have a spleen (or a functional spleen) are at risk of infections caused by capsulated bacteria (i.e., pneumococci, *Haemophilus* spp., and meningococci).

Clinical presentations may be atypical in immunocompromised patients, with few, if any, localizing symptoms or signs. Infection can be caused by organisms that are not usually pathogenic, including environmental bacteria and fungi (opportunistic microbes). The normal physiological responses to infection (e.g., fever, neutrophilia) may be diminished or absent. The onset of symptoms may be sudden and the course of the illness fulminant. A high index of suspicion for atypical infections in immunosuppressed individuals is required, with early investigation (e.g., computed tomography [CT] of the thorax for invasive pulmonary aspergillosis) and rapid intervention. Common causes of infection in immunosuppressed patients are shown in **Box 42.7**. For neutropenic sepsis, see Chapter 11 ('The unwell cancer patient' section).

Clinical examination

A careful and systematic examination covering all systems is required to avoid missing subtle signs, such as splinter haemorrhages in patients with endocarditis or the petechial rash of early meningococcal disease. The examination is used to support or refute likely differential diagnoses based on the history and may also help guide the approach to investigations; new differential diagnoses may also emerge based on examination findings. The fever pattern may occasionally be helpful but in most patients fever is non-specific and not diagnostic.

- Clothes and dressings should be removed to inspect the underlying skin, wounds (including historic wounds), and invasive devices (e.g., pacemaker sites).
- Skin rashes are commonly associated with infection (**Box 42.8**) and range from a diffuse, blanching maculopapular rash seen in many viral infections to the purpuric, non-blanching rash associated with meningococcal bacteraemia (**Fig. 42.3**).
- Lymphadenopathy is a common feature of infectious diseases but can also occur in patients with non-infectious conditions, such as lymphoma.
- The ears (necrotizing otitis externa), nose (common cold), eyes (Roth's spots in endocarditis), mouth (Koplik's spots in measles), and throat (tonsillitis) should all be inspected carefully.
- Auscultation of the heart for murmurs is critical in patients with fever of unknown cause, bloodstream infections, and other potential signs of endocarditis.
- Likewise, examination of the musculoskeletal system, including palpation of the spine (discitis), is performed in patients with bloodstream infection, especially those caused by *S. aureus*, and fever or pyrexia of unknown cause.
- Abdominal examination, including the renal angles (pyelonephritis; see Chapter 26, 'Urinary tract infection' section), should be performed in patients with Gram-negative bloodstream infection (e.g., that caused by *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*) because the urinary tract (most commonly), intra-abdominal sites, and the liver and biliary tract (liver enzymes are often elevated) are the most common underlying foci of infection.
- Rectal, vaginal, and penile examinations are required in those at risk of STIs (see Chapter 43).

Box 42.4 outlines the potential links between some examination findings and diagnoses of infection.

Box 42.7 Common causes of infection in immunocompromised patients

Deficiency	Causes	Organisms (examples)
Neutropenia	Chemotherapy Myeloablative therapy Immunosuppressant drugs	*Escherichia coli* *Klebsiella pneumoniae* *Staphylococcus aureus* *Staphylococcus epidermidis* *Aspergillus* spp. *Candida* spp.
Cellular immune defects	HIV infection Lymphoma Myeloablative therapy Congenital syndromes	Respiratory syncytial virus Cytomegalovirus Epstein–Barr virus Herpes simplex and zoster *Salmonella* spp. *Mycobacterium* spp. (esp. *Mycobacterium avium* complex infections) *Cryptococcus neoformans* *Candida* spp. *Cryptosporidium parvum* *Pneumocystis jirovecii* *Toxoplasma gondii*
Humoral immune deficiencies	Congenital syndromes Chronic lymphocytic leukaemia Corticosteroids	*Haemophilus influenzae* *Streptococcus pneumoniae* Enteroviruses
Terminal complement deficiencies (C5–C9)	Congenital syndromes	*Neisseria meningitidis* *Neisseria gonorrhoeae*
Splenectomy	Surgery Trauma	*Streptococcus pneumoniae* *N. meningitidis* *H. influenzae* Malaria

HIV, Human immunodeficiency virus.

Investigations

The results of investigations are used to support, confirm, or refute likely differential diagnoses based on the history and examination findings and may also lead to new differential diagnoses and the need for further investigations.

In some infections, such as chickenpox, the clinical presentation is so distinctive that no investigations are necessary to confirm the diagnosis. In other mild and self-limiting infections, such as those frequently managed in primary and ambulatory care settings (e.g., minor skin infections, upper respiratory tract infections [URTIs], cystitis), extensive investigations will not change management and are therefore unwarranted because the diagnosis and treatment are clear.

Some patients, especially when they are being managed in secondary care or when an antibiotic prescription may be avoidable, require further tests to determine the organ, system, or site of infection and the microbiological cause to guide required intervention(s). A shared decision-making approach should be taken with the patient to avoid tests, treatments, and procedures that are unlikely to be of benefit.

General investigations

Box 42.9 shows general investigations for a patient with acute fever or suspected infection of unclear cause. It is vital to review at presentation any tests that have been performed previously, including prior microbiological tests. Treating a patient known to harbour resistant microorganisms with an antibiotic to which those organisms are

Fig. 42.3 Non-blanching urticarial rash associated with meningococcal bacteraemia and other bloodstream infections.

Box 42.8 Infections commonly associated with a rash

Macular or maculopapular
- Measles
- Rubella
- Enteroviruses
- Human herpesvirus 6
- Epstein–Barr virus
- Cytomegalovirus
- Human erythrovirus (parvovirus) B19
- Human immunodeficiency virus
- Dengue
- Typhoid
- Secondary syphilis
- Rickettsial spotted fevers

Vesicular
- Chickenpox (varicella zoster virus)
- Shingles (varicella zoster virus)
- Herpes simplex virus
- Hand, foot, and mouth disease (enteroviruses, enterovirus 71)
- Herpangina (enteroviruses)

Petechial or haemorrhagic
- Meningococcal septicaemia
- Any septicaemia with disseminated intravascular coagulation
- Rickettsiae
- Viruses (see Box 42.37)

Erythematous
- Scarlet fever
- Lyme disease (erythema chronicum migrans)
- Toxic shock syndrome
- Human erythrovirus (parvovirus) B19

Urticarial
- *Toxocara* spp.
- *Strongyloides* spp.
- *Schistosoma* spp.
- Cutaneous larva migrans

Others
- Tick typhus (eschar)
- Primary syphilis (chancre)
- Anthrax (ulcerating papule)

Box 42.9 General investigations and possible causes in suspected infection

Investigation	Possible causes
Full blood count	
Neutrophilia	Bacterial infection Inflammation
Neutropenia	Viral infection Brucellosis Typhoid Typhus Severe sepsis
Lymphocytosis	Viral infection
Lymphopenia	HIV infection (not specific) Other viral infections
Atypical lymphocytes	Infectious mononucleosis
Eosinophilia	Invasive parasitic infection
Thrombocytopenia	Sepsis Malaria Some viral infections
Erythrocyte sedimentation rate or C-reactive protein	Elevated in many infections
Serum creatinine and electrolytes	Potentially deranged in severe illness from any cause
Procalcitonin	Elevated particularly in bacterial infection
Beta-D-glucan and galactomannan	Maybe elevated in fungal infection
Liver enzymes	
Minor elevation of transferases	Non-specific feature of many infections Mild viral hepatitis
High transferases, elevated bilirubin	Viral hepatitis (usually A, B, or E)
Coagulation	May be deranged in hepatitis and sepsis
Serum lactate	Used in the assessment of sepsis

HIV, Human immunodeficiency virus.

resistant may be unwise, depending on clinical circumstances; for example, a patient presenting with pyelonephritis should not be treated with co-amoxiclav if *E. coli* resistant to co-amoxiclav were recently grown from a midstream urine specimen. The exact tests performed will vary, depending on clinical presentation and differential diagnoses, severity of illness, and available resources:

General blood tests

These provide clues to the diagnosis or organ or system involved (e.g., raised liver enzymes in liver or biliary tract infection) but in general are non-specific and non-diagnostic. Helpful tests may include:

- ***The full blood count and differential white cell count (WCC).*** In adults, lymphopenia is commonly associated with various viral infections, whereas neutrophilia, particularly if marked, is more likely to be associated with certain bacterial infections, although such associations are far from precise.
- ***The erythrocyte sedimentation rate, plasma viscosity, and C-reactive protein (CRP)*** may be raised in infection and other inflammatory states.
- ***Liver biochemistry and function.***
- ***Serum creatinine and electrolytes.*** These assess for infection-related acute kidney injury.
- ***Coagulation screen***, ***fibrinogen***, and ***D-dimer*** (to exclude disseminated intravascular coagulation [DIC] in severe sepsis or liver dysfunction in viral hepatitis).
- ***Serum lactate*** (in suspected sepsis).

CRP is a non-specific marker of inflammation and is raised in many different infections and in acute and chronic non-infection conditions associated with inflammation (e.g., rheumatoid arthritis). It has a short plasma half-life (19 hours) and is more useful in monitoring response to treatment than in making a diagnosis, although it is sometimes used as a point-of-care test in primary or ambulatory care to guide the need for antibiotic therapy, for example, in acute bronchitis, using cut-offs of the following:

- 100 mg/L for an antibiotic prescription
- 20 to 100 mg/L for a delayed prescription
- Less than 20 mg/L for no antibiotic.

The exact role of ***procalcitonin*** in the diagnostic and prognostic assessment of bacterial infections is controversial; it may have a useful role in antibiotic stewardship (see Chapter 12, 'Treatment of infection caused by multidrug-resistant organisms' section) when used within algorithms, particularly for respiratory tract infections and in the critical care environment, to determine when it is safe to start or stop antibiotic therapy.

Radiological imaging

X-ray (e.g., pneumonia), ultrasonography (e.g., abscess), echocardiography (endocarditis), CT (e.g., intra-abdominal infection), and magnetic resonance imaging (MRI; e.g., bone and spinal infections) are used to identify and localize infections. Positron emission tomography (PET) and single-photon emission computed tomography have also proved useful in localizing infection, especially when combined with CT scanning, when the focus of infection is unclear (**Fig. 42.4**). Biopsy or aspiration of tissue for microbiological examination is often facilitated by ultrasound or CT guidance. Indium- or technetium-labelled white blood cell (WBC) scans (using WBCs harvested from the patient before the test) may also help to localize infection, but their role has largely been replaced by PET scans. When possible, cases should be discussed with a radiologist before ordering tests to ensure that patients receive the optimal investigations in the context of their individual clinical presentation and prior investigations.

Microbiological investigations

It is often helpful to discuss the clinical problem with an infection specialist to ensure that appropriate tests are performed to identify the causative organism and that specimens are collected and transported correctly. Accurate completion of the request form, including clinical information, antimicrobial history, and epidemiological and risk factor details (e.g., onset and duration or symptoms, recent travel) enable laboratory staff to add or delete tests appropriately.

Microscopy

The most widely used microscopic technique is the Gram-stain, which determines the shape (cocci or bacilli) and Gram status (positive or negative) of bacteria. This allows most pathogenic bacteria to be classified into four groups: Gram-positive cocci, Gram-negative cocci, Gram-positive bacilli, and Gram-negative bacilli. To some extent, this then dictates empirical antibacterial therapy, if appropriate. **Box 42.10** shows some key bacterial causes of bloodstream infections in the UK, along with their shape and Gram status, and how bacterial identity links to potential foci of infection.

Culture

Specimens for culture should, ideally, be taken before administration of or a change in antibiotic therapy. After antibiotics are commenced, however, there will be an impact on the host's resident

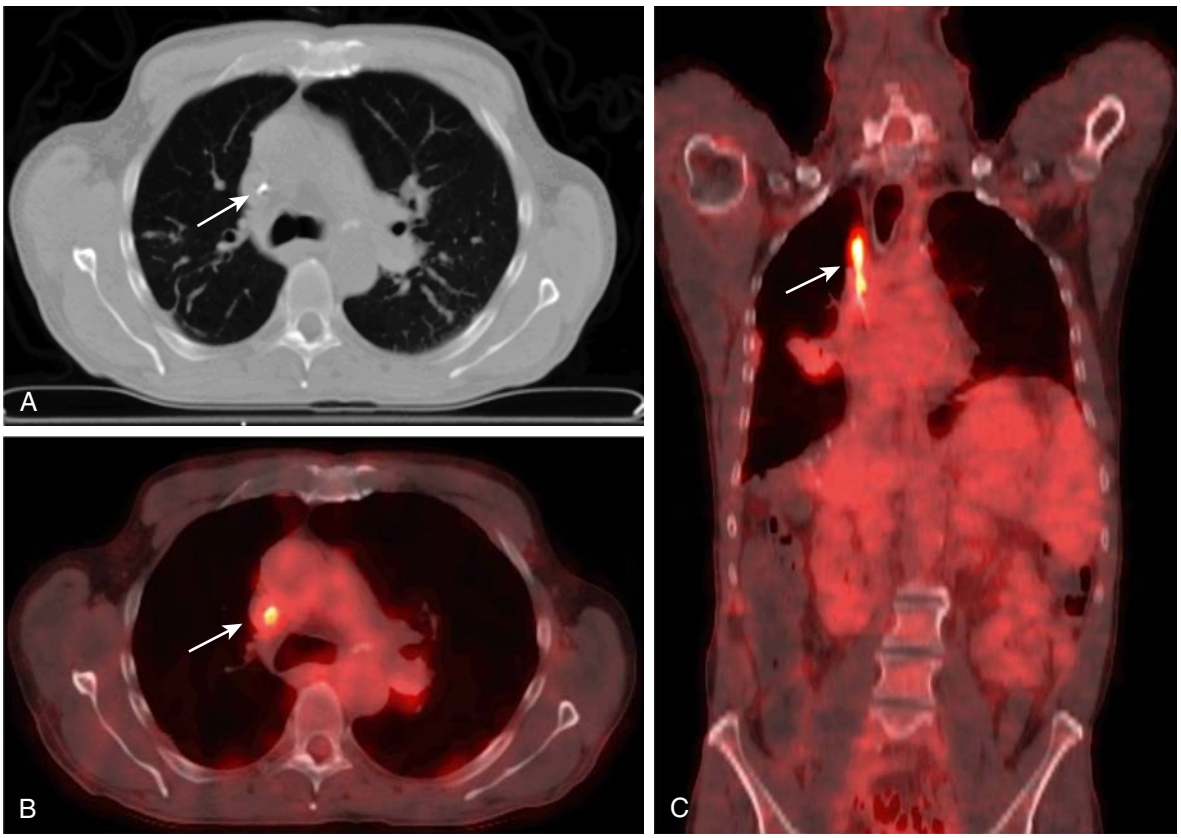

Fig. 42.4 ^{18}Fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) in infection. Axial computed tomography images **(A)** of a 67-year-old male with a history of colon cancer and longstanding chest port *(arrow)* for chemotherapy, presenting with recurrent fevers and rigors of unknown origin with negative blood cultures, unresponsive to antibiotics. Axial **(B)** and coronal **(C)** fused ^{18}FDG-PET scans demonstrate metabolic uptake *(arrow)* along the catheter fibrin sheath. Explant of the port revealed colonization by *Stenotrophomonas maltophilia*, a multidrug-resistant organism known to colonize medical devices. Patient symptoms resolved after removing the port. *(From CPET.)*

microbiome, including infecting pathogens, resulting in potentially misleading results. Culture techniques can be applied to a wide variety of bacteria, fungi, protozoa, and viruses. However, some organisms are difficult to grow and may require special culture media or conditions. Viruses are particularly difficult (and, in many cases, impossible) to culture in a laboratory.

Antimicrobial susceptibility testing is performed on isolates thought to be clinically significant. Increasingly, traditional culture techniques are combined with new technologies, such as fluorescence *in situ* hybridization, matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectroscopy, morphokinetic cellular analysis, polymerase chain reaction (PCR) testing of identifier genes, and whole-genome sequencing of pathogenic organisms. This reduces the time to identification of pathogens, informs subsequent antimicrobial susceptibility testing (including whether a pathogen produces an extended-spectrum β-lactamase or carbapenemase resulting in multidrug resistance in Gram-negative bacteria), and enables linkage of bacteria and patients in outbreaks. In the future, new technologies may be applied directly to blood samples, possibly replacing the current culturing process.

Specimens sent for microscopy or culture (**Box 42.11**) are described as follows:

- ***Blood*** is sent for bacterial culture in hospitalized patients if systemic infection is suspected, regardless of whether fever is present at the time of presentation. Additional blood cultures are taken if fever subsequently occurs. In patients with suspected endocarditis or cardiac device infection or other 'deep' foci of infection (e.g., psoas abscess, discitis), at least three sets of blood cultures are taken because bacteraemia may be intermittent. Whole-blood samples may also be useful for genome detection, usually by PCR, of a range of viruses present in the bloodstream.
- ***Urine*** is sent for microscopy and culture in patients with urinary tract symptoms, and also in patients unable to provide a clear history, when UTI or sepsis is suspected. Urine culture is not indicated in asymptomatic patients able to provide a clear history regardless of whether they are catheterized.
- ***Cerebrospinal fluid (CSF)*** (meningitis, encephalitis), ***sputum*** (e.g., pneumonia, TB), ***articular fluid*** (e.g., septic arthritis, prosthetic joint infection), ***pus*** (e.g., abscess), and ***biopsy*** (e.g., of a lymph node) specimens are sent for microscopy and culture when clinically indicated.
- ***Swabs*** of clean wounds, without pus or surrounding cellulitis, are avoided because of the risk of identifying colonizing bacteria and encouraging inappropriate antibiotic prescribing. Tissues, aspirates, and fluids are usually preferred to swabs. Vaginal swabs are useful, however, to identify *Candida* spp., *Trichomonas vaginalis*, and other bacterial causes of vaginitis; nucleic acid amplification techniques (NAATs; see next section) are more commonly used to screen for *Neisseria gonorrhoeae*, *Chlamydia* spp., and HSV.
- ***Special culture techniques or prolonged culture*** is required for *Mycobacteria* spp.; slow-growing bacteria, such as *Actinomyces* spp. and *Brucella* spp.; and sometimes fungi. The laboratory must be informed of patients with suspected unusual infections or infections caused by fastidious microbes.

Box 42.10 Key bacterial and fungal causes of bloodstream infections in the UK

Common bacterial causes of bloodstream infection	Potential sources (foci) of bloodstream infection
Gram-negative bacilli (rods)	
Escherichia coli and other coliforms	Urinary tract (most commonly) Biliary tract (common) Other intra-abdominal sources, e.g., diverticular abscess Healthcare-associated pneumonia; community-acquired pneumonia if *Klebsiella pneumoniae* Other HAIs Bone, joint, or spine Meningitis (especially neonates)
Pseudomonas spp.	HAIs, especially pneumonia and i.v. or urinary catheters (most common) Neutropenic mucositis Urinary tract Skin or soft tissue, wounds (less common) Bone, joint, spine (less common)
Bacteroides spp.	Intra-abdominal Wounds
Gram-positive cocci	
Staphylococcus aureus (MSSA and MRSA)	Skin or soft tissue, wounds Bone, joint, spine Endocarditis Intravenous drug use, including infected deep venous thrombosis and septic pulmonary emboli Vascular infections, including grafts i.v. and urinary catheters Other HAIs Abscesses, especially psoas, epidural, and pyomyositis Meningitis (rare)
Group A *(Streptococcus pyogenes)*, B, C, and G streptococci	Skin or soft tissue, wounds, necrotizing fasciitis Bone, joint, spine Genitourinary (especially group B streptococci) Neonatal sepsis or meningitis (group B streptococci) Tonsillitis
Viridans group streptococci (e.g., *Streptococcus mitis* and *mutans* groups)	Endocarditis Abscesses, especially liver and brain Bone, joint, spine (rare)
Streptococcus pneumoniae (pneumococcus)	Upper or lower respiratory tract Pneumonia Meningitis Endocarditis (rare)
Coagulase-negative staphylococci	Usually skin contamination but consider prosthesis or device infection if repeat multiple blood cultures are positive for same bacteria with same antibiotic susceptibilities
Enterococcus spp.	HAIs, especially i.v. and urinary catheters (common) Urinary tract Intra-abdominal Endocarditis
Gram-negative cocci	
Neisseria meningitidis (meningococcus)	Meningitis Bloodstream infection Others, including septic arthritis and pneumonia, are rare
Fungi	
Candida spp.	HAIs, especially i.v. catheters and other devices (common) Intra-abdominal (especially patients who have had abdominal surgery and prolonged hospital stay or are or have been in critical care) Urinary tract i.v. drug use Endocarditis

HAI, Healthcare-associated infection; *i.v.,* intravenous; *MRSA,* meticillin-resistant *Staphylococcus aureus*; *MSSA,* meticillin-susceptible *Staphylococcus aureus.*
Gram positive rods are rarely a cause of human disease, and when cultured often represent sample contaminants.

- ***Faecal culture*** should be reserved for cases of suspected bacterial gastroenteritis or dysentery, especially when there may be public health implications. Faecal culture for viruses is not helpful; antigen or nucleic acid detection techniques (see next section) are more appropriate, especially in the investigation of an outbreak of diarrhoea and vomiting (e.g., norovirus). Protozoa (e.g., amoebiasis, giardiasis) may be a cause of diarrhoea in returning travellers, immunocompromised patients, toddlers, males who have sex with males, farm workers, and in any case of prolonged unexplained diarrhoea. Antigen or PCR-based tests are useful adjuncts to traditional stool microscopy for ova, cysts, and parasites. Detection of a specific clostridial toxin is a more reliable test for *C. difficile* infection than culture.

Box 42.11 Specimens and indications for microscopy, culture, and other microbiological tests

Specimen	Investigation	Indication
Blood	Giemsa stain for malaria	Any symptomatic traveller returning from a malarious area
	Malaria rapid antigen detection test	
	Stains for other parasites	Specific tropical infections
	Culture	All suspected bacterial infections
	PCR (viruses)	Fever, blood-borne viruses, HIV
Urine	Microscopy and culture	All suspected bacterial infections
	TB culture	Suspected TB Unexplained leucocytes in urine
	NAAT	STIs
Faeces	Microscopy ± iodine stain	Suspected protozoal diarrhoea, helminth infection
	Culture	All unexplained diarrhoea
	PCR, antigen detection	Suspected viral diarrhoea in children
	Clostridioides difficile toxin	Diarrhoea after hospital stay or antibiotic treatment
Throat swabs	Culture	Suspected bacterial tonsillitis and pharyngitis
	PCR, antigen detection	Viral respiratory infections
Sputum	Culture	Pneumonia, respiratory tract infections
	Auramine stain, TB culture (liquid culture; see Chapter 20, 'Tuberculosis' section)	Suspected TB
	Other special stains, cultures	Immunocompromised patients Suspected fungal infections
Cerebrospinal fluid	Microscopy and culture	Suspected meningitis
	Auramine stain, TB culture	Suspected TB, meningitis
	Other special stains, cultures	Immunocompromised patients Suspected fungal infections
	PCR	Suspected encephalitis or viral or bacterial meningitis
Rash aspirate		
Petechial	Microscopy and culture	Meningococcal disease
Vesicular	PCR, antigen detection, viral culture	Herpes simplex, zoster

HIV, Human immunodeficiency virus; *NAAT,* nuclear acid amplification test; *PCR,* polymerase chain reaction; *STI,* sexually transmitted infection; *TB,* tuberculosis.

Nucleic acid detection

Specific genes from many pathogenic microorganisms have been cloned and sequenced. Nucleic acid probes can be designed to detect these sequences, identifying pathogen-specific nucleic acid in body fluids or tissue. The use of NAATs, such as PCR, has increased the power of these tests to detect very small quantities of microbial material. Such techniques not only are exquisitely sensitive but also enable quantitation (e.g., viral load testing in HIV, HBV, and HCV) and subspeciation (e.g., at the genotype level). NAAT tests can be multiplexed (i.e., designed to detect a range of different pathogens in the same reaction mixture). Such assays have been widely used for viral infections (e.g., a respiratory panel may contain primers and probes able to detect up to 20 different viruses), but increasingly, PCR-based bacterial identification is also used in clinical practice. This allows 'screening' of clinical samples from sterile sites for a wider range of organisms, but because of the risk of detecting contaminating, colonizing, or multiple bacteria, results must be interpreted carefully in the context of clinical findings.

Immunodiagnostic tests

These can be divided into two types:

- Tests that detect ***microbial components*** (antigens) using a polyvalent antiserum or a monoclonal antibody (e.g., hepatitis B surface antigen, galactomannan in *Aspergillus* spp. infections)
- Tests that detect an ***immune response*** to infection (serological tests for antibodies and lymphocyte stimulation assays such as interferon-gamma (IFN-γ) release assays in TB for cellular immunity).

These investigations are valuable in the identification of organisms that are difficult to culture, especially viruses, atypical bacteria, and fungi, and they can also be helpful when antibiotics have been administered before samples were obtained. Elevated antibody titres on a single occasion (especially of immunoglobulin G (IgG) are rarely diagnostic, and it may be difficult to distinguish between past and acute infection. Specific assays for pathogen-specific IgM antibodies are useful for diagnosing an acute infection but may be poorly specific (e.g., for *Mycoplasma pneumoniae*). Paired serological tests taken a few weeks apart to observe IgG seroconversion are useful retrospectively to confirm the diagnosis but rarely change the acute management of the patient. Avidity testing may also enable recent infection (low-avidity antibodies) and historical infection (high-avidity antibodies) to be distinguished. Numerous serological tests are available; they should be used only in light of the clinical presentation and exposure and risk history.

Management of infectious diseases

Multidisciplinary infection care

It has increasingly been recognized that complex infectious diseases cannot be managed singlehandedly by a lone specialist clinician regardless of experience. Many infections require multidisciplinary teams (MDTs) to provide optimal care and clinical outcomes. A good example is that of orthopaedic infections. These require the expertise of multiple doctors (e.g., orthopaedic surgeons, plastic surgeons, infection doctors, and radiologists), nurses (e.g., specialist OPAT staff), pharmacists, and professionals allied to medicine (e.g., physiotherapists). Care plans are discussed at MDT meetings or clinics, which all attend. Skills and technologies developed during the COVID pandemic have led to many MDT meetings now being held online. There are many other infections and situations for which the MDT approach is necessary, such as HIV infection, TB, hepatitis, diabetic foot infection, OPAT, infection prevention and control, and antimicrobial stewardship. A weekly multidisciplinary infection meeting to discuss outpatients or inpatients with complicated infections, when decisions taken are recorded, is a standard of good departmental practice for adequately resourced infectious disease departments.

Shared decision-making

Infection practice is often 'grey'. Patients frequently present with non-specific histories and examination findings, and tests are often not diagnostic. The degree of investigation and intervention is determined by the severity or seriousness of the clinical presentation. A clear diagnosis is not always possible, and it is therefore important to use a shared decision-making approach to avoid tests, treatments, and procedures that are unlikely to be of benefit. Discussing the following four questions with patients may be useful in determining appropriate investigation and management strategies:

- What are the benefits?
- What are the risks?
- What are the alternatives?
- What if I do nothing?

Confidentiality

Many infections (e.g., hepatitis, HIV, TB) continue to be associated with social stigma. It is important to maintain patient confidentiality about the diagnosis at all times. Case notes should not be left lying around, and electronic patient records should not be visible in public areas. The patient's permission is always sought before discussion with spouses, partners, relatives, or friends. Communication with their primary care physicians is always encouraged to facilitate high-quality integrated care. Confidentiality is broken only when there is an overwhelming individual or public health risk, although multidisciplinary discussion and legal advice are usually sought beforehand.

Re-evaluation

Patients with sepsis and other serious infections need to be evaluated regularly, sometimes several times a day. Whether as an outpatient or inpatient, those who remain symptomatic without a clear diagnosis are re-evaluated by retaking the history and performing repeat examinations and appropriate investigations using a shared decision-making approach. If the patient's clinical condition deteriorates or does not respond to therapy or if adverse effects occur on intervention, careful re-evaluation is essential. Such patients are discussed at the hospital's multidisciplinary infection meeting.

EPIDEMIOLOGY AND PREVENTION OF INFECTIONS

Infectious diseases continue to be major causes of morbidity and mortality in humans, particularly in low- and middle-income countries (LMICs), where they are associated with poverty, overcrowding, and poor healthcare access. In high-income countries (HICs), increasing prosperity and hygiene (most important) along with high immunization coverage and prompt antimicrobial treatment have reduced the burden of infectious disease. However, antimicrobial-resistant and some difficult-to-treat microorganisms are increasingly prevalent in all settings, and diseases such as HIV infection, TB, malaria, and Gram-negative bacterial sepsis remain problematic. Major respiratory viral pathogens such as influenza, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), and measles, as well as arthropod-borne viruses such as Zika and Chikungunya and highly pathogenic zoonoses such as Ebola have demonstrated significant potential for severe epidemic spread. Highly pathogenic avian influenza is top of the international watch list for transforming into a disease that could transmit to and between humans with devastating consequences.

Increased population mobility

The phenomenon of ever-increasing global mobility, whether driven by war, civil unrest, climate change, habitat disruption, or tourism, has aided the spread of infectious diseases and allowed previously localized pathogens to establish themselves across much wider territories (e.g., New Delhi metallo-β-lactamase–producing Gram-negative bacteria). Greater movement of livestock and animals, and encroachment of humans into new ecosystems has enabled the spread of zoonotic diseases. Additionally, changes in farming and food processing methods have contributed to an increase in the incidence of food- and water-borne disease. Deteriorating social conditions in major cities have facilitated the resurgence of TB and other infections. Refugee camps, where large numbers of people are forced to live in close proximity, also continue to provide breeding grounds for devastating epidemics such as diphtheria and cholera. There are ongoing concerns about the deliberate release of infectious agents, such as anthrax, by terrorist groups or national governments.

Changing patterns of disease

In LMICs, there have been notable successes such as:

- The eradication of smallpox and near eradication of polio and Guinea worm infection (dracunculiasis)
- Reductions in the incidence of HIV infection
- Reductions in the mortality rates of TB and malaria, as well as in many of the 'neglected tropical diseases'.

These have been balanced or outweighed by new problems to the extent that communicable diseases were still responsible for nearly half of all deaths in low-income countries (LICs) in 2019. Although the leading causes of death globally are increasingly non-communicable diseases, in LICs, malaria (sixth), TB (eighth), and HIV (ninth), as well as lower respiratory tract infections (LRTIs) and diarrhoeal diseases feature prominently (**Box 42.12**).

- The COVID-19 pandemic stalled progress in reducing TB incidence, with 10.6 million new cases and 1.6 million deaths in 2021. About 450 000 people developed multidrug resistant disease.
- Progress in reducing malaria also stalled during the pandemic, with an estimated 234 million cases in 2021, 95% in the Africa region. There were more than 600 000 deaths, 75% being in children younger than 5 years of age. Resistance to the key antimalarial (artemisinins) is rising with associated treatment failure in >10% cases.
- Some 360 million people were estimated to be living with hepatitis B or C in 2019, although the incidence of hepatitis B in those younger than 5 years old has decreased from 4.7% in the pre-vaccine era to less than 1% in 2022.
- In 2022, approximately 630 000 people still died of HIV-related disease (compared with 1.9 million in 2005) despite the

Box 42.12 Leading causes of mortality worldwide, 2019

Cause of death	Mortality	
	Millions (annual)	Crude mortality (/100 000)
Ischaemic heart disease	8.9	126
Stroke	6.2	77
Chronic obstructive pulmonary disease	3.2	41
Lower respiratory infections	2.6	40
Neonatal conditions	2.0	
Trachea, bronchus and lung cancers	1.8	
Alzheimer's disease and other dementias	1.6	27
Diarrhoeal diseases	1.5	
Diabetes mellitus	1.5	21
Kidney diseases	1.3	19
Liver cirrhosis	1.3	17
Road injury	1.3	
Tuberculosis	1.2	

Data from World Health Organization, http://ww.who.int.

availability of effective therapy; globally, only 76% living with HIV receive anti-retroviral therapy. The global incidence of HIV has fallen, however, from 0.4 per 1000 uninfected population in 2005 to 0.17 per 1000 uninfected population in 2022 but remains high in Africa (0.57 per 1000 population).

- Neglected tropical diseases, such as filariasis, onchocerciasis, and trachoma remain problematic, with 1.65 billion persons requiring mass or individual treatment in 2021, of whom 80% were in 16 LICs.

Factors limiting control of infectious diseases in low- and middle-income countries

Most infectious diseases affecting LMICs are preventable or treatable, but they continue to thrive because of a lack of resources and political commitment and disruption by conflict. The surveillance of infectious diseases has often been poor in many regions, resulting in a slow response to emerging problems. Distrust of immunization programmes in conflict zones (especially Pakistan and Afghanistan) has been key in delaying the eradication of polio. It seems likely that the ongoing emergence of highly drug-resistant Gram-negative bacterial infections will affect poor and vulnerable populations disproportionately. The impact of global warming on the spread and incidence of infections remains uncertain, but it is clearly driving transmission of infectious diseases through direct influence on the spread of insect vectors and by population movement and migration in response to climate change.

Goals in international development

The World Health Organization (WHO) has established a portfolio of targets to combat disease burden (see Chapter 10). The 17 Sustainable Development Goals (SDGs) include SDG 3, which is 'to ensure healthy lives and promote wellbeing for all at all ages', with the specific commitment to 'end the epidemics of AIDS [acquired immunodeficiency syndrome], tuberculosis, malaria and neglected tropical diseases, and combat hepatitis, waterborne diseases and other communicable diseases by 2030'. Although a lot has been achieved by public–private partnerships and other charitable funders, including major technological breakthroughs in terms of antimicrobial developments and new vaccinations, as well as improved reporting systems, it is clear that there is still much to be done.

Acquisition of infection

Many infections are acquired from other people, who may be symptomatic or asymptomatic carriers. Some bacteria, like the meningococcus, are common transient commensals but cause invasive disease in a small minority of those colonized, sometimes after other infections such as influenza. Infections with organisms such as HIV and hepatitis B viruses (HBVs) are followed in most cases by a carrier state that has potential to transmit while the patient is asymptomatic, and *M. tuberculosis* infection can become transmissible after reactivation after even prolonged periods of asymptomatic 'latent' infection.

Zoonoses are infections that can be transmitted from wild or domestic animals to humans. Infection can be acquired in a number of ways:

- Direct contact with the animal
- Ingestion of meat or animal products
- Contact with animal urine or faeces, including aerosol inhalation
- Via an arthropod vector
- By inoculation of saliva in a bite wound.

Many zoonoses can also be transmitted from person to person. Some zoonoses are listed in **Box 42.13**.

Most microorganisms do not have a vertebrate or arthropod host but are free living in the environment. The vast majority of these environmental organisms are non-pathogenic, but some can cause human disease (**Box 42.14**). Person-to-person transmission of these infections is rare. Some parasites may have a stage of their life cycle that is environmental (e.g., the free-living larval stage of *Strongyloides stercoralis* and the hookworms) even though the adult worm requires a vertebrate host. Other pathogens can survive for periods in water or soil and are transmitted from host to host via this route (see later).

Routes of transmission

Endogenous infection

The body's own endogenous flora (often called the ***microbiome***) can cause infection if the organism gains access to a usually sterile site. Non-specific host defences are breached, for example, by cutting or scratching the skin and allowing surface commensals to gain access to deeper tissues; this is the aetiology of staphylococcal wound infections and folliculitis. Similarly, cystitis and ascending UTI occur when colonic bacteria enter the female urinary tract through the urethra. There may be more serious defects in host immunity owing to disease or chemotherapy, allowing normally harmless skin and bowel flora ('opportunist infections') to produce invasive disease.

Air-borne spread

Many respiratory tract pathogens are spread from person to person by aerosol or droplet transmission. Secretions containing the infectious agent are coughed, sneezed, or breathed out and are then inhaled by a new host. Some enteric viral infections may also be spread by aerosols of faeces or vomit. Environmental pathogens, such as *Legionella pneumophila*, and zoonoses such as histoplasmosis are also acquired by aerosol inhalation.

Box 42.13 Zoonotic infections

Disease	Pathogen	Animal reservoir	Mode of transmission
Prions			
vCJD	Prion protein	Cattle	Ingestion (CNS tissue)
Viruses			
Lassa fever	Arenavirus	Multimammate rats	Direct contact
Avian influenza	Influenza H5N1	Birds	Inhalation
Japanese encephalitis	Flavivirus	Pigs	Mosquito bite
Rabies	Rhabdovirus	Dogs and other mammals	Saliva, faeces (bats)
Yellow fever	Flavivirus	Primates	Mosquito bite
Mpox	Orthopox virus	Rodents, small mammals	Uncertain
SARS	Coronavirus	Unsure, most likely bats	Droplet
MERS	Coronavirus	Camels	Droplet
SARS-CoV-2	Coronavirus	Unsure, most likely bats	Droplet
Bacteria			
Gastroenteritis	*Escherichia coli* *Salmonella enteritidis* and others *Campylobacter jejuni*	Cattle, chickens Chickens, cattle Various, e.g., chickens	Ingestion (contaminated food) Ingestion (meat, eggs) Ingestion (meat, milk, water)
Leptospirosis	*Leptospira interrogans*	Rodents	Ingestion (urine)
Brucellosis	*Brucella abortus* *Brucella melitensis*	Cattle Sheep, goats	Contact; ingestion of milk or cheese
Anthrax	*Bacillus anthracis*	Cattle, sheep	Contact; ingestion
Lyme disease	*Borrelia burgdorferi*	Deer	Tick bite
Cat-scratch disease	*Bartonella henselae*	Cats	Flea bite
Plague	*Yersinia pestis*	Rodents	Flea bite
Typhus	Various *Rickettsia* spp.	Various	Arthropod bite
Ornithosis (psittacosis)	*Chlamydia psittaci*	Psittacine and other birds	Aerosol
Others			
Toxoplasmosis	*Toxoplasma gondii*	Cats and other mammals	Ingestion (meat, faeces)
Hydatid disease	*Echinococcus granulosus*	Dogs	Ingestion (faeces)
Trichinosis	*Trichinella spiralis*	Pigs, bears	Ingestion (meat)
Toxocariasis	*Toxocara canis*	Dogs	Ingestion
Cutaneous larva migrans	*Ancylostoma caninum*	Dogs	Penetration of skin by larvae
Leishmaniasis	*Leishmania* spp.	Dogs	Ingestion

CNS, Central nervous system; *SARS-CoV-2,* severe acute respiratory syndrome coronavirus 2; *vCJD,* variant Creutzfeldt–Jakob disease.

Faecal–oral spread

Transmission of organisms by the faecal–oral route occurs by direct transfer, by contamination of clothing or household items or, most commonly, via contaminated food or water. Human and animal faecal pathogens enter the food supply at any stage. Raw sewage is used as fertilizer in many parts of the world, contaminating growing vegetables and fruit. Poor personal hygiene can result in contamination during production, packaging, preparation, or serving of food. In HICs, centralization of the food supply and increased processing of food have allowed the potential for relatively minor episodes of contamination to cause widely disseminated outbreaks of infection, such as *Salmonella* from the egg industry and *Listeria* from refrigerated sandwiches and other prepared foods.

Water-borne faecal–oral spread is usually the result of inadequate access to clean water and safe sewage disposal and is common throughout the developing world. Worldwide, 74% of the global population have access to safely managed drinking water, but only 54% have access to safe sanitation. There are major regional differences with 80% those without safe drinking water living in rural areas.

Vector-borne disease

Many tropical infections, including malaria, are spread from person to person or from animal to person by an arthropod vector. Vector-borne diseases are also found in temperate climates but are relatively uncommon, although some are becoming more prevalent because of climate change, most notably tick- and mosquito-borne pathogens in Europe. In most cases, part of the life cycle takes place within the body of the arthropod and each species requires a specific vector. Some vector-borne diseases are shown in **Box 42.15**.

Direct person-to-person spread

Organisms can be passed on directly in a number of ways. STIs are dealt with in Chapter 42. Skin infections such as PVL toxin-expressing *S. aureus* folliculitis, mpox among males who have sex with males, and ectoparasites such as scabies and head lice, can be spread by simple skin-to-skin contact. Other organisms are passed on by transmission from blood (or, occasionally, some other body fluid) to blood. Blood-to-blood transmission can occur during sexual contact; from mother to infant, either transplacentally or in the peripartum period; between intravenous drug users sharing any

Box 42.14 Environmental organisms that can cause human infection

Organism	Disease (most common presentations)
Bacteria	
Burkholderia pseudomallei	Melioidosis
Burkholderia cepacia	Lung infection in cystic fibrosis
Pseudomonas spp.	Various
Legionella pneumophila	Legionnaires' disease (pneumonia)
Bacillus cereus	Gastroenteritis
Listeria monocytogenes	Various
Clostridium tetani	Tetanus
Clostridium perfringens	Gangrene, septicaemia
Non-tuberculous mycobacteria	Pulmonary infections
Fungi	
Candida spp.	Local and disseminated infection
Cryptococcus neoformans	Meningitis, pulmonary infection
Histoplasma capsulatum	Pulmonary infection
Coccidioides immitis	Pulmonary infection
Mucor spp.	Mucormycosis (rhinocerebral, cutaneous)
Sporothrix schenckii	Lymphocutaneous sporotrichosis
Blastomyces dermatitidis	Pulmonary infections
Aspergillus fumigatus	Pulmonary infections

part of their injecting equipment; when infected medical or other (e.g., tattoo needles) equipment is reused; if contaminated blood or blood products are transfused; and in any sporting or accidental contact when blood is spilled. Ingestion of infected breast milk is another route of person-to-person spread for some infections (e.g., HIV).

Indirect person-to-person spread

Many organisms can be spread from person to person indirectly by contamination by fomites (e.g., on door handles), which are subsequently touched by another person. Common examples include respiratory viruses, such as influenza, and healthcare-associated pathogens, such as MRSA and the spores of *C. difficile*. This is sometimes an overlooked route of transmission; minimization requires, for example, hand-washing immediately after sneezing or coughing and when moving from ward to ward in a hospital, and optimal cleaning regimens in institutions.

Direct inoculation

Infection can occur when organisms breach the normal mechanical defences by direct inoculation from the environment (e.g., contamination of bone after an open fracture, leading to subsequent osteomyelitis, or as seen in tetanus and certain fungal and mycobacterial infections). Some of the circumstances in which this can occur are covered under endogenous infection and blood-to-blood transmission, described earlier. Rabies virus is inoculated by the bite of an infected animal.

Consumption of infected material

Although many food-related zoonotic infections are caused by contamination of food with animal faeces (and are thus spread by the faecal–oral route), several diseases are transmitted directly in animal products. These include *Listeria* (from soft cheeses and pates among other foods), some strains of *Salmonella* (eggs, chicken meat), brucellosis (unpasteurized milk), *E. coli*, and the prion diseases kuru and variant Creutzfeldt–Jakob disease (CJD; ingested neural tissue).

Box 42.15 Infections transmitted by arthropod vectors

Vector	Disease	Microorganism
Mosquito	Malaria	*Plasmodium* spp.
	Lymphatic filariasis	*Wuchereria bancrofti*, *Brugia malayi*
	Yellow fever	Flavivirus
	West Nile fever	Flavivirus
	Dengue	Flavivirus
	Zika	Flavivirus
Sandfly	Leishmaniasis	*Leishmania* spp.
	Bartonellosis	*Bartonella bacilliformis*
Blackfly	Onchocerciasis	*Onchocerca volvulus*
Tsetse fly	Sleeping sickness	*Trypanosoma brucei*
Flea	Plague	*Yersinia pestis*
	Endemic typhus	*Rickettsia typhi*
Reduviid bug	Chagas' disease	*Trypanosoma cruzi*
Louse	Epidemic typhus	*Rickettsia prowazekii*
	Louse-borne relapsing fever	*Borrelia recurrentis*
Hard tick	Lyme disease	*Borrelia burgdorferi*
	Typhus (spotted fever group)	*Rickettsia* spp.
	Babesiosis	*Babesia* spp.
	Tick-borne relapsing fever	*Borrelia duttonii*
	Tick-borne encephalitis	Flavivirus
	Congo–Crimean haemorrhagic fever	*Orthonairovirus* (Nairoviridae)
Trombiculid mite	Scrub typhus	*Orientia tsutsugamushi*

Classification of outbreaks

The type of outbreak has a bearing on the public health measures that need to be instituted for its control.

- ***Person-to-person*** is when infection is passed from one infected individual to another and outbreaks of infection are separated by the incubation period. Control measures may include hand and personal hygiene (a sensible early control measure in any outbreak), immunization (e.g., influenza, measles), and antimicrobial agents (e.g., anti-retroviral therapy).
- ***Point source*** is when there is a single source of infection (e.g., food eaten at a social function). All those infected develop symptoms at the same time, around the expected incubation period. If the point source is temporary or removed and there is no person-to-person or other mode of transmission, new cases decline after the incubation period.
- ***Common source*** is when there is a single source of infection but infections are spread over a period of time (e.g., a contaminated food preparation facility or restaurant). Many people may be exposed over a potentially long period of time. Recent large-scale epidemics of enteric fever in sub-Saharan Africa have been

associated with street-vended beverages from contaminated water supplies, and other outbreaks (most famously 'Typhoid Mary') have been associated with transmission from asymptomatic carriers via food preparation. After the source is identified, control measures may include cleaning and disinfecting the facility, closing the facility or restaurant, testing and excluding asymptomatic carriers from the workforce, recalling food, and informing the public on how to make food safe (e.g., by cooking it) or to avoid or throw food away.

- An ***epidemic*** is when there is an increased and unusually widespread infection in the community, causing waves of infection. Epidemics spread through communities and may affect those who have no active immunity to the infection.
- A ***pandemic*** is an epidemic, as defined earlier, occurring worldwide or over a very wide geographical area and crossing international boundaries, usually affecting a large number of people.

Some infectious diseases should be notified to the public health authorities so that they are aware of cases and outbreaks and can respond accordingly. Diseases that are notifiable in England and Wales are listed in **Box 42.16** (see also Further reading for the *List of Notifiable Organisms [Causative Agents]* in the UK).

The prevention of and response to epidemics and pandemics are complex and depend on the underlying cause but are multifactorial in approach and may include:

- Routine and enhanced disease surveillance
- Identification and tracing of contacts, including use of rapid diagnostics, through epidemiological investigation increasingly informed by pathogen genome sequencing
- Public awareness campaigns (e.g., focused on hand and personal hygiene or other control measures; to provide reassurance)
- Enhanced infection prevention and control procedures, including wearing of face masks, personal distancing, and prevention of mass gatherings
- Isolation or cohort nursing in healthcare facilities admitting patients and other institutions (e.g., nursing homes)
- Use of mass antimicrobials (e.g., antiviral agents in influenza epidemics or the universal test and treat approach to HIV prevention) and immunization as appropriate and available.

Efficient coordination of such responses by local, regional, national (e.g., UK Health Security Agency), or international organizations (e.g., WHO) is essential. The SARS-CoV-2 pandemic in 2020 is a good example of how a slow initial response can lead to grave consequences.

Infection prevention and control

Relatively few patients with infections present a serious risk to healthcare workers and other contacts or patients. However, the potential remains for unexpected outbreaks of life-threatening or almost untreatable infections, including within healthcare settings, associated with the appearance of diseases such as SARS-CoV-2 infection or strains of influenza with high mortality, occasional cases of Lassa fever or Ebola, bioterrorist use of microbes, and the emergence of extensively drug-resistant bacterial infections (e.g., TB, *Mycobacterium abscessus* and Gram-negative bacteria, especially

i Box 42.16 Notifiable diseases in England and Wales[a]

[a]Diseases are notifiable to Local Authority Proper Officers under the Health Protection (Notification) Regulations 2010. Report other diseases that may present significant risk to human health under the category 'other significant disease'.

SARS-CoV-2, Severe acute respiratory syndrome coronavirus 2.

carbapenemase-producing or carbapenemase-resistant *E. coli* and *K. pneumoniae*).

During the worldwide outbreak of SARS in 2003, scrupulous infection control procedures reduced the spread of infection. However, in the 'inter-epidemic' period, it is difficult to maintain a high level of alert, and indeed, many countries were not properly prepared for the SARS-CoV-2 pandemic of 2020. Healthcare workers should remain vigilant because the early symptoms of many of these diseases are non-specific. Methods of preventing infection depend on the source and route of transmission.

Healthcare-associated infections

The burden of morbidity, mortality, and costs attributed to healthcare-associated infection (HAI) has been highlighted in many HICs. Although data from LMICs are sparse, the impact of HAI is likely to be even greater. *C. difficile*, *S. aureus* (especially MRSA), vancomycin-resistant enterococci, and the increasingly difficult-to-treat multi- and extensively drug-resistant Gram-negative infections are all strongly associated with healthcare contact and remain a problem in hospitals worldwide. In 2016, the proportion of inpatients with HAIs in acute hospitals in England was 6.4%. The most frequent HAIs affect the respiratory and urinary tracts, as well as surgical sites. There has been a notable decline, however, in the incidences of and death caused by MRSA bloodstream and *C. difficile* infections in the UK. This has been attributed to higher standards of basic infection prevention and control, including rapid isolation of patients, hospital 'deep cleaning', universal MRSA screening (and decolonization therapy, if positive) on entry to acute hospitals and before surgery, and improved care of intravenous access devices.

Healthcare-associated infection prevention and control measures

Poor infection control practice in hospitals and other healthcare environments can cause the transfer of infection from person to person. Healthcare workers are strongly encouraged to wash or clean their hands before and after patient contact; whenever necessary, they should wear gloves, aprons, and other protective equipment. This is particularly important when they are performing invasive procedures, dealing with infected wounds, and manipulating indwelling devices. Additional control measures are recommended for contact with patients known to be colonized or infected with a resistant organism (e.g., carbapenemase-producing *K. pneumoniae*), those infected by communicable pathogens with high mortality (e.g., Lassa or Ebola, for which high-security isolation and extreme care are mandatory), and those with diarrhoea (e.g., *C. difficile* infection).

Interventions that health workers should focus on to prevent and control HAIs are listed next.

Care bundle approach

This is a set of three to five simple, evidence-based actions that healthcare professionals should always implement in certain clinical situations to minimize the risk of infection. For example, care bundles have been developed for the insertion and ongoing care of urinary catheters, insertion and use of central lines (to prevent central line-associated bloodstream infections [**Box 42.17**]), and to prevent ventilator-associated pneumonia or surgical site infections.

Hand hygiene

The WHO's 'Five Moments for Hand Hygiene' (see Further reading) are applied before and after all patient contacts, including before and after aseptic procedures and after contact with body fluids and the patient environment. Soap and water (rather than an alcohol-based rub) should be used after visible contamination of hands and when patients are vomiting or have diarrhoea even if gloves are used. In low-income settings, in the absence of soap and water, alcohol-based hand rub should be used if available.

Box 42.17 Central line–associated bloodstream infection care bundles

Central line insertion bundle

Hand hygiene

Wash hands or use an alcohol-based, waterless hand cleaner when caring for central lines:

- Before and after palpating the catheter insertion site
- Before and after inserting, replacing, adjusting, or dressing the site
- During palpation of the insertion site and after application of antiseptic and only if full asepsis is maintained.

Complete maximal barrier

- The operator inserting the central venous catheter should adhere to strict aseptic techniques and wear sterile gloves, a gown, a surgical cap. and a surgical mask.

Chlorhexidine 2% skin antisepsis

Prepare skin with 2% chlorhexidine in 70% alcohol using swabs and a friction scrub for at least 30 seconds. Do not wipe or blow dry and allow to dry completely before skin puncture:

- 30 seconds for a dry site
- 2 minutes for a moist site (especially femoral)

Optimal catheter site selection

- In adult patients, there is some evidence that the subclavian site has a lower risk of catheter-related bloodstream infections. However, there is usually more experience with the internal jugular site. The subclavian and internal jugulars are the preferred sites for infection-control purposes.
- Use sterile, single-use jelly
- Use sterile, single-use jelly for ultrasound-guided insertions

Central line maintenance bundle

Practice hand hygiene at five moments:

- Before touching a patient
- Before clean or aseptic procedures
- After body-fluid exposure or risk
- After touching a patient
- After touching patient surroundings

Aseptic technique for accessing and changing needleless connectors

- Scrub the access port or hub immediately before each use with an appropriate antiseptic.

Standardised tubing change

- Intravenous medication administration tubing should be changed as per the recommendation in the local organisations policy.

Daily review of catheter necessity

- Daily review of line necessity during rounds so the necessity of the lines can be determined and unnecessary lines removed.

Personal protective equipment

Gloves should be worn for all invasive procedures, including venesection, and contact with sterile sites, mucous membranes, bodily fluids, or non-intact skin. Disposable plastic aprons should be used when there is a risk of contamination of clothing or skin; if there is a risk of extensive contamination, surgical gowns should be worn and, in some situations, plastic visors should be worn. Respiratory protection should be worn for patients with respiratory-spread pathogens, such as measles, influenza, SARS-CoV-2, and TB.

Urinary catheters

These should be inserted only when it is essential to do so and then removed as soon as possible; they must be inserted using an aseptic technique. A clear care plan should be in place for longer-term

catheters. Overuse or poor care of urinary catheters increases the risk of *E. coli* bloodstream infection, a current target for HAI reduction in the UK.

Vascular access devices

A vascular catheter should only be inserted when there is a clear plan to use it, it is checked daily, and it is removed as soon as possible. Two percent chlorhexidine gluconate in 70% isopropyl alcohol is used for skin decontamination before insertion and to clean the access port or hub before use. A clear care plan should be instituted for medium- or long-term devices.

Adequate hydration

Dehydrated patients are at higher risk of UTIs. Oral hydration is preferred to intravenous hydration if possible (there is a lower risk of infection than with an intravenous device), and patients should be encouraged to drink an adequate quantity of fluids.

Communication

This is essential when transferring patients with transmissible infections (e.g., chickenpox, SARS-CoV-2, and infections caused by multi- and extensively drug-resistant bacteria) between admission areas, wards, hospitals, and institutions, including residential and nursing homes, so that appropriate infection control measures can be put in place for patients with known infections.

Isolation

The appropriateness of isolation, if available, should be considered. Infections with a high risk to public health (e.g., Lassa and Middle East respiratory syndrome [MERS]) are isolated within high-security, hospital-based, negative-pressure isolation facilities using enhanced respiratory, personal protective equipment (PPE), and decontamination procedures. In the UK, there are a small number of sites for the management of confirmed high-consequence infections transmitted by air-borne or contact spread, but many hospitals (particularly those with specialist infectious disease units) have facilities to manage patients who are being tested for these infections or to act as surge centres in the event of a large epidemic. Patients hospitalized with highly infectious respiratory-spread pathogens, such as chickenpox and measles, are isolated in negative-pressure isolation facilities. Patients with pathogens spread by direct or indirect person-to-person contact (colonization or infection), such as *C. difficile* and multidrug-resistant Gram-negative bacteria, are, ideally, housed in side-rooms with *en suite* toileting facilities and appropriate contact precautions (hand hygiene and PPE). If such facilities are limited, then basic precautions (hand hygiene, PPE) are still applied, and cohort isolation is considered (i.e., patients with the same microbiologically confirmed infection are housed on the same ward).

Other infection prevention and control measures (non–hospital-acquired infections)

Although effective antimicrobial chemotherapy is available for many diseases, the ultimate aim of any infectious disease control programme is to prevent infection occurring. This is achieved either by eliminating the source or mode of transmission of an infection *or* reducing host susceptibility to environmental pathogens.

Eradication of reservoir

In a few diseases for which humans are the only natural reservoir of infection, it may be possible to eliminate disease by an intensive programme of case finding, isolation, treatment, and immunization (as in the case of smallpox). If there is an animal or environmental reservoir, complete eradication is unlikely, but local control methods may decrease the risk of human infection (e.g., killing of rodents to control plague, management of poultry and other birds to prevent avian influenza).

For arthropod- or vector-borne infections

It may be possible to destroy the vector species or to take measures to avoid being bitten (e.g., insect repellent sprays, insecticide-impregnated bed nets, indoor residual spraying). Release of genetically modified sterile mosquitoes has potential to reduce transmission of dengue and malaria.

For food-borne infections

Improvements in food handling and preparation result in less contamination during processing, transport, or preparation. Organisms that are intrinsically present in food can be killed by appropriate preparation and cooking. Improved surveillance and regulation of the food industry, as well as better health education for the public, reduce risk.

For faecal–oral infections

Improvements in water supply and sanitation (following Water, Sanitation & Hygiene [WASH] strategies; see Further reading) may dramatically decrease the prevalence of faecal-oral infections.

For blood-borne infections

Blood transfer may be prevented by optimal use of medical equipment. Donated blood is routinely tested for infection in most HICs.

For infections spread by air-borne and direct contact

Some air-borne respiratory infections and some infections spread by direct contact can be controlled by isolating patients, although this is often difficult. Positive-pressure isolation (in which the flow of air is from the patient's room or ventilated lobby into the ward) is useful in uninfected patients with severe immunodeficiency to protect them from infection. Neuraminidase inhibitors may reduce the transmission of influenza viruses to at-risk persons.

Immunization, immunoprophylaxis, and immunotherapy

Immunization has changed the course and natural history of many infectious diseases. Passive immunization by administering preformed antibody, in the form of either immune serum or purified normal immunoglobulin, provides short-term immunity and has been effective in both the prevention (immunoprophylaxis) and the treatment (immunotherapy) of patients with a number of bacterial and viral diseases (**Box 42.18**).

The active childhood immunization schedule currently recommended by the WHO is summarized in **Box 42.19**. Long-lasting immunity is achieved by active immunization with a live attenuated or an inactivated organism, a subunit of an infectious agent, or sometimes a microbial toxin (either native or modified), that is, a toxoid (**Box 42.20**). Immunization should be kept up to date, with booster doses being given throughout life according to the vaccines booster schedule. Travellers to LMICs, especially if visiting rural areas for prolonged periods, may warrant specific immunizations (with yellow fever vaccination being mandatory for entry to some countries).

In 1974, the WHO introduced the Expanded Programme on Immunization (EPI). By 1994, more than 80% of the world's children had been immunized against TB, diphtheria, tetanus, pertussis, poliomyelitis, and measles. It is hoped that poliomyelitis will be eradicated worldwide in the near future, matching the past success of global smallpox eradication. The rapid development and testing of novel vaccines against SARS-CoV-2 saved millions of lives during the pandemic. Introduction of conjugate vaccines against

Box 42.18 Examples of passive immunization available

Infection	Antibody	Indication
Bacterial		
Tetanus	Human tetanus immune globulin	Prevention and treatment
Diphtheria	Horse serum	Prevention and treatment
Botulism	Horse serum	Treatment
Clostridioides difficile diarrhoea	Bezlotoxumab	Prevention of recurrent infection
Viral		
Hepatitis A Measles	Human normal immune globulin	Prevention (rarely required since vaccine introduced)
Hepatitis B	Human hepatitis B immune globulin	Prevention
Rabies	Human rabies immunoglobulin	Prevention
Varicella zoster	Human varicella zoster immune globulin	Prevention
SARS-CoV-2	Human neutralizing monoclonal antibody (e.g., sotrovimab)	Treatment

Box 42.19 Recommended childhood immunization schedules[a]

Time of immunization	Vaccine
As soon as possible after birth	BCG + HBV
6 weeks old	DPT + PV + HBV + Hib + PCV + rotavirus
10 weeks old	DPT + PV + HBV + Hib + PCV + rotavirus
14 weeks old	DPT + PV + Hib + PCV + rotavirus
9 or 12 months old	Measles (second dose at a minimum of 4 weeks later) + rubella
As soon as possible after 9 years old	HPV (two doses at least 6 months apart)

[a]WHO vaccination schedule for all children; different schedules or additional vaccines are recommended in some locations: https://www.who.int/immunization/policy/Immunization_routine_table2.pdf?ua=1. Mumps vaccine is also given in many low- and middle-income countries.
BCG, Bacille Calmette–Guérin; *DPT,* diphtheria, pertussis, tetanus triple vaccine; *HBV,* hepatitis B vaccine; *Hib, Haemophilus influenzae* type b; *HPV,* human papillomavirus vaccine; *PCV,* pneumococcal conjugate vaccine; *PV,* polio vaccine.

Haemophilus influenzae type b (Hib) and *S. pneumoniae* has proved highly effective in controlling invasive *H. influenzae* infection, notably meningitis, and reducing invasive disease, and can have a positive effect on antibiotic resistance (**Fig. 42.5**). A safe and immunogenic vaccine against *Neisseria meningitidis* serogroup B has now been included in the childhood vaccination schedules of some countries. Waning immune responses years after childhood immunization (e.g., tetanus and pertussis) may warrant additional or maintained vaccination boosting into adulthood.

Protection for travellers to developing and tropical countries

There has been a huge increase in the number of people travelling to low- and middle-income countries, mainly for recreation, leisure, and family visits. The risk of infection depends on the area to be visited, the type of activity, and the underlying health of the traveller. Advice should always be based on an individual assessment.

Box 42.20 Examples of active immunization available

Live attenuated vaccines
- Oral polio (Sabin) (not recommended, used only for outbreaks)
- MMR[a]
- Rotavirus
- Varicella zoster
- Yellow fever
- BCG
- Typhoid

Toxoids
- Diphtheria
- Tetanus

Recombinant vaccines
- Hepatitis B
- Varicella zoster (for shingles)
- Astra-Zeneca and Janssen/Johnson & Johnson SARS-CoV-2 vaccine (adenovirus vector)
- Respiratory syncytial virus

In activated and/or conjugate vaccines
- Hepatitis A
- Pertussis
- Typhoid: whole-cell and Vi antigen
- Polio (Salk) for routine use
- Influenza
- Human papillomavirus
- Cholera (oral): includes toxoid
- Meningococcus groups A, B, C, W135, and Y
- Rabies
- Anthrax
- Tick-borne encephalitis
- Japanese encephalitis
- Pneumococcal
- *Haemophilus influenzae* type b

Messenger RNA vaccines
- Moderna and Pfizer-BioNTech SARS-CoV-2 vaccine

Viral subunit vaccine
- Novavax SARS-CoV-2 vaccine (viral subunit)

[a]Individual vaccines for measles, mumps, and rubella (MMR) are not licensed in the UK.
BCG, Bacille Calmette–Guérin; *SARS-CoV-2,* severe acute respiratory syndrome coronavirus 2.

Protection for travellers against infection can be divided into three categories (**Box 42.21**). Because situations and risks can change rapidly, websites such as Travel Health Pro (which are regularly updated) are often the best source of advice on travel health (see Further reading).

Box 42.21 Protection for travellers against infection

Personal protection, e.g.,
- Insect repellents
- Impregnated bed netting
- Avoidance of animals
- Care with food and drink
- Condoms
- Care with travel (i.e., road traffic accidents)

Chemoprophylaxis, e.g., antimalarials

Immunization, e.g.,
- Yellow fever
- Hepatitis A and B
- Typhoid
- Cholera
- Rotavirus
- Rabies

PRINCIPLES AND MECHANISMS OF INFECTION

Host–organism interactions, including the human microbiome

Although many infectious diseases are caused by exposure to exogenous pathogenic organisms (e.g., *Legionella* spp., malaria, leptospirosis, scabies), a significant proportion are caused by microorganisms that are part of the human microbiome.

Each of us is colonized by huge numbers of microorganisms (10^{14} bacteria, plus viruses, fungi, protozoa, and worms), with which we coexist. Many mucosal surfaces and organs (e.g., skin, lungs, and GI and genitourinary tracts) in humans have their own unique community of microbes, often called the ***microbiome***. Within the GI tract, for example, there are approximately 10^{11} to 10^{12} microbes per gram of content with each person carrying at least 160 species but often many more. A very high proportion of the GI tract microbiome bacteria are anaerobic, which means that antibiotics with anti-anaerobic activity (e.g., co-amoxiclav and metronidazole) can profoundly disrupt the nature of this microbial community. The human microbiome also acts as a reservoir for antimicrobial resistance, with many antimicrobials promoting the emergence and transfer of resistance elements within this habitat.

The development of the human microbiome is complex; normal vaginal delivery (as opposed to caesarean section), breastfeeding, diet, and the living environment, for example, exert major and lasting impacts. The effect of change in the human microbiome, particularly of the GI tract, on host metabolism and immunity is increasingly associated with health states, including, for example, cancer (in which it has been shown to change the patient's response to chemotherapy), diabetes and other metabolic diseases, host metabolism of medications, inflammatory bowel disease, mental health, and rheumatological diseases. Early use of antibiotics and disruption of the microbiome by other means have a prolonged impact on microbiome community structure and, it seems increasingly apparent, on health and disease states later in life. On the other hand, it is possible to protect and manipulate the microbiome therapeutically; existing examples include the use of faecal transplantation to treat recurrent *C. difficile* infection and selective decontamination of the digestive tract to prevent infections in critically ill patients. Wider therapeutic benefits of faecal transplantation and dietary manoeuvres to increase microbiome diversity are increasingly gaining an evidence base for treatment and prevention, revolutionizing our understanding of the pathogenesis of non-communicable diseases.

Development of infection by commensal organisms

Most microbiome microorganisms are commensal or symbiotic, living on or within humans without causing harm, but some are potentially pathogenic in the right circumstances. Infection and illness may be caused by usually harmless commensal microbes evading the body's defences and infecting abnormal sites. Examples include skin or mucosal commensals latching onto abnormal internal surfaces (e.g., *Staphylococcus epidermidis* infecting a prosthetic joint, an oral streptococcus causing endocarditis on an abnormal heart valve). UTI most commonly occurs, however, in the context of normal bladder epithelium, simply by physical transfer from the bowel to the bladder via the urethra. Bacterial liver abscess can occur by ascending infection of the biliary tract or via the portal venous route from a normal gut mucosa.

In other circumstances, the host immune response may be reduced, and normally commensal organisms cause 'opportunistic infection' (e.g., oral candidiasis in an immunocompromised host and following exposure to antibiotics). Common latent infections,

such as cytomegalovirus (CMV) and toxoplasma, exist in stable controlled equilibrium in host immune cells or other tissues of the immunocompetent host after initial infection but reactivate and multiply as 'opportunistic infections' after immunosuppression.

Symptoms of infection and the host response

The symptoms and signs of infection are a result of the interaction between host and pathogen. In some cases, such as the early stages of influenza, symptoms are almost entirely caused by killing of host cells by the invading organism. Usually, however, the harmful effects of infection are caused by a combination of direct microbial pathogenicity and the body's immune response to infection. In Gram-negative bloodstream infection, for example, much of the tissue damage is caused by cytokines released in an attempt to fight bacteria.

Specificity of microorganisms

Microbes are highly specific with respect to the organ or tissue they infect. For example, a number of viruses are hepatotropic, such as those responsible for hepatitis A, B, C, D, and E and for yellow fever. This predilection for specific sites in the body relates partly to the presence of appropriate receptors on different cell types, partly to the immediate environment in which the organism finds itself, and partly to the nature of the organism. *S. epidermidis*, for example, is a facultative anaerobe (i.e., can live in oxygenated and non-oxygenated environments) that usually lives on the human skin, an aerobic environment, but that has a predilection to forming biofilms on medical devices (e.g., of central venous lines and joint replacements) in less aerobic environments. In contrast, *Mycobacterium tuberculosis* is an obligate aerobe (i.e., it needs oxygen to replicate), and *Bacteroides* spp. and *Clostridium* spp. (found in the human GI tract) are obligate anaerobes (i.e., cannot live in atmospheric conditions), which partly explains the nature of the infections these bacteria cause. *Clostridium* spp. form spores, however, that enable survival in atmospheric conditions and thereby their spread to other human hosts.

Even within a species of bacterium, there are sometimes clear differences between strains with regard to their ability to cause certain clinical presentations. There are many different strains of *S. pneumoniae*, for example, with some asymptomatically colonizing the nasopharyngeal mucosa, some more likely to invade and cause pneumococcal bloodstream infection, and certain different invasive strains more likely to cause empyema or meningitis; other strains are more likely to cause pneumonia without bloodstream infection. Likewise, whereas some strains of *E. coli* (enterotoxin-producing strains) are more likely to cause GI disease, 'uropathogenic' strains are more likely to cause UTIs.

Pathogenesis

Fig. 42.6 summarizes some of the steps that are followed during the pathogenesis of infection. Pathogens have developed a variety of mechanisms to evade host defences. For example, some produce toxins directed at phagocytes—*S. aureus* (α-toxin), *S. pyogenes* (streptolysin), and *Clostridium perfringens* (α-toxin)—but others can survive within macrophages. Several pathogens possess a capsule that protects against complement activation (e.g., *S. pneumoniae*). Antigenic variation can also help evasion of host defences (e.g., antigenic shift and drift in influenza), which is the reason why influenza vaccines are modified from year to year.

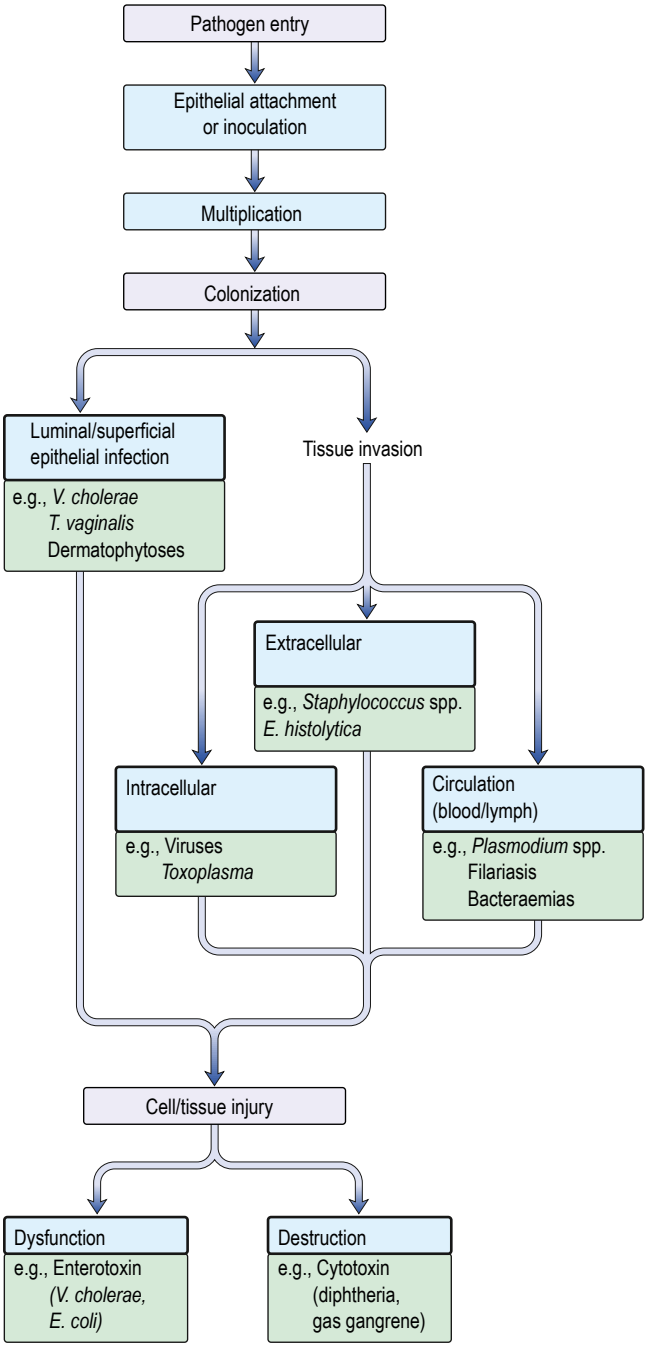

Fig. 42.6 The pathogenesis of infection.

Epithelial attachment

Many bacteria attach to epithelium cells using the adhesion molecules (called adhesins) of specific organelles called pili (or fimbriae). Enterotoxigenic and uropathogenic *E. coli* use fimbriae, for example, to attach to enterocytes and urothelial cells, respectively. After attachment, some bacteria, such as *S. epidermidis* and *Pseudomonas aeruginosa*, may produce an extracellular 'slime' layer and recruit additional bacteria to form a 'protective' biofilm. Biofilms are difficult to eradicate and are frequently associated with medical devices and persistent infections. Many viruses and protozoa (e.g., *Plasmodium* spp., *Entamoeba histolytica*) attach to

specific target-cell receptors, but others have attachment organs (e.g., the buccal plates of hookworms) that firmly grip the intestinal epithelium.

Colonization and invasion

After epithelial attachment, pathogens may remain on the surface epithelium or tissue invasion may follow. Invasion may result in:

- An intracellular location for the pathogen (e.g., viruses, *Mycobacterium* spp., *T. gondii*, *Plasmodium* spp.)
- An extracellular location for the pathogen (e.g., pneumococci, *E. coli*, *E. histolytica*)
- Invasion directly into the blood or lymph circulation (e.g., schistosome schistosomula and lymphatic filariasis).

Tissue dysfunction or damage

Microorganisms produce disease by a number of mechanisms, as described next.

Cell lysis

The presence of replicating viruses may interfere with host-cell metabolism, resulting in cell death.

Exotoxins and endotoxins

- ***Exotoxins*** have many diverse actions, including inhibition of protein synthesis (diphtheria toxin), neurotoxicity (*Clostridium tetani* and *Clostridium botulinum*) and enterotoxicity, which results in intestinal secretion of water and electrolytes *(E. coli, Vibrio cholerae).*
- ***Endotoxin*** is a lipopolysaccharide (LPS) in the cell wall of Gram-negative bacteria. It stimulates a variety of host responses characterized by release of pro-inflammatory cytokines and is responsible for many of the features of sepsis (see Chapter 12).

The clinical expression of disease caused by *S. aureus* varies according to site, invasion, and toxin production (**Box 42.22**). Furthermore, host susceptibility to infection may be linked to genetic or acquired defects in host immunity that may complicate intercurrent infection, injury, ageing, and metabolic disturbances (**Box 42.23**).

Host response to infection

Natural defences

The natural host defences to infection are those of an intact surface epithelium with local production of secretions; antimicrobial enzymes (e.g., lysozyme in the eye); and in the stomach, gastric acidity. The latter is reduced by proton pump inhibitors, increasing the risk of some GI infections, including *C. difficile* infection. The mucociliary escalator of the large airways is destroyed by smoking.

Immunological defences

The immunological response to infection is described in Chapter 6.

Metabolic and immunological consequences of infection

Fever

Body temperature is controlled by the thermoregulatory centre in the anterior hypothalamus and is usually maintained at approximately

Box 42.22 Clinical conditions produced by *Staphylococcus aureus*

Caused by invasion

[b]Often *Staphylococcus epidermidis.*

36.8°C in health, with diurnal and inter-individual variation of about ±1.0°C. Gram-negative bacteria contain LPS and peptidoglycan; the latter is also a component of Gram-positive bacterial cell walls. Monocytes and dendritic cells recognize these, leading to the formation of inflammatory cytokines, such as interleukin (IL)-1, IL-6, IL-12, tumour necrosis factor alpha (TNF-α) and many others. These act on the thermoregulatory centre by increasing prostaglandin synthesis. The antipyretic effect of salicylates is brought about, at least in part, through their inhibitory effects on prostaglandin synthase.

Fever production has a positive effect on the course of infection. However, for every 1°C rise in temperature, there is a 13% increase in resting metabolic rate and oxygen consumption. Therefore, fever leads to increased energy requirements at a time when anorexia leads to decreased food intake, resulting in an increase in skeletal muscle breakdown to provide energy.

The inflammatory response

The inflammatory response is a fundamental biological response to a variety of stimuli, including microorganisms or their products, such as endotoxin, which acts on monocytes and macrophages. Non-phagocytic cells (lymphocytes, natural killer cells) are also involved. The release of cytokines—notably, TNF-α, IL-1, IL-6, and IL-17—leads to the release of a cascade of other mediators involved in direct antiviral responses, inflammation, and tissue remodelling, such as IFNs, prostaglandins, leukotrienes, and corticotropin. See Further reading for more information about the pathogenesis of infection by some key human bacterial, viral, and protozoan pathogens.

VIRAL INFECTIONS

Viruses are much smaller than other infectious agents and carry their genome as either DNA or RNA (but never both). Details of the structure, size, and classification of human DNA and RNA viruses are shown in **Boxes 42.24 and 42.25**, respectively. Because viruses are metabolically inert, they must live intracellularly, using the host cell for synthesis of viral proteins and nucleic acid. Viruses have a central nucleic acid (genome) surrounded by a protective protein coat (capsid) that is antigenically unique for a particular virus. The capsid imparts a helical or icosahedral structure to the virus. Some viruses also possess an outer envelope consisting of lipid and protein.

Outcomes of virus infection of a cell

Replication of viruses within a cell may result in sufficient distortion of normal cell function to result in cell death: a ***cytocidal*** or ***cytolytic*** infection. However, acute cell death is not an inevitable consequence of virus infection of a cell. In a ***chronic***, or ***persistent***, infection, virus replication continues throughout the lifespan of the cell but does not interfere with the normal cellular processes necessary for cell survival. Hepatitis B and C viruses may interact with cells in this way. Some viruses, such as those of the herpesvirus family, are able to go ***latent*** within a cell; in such a state, the virus genome is present within the cell, but there is very little, if any, production of viral proteins and no production of mature virus particles. Finally, some viruses are able to ***transform*** cells, leading to uncontrolled cell division; an example is Epstein–Barr virus (EBV) infection of B lymphocytes, resulting in the generation of an immortal lymphoblastoid cell line.

VIRUS INFECTIONS OF THE SKIN AND MUCOUS MEMBRANES

Many virus infections are associated with skin rashes (exanthems) or eruptions on the mucous membranes (enanthems) (see **Box 42.8**), so clinical syndromes based on the nature of the rash (which may be ***vesicular*** [i.e., consisting of fluid-filled vesicles] or ***maculopapular***) are often highly specific to the causative agent.

Vesicular viral rashes

Herpes simplex virus infection

Members of the *Herpesviridae* family of viruses cause a wide range of human diseases (Box 42.26). The hallmark of all herpesvirus infections is the ability of the viruses to establish latent infections that persist for the life of the individual.

Two types of HSV (Fig. 42.7) have been identified: HSV-1 is the major cause of herpetic stomatitis, herpes labialis ('cold sore'), keratoconjunctivitis, and encephalitis, and HSV-2 causes genital herpes and may also be responsible for systemic infection in immunocompromised hosts. These divisions are not rigid, however, because HSV-1 can give rise to genital herpes and HSV-2 can cause infections in the mouth. The site of latency for both HSV-1 and 2 is the nerve cell body.

Herpes simplex virus type 1

The portal of entry of HSV-1 infection is usually via the mouth or, occasionally, the skin. The primary infection may go unnoticed or may produce a severe inflammatory reaction with vesicle formation leading to painful ulcers (gingivostomatitis; Fig. 42.8). Latent virus may be reactivated from the trigeminal ganglion by stress, trauma, febrile illnesses, and ultraviolet radiation, producing the recurrent form of the disease known as herpes labialis ('cold sore'). Approximately 70% of the population is infected with HSV-1, and recurrent infections occur in one-third of individuals. Reactivation often produces localized paraesthesiae in the lip before the appearance of a cold sore.

Complications of HSV-1 infection include transfer to the eye (dendritic ulceration, keratitis), acute encephalitis (see Chapter 11, 'Viral encephalitis' section), nail-bed infections (herpetic whitlow), and erythema multiforme (see Chapter 45, 'Erythema multiforme' section).

[a]Signifies primary infection.

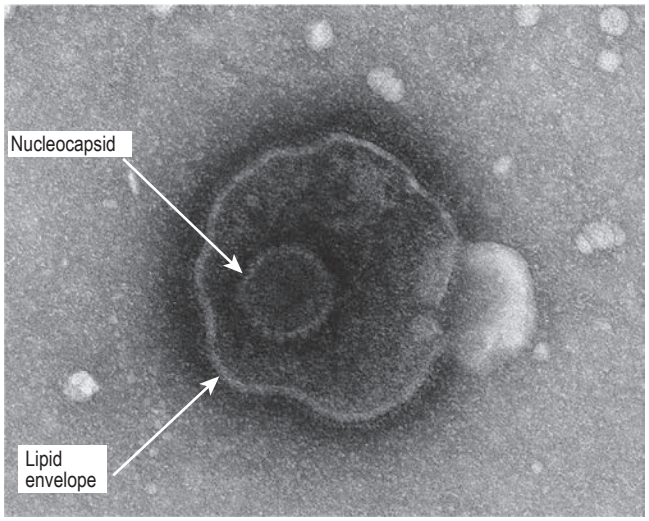

Fig. 42.7 Electron micrograph of herpes simplex virus.

Fig. 42.8 Primary herpes simplex type 1 (gingivostomatitis).

Herpes simplex virus type 2

The clinical features, diagnosis, and management of genital herpes are described in Chapter 43 ('Herpes simplex' section). The virus remains latent in the sacral ganglia and, during recurrence, can produce a radiculomyelopathy, with pain in the groin, buttocks, and upper thighs. Primary anorectal herpes infection is common in males who have sex with males.

Neonates may develop primary HSV infection after vaginal delivery in the presence of active genital HSV infection in the mother, particularly if the maternal disease is a primary, rather than a recurrent, infection. The disease in the baby varies from localized skin lesions (~10%–15%) to widespread visceral disease most often affecting the lungs, liver, and brain, with a poor prognosis. Caesarean section should therefore be performed if there is evidence of primary maternal HSV infection in the last trimester or if active genital HSV infection is present during labour.

In pregnancy and in immunocompromised patients, such as those receiving intensive cancer chemotherapy or those with AIDS, HSV infection may become disseminated, involving many of the viscera. In severe cases, death may result from hepatitis and encephalitis. Eczema herpeticum is a serious complication in individuals with eczema, in whom the non-intact skin allows spread of lesions across large areas and bloodstream access, which may lead to herpetic involvement of internal organs.

Diagnosis and management

Confirmation of clinical diagnosis is most commonly obtained by detection of HSV DNA in vesicle fluid or a peripheral blood sample

by genome amplification. Treatment of patients with HSV-associated disease is with aciclovir and derivatives.

Varicella (chickenpox) and herpes zoster (shingles)

Infection with varicella zoster virus (VZV), another herpesvirus, produces two distinct diseases: varicella (chickenpox) and herpes zoster (shingles). The ***primary infection***, chickenpox, usually occurs in childhood, the virus entering through the mucosa of the upper respiratory tract. In some countries (e.g., the Indian subcontinent), a different epidemiological pattern exists, with most infections occurring in adulthood. Chickenpox is rarely contracted twice by the same individual. Infectious virus is spread from the throat and from fresh skin lesions by air-borne transmission or direct contact. The period of infectivity in chickenpox extends from 2 days before the appearance of the rash until the skin lesions are all at the crusting stage. After recovery from chickenpox, the virus remains latent in dorsal root and cranial nerve ganglia. ***Reactivation*** of infection results in shingles.

Clinical features of chickenpox

About 14 to 21 days after exposure to VZV, a brief prodromal illness of fever, headache, and malaise heralds the eruption of chickenpox, characterized by the rapid progression of macules to papules to vesicles to pustules in a matter of hours (Fig. 42.9). In young children, the prodromal illness may be very mild or absent. The illness tends to be more severe in older children and can be debilitating in adults. The lesions occur on the face; scalp; trunk; and, to a lesser extent, the extremities. It is characteristic to see lesions at all stages of development on the same area of skin. Fever subsides as soon as new lesions cease to appear. Eventually, the pustules crust and heal without scarring.

Complications include pneumonia, which generally begins 1 to 6 days after the skin eruption, and bacterial superinfection of skin lesions. Pneumonia is more common in adults than in children, and cigarette smokers are at particular risk. The pulmonary symptoms are usually more striking than the physical findings, although a chest X-ray usually shows diffuse changes throughout both lung fields. Central nervous system (CNS) involvement occurs in about 1 per 1000 patients and most commonly presents as an acute truncal cerebellar ataxia. Immunocompromised people are susceptible to disseminated infection, with multiorgan involvement. Pregnancy increases the risk of severe chickenpox and, in addition, there is a risk of intrauterine infection with structural damage to the fetus. (If maternal infection is within the first 20 weeks of pregnancy, the risk of varicella embryopathy is 1%–2%.)

Clinical features of shingles

Shingles (see Chapter 45, 'Herpes zoster [shingles]' section) arises from the reactivation of VZV latent within the dorsal root or cranial nerve ganglia. It may occur at any age but is most common in older adults, producing skin lesions similar to those of chickenpox, although classically, they are unilateral and restricted to a sensory nerve (i.e., dermatomal) distribution (Fig. 42.10). The onset of a shingles rash is usually preceded by severe dermatomal pain, indicating the involvement of sensory nerves in its pathogenesis. The virus is disseminated from freshly formed vesicles and may cause chickenpox in susceptible contacts.

The most common complication of shingles is postherpetic neuralgia (PHN; see Chapter 28, 'Neuralgia' section). The occurrence of PHN is related to age (more likely in older adults) and the intensity of the original shingles rash.

Fig. 42.9 Chickenpox in an adult. Generalized varicella zoster virus infection.

Fig. 42.10 Shingles. Varicella zoster virus affecting a dermatome. *(Reproduced with kind permission of the Imperial College School of Medicine.)*

Diagnosis

The diseases are usually recognized clinically but can be confirmed by detection of VZV DNA within vesicular fluid, electron microscopy, immunofluorescence or culture of vesicular fluid, and serology.

Prevention and management

Chickenpox usually requires no treatment in healthy children, and infection results in life-long immunity. Aciclovir and derivatives are licensed for this indication in the USA. However, the disease may be fatal in immunocompromised people, who should therefore be offered protection after exposure to the virus, with zoster-immune globulin (ZIG) and high-dose aciclovir at the first sign of development of the disease.

Antiviral therapy with aciclovir or a similar drug may be offered to patients older than the age of 16 years if they present within 72 hours of onset. Prophylactic ZIG is recommended for susceptible pregnancies exposed to VZV, and if chickenpox develops, aciclovir treatment should be given if there are concerns around varicella pneumonia, but the drug is *not* licensed for use in pregnancy. Babies should be protected by ZIG if delivery occurs within 7 days of the onset of the mother's rash. An effective live attenuated varicella vaccine is licensed as a routine vaccination of childhood in the USA; it is available on a named patient basis in the UK and for susceptible healthcare workers.

+++, Often causes; *++*, sometimes causes; *+*, rarely causes; *±*, possibly causes; *EV*, enterovirus; *URTI*, upper respiratory tract infection.

Patients with ***shingles*** involving motor nerves (e.g., the VIIth cranial nerve, leading to facial palsy) are also treated with aciclovir (or derivatives). Antiviral therapy has been shown to reduce the burden of PHN when treatment is given in the acute phase and is therefore recommended for shingles patients older than 65 years. Shingles involving the ophthalmic division of the trigeminal nerve has an associated 50% incidence of acute and chronic ophthalmic complications. Early treatment with aciclovir reduces this to 20% or less. As for chickenpox, all immunocompromised individuals should be given aciclovir at the onset of shingles, no matter how mild the attack appears when it first presents.

Both recombinant and live attenuated vaccines have been shown to reduce shingles-related morbidity and PHN. Vaccination is recommended for all adults older than the age of 60 years (USA). In the UK, the age limit is currently older than 70 years, but this may be reduced to 65 years.

Picornavirus infections

The picornaviruses (pico = small) are a large family of RNA viruses, which includes the enteroviruses (EVs), rhinoviruses, parechoviruses, and hepatitis A virus (see Chapter 23, 'Hepatitis A' section). The term 'enterovirus' refers to their enteric means of spread, that is, via the faecal–oral route. The EVs include poliovirus types 1 to 3, coxsackie A and B viruses, echoviruses, and EVs 68 to 71. There are several newly described EVs yet to be officially classified. All EVs are now grouped into four species, A to D, with the species letter being incorporated in the virus type name (e.g., EV D68). They are responsible for a broad spectrum of disease involving the skin and mucous membranes; muscles; nerves; heart (**Box 42.27**); and, rarely, other organs, such as the liver and pancreas. They are frequently associated with pyrexial illnesses and are the most common causes of aseptic meningitis (see later).

Herpangina

This is mainly caused by coxsackie A viruses. It presents with a vesicular eruption on the fauces, palate, and uvula, and the lesions evolve into ulcers. The illness is usually associated with fever and headache but is short-lived, with recovery taking place within a few days.

Hand, foot, and mouth disease

This is mainly caused by coxsackievirus A16 or A10 (EV A16, EV A10, respectively). It is also the main feature of infection with EV A71. Oral lesions are similar to those seen in herpangina but may be more extensive in the oropharynx. Vesicles and a maculopapular eruption also appear, typically on the palms of the hands and the soles of the feet but also on other parts of the body. This infection commonly affects children. Recovery occurs within 1 week.

Poxvirus infections

Smallpox (variola)

This disease was eradicated in 1977 after an aggressive vaccination policy. Its possible use in bioterrorism has resulted in the reintroduction of smallpox vaccination in some countries.

Mpox (formerly known as monkeypox)

This was, until 2022, a rare zoonosis arising from infection with monkeypox virus in small villages in tropical rainforests in several countries of West and Central Africa. Its clinical effects, including a generalized vesicular rash, were indistinguishable from those of smallpox, but person-to-person transmission was unusual. Most infections occurred in children who were not vaccinated against smallpox. Disease could be severe, with mortality rates of 10% to 15% in unvaccinated individuals. Serological surveys indicated that several species of squirrel were the likely animal reservoir. The disease was renamed mpox in 2022 because there is very little evidence of monkeys being involved in its natural history. The virus was introduced into the USA in 2003 via small West African mammals illegally imported as pets. Widespread infection of prairie dogs resulted, and there were 37 laboratory-confirmed cases in humans.

However, in 2022, the WHO declared a Public Health Emergency of International Concern because of an unprecedented surge in reported cases in more than 70 countries around the world, with many previously unrecognized clinical features. In the UK, cases were overwhelmingly in males who have sex with males, presenting with penile, perianal, and rectal symptoms, with or without skin lesions (see Chapter 43, 'Mpox' section and Chapter 45, 'Mpox [formerly monkeypox]' section). The lesion count was often low at presentation, with some atypical single lesions mimicking abscesses e.g., in the

throat. Prodromal illness was often absent. Only a minority of patients required hospital admission and then mostly for pain management.

Diagnosis is by demonstration of mpox virus DNA in a lesion swab, the most common differential being HSV infection. Treatment is symptomatic, although tecovirimat, an antiviral developed for the treatment of smallpox, has also been recommended for severe cases. Prevention is by active immunization with a modified vaccinia Ankara vaccine, although there have been problems in generating adequate supplies.

Cowpox

Cowpox produces large vesicles that are classically found on the hands of individuals in contact with infected cows. The lesions are associated with regional lymphadenitis and fever. Cowpox virus has been found in a range of species, including domestic and wild cats, and the reservoir is thought to exist in a range of rodents.

Vaccinia virus

This laboratory virus does not occur in nature in either humans or animals. Its origins are uncertain, but it has been invaluable in its use as the vaccine to prevent smallpox.

Orf

This poxvirus causes contagious pustular dermatitis in sheep and hand lesions in humans.

Molluscum contagiosum

This is discussed in Chapter 43 ('Molluscum contagiosum' section).

Human papillomavirus infections

These cause warts (see Chapter 43, 'Human papillomavirus [anogenital warts]' section) and cervical cancer (see Chapter 47, 'Gynaecological malignancy' section).

Maculopapular viral rashes

Measles (rubeola)

Measles virus is a paramyxovirus (see **Box 42.25**). Measles is a highly communicable disease that occurs worldwide. With the introduction of aggressive immunization policies, the global incidence of and mortality rate from measles fell by 80% between 2000 and 2017, but there were still approximately 128 000 measles-related deaths in 2021, mostly in children younger than the age of 5 years and largely in Africa and South-east Asia. It is spread by droplet infection, and the period of infectivity is from 4 days before until 2 days after the onset of the rash.

Clinical features

The incubation period is 8 to 14 days. Two distinct phases of the disease can be recognized.

- The ***pre-eruptive and catarrhal stage***, the stage of viraemia and viral dissemination. Malaise, fever, rhinorrhoea, cough, conjunctival suffusion, and the pathognomonic Koplik's spots (small, greyish, irregular lesions surrounded by an erythematous base, found in greatest numbers on the buccal mucous membrane opposite the second molar tooth) are present during this stage.
- The ***eruptive or exanthematous stage***, characterized by the presence of a maculopapular rash that initially occurs on the face, chiefly the forehead, and then spreads rapidly to involve the rest of the body (**Fig. 42.11**). At first, the rash is discrete, but later it may become confluent and patchy, especially on the face and neck. It fades in about 1 week and leaves behind a brownish discoloration.

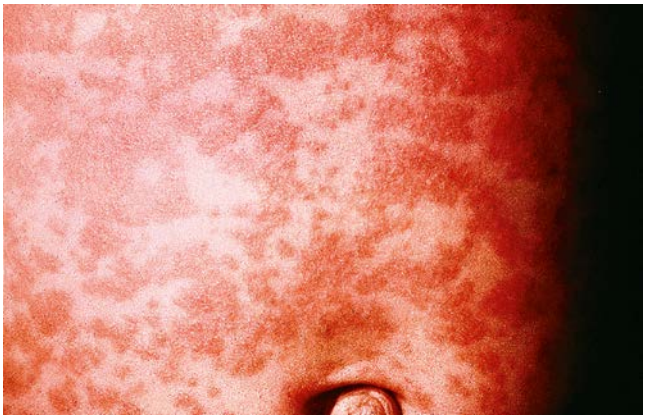

Fig. 42.11 Measles. *(Courtesy of Dr MW McKendrick, Royal Hallamshire Hospital, Sheffield.)*

The most feared complication in an immunocompetent child is post-measles encephalomyelitis, occurring within 2 weeks of the rash in 1 in 1000 to 1 in 5000 cases of measles. This is most likely an autoimmune disorder triggered by the measles infection because virus is not present in the brain substance. The prognosis is poor, with a high mortality rate (30%) and severe residual damage in survivors.

Measles carries a high mortality rate in malnourished people and those who have other diseases. Complications are common in such individuals and include bacterial pneumonia, bronchitis, otitis media, and severe diarrhoea. Less commonly, myocarditis, hepatitis, and encephalomyelitis occur. In malnourished people and those with defective cell-mediated immunity (CMI), the classical maculopapular rash may not develop, and there may be widespread desquamation. The virus also causes the rare condition subacute sclerosing panencephalitis, which may follow measles infection occurring early in life (before 18 months of age). Persistence of the virus with reactivation before puberty results in accumulation of virus in the brain, progressive mental deterioration, and a fatal outcome.

Maternal measles, unlike rubella, does not cause fetal abnormalities. It is, however, associated with spontaneous abortions and premature delivery.

Diagnosis and management

Most cases of measles are diagnosed clinically, but detection of measles-specific IgM in blood or oral fluid or genome or antigen detection from nasopharyngeal aspirates or throat swabs should be used to confirm the diagnosis.

Management is supportive. Antibiotics are indicated only if secondary bacterial infection occurs. Vitamin A supplements lower the number of deaths from measles by 50% and reduce eye damage and blindness; therefore, two doses of vitamin A supplements given 24 hours apart is recommended for all children with measles.

Prevention

A previous attack of measles confers a high degree of immunity, and second attacks are uncommon. Normal human immunoglobulin given within 5 days of exposure effectively aborts an attack of measles. It is indicated after exposure for previously unimmunized children younger than 3 years of age, in pregnancy, and for those with debilitating disease.

Active immunization

Children in the UK are immunized with the combined mumps, measles, and rubella (MMR) vaccine. In low- and middle-income countries, the first measles vaccination is given at 9 months.

Rubella

Rubella ('German measles') is caused by a spherical, enveloped RNA virus of the *Rubivirus* genus belonging to the Matonaviridae family. Although the disease can occur sporadically, epidemics are not uncommon. It has a worldwide distribution. Spread of the virus is via droplets; maximum infectivity occurs before and during the time the rash is present.

Clinical features

The incubation period is 14 to 21 days, averaging 18 days. The clinical features are largely determined by age, symptoms being mild or absent in children younger than 5 years.

During the prodrome, the patient may develop malaise, fever, mild conjunctivitis, and lymphadenopathy involving particularly the suboccipital, post-auricular, and posterior cervical groups of lymph nodes. Small petechial lesions on the soft palate (Forchheimer spots) are suggestive but not diagnostic. Splenomegaly may be present.

The eruptive or exanthematous phase usually occurs within 7 days of the initial symptoms. The rash first appears on the forehead and then spreads to involve the trunk and limbs. It is pinkish red, macular, and discrete, though some of these lesions may coalesce (Fig. 42.12). It usually fades by the second day and rarely persists beyond 3 days after its appearance.

Complications

Complications are rare. They include superadded pulmonary bacterial infection, arthralgia (more common in females), haemorrhagic manifestations caused by thrombocytopenia, and encephalitis. Maternal infection in pregnancy may result in the congenital rubella syndrome. Rubella affects the fetuses of up to 90% of all infections during the first trimester of pregnancy. The incidence of congenital abnormalities diminishes in the second trimester, and no ill-effects result from infection in the third trimester.

Congenital rubella syndrome is characterized by the presence of fetal cardiac malformations (especially patent ductus arteriosus and ventricular septal defect), eye lesions (especially cataracts), microcephaly, mental retardation, and deafness. Hepatosplenomegaly, myocarditis, interstitial pneumonia, and metaphyseal bone lesions also occur.

Diagnosis and management

Laboratory diagnosis is essential, especially in pregnancy, to distinguish the illness from other virus infections (e.g., erythrovirus B19, echovirus) and drug rashes. This is achieved by detection of rubella-specific IgM by enzyme-linked immunosorbent assay (ELISA) in an acute serum sample, preferably confirmed by demonstration of IgG seroconversion (or a rising titre of IgG) in a subsequent sample taken 14 days later. Viral genome can be detected in throat swabs (or oral fluid samples); urine; and, in the case of intrauterine infection, the products of conception.

Management is supportive.

Prevention

Several live attenuated rubella vaccines have been used and have had great success in preventing this illness. They have been successfully combined with measles and mumps vaccines in the MMR vaccine. Use of the vaccine is contraindicated during pregnancy or if there is a likelihood of pregnancy within 3 months of immunization. Inadvertent use of the vaccine during pregnancy has not, however, revealed a risk of teratogenicity.

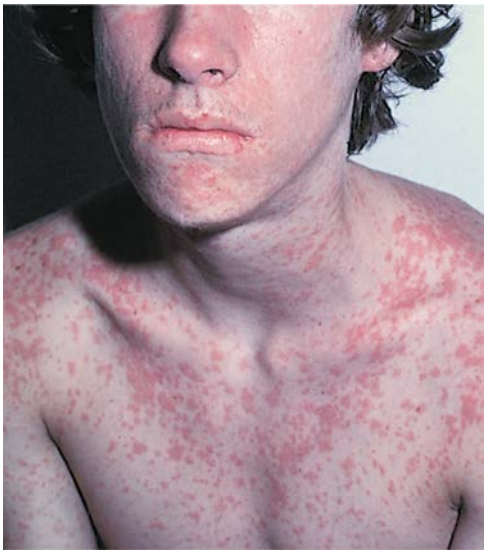

Fig. 42.12 **Rubella rash.**

Erythrovirus infections

Human erythrovirus (also known as parvovirus) B19 causes erythema infectiosum (fifth disease), a common infection in schoolchildren. The rash is typically on the face (the ***'slapped cheek'*** appearance). The patient is well, and the rash can recur over weeks or months. Asymptomatic infection occurs in 20% of children. Non-specific respiratory tract illness may also occur. In adults, the rash may be clinically indistinguishable from that of rubella. Moderately severe self-limiting polyarthropathy is common if infection occurs in adulthood, especially in females (this is also true of rubella). The virus infects bone marrow cells, and aplastic crisis may occur in patients with chronic haemolysis (e.g., sickle cell disease). Chronic infection with anaemia occurs in immunocompromised subjects. Hydrops fetalis (3% risk) and spontaneous abortion (9% risk) may result from maternal infection in the first and second trimesters of pregnancy.

Diagnosis of acute infection is by detection of parvovirus-specific IgM or DNA.

Human herpesvirus types 6 and 7 infection

These human herpesviruses (HHVs) occur worldwide and exist as latent infections in more than 85% of the adult population. They are spread by contact with oral secretions. HHV type 6 (HHV-6) causes roseola infantum (exanthem subitum), which presents as a high fever followed by a generalized macular rash in infants. HHV-6 is a common cause of febrile convulsions, and aseptic meningitis or encephalitis is a rare complication.

The full spectrum of disease caused by HHV-7 has not yet been fully characterized, but like HHV-6, it may cause roseola infantum in infants. Both viruses have been associated with encephalitis in heavily immunosuppressed patients, such as bone marrow transplant recipients.

Management

Supportive management is recommended for patients with the common infantile disease. Ganciclovir can be used in immunocompromised patients.

VIRUS INFECTIONS OF THE RESPIRATORY TRACT

Many viruses can cause URTIs, for example, in the nose (rhinitis), throat (tonsillitis, pharyngitis), sinuses (sinusitis), ear (otitis media), eye (conjunctivitis), or larynx (laryngitis) (**Box 42.28**). Infections below the larynx are referred to as LRTIs. URTIs are common but relatively trivial; LRTIs are less common but may result in hospitalization and even death.

Upper respiratory tract infections

The common cold: coryza and rhinitis

Rhinovirus infection is the most common cause of the common cold (see Chapter 20, 'Viral rhinitis' section). Peak incidence rates occur in the colder months, especially spring and autumn. There are multiple rhinovirus serotypes (>100), which explains why infection occurs throughout life and makes vaccine control impracticable. In contrast to EVs, which replicate at 37°C, rhinoviruses grow best at 33°C (the temperature of the upper respiratory tract), which explains the localized disease characteristic of common colds.

Human coronaviruses (CoVs) were first isolated in the mid-1960s, and the majority of isolates (related to the reference strains 229E and OC43) have been associated with common colds. In 2004 and 2005, two new CoV infections of humans were described, NL63 and HKU1. These are also associated with coryzal symptomatology. CoVs have recently become of interest owing to the discovery of three new viruses causing life-threatening LRTI (see later).

Parainfluenza

Parainfluenza is caused by the parainfluenza viruses types I to IV; these have a worldwide distribution and cause acute respiratory disease.

Parainfluenza is essentially a disease of children and presents with features similar to those of the common cold. When infection is severe, a brassy cough with inspiratory stridor and features of laryngotracheitis (croup) are present. Fever usually lasts for 2 to 3 days and may be more prolonged if pneumonia develops. The development of croup is caused by submucosal oedema and consequent airway obstruction in the subglottic region. This may lead to cyanosis, subcostal and intercostal recession, and progressive airway obstruction. Infection in immunocompromised patients is usually prolonged and may be severe. Management is supportive with oxygen, humidification, and sedation when required. The role of steroids and the antiviral agent ribavirin is controversial.

Adenovirus infection

More than 80 adenovirus serotypes split into 7 species labelled A to G have been identified as human pathogens, infecting a number of different cell types and therefore resulting in different clinical syndromes. Adenovirus infection commonly presents as an acute pharyngitis, and extension of infection to the larynx and trachea in infants may lead to croup. By school age, the majority of children show serological evidence of previous infection. Certain subtypes produce an acute conjunctivitis associated with pharyngitis. In adults, adenovirus causes acute follicular conjunctivitis and, rarely, pneumonia that is clinically similar to that produced by *M. pneumoniae*. Adenoviruses F40 and F41 cause gastroenteritis without respiratory disease, and adenovirus infection may be responsible for acute mesenteric lymphadenitis in children and young adults, which may lead to intussusception in infants. Infection in an immunocompromised host, such as a bone marrow transplant recipient, may result in multisystem failure and fatal disease. In 2022, a number of countries experienced a dramatic increase in cases of severe hepatitis in children mostly younger than the age of 10 years. There is considerable evidence that infection with Ad-F41, together with adeno-associated virus type 2, in individuals carrying particular HLA-D alleles, was a major contributor to this syndrome.

Box 42.28 Virus infections of the respiratory tract

Virus	Disease
Upper respiratory tract infections	
Rhinoviruses (>100 serotypes)	Common cold, rhinitis
Parainfluenza viruses 1–4	Croup
Coronaviruses OC43, 229E	Common cold
Respiratory syncytial virus	Cough, sore throat
Human metapneumovirus	Cough, sore throat
Adenoviruses (>80 serotypes)	Pharyngitis, conjunctivitis Common cold (see Chapter 20, 'Viral rhinitis' section)
Enteroviruses (coxsackie, echo, EV D68)	Bronchiolitis in young babies
Lower respiratory tract infections	
Influenza A, B	Epidemics and pandemics of influenza
Respiratory syncytial virus	Bronchiolitis, pneumonia in young babies
SARS-CoV-2	COVID-19
Rarely	
Cytomegalovirus	Pneumonitis in immunocompromised
Varicella zoster virus	Pneumonia in adults with primary infection
Measles	Giant-cell pneumonia in immunocompromised
Coronaviruses	Pneumonia, regional or widespread outbreaks

COVID-19, Coronavirus disease 2019; *EV,* enterovirus; *SARS-CoV-2,* severe acute respiratory syndrome coronavirus 2.

Other viral causes of upper respiratory tract infection

Human erythrovirus B19 infection may present as a URTI. Bocavirus is a recently identified parvovirus, which accounts for around 3% to 5% of respiratory tract infections in young children. EVs, such as coxsackie and echoviruses, are occasionally found in respiratory tract secretions of young babies, and there has been much interest recently in EV D68, which appears to infect the respiratory tract predominantly. WU and KI polyomaviruses may be associated with respiratory tract infections in young children.

Lower respiratory tract infections

Viral infections resulting in life-threatening LRTIs are SARS-CoV-2, the MERS-CoV and the original SARS-CoV-2, influenza, and respiratory syncytial virus (RSV). However, viral pneumonia may occasionally arise from infection with a number of other viruses (see **Box 20.29**), and as evidenced by the emergence of SARS-CoV-2, other, as yet unknown, viruses may yet appear.

Box 42.29 Emergent human coronaviruses in the 21st century

	SARS-CoV (2002–2003)	MERS-CoV (2012–)[a]	SARS-CoV-2 (2019–)[b]
Cases *(n)*	8096	2604	676 609 951
R_0 (uncontrolled)	2–5	<1–8	3.1
Deaths *(n)*	774	936	6 881 955
Case fatality rate (%)	9.6	36	1–2

Coronavirus infections

CoVs are a large family of positive single-stranded RNA viruses that infect a wide range of species, causing a variety of clinical syndromes. Human CoV OC43, 229E, NL63, and HKU1 have been recognized for many years as the second commonest cause (behind rhinoviruses) of a common-cold-like illness. Interest in HCoV dramatically increased in November 2002 when an apparently new viral LRTI occurred in China and spread rapidly in other parts of the Far East and, from there, across the world. This disease, of which bronchopneumonia was a major feature, became known as 'severe acute respiratory syndrome' (SARS); it was caused by a previously unknown CoV (SARS-CoV-2). Similarity of this virus to CoVs isolated from civet cats, raccoons, and ferret badgers indicates that SARS is a zoonotic disease. Bats are the likely host species. The epidemic was finally brought under control in the summer of 2003 with implementation of strict quarantining of infected individuals and contacts of infected individuals to prevent further spread, by which time there had been more than 8000 cases with approximately 800 deaths (**Box 42.29**). Naturally acquired infection has not been reported since.

In 2012, a new CoV, MERS-CoV, was identified in a patient who died of acute respiratory failure in Saudi Arabia. There have been more than 2600 cases since, across 27 countries, although mostly in the Middle East; the mortality rate is around 36%. The most likely source is from dromedary camels. Person-to-person spread within healthcare settings is another major source, with the largest outbreaks in Saudi Arabia, United Arab Emirates, and the Republic of Korea. New cases continue to occur sporadically.

In December 2019, yet another new CoV was identified in an outbreak of severe respiratory disease in Wuhan, China, which spread rapidly to cause a major pandemic. This virus is now known as SARS-CoV-2, and the associated disease is coronavirus disease 2019 (COVID-19). Although the case-fatality rate is not as high as with SARS-CoV or MERS-CoV, this virus is clearly more transmissible and has spread explosively around the world. The impact of this pandemic has been incalculable, with global infection rates of almost 1 billion people and almost 7 million recorded deaths. As with all RNA viruses, there is a relatively high rate of spontaneous mutation during replication, which results in genetic drift. Thus, the SARS-CoV-2 pandemic has seen global waves of infection associated with the evolution of novel variants. Major waves have involved alpha, beta, delta, and omicron variants.

The clinical presentation of SARS-CoV-2 infection is as an acute illness with high temperature, cough, and evidence of impaired lung function. The pathogenesis of disease is thought to involve initial viral replication followed a few days later by an exaggerated inflammatory response ('cytokine storm'), which is responsible for the severe pulmonary complications. An unusual manifestation is loss of taste, smell, or both. Many surviving patients have long-term clinical consequences, in a syndrome referred to as 'long COVID'. The mortality rate is age related, with much higher fatality rates in those older than 65 years old and in patients with underlying co-morbidities. The management and complications of COVID-19 illness is discussed in detail in Chapter 20 ('COVID-19 pneumonitis' section).

Diagnosis

Diagnosis of CoV infection is by detection of virus in a respiratory sample, with nose or throat swab being the most useful. The most sensitive approach is that of genome detection, usually by reverse transcription polymerase chain reaction (RT-PCR). This is mostly done in laboratories, but there are point-of-care PCR kits that can be used for less centralized diagnosis. Antigen detection assays, usually using lateral flow technology, are also available for SARS-CoV-2. These allow for self-sampling and rapid diagnostic testing in the home but are intrinsically less sensitive than genome detection assays. Both assays may generate false-negative results if there is sufficient genomic or antigenic change arising from virus evolution.

Serological assays for detection of antibodies have been developed, but they are mainly used for surveillance purposes. It is possible to differentiate antibody positivity arising from immunization (will comprise anti-spike antibodies only) as opposed to those arising from natural infection, in which a range of antibodies against different viral proteins are present.

Management

The sheer scale of the COVID-19 pandemic enabled very large clinical trials to be conducted very rapidly to test the efficacy of a variety of therapeutic approaches. Many existing drugs were repurposed for use in SARS-CoV-2 infection, but none showed significant effects. Three novel antiviral agents, remdesivir, molnupiravir, and nirmatrelvir, have been shown to be effective in reducing the risks of serious and life-threatening complications of infection, with the latter being the most effective. A number of monoclonal anti-spike antibodies (e.g., sotrovimab) have been developed, but these lose potency and clinical usefulness as the virus evolves in different waves of infection. Anti-inflammatory approaches, including dexamethasone and monoclonal antibodies, which block IL-6 receptors or Janus kinase, are of benefit in seriously ill hospitalized patients.

Prevention

Infection control approaches to reduce the spread and burden of SARS-CoV-2 infection have included relatively straightforward measures such as isolation of infected patients admitted to hospital; wearing of PPE, including face masks, by healthcare workers and by the public in general; social distancing; and encouraging adequate hand hygiene through to drastic ones such as school closures and societal lockdowns, which had major health, economic, and psychological consequences.

There has been an extremely rapid development of vaccines, most of which have focused on inducing an immune response to the virus spike (S) protein. There are a number of strategies in use, including mRNA, DNA vector (e.g., adenovirus), whole inactivated virus, and S protein subunit vaccines. Large-scale clinical trials have generated impressive protection data, and the emergence of this phalanx of vaccines has been critical in controlling the pandemic.

Influenza

Influenza viruses belong to the family of orthomyxoviruses, having a segmented negative-strand RNA genome. The influenza virus is a spherical or filamentous enveloped virus. Haemagglutinin (H), a surface glycoprotein, aids attachment of the virus to the surface of susceptible host cells at specific sialic acid receptor sites. Release of progeny viruses from the cell surface, effected by budding through the cell membrane, is facilitated by the enzyme neuraminidase (N), which is also present on the viral envelope. Three types of influenza virus are recognized—A, B, and C—distinguishable by the nature of their internal proteins. In addition, 18 H subtypes (H1–H18) and 11 N subtypes (N1–N11) have been identified for influenza A viruses but only H1, H2, H3, N1, and N2 have established stable lineages in the human population since 1918.

- ***Influenza A*** is generally responsible for pandemics and epidemics.
- ***Influenza B*** often causes smaller or localized, milder outbreaks but can also result in severe disease and death. There are no subtypes of influenza B.
- ***Influenza C*** rarely produces disease in humans.

Antigenic shift generates new influenza A subtypes carrying different H and/or N proteins on their surface, which emerge at irregular intervals and give rise to influenza pandemics. Possible mechanisms include:

- Genetic reassortment of the eight RNA segments of the virus with that of an avian influenza virus. This requires co-infection of a host with both human and avian viruses. Pigs are thought to be the likely mixing vessel, although this could theoretically also occur in humans.
- Trans-species transmission of an avian influenza virus to humans. Viruses transmitted in this way are usually not well adapted to growth in their new host, but adaptation may occur as a result of spontaneous mutations, leading to the emergence of a pandemic strain.

Antigenic drift (minor changes in influenza A and B viruses) results from Darwinian evolution, with randomly occurring point mutations leading to amino acid changes in the two surface glycoproteins, haemagglutinin and neuraminidase, against the selection pressure of previously existing humoral immunity. This enables the virus to evade previously induced immune responses and is the process whereby annual influenza epidemics arise.

Thus, changes caused by antigenic shift or drift render the individual's immune response less able to combat the new variant.

Incidence increases during the winter months. Spread is mainly by droplet infection, but fomites and direct contact have also been implicated. Influenza pandemics of the 20th century are listed in Box 42.30.

In 1997, avian influenza A/H5N1 viruses were first isolated from humans in Hong Kong, raising the spectre of another pandemic. Since then, the virus has spread across the world. There have been several hundred human cases, with a mortality rate approaching 50%. Although this virus is highly pathogenic to humans, because of the induction of a cytokine storm within the lungs, it still has not evolved to achieve efficient human-to-human spread. However, anxieties remain that either genetic reassortment will occur in a human co-infected with human A(H1N1)pdm09 or A(H3N2) virus or adaptive mutations will occur within infected human hosts, such that a truly pandemic strain will emerge.

In April 2009, a novel influenza A virus, now referred to as A(H1N1)pdm09, was identified in patients with severe respiratory illness in Mexico and North America. The virus quickly spread across the world, with the WHO declaring an official pandemic in June 2009. The virus was the end-product of several reassortments between pre-existing swine, avian, and human virus lineages, with the swine H1 protein showing around 20% amino acid sequence divergence from previously circulating human seasonal H1N1 influenza viruses. Although unquestionably highly transmissible (with estimates of millions of infections worldwide within 1 year), this pandemic virus was, fortunately, not especially virulent. Most infections occurred in children; adults older 50 years of age had evidence of pre-existing protective immunity. A minority of infections resulted in serious disease, with an estimated 200 000 deaths worldwide. Risk factors for serious disease included pre-existing underlying medical conditions, age younger than 5 years, obesity, and pregnancy. The pandemic was declared officially over by the WHO in August 2010, the virus now behaving as a normal seasonal influenza virus and replacing the previously circulating A(H1N1) virus.

Box 42.30 Influenza pandemics of the 20th century

Year	Virus subtype	Comments
1918–2019	H1N1	'Spanish' flu; >40 million deaths
1957	H2N2	'Asian' influenza
1968	H3N2	
1976	H1N1	'Russian' influenza; not thought to be a natural occurrence
2009	H1N1pdm09	Derived from swine influenza

Novel influenza viruses may continue to infect humans sporadically, raising the possibility of a new pandemic. In 2013, more than 100 cases of infection with an H7N9 virus were reported from China. As of December 2018, there were 1567 confirmed cases, with 615 deaths. Most patients gave a history of exposure to live animals, including chickens.

Purified haemagglutinin and neuraminidase from recently circulating strains of influenza A and B viruses are incorporated in current vaccines.

The clinical features, diagnosis, treatment, and prophylaxis of influenza are discussed in Chapter 20 ('Influenza' section).

Respiratory syncytial virus infection

RSV is a paramyxovirus that causes many respiratory infections in epidemics each winter. It is a common cause of bronchiolitis in infants, complicated by pneumonia in approximately 10% of cases. The infection normally starts with upper respiratory symptoms. After an interval of 1 to 3 days, a cough and low-grade fever may develop. The onset of bronchiolitis is characterized by dyspnoea and hyperexpansion of the chest with subcostal and intercostal recession. The disease may be severe and potentially fatal in babies with underlying cardiac, respiratory (including prematurity), or immunodeficiency disease. The virus undergoes antigenic drift; consequently, re-infection occurs throughout life. RSV is occasionally the cause of outbreaks of influenza-like illness or pneumonia in older adults (in residential homes) and immunocompromised individuals.

Transfer of infection between children in hospital (hospital-acquired infection) commonly occurs unless infected patients are isolated or cohorted. Meticulous attention to hand-washing and other infection control measures reduces the risk of transmission by staff members.

Diagnosis and management

Genome detection or immunofluorescence on nasopharyngeal aspirates is the usual way of confirming the diagnosis.

Management is generally supportive, but aerosolized ribavirin has been given to patients with severe disease, particularly those with underlying cardiac or respiratory disease.

Prevention

Recent clinical trials have shown the efficacy of both passive and active immunization in preventing the severe consequences of RSV infection in neonates, infants, and in older adults (older than 75 years of age). Passive protection is with nirsevimab, a long-acting monoclonal antibody directed at the viral F protein; active vaccines use a pre-fusion version of the F protein as antigen. National immunization campaigns targeted at the elderly and also pregnant women have now been initiated in several countries to reduce the burden of RSV infection.

Metapneumovirus

Human metapneumovirus belongs to the same virus family as RSV and causes approximately 10% of LRTIs in infants and young children. Infection is clinically indistinguishable from that caused by RSV.

SYSTEMIC VIRAL INFECTIONS

Dengue

This is the most common arthropod-borne viral infection in humans, and its global incidence has increased dramatically in recent years; an estimated 100 to 400 million cases occur every year in the tropics, with more than 10000 deaths from severe dengue (previously known as haemorrhagic fever) (Fig. 42.13). Dengue is caused by a flavivirus. The disease is endemic in all tropical regions, including northern Australia, most South-east Asian countries, tropical Africa and the Middle East, and Caribbean countries. Cases of dengue are also imported into the continental USA and Europe (e.g., Italy) via tourists returning from endemic countries.

Viruses spread by insects are collectively referred to as arthropod-borne viruses, or arboviruses (Boxes 42.31 and 42.32). Four different antigenic serotypes of dengue virus are recognized, and all are transmitted by the daytime-biting mosquito *Aedes aegypti*, which breeds in standing water in refuse dumps in inner cities. *Aedes albopictus* is a less common transmitter. Humans are infective during the first 3 days of the illness (viraemic stage; Fig. 42.14). Mosquitoes become infective about 2 weeks after feeding on an infected individual and remain so for life. The disease is usually endemic. Heterotypic immunity between serotypes after the illness is partial and lasts only a few months, although homotype immunity is life-long.

Clinical features

The incubation period is 5 to 6 days after the mosquito bite. Asymptomatic or mild infections are common. Two clinical forms are recognized (see Fig. 42.15).

Classic dengue fever

Classic dengue fever is characterized by the abrupt onset of fever, malaise, headache, facial flushing, retrobulbar pain that worsens on eye movements, conjunctival suffusion, and severe backache, which is a prominent symptom. Lymphadenopathy, petechiae on the soft palate, and transient morbilliform skin rashes may also

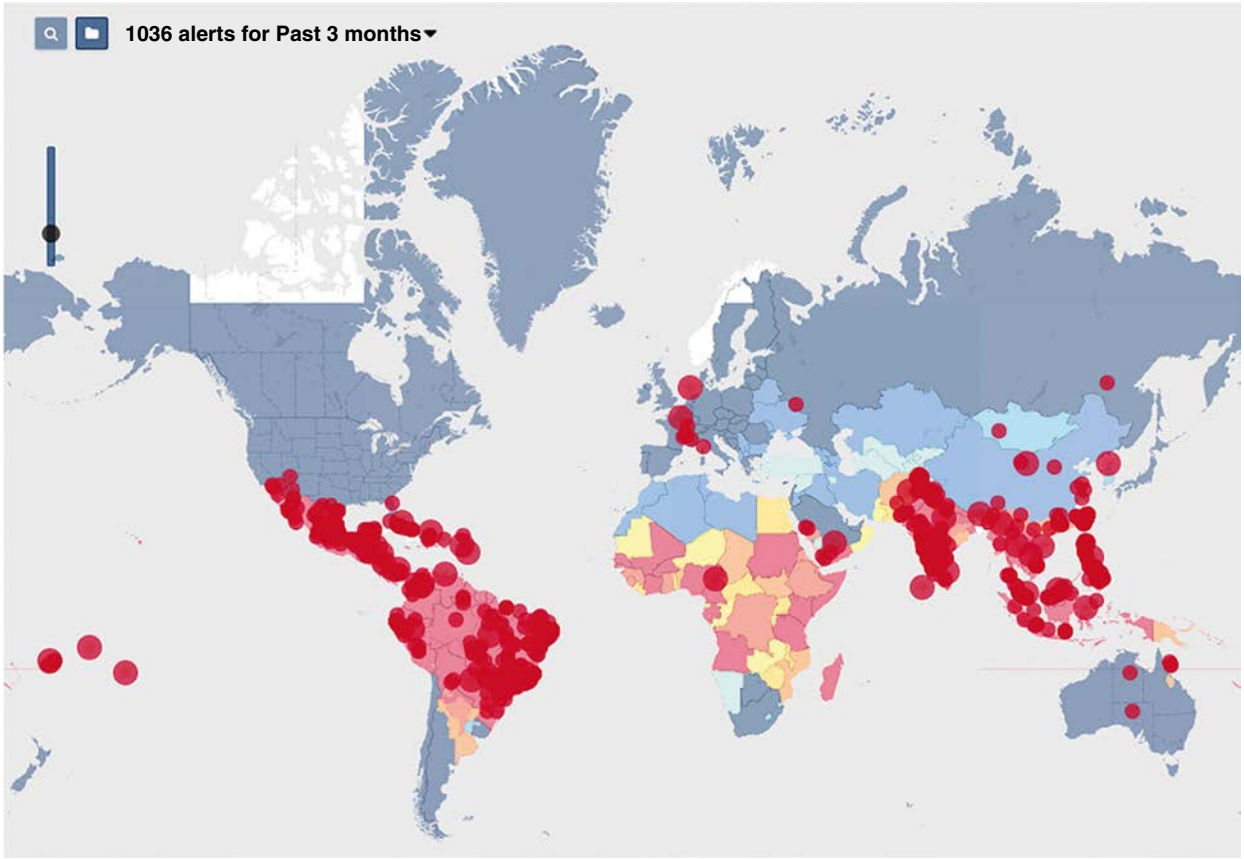

Fig. 42.13 Global dengue burden. Map lines delineate study areas and do not necessarily depict accepted national boundaries.

Box 42.31 Arbovirus (arthropod-borne) infection

Defining features of arboviruses

- Arboviruses are zoonotic viruses, transmitted through the bites of insects, especially mosquitoes and ticks.
- >385 viruses are classified as arboviruses.
- Most are members of the families of togaviruses, flaviviruses, and bunyaviruses (see **Box 42.32**).
- *Culex*, *Aedes*, and *Anopheles* mosquitoes account for transmission of the majority of these viruses.

Clinical features of arbovirus infection

- Most arbovirus diseases are generally mild; epidemics are frequent, and when they occur, the mortality rate is high.
- In general, the incubation period is short (<10 days). Common features include a biphasic illness, pyrexia, conjunctival suffusion, a rash, retro-orbital pain, myalgia, and arthralgia. Lymphadenopathy is seen in patients with dengue.
- ***Haemorrhage*** (from increased vascular permeability, capillary fragility, consumptive coagulopathy) is a feature of some arbovirus infections (see **Box 42.37**).
- ***Encephalitis*** resulting from cerebral invasion may be prominent in some arbovirus fevers.

Box 42.32 Some arboviruses

E, Encephalitis; *F*, febrile illness; *H*, haemorrhagic disease.

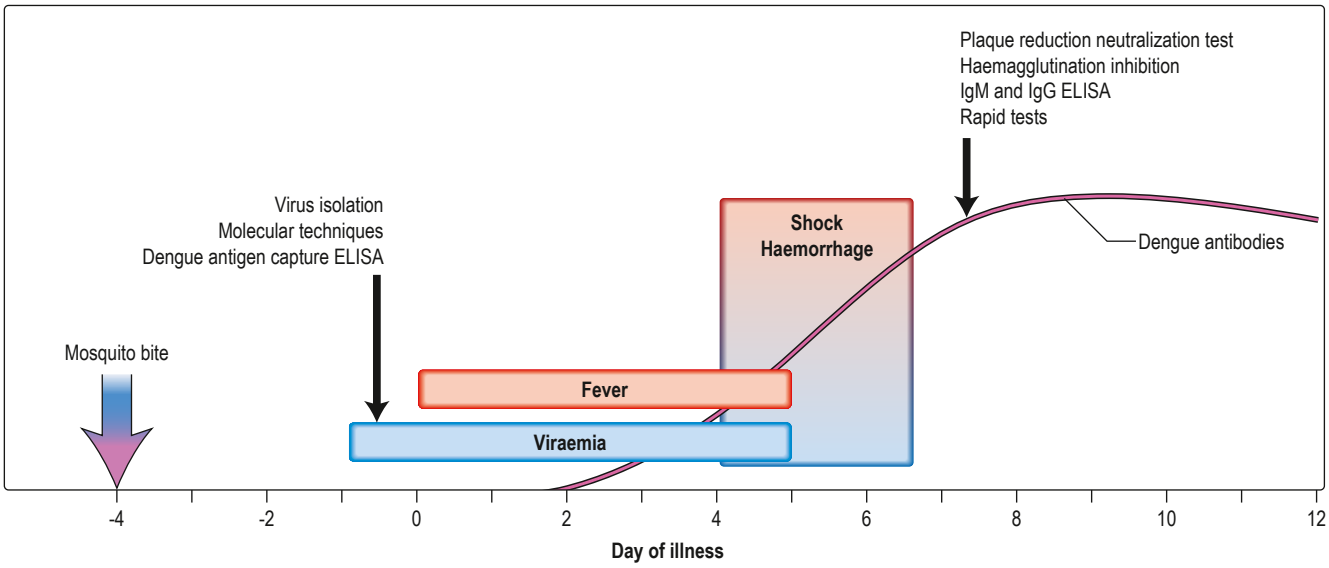

Fig. 42.14 Dengue infection: course and timing of diagnosis. *ELISA*, Enzyme-linked immunosorbent assay; *Ig*, immunoglobulin. *(From Halstead SB. Dengue.* Lancet *2007; 370:1644–1652, with permission.)*

appear on the limbs with subsequent spread to involve the trunk. Desquamation occurs subsequently. Cough is uncommon. The fever subsides after 3 to 4 days, the temperature returning to normal for a couple of days, after which the fever returns, together with the features already mentioned but milder. This biphasic or 'saddleback' pattern is considered characteristic. Severe fatigue, a feeling of being unwell, and depression are common for several weeks after the fever has subsided.

Severe dengue

Severe dengue is potentially deadly and is believed to arise from two or more sequential infections with different dengue serotypes. It is characterized by the capillary leak syndrome, thrombocytopenia, haemorrhage, hypotension, and shock. It is characteristically a disease of children, occurring most commonly in South-east Asia. The disease has a mild start, often with symptoms of an URTI. This is followed by the abrupt onset of shock and haemorrhage into the skin and ear, epistaxis, haematemesis, and melaena, known as the ***dengue shock syndrome***, which has a mortality rate of up to 44%. Serum complement levels are depressed, and there is laboratory evidence of DIC (see Chapter 38, 'Disseminated intravascular coagulation' section).

Diagnosis and management

- Isolation of dengue virus by tissue culture or detection of viral RNA by genome amplification in sera obtained during the first few days of illness is diagnostic.
- Detection of virus-specific IgM antibodies or of rising IgG titres in sequential serum samples confirms the diagnosis.
- Blood tests show leucopenia and thrombocytopenia.

Management is supportive, with analgesics and adequate fluid replacement. Corticosteroids are of no benefit, and convalescence can be slow. In dengue haemorrhagic fever, blood transfusion may be necessary, as well as intensive care support.

Prevention

Travellers should be advised to sleep under impregnated nets, but this is not very effective because the mosquito bites in the daytime. Topical insect repellents should be used. Adult mosquitoes should be destroyed by sprays, and breeding sites, such as small pools of stagnant water, should be eradicated. A live recombinant tetravalent dengue vaccine has been licensed, although it should only be administered to individuals who have evidence of previous dengue infection because in naïve individuals, immunization may increase the risk of subsequent dengue shock syndrome.

Zika virus infection

Zika virus, a flavivirus closely related to dengue viruses, came to prominence in 2016 after an explosive pandemic throughout South and Central America and the Caribbean. Like dengue, Zika is an arbovirus, transmitted to humans by *Aedes* mosquitoes. Illness, when it arises, is usually unremarkable, with fever, myalgia, eye pain, prostration, and maculopapular rash, with spontaneous resolution, although infection may also be associated with Guillain–Barré syndrome, neuropathy and myelitis. However, the epidemiological association of Zika virus outbreaks with subsequent dramatic increases in the number of cases of microcephaly in infants (e.g., Brazil reported a 20-fold increase in incidence from 2014 to 2015) led the WHO to declare Zika a public health emergency of international concern. Accurate diagnosis of infection is complicated by serological cross-reactivity with dengue viruses.

Chikungunya

Chikungunya virus is an alphavirus, a genus within the family of togaviruses. There are eight alphaviruses that result in human disease, and all are arboviruses, transmitted by mosquitoes. They are globally distributed and tend to acquire their names from the location where they were first isolated (e.g., Ross River, Eastern, Venezuelan, and Western equine encephalitis viruses) or from the local expression for a major symptom caused by the virus (e.g., chikungunya, meaning 'doubled up'). Chikungunya infection is characterized by fever, headache, maculopapular skin rash, arthralgia, myalgia, and sometimes encephalitis. After 1 year, at least 20% of patients still have recurrent joint pains. The mortality rate is approximately 0.1%, mostly in very old and very young patients.

Major epidemics of chikungunya, spread via *A. aegypti* or *A. albopictus*, were reported in India, Sri Lanka, and islands in the Indian Ocean (including Reunion, Mauritius, and the Seychelles) in 2005 and 2006, with at least 1 million cases and several hundred deaths. The severity of these epidemics is possibly due to a viral strain, with mutations resulting in a higher neurovirulence. Several European countries reported cases of chikungunya in returning travellers, including 133 cases in the UK in 2006. The increased numbers of infected returning travellers may result in the local *Aedes* mosquito population becoming infected, giving rise to outbreaks in countries where it has not previously been described, for example, in Italy (2007) and the French mainland (2010). In 2013, an outbreak in the Caribbean islands spread to contiguous Central and South American countries, and more than 200 cases were reported in 2014 in the USA. Clinical diagnosis is complicated by the similarities with dengue and zika virus infections. Detection of viral RNA in blood samples taken early in the illness is the gold standard for laboratory confirmation.

A number of chikungunya vaccines are currently undergoing clinical trials.

Infectious mononucleosis: Epstein–Barr virus infection

Globally, most individuals are infected with the herpesvirus EBV at an early age (0–5 years), at which time clinical symptoms are unusual. Infection at an older age is associated with an acute febrile illness known as infectious mononucleosis (glandular fever), which occurs worldwide in adolescents and young adults. EBV is probably transmitted in saliva and by aerosol.

Clinical features

The predominant symptoms of infectious mononucleosis are fever, headache, malaise, and sore throat. Palatal petechiae and a transient macular rash are common, the latter occurring in 90% of patients who have received ampicillin (inappropriately) for the sore throat. Cervical lymphadenopathy, particularly of the posterior cervical nodes, and splenomegaly are characteristic. Mild hepatitis is common, resulting in clinical jaundice in 10% of young adults, but other complications such as myocarditis, meningitis, encephalitis, mononeuritis multiplex, cerebellar ataxia, and mesenteric adenitis are rare. Splenic rupture may occur in the first 3 weeks of illness, and contact sport should be avoided during this period. Some young adults may remain debilitated and depressed for some months after infection.

The site of EBV latency is resting memory B lymphocytes. Evidence for reactivation of latent virus in healthy individuals is controversial, although this does occur in immunocompromised patients. Severe, often fatal, infectious mononucleosis may result from a rare

X-linked lymphoproliferative syndrome affecting young boys. Those who survive have an increased risk of hypogammaglobulinaemia and lymphoma. EBV is the cause of oral hairy leucoplakia in AIDS patients and is intimately linked to the generation of a number of malignancies (see later). EBV is a cause of haemophagocytic lymphohistiocytosis (HLH), a rare condition presenting with fever, rash, jaundice, hepatosplenomegaly, and enlarged lymph nodes. Blood tests show cytopenia and a high ferritin level, and the bone marrow shows haemophagocytosis. HLH can be primary (inherited) or secondary (e.g., to EBV) and has a high mortality rate.

Diagnosis

EBV infection should be strongly suspected if atypical mononuclear cells (activated CD8-positive T lymphocytes) are found in the peripheral blood in large numbers. It can be confirmed during the second week of infection by a positive Paul–Bunnell reaction, which detects heterophile antibodies (IgM) that agglutinate sheep erythrocytes, in around 90% of cases. False-positives can occur in other conditions, such as viral hepatitis, Hodgkin lymphoma, and acute leukaemia. The Monospot test is a sensitive and easily performed screening test for heterophile antibodies. Specific EBV IgM antibodies indicate recent infection by the virus. Clinically similar illnesses are produced by CMV, toxoplasmosis, and acute HIV infection (the so-called seroconversion illness), but these can be distinguished serologically.

Management

The majority of cases require no specific treatment, and recovery is rapid. Corticosteroid therapy is advised when there is neurological involvement (e.g., encephalitis, meningitis, Guillain–Barré syndrome), marked thrombocytopenia or haemolysis, or tonsillar enlargement that is so marked as to cause respiratory obstruction.

Cytomegalovirus infection

Clinically significant CMV infection arises in two patient groups in particular:

- Fetuses who acquire the infection transplacentally and are born congenitally infected
- Patients who are immunocompromised, such as transplant recipients and people with HIV infection.

As with all herpesviruses, CMV persists for life, usually as a latent infection in cells of the monocyte/macrophage lineage, so it may become reactivated, especially in immunocompromised patients. More than 50% of the adult population has serological evidence of latent CMV infection.

Clinical features

In healthy children and adults, CMV infection is usually asymptomatic but occasionally may result in a glandular fever–like illness, with fever, lymphocytosis with atypical lymphocytes, and hepatitis with or without jaundice. The result of the Paul–Bunnell test for heterophile antibody is negative. Infection may be spread in saliva (accounting for extensive person-to-person spread in childcare units), sexual intercourse, or blood transfusion and transplacentally to fetuses. In an immunocompromised patient, CMV infection may involve multiple organ systems, common manifestations being retinitis, pneumonitis, diffuse involvement of the GI tract, and encephalitis.

Intrauterine infection may arise from either primary or reactivated maternal infection. CMV is, by far, the most common congenital infection; in high-income countries, 0.3% to 1% of all babies are born congenitally infected with CMV. Around 5% to 10% of such babies have severe disease evident at birth, with a poor prognosis (cytomegalic inclusion disease). CNS involvement may cause microcephaly and motor disorders. Jaundice and hepatosplenomegaly

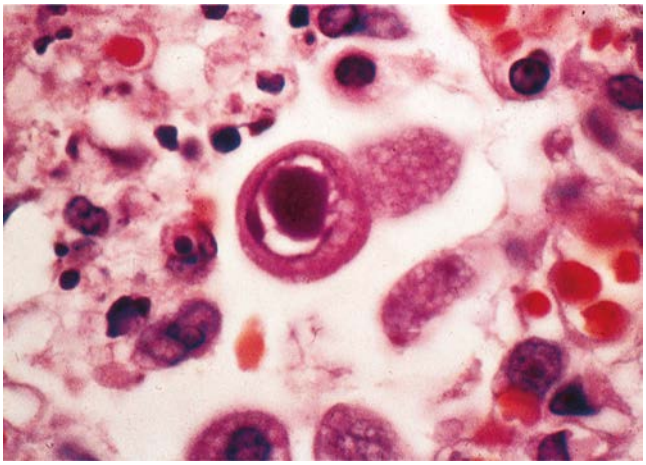

Fig. 42.15 Typical 'owl's eye' inclusion-bearing cell infected with cytomegalovirus.

are common, and thrombocytopenia and haemolytic anaemia also occur. Periventricular calcification is seen on skull X-ray. A further 5% to 10% of infected babies are normal at birth, but developmental abnormalities become apparent later (e.g., sensorineural nerve deafness). The remaining 80% to 85% of infected babies are normal at birth and develop normally.

Diagnosis

Serological tests can identify latent (IgG) or primary (IgM) infection. However, most infections are now diagnosed by detection and quantification of CMV DNA or RNA using molecular amplification techniques in blood or other body fluid samples. The virus can also be identified in tissues by the presence of characteristic intranuclear 'owl's eye' inclusions (see Fig. 42.15) on histological staining and by direct immunofluorescence.

Management

In immunocompetent patients, infection is usually self-limiting, and no specific treatment is required. In immunosuppressed patients, ganciclovir reduces retinitis and GI damage and can eliminate CMV from blood, urine, and respiratory secretions. It is less effective against pneumonitis. In patients who are continually immunocompromised, maintenance therapy may be necessary. Drug resistance may arise during long-term therapy, such as in transplant recipients. Bone marrow toxicity is common. Valganciclovir, foscarnet, cidofovir (and its derivative brincidofovir), and maribavir are also available for treatment and letermovir for prophylaxis (see 'Antiviral drugs' section). Treatment of CMV in neonates is difficult, but therapy of infected babies with evident CNS involvement has been shown to improve long-term hearing outcome, and 6 months of valganciclovir therapy is now recommended for symptomatic neonates.

Mumps

Mumps virus is a paramyxovirus. It is spread by droplet infection, by direct contact, or through fomites. Humans are the only known natural hosts. The peak period of infectivity is 2 to 3 days before the onset of the parotitis and for 3 days afterward.

Clinical features

The incubation period averages 18 days. Although no age is exempt, this is primarily a disease of school-aged children and young adults; it is uncommon before the age of 2 years. The prodromal symptoms are non-specific and include fever, malaise, headache, and

anorexia. This is usually followed by severe pain over the parotid glands, with either unilateral or bilateral parotid swelling (Fig. 42.16). The enlarged glands obscure the angle of the mandible and may elevate the ear lobe, which does not occur in cervical lymph node enlargement. Trismus because of pain is common at this stage. Submandibular gland involvement occurs less frequently.

Complications

CNS involvement is the most common extra-salivary gland manifestation of mumps. Clinical meningitis occurs in 5% of all infected patients, and 30% of patients with CNS involvement have no evidence of parotid gland involvement.

Epididymo-orchitis develops in about one-third of patients who develop mumps after puberty. Bilateral testicular involvement results in sterility in only a small percentage of these patients. Pancreatitis, oophoritis, myocarditis, mastitis, hepatitis, and polyarthritis may also occur.

Diagnosis and management

The diagnosis of mumps is on the basis of the clinical features. Viral RNA can be demonstrated by genome detection assays in saliva, throat swabs, urine, and CSF. Serological demonstration of a mumps-specific IgM response in an acute blood or oral fluid sample is also diagnostic.

Treatment is supportive. Attention should be paid to adequate nutrition and mouth care. Analgesics should be used to relieve pain.

Prevention

Children in the UK are immunized with the live attenuated MMR vaccine (see Box 42.19), and the mumps vaccine is given in most low- and middle-income countries. Vaccination is contraindicated in immunosuppressed individuals, pregnant females, and in those with severe febrile illnesses.

HIV infections

The HIVs belong to the family of retroviruses (Box 42.33) and are characterized by their ability to replicate through a DNA intermediate using the enzyme reverse transcriptase.

HIV-1 and the related virus HIV-2 are further classified as lentiviruses ('slow' viruses) because of their slowly progressive clinical effects. They give rise to the AIDS and are discussed in Chapter 44.

Human T-cell leukaemia/lymphotropic virus infection

Human T-cell leukaemia/lymphotropic virus type 1 (HTLV-1) causes adult T-cell leukaemia/lymphoma and tropical spastic paraparesis.

Myocarditis and skeletal muscle infection

EV infection is a cause of acute myocarditis and pericarditis (see Box 42.27), from which, in general, there is complete recovery. However, these viruses can also cause chronic congestive cardiomyopathy and, rarely, constrictive pericarditis. Skeletal muscle involvement, particularly of the intercostal muscles, is a feature of Bornholm disease, a febrile illness usually caused by coxsackie B viruses. The pain may be of such intensity as to mimic pleurisy or an acute abdomen. The infection affects both children and adults and may be complicated by meningitis or cardiac involvement. Myocarditis and pericarditis are also discussed in Chapter 17 ('Myocarditis' and 'Pericardial disease' sections).

Postviral or chronic fatigue syndrome

Many viral infections, including EBV, coxsackie B viruses, echoviruses, CMV, and hepatitis A virus, are associated with a postviral chronic fatigue syndrome (see Chapter 30, 'Medically unexplained symptoms and functional neurological disorders' section).

VIRUS INFECTIONS OF THE NERVOUS SYSTEM

Acute flaccid paralysis, including poliomyelitis

A number of EVs may infect the nervous system (see Box 42.24), with different clinical outcomes. Infection with polioviruses 1, 2, and 3, classified within EV species C, may result in acute flaccid paralysis (AFP). Polioviruses are excreted in faeces and spread via the

faecal–oral route. They have a propensity for the nervous system, especially the anterior horn cells of the spinal cord and cranial motor neurones.

Clinical features

The incubation period is 7 to 14 days. Although polio is essentially a disease of childhood, no age is exempt. The clinical manifestations vary considerably. The most common outcome (95% of individuals) is asymptomatic seroconversion. AFP, also known as ***paralytic poliomyelitis***, arises in only approximately 0.1% and 1% of infected children and adults, respectively. It follows about 4 to 5 days after an initial illness of fever, sore throat, and myalgia. Meningeal irritation and muscle pain occur and are followed by the onset of asymmetric flaccid paralysis without sensory involvement. Factors predisposing to the development of paralysis include male sex, exercise early in the illness, trauma, surgery, or intramuscular injection, which localize the paralysis, and recent tonsillectomy (bulbar poliomyelitis).

Aspiration pneumonia, myocarditis, paralytic ileus, and urinary calculi are late complications of poliomyelitis.

AFP may also arise from infection with a number of other EVs, and indeed, AFP is now more commonly caused by these viruses than by polioviruses. EV A71, more usually associated with hand, foot, and mouth disease, has a particular predilection for neuroinvasion. Epidemics of EV A71 are not infrequent; an estimated 6 million cases have occurred globally since 2009, with more than 2000 deaths from a variety of serious neuromotor syndromes. Inactivated EV A71 vaccines have been approved for clinical use in China. Acute flaccid myelitis has also been associated recently with outbreaks of EV D68 infection in the USA and UK.

Diagnosis

All cases of AFP must be investigated to exclude poliovirus infection. Diagnosis is by detection of EV RNA in a throat swab, faecal sample, or CSF followed by sequencing to identify precisely which EV is present. Sequencing also enables a distinction to be made between wild poliovirus and vaccine strains.

Management

Management is supportive. Bed rest is essential during the early course of the illness. Respiratory support with intermittent positive-pressure respiration is required if the muscles of respiration are involved.

Prevention and control of poliomyelitis

In 1988, the World Health Assembly adopted the goal of eliminating poliomyelitis worldwide. Since then, the estimated 350 000 cases arising annually in 125 countries have been reduced by more than 99%, with only Pakistan and Afghanistan never having terminated indigenous transmission. Only 30 cases of wild-type poliomyelitis were documented in 2022. The eradication campaign has relied on improvements in sanitation, hygiene, and the widespread use of polio vaccines. However, spread of infection via travel from endemic countries is an ongoing threat. The creation of a poliomyelitis-free world remains the goal, and the WHO Polio Eradication Strategy 2022–2026 describes a pathway to a world free of this infection. However, a temporary halt to immunization campaigns during the COVID pandemic put more than 80 million children at risk, with outbreaks of circulating vaccine-derived poliovirus (cVDPV, arising from mutations in the oral polio vaccine strains after delivery) tripling from 2019 to 2020, and more than 1100 children paralyzed. Vaccination remains the bedrock of the campaign. New vaccine preparations include an oral vaccine containing a more genetically stable polio type 2 virus and inactivated intramuscular poliovirus vaccines (IPV) with greater potency than the original Salk IPV. The greater reliability of IPV in hot climates and the scientific and ethical problems of continuing to use oral polio vaccine (OPV) in countries free from poliomyelitis mean that IPV has replaced OPV in the routine immunization schedules in many countries.

Meningitis

EVs are the most common viral cause of aseptic meningitis, although a number of other viruses may also result in this syndrome (**Box 42.34**).

Encephalitis

Encephalitis may arise by direct virus invasion of nervous tissue or by induction of an aberrant cross-reactive immune response (post-infectious encephalitis). Although HSV is the most common cause of sporadic encephalitis worldwide, a number of other virus infections may also present with an encephalitic illness.

Japanese encephalitis

Japanese encephalitis is a mosquito-borne encephalitis caused by a flavivirus. It has been reported most frequently in the rice-growing countries of South-east Asia and the Far East. *Culex tritaeniorhynchus* is the usual vector and feeds mainly on pigs, as well as birds such as herons and sparrows. Humans are accidental hosts.

The incubation period is 5 to 15 days. Most infections are asymptomatic. When disease arises, the onset is heralded by severe rigors. Fever, headache, and malaise last 1 to 6 days. Weight loss is prominent. In the acute encephalitic stage, the fever is high (38°–41°C); neck rigidity occurs; and neurological signs, such as altered consciousness, hemiparesis, and convulsions, develop. Mental deterioration occurs over a period of 3 to 4 days and culminates in coma. The mortality rate varies from 7% to 40% and is higher in children. Residual neurological defects, such as deafness, emotional lability, and hemiparesis, occur in about 70% of patients who have had CNS involvement. Convalescence is prolonged. Antibody detection in serum and CSF by IgM capture ELISA is a useful rapid diagnostic test. Vaccines containing formalin-inactivated viruses derived from mouse brain are available and effective. Management is supportive.

West Nile encephalitis

West Nile virus was first recognized in the Western hemisphere (New York, USA) in 1999, having been previously reported in Africa, Asia, and parts of Europe. By the end of 2009, the US outbreak had resulted in more than 25 000 human cases and more than 1100 deaths. The vast majority of infections are asymptomatic. In a minority of cases, infection presents as a febrile illness with a maculopapular rash, 1% resulting in severe encephalitis. Disease severity and mortality are age related, being greatest in older adults. The primary hosts of infection are birds. It is spread by mosquitoes (*Culex* spp.) and may also infect humans and horses. It can also be transmitted by blood transfusions, breast-feeding, and organ donation from an infected individual. Diagnosis is by genome detection in appropriate samples or specialized serology for the detection of IgM virus-specific antibodies.

Tick-borne encephalitis

This arises from infection with a flavivirus (actually a series of closely related viruses) transmitted by *Ixodes* spp. ticks. It occurs in an area extending from Western Europe to Japan. The tick is the main reservoir for the virus, which is transmitted when it feeds on mice and other rodents.

Box 42.34 Viral causes of meningitis and encephalitis

Virus	Comments	Outcome
Meningitis		
Enteroviruses, especially enterovirus B species (coxsackie B and echoviruses)	Commonest cause of viral meningitis	Relatively benign prognosis
Mumps virus	Rare in countries with MMR vaccine policy. May occur in absence of parotitis	Relatively benign prognosis
Herpes simplex viruses	More common in women and may recur—Mollaret's meningitis	Benign prognosis in absence of signs of encephalitis
Encephalitis, direct invasion		
Herpes simplex viruses	Most common cause of sporadic encephalitis; any age	High morbidity and mortality
Mumps virus	Spread from meninges, resulting in meningo-encephalitis	Most patients recover
Measles virus	Subacute sclerosing encephalitis	Rare, high mortality rate
Varicella zoster virus	May cause vasculitis	May arise with reactivation (shingles)
Cytomegalovirus	Only in immuno-compromised	Poor prognosis
Enteroviruses	EV 71; otherwise, usually in immuno-compromised only	
HIV	Dementia is the main feature	
Japanese encephalitis virus	Flavivirus, mosquito borne	
West Nile encephalitis virus	Flavivirus, mosquito borne	Birds are the primary hosts; higher mortality rate in older adults
Tick-borne encephalitis viruses	Flaviviruses, tick borne	
Lymphocytic choriomeningitis virus	Arenavirus	House mouse is primary host
Hendra, Nipah viruses	Paramyxoviruses	Zoonotic infections from horses, pigs
Rabies virus	Acquired from animal or bat bite	Almost always fatal
JC virus	Only in immuno-compromised	Results in progressive multifocal leucoencepha-lopathy
Eastern, Venezuelan encephalitis viruses	Alphaviruses, mosquito borne	Geographically restricted to the Americas
Encephalitis, post-infectious		
May arise from a number of different virus infections, including measles (1 in 1000–5000 cases of measles), influenza, varicella zoster		

EV, Enterovirus; *HIV,* human immunodeficiency virus.

The disease starts 4 to 28 days after a bite from an infected tick and is biphasic in 80% of patients. After a symptom-free period of about 7 days, fever, malaise, headache, and fatigue are followed by encephalitis. There may be associated limb paralysis, which is caused by anterior horn cell involvement, mainly of the cervical region. Cranial nerve involvement also occurs. Tick-borne encephalitis virus IgM and IgG antibodies are present, and the virus can be detected in blood by genome detection assays. The overall mortality rate is about 1% (but can be considerably higher for certain strains); 30% of patients have impairment in neurological function with persistent paralysis in 6%. A preventive vaccine is available.

Lymphocytic choriomeningitis

This infection is a zoonosis, the natural reservoir of lymphocytic choriomeningitis virus (an arenavirus; see **Box 42.25**) being the house mouse. Infection is by inhalation from urine-contaminated rubbish and is characterized by:

- Non–nervous system illness, with fever, malaise, myalgia, headache, arthralgia, and vomiting
- ***Meningitis*** in addition to the above symptoms.

Occasionally, a more severe form occurs, with encephalitis leading to disturbance of consciousness.

This illness is generally self-limiting and requires no specific treatment.

Hendra and Nipah virus infection

Hendra and Nipah viruses cause zoonotic infections in humans who have been in contact with infected animals (horses and pigs, respectively). The viruses are named after the locations where they were first isolated: Hendra in Australia and Nipah in Malaysia. Both are classified as paramyxoviruses, and fruit bats are their natural hosts. Hendra virus has caused severe respiratory distress in horses and humans, and Nipah virus caused a major outbreak of viral encephalitis (265 cases and 105 deaths) in Malaysia between September 1998 and April 1999. Subsequent outbreaks have been reported in India and Bangladesh. Management of these conditions is supportive, and no vaccines are currently available.

Rabies

Rabies is a major problem in some countries, with an estimated tens of thousands of deaths per year worldwide. Established infection is almost invariably fatal; there are only a handful of recorded cases of survival from clinical rabies. It is caused by the rabies virus, a single-stranded RNA virus of the lyssavirus genus within the family of rhabdoviruses. The virus is bullet shaped and has spike-like structures arising from its surface containing glycoproteins that cause the host to produce neutralizing, haemagglutination-inhibiting antibodies. The virus has a marked affinity for nervous tissue and the salivary glands. It exists in two major epidemiological settings:

- ***Urban rabies*** is most frequently transmitted to humans through rabid dogs and, less frequently, cats.
- ***Sylvan (wild) rabies*** is maintained in the wild by a host of animal reservoirs such as foxes, skunks, jackals, mongooses, and bats.

With the exceptions of Australia, New Zealand, and the Antarctic, human rabies has been reported on all continents. Transmission is usually through the bite of an infected animal, most commonly a dog. However, the percentage of rabid bites leading to clinical disease ranges from 10% (on the legs) to 80% (on the head). Other forms of transmission, if they occur, are rare.

The virus replicates in the muscle cells near the entry wound. It penetrates the nerve endings and travels in the axoplasm to the

spinal cord and brain. In the CNS, the virus again proliferates before spreading to the salivary glands, lungs, kidneys, and other organs via the autonomic nerves.

Clinical features

The incubation period is variable, ranging from a few weeks to several years; on average, it is 1 to 3 months. In general, bites on the head, face, and neck have a shorter incubation period than those elsewhere. In humans, two distinct clinical varieties of rabies are recognized:

- ***Furious rabies***, the classic variety. The only characteristic feature in the prodromal period is the presence of pain and tingling at the site of the initial wound. Fever, malaise, and headache are also present. About 10 days later, marked anxiety and agitation or depressive features develop. Hallucinations, bizarre behaviour, and paralysis may also occur. Hyperexcitability, the hallmark of this form of rabies, is precipitated by auditory or visual stimuli. Hydrophobia (fear of water) is present in 50% of patients and is caused by severe pharyngeal spasms on attempting to eat or drink. Aerophobia (fear of air) is considered pathognomonic of rabies. Examination reveals hyper-reflexia, spasticity, and evidence of sympathetic overactivity indicated by pupillary dilation and diaphoresis. The patient goes on to develop convulsions, respiratory paralysis, and cardiac arrhythmias. Death usually occurs in 10 to 14 days.
- ***Dumb rabies***, the paralytic variety. This presents with a symmetrical ascending paralysis that resembles Guillain–Barré syndrome.

Diagnosis

The diagnosis of rabies is generally made clinically. Skin-punch biopsies are used to detect antigen with an immunofluorescent antibody test on frozen section. Viral RNA can be detected by genome amplification. Isolation of virus from saliva or the presence of antibodies in blood or CSF may establish the diagnosis. Negri bodies are detected at postmortem in 90% of all patients with rabies; these are eosinophilic, cytoplasmic, ovoid bodies, 2 to 10 nm in diameter, seen in greatest numbers in the neurones of the hippocampus and the cerebellum. The diagnosis should be made pathologically on the biting animal using genome amplification, immunofluorescence on brain tissue using fluorescently labelled anti-rabies antibody, or tissue culture of the brain.

Management

When CNS disease is established, therapy is symptomatic because death is virtually inevitable. The patient should be nursed in a quiet, darkened room. Nutritional, respiratory, and cardiovascular support may be necessary.

Drugs such as morphine, diazepam, and chlorpromazine should be used liberally in patients who are excitable.

Prevention and control

Pre-exposure prophylaxis

This is given to individuals with a high risk of contracting rabies, such as laboratory workers, animal handlers and veterinarians. Three doses of human diploid (HDCV) or purified chick embryo cell vaccine, given by deep subcutaneous or intramuscular injection on days 0, 7, and 28, provide effective immunity. A reinforcing dose is given after 12 months, and additional reinforcing doses are given every 3 to 5 years, depending on the risk of exposure. Vaccines of nervous tissue origin are still used in some parts of the world. These, however, are associated with significant side-effects and should not be used if HDCV is available.

Post-exposure prophylaxis

The wound should be cleaned carefully and thoroughly with soap and water, and left open. Human rabies immunoglobulin should be given immediately (20 IU/kg); half should be injected around the area of the wound, and the other half should be given intramuscularly. Four 1.0-mL doses of HDCV should be given intramuscularly: the first dose is given on day 0 and is followed by injections on days 3, 7, and 21. Reaction to the vaccine is uncommon. Protection mediated by this protocol is almost 100%.

Control

Domestic animals should be vaccinated if there is any risk of rabies in the country. In the UK, control has been by quarantine of imported animals for 6 months, and no indigenous case of rabies has been reported for many years. The Pet Travel Scheme (PETS) enables certain pet animals to enter or re-enter Great Britain without quarantine if they come from qualifying countries via designated routes, are carried by authorized transport companies, and meet the conditions of the scheme. Wild animals in 'at-risk' countries must be handled with great care.

Progressive multifocal leucoencephalopathy

JC virus, a polyomavirus, is the cause of progressive multifocal leucoencephalopathy (PML), which presents as dementia in the immunocompromised and is caused by multiple foci of demyelination in cerebral white matter. Virus replicates in the nucleus of oligodendrocytes, resulting in cell lysis and breakdown of the myelin sheath. The virus is usually acquired in childhood and may reactivate if the host immune system becomes compromised in later life. Reactivation of JC virus and development of PML have recently been described in patients with multiple sclerosis treated with the monoclonal antibody natalizumab directed against the cell adhesion molecule, α4-integrin.

VIRUS INFECTIONS OF THE GASTROINTESTINAL TRACT

Virus infections that commonly result in acute gastroenteritis (diarrhoea and vomiting) are listed in **Box 42.35**.

Rotavirus infection

Rotaviruses are a major cause of infantile gastroenteritis worldwide. The virus (Latin *rota*, meaning wheel) is so named because of its electron microscopic appearance with a characteristic circular outline and radiating spokes (**Fig. 42.17**). It belongs to the reoviruses family, which have double-stranded RNA segmented genomes. More than 200 000 infected children younger than the age of 5 years are estimated to die annually in resource-deprived countries. The prevalence is higher during the winter months in non-tropical areas. Asymptomatic infections are common and bottle-fed babies are more likely to be symptomatic than those that are breast-fed.

Adults may become infected with rotavirus, but the symptoms are usually mild or absent. The virus may, however, cause diarrhoea

Box 42.35 Viruses associated with gastroenteritis

- Rotaviruses (groups A, B, and C)
- Enteric adenoviruses (types 40 and 41)
- Caliciviruses (includes noroviruses and sapoviruses)
- Astroviruses

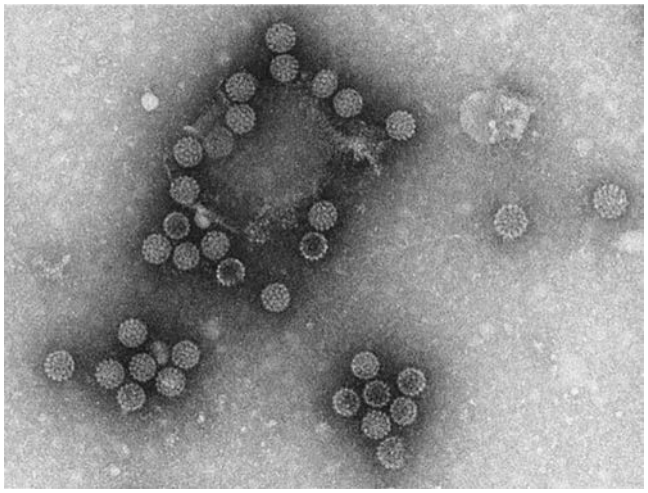

Fig. 42.17 Electron micrograph of human rotavirus.

in immunosuppressed adults or outbreaks in patients on care in older adult wards.

Clinical features

The illness is characterized by vomiting, fever, diarrhoea, and the metabolic consequences of water and electrolyte loss.

Diagnosis and differential diagnosis

The diagnosis can be established by genome amplification, or ELISA for the detection of rotavirus antigen in faeces and by electron microscopy of faeces. Histology of the jejunal mucosa in children shows shortening of the villi, with crypt hyperplasia, and mononuclear cell infiltration of the lamina propria.

Management and prevention

Management is directed at overcoming the effects of water and electrolyte imbalance with adequate oral rehydration therapy and, when indicated, intravenous fluids (**Box 42.36**). Antibiotics should not be prescribed.

Rotavirus vaccines

Despite a major setback when the first licensed rotavirus vaccine was rapidly withdrawn from the market in 1999 after reports of increased rates of intussusception, two live vaccines have been developed and are now used in many countries. One (Rotarix) contains an attenuated human strain, the relevant antigens being P[8] and G1; the other (Rotateq) is based on a bovine parent strain and comprises five single-gene reassortants, each containing a human-strain outer capsid gene encoding the most common human antigenic types (P[8] and G1–4). Routine rotavirus vaccination (two doses at 8 and 12 weeks of age) was introduced in the UK in 2012. Vaccine efficacy against severe rotavirus gastroenteritis is around 90%.

Calicivirus infection

The caliciviruses are an extensive virus family, named after the cup-shaped (Latin *calyx*, meaning cup) indentations on their viral surface seen by electron microscopy. The family contains four genera, two of which, the noroviruses and sapoviruses, infect humans and cause gastroenteritis.

Norovirus is the major cause of acute non-bacterial gastroenteritis, causing outbreaks in nursing homes, hospitals, schools, leisure centres, and restaurants and on cruise ships. In countries that have adopted routine rotavirus vaccination of infants, norovirus has become the leading cause of clinically significant acute gastroenteritis in children. Transmission is mostly faecal–oral, with outbreaks suggesting a common source, such as food and water, and fomites. Aerosol transmission also occurs, and noroviruses can be detected in vomit. Illness is usually self-limiting (12–48 hours) and mild, consisting of nausea, headache, and abdominal cramps followed by diarrhoea and vomiting, which may be the only feature (winter vomiting). Diagnosis is by demonstration of viral nucleic acid or antigen in diarrhoeal faeces. Treatment is with oral rehydration solutions. Prevention can be difficult, but hand-washing and good hygienic food preparation are required.

Sapovirus causes gastroenteritis, mainly in children.

Omatola CA, Olaniran AO. Rotaviruses: from pathogenesis to disease control—a critical review. *Viruses* 2022; 14(5):875.

VIRAL HEPATITIS

A number of distinct virus infections may result in inflammation of the liver (hepatitis). The viruses belong to different virus families, are spread by different routes and may have differing clinical consequences (see **Box 34.7**). Viral hepatitis is discussed further in Chapter 23 ('Viral hepatitis' section).

VIRUSES AND MALIGNANT DISEASE

Around 15% to 20% of all human malignant disease arises from infection. Recognition of the infectious cause of a particular cancer raises the possibility of developing an anticancer vaccine, as has now happened for both HBV and human papillomavirus (HPV).

Hepatitis viruses and primary hepatocellular carcinoma

Globally, hepatocellular carcinoma is the second most common cause of death from malignant disease. A high percentage arises in patients infected with either HBV or HCV (see Chapter 23).

Human papillomaviruses and cancer of the uterine cervix

Papillomaviruses tend to produce chronic infections (see Chapter 45, 'Human papillomavirus' section). HPVs, of which there are at least 100 types, are responsible for the common skin and genital warts, and certain types (mainly 16 and 18) are the cause of carcinoma of the cervix, cancers in other genital areas (vagina, vulva, penis, anus), and some oral cancers (type 16). Multivalent vaccines against a number of HPV types (but always including 16 and 18) are available. The current recommendations in many countries are for vaccination of all girls at age 9 to 14 years, although some countries (including the UK) are increasingly opting to vaccinate both boys and girls. (For ***anogenital warts***, see Chapter 43, 'Human papillomavirus [anogenital warts]' section.)

Box 42.36 Oral rehydration solutions and intravenous solutions used in moderate and severe diarrhoea[a]

Solution	Salts (mmol/L)				Substance added (per L of water)

[a]In children younger than 5 years of age, zinc supplements (10 mg/day in those younger than 6 months; 20 mg/day in those older than 6 months) should ideally be given along with oral rehydration solution.
[b]Oral rehydration solution should be administered by encouraging the patient to take small, regular sips of fluid. If vomiting occurs, administration should be paused for 10 minutes and then cautiously restarted. Oral rehydration solution can be administered via a nasogastric tube if swallowing is impaired. If patients are severely dehydrated, intravenous fluids are preferred.
[c]Contains Ca^{2+} 2 mmol/L and HCO_3^- (as lactate).
WHO, World Health Organization.

Epstein–Barr virus and malignant disease

EBV infection has been associated with a number of malignant diseases, including Burkitt lymphoma, undifferentiated nasopharyngeal carcinoma, post-transplant lymphoproliferative disease, the immunoblastic lymphoma of patients with AIDS, some forms of Hodgkin lymphoma, and gastric cancer. Different levels of expression of EBV latency genes occur in patients with these proliferative conditions, and various co-factors are also involved in their pathogenesis; for example, in Burkitt lymphoma, the most common tumour of childhood in sub-Saharan Africa, epidemiological evidence points to an interplay between EBV infection and the presence of hyperendemic (i.e., present all year round) malaria.

Kaposi's sarcoma and human herpesvirus type 8

HHV-8 is strongly associated with the aetiology of all forms of Kaposi's sarcoma. Antibody prevalence is high in those with tumours but relatively low in the general population of most industrialized countries. High rates of infection (>50% population) have been described in Central and Southern Africa, and this matches the geographical distribution of classical Kaposi's sarcoma before the era of AIDS. HHV-8 is transmitted sexually and through exposure to blood from needle sharing. It is thought that salivary transmission may be the predominant route in Africa. HHV-8 RNA transcripts have been detected in Kaposi's sarcoma cells and in circulating mononuclear cells from patients with the tumour. This virus also has an aetiological role in two rare lymphoproliferative diseases: multicentric ***Castleman's disease*** (a disorder of the plasma cell type) and ***primary effusion lymphoma*** (body cavity–based lymphoma), which is characterized by pleural, pericardial, or peritoneal lymphomatous effusions in the absence of a solid tumour mass.

Other rare malignancies caused by virus infections

HTLV-1, a lentivirus belonging to the same virus family as HIV, is the aetiological agent of adult T-cell leukaemia/lymphoma. Merkel cell polyomavirus has been identified in the malignant tissue of the rare Merkel cell carcinoma of the skin.

VIRAL HAEMORRHAGIC FEVERS

These comprise infection with a range of different viruses (**Box 42.37**), which have in common the clinical feature of haemorrhagic manifestations.

Yellow fever

Yellow fever, caused by a flavivirus, is an illness of widely varying severity. It is confined to Africa (90% of cases) and South America between latitudes 15°N and 15°S. For poorly understood reasons, yellow fever has not been reported from Asia even though climatic conditions are suitable and the vector, *A. aegypti*, is common. The infection is transmitted in the wild by *Aedes africanus* in Africa and *Haemagogus* spp. in South and Central America. Extension of infection to humans (via the mosquito from monkeys) leads to the occurrence of 'jungle' yellow fever. *A. aegypti*, a domestic mosquito that lives in close relationship to humans, is responsible for human-to-human transmission in urban areas (urban yellow fever). After being infected, a mosquito remains so for life.

Clinical features

The incubation period is 3 to 6 days. Mild infection is indistinguishable from other viral fevers such as influenza and dengue.

Three phases are recognized in the severe (classical) illness. Initially, the patient presents with a high fever of acute onset, usually 39° to 40°C, which then returns to normal in 4 to 5 days. During this time, headache is prominent. Retrobulbar pain, myalgia, arthralgia, a flushed face, and suffused conjunctivae are common. Epigastric discomfort and vomiting are present when the illness is severe.

Box 42.37 Viral infections associated with haemorrhagic manifestations[a]

Flavivirus
- Yellow fever (urban and sylvan)
- Dengue haemorrhagic fever
- Kyasanur Forest disease
- Omsk haemorrhagic fever

Phenuivirus
- Rift Valley fever

Orthonairovirus
- Congo–Crimean haemorrhagic fever

Hantavirus
- Hantavirus infections

Arenavirus
- Argentinian haemorrhagic fever
- Bolivian haemorrhagic fever
- Lassa fever
- Epidemic haemorrhagic fever

Filovirus
- Marburg
- Ebola

[a]Most of these are arboviruses. Some (e.g., hantavirus, Lassa fever) have a rodent vector. The source and transmission route of filoviruses are not known.

Relative bradycardia (Faget's sign) is present from the second day of illness. The patient then makes an apparent recovery and feels well for several days. After this 'phase of calm', the patient again develops increasing fever, deepening jaundice, and hepatomegaly. Ecchymosis, bleeding from the gums, haematemesis, and melaena may occur. Coma, which is usually a result of uraemia or haemorrhagic shock, occurs for a few hours preceding death. The mortality rate is up to 40% in severe cases. Liver pathology shows mid-zone necrosis and eosinophilic degeneration of hepatocytes (Councilman bodies).

Diagnosis and management

The diagnosis is established by a history of travel and vaccination status and genome detection or by isolation of the virus (when possible) from blood during the first 3 days of illness. Serodiagnosis is possible, but in endemic areas, cross-reactivity with other flaviviruses is a problem.

Management is supportive. Bed rest (under mosquito nets), analgesics, and maintenance of fluid and electrolyte balance are required.

Prevention and control

Yellow fever is an internationally notifiable disease. It is easily prevented by using the attenuated 17D chick embryo vaccine. Vaccination is not recommended for children younger than 9 months of age or in pregnant or immunosuppressed patients unless there are compelling reasons. For the purposes of international certification, immunization is valid for 10 years, but protection lasts much longer than this and probably for life. The WHO EPI includes yellow fever vaccination in endemic areas.

Congo–Crimean haemorrhagic fever

Congo–Crimean haemorrhagic fever (CCHF) virus belongs to the *Orthonairovirus* genus of the family Nairoviridae. This family contains more than 200 viruses, grouped into a number of genera, most of which are arthropod borne.

CCHF disease is found mainly in Asia and Africa. The primary hosts are cattle and hares, and the vectors are *Hyalomma* ticks. After an incubation period of 3 to 6 days, there is an influenza-like illness with fever and haemorrhagic manifestations. The mortality rate is 10% to 50%.

Hantavirus infection

Hantaviruses belong to the *Orthohantavirus* genus of the Hantaviridae family and are enzootic viruses of wild rodents, which are spread by aerosolized excreta and not by insect vectors. The most severe form of this infection is Korean haemorrhagic fever (also known as haemorrhagic fever with renal syndrome). This condition has a mortality rate of 5% to 10% and is characterized by fever, shock, and haemorrhage followed by an oliguric phase. Milder forms of the disease are associated with related viruses (e.g., Puumala virus) and may present as nephropathia epidemica, an acute fever with renal involvement, seen in Scandinavia and other European countries in people who have been in contact with bank voles. In the USA, a hantavirus (transmitted by the deer mouse) termed 'Sin Nombre' was identified as the cause of outbreaks of acute respiratory disease (hantavirus pulmonary syndrome) in adults. Other hantavirus types and rodent vector systems have been associated with this syndrome.

Diagnosis of hantavirus infection is made by ELISA detection of specific antibodies.

Rift Valley fever

Rift Valley fever, caused by a virus from the *Phlebovirus* genus of the Phenuiviridae family, is primarily an acute febrile illness of livestock: sheep, goats, and camels. It is found in southern and eastern Africa. The vectors are *Culex pipiens* in East Africa and *Aedes caballus* in southern Africa, but disease can be transmitted by the bite of an infected animal. After an incubation period of 3 to 6 days, the patient has an acute febrile illness that is difficult to distinguish clinically from other viral fevers. The temperature pattern is usually biphasic. The initial febrile illness lasts 2 to 4 days and is followed by a remission and a second febrile episode. Complications are indicative of severe infection and include retinopathy, meningoencephalitis, haemorrhagic manifestations, and hepatic necrosis. The mortality rate approaches 50% in severe forms. Management is supportive. Animals can be vaccinated.

Lassa fever

Lassa fever virus belongs to the family *Arenaviridae*. Arenaviruses are pleomorphic, round, or oval viruses with diameters ranging from 50 to 300 nm. The virion surface has club-shaped projections, and the virus itself contains a variable number of characteristic electron-dense granules that represent residual, non-functional host ribosomes. Lassa fever illness was first documented in the town of Lassa, Nigeria, in 1969 and is confined to sub-Saharan West Africa (Nigeria, Liberia, and Sierra Leone). The multimammate rat *Mastomys natalensis* is known to be the reservoir. Humans are infected by ingesting foods contaminated by rat urine or saliva containing the virus. Person-to-person spread by body fluids also occurs. Only 10% to 30% of infections are symptomatic. Related arenaviruses are the causative agents of Argentinian and Bolivian haemorrhagic fevers.

Clinical features

The incubation period is 7 to 18 days. The disease is insidious in onset and characterized by fever, myalgia, severe backache, malaise, and headache. A transient maculopapular rash may be present. A sore throat, pharyngitis, and lymphadenopathy occur in more than 50% of patients. In severe cases, there may be epistaxis and GI bleeding, hence the classification of Lassa fever as a viral haemorrhagic fever. The fever usually lasts 1 to 3 weeks, and recovery within 1 month of the onset of illness is usual. However, death occurs in 15% to 20% of hospitalized patients, usually from irreversible hypovolaemic shock.

Diagnosis

The diagnosis is established by serial serological tests (including the Lassa virus-specific IgM titre) or by genome detection in throat swab, serum, or urine.

Management

Management is supportive. In addition, clinical benefit and a reduction in the mortality rate can be achieved with ribavirin therapy if given in the first week.

In non-endemic countries, strict isolation procedures should be used, the patient ideally being nursed in a flexible-film isolator. Specialized units for the management of Lassa fever and other haemorrhagic fevers have been established in the UK. Because Lassa fever virus and other causes of haemorrhagic fever (Marburg/Ebola and Congo–Crimean haemorrhagic fever viruses; see **Box 42.37**) have been transmitted from patients to staff in healthcare situations, great care should be taken in handling specimens and clinical material from these patients.

Marburg virus disease and Ebola virus disease

These severe, haemorrhagic, febrile illnesses are discussed together because their clinical manifestations are similar, and the causative negative-strand RNA viruses belong to the same virus family, the *Filoviridae*, so called because the viruses have a filamentous appearance on electron microscopy. The diseases are named after Marburg in Germany and the Ebola river region in the Sudan and Zaire, where these viruses first appeared. Filoviruses are zoonotic pathogens, with fruit bats thought to be the natural host. The mode of spread from one individual to another involves contact with infected animals or the body fluids (or objects contaminated by the body fluids) of an infected patient. The genus *Ebolavirus* contains six defined species, which vary in terms of case fatality rates: less than 40% for Bundibugyo, 50% for Sudan, and 40% to 90% for Ebola viruses. There has been only one (non-fatal) case of Tai Forest virus infection. Reston virus, the only Asian species, and Bombali virus have not been associated with death in humans.

Epidemics have occurred periodically in recent years, mainly in sub-Saharan Africa. The illness is characterized by the acute onset of severe headache, myalgia, vomiting, and high fever followed by prostration. On about the fifth day of illness, a non-pruritic maculopapular rash develops on the face and then spreads to the rest of the body. Diarrhoea is profuse and associated with abdominal cramps and vomiting. Haematemesis, melaena, or haemoptysis may occur between days 7 and 16. Hepatosplenomegaly and facial oedema are usually present. In Ebola virus disease (EBOV), chest pain and a dry cough are prominent symptoms.

The largest outbreak of EBOV began in West Africa in August 2014 and was declared over by the WHO in June 2016. More than 28 000 individuals were infected, and more than 11 000 people died. The most recent outbreak occurred in Uganda from September 2022 to January 2023 with 164 cases and 77 deaths; that of Marburg virus disease is ongoing in Equatorial Guinea.

Treatment is symptomatic, although a number of experimental therapies, including monoclonal antibodies (e.g., Mab114 and REGN-EB3) and the antivirals remdesivir and favipiravir, are being tried. Ebola vaccines, including a live-attenuated recombinant vesicular stomatitis virus vaccine containing the Ebola virus glycoprotein, have been developed and are recommended by the WHO for use in outbreak situations. In the absence of effective therapy, accurate diagnosis and infection control precautions are the only intervention strategies. Lack of infrastructure to support rapid molecular diagnostic techniques and to allow institution of the meticulous patient isolation necessary to interrupt human-to-human transmission of infection has contributed to generating the recent large outbreaks. Asymptomatic people may be infected but have a low viral count, making transmission unlikely.

ANTIVIRAL DRUGS

Drugs for HIV infection are discussed in Chapter 44 ('Anti-retroviral therapy' section).

Anti-herpesvirus drugs

Nucleoside analogues

Aciclovir

Aciclovir (**Fig. 42.18A**; also known as acycloguanosine) is an acyclic nucleoside analogue that acts as a chain terminator of herpesvirus DNA synthesis. This drug is converted to aciclovir monophosphate by a virus-encoded thymidine kinase produced by the alpha herpesviruses, HSV types 1 and 2, and VZV (**Box 42.38**). Conversion to the triphosphate is then achieved by cellular enzymes. Aciclovir triphosphate acts as a potent inhibitor of viral (but not cellular) DNA polymerase and competes with deoxyguanine triphosphate for incorporation into the growing chains of herpesvirus DNA, thereby resulting in chain synthesis termination because of its acyclic structure. This highly specific mode of activity, targeted only to virus-infected cells, means that aciclovir has very low toxicity. Crystallization in the renal tubules is a well-recognized adverse effect, and patients should be well hydrated, particularly when high-dose intravenous therapy is being used. Intravenous, oral, and topical preparations are available for the treatment of patients with HSV and VZV infections. Treatment does not eliminate latent virus, so relapses do occur.

Valaciclovir

Valaciclovir is an oral prodrug of aciclovir. Coupling of valine to the acyclic side chain of aciclovir allows better intestinal absorption. The valine is removed by enzymic action, and aciclovir is released into the circulation. A similar prodrug of a related nucleoside analogue (penciclovir) is the antiherpes drug famciclovir. The mode of action and efficacy of famciclovir are similar to those of aciclovir.

Ganciclovir

The guanine analogue ***ganciclovir*** is structurally similar to aciclovir, with extension of the acyclic side chain by a carboxymethyl group.

It is active against HSVs and VZV by the same mechanism as aciclovir. In addition, phosphorylation by a protein kinase, encoded by the *UL97* gene of CMV, renders it potently active against this virus.

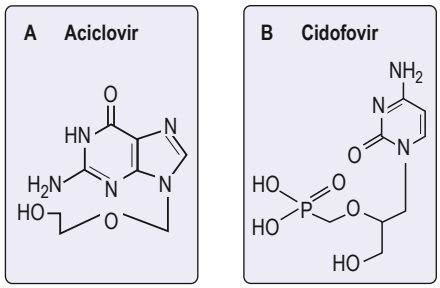

Fig. 42.18 The structures of antiviral drugs. (A) Aciclovir. (B) Cidofovir.

Thus, ganciclovir is currently the first-line treatment for patients with CMV disease. Intravenous and oral preparations are available, as is an oral prodrug, valganciclovir. Unlike aciclovir, ganciclovir has a significant toxicity profile, including neutropenia; thrombocytopenia; and, rarely, sterilization by inhibition of spermatogenesis. It is therefore usually reserved for the treatment or prevention of life- or sight-threatening CMV infection in immunocompromised patients, but it is also recommended for the treatment of symptomatic babies with congenital CMV infection.

Nucleotide analogues

Cidofovir

Cidofovir is a phosphonate derivative of an acyclic nucleoside that acts as a viral DNA polymerase inhibitor (Fig. 42.18B). Phosphorylation to the active triphosphate moiety is entirely by host cell enzymes. It is administered intravenously for the treatment

Box 42.38 Antiviral agents[a]

Virus	Structure or mode of action	Drug	Route of administration	Notes
Anti-herpesvirus	Nucleoside analogue	Aciclovir	Oral, i.v., topical	HSV, VZV
		Valaciclovir	Oral	HSV, VZV
		Famciclovir	Oral	HSV, VZV
		Ganciclovir	i.v.	CMV
		Valganciclovir	Oral	CMV
	Nucleotide analogue	Cidofovir	i.v.	CMV
		Brincidofovir	Oral	CMV
	Pyrophosphate analogue	Foscarnet	i.v.	CMV
	Helicase primase inhibitor	Pritelivir	Oral	HSV
	UL97 inhibitor	Maribavir	Oral	CMV
	Terminase inhibitor	Letermovir	Oral	CMV
Anti-SARS-CoV-2	Inhibitor of viral RNA replication	Remdesivir	i.v.	
	Induces copying errors in viral RNA replication	Molnupiravir	Oral	
	Protease inhibitor	Nirmatrelvir	Oral	Co-administered with ritonavir
Anti-influenza	Neuraminidase inhibitor	Zanamivir	Inhaled	Influenza A, B
		Oseltamivir	Oral	Influenza A, B
		Peramivir	i.v.	Influenza A, B
	Endonuclease inhibitor	Baloxavir	Oral	Influenza A, B
Anti-hepatitis B virus	Nucleoside analogue	Lamivudine	Oral	Rapid resistance
		Telbivudine	Oral	Rapid resistance
		Entecavir	Oral	High barrier to resistance
	Nucleotide analogue	Adefovir	Oral	
		Tenofovir	Oral	High barrier to resistance
Anti-hepatitis C virus (directly acting antivirals, DAA)	NS3 protease inhibitors	Suffix -previr, e.g., grazoprevir	Oral	Usually co-formulated with an NS5a inhibitor
	NS5a inhibitors	Suffix -asvir, e.g., velpatasvir	Oral	Usually co-formulated with an NS3 protease inhibitor or an NS5b polymerase inhibitor
	NS5b polymerase inhibitors	Suffix -buvir, e.g., sofosbuvir	Oral	Usually co-formulated with an NS5a inhibitor
Other	Nucleoside analogue	Ribavirin	Oral, i.v.	Broad spectrum; RSV, HCV
	Interferons		i.m.	Pegylated
	Monoclonal antibodies	Palivizumab Nirsevimab	i.m.	RSV

[a]For drugs used in human immunodeficiency virus, see Chapter 44; for drugs used in the treatment of hepatitis C virus infection, see Chapter 23.
CMV, Cytomegalovirus; *HCV,* hepatitis C virus; *HSV,* herpes simplex virus; *i.m.,* intramuscular; *i.v.,* intravenous; *RSV,* respiratory syncytial virus; *SARS-CoV-2,* severe acute respiratory syndrome coronavirus 2; *VZV,* varicella zoster virus.

of severe CMV infections when other drugs are inappropriate. It is given with probenecid, and because it is nephrotoxic, particular attention should be paid to hydration and monitoring of renal function.

Brincidofovir

Brincidofovir consists of cidofovir bound to a lipid moiety, enabling an oral route of administration and avoiding renal toxicity; it has shown promise in clinical trials.

Pyrophosphate analogue

Foscarnet (sodium phosphonoformate) is a simple pyrophosphate analogue that inhibits viral DNA polymerases. It is active against herpesviruses, and its main roles are as a second-line treatment for severe CMV disease and in the treatment of patients with aciclovir-resistant HSV infection. It is given intravenously, but the potential for severe side-effects, particularly nephrotoxicity, limits its use.

Other anti-herpesvirus agents

Maribavir, an inhibitor of the protein kinase product of the *UL97* gene of CMV, which plays a key role in allowing viral egress from an infected cell, is licensed for use as treatment of CMV-associated disease in transplant recipients. Letermovir, an inhibitor of the CMV terminase enzyme complex, which cuts the string of CMV genomes synthesized in an infected cell into unit-length genomes for packaging in the capsid, is recommended for prevention of CMV reactivation and disease in haemopoietic stem cell transplant recipients. New drugs undergoing clinical trials include pritelivir, an inhibitor of the herpes simplex viral helicase–primase enzyme complex.

Anti-SARS-CoV-2 drugs

Remdesivir

Remdesivir, broad-spectrum adenosine nucleotide analogue, was first developed for the treatment of hepatitis C virus (HCV) infection and was subsequently trialled in the West Africa Ebola virus epidemic. It is administered by intravenous injection and therefore is limited to use in hospital or similar settings. After diffusion into cells and phosphorylation, it interferes with the function of the viral RNA-dependent RNA polymerase enzyme, causing termination of viral RNA synthesis.

Molnupiravir

Molnupiravir is a cytosine nucleoside analogue that introduces copying errors, leading to hypermutation of the genome as the virus replicates. It is administered orally.

Nirmatrelvir

Nirmatrelvir, administered orally, is an inhibitor of the viral protease enzyme responsible for digesting the newly synthesized polyprotein into its component individual proteins. It is co-administered with ritonavir, which was originally developed as an HIV protease inhibitor but more usefully acts as an inhibitor of the liver cytochrome P450 system, which would otherwise metabolise nirmatrelvir.

Anti-influenza drugs

Adamantanes

The use of ***amantadine*** and derivatives in the treatment and prophylaxis of influenza has largely been superseded by the neuraminidase inhibitors. Amantadine is active prophylactically and therapeutically against influenza A (but not B) virus. It is an ion-channel blocker that inhibits viral uncoating after cell entry. CNS side-effects, such as insomnia, dizziness, and headache, may occur, and the drug is poorly tolerated, especially in older adults.

Neuraminidase inhibitors

Zanamivir (administered by inhalation) and ***oseltamivir*** (an oral preparation). These drugs inhibit the action of the neuraminidase of influenza A and B. Both have been shown to be effective in reducing the duration of illness in influenza if given within the first 48 hours. Both may also be used as prophylaxis of influenza among contacts of an index case. Intravenous ***peramivir*** and zanamivir are available for complicated and potentially life-threatening infection resistant to other treatments.

Novel anti-influenza drugs

Baloxavir inhibits the cap-dependent endonuclease activity of the influenza polymerase. Its efficacy is similar to that of oseltamivir, but resistance arises rapidly even after a single dose caused by a mutation in the polymerase gene.

Anti–hepatitis B and anti–hepatitis C drugs

A number of nucleoside and nucleotide analogues have been shown to inhibit the reverse transcriptase function of HBV and thereby suppress viral replication (see Chapter 23). The first such agents, ***lamivudine*** and ***adefovir***, have largely been superseded by the more potent drugs ***entecavir*** and ***tenofovir***, both of which also have a considerably higher barrier to resistance. ***Telbivudine*** is also a nucleoside analogue inhibitor of HBV DNA polymerase activity.

There are three classes of directly acting antiviral drugs (DAAs) used in the treatment of patients with chronic HCV infection. Inhibitors of the viral NS3 protease have the suffix -previr (e.g., grazoprevir), inhibitors of the NS5a multi-functional protein have the suffix -asvir (e.g., pibrentasvir), and inhibitors of the NS5b polymerase enzyme have the suffix -buvir (e.g., sofosbuvir).

The treatment of patients with hepatitis C and B virus infections is discussed in Chapter 23.

Other antiviral drugs

Ribavirin is a synthetic purine nucleoside derivative that interferes with 5′ capping of messenger RNA. It is active against several RNA and DNA viruses, at least *in vitro*. It is occasionally used in the treatment of patients with chronic hepatitis C infection in combination with other agents and for those with chronic hepatitis E virus infection. It is administered orally. Haemolytic anaemia is the most frequent adverse reaction. It is also administered by a small-particle aerosol generator to infants with acute RSV infection. Another indication is in the treatment of patients with Lassa fever virus infection.

Tecovirimat was developed and approved as a treatment of patients with smallpox, with a mechanism of action of inhibiting the orthopoxvirus VP37 envelope wrapping protein. It has subsequently been recommended as a possible therapy for mpox virus infection.

Palivizumab. This monoclonal antibody is specifically indicated to prevent seasonal RSV infection in infants at high risk of severe complications of this infection (including those with bronchopulmonary dysplasia and congenital heart disease). However, this is likely to be replaced by use of nirsevimab, which has an extended half-life and has been trialled successfully for the prevention of RSV disease in neonates and infants.

Interferons

These are naturally occurring proteins with a multiplicity of actions, including antiviral, immunomodulatory, and antiproliferative effects. IFNs are produced by virus-infected cells, macrophages, and lymphocytes. They induce an antiviral state in uninfected cells through activation of a complex set of biochemical pathways. They have been synthesized commercially and are licensed for therapeutic use.

The potency of IFN-α has been enhanced by coupling the protein with polyethylene glycol. The resulting pegylated IFN, given once weekly, has been shown to improve the response to and reduce the side-effects from treatment for hepatitis B and C, although its use in the latter condition has been replaced by the advent of directly acting antiviral agents.

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES (PRION DISEASES)

Transmissible spongiform encephalopathies are caused by the accumulation in the nervous system of a protein, termed a 'prion', which is an abnormal isoform (PrP^{Sc}) of a normal host protein (PrP^{c}).

Although familial forms of prion disease are known to exist, these conditions can be transmissible, particularly if brain tissue enters another host. There is no convincing evidence for the presence of nucleic acid in association with prions, and it is the abnormal prion protein itself that is infectious and can trigger a conversion of the normal protein into the atypical isoform. After infection, a long incubation period is followed by CNS degeneration associated with dementia or ataxia, which invariably leads to death. Histology of the brain reveals spongiform change with an accumulation of the abnormal prion protein in the form of amyloid plaques.

The human prion diseases are CJD, including the sporadic, familial, iatrogenic, and variant forms of the disease; Gerstmann–Straussler–Scheinker syndrome; fatal familial insomnia; and kuru.

- ***CJD.*** CJD occurs sporadically worldwide with an annual incidence of 1 per million of the population. Although in most cases, the epidemiology remains obscure, iatrogenic transmission to others has occurred as a result of administration of human cadaveric growth hormone or gonadotrophin, from dura mater and corneal grafting, and in neurosurgery from reuse of contaminated instruments and electrodes (iatrogenic CJD).
- ***Variant CJD (vCJD).*** In the UK, knowledge that large numbers of cattle with the prion disease, bovine spongiform encephalopathy (BSE), had gone into the human food chain led to enhanced surveillance for emergence of the disease in humans. Based on transmission studies in mice and on glycosylation patterns of prion proteins, the evidence is convincing that this has occurred, and to date, there have been approximately 180 confirmed and suspected cases of vCJD (human BSE) in the UK and 50 in the rest of the world. In contrast to sporadic CJD, which presents with dementia at a mean age of onset of 60 years, vCJD presents with ataxia, dementia, myoclonus, and chorea at a mean age of onset of 29 years. Although the epidemic in the 1990s has now passed and new cases are extremely rare, there remains a concern about longer incubation periods, and there are ongoing international restrictions on blood transfusion from those who were resident in or received transfusions from the UK at that time.
- ***Gerstmann–Straussler–Scheinker syndrome and fatal familial insomnia.*** These are rare prion diseases, usually occurring in families with a positive history. The pattern of inheritance is autosomal dominant with some degree of variable penetrance. The gene encoding PrP^{C} in these families often contains mutations.
- ***Kuru.*** This disease was described and characterized in the Fore highlanders in northeast New Guinea. Transmission was associated with ritualistic cannibalism of deceased relatives. With the cessation of cannibalism by 1960, the disease has gradually diminished, and recent cases were all exposed to the agent before 1960.

The infectious agents of prion disease have remarkable characteristics. In an infected host, there is no evidence of inflammatory, cytokine, or immune reactions. The agent is highly resistant to decontamination, and infectivity is not reliably destroyed by autoclaving or by treatment with formaldehyde and most other gas or liquid disinfectants. It is very resistant to γ-irradiation. Autoclaving at a high temperature (134°–137°C for 18min) is used for decontamination of instruments and hypochlorite (20 000 ppm available chlorine) or 1-molar sodium hydroxide is used for liquid disinfection. Uncertainty about the reliability of any methods for safe decontamination of surgical instruments has necessitated the introduction of guidelines for patient management.

BACTERIAL INFECTIONS

Bacteria are single-celled organisms that form the major part of the normal human microbiome. Bacterial infection is caused by commensal bacteria invading normally sterile parts of the body or by pathogenic bacteria that are not normal commensal organisms. Infection can be the result of translocation of bacteria from non-sterile to sterile areas (e.g., from the gut to the urinary tract), acquisition from other people or animals, or transmission on fomites or in the environment.

In some cases, bacterial infection may be localized to a specific site, without systemic symptoms. In other circumstances, a localized infection may be accompanied by systemic illness or sepsis (see Chapter 12). Sometimes there is no obvious focus of infection, and the presentation is with undifferentiated fever. In a few cases, bacteria cause illness through release of a specific toxin, which produces symptoms distant from the actual site of infection (**Box 42.39**).

Some bacterial infections are found worldwide, but others are geographically restricted. Often these relate to particular climates and habitats that support the transmitting vector or disease or certain communities, such as those that have limited access to fresh water, good hygiene, and medical care. These factors are often interdependent, and many of the conditions that are traditionally labelled as 'tropical' are, in fact, related to socioeconomic conditions rather than climate.

Many of the common organ-specific bacterial conditions are covered in the relevant system chapters and sepsis is described in Chapter 12. This section deals with those bacterial infections that

do not fit readily into an organ-specific model and those that are more defined by geographical and economic constraints than by body site.

BACTERIAL INFECTIONS OF THE SKIN AND SOFT TISSUES

The most common bacterial infections of skin and soft tissue are covered in Chapter 11, although some of the more unusual causes are described here and listed in **Box 42.40**. Although the commonest cause of cellulitis is beta-haemolytic streptococci, the majority of infections localized to skin and soft tissue structures (folliculitis, boils, infected insect bites, wounds, and ulcers) are caused by *S. aureus*. Staphylococci are part of the normal microflora of the human skin and nasopharynx and up to 25% of people are carriers of *S. aureus*. Although most *S. aureus* infections remain superficial, this organism can spread from the skin to cause a variety of more serious infections (see **Box 42.22**). Other species of staphylococci are only rarely pathogenic.

Invasive staphylococcal infection

Invasive staphylococcal infection is often associated with breaches in the skin, for example, those caused by injecting drug use, iatrogenic cannulation, surgery, or trauma, although an entry point is not always identified. Other predisposing factors are listed in **Box 42.23**. In clinical situations, scrupulous attention to disinfection and hygiene when performing invasive procedures can minimize the risk of infection. Although *S. aureus* is the most common cause of intravenous catheter–related infections, other normally non-pathogenic species, such as *S. epidermidis*, may be found. The distinction is important: *S. epidermidis*, sometimes known as coagulase-negative *Staphylococci*, are ubiquitous on the skin and may 'contaminate' blood culture samples, leading to false-positive results. When identified as a genuine cause of bloodstream infection, *S. epidermidis* usually colonizes indwelling catheters or prosthetic heart valves, and although generally less aggressive than *S. aureus*, it is increasingly resistant to beta-lactam antibiotics.

Flucloxacillin is a beta-lactam antibiotic and remains the first choice for staphylococcal infection when the organism is known to be sensitive

Box 42.40 Bacterial causes of superficial skin and soft tissue infections

Specific risk factors	Likely organisms
None	*Streptococcus pyogenes* *Staphylococcus aureus*
Diabetes, peripheral vascular disease	Group B streptococci
Animal bite	*Pasteurella multocida*, *Capnocytophaga canimorsus*
Freshwater exposure	*Aeromonas hydrophila*
Seawater exposure	*Vibrio vulnificus*
Lymphoedema, stasis dermatitis	Groups A, C, and G streptococci
Hot tub exposure	*Pseudomonas aeruginosa*
Malignant otitis externa	*Pseudomonas aeruginosa*
Human bite	*Fusobacterium* spp.

(see Chapter 12 , 'Treatment of infection caused by multidrug-resistant organisms' section and Fig. 12.2), but when MRSA is confirmed or suspected, alternative anti-staphylococcal agents are required.

Staphylococcal virulence factors

S. aureus can produce a variety of toxins and virulence factors that affect the type and severity of infection. These include staphylococcal enterotoxin A, superantigenic staphylococcal exotoxins, toxic shock toxin 1, and PVL. The last of these has been found mainly in community-associated strains of *S. aureus* (both MRSA and meticillin-sensitive *S. aureus* [MSSA]) rather than in hospital-acquired or epidemic strains. PVL-producing MRSA and MSSA are common causes of invasive soft tissue infections in some countries such as the USA, although it is unclear whether PVL itself is directly responsible for the increased virulence. Severe lung infections with PVL-associated strains also occur.

Meticillin-resistant *Staphylococcus aureus*

Penicillin was introduced for public use in 1946 and transformed the treatment of patients with skin and soft tissue infections. However, by the late 1960s, more than 80% of *S. aureus* infections had become resistant to penicillin, and the semi-synthetic meticillin (now rarely used) and flucloxacillin became the drugs of choice. However, since their introduction, strains of MRSA with resistance to a much wider range of antibiotics have emerged and are now a major cause of concern.

MRSA is usually found as a skin commensal, especially in hospitalized patients and nursing home residents in the UK. Often the organisms found in community settings are the typical 'hospital' strains of MRSA and have been acquired directly or indirectly from a healthcare setting (e.g., in workers in care homes). However, there is an increasing prevalence in some countries of true community-associated MRSA (CA-MRSA), with no discernible links to hospital or residential care. These CA-MRSA strains have different resistance profiles to those of typical hospital strains (often retaining sensitivity to tetracyclines, clindamycin, and co-trimoxazole) and are more likely to produce PVL. They are particularly associated with surgical wound infections. Eradication of the organisms is difficult, and patients who are known to be colonized should be isolated or barrier nursed. Topical decolonization is used to decrease bacterial load before invasive procedures but is of limited efficacy in completely clearing carriage. Careful attention to hand-washing and hygiene is the main method of controlling spread.

Pasteurellosis

Pasteurella multocida is found in the oropharynx of up to 90% of cats and 70% of dogs. It can cause soft tissue infections after animal bites. Although the infection initially resembles other forms of cellulitis, there is a greater tendency to spread to deeper tissues, resulting in osteomyelitis, tenosynovitis, or septic arthritis. It can also spread haematogenously to other organs, including the lungs, brain, and heart. The organism is sensitive to penicillin, but because infections are often polymicrobial, co-amoxiclav is recommended after animal bites.

Cat-scratch disease

Cat-scratch disease is a zoonosis caused by *Bartonella henselae*. Up to one-third of cats, and in particular kittens, carry *B. henselae* in their blood but are generally asymptomatic. Human infection is uncommon and is probably caused by direct inoculation from the claws or via cat flea bites. Regional lymphadenopathy appears 1 to 2 weeks after infection; the nodes become tender and may suppurate. Histology of the nodes shows granuloma formation, and the illness may be mistaken for mycobacterial infection or lymphoma. There are usually few systemic symptoms in immunocompetent patients, although more severe disease may be seen in immunocompromised patients. In these patients, tender cutaneous or subcutaneous nodules are seen ***(bacillary angiomatosis)***, which may ulcerate. The lymphadenopathy resolves spontaneously over weeks or months, although surgical drainage of very large suppurating nodes may be necessary. Rarely, *B. henselae* may cause 'culture-negative' endocarditis, retinitis, or meningoencephalitis. It is sensitive to azithromycin, doxycycline, and ciprofloxacin, but drug selection and clinical benefit of treatment vary according to the primary site of the infection and the immune status of the patient.

Toxin-mediated skin disease

A number of skin conditions, although caused by bacteria, are mediated by exotoxins rather than direct local tissue damage.

Staphylococcal scalded skin syndrome

The scalded skin syndrome is caused by a toxin-secreting strain of *S. aureus*. It principally affects children younger than the age of 5 years. The toxin, exfoliatin, causes intra-epidermal cleavage at the level of the stratum corneum, leading to the formation of large, flaccid blisters that shear readily. It is a relatively benign condition and responds to treatment with flucloxacillin.

Toxic shock syndrome

TSS is usually caused by toxin-secreting staphylococci, but toxin-secreting streptococci have also been implicated. Although historically associated with vaginal colonization and tampon use, changes in tampon constituents have made this a rare portal of entry now. The exotoxin (normally toxic shock syndrome toxin 1) induces cytokine release, causing abrupt onset of fever and shock, with a diffuse macular rash and desquamation of the palms and soles. Many patients are severely ill, and the mortality rate is about 5%. It is important to look for and remove the source. Management is mainly supportive, although the organism should be eradicated, and there is evidence to support use of intravenous immunoglobulin.

BACTERIAL INFECTIONS OF THE RESPIRATORY TRACT

Infections of the respiratory tract are divided into those affecting the upper respiratory tract and those affecting the lower respiratory tract, which are separated by the larynx. The majority of common respiratory infections are covered elsewhere.

Upper respiratory tract infections

Scarlet fever

Scarlet fever occurs when the infectious organism (usually GAS but occasionally group C or G streptococci) produces erythrogenic toxin in an individual who does not possess neutralizing antitoxin antibodies. Infections may be sporadic or epidemic, occurring in residential institutions such as schools, prisons, and military establishments. It was an important cause of mortality in children in the early part of the 20th century, but improvements in living conditions and sanitation between the wars led to a decline in the mortality rate even before the introduction of antibiotics.

Clinical features

The onset of this relatively mild disease, which mainly affects children, is 2 to 4 days after a streptococcal infection (usually in the pharynx). It is often sore to swallow. Common features include regional lymphadenopathy, fever, rigors, headache, and vomiting. The rash usually appears on the second day of illness and is generalized but typically absent from the face, palms, and soles. It is described as having a sandpaper texture and blanches on pressure. It usually lasts for about 5 days and is followed by extensive desquamation of the skin (Fig. 42.19). The face is flushed, with characteristic circumoral pallor. Early in the disease, the tongue has a white coating, through which prominent bright red papillae can be seen ('strawberry tongue'). Later the white coating disappears, leaving a raw-looking, bright red colour ('raspberry tongue'). The patient is infectious for 10 to 21 days after the onset of the rash unless treated with antibiotics. A runny nose, hoarse voice, and conjunctivitis are usually absent, helping to differentiate scarlet fever from a viral infection.

Scarlet fever may be complicated by peritonsillar or retropharyngeal abscesses and otitis media.

The diagnosis is established by a combination of the typical clinical features with culture of a throat swab. Patients with scarlet fever should be treated with penicillin, to which GAS are invariably sensitive.

Diphtheria

Diphtheria occurs worldwide and is caused by *Corynebacterium diphtheriae*. It is a Gram-positive bacillus and is mainly transmitted through air-borne droplet spread. Only strains that carry the *tox+* gene are capable of toxin production. *C. diphtheriae* is closely related to *Corynebacterium ulcerans*, which is primarily a disease of livestock, although toxigenic strains have been reported to cause human disease. Once common, diphtheria is now seldom seen in countries with effective vaccination programmes and is most likely to occur in migrants who have not been vaccinated.

Clinical features

Diphtheria was formerly a disease of childhood but may affect adults in countries where childhood immunization has been interrupted or uptake is poor. The incubation period is 2 to 7 days. The manifestations are local (caused by the membrane) or systemic (caused by exotoxin). The presence of a membrane, however, is not essential to the diagnosis.

Fig. 42.19 **Scarlet fever rash, showing desquamation.**

Nasal diphtheria is characterized by the presence of a unilateral, serosanguineous nasal discharge that crusts around the external nares.

Pharyngeal diphtheria is associated with the greatest toxicity and is characterized by marked tonsillar and pharyngeal inflammation and usually the presence of a membrane. The tough, greyish-yellow membrane is formed by fibrin, bacteria, epithelial cells, mononuclear cells, and polymorphs and is firmly adherent to the underlying tissue. Regional lymphadenopathy, often tender, is prominent and produces the so-called 'bull-neck'.

Laryngeal diphtheria is usually a result of extension of the membrane from the pharynx. A husky voice, brassy cough, and later dyspnoea and cyanosis caused by respiratory obstruction are common features.

Diphtheria toxin principally affects the heart and the nervous system. Clinically evident myocarditis occurs in a proportion of patients with pharyngeal or laryngeal diphtheria, sometimes weeks after initial infection. Acute circulatory failure caused by myocarditis may occur in convalescent individuals around the 10th day of illness and can be fatal. Neurological manifestations occur either early in the disease (palatal and pharyngeal wall paralysis) or several weeks after its onset (cranial nerve palsies; paraesthesiae; polyneuropathy; or, rarely, encephalitis).

Cutaneous diphtheria, caused by *C. ulcerans*, is uncommon. It is mostly seen in association with residence in or travel to endemic countries, with farm or companion animal contact, and in individuals with poor personal hygiene. Typically, the ulcer is punched out with undermined edges and is covered with a greyish white to brownish adherent membrane. Constitutional symptoms are uncommon.

Diagnosis

This must be made on clinical grounds because therapy is usually urgent; the untreated mortality rate is about 10%. It is confirmed by bacterial culture from a pharyngeal swab and toxin studies.

Management

Antitoxin therapy is the only specific treatment. One trial showed that it reduced the mortality rate from 12.2% to 3.3%. It must be given promptly to prevent further fixation of toxin to tissue receptors because fixed toxin is not neutralized by antitoxin. Depending on the site and severity, 40 000 to 100 000 units of horse-serum antitoxin should be administered intramuscularly after an initial test dose to exclude any allergic reaction. Intravenous therapy may be required in very severe cases. There is a small risk of anaphylaxis after antitoxin administration and of serum sickness 2 to 3 weeks later (Box 42.41). However, the risk of death outweighs the problems of anaphylaxis. Antibiotics (penicillin, amoxicillin, or a macrolide) should be administered concurrently to eliminate the organisms and thereby remove the source of toxin production.

Box 42.41 Antitoxin administration

- Many antitoxins are heterologous and therefore dangerous.
- Hypersensitivity reactions are common.

Before treatment

- Question the patient about:
  - Allergic conditions (e.g., asthma, hay fever)
    - Previous antitoxin administration
- Read the instructions on the antitoxin package carefully.
- Always give a subcutaneous test dose.
- Have adrenaline (epinephrine) available.

The cardiac and neurological complications need intensive supportive therapy. Recovery and rehabilitation may take many weeks.

Prevention

Patients with suspected diphtheria must be kept in respiratory isolation, and the local public health authorities should be informed. Staff caring for the patient should have documented immunization status. All contacts of the patient should have throat swabs sent for culture; those with positive results should be treated with antibiotics and given active immunization or a booster dose of diphtheria toxoid. Diphtheria is prevented by immunization in childhood (see Chapter 9, 'Vaccination' section). Travellers to high-risk countries may require a booster dose, usually in combination with tetanus and pertussis, because monovalent diphtheria vaccine is no longer available.

Acute epiglottitis

Acute epiglottitis has been virtually eliminated among children in countries that have introduced *H. influenzae* vaccination. Infections are occasionally seen in adults. The clinical features are described in Chapter 21 ('The throat' section).

Lower respiratory tract infections

Pneumonia, lung abscess, and tuberculosis

For community-acquired pneumonia, see Chapter 11 ('Community-acquired pneumonia' section); hospital-acquired pneumonia, Chapter 11 ('Hospital-acquired pneumonia' section); and pneumonia in immunocompromised persons, Chapter 11 ('Pneumonia in immunocompromised patients' section.

Lung abscess is described in Chapter 11 ('Lung abscess' section).

TB is described in Chapter 20 ('Tuberculosis' section).

BACTERIAL INFECTIONS OF THE GASTROINTESTINAL TRACT

Gastroenteritis

The most common form of acute GI infection is gastroenteritis, causing diarrhoea with or without vomiting. Children in LMICs can expect, on average, 3 to 6 bouts of severe diarrhoea annually. Although oral rehydration programmes have cut the death toll significantly, more than half a million children die every year as a direct result of diarrhoeal disease. In high-income settings, diarrhoea is both less common and less likely to cause death but remains a major cause of morbidity, especially in older adults. Other groups at increased risk of infectious diarrhoea include travellers to LMICs, people in residential care, and infants in day-care facilities.

Viral gastroenteritis (see Chapter 11, 'Acute gastrointestinal infections' section) is the commonest cause of diarrhoea and vomiting in young children but is less commonly seen in adults, other than in the context of common source outbreaks (usually caused by norovirus). Protozoal and helminthic gut infections (see 'Protozoal infections' section) are rare in HICs but relatively common in LICs. The most common cause of significant adult gastroenteritis worldwide is bacterial infection.

Bacteria can cause diarrhoea in three different ways (**Box 42.42**). Some species may use more than one of these methods. In addition to these direct mechanisms, a proportion of people develop post-infectious irritable bowel syndrome, a functional bowel disorder triggered by infection but persisting after resolution of the inflammation (see Chapter 22, 'Eosinophilic gastroenteritis' section).

Mucosal adherence

Most bacteria causing diarrhoea must first adhere to specific receptors on the gut mucosa; a number of different molecular adhesion mechanisms have been elaborated. For some pathogens, this is merely the prelude to invasion or toxin production, but others, such as enteropathogenic *E. coli*, cause mucosal lesions and produce a secretory diarrhoea as a direct result of adherence. Enteroaggregative *E. coli* adhere in an aggregative pattern, with the bacteria clumping on the cell surface, and their toxin causes persistent diarrhoea. Diffusely adhering *E. coli* adheres in a uniform manner and

Box 42.42 Pathogenic mechanisms of bacterial gastroenteritis

Pathogenesis	Mode of action	Clinical presentation	Examples
Mucosal adherence	Effacement of intestinal mucosa	Moderate watery diarrhoea	Enteropathogenic *Escherichia coli* Enteroaggregative *E. coli* *E. coli* O14:H4 Diffusely adhering *E. coli*
Mucosal invasion	Penetration and destruction of mucosa	Dysentery	*Shigella* spp. *Campylobacter* spp. Enteroinvasive *E. coli*
Toxin production			
Enterotoxin	Fluid secretion without mucosal damage	Profuse watery diarrhoea	*Vibrio cholerae* *Salmonella* spp. *Campylobacter* spp. Enterotoxigenic *E. coli* *Bacillus cereus* *Staphylococcus aureus* producing enterotoxin B *Clostridium perfringens* type A
Cytotoxin	Damage to mucosa	Dysentery	*Salmonella* spp. *Campylobacter* spp. Enterohaemorrhagic *E. coli* O157 *E. coli* O104:H4

may also cause diarrhoea. Both are seen mainly in LICs with poor hygiene and inadequate clean water supply.

E. coli O104:H4, which has caused huge outbreaks of gastroenteritis in Germany and other high-income countries, has two different diarrhoea-causing *E. coli* pathotypes: typical enteroaggregative *E. coli* and Shiga-toxin-producing *E. coli*.

Mucosal invasion

Invasive pathogens, such as *Shigella* spp., enteroinvasive *E. coli* (EIEC) and *Campylobacter* spp., penetrate the intestinal mucosa. Initial entry into the mucosal cells is facilitated by the production of 'invasins', which disrupt the host-cell cytoskeleton. Subsequent destruction of the epithelial cells allows further bacterial entry and associated colitis, with the typical symptoms of dysentery: low-volume bloody diarrhoea with abdominal pain.

Toxin production

Gastroenteritis can be caused by different types of bacterial toxin. ***Enterotoxins*** produced by bacteria adhering to the intestinal epithelium induce excessive fluid secretion into the bowel lumen, leading to watery diarrhoea without physically damaging the mucosa (e.g., cholera, enterotoxigenic *E. coli* [ETEC]). Some enterotoxins that are pre-formed in food primarily cause vomiting (e.g., enterotoxigenic *S. aureus* and *Bacillus cereus*). ***Cytotoxins*** damage the intestinal mucosa and, in some cases, vascular endothelium as well (e.g., *E. coli* O157).

Clinical syndromes

Bacterial gastroenteritis can be divided on clinical grounds into two broad syndromes: ***watery diarrhoea*** (usually due to enterotoxins or adherence) and ***dysentery*** (characterized by bloody diarrhoea; usually caused by mucosal invasion and damage in the colon) (**Box 42.43**). With some pathogens, such as *Campylobacter jejuni*, there may be overlap between the two syndromes. A third clinical type of infective gastroenteritis, ***chronic diarrhoea***, is rarely bacterial in origin.

Management of infective diarrhoea is usually syndromic (see later) because except during outbreaks, the causative organism is rarely known at presentation. Bacterial gastroenteritis is usually self-limiting and in otherwise healthy individuals does not require antibacterials unless the infection is particularly severe or prolonged. Patients with dysentery are generally treated with antibiotics in all age groups; in children, this is proven to reduce mortality rates (**Box 42.44**).

Box 42.43 Bacterial causes of watery diarrhoea and dysentery

Watery diarrhoea	Dysentery
• *Bacillus cereus* • *Staphylococcus aureus* } plus profuse vomiting	• *Shigella* spp. • Salmonella spp.
• *Vibrio cholerae*	• *Campylobacter* spp.
• *Enterotoxigenic Escherichia coli*	• *Enteroinvasive E. coli*
• Enteropathogenic *E. coli*	• Enterohaemorrhagic *E. coli*
• *Salmonella* spp.	• *Yersinia enterocolitica*
• *Campylobacter jejuni*	• *Vibrio parahaemolyticus*
• *Clostridium perfringens*	• *Clostridioides difficile*
• *Clostridioides difficile*	

Salmonella spp.

Gastroenteritis can be caused by many of the numerous serotypes of non-typhoidal *Salmonella enterica*, but the most commonly implicated are *S. enterica enteritidis* and *S. enterica typhimurium* (*S. enterica typhi* and *S. enterica paratyphi*, the causes of enteric fever, which are covered in the 'Enteric fever' section). These organisms, which are found all over the world, are commensals in the bowels of livestock (especially poultry) and oviducts of chicken (where the eggs can become infected). They are usually transmitted to humans in contaminated foodstuffs and water.

Salmonellae can affect both the large and the small bowel and induce diarrhoea both by production of enterotoxins and by invasion. The typical symptoms commence abruptly, 12 to 48 hours after infection, and consist of nausea, cramping abdominal pain, diarrhoea, and sometimes fever. The diarrhoea can vary from profuse and watery to a bloody dysentery syndrome. Spontaneous resolution usually occurs in 3 to 6 days, although the organism may persist in the faeces for several weeks. Bloodstream infection occurs in 1% to 4% of cases. Some serotypes are more prone to cause bacteraemia than others, but it is also more common in older adults and immunosuppressed people; in settings of high HIV prevalence, bacteraemia without gastroenteritis is common. Occasionally, bacteraemia is complicated by metastatic infection, especially of atheroma on vascular endothelium, with potentially devastating consequences. Salmonella osteomyelitis is seen in people with sickle cell disease. In healthy adults, *Salmonella* gastroenteritis is usually a relatively minor illness, but young children and older adults are at risk of significant dehydration.

Specific diagnosis is made by isolating the organism in blood or faeces, but management is usually empirical and includes oral rehydration. Antibiotic resistance in salmonellae is increasing, with more than 10% of European human isolates resistant to ciprofloxacin and in some countries more than 50%. Resistance third-generation cephalosporins and azithromycin remains rare (<1%).

Campylobacter jejuni

The Gram-negative bacillus *C. jejuni* is a zoonotic organism, existing as a bowel commensal in many species of livestock, including poultry and cattle. It is found worldwide and is an important cause of childhood gastroenteritis in low- and middle-income countries. Adults in these countries may be tolerant of the organism, excreting it asymptomatically. In the West, it is a common cause of sporadic food-borne outbreaks of gastroenteritis. About 50 000 cases are confirmed annually in England and Wales, but the actual incidence is much higher. The most common sources are undercooked meat (especially beefburgers and chicken) and contaminated milk products and water. In many high-income countries, there is significant seasonal variation, with peaks associated with warm weather and barbecues.

Like *Salmonella*, *Campylobacter* spp. can affect the large and small bowel and can cause a wide variety of symptoms. The incubation period is usually 2 to 4 days, after which there is an abrupt onset of nausea, diarrhoea, and severe abdominal cramps. The diarrhoea is usually profuse and watery, but an invasive haemorrhagic colitis is sometimes seen. Bacteraemia is very rare, and infection is usually self-limiting in 3 to 5 days. Diagnosis is made from culture or, increasingly, molecular tests such as multiplex PCR, on stool. Quinolone resistance is now widespread in Europe (>60%); this is due in part to the use of antibiotics in intensive livestock farming. Antibiotics are not usually indicated, but if symptoms are severe, azithromycin is the drug of choice.

Box 42.44 Antibiotics in adult acute bacterial gastroenteritis

Condition	Indications	Drug of choice	Other drugs	Benefits
Cholera	Severely dehydrated patients only (World Health Organization guidance)	Ciprofloxacin 500 mg twice daily	Tetracycline 250 mg four times daily Azithromycin 1 g single dose Doxycycline 300 mg single dose	Relieve symptoms Shorten illness
Treatment of confirmed *Salmonella* spp. infection[a] (depending on resistance profile)	Symptoms not improving (rarely needed)	Azithromycin 500 mg once daily	Ciprofloxacin 500 mg twice daily for 7–10 days; ceftriaxone 2 g i.v. daily	May shorten illness
Treatment of confirmed *Campylobacter* spp. infection[a]	Symptoms not improving (rarely needed)	Azithromycin 500 mg once daily for 3 days	Erythromycin 500 mg four times a day for 3 days	May shorten illness
Treatment of confirmed shigellosis (depending on resistance profile)	Most patients (unless symptoms resolved)	Ciprofloxacin 500 mg twice daily	Azithromycin 500 mg once daily Ceftriaxone 2 g daily (i.v. or i.m.)	Relieve symptoms Shorten illness Reduce mortality rate in children Decrease transmission
Clostridioides difficile	Most cases (unless symptoms resolved)	Vancomycin 125–250 mg four times daily	Metronidazole 400 mg three times daily Fidaxomicin 200 mg twice daily	Relieve symptoms Shorten illness May reduce relapse rate
Empirical therapy of watery diarrhoea[a]	Severe symptoms Prolonged illness Older adult patients Immunosuppressed	Azithromycin 500 mg once daily	Ceftriaxone 2 g/day i.v.	Relieve symptoms Shorten illness May decrease complications
Travellers' diarrhoea[a]	Rarely used	Azithromycin 500 mg/day for three days	Ciprofloxacin 500 mg twice daily for 3 days	Relieve symptoms Shorten illness
Empirical therapy for dysentery (unless E, histolytica suspected)	Most patients	Azithromycin 500 mg/day for 3 days	Ciprofloxacin 500 mg twice daily for 3 days	Relieve symptoms Shorten illness

[a]Antibiotics are not needed for the majority of adult cases in high-income countries.
i.m., Intramuscular; *i.v.*, intravenous.

Shigella spp.

Shigellae are enteroinvasive Gram-negative bacteria, which cause classical bacillary dysentery. The principal species causing gastroenteritis are *Shigella dysenteriae*, *Shigella Flexneri*, and *Shigella sonnei*, which are found with varying prevalence in different parts of the world. All cause a similar syndrome as a result of damage to the intestinal mucosa. Some strains of *S. dysenteriae* also secrete a cytotoxin affecting vascular endothelium. Although shigellae are found worldwide, transmission is strongly associated with poor hygiene, and of the 165 million episodes of shigella dysentery estimated by the WHO to occur every year, 99% are in economically low- and middle-income countries. The main burden falls on children: *Shigella* dysentery kills nearly 50 000 children younger than 5 years old every year. There have been recent major European outbreaks of *Shigella* among males who have sex with males, often associated with significant antimicrobial resistance.

The organism is spread from person to person (either directly or via contaminated food or water), and only a small number of bacteria need to be ingested to cause illness (<200 compared with 10^4 for *Campylobacter* spp. and >10^5 for *Salmonella* spp.). Symptoms start 24 to 48 hours after ingestion and typically consist of frequent, small-volume stools containing blood and mucus. Dehydration is not as significant as in the secretory diarrhoeas, but systemic symptoms and intestinal complications are worse. The illness is usually self-limiting in 7 to 10 days, but in children in low-income settings, it can carry a significant mortality rate.

Antibiotic treatment decreases the severity and duration of diarrhoea, reduces the mortality rate in children, and possibly lowers the risk of further transmission. Resistance to antibiotics is widespread and, wherever possible, treatment should be based on known local sensitivity patterns. Antibiotics such as co-trimoxazole, which were widely used in the past, are no longer recommended by the WHO because of extensive resistance. This is increasingly the case for fluoroquinolones also, and most guidelines increasingly recommend azithromycin as the first-choice antibiotic, with ceftriaxone for severe disease. Resistance to both these antibiotics has been recognized in a recent outbreak in males who have sex with males.

Enteroinvasive *Escherichia coli*

EIEC cause an illness that is indistinguishable from shigellosis. Definitive diagnosis is made by isolation in stool, but most patients are probably treated empirically as having shigellosis.

Enterohaemorrhagic *Escherichia coli*

Enterohaemorrhagic *E. coli* (EHEC; usually serotype O157:H7, also known as verotoxin-producing *E. coli*) is a well-recognized cause of gastroenteritis in humans. It is a zoonosis that is usually associated with cattle, and there have been a number of major outbreaks linked to contaminated food. A variety of modes of transmission have been reported and the epidemiology of EHEC infection is a paradigm for all enteric livestock-associated zoonoses (Fig. 42.20). EHEC secretes a toxin (Shiga-like toxin 1) that affects vascular endothelial cells in the gut and in the kidney. After an incubation period of 12 to 48 hours, it causes diarrhoea (frequently bloody), associated with abdominal pain and nausea. Some days after the onset of symptoms, the patient may develop thrombotic thrombocytopenic purpura (see Chapter 38, 'Thrombotic

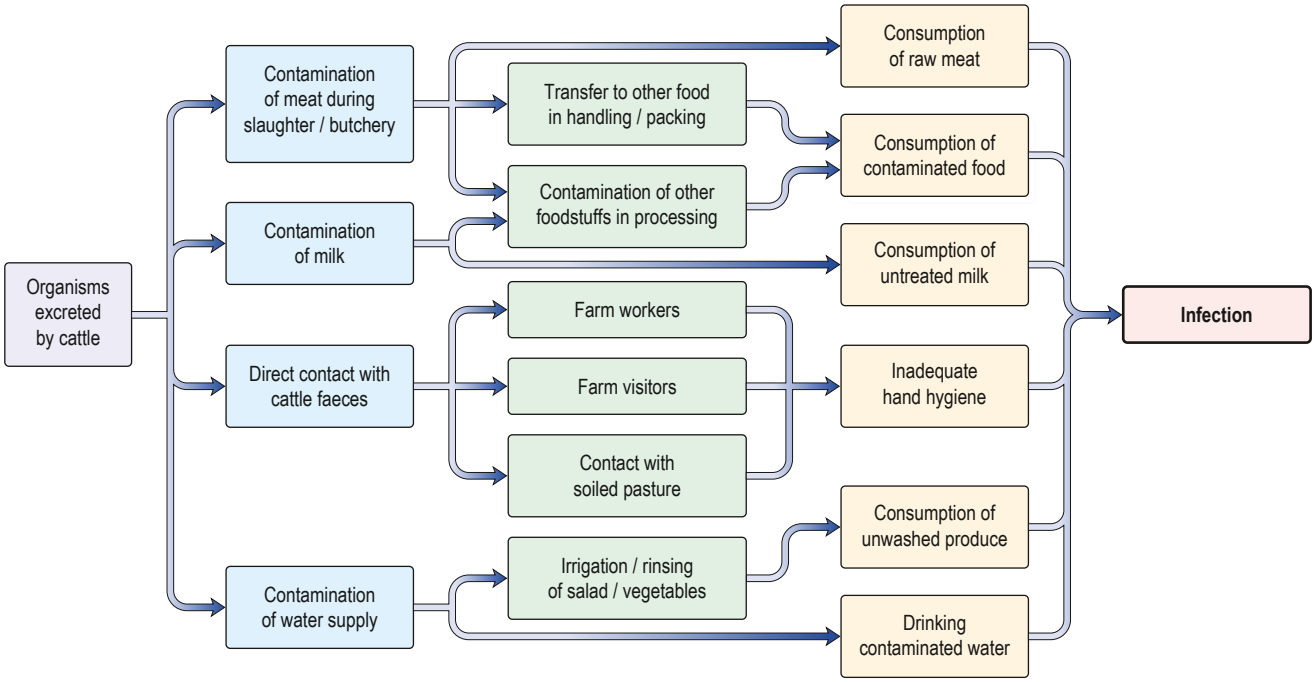

Fig. 42.20 **Routes of human infection with *Escherichia coli* O157.**

thrombocytopenic purpura' section) or haemolytic uraemic syndrome (HUS; see Chapter 26, 'Haemolytic uraemic syndrome' section). These are more common in children and may lead to permanent renal damage or death. Non-O157 serotypes are of increasing concern.

Between May and June 2011, the largest ever recorded outbreak of *Shiga* toxin–producing *E. coli* causing HUS was recorded in Germany. The outbreak was caused by the O104 serotype, and more than 2000 people were affected. High rates of HUS were observed in adults not in the typical 'at-risk' age range. The increased virulence of this strain is possibly due to its having two different pathotypes.

Treatment is mainly supportive; there is evidence that antibiotic therapy might precipitate HUS by causing increased toxin release, although this remains controversial.

Enterotoxigenic *Escherichia coli*

ETEC produce both heat-labile and heat-stable enterotoxins, which stimulate secretion of fluid into the intestinal lumen. The result is watery diarrhoea of varying intensity, which usually resolves within a few days. Transmission is normally from person to person via contaminated food and water. The organism is common in low- and middle-income countries and is a major cause of travellers' diarrhoea (see later).

Vibrio spp.

Cholera, caused by *V. cholerae*, is the prototypic pure enterotoxigenic diarrhoea; it is described in the 'Cholera' section.

Vibrio parahaemolyticus can cause acute watery diarrhoea after consumption of contaminated raw fish or shellfish. Explosive diarrhoea, abdominal cramps, and vomiting occur, with fever in 50%. The infection is self-limiting but can last for up to 10 days.

Yersiniosis

Yersinia enterocolitica infection is a zoonosis of a variety of domestic and wild mammals. Human disease can arise via either contaminated food products, such as pork, or direct animal contact. *Y. enterocolitica* can cause a range of gastroenteric symptoms, including watery diarrhoea, dysentery, and mesenteric adenitis. The illness is usually self-limiting, but ciprofloxacin may shorten the duration. *Y. pseudotuberculosis* is a much less common human pathogen; it causes mesenteric adenitis and terminal ileitis.

Enterotoxin-producing *Staphylococcus aureus*

Some strains of *S. aureus* can produce a heat-stable toxin (enterotoxin B), which causes massive secretion of fluid into the intestinal lumen. It is a common cause of food-borne gastroenteritis in Europe and the USA, where outbreaks usually occurring as a result of poor food hygiene. Because the toxin is pre-formed in the contaminated food, onset of symptoms is rapid, often within 2 to 4 hours of consumption. There is violent vomiting followed within hours by profuse watery diarrhoea. Symptoms usually settle within 24 hours.

Bacillus cereus

Bacillus cereus produces two toxins. The first causes vomiting 2 to 4 hours after ingestion of pre-formed heat-stable exotoxins. The second causes watery diarrhoea up to 12 hours after ingestion of uncooked food that contains spores or viable bacteria that multiply and produce a toxin within the bowel.

Clostridioides difficile

C. difficile can cause watery diarrhoea, colitis, and pseudomembranous colitis. It is a Gram-positive, anaerobic, spore-forming bacillus that is found in the bowel flora of 3% to 5% of the asymptomatic population (increasing to up to 20% in hospitalized people).

Pathogenesis

C. difficile produces two toxins; whereas toxin A is an enterotoxin, toxin B is cytotoxic and causes bloody diarrhoea. It usually causes illness either in patients who have been given antibiotic therapy that has eliminated other bowel commensals or in those who are debilitated for other reasons. Almost all antibiotics have been implicated, but an increase in cases has been attributed in part to greater use of quinolones. Hospital-acquired infection has been a major cause

of morbidity in recent decades, partly because of increased spread from person to person and via fomites and partly because of high rates of antibiotic use in hospitalized people. Stewardship interventions have reduced disease prevalence over the past decade, but an increasing proportion of cases appears to have no association with healthcare settings.

Clinical features

C. difficile–associated diarrhoea can begin any time from 2 days to some months after taking antibiotics. Older hospitalized patients are most frequently affected. It is unclear why some carriers remain asymptomatic. Symptoms can range from mild diarrhoea to profuse, watery, haemorrhagic colitis, along with lower abdominal pain. The colonic mucosa is inflamed and ulcerated and can be covered by an adherent membrane-like material (pseudomembranous colitis). The disease is usually more severe in older adults and can cause intractable diarrhoea; occasionally, it can cause toxic megacolon. Markers of severity include:

- Temperature greater than 38.5°C
- WCC greater than 15×10^9/L
- Serum creatinine greater than 50% above baseline
- Raised serum lactate
- Severe abdominal pain.

Diagnosis

Diagnosis is made by detecting A or B toxins in the stools using ELISA or PCR for *C. difficile* nucleic acid.

Management

Treatment is with oral vancomycin 125 mg four times daily, which has been shown to be more effective than metronidazole, the previously recommended first-line antibiotic. Fidaxomicin, higher vancomycin doses, and intravenous metronidazole are indicated in more severe or recurrent cases. Other antibiotics should be discontinued if possible. In refractory or relapsing cases, instilling faeces from the bowel of a healthy donor (faecal transplant) can restore normal bowel flora and eradicate the *C. difficile* infection. This therapy is increasingly becoming the standard for refractory *C. difficile* infections; bezlotoxumab, a monoclonal antibody targeting toxin B, has demonstrated efficacy in reducing recurrence.

Prevention

Infection control relies on:

- Responsible use of antibiotics (see Chapter 12, 'Antimicrobial stewardship' section)
- Hygiene, which should involve all health workers, as well as patients and relatives. Washing hands thoroughly using soap and water is essential because alcohol disinfectants do not kill spores.
- Isolation of patients with symptomatic *C. difficile* in hospitals or residential care.

Clostridium perfringens

C. perfringens infection is caused by inadequately cooked food, usually meat or poultry allowed to cool for a long time, during which period the spores germinate. The ingested organism produces an enterotoxin that causes watery diarrhoea with severe abdominal pain, usually without vomiting.

Travellers' diarrhoea

Travellers' diarrhoea is defined as the passage of three or more unformed stools per day in a traveller to an LMIC. Infection is usually food- or water-borne and commonly occurs in the first week of travel. Reported attack rates vary from country to country but approach 50% for a 2-week stay in some nations. The disease is usually benign and self-limiting; treatment with ciprofloxacin or azithromycin may hasten recovery but is not normally necessary. The common causative organisms are listed in Box 42.45.

? Box 42.45 Commonly identified causes of travellers' diarrhoea[a]

Organism	Frequency (%) (varies from country to country)
Enterotoxigenic *Escherichia coli*	30–70
Shigella spp.	0–15
Campylobacter spp.	0–15
Salmonella spp.	0–10
Viral pathogens	0–10
Giardia intestinalis	0–3

[a]In most cases, no microbiological diagnosis is made.

Management of acute gastroenteritis

In children in LICs, untreated diarrhoea has a high mortality rate caused by dehydration, often on a background of malnutrition and other chronic infection. Death and serious morbidity are less common in adults but still occur, particularly in low- and middle-income countries and in older adults.

The mainstay of treatment for all types of gastroenteritis is oral rehydration solutions (Fig. 42.21; see Box 42.36). The use and formulation of oral rehydration solutions are discussed earlier in this chapter. Antibiotics may sometimes have a role, especially in children in low- and middle-income countries. It is also important to remember that diarrhoea can be a 'false localizing symptom' in sepsis, and a resulting delay in diagnosis of, for example, malaria, can have major consequences. Most cases of acute gastroenteritis resolve within 10 days; if symptoms persist, protozoal causes such as *Giardia* spp. in the context of a relevant exposure history or inflammatory bowel disease and other non-infectious causes of colitis become more likely.

Food poisoning

Food poisoning is a legally notifiable condition in England and Wales. There is some overlap between food poisoning (defined as 'any disease of an infective or toxic nature caused by or thought to be caused by the consumption of food and water') and gastroenteritis. However, not all cases of gastroenteritis are caused by food poisoning because the pathogens are not always food or water borne. Conversely, some types of food poisoning (e.g., botulism) do not primarily cause gastroenteritis. Common bacterial causes of food poisoning are listed in Box 42.46. Food poisoning may also be caused by a number of non-infectious organic and inorganic toxins (Box 42.47).

Food poisoning is associated with modern intensive farming practices in the production and distribution of food. Livestock is frequently contaminated with *Salmonella* or *Campylobacter* spp., and flaws in the processing, storage, and distribution of food products allow massive amplification of the infection, resulting in extensive contamination. The internationalization of the food supply encourages widespread and distant transmission of the resulting infections.

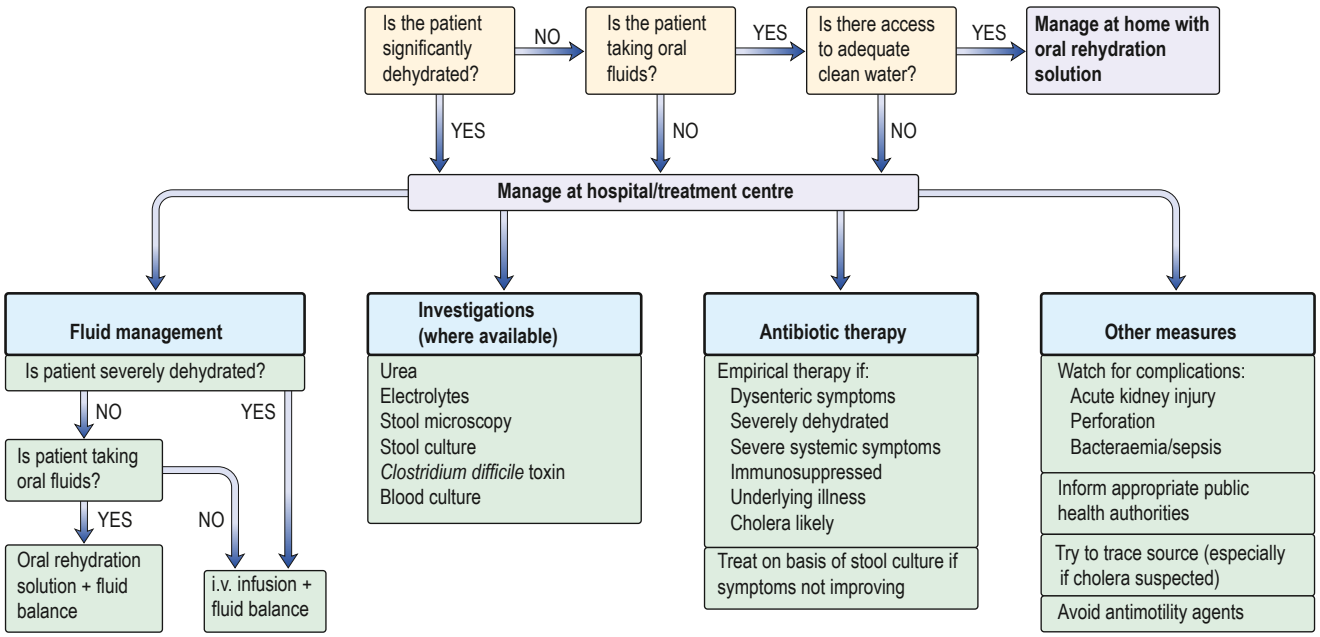

Fig. 42.21 Gastroenteritis: management plan. *i.v.,* Intravenous.

Box 42.46 Bacterial causes of food poisoning

Organism	Source/vehicles	Incubation period	Symptoms	Diagnosis	Recovery
Staphylococcus aureus	Humans: contaminated food and water	2–4 h	Diarrhoea, vomiting, dehydration	Culture of organism in vomitus or remaining food	<24 h
***Escherichia coli* (ETEC)**	Salads, water, ice	24 h	Watery diarrhoea	Stool PCR	1–4 days
***E. coli* O157:H7**	Cattle: contaminated foodstuffs	12–48 h	Watery diarrhoea ± haemorrhagic colitis, HUS	Stool culture or PCR	10–12 days
Yersinia enterocolitica	Milk, pork	2–14 h	Abdominal pain, vomiting, diarrhoea	Stool culture with specific media	2–30 days
Bacillus cereus	Environment: rice, ice cream, chicken	1–6 h 6–14 h	Vomiting Diarrhoea	Culture of organism in faeces and food	Rapid
Clostridium perfringens	Environment: contaminated food	8–22 h	Watery diarrhoea, cramping pain	Culture of organism in faeces and food	2–3 days
Listeria monocytogenes	Environment: milk, raw vegetables, dairy products, unpasteurized cheese	Variable	Colic, diarrhoea, vomiting	Stool culture	Variable
Vibrio parahaemolyticus	Seafood	2–48 h	Diarrhoea, vomiting	Stool, food	2–10 days
Clostridium botulinum	Environment: bottled or canned food	18–24 h	Brief diarrhoea and paralysis caused by neuromuscular blockade	Demonstration of toxin in food or faeces	10–14 days
***Salmonella* spp.**	Cattle and poultry: eggs, meat	12–48 h	Abrupt diarrhoea, fever, vomiting	Stool culture or PCR	Usually 3–6 days but may be up to 2 weeks
Campylobacter jejuni	Cattle and poultry: meat, milk	48–96 h	Diarrhoea ± blood, fever, malaise, abdominal pain	Stool culture or PCR	3–5 days
***Shigella* spp.**	Humans: contaminated food and water	24–48 h	Acute watery, bloody diarrhoea	Stool culture or PCR	7–10 days

ETEC, Enterotoxigenic *Escherichia coli*; *HUS,* haemolytic uraemic syndrome; *PCR,* polymerase chain reaction.

Box 42.47 Organic toxins causing food poisoning[a]

Toxin	Source	Illness
Scombrotoxin	Tuna, mackerel	Histamine fish poisoning
Ciguatoxin	Barracuda, snapper	Ciguatera (diarrhoea and paraesthesia)
Dinoflagellate plankton toxin	Shellfish	Neurotoxic shellfish poisoning
Haemagglutinins	Inadequately prepared dried kidney beans	Diarrhoea and vomiting
Unknown	Buffalo fish	Haff disease (toxic rhabdomyolysis)
Phallotoxins, amatoxins	Mushrooms	Various
Alpha-galactosidase	Lone star tick	Mammalian meat allergy

BACTERIAL INFECTIONS OF THE CARDIOVASCULAR SYSTEM

Infective endocarditis is discussed in Chapter 17 ('Infective endocarditis' section).

Rheumatic fever

Rheumatic fever is a multisystem disorder but is included here because the cardiac effects are usually the most significant. (About 35 million people worldwide have rheumatic heart disease.) It is an immune-mediated inflammatory disease that occurs in children and young adults as a result of infection with GAS. It affects the heart, skin, joints and CNS. It is relatively common in LMICs but very rare in Western Europe and North America. The decline in the incidence of rheumatic fever in these settings (from 10% of children in the 1920s to 0.01% today) parallels the reduction in all streptococcal infections and is largely attributable to improved hygiene and the use of antibiotics.

Pharyngeal infection with GAS is followed, in a small proportion of cases, by the clinical syndrome of rheumatic fever. This is thought to develop because of an autoimmune reaction triggered by molecular mimicry between the cell-wall M proteins of the infecting *S. pyogenes* and cardiac myosin and laminin. The condition is not caused by direct infection of the heart or the production of a toxin.

Clinical features

The disease presents 2 to 3 weeks after the initial GAS infection with fever, joint pains, and malaise. Diagnosis relies on the presence of two or more major clinical manifestations or one major manifestation plus two or more minor features in addition to evidence of current or recent streptococcal infection. These are known as the modified Jones criteria (**Box 42.48**).

Carditis manifests as new or changed heart murmurs, development of cardiac enlargement or cardiac failure, appearance of a pericardial effusion, or electrocardiographic changes of pericarditis, myocarditis, or cardiac arrhythmias.

Non-cardiac features include fever, arthritis, Sydenham's chorea (see Chapter 28, 'Chorea' section), and skin lesions. The arthritis is typically a fleeting migratory polyarthritis affecting large joints such as the knees, elbows, ankles, and wrists. When the acute inflammation disappears, the rheumatic process leaves the joints normal. Skin manifestations include erythema marginatum, a transient pink rash with slightly raised edges, which occurs in 20% of cases, and small painless subcutaneous nodules.

Management

The streptococcal infection should be eradicated with penicillin. If the diagnosis is suspected clinically, antibiotics should be administered even if nasal or pharyngeal swabs do not culture the streptococci.

The arthritis of rheumatic fever usually responds to non-steroidal anti-inflammatory drugs, although these have no impact on long-term cardiac sequelae. There is no good evidence that steroids are of benefit, although some experts give high-dose prednisolone if there is severe carditis. In areas of high prevalence, recurrence is common, and persistent cardiac damage is more likely. Further infection can largely be prevented by prophylaxis with daily oral or monthly intramuscular benzathine penicillin until the age of 20 years or for 10 years after the latest attack. Erythromycin or clarithromycin is used if the patient is allergic to penicillin. Any streptococcal infection that does develop should be treated promptly.

Prognosis

More than 50% of those who suffer acute rheumatic fever with carditis later (after 10–20 years) develop chronic rheumatic valvular disease, predominantly affecting the mitral and aortic valves.

BACTERIAL INFECTIONS OF THE NERVOUS SYSTEM

The central and peripheral nervous systems can be affected by a variety of microorganisms, including bacteria, viruses, and protozoa, which cause disease by direct invasion or via toxins. The nervous system is also vulnerable to prion disease (see 'Transmissible spongiform encephalopathies [prion diseases]' section).

Bacterial meningitis

The most common bacterial disease affecting the CNS is acute meningitis (see Chapter 28, 'Meningitis' section), which causes around 200 000 deaths per year, predominantly in LICs. *S. pneumoniae* is now the commonest cause of community-acquired bacterial meningitis followed by *N. meningitidis* (or meningococcus), with

Box 42.48 Modified Jones criteria for the diagnosis of rheumatic fever

Evidence of antecedent streptococcal infection
- Positive throat culture for group A streptococcus
- Good clinical history (e.g., of scarlet fever)
- Elevated antistreptolysin O titre (or other serological assay for streptococci)

Major criteria
- Carditis
- Polyarthritis
- Chorea
- Erythema marginatum
- Subcutaneous nodules

Minor criteria
- Fever
- Arthralgia (unless arthritis counted as major criterion)
- Previous rheumatic fever
- Raised erythrocyte sedimentation rate or C-reactive protein
- Leucocytosis
- Prolonged PR interval on electrocardiogram (unless carditis counted as major criterion)

tuberculous meningitis (see Chapter 20, 'Tuberculosis' section) also common in sub-Saharan Africa and parts of Asia.

Hib was once a common cause of meningitis in children, but since an effective vaccine has been available, serious *H. influenzae* infections have become rare in countries that have also instituted immunization programmes; however, invasive *H. influenzae* infection remains common in some parts of the world.

Other less common causes of meningitis in adults include group B streptococci, *L. monocytogenes*, *S. aureus*, and Gram-negative bacilli. These organisms are usually associated with an underlying illness or immunocompromising condition or with a CSF leak.

N. meningitidis is also an important cause of bloodstream infection and sepsis. There is a spectrum of presentation ranging from pure meningitis with few systemic features to a typical sepsis syndrome without clinical evidence of meningitis.

Meningococcal sepsis

N. meningitidis is found worldwide. Twelve serogroups have been identified, of which six (A, B, C, W, X, and Y) cause significant outbreaks of infection. The main burden falls on the so-called 'meningitis belt', which includes 25 countries across Africa stretching from Senegal in the west to Ethiopia in the east. Traditionally, massive seasonal outbreaks of serotype A occurred in the dry season every 5 to 12 years, with attack rates up to 1000 per 100 000 children per year, associated with disruption to host pharyngeal defences. The Menafrivac conjugate vaccine roll-out, focused on serotype A, has been highly successful but at the expense of replacement with other serotypes, including C and W, which are now also causing epidemics. In Europe and North America, cases associated with all serotypes have declined enormously over the past decades, with introduction of serotype-specific vaccines into the routine schedule, but sporadic cases do occur.

Humans are the only known reservoir for the organism, which is carried asymptomatically in the nasopharynxes of 5% to 20% of the general population. Meningococcal disease occurs when the bacteria invade the nasal mucosa and enter the bloodstream; this happens only in a small percentage of those colonized. Invasion depends on both host and bacterial factors. It is more likely to take place soon after colonization has occurred and after viral upper respiratory infections.

Clinical features

Invasive meningococcal infection may cause meningitis, the meningococcal sepsis syndrome, or both. Meningitic disease (see Chapter 28, 'Meningitis' section) usually presents with the classical triad of headache, fever, and neck stiffness. Vomiting, diminished consciousness, and focal neurological signs sometimes occur, although many patients, especially in the early stages, have only mild symptoms. Meningococcal bloodstream infection causes the typical features of septic shock, such as fever, myalgia, and hypotension (see Chapter 12), and may be accompanied by a petechial or haemorrhagic rash (see Fig. 42.4). False localizing symptoms such as diarrhoea can cause a fatal delay in diagnosis. Patients can deteriorate rapidly, with shock, DIC, and multiorgan failure.

Diagnosis

The presence of meningitis and sepsis syndrome with a typical rash is strongly suggestive of meningococcal disease. The rash is not always present, however, and its absence does not rule out the diagnosis. Gram-negative diplococci may be seen on Gram-stain of CSF or of aspirate from petechiae; meningococci can also be cultured from CSF or blood or detected by PCR. PCR can also be used to identify the serogroup, which may be important for public health management.

Management

N. meningitidis is sensitive to benzylpenicillin (in most cases), third-generation cephalosporins, and chloramphenicol; cefotaxime or ceftriaxone is the recommended treatment in the UK (see Box 26.57). Meningococcal sepsis should be managed in the same way as any other form of bacterial sepsis (see Chapter 12). Whereas the mortality rate from meningococcal sepsis in high-income countries is currently approximately 10%, that from meningococcal meningitis alone is less than 5% (see later). Mild neurological sequelae (especially vestibular nerve damage) are common, but serious brain damage is relatively unusual.

The meningococcal C conjugate vaccine was introduced to routine childhood immunization schedules in the UK in 1999, group B protein-based vaccine in in 2017, and the MenACYW conjugate vaccine for adolescents in 2015.

In an outbreak, close contacts of a case of meningococcal disease should be given prophylaxis with oral rifampicin or ciprofloxacin to eradicate the bacteria from the nasopharynx and reduce the risk of onward spread. (This has little impact in epidemic areas.) In some outbreak situations, contacts are offered immunization.

Cerebral abscess

This is covered in Chapter 28 ('Brain abscess' section).

Toxin-mediated infections

Botulism

C. botulinum is a common environmental organism that produces spores that can survive heating to 100°C. It can cause illness through a number of routes:
- Contamination of canned or bottled foodstuffs, in which the anaerobic organism can multiply and elaborate a neurotoxin
- Infection of wounds
- Contamination of injectable drugs (especially heroin).

In botulism (food poisoning), the toxin is ingested and causes profound neuromuscular blockade, leading to autonomic and motor paralysis. The first symptoms, occurring 18 to 24 hours after ingestion, are nausea and diarrhoea. These are followed by cranial nerve palsies and then progressive symmetrical paralysis, leading to respiratory failure.

The diagnosis is usually clinical and is confirmed by detection of toxin in faeces or in contaminated food. Management is mainly supportive, with mechanical ventilation if necessary. Antitoxin is available in some countries (including the UK); the risk of anaphylaxis is relatively high, and antitoxin should be used only in severe cases. A subcutaneous test dose should be given before intravenous or intramuscular injection. Antibiotics have no proven role. The overall mortality rate from botulism is high, but patients who survive the acute paralysis can make a full recovery.

A similar clinical picture can follow the contamination of wounds or injection of street heroin contaminated with *C. botulinum*; in infants, botulism may be related to bowel colonization by the organism.

Tetanus

Tetanus is also caused by a toxin-secreting clostridium: *C. tetani*. The organism is found in soil, and illness usually results from a contaminated wound. The injury itself may be trivial and disregarded by the individual. Tetanus can also complicate injecting drug use if the drug (usually heroin) is contaminated with *C. tetani*. In low- and middle-income countries, neonatal tetanus follows contamination of the umbilical stump, often after the area is dressed with dung. The overall incidence of tetanus across the world has fallen significantly in the past 30 years mainly because of active immunization.

The organism is not invasive and clinical manifestations of the disease are caused by the potent neurotoxin tetanospasmin. Tetanospasmin causes disinhibition at synapses, neuromuscular blockade, and skeletal muscle spasm and acts on the sympathetic nervous system. The end results are marked flexor muscle spasm and autonomic dysfunction.

Clinical features

The incubation period varies from a few days to several weeks. The most common form of the disease is generalized tetanus. General malaise is rapidly followed by trismus (lockjaw) caused by masseter muscle spasm. Spasm of the facial muscles produces the characteristic grinning expression known as *risus sardonicus*. If the disease is severe, painful reflex spasms develop, usually within 24 to 72 hours of the initial symptoms. The interval between the first symptom and the first spasm is referred to as the 'onset time'. The spasms may occur spontaneously but are easily precipitated by noise, handling of the patient, or light. Respiration may be impaired because of laryngeal spasm; oesophageal and urethral spasm lead to dysphagia and urinary retention, respectively, and there is arching of the neck and back muscles (opisthotonus). Autonomic dysfunction produces tachycardia, a labile blood pressure, sweating, and cardiac arrhythmias. Patients with tetanus are mentally alert.

Death results from aspiration, hypoxia, respiratory failure, cardiac arrest, or exhaustion. Mild cases with rigidity usually recover. Poor prognostic indicators include a short incubation period, short onset time, and extremes of age.

Localized tetanus is a milder form of the disease. Pain and stiffness are confined to the site of the wound, with increased tone in the surrounding muscles. Recovery is usual.

Cephalic tetanus is uncommon but invariably fatal. It usually occurs when the portal of entry of *C. tetani* is the middle ear. Cranial nerve abnormalities, particularly of the VIIth nerve, are usual. Generalized tetanus may or may not develop.

Neonatal tetanus is characterized by failure to thrive, poor sucking, grimacing, and irritability followed by the rapid development of intense rigidity and spasms. The mortality rate approaches 100%. Aims of the WHO's EPI are to eliminate this condition by immunizing all females of child-bearing age, providing clean delivery facilities, and strengthening surveillance in high-risk areas.

Diagnosis

Few diseases resemble tetanus in its fully developed form, and the diagnosis is therefore usually clinical. Rarely, *C. tetani* is isolated from wounds. Phenothiazine overdosage, strychnine poisoning, meningitis, and tetany can occasionally mimic tetanus.

Management

If tetanus is suspected, any wound must be cleaned and debrided to remove the source of toxin. Human tetanus immunoglobulin 250 units should be given along with an intramuscular injection of tetanus toxoid. If the patient is already protected, a single booster dose of the toxoid is given; otherwise, the full three-dose course of adsorbed vaccine is required (see later).

In established disease, management consists of supportive medical and nursing care. Improvement in this area has contributed, more than any other single measure, to the decrease in the mortality rate from 60% to nearer 20%. Patients are nursed in a quiet, isolated, well-ventilated, darkened room. Benzodiazepines are used to control spasms and sedate the patient; if the airway is compromised, intubation and mechanical ventilation may be necessary. Magnesium sulphate infusion may decrease the need for antispasmodics.

Antibiotics and antitoxin should be administered, even in the absence of an obvious wound. Intravenous metronidazole for 7 to 10 days is the drug of choice, although penicillin is also effective. Human tetanus immunoglobulin (HTIG) should be given as soon as possible, by either intravenous infusion or intramuscular injection, to neutralize any circulating toxin. If HTIG is not available, human normal immunoglobulin (HNIG) can be used. If the patient recovers, active immunization should be instituted because immunity after tetanus is incomplete.

Prevention

An effective, safe and relatively cheap vaccine means that tetanus is an eminently preventable disease. After initial active immunization at 2, 3, and 4 months of age, followed by pre-school and teenage doses, further boosters are no longer recommended at 10-year intervals for all adults; however, if there is any doubt regarding receipt of all five doses, then further boosters are recommended, typically in the context of potential contaminated injuries. Infant immunization schedules in all countries include tetanus. Protection by passive immunization with HTIG or HNIG is short-lived, lasting only about 2 weeks.

BACTERIAL BONE AND JOINT INFECTIONS

See Chapters 32 ('Infection of joints' section) and 33 ('Bone infections' section).

BACTERIAL INFECTIONS OF THE URINARY TRACT

See Chapter 26 ('Urinary tract infection' section).

SYSTEMIC AND MULTISYSTEM BACTERIAL INFECTIONS

Many infections are confined to a particular body organ or system, owing to the metabolic requirements of the organism, the route of infection, or the response of host defences. Other infections can potentially affect several systems or the entire body. Under unusual circumstances, such as altered host immunity, infections that are normally circumscribed may become systemic. The general principles of systemic infections, bacteraemia, and sepsis are described in Chapter 12, as are their common causes. This section describes some specific and less common bacterial infections that cause multisystem disease in immunocompetent hosts.

Leptospirosis

Leptospirosis is a zoonosis caused by the spirochaete *Leptospira interrogans*. There are more than 200 serotypes. The main types affecting humans are:

- *Leptospira i. icterohaemorrhagiae* (normal host rodents)
- *Leptospira i. canicola* (dogs and pigs)
- *Leptospira i. hardjo* (cattle)
- *Leptospira i. pomona* (pigs and cattle).

Leptospires are excreted in animal urine and enter the host through a skin abrasion or intact mucous membranes. They can also be transmitted by ingestion of contaminated water. The organism can survive for many days in warm freshwater and for up to 24 hours in seawater.

In England and Wales, between 100 and 150 cases of leptospirosis are reported every year, although many mild infections probably go undiagnosed. (About 90%–95% of infections are subclinical or cause only a mild fever.) It is traditionally an occupational disease of farmers, veterinarians, and others who work with animals but is increasingly associated with recreational activities that bring people into closer contact with rodents or contaminated water. Outbreaks of leptospirosis have also been associated with flooding, particularly in urban areas of LMICs.

Clinical features

In 1886, Adolf Weil described a severe illness consisting of jaundice, haemorrhage, and renal impairment caused by *L. i. icterohaemorrhagiae*, but the disease has long been recognized around the world in communities at risk such as 'autumn fever' in Chinese rice paddy workers and 'dairy farm fever' in New Zealand cattle farmers.

The incubation period of leptospirosis is usually 7 to 14 days, and the illness typically has two phases: a leptospiraemic phase, which lasts for up to 1 week, followed after a couple of days' interval by an immunological phase. The first phase is characterized by severe headache, malaise, fever, anorexia, and myalgia. Most patients have conjunctival suffusion. Hepatosplenomegaly, lymphadenopathy, and various skin rashes are sometimes seen. The second phase is usually mild. Meningism is common; if lumbar puncture is performed, there is often CSF lymphocytosis. The majority of patients recover uneventfully at this stage.

In severe disease, there may not be a clear distinction between phases. After the initial symptoms, patients progressively develop liver and kidney injury, haemolytic anaemia, and circulatory collapse. Cardiac failure and pulmonary haemorrhage may also occur. Even with full supportive care, the mortality rate is around 10%, rising to 15% to 20% in older adults.

Diagnosis

The diagnosis is usually a clinical one, in combination with epidemiological risk and laboratory data. Leptospires can be cultured from blood or CSF during the first week of illness, but culture requires special media and may take several weeks. Leptospiral DNA can be detected by PCR in the blood and urine. A minority of patients may also excrete the organism in their urine from the second to the fourth week. Confirmation is usually serological. Specific IgM antibodies start to appear from the end of the first week and the diagnosis is often made retrospectively with a microscopic agglutination test showing a fourfold rise. There is typically a leucocytosis and transaminitis and, in severe infection, thrombocytopenia and an elevated creatine kinase.

Management

Early antibiotic therapy may limit progress of the disease, and penicillin or ceftriaxone should be given in severe cases. The efficacy of antibiotics in mild disease is debated; if they are used, oral doxycycline is first-line therapy. Patients who develop hepatorenal syndrome may need intensive care.

Brucellosis

Brucellosis (Malta fever, undulant fever) is caused by various species of *Brucella*, a Gram-negative intracellular coccobacillus. It is a zoonosis, especially of goats, sheep, and cattle, and has a worldwide distribution. Some countries, such as the UK, have been declared 'brucellosis free', although a handful of imported human cases are diagnosed each year. There are around half a million new cases a year with the highest incidence occurring in the Mediterranean, Middle East, and tropical belt.

The bacteria usually gain entry to the human body via the mouth; less frequently, they may enter via the respiratory tract, genital tract, or broken skin. The bacilli travel in the lymphatics and infect lymph nodes. This is followed by haematogenous spread with ultimate localization in the reticulo-endothelial system. Acquisition is usually by the ingestion of raw milk from infected cattle, goats, or camels, although occupational exposure is also common. Person-to-person transmission is rare.

Clinical features

The incubation period of acute brucellosis is 1 to 3 weeks. The onset is insidious, with malaise, headache, weakness, generalized myalgia, and night sweats. The fever pattern is classically waxing and waning (undulant), although continuous and intermittent patterns are also seen. Lymphadenopathy and hepatosplenomegaly are common; sacroiliitis, arthritis, osteomyelitis, epididymo-orchitis, meningoencephalitis, and endocarditis have all been described.

Untreated brucellosis can give rise to chronic infection, lasting 1 year or more. This is characterized by easy fatigability, myalgia, and occasional bouts of fever and depression. Splenomegaly is usually

present. Occasionally, brucellosis can cause a localized infection in almost any organ that is not associated with systemic features.

Diagnosis

Blood and bone marrow cultures are positive in more than half of patients with acute *Brucella* (higher in *Brucella melitensis*) but prolonged culture is needed and the success rate falls with time. In chronic disease, serological tests are of greater value. The *Brucella* agglutination test, which demonstrates a fourfold or greater rise in titre (>1 in 160) over a 4-week period, is highly suggestive of brucellosis. An elevated serum IgG level is evidence of current or recent infection; a negative test result excludes chronic (non-localized) brucellosis. In localized brucellosis, antibody titres are low, and the diagnosis is usually established by culturing the organisms from the involved site. Species-specific PCR tests are also available.

Management and prevention

Brucellosis should be treated with a combination of doxycycline, rifampicin, and an aminoglycoside (usually gentamicin) for 6 weeks. Prevention and control involve careful attention to hygiene when handling infected animals, eradication of infection in animals through vaccination, and the pasteurization of milk. No vaccine is available for use in humans.

Listeriosis

L. monocytogenes is an environmental organism that is widely disseminated in soil and decayed matter. It affects both animals and humans; the most common route of human infection is in contaminated foodstuffs. The organism can grow at temperatures as low as 4°C, and the most commonly implicated foods are unpasteurized soft cheeses, raw vegetables, and chicken pâtés. Listeriosis is a rare but serious infection affecting mainly neonates, pregnant females, older adults, and immunocompromised people. *L. monocytogenes* has also been recognized as a cause of self-limiting, food-borne gastroenteritis in healthy adults, but the incidence of this is unknown.

In pregnancy, *Listeria* causes an influenza-like illness, but infection of the fetus can lead to septic abortion, premature labour, and stillbirth in up to half of cases when treatment is delayed. In older adults and immunocompromised patients, *Listeria* can cause bacteraemia, meningoencephalitis, and various focal infections. The diagnosis is established by culture of blood, CSF, or other body fluids. The treatment of choice for adult listeriosis is ampicillin plus gentamicin. Co-trimoxazole and meropenem are also effective, but the organism is resistant to cephalosporins.

Q fever

In 1937 Edward Derrick documented a new disease in Australian slaughterhouse workers and called it ‘Q fever’ for ‘query cause’. We now know that Q fever is a zoonosis caused by *C. burnetii*, a Gram-negative intracellular bacterium. The infection is widespread in domestic, farm, and other animals; birds; and arthropods, and it is transmitted mainly by ticks. Animal-to-human spread is through contaminated dust, aerosol, and unpasteurized milk from infected cows. The formation of spores means that *C. burnetii* can survive in extreme conditions for long periods; moreover, the infective dose is very small, so minimal animal contact is required. An outbreak affecting more than 4000 people in the Netherlands linked to goat farming had the main risk factor as being resident within 5 km of an affected farm. Diagnosis is difficult, so the disease is underdiagnosed, particularly in resource-limited settings. One prospective study in northern Tanzania found that almost 10% of cases of severe non-malarial fever were caused by *C. burnetii*.

Clinical features

Symptoms begin insidiously 2 to 4 weeks after infection. Fever is accompanied by influenza-like symptoms with myalgia and headache. The acute illness usually resolves spontaneously, but pneumonia or hepatitis may develop. In pregnancy, Q fever can cause severe fetal damage. Occasionally, infection can become chronic, resulting in endocarditis, myocarditis, uveitis, osteomyelitis, and other focal infections.

C. burnetii is an obligate intracellular organism and does not grow on standard culture media. Diagnosis is made serologically using an immunofluorescent assay. Antibody tests for two different bacterial antigens allow distinction between acute and chronic infection. A PCR assay is available, but the sensitivity is low.

Management

Treatment with doxycycline or azithromycin shortens the duration of the acute illness, and there is emerging evidence that it may reduce the incidence of chronic sequelae. For chronic Q fever, including endocarditis, doxycycline is often combined with rifampicin or hydroxychloroquine, but even prolonged courses of treatment may not clear the infection. A vaccine is available for those at high risk.

Lyme disease

Lyme disease is caused by spirochaetes of the genus *Borrelia*. *Borrelia burgdorferi* is the sole cause of Lyme disease in the USA. In Europe, *Borrelia afzelii* and *Borrelia garinii* are also implicated. Lyme disease is a zoonosis of deer and other wild mammals. It has increased in both incidence and detection, and it is now known to be widespread in the USA, Europe, Russia, and the Far East. The vector is not present in most of the Southern Hemisphere, and case reports from South America, sub-Saharan Africa, and South Asia are rare.

More than 1000 laboratory-confirmed infections are reported in England and Wales each year, with two to three times more diagnosed clinically. By comparison, around 30 000 cases per year are reported to the US Centers for Disease Control and Prevention. Infection is transmitted from animal to human by *Ixodid* ticks and is most likely to occur in wooded areas, including urban gardens and parks, in spring and early summer when the ticks are feeding. In places where other tick-borne infections such as ehrlichia and babesia are endemic, simultaneous co-infection may occur.

Clinical features

Early localized disease presents about a week after the tick bite with erythema migrans: a macular ‘bull’s eye’ rash usually occurring around the site of the tick bite (**Fig. 42.22**). This progresses to regional lymphadenopathy and associated fever and headache. Most people recover spontaneously with no further symptoms or signs. A small number may develop early disseminated disease, which occurs days to weeks after the appearance of erythema migrans. The rash may spread, and a small proportion of untreated patients may develop neurological complications such as meningitis, encephalitis, cranial or peripheral neuritis, or radiculopathies. Cardiac involvement is seen in the USA but is rare elsewhere. Myalgia and migratory arthritis may also occur at this stage. Late Lyme disease, which is rare, can cause chronic arthritis, encephalomyelitis, and other neurological disorders, along with acrodermatitis chronica atrophicans. Much of the damage in late Lyme disease is likely to be immune-mediated, and although antibiotics should be given to eradicate any persistent infection, there is no evidence to support a role for extended treatment.

Fig. 42.22 **The skin lesion erythema migrans at the site of a tick bite.**

Diagnosis

The clinical features and epidemiological considerations are usually strongly suggestive. The presence of erythema migrans after a risk exposure requires antibiotic treatment without further diagnostic tests (which may well be negative at this stage anyway). In patients with a high clinical suspicion of Lyme disease but no sign of erythema migrans, it is reasonable to start treatment while waiting for a confirmatory test using a combined IgG and IgM ELISA. If the ELISA result is equivocal or positive, then follow-up with a Lyme immunoblot test because of the high rate of false-positive results. When the ELISA is negative and Lyme disease is still suspected, the ELISA is repeated 4 to 6 weeks after the onset of symptoms, or if the symptoms have been present for more than 3 months, an immunoblot test should be performed. The diagnosis can be confirmed only rarely by isolation of the organisms from blood, skin lesions, or CSF, and although it is occasionally possible to find patients who have PCR evidence of Lyme disease and negative serology, this is the exception; an alternative diagnosis should be sought in patients with persistently negative Lyme serology. As in all cases, but particularly regarding assays for Lyme disease, samples should only be sent to accredited laboratories that take part in external quality assurance programmes.

Management

Antibiotics given early in the course of disease shorten the duration of illness and significantly reduce the risk of complications. Doxycycline given for 3 weeks is first-line treatment for erythema migrans and most cases of early disseminated disease. Amoxicillin is an alternative. Ceftriaxone is the treatment of choice for CNS disease. It is reasonable to offer a second course of a different class of antibiotics for patients with persisting symptoms. However, after this, when the diagnosis is secure, care is principally supportive. Patients may have chronic pain, fatigue, depression, and loss of function over a prolonged period, requiring specialist support and information.

Repellents and protective clothing should be worn in areas with high tick burden. Checking for ticks at the end of the day and prompt removal are essential because infection is unlikely to take place unless the tick has been attached for more than 48 hours. Ticks should be grasped with forceps near to the point of attachment to the skin and then withdrawn by gentle traction. Antibiotic prophylaxis after a tick bite is not usually justified even in areas where Lyme disease is common. There is no effective vaccine.

Tularaemia

Tularaemia is caused by infection with *Francisella tularensis*, a Gram-negative coccobacillus. It is primarily a zoonosis, usually acquired from rodents. Infection can be transmitted by arthropod vectors or by handling infected animals, when the microorganisms enter through minor abrasions or intact mucous membranes. Occasionally, infection occurs from contaminated water or from uncooked meat. The organism is widely distributed in North America, Northern Europe, and Asia, but the particularly virulent type A subspecies is seen only in the USA. It is relatively rare, occurring mainly in hunters, trappers, and others in close contact with animals; about 800 cases per year are recorded in Europe, mainly in Scandinavia.

The incubation period of 2 to 7 days is followed by a systemic illness. The most common presentation is ulceroglandular tularaemia. A papule occurs at the site of inoculation; this ulcerates and is followed by tender, suppurative lymphadenopathy. Rarely, this can be followed by septicaemia, pneumonia, or meningitis. These forms of the disease carry a high mortality rate if left untreated.

Routine culture results are often negative, and diagnosis has traditionally been made serologically. PCR is now becoming the standard diagnostic test.

Doxycycline can be used in mild disease, but the most effective antibiotics are aminoglycosides and fluoroquinolones.

BACTERIAL INFECTIONS SEEN IN LOW- AND MIDDLE-INCOME COUNTRIES

Skin, soft tissue, and eye diseases

Leprosy (Hansen's disease)

Leprosy is caused by the acid-fast bacillus *Mycobacterium leprae*. Unlike other mycobacteria, this does not grow in artificial media or even in tissue culture, although it can be grown in the footpads of mice for research purposes. Apart from nine-banded armadillos, humans are the only natural host of *M. leprae*.

Leprosy has a global distribution, and new cases are currently reported in 127 countries. The WHO has provided free drug treatment since 1995, and the campaign to control the disease has been hugely successful. In 2016 the WHO published a new Global Leprosy Strategy, with the aim of reducing the number of children diagnosed and presenting with physical deformities to zero. However, by the end of 2019, 202 256 patients worldwide were still undergoing treatment for leprosy with a prevalence of 22.9 cases per million. Several countries, principally India, Brazil, and Indonesia, continue to report high numbers of new cases with more than half of them being in children, indicating ongoing early exposure to infection.

The precise mode of transmission of leprosy is still uncertain, but it is likely that nasal secretions play a role. Infection is related

to poverty and overcrowding. After an individual has been infected, subsequent progression to clinical disease appears to be dependent on several factors. Males are more susceptible than females, and there is evidence from twin studies of a genetic susceptibility. The main factor, however, is the response of the host's cell-mediated immune system.

Two ***polar types*** of leprosy are recognized, with most patients falling on a spectrum between the two (Fig. 42.23):

- ***Tuberculoid leprosy*** is a localized disease that occurs in individuals with a high degree of CMI. The T-cell response to the antigen releases IFN-γ, which activates macrophages to destroy the bacilli (Th1 response) but with an associated destruction of tissue.
- ***Lepromatous leprosy*** is a generalized disease that occurs in individuals with impaired CMI. Here the tissue macrophages fail to be activated, and the bacilli multiply intracellularly. Th2 cytokines are produced, and patients develop a fever and systemic illness.

In 1966 Ridley and Jopling divided leprosy into five clinicopathological groups (Fig. 42.24). This remains the 'gold standard' classification, but for the purposes of treatment, the WHO has defined two main patterns of disease:

- ***Paucibacillary leprosy***, with five or fewer skin lesions and no bacilli on microscopy
- ***Multibacillary leprosy***, with six or more lesions that may have bacilli on microscopy.

Slit-skin smears are not always available in practice, and the distinction must be made on clinical grounds alone. Concern has been raised that this may lead to undertreatment of some people incorrectly identified as having paucibacillary leprosy, but overall, the WHO regimen has been remarkably successful.

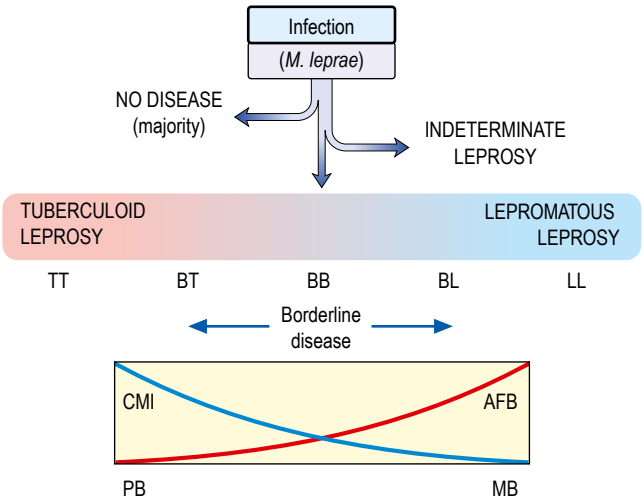

Fig. 42.23 Clinical spectrum of leprosy with the combined Ridley–Jopling and World Health Organization classification. *AFB,* Acid-fast bacilli; *BB,* borderline; *BL,* borderline lepromatous; *BT,* borderline tuberculoid; *CMI,* cell-mediated immunity; *LL,* lepromatous leprosy; *MB,* multibacillary; *PB,* paucibacillary; *TT,* tuberculoid leprosy.

Clinical features

The incubation period is 5 years on average, although it may be as short as 1 year or as long as 20 years and differs between tuberculoid (shorter) and lepromatous (longer). The onset is generally insidious, although acute onset is known to occur. Patients may present with a transient rash, features of an acute febrile illness, evidence of nerve involvement, or any combination of these.

Diagnosis

The diagnosis of leprosy is essentially clinical, with anaesthetic hypopigmented or reddish skin patches and thickened peripheral nerves. Acid-fast bacilli (AFB) may be seen on slit-skin smears. These are 3- to 5-mm long and 2- to 3-mm deep incisions taken

A Tuberculoid (TT)	B Borderline tuberculoid (BT)	C Borderline (BB)	D Borderline lepromatous (BL)	E Lepromatous (LL)
				Skin lesion (usually single) - hypopigmented - anaesthetic - clearly defined edges - thickened local nerve(s) May heal spontaneously	Several skin lesions - similar to TT Thickened peripheral nerves - deformities of hands/feet	Numerous skin lesions - varying size Widespread nerve involvement and deformity	Numerous florid skin lesions - variable size and form - contain many AFB Variable nerve involvement Neurotrophic atrophy of digits	Extensive skin infiltration Mucous membrane involvement Nasal septal perforation - 'Leonine facies' Glove and stocking anaesthesia Multiple nerve palsies Neurotrophic atrophy of digits

Fig. 42.24 The spectrum of disease in leprosy. *AFB,* Acid-fast bacilli. *(C, From Cohen J, Powderly JG.* Infectious Diseases, *3rd edn. London: Mosby; 2010, with permission. E, From Goering R, et al.* Mims' Medical Microbiology, *5th edn. London: Mosby; 2013, courtesy of DA Lewis, with permission.)*

from the ear lobes, elbows, and knees of the patient with a scalpel and examined under the microscopy for AFB using a modified Ziel-Neelsen stain. Results are expressed on a semi-logarithmic scale as the bacillary index. Occasionally, nerve biopsies are helpful. Detection of *M. leprae* DNA is possible in all forms of leprosy and can be used to assess the efficacy of treatment. The Lepromin test and leprosy serology are poorly sensitive and specific and are not routinely used for diagnosis in clinical practice.

Management

In some areas up to 40% of bacilli are resistant to dapsone and so multidrug therapy (MDT) is essential. Much shorter courses of treatment are now being used; the current WHO-recommended drug regimens for leprosy are shown in **Box 42.49** but longer therapy is required in severe cases. Follow-up, including skin smears where possible, is obligatory. Immunological reactions ('lepra reactions') can occasionally occur after treatment is started, especially in borderline and lepromatous disease (**Box 42.50**).

Patients with leprosy should be treated in specialist centres with adequate physiotherapy and occupational therapy support. Surgery and physiotherapy also play a role in the management of trophic ulcers and deformities of the hands, feet, and face. Patients should be taught self-care of their anaesthetic hands and feet to prevent ulcers. Cheap canvas shoes with cushioned insoles are protective. Psychosocial and financial support are as important as drug therapy in addressing the societal impact of the disease on patients and their families.

The prognosis in tuberculoid leprosy is good, even if untreated; lepromatous leprosy is progressive if untreated.

Prevention

The prevention and control of leprosy depend on the rapid treatment of infected patients, particularly those with lepromatous and borderline lepromatous types, to decrease the bacterial reservoir. Bacille Calmette–Guérin vaccination has a modest effect in protection against leprosy, but the effect tends to wane, and its use remains controversial.

Anthrax

Anthrax is caused by *Bacillus anthracis*. The spores of these Gram-positive bacilli are extremely hardy and withstand extremes of temperature and humidity. The organism is capable of toxin production, and this property correlates most closely with its virulence. The disease occurs worldwide but is most common in Africa and Southern Asia. Surveillance data are limited, but the likely global annual incidence is in the tens of thousands. In Europe and the USA, there are only very occasional cases. Transmission is through direct contact with an infected animal or its carcass; infection is most frequently seen in farmers, butchers, and dealers in wool and animal hides. Spores can also be ingested or inhaled. Cases in the USA have been caused by the deliberate release of anthrax spores as a bioterrorist weapon.

Box 42.49 Recommended treatment regimens for leprosy in adults (modified World Health Organization guidelines)

Multibacillary leprosy (LL, BL, BB)	Paucibacillary leprosy (BT, TT)
• Rifampicin 600 mg once monthly, supervised	• Rifampicin 600 mg once monthly, supervised
• Clofazimine 300 mg once monthly, supervised	• Dapsone 100 mg/day, self-administered • Clofazimine 300 mg once monthly plus 50 mg daily
	• Treatment continued for 6 months
• Clofazimine 50 mg/day, self-administered	**Single-lesion paucibacillary leprosy**
• Dapsone 100 mg/day, self-administered • Treatment continued for12 months	• Rifampicin 600 mg • Ofloxacin 400 mg • Minocycline 100 mg (as a single dose)

Clinical features

The incubation period is 1 to 10 days.

Cutaneous anthrax is the most common form. The small, erythematous, maculopapular lesion is initially painless. It may subsequently vesiculate and ulcerate, with formation of a central black eschar. The illness is self-limiting in most patients, but occasionally, perivesicular oedema and regional lymphadenopathy may be marked, and toxaemia can occur.

Inhalational anthrax (wool-sorter's disease) follows inhalation of spores. A febrile illness is accompanied by a non-productive cough and retrosternal discomfort; pleural effusions are common. If the disease is untreated, the mortality rate is about 90%; in bioterrorism cases in the USA, it was 45% despite treatment.

GI anthrax is caused by consumption of undercooked, contaminated meat. It presents as severe gastroenteritis, sometimes with haematemesis and bloody diarrhoea. In some cases, systemic toxin spread may lead to shock and death.

Diagnosis

The diagnosis is established by demonstrating the organism in smears from cutaneous lesions or by culture of blood and other body fluids. Serological confirmation can be obtained using an ELISA that detect antibodies to both the organism and the toxin. PCR tests are available.

Management

Ciprofloxacin is considered the best treatment. In mild cutaneous infections, oral therapy for 2 weeks is adequate. In more severe infections, high doses of intravenous antibiotics are needed, along with appropriate supportive care. The monoclonal antibody raxibacumab has been shown in animal studies to improve survival in those with inhalational anthrax. All suspected cases should be reported to the relevant authority.

Control

All infected animals that die should be burned and the area where it was housed disinfected. Where animal husbandry is poor, mass vaccination of animals may prevent widespread contamination but needs to be repeated annually. A human vaccine is available for those at high risk, and prophylactic ciprofloxacin is used after exposure. Some countries have established public health policies to deal with the deliberate release of anthrax spores.

Mycobacterial ulcer (buruli ulcer)

Buruli ulcer, caused by *Mycobacterium ulcerans*, is occasionally reported in humid parts of the tropics near slow-moving or stagnant water, but it is particularly prevalent in rural west Africa. It is found in water, soil, and fish and invertebrates that live in or near water. The mode of transmission is unknown, but it does not seem to be spread by human-to-human contact. About 3000 cases per year are reported to the WHO, but the true prevalence is much higher.

Box 42.50 Leprosy reactions after commencement of anti-mycobacterial treatment

Type 1
- Occurs in borderline disease
- Type IV hypersensitivity reaction
- Lasts for many months
- Upgrading (→TT) or downgrading (→BB)
- Abrupt onset of nerve palsies in upgrading
- Treatment: prednisolone

Type 2 (erythema nodosum leprosum)
- Occurs in lepromatous disease
- Type III (immune complex) hypersensitivity reaction
- Lasts days to weeks
  - Fever
  - Arthralgia
  - Subcutaneous nodules
  - Iridocyclitis
- Rare since clofazimine included in treatment
- Treatment[a]
  - Analgesia
  - Clofazimine (if not already started)
  - Prednisolone if eye involvement
  - Continuation of anti-mycobacterial treatment

[a]Thalidomide no longer has any role in the management of lepra reactions.
BB, Borderline; *TT*, tuberculoid.

A small subcutaneous nodule at the site of infection gradually ulcerates, involving subcutaneous tissue, muscle and fascial planes, and occasionally bone. The ulcers are usually large with undermined edges and markedly necrotic bases due to mycolactone (a toxin produced by the mycobacterium). Smears taken from necrotic tissue generally reveal numerous AFB; a PCR assay is widely available. Combination therapy with rifampicin plus one of streptomycin, clarithromycin, or moxifloxacin, given for 8 weeks, heals ulcers in many cases. However, in more severe cases, surgical debridement and, where possible, skin grafting may be needed as well.

Tropical ulcer

Tropical ulcer is a non-specific infection, usually polymicrobial, seen in damp, hot climates. A wide variety of organisms have been implicated, but there is no characteristic bacterium associated with the condition. Good wound hygiene is the mainstay of management, with antibiotic therapy used (either empirically or based on culture) as needed.

Endemic treponematoses

Yaws

Yaws is caused by *Treponema pallidum* subspecies *pertenue*. It is the most widespread and common of the endemic treponemal diseases and primarily occurs in children younger than 15 years. Most cases are now reported from West Africa and the South Pacific.

After an incubation period of weeks or months, a primary inflammatory reaction occurs at the inoculation site, from which organisms can be isolated. Dissemination of the organism leads to multiple papular lesions containing treponemes; these skin lesions usually involve the palms and soles. Left untreated, there may be bone involvement with a painful periostitis, commonly affecting the long bones and those of the hand.

Approximately 10% of those infected go on to develop late yaws. Bony gummatous lesions may progress to cause gross destruction and disfigurement, particularly of the skull and facial bones, interphalangeal joints, and long bones. Plantar hyperkeratosis is characteristic. As in syphilis, there may be a latent period between the early and late phases of the disease, but visceral, neurological, and cardiovascular problems do not occur.

The diagnosis is clinical. The causative organism can be identified from the exudative lesions under dark-ground microscopy. Serological tests for syphilis are positive and do not differentiate between the conditions. Rapid point-of-care, species-specific tests are used but do not distinguish between past and current infection. PCR diagnosis is not widely available but may become important in the yaws eradication campaign because it is necessary to distinguish active from treated infection.

Single-dose oral azithromycin has now replaced intramuscular benzathine penicillin as the treatment of choice. This drug has now been placed on the WHO list of essential medicines as part of the international strategy to eradicate yaws through mass treatment.

Bejel (endemic syphilis)

Bejel is seen in the arid parts of Africa, the Middle East, and Central Asia. The causative organism *(Treponema endemicum)* enters through abrasions in the skin directly or by mouth-to-mouth contact. Bejel differs from venereal syphilis in that the primary lesion is small and often in the mouth. The late stages resemble syphilis, but cardiological and neurological manifestations are rare.

Pinta

Pinta (caused by *Treponema carateum*) is restricted mainly to Central and South America. There is no effective surveillance, and the current prevalence is unknown. It is milder than the other treponematoses and confined to the skin. The primary lesion is a pruritic red papule, usually on the hand or foot. It may become scaly but never ulcerates. Lesions can occur for up to 1 year after onset and are often associated with generalized lymphadenopathy. Eventually, the lesions heal, leaving hyperpigmented or depigmented patches.

The diagnosis of bejel and pinta is largely clinical, but spirochaetes are visible on dark-ground microscopy of early lesions. Serological tests for syphilis cross-react and are usually positive. Treatment is with benzathine penicillin, although it is likely that azithromycin will prove to be effective. Surveillance, diagnosis, and treatment are less well coordinated than for yaws.

Trachoma

Trachoma is caused by the intracellular bacterium *Chlamydia trachomatis*, which can also cause a number of STIs (see Chapter 43). It is the most common infectious cause of blindness worldwide. The WHO launched a global elimination programme in 1996, and as a result, the number of people at risk has fallen from 1.5 billion to 115 million with 17 countries having eliminated the disease.

Trachoma is a disease of poverty. It was once found throughout the world but is now mainly limited to the tropics and the Middle East and is entirely preventable. It commonly occurs in children and is spread by direct contact, on fomites such as dirty washcloths, or through flies landing on the eyes. Isolated infection is self-limiting, but repeated infection leads to chronic inflammation and scarring.

Clinical features

Infection is bilateral and begins in the conjunctiva, with marked follicular inflammation and subsequent scarring. Damage to the upper

eyelid causes entropion, leaving the cornea exposed to further abrasion from the eyelashes turning in and rubbing against it (trichiasis) and eventually to corneal opacification and blindness.

Trachoma may also occur as an acute ophthalmic infection in neonates.

Diagnosis and management

The diagnosis is generally made clinically.

Systemic therapy with a single dose of azithromycin is the treatment of choice, but re-infection is common in endemic areas. Annual mass drug administration is recommended for communities with a prevalence of active disease greater than 10%. After the infection has been controlled, surgery may be required for patients with trichiasis to direct the eyelashes away from the cornea.

Prevention

Community health education, improvements in water supply and sanitation (pit latrines), and earlier case reporting have a substantial impact on disease prevalence. This is reflected in the 'SAFE' approach to trachoma:

- Surgery
- Antibiotics
- Facial cleanliness
- Environmental improvement

Gastrointestinal infections

Cholera

Cholera is caused by the curved, flagellated, Gram-negative bacillus *V. cholerae*. The organism is killed by temperatures of 100°C in a few seconds but can survive in ice for up to 6 weeks.

The fertile, humid plains of the River Ganges in West Bengal have traditionally been regarded as the home of cholera. However, a series of pandemics have spread the disease across the world, usually following trade routes. Until recently, all outbreaks of cholera were caused by *V. cholerae* O1, which is responsible for the recent pandemic (which spread internationally between the 1960s and 1990s). More recently, a new serogroup (O139 Bengal) caused outbreaks of an illness indistinguishable from O1 cholera, but it has not been reported outside of Bangladesh, India, and South-east Asia. Outbreaks of cholera are common when there is disruption of water supplies and sanitation, for example, with natural disasters or conflict. It was John Snow's observations linking cases of cholera to the use of a water pump in Broad Street, London, in 1854, which is seen as the origin of the science of epidemiology.

Transmission is by the faecal–oral route, and although contaminated water plays the major role in its spread, contaminated foodstuffs and contact carriers may contribute in cholera epidemics. Achlorhydria or hypochlorhydria facilitates passage of the cholera bacilli into the small intestine. There they attach to the wall and proliferate and produce an exotoxin that causes a massive secretion of isotonic fluid into the lumen through increasing the secretion of chloride and blocking the absorption of sodium. Cholera toxin also releases serotonin from enterochromaffin cells in the gut, which activates a neural secretory reflex in the enteric nervous system. This may account for at least 50% of cholera toxin's secretory activity. *V. cholerae* also produces other toxins, contributing to its pathogenic effect.

Clinical features

The incubation period varies from a few hours to 6 days. The vast majority of patients with cholera have a mild illness that is clinically indistinguishable from diarrhoea from other infective causes. In severe cases, there is abrupt onset of profuse painless diarrhoea followed by vomiting. As the illness progresses, the typical 'rice water' stool, flecked with mucus, may be seen. There is massive fluid loss, and if this is not replaced, the features of hypovolaemic shock (cold, clammy skin; tachycardia, hypotension; and peripheral cyanosis) and dehydration (sunken eyes, hollow cheeks, and a diminished urine output) can develop within hours. Muscle cramps may be severe. Children may present with convulsions owing to electrolyte disturbance and hypoglycaemia.

Severe cholera has an untreated mortality rate of up to 50% but as long as the patient can be adequately rehydrated, the prognosis is good, with a gradual return to normal clinical and biochemical parameters in 1 to 3 days.

Diagnosis

This is largely clinical, particularly in epidemic settings. Microscopy of freshly passed stools may demonstrate rapidly motile organisms, although this is not diagnostic because *C. jejuni* may give a similar appearance. A rapid dipstick test is also available in the field. Stool and rectal swabs should be taken for culture to confirm the diagnosis and establish antibiotic sensitivity. Cholera should always be reported to the appropriate public health authority.

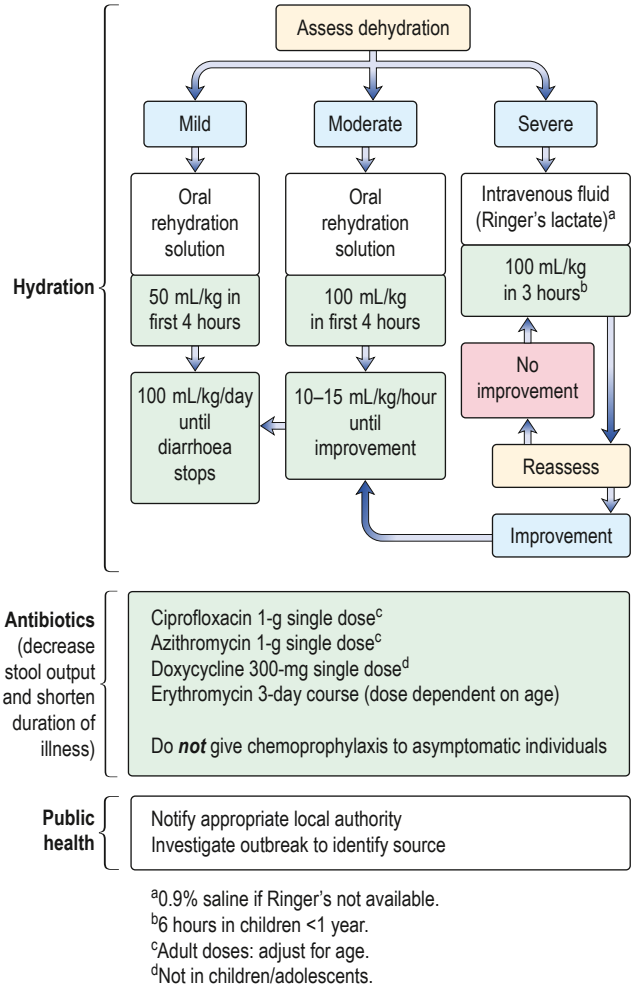
Management

The mainstay of treatment is rehydration. If done effectively the mortality decreases to less than 1%. Oral rehydration is usually adequate, but intravenous therapy is sometimes required (**Fig. 42.25**).

Oral rehydration solutions are based on the observation that glucose and other carbohydrates enhance sodium and water absorption in the small intestine even in the presence of secretory loss caused by toxins. Additions such as amylase-resistant starch to glucose-based oral rehydration solutions have been shown to increase the absorption of fluid. Cereal-based electrolyte solutions have been found to be as effective as sugar and salt oral rehydration solutions and reduce stool volume, as well as rehydrating. The WHO and UNICEF recommend the use of reduced-osmolarity oral rehydration solution with zinc supplementation for all types of diarrhoea; the small risk of hyponatraemia with this formulation is far outweighed by the improved efficacy. Suitable solutions for rehydration are listed in **Box 42.36**.

Infection gives protection for at least 3 years. Immunization is recommended in potential outbreak situations. The WHO recommends any of three oral, killed, whole-cell vaccines with efficacies of around 50% to 60% in outbreak settings. There is also an oral live-attenuated vaccine for travellers to endemic areas.

Antibiotics may shorten the duration and severity of diarrhoea but should be given only to patients with severe dehydration. Tetracyclines are the first-line treatment, although resistance is developing. Other options include co-trimoxazole, macrolides, and fluoroquinolones.



[a]0.9% saline if Ringer's not available.
[b]6 hours in children <1 year.
[c]Adult doses: adjust for age.
[d]Not in children/adolescents.

Fig. 42.25 The management of cholera.

The best preventive measures, however, are good hygiene and improved sanitation. Studies in Bangladesh have shown that using a folded sari cloth to filter river drinking water decreases the incidence of cholera by up to 50%. The cloth should be rinsed in clean water between use and dried in the sun to kill any bacteria.

In 2017 the WHO announced a strategy to end cholera by 2030. Although eradication is not possible because the organism persists in the environment, it is theoretically possible to eliminate human-to-human transmission. The strategy has three elements:

- Early detection and quick response to contain outbreaks
- Prevention of cholera recurrence in cholera 'hotspots'
- Coordination of technical support, advocacy, resource mobilization, and partnership at local and global levels.

Enteric fever

Enteric fever is an acute systemic illness characterized by fever, headache and abdominal discomfort. ***Typhoid***, the typical form of enteric fever, is caused by *Salmonella typhi*. A similar illness known as ***paratyphoid*** is caused by infection with *S. paratyphi* A, B, or C. Humans are the only natural host for *S. typhi*, which is transmitted in contaminated food or water. The incubation period is 10 to 14 days.

In 2017 typhoid fever was estimated to cause 10.9 million cases and 116 800 deaths worldwide with an overall case-fatality rate of 1%. South Asia accounted for three-quarters of all cases.

Clinical features

After ingestion, the bacteria invade the small bowel wall via Peyer's patches, from where they spread to the regional lymph nodes and then to the blood and reticulo-endothelial system. The onset of illness is insidious and non-specific, with intermittent fever, headache, and abdominal pain. Physical findings include abdominal tenderness and hepatosplenomegaly. Historically, a scanty, blanching maculopapular rash called 'rose spots' was observed, but this is less common in the antibiotic era. Without treatment and occasionally even after treatment, serious complications can arise, usually in the third week of illness. These include shock, jaundice, encephalopathy, intestinal perforation, and intestinal haemorrhage. The fourth week is characterized by gradual improvement, but in areas with limited healthcare, up to one-third of those infected die, and 10% of untreated survivors relapse.

After clinical recovery, 2% to 5% of patients continue to excrete *S. typhi* for several months and are termed ***convalescent carriers***. A smaller proportion continue to shed the organism in stool for more than 1 year and become ***chronic carriers***. The usual site of carriage is the gall bladder; it is associated with gallstones, which is perhaps one reason why chronic carriers are more likely to be older and female. In parts of the Middle East and Africa where urinary schistosomiasis is prevalent, chronic carriage of *S. typhi* in the urinary bladder is also common.

Paratyphoid fever is associated with a milder and shorter illness, and complications are uncommon.

Diagnosis

Diagnosing enteric fever in resource-limited settings can be challenging because the clinical syndrome is similar to other non-specific febrile illnesses. Patients are often treated empirically, given the risk of severe disease. The Widal test is commonly used but has moderate sensitivity and specificity because of patients having cross-reactive antibodies; its use is not recommended. The definitive diagnosis requires significant laboratory infrastructure to perform cultures for *S. typhi* or *S. paratyphi*. Blood culture is positive in 50% to 70% of cases if taken before antibiotics. Culture of intestinal secretions, faeces, and urine is also used, although care must be taken to distinguish acute infection from chronic carriage. Bone marrow culture is the most sensitive test but is rarely required except in patients who have already received antibiotics or when the diagnosis is in doubt. Leucopenia and transaminitis are common but non-specific features.

Management

Most patients can be managed in an outpatient setting, but it is often necessary to start treatment before making a microbiological diagnosis. The choice of empirical treatment changes frequently over time and geography. Increasing antibiotic resistance in *S. typhi* to the first-line drugs of chloramphenicol, co-trimoxazole, and amoxicillin was initially seen in South-east Asia and the Indian subcontinent in the 1970s. This became known as multidrug-resistant (MDR) typhoid because resistance occurs to all three antibiotics and is mediated by a single transmissible plasmid, which can be exchanged between bacteria. By the 1990s fluoroquinolones had become the first-line treatment in most of Asia. Unfortunately, resistance to fluoroquinolones followed shortly after because of the accumulation of mutations in the *S. typhi* topoisomerase gene. Empirical treatment shifted to azithromycin for mild cases and ceftriaxone for severe cases.

Efforts to control the widespread use of antibiotics have resulted in a gradual reduction in rates of MDR typhoid more recently.

However, a new strain of typhoid, resistant to all three first-line drugs, plus fluoroquinolones and third-generation cephalosporins, was reported in Pakistan in 2016. By 2019 this extensively drug-resistant strain had become the commonest cause of typhoid fever in Pakistan. Sporadic reports exist from other countries, but for now it is generally possible to identify a link with travel to Pakistan. At the time of writing in 2024, azithromycin remains effective for most strains of *S. typhi* around the world.

The patient's temperature may remain elevated for several days after antibiotics are started, and this alone is not a sign of treatment failure. Prolonged antibiotic therapy may eliminate the carrier state, but in the presence of gall bladder disease, it is rarely effective. Cholecystectomy is not usually justified on clinical or public health grounds.

Prevention

This is mainly through improved sanitation and clean water, which is easier said than done. It often requires government investment in infrastructure to provide uncontaminated drinking water, community campaigns to change people's behaviour, and even laws to ban industrial practices such as irrigating crops with untreated sewage.

Vaccination with either injectable inactivated or oral live attenuated vaccines gives partial protection and is recommended for travellers to high-risk areas. A new conjugate vaccine that protects up to 80% of children and has longer-lasting immunity has recently been developed. A single dose is now recommended by the WHO as part of the standard childhood vaccination programme in high-prevalence countries.

Systemic infections

Tuberculosis

See Chapter 20 ('Tuberculosis' section).

Non-tuberculous mycobacterial infections

Environmental mycobacteria can cause a wide variety of infections in susceptible hosts (**Box 42.51**). These are discussed in more detail in Chapter 44 ('*Mycobacterium avium-intracellulare* infection' section).

? Box 42.51 Examples of non-tuberculous mycobacteria causing disease in humans

Clinical	Common cause	Rare cause
Chronic lung disease	*Mycobacterium avium-intracellulare* *Mycobacterium kansasii*	*Mycobacterium malmoense* *Mycobacterium xenopi*
Local lymphadenitis	*M. avium-intracellulare* *Mycobacterium scrofulaceum*	*Mycobacterium malmoense* *Mycobacterium fortuitum*
Skin and soft tissue infection		
Fish tank granuloma	*Mycobacterium marinum*	
Abscesses, ulcers, sinuses	*Mycobacterium fortuitum* *Mycobacterium chelonae*	*Mycobacterium haemophilum*
Bone and joint infection	*Mycobacterium kansasii* *M. avium-intracellulare*	*M. scrofulaceum*
Disseminated infection (in HIV)	*M. avium-intracellulare*	

HIV, Human immunodeficiency virus.

Plague

Plague is caused by *Yersinia pestis*, a Gram-negative bacillus. Sporadic cases of plague, as well as occasional epidemics, occur worldwide, but it is relatively uncommon: about 1000 cases per year are reported to the WHO, with a 10% mortality rate. The majority are in Madagascar and Central Africa, although the disease is occasionally seen in high-income countries, usually associated with hunting. The main reservoirs are woodland rodents, which transmit infection to domestic rats *(Rattus rattus)*. The usual vector is the rat flea, *Xenopsylla cheopis*. These fleas bite humans when there is a sudden decline in the rat population. Occasionally, spread of the organisms may be through infected faeces being rubbed into skin wounds or through inhalation of droplets. A modern re-analysis of the 1665 outbreak of plague in the isolated English village of Eyam found that three-quarters of cases were transmitted by human-to-human contact within families.

Clinical features

Four clinical forms are recognized: bubonic, pneumonic, septicaemic, and cutaneous.

- ***Bubonic plague*** is the most common form, accounting for about 90% of cases. The incubation period is 2 to 7 days. The onset of illness is acute, with high fever; chills; headache; myalgia; nausea; vomiting; and, when severe, prostration. This is rapidly followed by the development of lymphadenopathy (buboes), most commonly involving the inguinal region. Characteristically, these are matted and tender and suppurate in 1 to 2 weeks.
- ***Pneumonic plague*** is characterized by the abrupt onset of features of a fulminant pneumonia with bloody sputum, marked respiratory distress, cyanosis, and death in almost all affected patients.
- ***Septicaemic plague*** presents as an acute fulminant infection with evidence of shock and DIC. If it is left untreated, death usually occurs in 2 to 5 days.
- ***Cutaneous plague*** can present as a pustule, eschar, or papule or as extensive purpura, which can become necrotic and gangrenous.

Diagnosis

This is based on clinical, epidemiological, and laboratory findings. Microscopy (on blood or lymph node aspirate) or a rapid dipstick antigen detection test can provide a presumptive diagnosis in an appropriate clinical setting. Confirmation is by blood or lymph node culture or paired serological tests.

Management

Treatment is urgent and should be instituted before the results of culture studies are available. *Y. pestis* remains sensitive to most antibiotics for Gram-negative bacteria. Gentamicin is the most widely used agent; doxycycline, ciprofloxacin, and chloramphenicol are also effective.

Prevention

Prevention of plague is largely dependent on control of the flea population. Outhouses or huts should be sprayed with insecticides

that are effective against the local flea. During epidemics, rodents should not be killed until the fleas are under control because the fleas will leave dead rodents to bite humans. Tetracycline is an effective chemoprophylactic agent for those at risk during an outbreak. Both killed and attenuated vaccines have been available for many years but have limited efficacy and are not widely used.

Relapsing fevers

These conditions are so named because after apparent recovery from the initial infection, recurrences may occur after 1 week or more without fever. They are caused by spirochaetes of the genus *Borrelia*.

Louse-borne relapsing fever

This condition (caused by *Borrelia recurrentis*) is spread by body lice, and only humans are affected. Classically, it is an epidemic disease of armies and refugees, although it is also endemic in the highlands of Ethiopia and Yemen and in the Andes. Lice are spread from person to person when humans live in close contact in impoverished conditions. The spirochaete penetrates through the skin or mucosa when infected lice are crushed by scratching or by biting, a traditional means of killing the insect, hence the adage 'man bites louse is more dangerous than louse bites man'. Symptoms begin 3–10 days after infection and consist of an abrupt high fever, myalgia, and headache. A petechial or ecchymotic rash may be seen. In severe cases, the condition then deteriorates, with delirium, hepatosplenomegaly, jaundice, bleeding, and circulatory collapse. A proportion of those who recover have no further symptoms, but the majority experience one or more relapses of diminishing intensity over the weeks after the initial illness. The severity varies enormously, with many people experiencing only mild symptoms and some developing antibodies with no history of clinical illness. In some epidemics, however, the mortality rate in untreated people has exceeded 50%.

Tick-borne relapsing fever

This is caused by *Borrelia duttoni* and other *Borrelia* species, spread by soft (argasid) ticks of the genus *Ornithodoros*. Rodents are the main reservoir of infection, and humans are incidental hosts, acquiring the spirochaete from the saliva of the infected tick. The disease is found worldwide and is endemic in parts of North America and Europe, but the clinical burden falls mainly in Africa. It is particularly common where traditional mud huts are the principal form of human shelter because the ticks live in the walls and feed on the inhabitants at night. The illness is generally similar to the louse-borne disease, with the same variability in presentation and severity.

Diagnosis and management

Spirochaetes can be demonstrated microscopically in the blood during febrile episodes; organisms are more numerous in louse-borne relapsing fever. PCR is more sensitive and is replacing traditional microscopy where available. Treatment is usually with tetracycline. A severe drug reaction (Jarish-Herxheimer reaction) occurs in many patients, especially those who have the louse-borne form.

Prevention

Control of infection relies on eliminating the vector. Ticks live for years and remain infected, passing the infection to their progeny. These reservoirs of infection may be controlled by spraying houses with insecticides and reducing the number of rodents. Post-exposure prophylaxis has been shown to be effective in areas where tick-borne disease is highly endemic. Infested patients should be deloused by washing with a suitable insecticide. All clothes must be thoroughly disinfected.

Rickettsiae and rickettsia-like infections

Rickettsiae, which include the genera *Ehrlichia*, *Orientia*, and *Coxiella*, are small intracellular bacteria that are spread to humans by arthropod vectors, including body lice, fleas, hard ticks, and larval mites. Rickettsiae inhabit the alimentary tracts of these arthropods, and infection is spread to the human host by inoculation of their faeces through broken human skin, generally produced by scratching. Rickettsiae multiply intracellularly and can enter most mammalian cells, although the main lesion produced is a vasculitis caused by invasion of endothelial cells of small blood vessels. Multisystem involvement is usual.

Typhus is the collective name given to a group of diseases caused by *Rickettsia* species. **Box 42.52** provides a list of some of the more important rickettsial diseases; with the advent of molecular techniques, more than 30 pathogenic species of *Rickettsia* are now recognized. Various classifications have been proposed, based on genetic typing, clinical presentation, and geography. None of these is ideal because species that are genetically very similar can occur in different parts of the world, and there is considerable overlap between the various rickettsial syndromes. A useful clinical approach is to divide rickettsial infections into three groups: typhus, spotted fever, and scrub typhus, although the organisms causing the last of these are now strictly classified as orientiae and not rickettsiae.

Typhus group

Epidemic typhus

The vector of epidemic typhus is the human body louse and, as with louse-borne relapsing fever, epidemics are associated with war and refugees.

The incubation period of 1 to 3 weeks is followed by an abrupt febrile illness associated with profound malaise and generalized myalgia. Headache is severe, and there may be conjunctivitis with orbital pain. A measles-like eruption appears around the fifth day. At the end of the first week, signs of meningoencephalitis appear, and CNS involvement may progress to coma. At the height of the illness, splenomegaly, pneumonia, myocarditis, and gangrene at the peripheries

? Box 42.52 Infections caused by rickettsiae

Disease	Organism	Reservoir	Vector
Typhus fever group			
Epidemic typhus	*Rickettsia prowazekii*	Human	Human body louse
Endemic (murine) typhus	*Rickettsia typhi*	Rodent	Rat flea
Spotted fever group			
African tick typhus	*Rickettsia africae*	Various mammals	Hard tick
Mediterranean spotted fever	*Rickettsia conorii*	Rodent, dog	Hard tick
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Rodent, dog	Hard tick
Rickettsial pox	*Rickettsia akari*	Rodent	Mite
Flea-borne spotted fever	*Rickettsia felis*	Various mammals	Flea
Scrub typhus	*Orientia tsutsugamushi*	Trombiculid mite	Trombiculid mite

may be evident. Oliguric acute kidney injury occurs in fulminating disease, which is usually fatal. Recovery begins in the third week but is generally slow. If untreated, the disease may recur many years after the initial attack, owing to rickettsiae that lie dormant in lymph nodes. The recrudescence, which is now rarely seen because of appropriate use of antibiotics in the primary phase, is known as Brill–Zinsser disease.

Endemic (murine) typhus

This is an infection of rodents that is inadvertently spread to humans by rat fleas. The disease closely resembles epidemic typhus but is much milder and rarely fatal.

Spotted fever group

A variety of *Rickettsia* species, collectively known as the spotted fever group rickettsiae, cause the illnesses known as spotted fevers. In most cases, the vector is a hard tick. Although the causative organism and the name of the illness vary from place to place, the clinical course is common to all.

The typical feature of the spotted fevers is a widespread petechial rash (Fig. 42.26), although a variety of other types of skin lesion are seen, especially in Rocky Mountain spotted fever. An exception is the form of African tick typhus caused by *Rickettsia africae*, which often presents without a rash.

After an incubation period of 4 to 10 days, an eschar (a black, crusted, necrotic papule) may develop at the site of the bite in association with regional lymphadenopathy (Fig. 42.27). There is abrupt onset of fever, myalgia, and headache accompanied by a maculopapular rash that may become petechial. Neurological, haematological, and cardiovascular complications can occur, as in epidemic typhus, although these are uncommon.

Scrub typhus

Found throughout Asia and the Western Pacific (and also reported occasionally from Africa), this disease is spread by larval trombiculid mites (chiggers). An eschar can often be found at the site of the bite. The clinical illness is very variable, ranging from a mild illness to fulminant and potentially fatal disease. The more severe cases resemble epidemic typhus. Unlike in other types of typhus, the organism is passed on to subsequent generations of mites, which consequently act as both reservoir and vector.

Diagnosis

The diagnosis of all types of rickettsial infection is generally made on the basis of the history and clinical course. It can be confirmed serologically or by PCR.

Management and prevention

Doxycycline given for 5 to 7 days is the treatment of choice for uncomplicated disease. Ciprofloxacin is also effective. Seriously ill patients may need intensive care, and the addition of azithromycin to doxycycline improves outcome. Prophylactic doxycycline 200 mg weekly protects against scrub typhus; it is reserved for highly endemic areas. Rifampicin is also used when resistance to tetracycline is present. Control of typhus is achieved by eradication of the arthropod vectors: lice and fleas can be eradicated from clothing with insecticides (0.5% malathion or DDT). Control of rodents is necessary in endemic typhus and some of the spotted fevers. Areas of vegetation infested with trombiculid mites can be cleared by chemical spraying from the air. Bites from ticks and mites should be avoided by wearing protective clothing on exposed areas of the body. The likelihood of infection from ticks is related to the duration of feeding; in high-risk areas, the body should be inspected twice a day because the bites are painless, and any ticks should be removed.

Bartonellosis

Bartonella spp. are intracellular bacteria closely related to the rickettsiae. A number of human diseases can be caused by these organisms, including cat-scratch disease and bacillary angiomatosis *(Bartonella henselae)*. As in rickettsial disease, infection is usually spread from animals via an arthropod vector (Box 42.53).

Carrion's disease *(Bartonella bacilliformis)*

This disease is largely restricted to the habitat of its main vector, the sandfly, in the river valleys of the Andes mountains at an altitude of 500 to 3000 m. Two clinical presentations are seen, which may occur alone or consecutively. ***Oroya fever*** is an acute febrile illness causing myalgia, arthralgia, severe headache, and confusion followed by a haemolytic anaemia. ***Verruga peruana*** consists of eruptions of reddish-purple haemangiomatous nodules, resembling bacillary angiomatosis. It may follow 4 to 6 weeks after Oroya fever or be the presenting feature of infection. Spontaneous resolution may occur over a period of months or years. Carrion's disease is frequently complicated by superinfection, especially with *Salmonella* spp.

The diagnosis is made by culturing bacilli from blood or peripheral lesions. Serological tests have been developed but are not widely available.

Fig. 42.26 **The petechial rash of rickettsial spotted fever.**

Fig. 42.27 **An eschar developing at the site of the bite in rickettsial disease.**

Box 42.53 Human infections caused by *Bartonella* spp. and *Ehrlichia* spp.

Disease	Organism	Reservoir	Vector
***Bartonella* spp.**			
Carrion's disease	*Bartonella bacilliformis*	Unknown	Sandfly
Cat-scratch disease	*Bartonella henselae*	Cat	Cat flea
Bacillary angiomatosis	*Bartonella henselae*	Cat	Cat flea
Trench fever	*Bartonella quintana*	Human	Body louse
***Ehrlichia* spp.**			
Human monocytic ehrlichiosis (HME)	*Ehrlichia chaffeensis*	Deer	Hard tick
Human granulocytic ehrlichiosis (HGE)[a]	*Ehrlichia ewingii* *Anaplasma phagocytophilum*[b]	Small mammals and deer	Hard tick

[a]Also known as human granulocytic anaplasmosis.
[b]Formerly known as Ehrlichia phagocytophilia.

Treatment with chloramphenicol or tetracycline is effective in acute disease but less so in verruga peruana. It has no known hosts other than humans.

The disease is named after Daniel Alcides Carrion Garcia, a Peruvian medical student who died from the disease in 1885. Carrion was trying to demonstrate the link between the acute Oroya fever and chronic verruga peruana when he inoculated himself with blood from the wart of a 14-year-old patient. It has the potential for eradication, but there is currently no surveillance programme, and it is a paradigm for a neglected disease of poverty.

Trench fever

Trench fever is caused by *Bartonella quintana* and transmitted by human body lice. It is mainly seen in refugees and homeless people. It is characterized by cyclical fever, chills, and headaches accompanied by myalgia and pretibial pain. The disease is usually self-limiting, but it can be treated with erythromycin or doxycycline if symptoms are severe.

Ehrlichiosis

Ehrlichiosis and anaplasmosis are infections caused by tick-borne, rickettsia-like bacteria. At least three species have been implicated: *Ehrlichia chaffeensis*, which causes human monocytic ehrlichiosis, and *Ehrlichia ewingii* and *Anaplasma phagocytophilum* (formerly known as *Ehrlichia phagocytophilum*), which cause human granulocytic ehrlichiosis (also known as human granulocytic anaplasmosis). All cause a rather non-specific febrile illness with fever, myalgia, and headache. Treatment is with doxycycline. The vectors are hard ticks, and the main reservoir hosts are deer. As with most tick-borne zoonoses, the avoidance of tick bites and the prompt removal of feeding ticks are the best forms of prevention.

OTHER BACTERIAL INFECTIONS

Melioidosis

This term refers to infections caused by the Gram-negative bacterium *Burkholderia pseudomallei*. This environmental organism, which is found in soil and surface water, is distributed widely in the tropics and subtropics. Most clinical cases of melioidosis occur in South-east Asia and the Northern Territories of Australia with a peak presentation during the rainy season. Infection follows inhalation or direct inoculation. More than half of all patients with melioidosis have predisposing underlying disease; it is particularly common in people with diabetes. The organism may remain latent for many years and may reactivate when patients become immunosuppressed from conditions such as renal failure, diabetes, and alcoholism.

B. pseudomallei causes a wide spectrum of disease, and the majority of infections are probably subclinical. Illness may be acute or chronic and localized or disseminated, but one form may progress to another, and individual patients may be difficult to categorize. The most serious form is septicaemic melioidosis, which is often complicated by multiple metastatic abscesses; it is frequently fatal. Serological tests are available, but definitive diagnosis depends on isolating the organism from blood or appropriate tissue. *B. pseudomallei* has extensive intrinsic antibiotic resistance. The most effective agent is ceftazidime, given intravenously for 2 to 4 weeks; this should be followed by several months of co-amoxiclav or co-trimoxazole to prevent relapses.

Actinomycosis

Actinomyces spp. are branching, Gram-positive higher bacteria, which are normal mouth and intestine commensals; they are particularly associated with poor mouth hygiene. *Actinomyces* spp. have a worldwide distribution but are a rare cause of disease in the West.

Cervicofacial actinomycosis, the most common form, usually occurs after dental infection or extraction. It is often indolent and slowly progressive, is associated with little pain, and results in induration and localized swelling of the lower part of the mandible. Sinuses and tracts develop, with discharge of 'sulphur' granules. ***Thoracic actinomycosis*** follows inhalation of organisms, usually into a previously damaged lung. The clinical picture is not distinctive and is often mistaken for malignancy or TB. Symptoms such as fever, malaise, chest pain, and haemoptysis are present. Empyema occurs in 25% of patients, and local extension produces chest-wall sinuses with discharge of 'sulphur' granules.

Abdominal and pelvic actinomycosis most frequently affects the caecum. Characteristically, an indurated mass is felt in the right iliac fossa. Later, sinuses develop. The differential diagnosis includes malignancy, TB, Crohn's disease, and amoeboma. The incidence of pelvic actinomycosis appears to be increasing with wider use of intrauterine contraceptive devices. Occasionally, actinomycosis becomes disseminated to involve any site.

Diagnosis is by microscopy and culture of the organism. The presence of firm 'sulphur granules' containing collections of filamentous rods is virtually pathognomonic. Treatment often involves surgery, as well as very long courses of antibiotics. Penicillin is the drug of choice and is usually given until 3 to 4 months after clinical resolution. Tetracyclines and sulphonamides are also effective.

Nocardia infections

Nocardia spp. are Gram-positive branching bacteria found in soil and decomposing organic matter. *Nocardia asteroides* and, less often, *Nocardia brasiliensis* are the main human pathogens.

Mycetoma is the most common illness. It is a result of local invasion by *Nocardia* spp. and presents as a painless swelling, usually on the sole of the foot (Madura foot). The swelling of the affected part of the body continues inexorably. Nodules gradually appear, which eventually rupture and discharge characteristic 'grains', which are colonies of organisms. Systemic symptoms

and regional lymphadenopathy are rare. Sinuses may occur several years after the onset of the first symptom. A similar syndrome may be produced by other branching bacteria and also by species of eumycete fungi, such as *Madurella mycetomi*. Most cases of Madura foot occur in rural parts of India, sub-Saharan Africa, and Mexico.

Pulmonary disease, which follows inhalation of the organism, presents with cough, fever, and haemoptysis; it is usually seen in immunocompromised people. Pleural involvement and empyema occur. In severely immunosuppressed patients, initial pulmonary infection may be followed by disseminated disease.

The diagnosis is often delayed, partly because of inadequate specimens and partly because *Nocardia* spp. require prolonged culture on standard media. Severe pulmonary or disseminated infection may require parenteral treatment. Co-trimoxazole, linezolid, ceftriaxone, and amikacin have all been used successfully, but *in vitro* sensitivities are variable, and there is no consensus on the best treatment.

Antibiotic therapies

Drugs used to combat bacterial infections are described in Chapter 12 ('Antibiotic therapies' section).

FUNGAL INFECTIONS

Morphologically, fungi can be grouped into three major categories:

- ***Yeasts and yeast-like fungi***, which reproduce by budding
- ***Moulds***, which grow by branching and longitudinal extension of hyphae
- ***Dimorphic fungi***, which behave as yeasts in the host but as moulds *in vitro*.

Even though fungi are ubiquitous, systemic fungal infections are relatively rare, in contrast to superficial fungal infections of the skin, nails, and orogenital mucosae. Systemic mycoses are usually seen in immunocompromised patients and in critical care settings and are becoming more prevalent as this population increases.

Fungal infections are transmitted by inhalation of spores, contact with the skin, or direct inoculation. This last can occur through penetrating injuries, injecting drug use, or iatrogenic procedures. Fungi may also produce allergic pulmonary disease. Some fungi, such as *Candida albicans*, are human commensals. Fungal infections are usually divided into systemic, subcutaneous, or superficial (**Box 42.54**). However, these divisions can be misleading because many fungi that cause superficial infection in healthy hosts can cause invasive or disseminated infection in immunocompromised patients, but 'deep' subcutaneous infections can invade other organs to cause systemic disease.

Systemic fungal infections

Candidiasis

Candidiasis is the most common fungal infection in humans and is predominantly caused by *Candida albicans*, although other species of *Candida* are increasingly seen. *Candida* are small asexual yeasts. They are found worldwide, and most species that cause serious invasive disease are also normal oropharyngeal and GI commensals.

Clinical features

Most human candidiasis is superficial. Vaginal thrush and oral thrush are the most common forms, typically seen in very young patients, older adults, patients on antibiotic therapy, and patients who are immunosuppressed. Cutaneous candidiasis typically occurs in intertriginous areas. It is also a cause of paronychia.

Invasive candidiasis is usually associated with intravascular devices (especially in intensive care units) and with profound immunosuppression (e.g., caused by treatment of haematological malignancy). Dissemination can lead to meningitis, visceral and pulmonary abscesses, endophthalmitis, and osteomyelitis. *Candida* oesophagitis presents with painful dysphagia and is generally seen in patients with cancer, diabetes, and cellular immunosuppression (e.g., from long-term steroid use and uncontrolled HIV infection).

Diagnosis and management

The fungi can be demonstrated in scrapings from infected lesions; from tissue secretions; or in invasive disease, from standard blood cultures. Serological tests for beta-D-glucan, a fungal cell wall component, can be used to look for systemic fungal infection but are common to many pathogenic fungi, and the tests do not distinguish different infections.

Treatment varies, depending on the site and severity of infection and on the sensitivity of the organism. Superficial lesions may respond to topical nystatin or amphotericin B, although systemic agents may be needed for more extensive infection. For invasive

Box 42.54 Important fungal infections

infection, parenteral therapy with amphotericin B, azoles, or echinocandins is necessary. Many non-*albicans* species are intrinsically resistant to many antifungals, and even *C. albicans* can develop extensive resistance (especially to azoles).

Candida auris

Since 2010 there has been an increase in human colonization and infection with *C. auris*, a species first identified in Japan in 2009 and that has no known environmental niche. *C. auris* is particularly worrying because it is intrinsically resistant to many antifungals and sometimes to all three major classes of drug. It is also spread readily from person to person (especially in healthcare settings) and can survive for extended periods on hard surfaces despite normal cleaning and disinfection processes. Laboratory diagnosis is difficult and it can easily be mistaken for other species. Healthcare-associated outbreaks have been reported from a number of countries across all continents, and it is common to screen patients who have recently been in hospital in countries with high rates of nosocomial *C. auris*.

Histoplasmosis

Histoplasmosis is caused by *Histoplasma capsulatum*. Spores can survive in moist soil for several years, particularly when the soil is enriched by bird and bat droppings. Histoplasmosis occurs worldwide but is most commonly seen in the Ohio and Mississippi river valleys, where more than 80% of the population have been subclinically exposed. An increasing number of cases are being reported from parts of Asia (especially China). Transmission is mainly by inhalation of the spores, particularly when clearing out attics, barns, or bird roosts or exploring caves.

Clinical features

Primary pulmonary histoplasmosis is usually asymptomatic. Calcification in the lungs, spleen, and liver occurs in patients from areas of high endemicity. When symptomatic, primary pulmonary histoplasmosis generally presents as a mild influenza-like illness, although symptoms can be more severe. Occasionally, there can be complications such as secondary bacterial pneumonia, pleural effusions, erythema nodosum, and erythema multiforme.

Chronic pulmonary histoplasmosis is clinically similar to pulmonary TB. It is usually seen in White American males older than the age of 50 years. Disseminated histoplasmosis resembles disseminated TB, with fever, lymphadenopathy, hepatosplenomegaly, weight loss, leucopenia, and thrombocytopenia. Rarely, features of meningitis, hepatitis, hypoadrenalism, endocarditis, and peritonitis may dominate the clinical picture. Histoplasmosis sometimes remains latent for years and reactivates when the patient becomes immunosuppressed. This long interval between exposure and disease may result in delayed recognition.

Diagnosis

Definitive diagnosis is possible by culturing the fungi (e.g., from sputum) or by demonstrating them on histological sections. *H. capsulatum* glycoprotein can be detected in the urine and serum of those with acute pulmonary and disseminated infections. Diagnostic tests using urinary antigens are becoming more widely available. Antibodies usually develop within 3 weeks of the onset of illness and are best detected by complement fixation or immunodiffusion (sensitivities of 95% and 90%, respectively).

Management

Only symptomatic acute pulmonary histoplasmosis, chronic histoplasmosis, and acute disseminated histoplasmosis require therapy. Itraconazole is effective in mild to moderate disease. Severe infection is treated with intravenous amphotericin B followed by itraconazole for a total of 3 months or with voriconazole. Surgical excision of histoplasmomas (granulomatous pulmonary nodules caused by *H. capsulatum*) or chronic cavitatory lung lesions and release of adhesions after mediastinitis may be required.

African histoplasmosis

This is caused by a specific subspecies, *Histoplasma capsulatum* var. *duboisii*, the spores of which are larger than those of *H. capsulatum*. Skin lesions (e.g., abscesses and nodules), lymph node involvement, and lytic bone lesions are prominent. Pulmonary lesions do not occur. Treatment is similar to that for *H. capsulatum* infection.

Aspergillosis

Aspergillosis is caused by one of several species of dimorphic fungi of the genus *Aspergillus*. Of these, *Aspergillus fumigatus* is the most common, although *Aspergillus flavus* and *Aspergillus niger* are also recognized. These fungi are ubiquitous in the environment and are commonly found on decaying leaves and trees. Humans are infected by inhalation of the spores. Disease manifestation depends on the dose of the spores inhaled, as well as the immune response of the host. Three major forms of the disease are recognized: bronchopulmonary allergic aspergillosis, aspergilloma, and invasive aspergillosis.

Diagnosis and treatment are described in Chapter 20 (‘Aspergilloma and invasive aspergillosis’ section).

Cryptococcosis

Cryptococcosis is caused by the yeast-like fungus *Cryptococcus neoformans*. It has a worldwide distribution, with bird droppings being an important mode of spread. The spores enter the body through the respiratory tract, where they elicit a granulomatous reaction. Pulmonary symptoms are, however, uncommon, although lung cavitation, hilar lymphadenopathy, pleural effusions, and pulmonary fibrosis occur. Skin and bone involvement are rare. Cryptococcal meningitis is primarily a disease of advanced HIV infection and often presents subacutely with fever and headache caused by raised intracranial pressure. It sometimes occurs in patients with lymphoma or iatrogenic suppression of cellular immunity.

Diagnosis and management

Diagnosis is established by demonstrating the organisms in appropriately stained tissue sections. A positive latex cryptococcal agglutinin test performed on the CSF is diagnostic of cryptococcal meningitis. Patients need indefinite treatment until their cellular immunity recovers.

Guidelines for the treatment of HIV-related cryptococcal meningitis, which carries a high mortality rate, have recently changed based on the Ambition study. This study showed that a single dose of liposomal amphotericin B, at 10 mg/kg given in combination with flucytosine and fluconazole is as effective as a standard 2-week course of amphotericin B plus flucytosine, better tolerated, and far cheaper. Therapeutic lumbar puncture has an important role in acute illness.

Coccidioidomycosis

Coccidioidomycosis is caused by the non-budding spherical form (spherule) of *Coccidioides immitis*. This is a soil saprophyte and is found in the southern USA, Central America, and parts of South America. Humans are infected by inhalation of the thick-walled,

barrel-shaped spores called arthrospores. Occasionally, epidemics of coccidioidomycosis have been documented after dust storms.

Clinical features

The majority of patients are asymptomatic, and the infection is detected only by the conversion of a skin test using coccidioidin (extract from a culture of mycelial growth of *C. immitis*) from negative to positive. Acute pulmonary coccidioidomycosis presents after an incubation period of about 10 days with fever, malaise, and cough. Erythema nodosum; erythema multiforme; phlyctenular conjunctivitis; and less commonly, pleural effusions may occur. Complete recovery is usual.

Pulmonary cavitation with haemoptysis, pulmonary fibrosis, meningitis, lytic bone lesions, hepatosplenomegaly, skin ulcers, and abscesses may occur in severe disease.

Diagnosis

The organism can be identified in respiratory secretions and cultured in specialist laboratories. Serological tests are also widely used for diagnosis. These include the highly specific latex agglutination and precipitin tests (IgM); the test results are positive within 2 weeks of infection and decline thereafter. Other tests include complement fixation, ELISA, and radioimmunoassay.

A complement fixation test (IgG) performed on the CSF is diagnostic of coccidioidomycosis meningitis; it becomes positive within 4 to 6 weeks and remains so for many years.

Management

Mild pulmonary infections are self-limiting and require no treatment, but progressive and disseminated disease mandates urgent therapy. Itraconazole or fluconazole for 6 months is the treatment of choice for patients with primary pulmonary disease, with more prolonged courses for cavitating or fibronodular disease. Fluconazole in high dose (600–1000 mg/day) is given for meningitis. Voriconazole or posaconazole is used for poor responders. Surgical excision of cavitatory pulmonary lesions or localized bone lesions may be necessary.

Blastomycosis

Blastomycosis is a systemic infection caused by the biphasic fungus *Blastomyces dermatitidis*. Although previously believed to be confined to certain parts of North America, it has now been reported in South America, India, and the Middle East.

Clinical features

Blastomycosis primarily involves the skin, causing non-itchy papular lesions that later develop into ulcers with red verrucous margins. The ulcers are initially confined to the exposed parts of the body but later involve the unexposed parts as well. Atrophy and scarring may occur. Pulmonary involvement presents as a solitary lesion resembling a malignancy or gives rise to radiological features similar to the primary complex of TB. Systemic symptoms, such as fever, malaise, cough, and weight loss, are usually present. Bone lesions are common and present as painful swellings.

Diagnosis and management

The diagnosis is confirmed by demonstrating the organism in histological sections or by culture, although results can be negative in 30% to 50% of cases. Enzyme immunoassay may be helpful, although there is some cross-reactivity of antibodies to *Blastomyces* spp. with *Histoplasma* spp.

Itraconazole is preferred for treating mild to moderate disease in immunocompetent patients for periods of up to 6 months. In severe or unresponsive disease and in immunocompromised patients, amphotericin B is usually used.

Paracoccidioidomycosis

Sometimes known as 'South American blastomycosis', paracoccidioidomycosis is caused by dimorphic fungi of the genus *Paracoccioides*. It is confined to localized areas of Brazil and neighbouring countries. Like the other pathogenic dimorphic fungi, it is usually acquired by inhalation. It can cause a wide variety of systemic and local manifestations, although skin lesions are particularly common. Itraconazole is generally the best treatment, although amphotericin B can be used in severe cases.

Mucormycosis

The terminology relating to mucormycosis and zygomycosis is confusing. ***Invasive zygomycosis*** (also known as ***mucormycosis***) is rare and is caused by several fungi, including *Mucor*, *Rhizopus*, and *Absidia* spp. It usually occurs in immunocompromised or severely ill patients and has a high mortality rate. The hallmark of the disease is vascular invasion with marked haemorrhagic necrosis.

Rhinocerebral mucormycosis is a specific, locally invasive form of the condition. Nasal stuffiness; facial pain and oedema; and necrotic, black nasal turbinates are characteristic. It is rare and is mainly seen in people with poorly controlled diabetes.

Other forms of invasive zygomycosis include pulmonary and disseminated infection (in immunosuppressed patients) and GI infection (in malnutrition).

Subcutaneous zygomycosis is described later. Management of locally invasive and systemic disease is with amphotericin B and surgical debridement, but even with the best care, the mortality rate exceeds 50%. The newer triazoles, posaconazole and isavuconazole, have been shown to be effective in mucormycosis, but their role in therapy remains unclear.

Subcutaneous fungal infections

Sporotrichosis

Sporotrichosis is caused by the saprophytic fungus *Sporothrix schenckii*, which is found worldwide. It is common in soil and on plants, and infection classically follows cutaneous inoculation from thorns ('rose handler's disease). A reddish, non-tender, maculopapular lesion develops at the site of inoculation; this is referred to as 'plaque sporotrichosis'. Satellite lesions may develop over

time. Pulmonary involvement and disseminated disease occur very rarely.

Treatment with itraconazole for 3 to 6 months is usually curative.

Subcutaneous zygomycosis

Subcutaneous zygomycosis can be a form of mucormycosis in immunocompromised patients, as described earlier. However, the term is also used to describe a largely tropical condition caused by filamentous fungi of the *Basidiobolus* genus, typically associated with inoculation injuries and trauma. The disease usually remains confined to the subcutaneous tissues and muscle fascia. It presents as a brawny, woody infiltration involving the limbs, neck, and trunk. Amphotericin B is the drug of choice, usually in combination with surgical debridement. Even the cutaneous and subcutaneous form of the infection carries a significant mortality.

Chromoblastomycosis

Chromoblastomycosis (chromomycosis) is caused by fungi of various genera, including *Phialophora*, *Wangella*, and *Fonsecaea* spp. These are found mainly in tropical and subtropical countries. Chromoblastomycosis presents initially as a small papule, usually at the site of a previous injury, which persists for several months before ulcerating. The lesion later becomes warty and encrusted and gradually spreads. Satellite lesions may be present. Itching is common. The drug of choice is amphotericin B in combination with itraconazole or voriconazole. Cryosurgery is used to remove local lesions.

Mycetoma (Madura foot)

Mycetoma may be caused by subcutaneous infection with fungi (*Eumycetes* spp.) or bacteria. It is largely confined to the tropics and is a disease of poverty in patients with poor or no footwear. Infection results in local swelling, which may discharge through sinuses. Bone involvement may follow.

Management consists of surgical debridement combined with antimicrobials chosen according to the aetiological agent.

Pneumocystis jirovecii infection

Genetic analysis has shown *P. jirovecii* to be homologous with fungi. *P. jirovecii* disease is almost invariably associated with immunodeficiency states, particularly HIV infection (see Chapter 44).

Superficial fungal infections

Dermatophytosis

Dermatophytoses are chronic fungal infections of keratinous structures, such as the skin, hair, or nails. The main causative organisms are species of the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*.

Malassezia infection

Malassezia spp. are found on the scalp and greasy skin and are responsible for seborrhoeic dermatitis, pityriasis versicolor (hypo- or hyperpigmented rash on the trunk), and *Malassezia* folliculitis (itchy rash on the back).

Treatment of any superficial fungal infection is with topical antifungals or with oral triazole drugs if infection is refractory or more extensive.

Antifungal drugs

Fungal infections range from trivial superficial skin and nail infections to life-threatening systemic conditions. The antifungal armory is relatively limited, and because fungal cells share more enzymes and other pathways with human cells than do bacteria, targeting the pathogen without harming host metabolism is more difficult. There are three main groups of parenteral drugs for treating severe fungal infections: amphotericin, triazoles, and echinocandins (**Box 42.55**). Although each has specific licenced indications, antifungal drugs are often given empirically in severely ill patients. The best choice from among the available agents depends on several factors, including local resistance patterns and availability, potential for toxicity, and cost. Many countries have specific national guidelines.

Polyenes

Polyenes react with the sterols in fungal membranes, increasing permeability and thus damaging the organism. The most potent is ***amphotericin***, which is used intravenously in severe systemic fungal infections. Nephrotoxicity is a major problem, and dosage levels must take background renal function into account. Liposomal formulations of amphotericin are less toxic and are used in preference, although they are very expensive. ***Nystatin*** is not absorbed through mucous membranes and is therefore useful for the treatment of oral and enteric candidiasis and for vaginal infection. It can only be given orally or as pessaries.

Azoles

Imidazoles

Imidazoles are broad-spectrum antifungal drugs. They act by inhibiting fungal sterol synthesis, resulting in damage to the cell wall. ***Ketoconazole*** is active orally but can produce liver damage and is now rarely used systemically. It continues to be used topically, along with ***clotrimazole*** and ***miconazole***, for the treatment of ringworm and cutaneous and genital candidiasis. ***Econazole*** is used for the topical treatment of cutaneous and vaginal candidiasis and dermatophyte infections, and ***tioconazole*** is indicated for fungal nail infections.

Box 42.55 Antifungal agents

Polyenes
- Amphotericin, nystatin

Echinocandins
- Caspofungin
- Anidulafungin
- Micafungin

Azoles
- Miconazole, ketoconazole, fluconazole, itraconazole, voriconazole, posaconazole, isavuconazole
- Topical clotrimazole, sulconazole, tolnaftate, econazole, tioconazole

Allylamines
- Terbinafine

Other antifungals
- Amorolfine (topical only)
- 5-Flucytosine
- Griseofulvin

Triazoles

These drugs also act by interfering with fungal sterol synthesis. ***Itraconazole*** was the first triazole to be used widely in clinical practice, but its relatively poor absorption and failure to penetrate CSF mean that it has largely been superseded (except for a few specific conditions such as histoplasmosis and blastomycosis). ***Fluconazole*** is well absorbed and has excellent CNS penetration; it is used for mucosal and invasive candidiasis and for the treatment of CNS infection with *C. neoformans*. Some non-*albicans Candida* species are intrinsically resistant to fluconazole, and resistance can develop in *C. albicans*. ***Voriconazole*** has broad-spectrum activity that includes most *Candida*, *Cryptococcus*, and *Aspergillus* spp. and other filamentous fungi. It is available for oral and intravenous use. Adverse effects include visual disturbance, abnormalities of liver enzymes, and a variety of dermatological problems (including a possible link with squamous cell carcinoma). It also has significant drug–drug interactions with drugs metabolized by the CYP450 enzymes, and like all the triazoles, can cause QTc prolongation. It is indicated for invasive aspergillosis and severe *Candida* infections unresponsive to amphotericin and fluconazole, respectively, and for empirical treatment of suspected or confirmed severe fungal infection. ***Posaconazole*** has a similar range of activity and is also associated with hepatotoxicity and CYP450 interactions. ***Isavuconazole*** is a new triazole: it is licensed for use in invasive mould disease and mucormycosis but (largely because of cost) is generally a second- or third-line agent.

Echinocandins

These act by inhibiting the cell-wall polysaccharide glucan. ***Caspofungin***, which is administered intravenously, is active against *Candida* spp. and *Aspergillus* spp. and is indicated for invasive candidiasis and invasive aspergillosis unresponsive to other drugs, as well as for empirical therapy in seriously ill patients. Other echinocandins include ***micafungin*** and ***anidulafungin***, approved for the treatment of patients with disseminated candidiasis. Severe hepatotoxicity has been reported with micafungin, and liver biochemistry must be monitored.

Flucytosine

The fluorinated pyridine derivative flucytosine is used in combination with amphotericin B for cryptococcal meningitis. Side-effects are uncommon, although it may cause bone marrow suppression. It is active when given orally or parenterally, but there is very limited availability in resource-poor settings.

Allylamines

Terbinafine has broad-spectrum antifungal and also has anti-inflammatory activity. It is well absorbed orally and accumulates in keratin. It is useful for the treatment of patients with superficial mycoses, such as dermatophyte infections, onychomycosis, and cutaneous candidiasis. A topical formulation is also available to treat those with fungal skin infections.

PROTOZOAL INFECTIONS

Protozoa are unicellular eukaryotic organisms. They are more complex than bacteria and belong to the animal kingdom. Although many protozoa are free living in the environment, some have become parasites of vertebrates, including humans, often developing complex life cycles involving more than one host species. To be transmitted to a new host, some protozoa transform into hardy cyst forms, which can survive harsh external conditions. Others are transmitted by an arthropod vector, in which a further replication cycle takes place before infection of a new vertebrate host.

BLOOD AND TISSUE PROTOZOA

Malaria

Human malaria is usually caused by one of five species of the genus *Plasmodium: Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and rarely *Plasmodium knowlesi* (an occasional spillover from primates in Indonesia). Human malaria probably originated from animal malarias in Central Africa but was spread around the globe by human migration. Public health measures and changes in land use have eradicated malaria in much of the world where it was previously endemic, although the potential for malaria transmission still exists in many areas. Some 247 million people were infected in 2021, although 29 countries account for 96% cases, with more than 600 000 deaths (mainly in African children). The COVID pandemic stalled global reductions in incidence and mortality seen over prior decades. More than 30 000 infections per year occur in travellers from non-malarious countries.

Epidemiology

Malaria is transmitted by the bite of female anopheline mosquitoes. The parasite undergoes a temperature-dependent cycle of development in the gut of the insect, and its geographical range therefore depends on the presence of the appropriate mosquito species and an adequate temperature. The disease occurs in endemic or epidemic form throughout the tropics and subtropics except for some areas above 2000 m (Fig. 42.28), although an increasing number of countries have been declared malaria free in the past 10 years.

In areas of so-called ***stable transmission*** (including much of sub-Saharan Africa), transmission occurs consistently year-round. The bulk of the deaths are seen in children, and those who survive to adulthood acquire significant immunity; low-grade parasitaemia is still present but causes few symptoms. ***Unstable transmission*** occurs when there is erratic, seasonal, or low-level transmission (e.g., in the Sahel belt, where mosquitoes feed only in the rainy season). In these circumstances, little protective immunity develops, and symptomatic malaria occurs at all ages. Changes in environmental or social conditions in such areas can lead to epidemics with substantial mortality rates in all age groups.

Malaria can also be transmitted in contaminated blood transfusions. It has occasionally been seen in patients with a hospital-acquired infection related to contaminated equipment. Rare cases are acquired outside the tropics when mosquitoes are transported from endemic areas (‘airport malaria’) or when the local mosquito population becomes infected by a returning traveller.

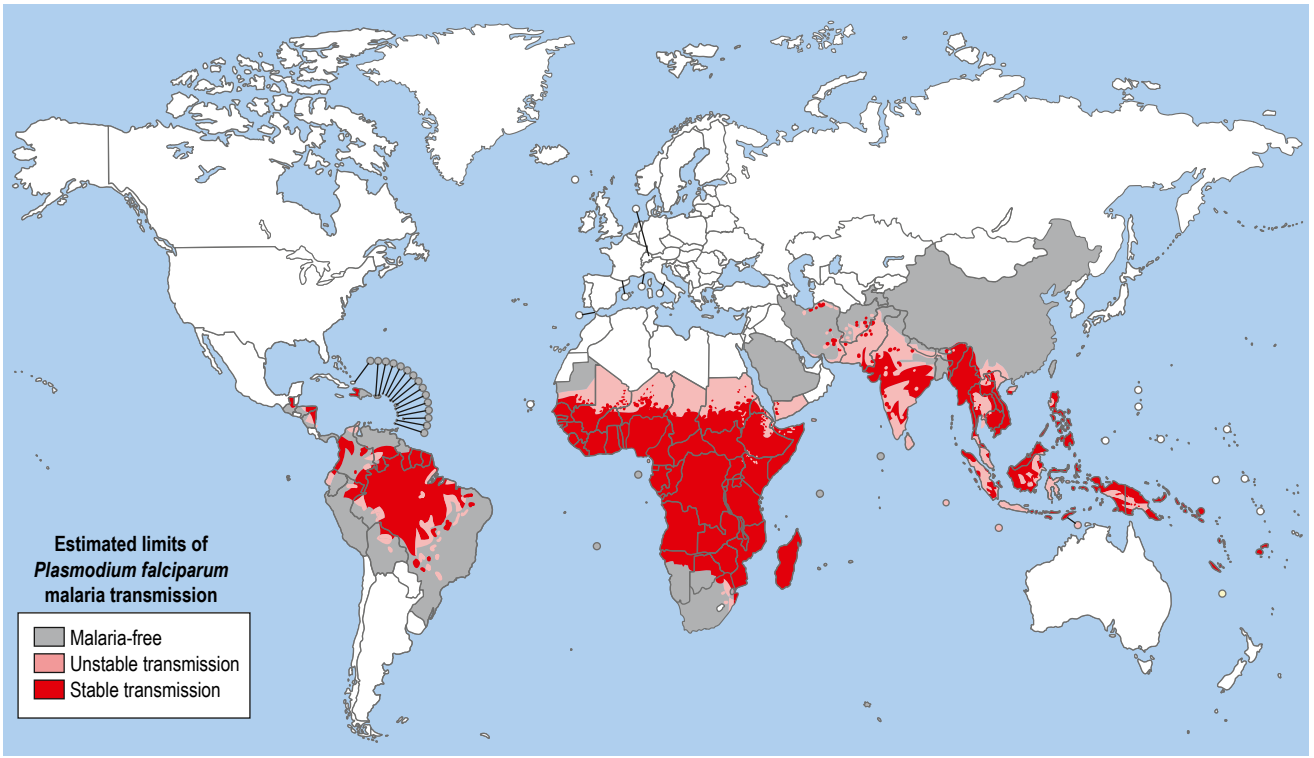

Fig. 42.28 ***Plasmodium falciparum*** **malaria transmission: geographical distribution.** Map lines delineate study areas and do not necessarily depict accepted national boundaries. *(From Malaria Atlas Project, with permission; https://data.malariaatlas.org/maps?layers=Malaria:202206_Global_Pf_Parasite_Rate.)*

Parasitology

The female mosquito becomes infected after taking a blood meal containing gametocytes, the sexual form of the malarial parasite (Fig. 42.29). The developmental cycle in the mosquito usually takes 7 to 20 days (depending on temperature), culminating in the migration of infective sporozoites to the insect's salivary glands. The sporozoites are inoculated into a new human host, and those not destroyed by the immune response are rapidly taken up by the liver. There they multiply inside hepatocytes as merozoites; this is pre-erythrocytic (or hepatic) sporogeny. After a few days, the infected hepatocytes rupture, releasing merozoites into the blood, from where they are rapidly taken up by erythrocytes. In the case of *P. vivax* and *P. ovale*, a few parasites remain dormant in the liver as hypnozoites. These may reactivate at any time subsequently, causing relapsing infection.

Inside the red blood cell, the parasites again multiply, changing from merozoite to trophozoite to schizont and finally appearing as 8 to 24 new merozoites. The erythrocyte ruptures, releasing the merozoites to infect further cells. Each cycle of this process, which is called erythrocytic schizogony, takes about 48 hours in *P. falciparum*, *P. vivax*, and *P. ovale* disease and about 72 hours in *P. malariae* disease. *P. knowlesi* has the shortest cycle at 24 hours. *P. vivax* and *P. ovale* mainly attack reticulocytes and young erythrocytes, and *P. malariae* tends to attack older cells; *P. falciparum* parasitizes any stage of erythrocyte.

A few merozoites develop not into trophozoites but into gametocytes. These are not released from the red cells until taken up by a feeding mosquito to complete the life cycle.

Pathogenesis

The pathology of malaria is related to anaemia; cytokine release; and in the case of *P. falciparum*, widespread organ damage because of impaired microcirculation. The anaemia seen in malaria is multifactorial (Box 42.56). In *P. falciparum* malaria, red blood cells containing schizonts adhere to the lining of capillaries in the brain, kidneys, gut, liver, and other organs. As well as causing mechanical obstruction, these schizonts rupture, releasing toxins and stimulating further cytokine release.

After repeated infections, partial immunity develops, allowing the host to tolerate parasitaemia with minimal ill effects. This immunity is largely lost if there is no further infection for a few years. Certain genetic traits also confer some immunity to malaria. People who lack the Duffy antigen on the red blood cell membrane (a common finding in West Africa) are not susceptible to infection with *P. vivax*. Certain haemoglobinopathies (including sickle cell trait) also give some protection against the severe effects of malaria, explaining the persistence of these otherwise harmful mutations in tropical countries. Iron deficiency may also have some protective effect. The spleen appears to play a role in controlling infection, and splenectomized people are at risk of overwhelming malaria. Pregnancy increases susceptibility to severe disease.

Clinical features

Typical malaria is seen in non-immune individuals. This includes children in any area, adults in areas of unstable transmission, and any visitors from a non-malarious region.

The normal incubation period is 10 to 21 days, but it can be longer. The most common symptom is fever, although malaria may present initially with general malaise, headache, vomiting, or diarrhoea. At first the fever may be continual or erratic; the classical tertian or quartan fever appears only after some days. The temperature often reaches 41°C and is accompanied by rigors and drenching sweats.

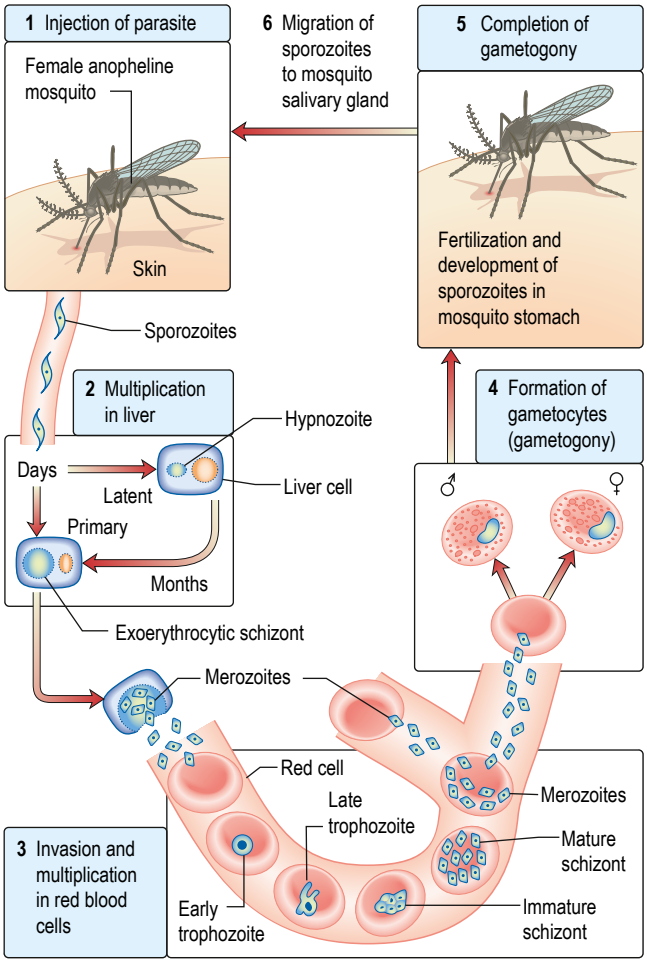

Fig. 42.29 **A schematic life cycle of *Plasmodium vivax*.**

Box 42.56 Causes of anaemia in malaria infection

- Haemolysis of infected red blood cells
- Haemolysis of non-infected red cells (blackwater fever)
- Dyserythropoiesis
- Splenomegaly and sequestration
- Folate depletion
- Haemolysis after intravenous artesunate treatment (probably caused by decreased erythrocyte lifespan)

The illness caused by ***P. vivax*** **or** ***P. ovale*** infection is usually relatively mild (although *P. vivax* can occasionally cause severe disease). Anaemia develops slowly, and there may be tender hepatosplenomegaly. Spontaneous recovery usually occurs within 2 to 6 weeks, but hypnozoites in the liver can cause relapses for many years after infection. Repeated infections often cause chronic ill health because of anaemia and hyper-reactive malarial splenomegaly.

P. malariae infection also causes a relatively mild illness but tends to run a more chronic course. Parasitaemia may persist for years, with or without symptoms. In children, *P. malariae* infection is associated with glomerulonephritis and nephrotic syndrome.

P. knowlesi is primarily a parasite of macaque monkeys but causes human malaria in certain areas of South-east Asia. The clinical picture is very variable, ranging from a chronic relatively mild illness similar to *P. malariae*, through to fulminant and fatal disease.

P. falciparum infection causes, in many cases, a self-limiting illness similar to the other types of malaria, although the paroxysms of fever are usually less marked. However, it may also cause serious complications (Fig. 42.30), and the vast majority of malaria deaths are caused by *P. falciparum*. Patients can deteriorate rapidly, and children in particular progress from reasonable health to coma and death within hours. A high parasitaemia (>10% of red blood cells infected; >2% is used as a cut-off in non-endemic settings) is an indicator of severe disease, although patients with apparently low parasite levels may also develop complications (peripheral parasite counts can be misleading because many parasitized cells are sequestered in the microcirculation). Cerebral malaria is marked by diminished consciousness, confusion, and convulsions, often progressing to coma and death. Untreated, it is universally fatal. Blackwater fever is caused by widespread intravascular haemolysis, affecting both parasitized and unparasitized red cells, giving rise to dark urine. In children, concurrent bacteraemia is common.

Hyper-reactive malarial splenomegaly (tropical splenomegaly syndrome) is seen in older children and adults in areas where malaria is hyperendemic. It is associated with an exaggerated immune response to repeated malaria infections and is characterized by anaemia, massive splenomegaly, elevated IgM levels, and anti-plasmodium antibodies. Malaria parasites are scanty or absent, but PCR increases parasitological yield. Traditionally treated with prolonged courses of prophylactic antimalarials where patients are in a setting of persistent re-exposure, a single treatment course is effective in non-endemic settings.

Diagnosis

Malaria should be in the differential diagnosis of anyone who presents with a febrile illness in, or having recently left, a malarious area. *Falciparum* malaria is unlikely to present more than 3 months after exposure even if the patient has been taking prophylaxis, but *vivax* malaria may cause symptoms for the first time up to 1 year after leaving a malarious area.

Diagnosis is usually made by identifying parasites on a Giemsa-stained thick blood film (with thin films subsequently used to speciate the parasite and determine parasitaemia). Rapid antigen detection tests (RDTs) are increasingly used for near-patient diagnosis or where laboratory staff with sufficient competence in microscopy are unavailable. Repeat films (often three are recommended) should be examined if the diagnosis remains a concern despite initial negative test results because both RDTs and thick films have insufficient sensitivity to rule out infection. In many endemic areas, malaria is over-diagnosed on clinical grounds (with the risk that the true cause of the febrile illness is missed), and a definite diagnosis should be made wherever possible. There is an increasing prevalence of parasites with a gene deletion in the histidine-rich protein 2 (pfhrp2), which leads to a false-negative result when using RDTs as a result of selection pressure through widespread use of these tests, raising concerns with regard to their sensitivity. Serological tests are of no diagnostic value, but PCR and other molecular amplification techniques are gaining traction.

Parasitaemia is common in endemic areas, and the presence of parasites does not necessarily mean that malaria is the cause of the patient's symptoms. Further investigation, including a lumbar puncture, may be needed to exclude other infections, and presumptive antibiotics are recommended in children with confirmed *P. falciparum* infection who are septic or comatose.

Management

Uncomplicated malaria

Chloroquine is still widely used to treat patients with non-*falciparum* malaria (Box 42.57), and in many areas, it remains effective. However,

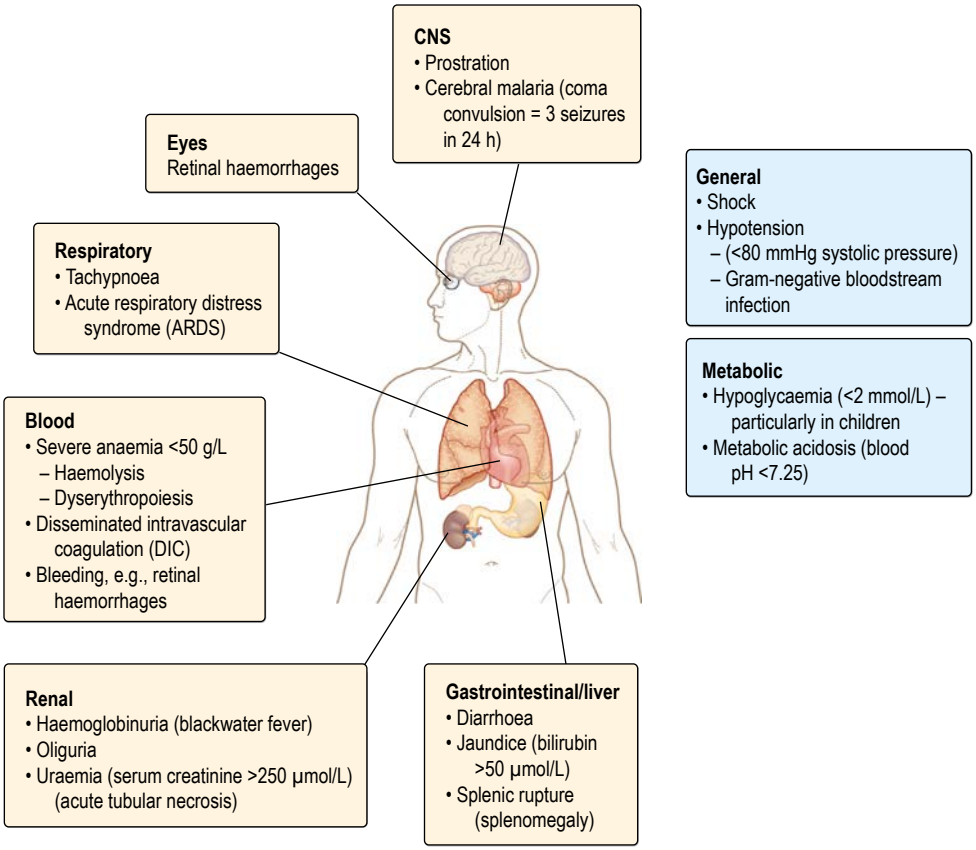

Fig. 42.30 Features of severe *falciparum* malaria. *CNS,* Central nervous system.

Box 42.57 Drug treatment of uncomplicated malaria

Parasite	Drug	Regimen	Plus	Regimen
Plasmodium vivax *Plasmodium ovale* *Plasmodium malariae*	ACT	3 days	Primaquine	0.25–0.5 mg/kg per day for 2–3 weeks
Plasmodium falciparum (adults, endemic zone)	ACT	3 days		
	or (if not available)			
	Quinine + doxycycline	7 days		
P. falciparum (pregnancy)	ACT	3 days		
P. falciparum (infants)	ACT	3 days; appropriate dose for body weight		
P. falciparum (returning travellers)	ACT or atovaquone + proguanil *or* quinine + doxycycline	3 days		

there is increasing resistance to chloroquine in some strains of *P. vivax*, and co-infection with *P. falciparum* is common in some parts of the world. It is therefore sensible to use oral artemisinin combination therapy, where available, for all cases of malaria. After successful treatment of a patient with *P. vivax* or *P. ovale* malaria, it is necessary to give a 2- to 3-week course of primaquine (0.25–0.5 mg/day) to eradicate the hepatic hypnozoites and prevent relapse ('radical cure'). This drug can precipitate haemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, which should be excluded before administration (see Chapter 38, 'Glucose-6-phosphate dehydrogenase deficiency' section). Tafenoquine given as a single dose (developed for its long half-life) is also licensed in some countries.

The artemisinin-based drugs are the most effective treatment for both uncomplicated and severe infections with *P. falciparum* in adults and in children. Artemisinin-based combination therapy (ACT) is the recommended oral treatment for uncomplicated *P. falciparum* malaria worldwide, in which the artemisinin compound is co-administered with a long half-life partner drug. These drugs are now widely available and standard of care globally, partly through the efforts of the Global Fund. Several different fixed-dose combinations are recommended by the WHO (**Box 42.58**); the choice

Box 42.58 Suitable artemisinin combination therapies for malaria

Drugs	Regimen
Fixed-dose combination tablets available	
Artemether–lumefantrine	4 tablets twice daily for 3 days[a]
Artesunate–amodiaquine	4 mg/kg per day of artesunate for 3 days
Dihydroartemisinin–piperaquine	4 mg/kg per day of dihydroartemisinin for 3 days
Available as fixed-dose, co-packaged, separate tablets	
Artesunate–mefloquine[b]	4 mg/kg per day of artesunate for 3 days
Artesunate–sulfadoxine–pyrimethamine[c]	4 mg/kg per day of artesunate for 3 days
Alternatives where no combination packages are available	
Artesunate + clindamycin	2 mg/kg per day + 10 mg/kg twice daily for 7 days
Artesunate + doxycycline	2 mg/kg per day + 3.5 mg/kg per day for 7 days

[a]Adult dose: reduce dose by body weight for children.
[b]Combination tablet manufactured but not widely available.
[c]Not suitable for *Plasmodium vivax* or mixed infections. Different fixed-dose combinations are available.

Box 42.59 Drug treatment of severe *falciparum* malaria in adults and children

Drug and route	Immediate dose	Subsequent doses
Severe malaria is an emergency: after rapid assessment and confirmation of diagnosis, if possible, treatment should be started with whatever parenteral treatment is available. The options, in order of preference, are:		
1. i.v. artesunate	2.4 mg/kg	2.4 mg/kg at 12 and 24 h, then daily (up to 7 days)
2. i.v. quinine	20 mg/kg[a]	10 mg/kg 8-hourly (up to 7 days)
3. i.m. artesunate	2.4 mg/kg	2.4 mg/kg at 12 and 24 h, then daily (up to 7 days)
4. i.m. artemether	3.2 mg/kg	1.6 mg/kg daily
5. Rectal artesunate	10 mg/kg	Transfer to centre where parenteral therapy available
Continue parenteral treatment for at least 24 hours regardless of improvement in condition. After this, if the patient is improving, switch to oral therapy to complete 7 days with:		
ACT		
Or		
Quinine + doxycycline		

[a]10 mg/kg if patient has already received oral quinine or mefloquine.
ACT, Artemisinin-based combination therapy; *i.m.,* intramuscular; *i.v.,* intravenous.

should be based on local resistance to the 'partner'. To limit the development of resistance, artemisinin derivatives should never be given as monotherapy. Partial resistance to artemesinins is already widespread in parts of South-east Asia and has emerged in India, South America, and *de novo* in East Africa. As long as combination therapy is used and the parasite is sensitive to the partner drug, ACT will still be effective. Longer courses of artemether may also overcome the partial resistance, and in areas along the Mekong river in South-east Asia, triple ACT is now required.

In addition to treating the acute infection, the WHO recommends that a single dose of primaquine should be given as a gametocide to decrease onward transmission.

Severe *P. falciparum* malaria

Severe malaria, indicated by the presence of any of the complications discussed earlier or a parasite count of more than 10% (lower thresholds, e.g., 2%, are used in non-immune patients) is a medical emergency (**Box 42.59**). Anyone involved in managing patients with malaria should be familiar with the latest WHO guidelines.

- Intravenous artesunate has replaced intravenous quinine because it is more effective, and clinicians should ensure its availability in all acute hospital settings. It is now recommended in all trimesters of pregnancy.
- Intensive care facilities may be needed, including mechanical ventilation and dialysis.
- Patients with severe anaemia may require transfusion.
- Careful monitoring of fluid balance is essential; both pulmonary oedema and pre-renal failure are common.
- Hypoglycaemia can be induced both by the infection itself and by quinine treatment, when used.
- Superadded bacterial infection is common, particularly in children.

Prevention and control

Malaria is a priority for the WHO, which announced its 'Roll Back Malaria' campaign in 1998. This has had considerable success, and the global malaria-specific mortality rate decreased by nearly 40% between 2000 and 2019. However, progress has stalled, with a deteriorating picture through the COVID pandemic. Although some countries either have eradicated malaria or plan to do so soon, for much of Africa, the aim remains control rather than eradication. Recent WHO recommendations have been widely endorsed and supported by governments and non-governmental organizations (**Box 42.60**).

As with many vector-borne diseases, control of malaria relies on a combination of case treatment, vector eradication, and personal protection from vector bites, such as that provided by insecticide (permethrin)-treated nets. Mosquito eradication is usually achieved by a combination of insecticide use (e.g., house spraying with DDT) and manipulation of the habitat (e.g., marsh drainage). Alongside these elements, there has been renewed interest in seasonal and perennial malaria chemoprevention, in which children in endemic areas are given monthly doses of antimalarials during the rainy season or year-round, respectively. This has been shown to reduce the incidence of malaria but may lead to an increased risk of drug resistance. Safe and effective intermittent chemoprevention is now recommended during pregnancy and in school-age children because of the greater risk of complications. Post-discharge malaria chemoprevention, given for 6 months to children found to be severely anaemic for any reason, is recommended in high-transmission settings to reduce subsequent deaths and hospitalizations. Mass drug administration is recommended in emergency settings and in areas of moderate to high transmission, as well as in settings with very low to low transmission and to reduce *P. vivax* transmission.

Enormous effort (and resource) has been devoted to the search for a malaria vaccine, and significant progress has been made. In October 2021, the WHO recommended the RTS,S/AS01 malaria vaccine for the prevention of *P. falciparum* malaria in children living in regions with moderate to high transmission (as defined by the WHO). After further phase 3 trials demonstrating 75% efficacy, in 2022 WHO issued prequalification approval for the RTS,S vaccine, and UNICEF announced that it had secured 18 million doses over

Box 42.60 Key elements in the strategy for reducing the global burden of malaria by 90%[a]

- Vector control
  - Long-lasting insecticide-treated bed nets
  - Indoor residual spraying
- Adequate entomological surveillance and monitoring
  - Periodic assessment of vector species, abundance, seasonality, and behaviour
  - Insecticide susceptibility status and underlying resistance mechanisms
  - Routine monitoring of coverage and impact of interventions, including use and condition of bed nets
- Managing insecticide resistance and residual transmission
  - Use insecticides with different modes of action
  - Forecast vector control product requirements and support pooled procurement
- Expanding preventive treatment to prevent disease in the most vulnerable groups
  - Intermittent preventive treatment of pregnant females
  - Intermittent preventive treatment of infants and children
  - Seasonal chemoprevention for children aged younger than 5 years
  - Protecting all non-immune travellers and migrants
- Ensuring universal diagnostic testing of all suspected malaria cases
  - All suspected cases to have malaria should have the diagnosis confirmed by quality-assured microscopy or a rapid diagnostic test before treatment
  - Track and report all cases
- Providing quality-assured treatment to all patients
- Scaling up community-based diagnostic testing and treatment
- Monitoring safety and efficacy of antimalarial medicines and managing antimalarial drug resistance
- Eliminating *falciparum* malaria from the Greater Mekong subregion where artesunate resistance is endemic
- Removing all inappropriate antimalarial medicines from markets

[a]These strategies include ensuring universal access to malaria prevention, diagnosis, and treatment.

Box 42.61 Malaria prophylaxis for adult travellers

Area visited	Advice or prophylaxis
Countries or regions of low risk or certain higher risk areas out of malaria risk season	Bite avoidance measures advised
Countries or regions of significant malaria risk	Mefloquine 250 mg, one tablet weekly *or* Atovaquone (250 mg) plus Proguanil (100 mg) combination tablet, one tablet daily *or* Doxycycline 100 mg, one tablet daily
Thai–Myanmar border (high levels of mefloquine resistance)	Atovaquone (250 mg) plus Proguanil (100 mg) combination tablet, one tablet daily *or* Doxycycline 100 mg, one tablet daily

the next 3 years (2023–2025). It is now recommended in a four- or five-dose schedule to all children from 5 months of age living in regions with moderate or high transmission.

Non-immune travellers to malarious areas should take measures to avoid insect bites, such as using a repellent (diethyltoluamide [DEET] 20%–50% in lotions and sprays) and sleeping under a mosquito net. Antimalarial prophylaxis should also be taken in most cases, although this is never 100% effective (**Box 42.61**). The precise choice of prophylactic regimen depends both on the individual traveller and on the specific itinerary; further details can be found in national formularies or travel advice centres.

Trypanosomiasis

African trypanosomiasis (sleeping sickness)

Sleeping sickness is caused by trypanosomes transmitted to humans by the bite of the tsetse fly (genus *Glossina*), although mother-to-child transmission has also occasionally been reported. It is endemic in a belt across sub-Saharan Africa, extending to about 14 degrees north and 20 degrees south; this marks the natural range of the tsetse fly. Two subspecies of trypanosome cause human sleeping sickness: *Trypanosoma brucei gambiense* ('West African trypanosomiasis') and *Trypanosoma brucei rhodesiense* ('East African trypanosomiasis').

Epidemiology

Sleeping sickness caused by *T. b. gambiense* accounts for 97% of reported new cases. It is currently found in 24 countries in an area stretching from Uganda in Central Africa, west to Cameroon, and south as far as Angola; however, the Democratic Republic of Congo (with 61% cases) and a few other Central African states are now the only countries still reporting significant numbers. Humans are the major reservoir and infection is transmitted by riverine *Glossina* spp. (e.g., *Glossina palpalis*).

Sleeping sickness caused by *T. b. rhodesiense* occurs in 13 countries in East and Central Africa, but cases are rare and sporadic. It is a zoonosis of both wild and domestic animals. In endemic situations, it is maintained in game animals and transmitted by savannah flies such as *Glossina morsitans*. Previous epidemics have been related to cattle and the vectors were riverine flies.

Despite disruption to established treatment and control programmes related to repeated political upheaval and armed conflict in Central Africa, numbers have reduced greatly, with fewer than 1000 cases in 2022 compared with 500 000 in 1997. The WHO believes that it is on course to eliminate African trypanosomiasis (zero cases) by 2030.

Parasitology

Tsetse flies bite during the day, and unlike most arthropod vectors, both males and females take blood meals. An infected insect may deposit metacyclic trypomastigotes (the infective form of the parasite) into the subcutaneous tissue. These cause local inflammation ('trypanosomal chancre') and regional lymphadenopathy. Within 2 to 3 weeks, the organisms invade the bloodstream, subsequently spreading to all parts of the body, including the brain.

Clinical features

T. b. gambiense causes a chronic, slowly progressive illness. Episodes of fever and lymphadenopathy occur over months or years, and hepatosplenomegaly may develop. Eventually, infection reaches the CNS, causing headache, behavioural changes, confusion, and daytime somnolence. As the disease progresses, patients may develop tremors, ataxia, convulsions, and hemiplegias; eventually, coma and death supervene. Histologically, there is a lymphocytic meningoencephalitis, with scattered trypanosomes visible in the brain substance.

T. b. rhodesiense sleeping sickness is a much more acute disease. Early systemic features may include myocarditis, hepatitis, and serous effusions, and patients can die before the onset of CNS disease. If they survive, cerebral involvement occurs within weeks of infection and is rapidly progressive.

Diagnosis

Diagnosis involves three stages:

- Screening using serological tests (only available for *T. b. gambiense*) and clinical signs
- Confirmation of the presence of parasites in body fluids
- Assessment of stage of disease

The card agglutination test for trypanosomiasis is a robust and easy-to-use field assay for screening. If the result is positive (or there are clinical signs of disease), Giemsa-stained smears of thick or thin blood films or of lymph node aspirate should be examined for parasites. Blood films are usually positive in *T. b. rhodesiense* infection but are often negative in *T. b. gambiense* disease; concentration techniques may increase the yield. The main investigation for staging disease is lumbar puncture; examination of CSF is essential in patients with evidence of trypanosomal infection. CNS involvement causes lymphocytosis and elevated protein in the CSF, and parasites may be seen in concentrated specimens. Suramin should be given to patients with *T. b. rhodesiense* parasitaemia before lumbar puncture to avoid inoculation into the CSF.

Management

The treatment of patients with sleeping sickness is improving with better drugs now available for *T. b. gambiense* infection and ongoing clinical trials to define their use in *T. b. rhodesiense*. In both forms of disease, treatment is usually effective if given in the first stage (i.e., before the onset of CNS involvement) (**Box 42.62**). The treatment of choice for those with second-stage (CNS) disease in *T. b. gambiense* is now oral fexinidazole, although a combination of eflornithine and nifurtimox is effective and still recommended in young children or those with severe disease. Fexinidazole is also now indicated for all stages of *T.b.rhodesiense*, replacing melarsoprol for all except young children; melarsoprol is extremely toxic, causing an acute encephalopathy in up to 10% with a high mortality rate.

Control

Control programmes coordinated by the WHO have been effective in many areas. As in many vector-borne diseases, prevention depends largely on elimination, control, or avoidance of the vector.

South American trypanosomiasis (Chagas' disease)

Chagas' disease is widely distributed in rural areas of South and Central America, where up to 7 million people are infected. Since 2009, more cases have been detected in other parts of the world because of increased migration from Latin America. The disease is caused by *Trypanosoma cruzi*, which is transmitted to humans in the faeces of blood-sucking reduviid bugs (also called cone-nose or assassin bugs). Faeces infected with *T. cruzi* trypomastigotes are rubbed in through skin abrasions, mucosa, or conjunctiva. The bugs, which live in mud or thatch buildings, feed on a variety of vertebrate hosts (e.g., rats, opossums) at night, defecating as they do so.

The parasites spread in the bloodstream before entering host cells and multiplying. Cell rupture releases them back into the circulation, where they can be taken up by a feeding bug. Further multiplication takes place in the insect gut, completing the trypanosome life cycle. Human infection can also occur via contaminated blood transfusion or, occasionally, by transplacental spread.

Box 42.62 Drugs used in the treatment of African trypanosomiasis

Disease stage	*Trypanosoma brucei gambiense*	*Trypanosoma brucei rhodesiense*
1	Fexnidazole; pentamidine if <6 yrs old or <20 kg	Fexinidazole (suramin if <6 yrs old or <20 kg)[a]
2 (central nervous system)	If not severe: fexinidazole If severe: eflornithine + nifurtimox or eflornithine monotherapy	Fexinidazole (melarsoprol if <6 yrs old or <20 kg)

[a]Severe allergic reactions common: give test dose.

Clinical features

Acute infection usually occurs in children and often passes unnoticed. A firm, reddish papule is sometimes seen at the site of entry, associated with regional lymphadenopathy. In the case of conjunctival infection, there is swelling of the eyelid, which may close the eye (Romaña's sign). There may be fever; lymphadenopathy; hepatosplenomegaly; and rarely, meningoencephalitis. Acute Chagas' disease is occasionally fatal in infants, but normally there is full recovery within a few weeks or months.

Some 10% to 30% of people go on to develop chronic Chagas' disease after a latent period of many years. The pathogenesis remains controversial, although the most likely explanation is an autoimmune response to persistent parasite DNA integrated into the host genome. The heart is commonly affected, with conduction abnormalities, arrhythmias, aneurysm formation, and cardiac dilation. GI involvement leads to progressive dilation of parts of the GI tract; this commonly results in mega-oesophagus (causing dysphagia and aspiration pneumonia) and megacolon (causing severe constipation).

Diagnosis

Trypanosomes may be seen on a stained blood film during the acute illness. PCR is also sensitive in the acute phase. The chronic phase is typically 'indeterminate', with positive serology but no evidence of organ involvement, which develops in 20% to 30% cases over time. Blood PCR results may be positive in a proportion.

Management and control

Nifurtimox and benznidazole are the main drugs used. Both are highly effective in acute infection, with a cure rate of more than 90% but much less so in those with chronic disease. They are relatively toxic, with adverse reactions in up to 40% of patients, and new drugs are urgently needed. Antiarrhythmic drugs and pacemakers may be needed in patients with cardiac disease, and surgical treatment is sometimes required for GI complications.

In the long term, prevention of Chagas' disease relies on improved housing and living conditions and eradication of vectors. Several coordinated multinational vector control programmes have been implemented, with some success in reducing transmission. Screening of blood donors and pregnancies in high-risk areas can reduce transmission through non-vector routes; reactivation should be considered in the differential diagnosis of patients with suspected opportunistic infection after major iatrogenic immunosuppression such as organ transplantation.

Leishmaniasis

This group of diseases is caused by protozoa of the genus *Leishmania*, which are transmitted by the bite of the female phlebotomine sandfly (**Box 42.63**). Leishmaniasis is seen in localized areas of Africa,

Box 42.63 *Leishmania* species causing visceral and cutaneous disease

Mucocutaneous leishmaniasis		*Leishmania viannia*

Asia (particularly India and Bangladesh), Europe, the Middle East, and South and Central America. Certain parasite species are specific to each geographical area. The clinical picture is dependent on the species of parasite and on the host's cell-mediated immune response. Asymptomatic infection, in which the parasite is suppressed or eradicated by a strong immune response, is common in endemic areas. Symptomatic infection may be confined to the skin (cutaneous leishmaniasis, sometimes with spread to the mucous membranes) or widely disseminated throughout the body (visceral leishmaniasis); the propensity to these different forms depends predominantly on leishmania subspecies. Relapse of previously asymptomatic infection is seen in patients such as those with HIV infection or increasingly those with iatrogenic immunosuppression.

In some areas, leishmaniasis is primarily zoonotic, whereas in others, humans are the main reservoirs of infection. In the vertebrate host, the parasites are found as oval amastigotes (Leishman–Donovan bodies). These multiply inside the macrophages and cells of the reticuloendothelial system and are then released into the circulation as the cells rupture. Parasites are taken into the gut of a feeding sandfly (genus *Phlebotomus* in the Old World; genus *Lutzomyia* in the New World), where they develop into the flagellate promastigote form. These migrate to the salivary glands of the insect, where they can be inoculated into a new host.

Visceral leishmaniasis

Clinical features

Visceral leishmaniasis (kala azar) is caused by *Leishmania donovani*, *Leishmania infantum*, or *Leishmania chagasi* and is prevalent in localized areas of Asia, Africa, the Mediterranean littoral, and South America. In parts of India, where humans are the main host, the disease occurs in epidemics. In most other areas, it is endemic, and it is mainly children and visitors to the area who are at risk. The main animal reservoirs in Europe and Asia are dogs and foxes, but in Africa, it is carried by various rodents. Between 50 000 and 100 000 new cases occur each year, the vast majority in Brazil, East Africa, and the Indian subcontinent. Mortality rates have fallen in Asia because of improved treatment programmes, but not in Africa, where conflicts have disrupted management initiatives.

The incubation period is usually 1 to 2 months but may be several years. The onset of symptoms is insidious, and the patient may feel quite well despite markedly abnormal physical findings. Fever is common and may be high and intermittent, although is usually low grade. The liver and especially the spleen become enlarged. The skin becomes rough and pigmented, resulting in the common name 'kala azar', which means 'black fever' in Hindi. If the disease is not treated, profound pancytopenia develops, and the patient becomes wasted and immunosuppressed. Death usually occurs within 1 year and is normally caused by bacterial infection or uncontrolled bleeding.

Diagnosis

The specific diagnosis is made by demonstrating the parasite in stained smears of aspirates of bone marrow, lymph node, spleen, or liver. The organism can also be cultured from these specimens, but PCR is more sensitive. Specific serological tests are positive in 95% of cases. Pancytopenia, hypoalbuminaemia, and hypergammaglobulinaemia are common.

Management

Intravenous liposomal amphotericin B (which may be curative as a single-dose treatment) is effective but not universally available. The most widely used drugs for visceral leishmaniasis remain the pentavalent antimony salts (e.g., sodium stibogluconate and meglumine antimoniate) despite toxicity and increasing resistance. The oral drug miltefosine has been shown in India to be highly effective and may be used especially in combination with liposomal amphotericin or with paromomycin; combination therapies are increasingly being used to shorten treatment courses and limit resistance. The recommended treatment regimens vary from region to region (e.g., miltefosine has been less effective in Africa and the Mediterranean).

Successful treatment may be followed in a small proportion of patients by a skin eruption called ***post-kala azar dermal leishmaniasis***. It starts as a macular or maculopapular nodular rash, which spreads over the body. It is most often seen in Sudan and India and is difficult to treat, although it may improve with miltefosine. It is a major driver for onward transmission caused by high parasite numbers in the skin.

HIV co-infection

Visceral leishmaniasis is strongly associated with HIV-related immunosuppression (see Chapter 44), and the two infections may be passed on together through injecting drug use. Anti-retroviral therapy has largely controlled the problem, but in regions with suboptimal viral suppression, there are increasing case numbers.

Cutaneous leishmaniasis

Cutaneous leishmaniasis is caused by a number of geographically localized species, which may be zoonotic or anthroponotic. It is by far the most common form of the disease, with up to 1 million new cases worldwide every year. Some 95% of these occur in just seven countries: Iran, Iraq, Syria, Algeria, Afghanistan, Brazil, and Colombia.

After a sandfly bite, *Leishmania* amastigotes multiply in dermal macrophages. The local response depends on the species of *Leishmania*, the size of the inoculum, and the host immune response. Single or multiple painless nodules appear 1 week to 3 months after the bite (Fig. 42.31). These enlarge and ulcerate with a characteristic erythematous raised border. An overlying crust may develop. The

Fig. 42.31 Hyperkeratotic nodular cutaneous leishmaniasis lesions and leishmaniasis recidivans (on the right cheek) caused by *Leishmania tropica*. (*From Bailey MS, Lockwood DNJ. Cutaneous leishmaniasis.* Clin Dermatol *2007; 25:203–211.)*

lesions heal slowly over months or years, sometimes leaving a disfiguring scar.

Leishmania major and *Leishmania tropica* are found in Russia and Eastern Europe, the Middle East, Central Asia, the Mediterranean littoral, and sub-Saharan Africa. Whereas the reservoir for *L. major* is desert rodents, *L. tropica* has a mainly urban distribution with dogs and humans as reservoirs. *Leishmania aethiopica* is found in the highlands of Ethiopia and Kenya, where the animal reservoir is the hyrax. The skin lesions caused by these species usually heal spontaneously with scarring; this may take 1 year or more in the case of *L. tropica*. Leishmaniasis recidivans is a rare chronic relapsing form caused by *L. tropica*.

Leishmania mexicana is found predominantly in Mexico, Guatemala, Brazil, Venezuela, and Panama; infection usually runs a benign course with spontaneous healing within 6 months. *Leishmania braziliensis* infections (which are seen throughout tropical South America) also usually heal spontaneously but may take longer.

L. mexicana amazonensis and *L. aethiopica* may occasionally cause diffuse cutaneous leishmaniasis. This is rare and is characterized by diffuse infiltration of the skin by Leishman–Donovan bodies. Visceral lesions are absent.

Diagnosis and management

The diagnosis can often be made clinically in a patient who has been in an endemic area. Giemsa stain on a split-skin smear demonstrates *Leishmania* parasites in 80% of cases. Biopsy tissue from the edge of the lesion can be examined histologically and parasites identified by PCR; culture is less often successful. The leishmanin skin test result is positive in more than 90% of cases but does not distinguish between active and resolved infection. Serology is unhelpful.

Small lesions usually require no treatment and resolve spontaneously. Large lesions and those in cosmetically sensitive sites can sometimes be treated locally by topical antiparasitic agents (e.g., intralesional injections of meglumine antimonate, or topical paromomycin cream). Curettage and cryotherapy are also effective. In other cases, systemic treatment with pentavalent antimonials, amphotericin, or triazole antifungal drugs may be needed. Speciation by PCR of biopsy material should be performed for all lesions acquired in the 'New World' to identify species that are associated with subsequent mucosalization; systemic treatment is recommended to prevent this complication.

Mucocutaneous leishmaniasis

Mucocutaneous leishmaniasis occurs in 3% to 10% of infections with *L. b. braziliensis* and is most common in Bolivia and Peru. It can also follow infection with *L. aethiopica*. The cutaneous sores are followed months or years later by indurated or ulcerating lesions affecting mucosa or cartilage, typically on the lips or nose ('espundia'). The condition can remain static, or there may be progression over months or years affecting the nasopharynx, uvula, palate, and upper airways.

Diagnosis and management

Biopsies usually show only very scanty organisms, although parasites can be detected by PCR; results of serological tests are frequently positive.

Liposomal amphotericin B is the treatment of choice, if available, although systemic antimonial compounds are widely used; miltefosine may also be effective. Relapses are common after treatment. Patients may die because of secondary bacterial infection or, occasionally, laryngeal obstruction.

Prevention of leishmaniasis relies on control of vectors or reservoirs of infection. Insecticide spraying, control of host animals, and treatment of infected humans may all be helpful. Personal protection against sandfly bites is also important, especially in travellers visiting endemic areas. Sandflies are poor fliers and sleeping off the ground helps prevent bites.

Other protozoal diseases of the blood and tissues

Toxoplasmosis

Toxoplasmosis is caused by the intracellular protozoan parasite *T. gondii*. The sexual form of the parasite lives in the gut of the definitive host, the cat, where it produces oocysts. After a period of maturing in the environment, these oocysts become the source of infection for secondary hosts, which may ingest them. In the secondary hosts (which include humans, cattle, sheep, pigs, rodents, and birds) there is disseminated infection. After a successful immune response, the infection is controlled, but dormant parasites remain encysted in host tissue for many years. The life cycle is completed when carnivorous felines eat infected animal tissue. Humans are infected either from contaminated cat faeces or undercooked infected meat; transplacental infection may also occur.

Clinical features

Toxoplasmosis is common: seroprevalence in adults in the UK is about 25%, rising to 90% in some parts of Europe. Most infections are asymptomatic or trivial. Symptomatic patients usually present with lymphadenopathy, mainly in the head and neck. There may be fever, myalgia, and general malaise; occasionally, there are more severe manifestations, including hepatitis, pneumonia, myocarditis, and choroidoretinitis. Lymphadenopathy and fatigue can sometimes persist for months after the initial infection.

Congenital toxoplasmosis may also be asymptomatic but can produce serious disease. Clinical manifestations include microcephaly, hydrocephalus, encephalitis, convulsions, and mental retardation. Choroidoretinitis is common; occasionally, this may be the only feature.

Immunocompromised patients, especially those with HIV infection, are at risk of serious infections with *T. gondii*. In acquired

immunodeficiency states, this is usually caused by reactivation of latent disease.

Diagnosis

Toxoplasma lymphadenitis is often suspected after characteristic histological findings ('microgranulomas') identified through urgent cancer pathways. Diagnosis of this and other acute presentations is usually confirmed serologically. IgG antibodies detectable by the Sabin–Feldman dye test remain positive for years; acute infection can be confirmed by demonstrating a high titre of specific IgM. In immunosuppressed patients with suspected reactivation, diagnosis (e.g., of cerebral toxoplasmosis) is made on the basis of typical radiological findings but may be supported by PCR, whose results are often positive in tissue or fluid (e.g., CSF).

Management

Acquired toxoplasmosis in an immunocompetent host rarely requires treatment. In those with severe disease (especially eye involvement), sulfadiazine and pyrimethamine are given for 4 weeks, along with folinic acid. Azithromycin may also be effective. The management of toxoplasmosis in pregnancy aims to decrease the risk of fetal complications. However, there is only weak evidence that giving spiramycin, either alone or in combination with sulfadiazine (which is the recommended treatment), has any significant effect on the frequency or severity of fetal damage. Infected infants should be treated from birth. The treatment of toxoplasmosis in HIV-positive patients is covered in Chapter 44 ('Toxoplasmosis' section).

Babesiosis

Babesiosis is a tick-borne parasitic disease, diagnosed most commonly in North America and Europe. It is a zoonosis of rodents and cattle and is occasionally transmitted to humans; infection is more common and more severe in those who are immunocompromised after splenectomy. The causative organisms are the *Plasmodium*-like *Babesia microti* (rodents) and *B. divergens* (cattle).

The incubation period averages 10 days. In patients with normal splenic function, the illness is usually mild. In splenectomized individuals, systemic symptoms are more pronounced, and haemolysis is associated with haemoglobinuria, jaundice, and acute kidney injury. Examination of a peripheral blood smear may reveal the characteristic *Plasmodium*-like organisms.

The standard treatment of patients with severe babesiosis is a combination of quinine 650 mg and clindamycin 600 mg orally three times daily for 7 days. Atovaquone and azithromycin is an alternative combination therapy.

GASTROINTESTINAL PROTOZOA

The major GI protozoal parasites of humans are shown in **Box 42.64**.

Amoebiasis

Amoebiasis is caused by *E. histolytica*. There are two morphologically identical species of amoeba, which can be distinguished by molecular techniques.

- ***E. histolytica***, which is pathogenic
- ***Entamoeba dispar***, which is non-pathogenic.

Amoebiasis occurs worldwide, although much higher incidence rates are found in LMICs.

The organism exists both as a motile trophozoite and as a cyst that can survive outside the body. Cysts are transmitted by ingestion of contaminated food or water, or they can be spread directly by person-to-person contact, notably between males who have sex with males. Trophozoites emerge from the cysts in the small intestine and then pass on to the colon, where they multiply.

Clinical features

The long-held view that many individuals can carry the pathogen without obvious evidence of clinical disease (asymptomatic cyst passers) is based on misidentification of non-pathogenic *E. dispar*. True *E. histolytica* colonization and carriage is uncommon. In affected people, *E. histolytica* trophozoites invade the colonic epithelium using protozoal cytotoxins and proteolytic enzymes. The parasites continue to multiply and eventually cause frank ulceration of the mucosa. If penetration continues, trophozoites may enter the portal vein, via which they reach the liver and cause intrahepatic abscesses. This invasive form is serious and may even be fatal.

The incubation period of intestinal amoebiasis is highly variable and may be as short as a few days or as long as several months. In some patients, there may be mild chronic diarrhoea, but this may progress to bloody diarrhoea with mucus, sometimes accompanied by systemic symptoms such as headache, nausea, and anorexia. Acute amoebic dysentery, resembling a fulminant ulcerative colitis, may occur and is often misdiagnosed.

Complications are unusual but include toxic dilation of the colon with perforation, severe haemorrhage, amoeboma, and amoebic liver abscess. Amoebic liver abscesses often develop in the absence of a recent episode of colitis. Tender hepatomegaly, a high swinging fever, and profound malaise are characteristic, and early in the course of the disease, localizing symptoms may be minimal. The clinical features are described in more detail in Chapter 23 ('Liver abscess' section).

Box 42.64 Pathogenic human intestinal protozoa

Amoebae
- *Entamoeba histolytica*

Flagellates
- *Giardia intestinalis*

Ciliates
- *Balantidium coli*

Coccidia
- *Cyclospora cayetanensis*
- *Cryptosporidium parvum*
- *Isospora belli*
- *Sarcocystis* spp.

Microspora
- *Enterocytozoon bieneusi*
- *Encephalitozoon* spp.

Diagnosis

Microscopic examination of fresh stool or colonic exudate obtained at sigmoidoscopy (which is rarely performed but will demonstrate 'flask-shaped' ulceration) has been the standard means of diagnosing colonic amoebic infection. To confirm the diagnosis, motile trophozoites containing red blood cells must be identified; the presence of amoebic cysts alone does not imply disease. PCR techniques are also useful. Trophozoites may be seen in colonic biopsies but may be confused with host macrophages if the diagnosis is not suspected.

Results of ELISA-based serological tests are positive in at least 90% of patients with liver abscess and in 60% to 70% with active colitis.

Management

Metronidazole 800 mg three times daily for 5 days is given in amoebic colitis; a lower dosage (400 mg three times daily for 5 days) is usually adequate in liver abscess. Tinidazole is also effective. After treatment of the invasive disease, the bowel should be cleared of parasites with a luminal amoebicide such as paromomycin.

Prevention

Amoebiasis is difficult to eradicate because of the substantial human reservoir of infection. Progress will only be through improved standards of hygiene and sanitation and better access to clean water. Cysts are destroyed by boiling, but chlorine and iodine sterilizing tablets are not always effective.

Giardiasis

Giardia intestinalis is a flagellate (Fig. 42.32) that is found worldwide. It causes small intestinal disease, with diarrhoea and malabsorption. Prevalence is high in many LMICs, and it is the most common parasitic infection in travellers returning to the UK. In certain parts of Europe and some rural areas of North America, large water-borne epidemics have been reported. Person-to-person spread may occur in day nurseries and residential institutions and between males who have sex with males. Those with antibody deficient states such as selective IgA deficiency are at risk. The organism exists as both a trophozoite and a cyst, the latter being the form in which it is transmitted.

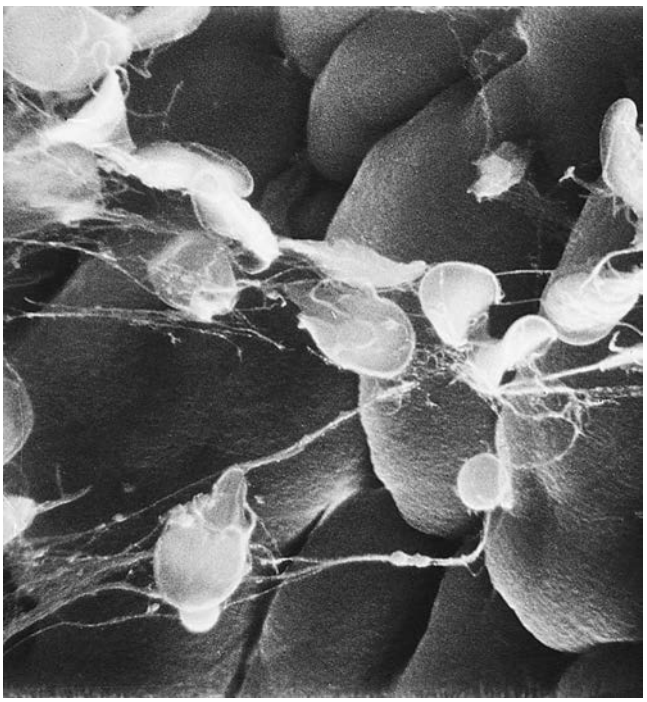

Fig. 42.32 *Giardia intestinalis* on small intestinal mucosa.
(Courtesy of Dr A Phillips.)

The organism sometimes colonizes the small intestine and may remain there without causing detriment to the host. In other cases, severe malabsorption may occur, which is thought to be related to morphological damage to the small intestine. The changes in architecture are usually mild partial villous atrophy; subtotal villous atrophy is rare. The mechanism by which the parasite causes alteration in mucosal architecture and produces diarrhoea and intestinal malabsorption is unknown, though there is evidence that the morphological damage is immune mediated. Bacterial overgrowth has also been found in association with giardiasis and may contribute to fat malabsorption.

Clinical features

Many individuals excreting *Giardia* cysts have no symptoms. Others become ill within 1 to 3 weeks of ingesting cysts; symptoms include diarrhoea, often watery in the early stage of the illness; nausea; anorexia; and abdominal discomfort and bloating. In most patients, these symptoms resolve after a few days, but in others they persist. Stools may then become paler, with the characteristic features of steatorrhoea. If the illness is prolonged, weight loss occurs and can be marked. Chronic giardiasis, frequently seen in low- and middle-income countries, can result in growth retardation in children.

Diagnosis

Both cysts and trophozoites can be found in the stool, but microscopy is inadequate because the parasite may be excreted at irregular intervals. Molecular stool techniques are much more sensitive. The parasite can also be seen in duodenal aspirates (obtained with either an endoscope or a luminal capsule) and in histological sections of jejunal mucosa.

Management

Tinidazole 2 g as a single dose, or metronidazole 400 mg three times daily for 5 to 7 days, will cure the majority of infections, although sometimes a second course is necessary or alternative agents may be required, such as tinidazole–albendazole combinations. Increasing numbers of patients are failing these treatments but can be cured with mepacrine. Immunoglobulin deficiency should be considered in recurrent infections, as well as screening of sexual contacts. Preventive measures are similar to those outlined earlier for *E. histolytica*.

Cryptosporidiosis

This organism is found worldwide, cattle being the major natural reservoir. It has also been demonstrated in supplies of drinking water in the UK. The parasite is able to reproduce both sexually and asexually; it is transmitted by oocysts excreted in the faeces.

In healthy individuals, cryptosporidiosis is a self-limiting illness. Acute watery diarrhoea is associated with fever and general malaise lasting for 7 to 10 days. In immunocompromised patients, especially those with HIV, diarrhoea is severe and intractable (see Chapter 44, 'Cryptosporidiosis' section). Cryptosporidium may also be an important cause of childhood diarrhoea in resource-poor countries, contributing to overall morbidity and mortality.

Diagnosis is usually made by faecal microscopy or PCR, although the parasite can also be detected in intestinal biopsies. Nitazoxanide may be of benefit but is ineffective in those with advanced HIV.

Balantidiasis

Balantidioides coli is the only ciliate that produces clinically significant infection in humans. It is found throughout the tropics, particularly in Central and South America, Iran, Papua New Guinea, and the Philippines. It is usually carried by pigs, and infection is most common in communities that live in close association with swine. Its life cycle is identical to that of *E. histolytica*. *B. coli* causes diarrhoea and sometimes a dysenteric illness, with invasion of the distal ileal and colonic mucosa. Trophozoites rather than cysts are found in the stool. Treatment is with tetracycline or metronidazole.

Blastocystis hominis infection

B. hominis is a strictly anaerobic protozoal organism that inhabits the colon. The pathogenicity for humans remains controversial. Many people appear to excrete the organism with no symptoms at all. There are numerous reports of people with diarrhoea whose symptoms improve after eradication of the parasite, but this could be a spillover effect from, for example, treatment of undiagnosed *Giardia* or alteration of the microbiome. Increasingly evidence suggests that at least some subspecies are a marker of a healthy and diverse microbiota. Treatment is very rarely recommended.

Cyclospora cayetanensis infection

Cyclospora cayetanensis, a coccidian protozoal parasite, infects the epithelium of the small intestine and presents with diarrhoea, usually watery and sometimes chronic. It is endemic in many LMICs, but large-scale outbreaks are also well described in the USA and Europe, associated with contaminated food, both imported and locally grown. Without specific microscopy techniques, the diagnosis may be missed. Infection is usually self-limiting but can be treated with co-trimoxazole.

Microsporidiosis

Protozoa of the phylum Microsporea can cause diarrhoea in patients with HIV and AIDS (see Chapter 44).

Free-living amoebae

Some amoebae, ubiquitous in the environment, can cause severe infections in humans. *Balamuthia mandrillaris*, *Naegleria fowleri*, and various *Acanthamoeba* species can cause a meningoencephalitis. Often the route of infection is across the cribriform plate after swimming or diving in freshwater or from nasal douching in people with pre-existing disruption of the skull base or in normal hosts. Some are associated with skin lesions, and some can involve other organs, especially in immunocompromised hosts. Outcomes of CNS involvement are almost always fatal. *Acanthamoeba* keratitis is a sight-threatening condition seen in contact lens wearers.

HELMINTH INFECTIONS

Worm infections are very common in rural areas of low- and middle-income countries, causing much disease in both humans and domestic animals. Worms are frequently imported into industrialized countries. The most common human helminth infections are listed in **Box 42.65**. Eight of the 20 'neglected tropical diseases' identified by the WHO as causing major morbidity in the poorest areas are caused by helminths. Even parasites that, in high-income countries, are regarded as little more than an inconvenience (e.g., roundworm or whipworm) cause huge morbidity in resource-poor settings because of the very high worm burden in children.

Helminths are the largest internal human parasites. They reproduce sexually, generating millions of eggs or larvae. Whereas ***nematodes*** and ***trematodes*** have a mouth and intestinal tract, ***cestodes*** absorb nutrients directly through the outer tegument. All worms are motile, but when the adults are established in their definitive site, they rarely migrate farther. In most cases, adult helminths are long-lived, for example, up to 30 years in the case of schistosomes.

Many helminths have developed complex life cycles, involving more than one host. Both primary and intermediate hosts

Box 42.65 Helminths commonly infecting humans

	Helminth	Common name or disease caused
Nematodes (roundworms)

	Echinococcus granulosus	Hydatid disease
	Echinococcus multilocularis	Hydatid disease
	Spirometra mansoni	Sparganosis

are often highly specific to a particular species of worm. In some cases of human infection, humans are the primary host, but in others, humans are a non-specific intermediary or are coincidentally infected. Multiple infections with different helminths are common in endemic areas and can lead to significant morbidity. The WHO recommends regular (usually annual) mass drug treatment for all at-risk people living where soil-transmitted helminths are common. This includes children from the age of 1 year and older, females of reproductive age, and adults in high-risk occupations such as mining and tea picking. There is, however, a lively debate about the strength of evidence supporting this guidance (Box 42.66).

NEMATODES

Tissue-dwelling worms

Filariasis

Several nematodes belonging to the superfamily Filarioidea can infect humans (Box 42.67). The adult worms are long and thread-like, ranging from 2 cm to 50 cm in length; females are generally much larger than males. Larval stages are inoculated into humans by various species of biting flies, each specific to a particular parasite. The adult worms that develop from these larvae mate and produce millions of offspring called microfilariae, which migrate through the blood or skin. These are ingested by feeding flies, in which the remainder of the life cycle takes place. Disease, which may be caused either by the adult worms or by microfilariae, stems from the host immune response to the parasite and is generally characterized by massive eosinophilia. Adult worms are long-lived (10–15 years), and re-infection is common, so disease tends to be chronic and progressive.

Box 42.66 Drugs used in mass treatment of helminth infections

Drug	Infection
Diethylcarbamazine (DEC)	Loiaisis Filariasis
Ivermectin	Loiaisis Filariasis Onchocerciasis Strongyloidiasis
Albendazole	Filariasis (with DEC) Intestinal helminths
Praziquantel	Schistosomiasis

It was Patrick Manson, working on filariasis in 1870s Formosa (now Taiwan), who was the first person to demonstrate a link between a human infectious disease and an arthropod vector. Having demonstrated that filaria were only present in human blood at night, he next conducted a series of experiments on his gardener, Hin Lo, who was infected with filaria. Manson got mosquitoes to feed on Hin Lo while he slept. Then, by dissecting the engorged mosquitoes, he demonstrated the presence of filaria under the microscope in the ones that had taken a blood meal. Sir Patrick Manson later became known as the *father of tropical medicine* but has recently attracted attention for his role in colonial medicine.

Lymphatic filariasis

Lymphatic filariasis may be caused by different species of filarial worm and has a scattered distribution in the tropics and subtropics. More than 120 million people are estimated to be infected, and almost 1 billion are at risk. *Wuchereria bancrofti* is transmitted to humans by *Culex* mosquitoes. Adult female worms are 5 to 10 cm long and live in the lymphatic vessels, disrupting the normal function of the lymphatic system and releasing large numbers of microfilariae into the blood. This generally occurs at night, coinciding with the nocturnal feeding pattern of *Culex* mosquitoes, so 'night bloods' may need to be taken to confirm a diagnosis. Note that non-periodic forms of *W. bancrofti*, transmitted by day-biting species of mosquito, are found in the South Pacific. *Brugia malayi*, and the closely related *Brugia timori*, is very similar to *W. bancrofti* and exhibits the same nocturnal periodicity. The usual vectors are mosquitoes of the genus *Mansonia*.

Many filarial worms coexist with symbiotic *Wolbachia* bacteria, which are, in themselves, a cause of inflammation in the human host and a target for adjunctive treatment.

Clinical features

After the bite of an infected mosquito, the larvae enter the lymphatics and are carried to regional lymph nodes. There, they grow and mature for 6 to 18 months.

Adult worms produce allergic lymphangitis. The clinical picture depends on the individual immune response, which in turn may depend on factors such as age at first exposure. In endemic areas, many people have asymptomatic infection. Sometimes early infection is marked by bouts of fever accompanied by pain, tenderness, and erythema along the course of affected lymphatics. Involvement of the spermatic cord and epididymis is common in Bancroftian filariasis. These acute attacks subside spontaneously in a few days but usually recur. Recurrent episodes cause intermittent lymphatic obstruction, which in time can become fibrotic and irreversible.

Box 42.67 Diseases caused by the filarial worms

Organism	Adult worm	Microfilariae	Major vector	Clinical signs	Distribution
Wuchereria bancrofti	Lymphatics	Blood	*Culex* spp.	Fever Lymphangitis Elephantiasis	Tropics
Brugia timori* and *Brugia malayi	Lymphatics	Blood	*Mansonia* spp.	Fever Lymphangitis Elephantiasis	East and South-east Asia, South India, Sri Lanka
Loa loa	Subcutaneous	Blood	*Chrysops* spp.	'Calabar' swellings Urticaria	West and Central Africa
***Onchocerca* spp.**	Subcutaneous	Skin, eye	*Simulium* spp.	Subcutaneous nodules Eye disease	Africa, South America
Mansonella perstans	Retroperitoneal	Blood	*Culicoides* spp.	Allergic eosinophilia	Sub-Saharan Africa, South America

Obstructed lymphatics may rupture, causing cellulitis and further fibrosis; there may also be chylous (lymph-containing) pleural effusions and ascites. Over time, augmented by repeated episodes of cellulitis and inflammation, there is progressive enlargement, coarsening, and fissuring of the skin, leading to the classical appearances of elephantiasis. The limbs or scrotum may become hugely swollen. Eventually, the adult worms die, but the lymphatic obstruction remains, and tissue damage continues. Elephantiasis takes many years to develop and is only seen in association with recurrent infection in endemic areas.

Occasionally, the predominant features of filarial infection are pulmonary. Microfilariae become trapped in the pulmonary capillaries, generating an intense local allergic response. The resulting pneumonitis causes cough, fever, weight loss, and shifting radiological changes, associated with a high peripheral eosinophil count. This is known as ***tropical pulmonary eosinophilia***.

Diagnosis

The clinical picture in established disease is usually diagnostic, although similar lymphatic damage may occasionally be caused by silicates absorbed through the feet from volcanic soil (podoconiosis). Parasitological diagnosis has traditionally relied on detecting microfilariae in blood films or skin snips. Rapid and sensitive near-patient antigen detection tests are now available for use in endemic areas, but there is a significant false-positive rate when used in travellers with a low pretest probability.

Management

Diethylcarbamazine (DEC) kills both adult worms and microfilariae. Serious allergic responses may occur as the parasites are killed, and particular care is needed when using DEC in areas endemic for loiasis. Mass treatment programmes, using combinations of DEC, ivermectin, and albendazole to target various helminthic infections, are deployed in many parts of the world; the exact regimens depend on local situations. There is currently much interest in using new agents to kill the symbiotic *Wolbachia* bacteria, without which the adult worm will eventually die. However, the best way of incorporating this tactic into the overall management strategy remains unclear. Vector control with insecticide bed nets is helpful in certain areas.

In 2021 the WHO reported that more than US $100 billion of economic loss had been averted through mass treatment campaigns but that 882.5 million people in 44 countries were still living in areas that require preventive chemotherapy to stop the spread of infection. The new neglected tropical diseases roadmap has set a goal of eliminating lymphatic filariasis as a public health problem in 80% of endemic countries by 2030.

Loiasis

Loiasis is found in the humid forests of West and Central Africa. The causative parasite, *Loa loa*, is a small (3–7 cm) filarial worm found in the subcutaneous tissues. The microfilariae circulate in the blood during the day but cause no direct symptoms. The vectors are day-biting flies of the genus *Chrysops*.

Adult worms migrate around the body in subcutaneous tissue planes. Worms may be present for years, frequently without causing symptoms. From time to time, localized, tender, hot, soft tissue swellings (Calabar swellings) occur because of hypersensitivity, often near a joint. These are produced in response to the passage of a worm and usually subside over a few days or weeks. There may also be more generalized urticaria and pruritus. Occasionally, a worm may be seen crossing the eye under the conjunctiva; it may also enter retro-orbital tissue, causing severe pain, but does not lead to blindness. Short-term residents of endemic areas often have more severe manifestations of the disease, presumably because of less opportunity to develop immune tolerance.

Microfilariae may be seen on stained blood films taken around noon, although these are often negative. Serological tests are relatively insensitive and cross-react with other microfilariae. There is usually massive eosinophilia. The Loascope is a useful tool for measuring microfilarial density in a finger-prick blood test taken in the field.

DEC, which was used in early treatment campaigns, can cause severe allergic reactions and encephalopathy associated with parasite killing when the microfilarial burden is high (>20 000/mL) and is being replaced by newer agents. Ivermectin in single doses of 200 to 400 μg/kg is effective but may also cause severe reactions occasionally. Albendazole, which brings about a more gradual reduction in microfilarial load, may be preferable in heavily infected patients. Mass treatment with either DEC or ivermectin can decrease the transmission of infection, but the mainstay of prevention is vector avoidance and control.

Onchocerciasis

Onchocerciasis is also known as river blindness because of the location of the vector and the affected population to rivers. It is the result of infection with *Onchocerca volvulus*, which is transmitted by day-biting flies of the genus *Simulium*. In 2017 the global burden of disease study estimated that there were at least 20.9 million people infected worldwide, of whom 14.6 million had skin disease and 1.15 million had visual loss. Ninety-nine percent of these people live in 31 countries in sub-Saharan Africa, with small foci in Yemen and Central and South America.

Pathogenesis

Infection occurs when larvae are inoculated into humans by the bite of an infected fly. The worms mature in 2 to 4 months and can live for more than 15 years. Adult worms, which can reach lengths of 50 cm (although they are <0.5 mm in diameter), live in the subcutaneous tissues. They may form fibrotic nodules, especially over bony prominences and sites of trauma. Huge numbers of microfilariae are distributed in the skin and may invade the eyes. Live microfilariae cause relatively little harm, but dead parasites may cause severe allergic reactions, with hyaline necrosis and loss of tissue collagen and elastin. In the eye, a similar process causes conjunctivitis, sclerosing keratitis, uveitis, and secondary glaucoma. Choroidoretinitis is also seen occasionally.

Clinical features

Symptoms usually start about 1 year after infection. Initially, there is generalized pruritus, with urticaria and fleeting oedema. Subcutaneous nodules (which can be detected by ultrasonography) start to appear, and in dark-skinned individuals, there is hypo- and hyperpigmentation from excoriation and inflammatory changes ('leopard skin'). Over time, more chronic inflammatory changes appear, with roughened, inelastic skin. Superficial lymph nodes become enlarged, and in the groin, may hang down in loose folds of skin ('hanging groin'). Eye disease, which is associated with chronic heavy infection, usually first manifests as itching and conjunctival irritation. This gradually progresses to more extensive eye disease and eventually to blindness.

Diagnosis

In endemic areas, the diagnosis can often be made clinically, especially if supported by finding eosinophilia on a blood film. To

identify parasites, skin snips taken from the iliac crest or shoulder are placed in saline under a cover slip. After 4 hours, microscopy will show microfilariae wriggling free on the slide. If this is negative, DEC can be applied topically under an occlusive dressing and will provoke an allergic rash in the majority of infected people (modified Mazzotti reaction). Slit-lamp examination of the eyes may reveal the microfilariae. However, skin snip tests are less reliable in lower worm loads and are therefore of limited value in assessing success of treatment. Rapid near-patient serological card tests are under evaluation, and PCR tests are being developed.

Management and prevention

A single dose of ivermectin kills microfilariae and prevents their return for 6 to12 months. There is little effect on adult worms, so annual (or more frequent) retreatment is needed. In patients co-infected with *Loa loa*, ivermectin may occasionally induce severe allergic reactions, including a toxic encephalopathy. When the two infections coexist, field teams may screen the blood of school children and adults using a Loascope to identify individuals carrying a high burden of *Loa loa* microfilariae to be given an alternative drug. Moxidectin has a longer lasting effect than ivermectin and has recently been approved for use in onchocerciasis control programmes.

The WHO Onchocerciasis Control Programme, which started in 1974, had a considerable impact on the disease in West Africa. A combination of vector control measures and, more recently, mass treatment with ivermectin led to a decrease in both infection rates and progression to serious disease. The control programme has been handed over to local governments by the WHO, and local mass treatment programmes are still running in most endemic countries. Eradication may eventually be possible because humans are the only host, but measures are required over a long period because of the longevity of the worm (10–15 years).

Mansonellosis

Mansonella perstans is a filarial worm transmitted by biting midges of the genus *Culicoides*. Small numbers of microfilariae are found in the blood, and although they do not cause serious disease, there may be minor allergic reactions and an eosinophilia.

Dracunculiasis

Infection with the Guinea worm, *Dracunculus medinensis*, occurs when water fleas (copepods) containing the parasite larvae are swallowed in contaminated drinking water. Ingested larvae mature, and the female worm, which can reach more than 1 m in length, migrates through connective and subcutaneous tissue for 9 to 18 months before surfacing on the skin. The uterus of the worm ruptures, releasing larvae that are ingested by the small crustacean water fleas, and the cycle is completed.

The diagnosis is clinical. The traditional management, extracting the worm over several days by winding it around a stick, is probably still the most effective. The worm should not be damaged, and the exit site should be kept clean and dressed. Antibiotics may be needed to control secondary infection.

Prevention and control of dracunculiasis has been one of the success stories in tropical medicine. Large-scale eradication programmes involving removal of water fleas, and thus infective larvae, by chemical treatment or simple filtration have been in place for many years. In 1989 active surveillance in Africa identified nearly 1 million cases of dracunculiasis; similar (though probably more robust) surveillance in 2022 found only 13 cases. Reports of the disease are now confined to four countries: Chad, Ethiopia, Mali, and South Sudan.

Human intestinal nematodes

Adult intestinal nematodes (also referred to sometimes as soil-transmitted helminths or geohelminths) live in the human gut. There are two main types of life cycle, both usually including a soil-based stage. In some species, infection is spread by ingestion of eggs (which often require a period of maturation in the environment); in others, the eggs hatch in the soil, and larvae penetrate directly through the skin of a new host. *Strongyloides* is unusual in that it is the only nematode able to complete its life cycle entirely within the human host without requiring a stage in the environment or an insect vector. Larvae may hatch before leaving the colon and so are able to re-infect the host by penetrating the intestinal wall and entering the venous system.

Although light infestations with intestinal worms cause few symptoms, heavy worm loads cause significant morbidity, especially in children. Cheap, effective, and safe treatments are available, and the WHO promotes mass treatment programmes for those at risk (**Box 42.68**). However, there is a healthy debate about the evidence to support these mass interventions.

Ascariasis (roundworm infection)

Ascaris lumbricoides is a pale-yellow worm, 20–35 cm in length (**Fig. 42.33**). It is found worldwide but is particularly common in poor rural communities, where there is heavy faecal contamination of the immediate environment. Larvae hatch and penetrate the duodenum, migrating through the tissues to the lungs before being expectorated and swallowed. The adult worms live in the small intestine. Ova are deposited in faeces and require a 2- to 4-month maturation in the soil before they are infective.

Infection is usually asymptomatic, although heavy infections are associated with nausea, vomiting, abdominal discomfort, and anorexia. Worms can sometimes obstruct the small intestine, the most common site being the ileocaecal valve. They may also occasionally invade the appendix, causing acute appendicitis, or the bile duct, resulting in biliary obstruction and suppurative cholangitis. Larvae in the lung may produce pulmonary eosinophilia. Heavy infection in children, especially those who are already malnourished, may have significant effects on nutrition and development. Serious morbidity and mortality are relatively rare in ascariasis, but the huge number of people infected means that on a global basis, roundworm infection causes a significant burden of disease, especially in children.

Ascaris eggs can be identified in the stool, and occasionally, adult worms emerge from the mouth or the anus. They may also be seen on barium enema studies. Appropriate drug treatments are shown in **Box 42.68**. Very rarely, surgical or endoscopic intervention may be required for intestinal or biliary obstruction.

Threadworm *(Enterobius vermicularis)*

Enterobius vermicularis is a small (2–12 mm) worm, which is common throughout the world. Larval development takes place mainly in the small intestine and adult worms are normally found in the colon. The gravid female deposits eggs around the anus, causing intense itching, especially at night. Unlike those of *A. lumbricoides*,

Box 42.68 Drugs used for treating human intestinal nematodes[a]

Drug	Dosage	*Ascaris* spp.	Hookworm	*Enterobius* spp.	*Trichuris* spp.	*Strongyloides* spp.
Piperazine	75 mg/kg	++	+	++	–	–
Pyrantel pamoate	10 mg/kg	++	+	++	–	–
Oxantel pamoate	10 mg/kg	++	+	N/A	++	–
Albendazole	400 mg[b]	++	++	++	+	+
Mebendazole	500 mg[c]	++	++	++	+	+
Tiabendazole	25 mg/kg[b]	N/A	N/A	N/A	N/A	++

Ivermectin	200 μg/kg[d]	N/A	N/A	N/A	N/A	++

[a]Single dose unless otherwise stated.
[b]Twice daily for 3 days in strongyloidiasis.
[c]World Health Organization–recommended dose for low- and middle-income countries; in the UK, commonly given as 100 mg single dose for threadworm or 100 mg twice daily for 3 days for whipworm.
[d]Once daily for 2 days.
++, Highly effective; *+*, moderately effective; *–*, ineffective; *N/A*, drug not used for this indication or no data available.

Fig. 42.33 ***Ascaris lumbricoides.*** The worm is approximately 20 cm long.

the eggs do not require a maturation period in soil, and infection is often directly transmitted from anus to mouth via the hands. Eggs may also be deposited on clothing and bed linen and are subsequently either ingested or inhaled. Apart from discomfort and local excoriation, infection is usually harmless.

Ova can be collected either by using a moistened perianal swab or by applying adhesive cellophane tape to the perianal skin. They can then be identified by microscopy.

The most commonly used drugs are mebendazole and piperazine (see **Box 42.68**). However, isolated treatment of an affected person is often ineffective. Other family members (especially small children) may also need to be treated, and the whole family should be given advice about personal hygiene. Two courses of treatment 2 weeks apart may break the cycle of autoinfection.

Whipworm *(Trichuris trichiura)*

Infections with whipworm are common worldwide, especially in poor communities with inadequate sanitation. Adult worms, which are 3 to 5 cm long, inhabit the terminal ileum and caecum, although in heavy infection, they are found throughout the large bowel. The head of the worm is embedded in the intestinal mucosa. Ova are deposited in the faeces and require a maturation period of 3 to 4 weeks in the soil before becoming infective.

Infection is usually asymptomatic, but mucosal damage can occasionally be so severe that there is colonic ulceration, dysentery, or rectal prolapse.

Diagnosis is made by finding ova on stool microscopy or occasionally by seeing adult worms on sigmoidoscopy. Drug treatment is shown in **Box 42.68**.

Hookworm

Hookworm infections, caused by the human hookworms *Ancylostoma duodenale* and *Necator americanus*, are found worldwide. They are relatively rare in high-income countries but very common in areas with poor sanitation and hygiene. Hookworm infection is one of many causes of anaemia in children living in poor rural communities in the tropics. *A. duodenale* is found mainly in East Asia, North Africa, and the Mediterranean, and *N. americanus* is the predominant species in South and Central America, South-east Asia, and sub-Saharan Africa.

Adult worms (which are about 1 cm long) live in the duodenum and upper jejunum, where they are often found in large numbers. They attach firmly to the mucosa using the buccal plate, feeding on blood. Eggs passed in the faeces develop in warm, moist soil, producing infective filariform larvae. These penetrate directly through the skin of a new host and are carried in the bloodstream to the lungs. Having crossed into the alveoli, the parasites are expectorated and then swallowed, thus arriving at their definitive home.

Clinical features

Local irritation as the larvae penetrate the skin ('ground itch') may be followed by transient pulmonary signs and symptoms, often accompanied by eosinophilia. Light infections, especially in a well-nourished person, are often asymptomatic. Heavier worm loads may be associated with epigastric pain and nausea, resembling peptic ulcer disease. Chronic heavy infection, particularly on a background of malnourishment, may cause iron-deficiency anaemia and hypoproteinaemia. Heavy infection in children is associated with delays in physical and mental development.

Diagnosis and management

The diagnosis is made by finding eggs on faecal microscopy. In infections heavy enough to cause anaemia, these are present in large numbers. The aim of treatment in endemic areas is reduction of worm burden rather than complete eradication; albendazole given as a single dose is the best drug (see **Box 42.68**).

Strongyloidiasis

Strongyloides stercoralis is a small (2-mm-long) worm that lives in the small intestine. It is found in many parts of the tropics and subtropics and is especially common in Asia. Eggs hatch in the bowel, and larvae are found in the stool. Usually, these are non-infective rhabditiform larvae, which require a further period of maturation in the soil before they can infect a new host, but sometimes this maturation can occur in the large bowel before leaving the human host. Infective filariform larvae can therefore penetrate directly through the perianal skin, re-infecting the host. In this way, autoinfection may continue for years or even decades. Some war veterans who were imprisoned in the Far East during the Second World War were found to have active strongyloidiasis more than 50 years later. After skin penetration, the life cycle is similar to that of the hookworm, except that the adult worms may burrow into the intestinal mucosa, causing a local inflammatory response.

Clinical features

After skin penetration, *S. stercoralis* causes a similar local dermatitis to hookworm. In autoinfection, this manifests as a migratory linear weal around the buttocks and lower abdomen ***(cutaneous larva currens)***. In heavy infections, damage to the small intestinal mucosa can cause malabsorption, diarrhoea, and even perforation. There is usually a persistent eosinophilia.

Strongyloides hyperinfection syndrome occurs in immunosuppressed patients such as those on long-term corticosteroids, after transplantation, or during cancer treatment. Filariform larvae penetrate directly through the bowel wall in huge numbers and migrate to the lungs. The larvae are accompanied by Gram-negative bacteria from the bowel lumen. Typically, patients with hyperinfection syndrome do not have an eosinophilia, and with the epidemiological exposure long ago, there is often delayed recognition and a fatal outcome.

Diagnosis and management

Motile larvae may be seen on stool microscopy, especially after a period of incubation on charcoal culture. Serological tests are also useful. The best drug for treating strongyloidiasis is ivermectin (200 μg/kg daily for 2 days); albendazole is also effective. In hyperinfection, patients may need a longer course of ivermectin, often given parenterally, which may involve off-licence use of veterinary preparations. Antibiotics against Gram-negative organisms should also be given.

Zoonotic nematodes

A number of nematodes that are principally parasites of animals may also affect humans. The more common ones are described here.

Trichinosis

The normal hosts of *Trichinella spiralis*, the cause of trichinosis, include pigs, bears, and warthogs. Humans are infected by eating undercooked meat from these animals. Ingested larvae mature in the small intestine, where adults release new larvae that penetrate the bowel wall and migrate through the tissues. Eventually, these larvae encyst in striated muscle. Meat inspection policies have reduced the risk of infection from domestic pork, and most infections in Asia, Europe, and North America come from eating wild animal products.

Light infections are usually asymptomatic. Heavier loads of worms produce GI symptoms as the adults establish themselves in the small intestine followed by systemic symptoms as the larvae invade. The latter include fever, oedema, and myalgia. Massive infection may occasionally be fatal, but usually the symptoms subside after the larvae encyst.

The diagnosis can usually be made from the clinical picture, associated eosinophilia, and serological tests. If necessary, it can be confirmed by muscle biopsy a few weeks after infection. Long-standing infection may be revealed by the presence of numerous calcified cysts on X-ray. A 2-week course of albendazole, given early in the course of the illness, will kill the adult worms and decrease the load of larvae reaching the tissues. Analgesia and steroids may be needed for symptomatic relief.

Toxocariasis (visceral larva migrans)

Eggs of the dog roundworm *Toxocara canis* are occasionally ingested by humans, especially children. The eggs hatch, and the larvae penetrate the small intestinal wall and enter the mesenteric circulation, but they are then unable to complete their life cycle in a 'foreign' host. Many are held up in the capillaries of the liver, where they generate a granulomatous response, but some may migrate into other tissues, including the lungs, striated muscle, heart, brain, and eye. In most cases, infection is asymptomatic, and the larvae die without causing serious problems. In heavy infections, there may be generalized symptoms (fever and urticaria) and eosinophilia, as well as focal signs related to the migration of the parasites. Pulmonary involvement may cause bronchospasm and chest X-ray changes. Ocular infection may produce a granulomatous swelling mimicking a retinoblastoma, and cardiac or neurological involvement is occasionally fatal. Rarely, larvae survive in the tissues for many years, causing symptoms long after infection.

Isolation of the larvae is difficult, and the diagnosis is usually made serologically. Albendazole is the most effective treatment.

Cutaneous larva migrans

Cutaneous larva migrans is a common condition caused by the larvae of the non-human hookworms, *Ancylostoma braziliense* and *Ancylostoma caninum*. Like human hookworms, these hatch in warm, moist soil and then penetrate the skin. In humans, they are unable to complete a normal life cycle and instead migrate under the skin for days or weeks until they eventually die. The wandering of the larvae is accompanied by a clearly defined, serpiginous, intensely itchy rash, which progresses at the rate of about 1 cm per day. The rash is normally found on the feet where the patient's skin has had contact with contaminated soil. The diagnosis is purely clinical. Single larvae may be treated with a 15% solution of topical tiabendazole; multiple lesions require systemic therapy with a short course of albendazole or ivermectin.

TREMATODES

Trematodes (flukes) are flat, leaf-shaped worms. They have complex life cycles, often involving freshwater snails and intermediate mammalian hosts. Disease is caused by the inflammatory response to eggs or to the adult worms.

Water-borne flukes

Schistosomiasis

Schistosomiasis is commonly known as Bilharzia, after Theodor Bilharz, who first identified the cause of urinary schistosomiasis in

1851. It affects more than 260 million people worldwide with 9 of 10 of cases occurring in sub-Saharan Africa. Chronic infection causes significant morbidity, and after malaria, it has the greatest socioeconomic impact of any parasitic disease. Schistosomiasis is largely a disease of rural poor individuals but has also been associated with major development projects, such as dams and irrigation schemes.

Parasitology and pathogenesis

There are three species of schistosome that commonly cause disease in humans: *Schistosoma mansoni*, *Schistosoma Haematobium*, and *Schistosoma japonicum*. *Schistosoma mekongi* and *Schistosoma intercalatum* also affect humans but have a very restricted distribution (Fig. 42.34). Eggs are passed in the urine or faeces of an infected person and hatch in freshwater to release the miracidia. These ciliated organisms penetrate the tissue of the intermediate host, a species of water snail specific to each species of schistosome. After multiplying in the snail, large numbers of fork-tailed cercariae are released back into the water, where they can survive for 2 to 3 days. During this time, the cercariae can penetrate the skin or mucous membranes of the definitive host, humans. Transforming into schistosomulae, they pass through the lungs before reaching the portal vein, where they mature into adult worms (the male is about 20 mm long and the female a little larger). Worms pair in the portal vein before migrating to their final destination: mesenteric veins in the case of *S. mansoni* and *S. japonicum* and the vesicular plexus for *S. haematobium*. There they may remain for many years, producing vast numbers of eggs. The majority of them are released in urine or faeces, but a small number become embedded in the bladder or bowel wall, and a few are carried in the circulation to the liver or other distant sites.

The pathology of schistosomiasis varies with species and stage of infection. In the early stages, there may be local and systemic allergic reactions to the migrating parasites. As eggs start to be deposited, there is a local inflammatory response in the bowel or bladder, and ectopic eggs may produce granulomatous lesions anywhere in the body. Chronic heavy infection, in which large numbers of eggs accumulate in the tissues, leads to fibrosis; calcification; and in some cases, dysplasia and malignant change. Morbidity and mortality are related to the duration of infection and worm load, as well as to the species of parasite. Children in endemic areas tend to have the heaviest worm load because of both increased exposure to infection and differences in the immune response between adults and children.

Clinical features

Cercarial penetration of the skin may cause local dermatitis ('swimmer's itch'). After a symptom-free period of 2 to 6 weeks, systemic allergic features may develop, including fever, rash, myalgia, and a patchy pneumonitis (Katayama fever). These phenomena are common in non-immune travellers but are rarely seen in local populations, who are usually exposed to infection from early childhood onwards. If infection is sufficiently heavy, symptoms from egg deposition may start to appear 2 to 3 months after infection.

S. haematobium infection (bilharzia)

The earliest symptom is usually painless terminal haematuria. As bladder inflammation progresses, there are increased urinary frequency and groin pain. Obstructive uropathy may develop, leading to hydronephrosis, recurrent UTIs, and kidney failure. There is a strong association between chronic urinary schistosomiasis and

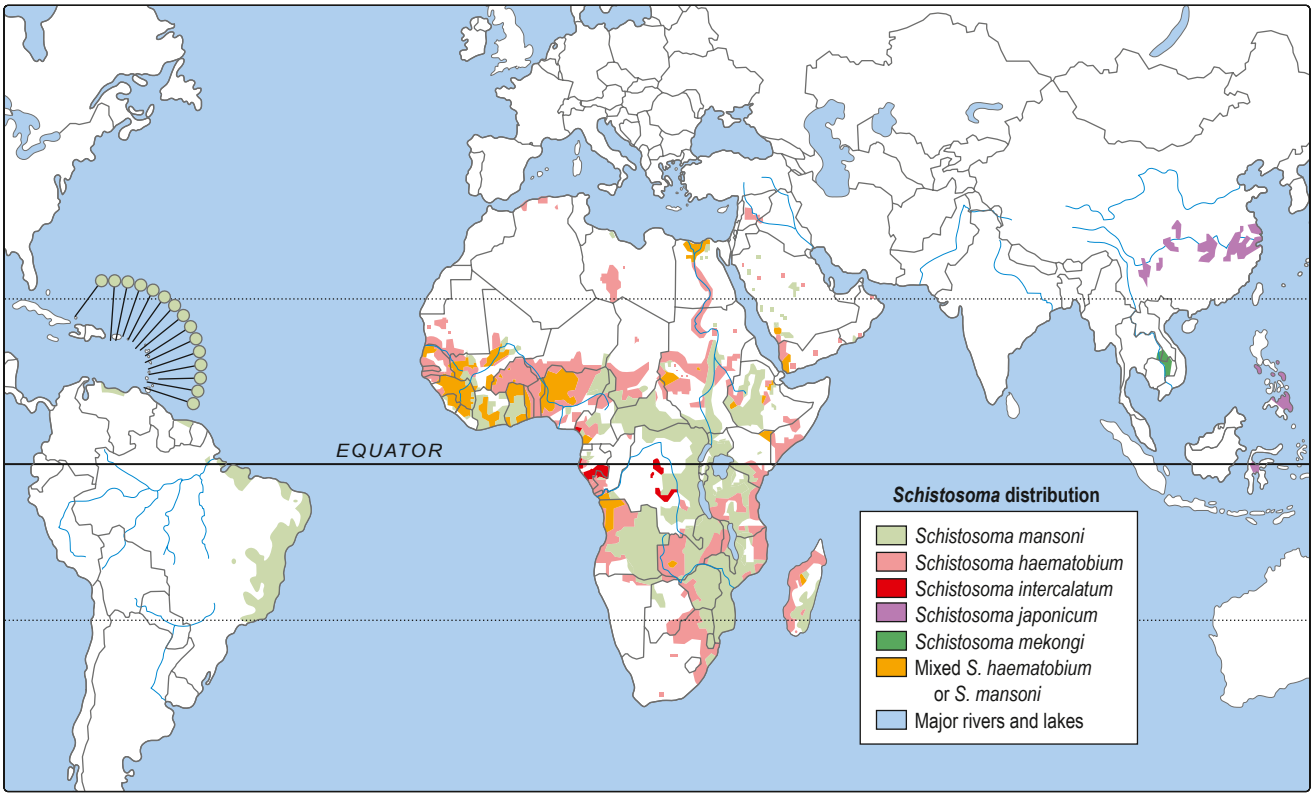

Fig. 42.34 Schistosomiasis: geographical distribution. Map lines delineate study areas and do not necessarily depict accepted national boundaries. *(From Colley DG, Bustinduy AL, Secor WE, King CH. Human schistosomiasis.* Lancet *2014; 383:2253–22264, with permission.)*

squamous cell bladder carcinoma. Ectopic eggs may cause pulmonary or neurological disease. Males may experience haematospermia. In females, *S. haematobium* infection causes genital ulceration, leading to painful sexual intercourse and an increased risk of acquiring HIV infection. If the uterine tubes and ovaries are involved, this may lead to infertility. These complications create a major psychosocial burden for young females already living in poverty.

S. mansoni infection

This usually affects the large bowel. Early disease produces superficial mucosal changes, accompanied by blood-stained diarrhoea. Later, the mucosal damage becomes more marked, with the formation of rectal polyps; deeper ulceration; and eventually, fibrosis and stricture formation. Ectopic eggs are carried to the liver, where they cause an intense granulomatous response. Hepatitis is followed by progressive periportal fibrosis, leading to portal hypertension, oesophageal varices, and splenomegaly. Hepatocellular function is usually well preserved.

S. japonicum infection

Unlike the other species, *S. japonicum* infects numerous other mammals apart from humans. It is similar to *S. mansoni* but infects both the large and small bowel and produces a greater number of eggs. Disease therefore tends to be more severe and rapidly progressive. Hepatic involvement is more common, and neurological involvement is seen in about 5% of patients. *S. japonicum* is now only found in pockets of China, Indonesia, and the Philippines, where it affects children and those working in high-risk occupations such as rice farmers and freshwater fishermen.

Diagnosis

Acute schistosomaisis (Katayama fever) is mainly seen in travellers with recent freshwater exposure in an endemic area. The snails are found in the slow flowing parts of the river or lake, around underwater vegetation near the shore. It is generally a clinical diagnosis. Patients usually have an eosinophilia but may not yet have developed schistosomal antibodies, which are directed against the adult worm and take 2 to 3 months to appear.

When egg deposition has started, the characteristic eggs (with a terminal spine in the case of *S. haematobium* and a lateral spine in the other species) can be detected on microscopy. In *S. haematobium* infection, the best specimen for examination is a filtered mid-day urine sample; parasites may also be found in semen. *S. mansoni* and *S. japonicum* eggs can usually be found on microscopy of faeces or in a rectal snip.

Chronic schistosomiasis may occur in travellers but is more common in citizens of endemic areas who have had significant exposure as children. The presenting syndrome depends on the organs affected and is generally secondary to the inflammatory response produced in response to ectopic egg deposition. Heavy and long-standing infection leads to end-organ damage such as renal failure from obstructive uropathy; pulmonary hypertension, ascites, and variceal bleeding from portal hypertension; and seizures, stroke, and flaccid paralysis from neurological involvement. Corticosteroids are given before praziquantel in spinal and CNS schistosomiasis.

Asymptomatic infection may be picked up when migrants or travellers attend clinic for screening. They generally have an eosinophilia but not always.

Management

The aim of treatment in endemic areas is to decrease the worm load and therefore minimize the chronic effects of egg deposition. It may not always be possible (or even desirable) to eradicate adult worms completely, and re-infection is common. However, a 90% reduction in egg output has been achieved in mass treatment programmes, and in light infections, in which there is no risk of re-exposure, the drugs are usually curative. The most widely used is praziquantel (**Box 42.69**), which is effective against all species of schistosome, and is well tolerated and reasonably cheap. The WHO estimated that in 2021, 251.4 million people required preventive treatment for schistosomiasis, but only 75.3 million people were reported to have been treated. Some of the disparity may have been because of the interruption of control programmes during the COVID pandemic.

Box 42.69 Treatment of trematode infections

Parasite	Drug and dose
Schistosoma mansoni	Praziquantel 40 mg/kg single dose[a]
Schistosoma haematobium	Praziquantel 40 mg/kg single dose[a]
Schistosoma japonicum	Praziquantel 60 mg/kg single dose[a]
***Paragonimus* spp.**	Praziquantel 25 mg/kg 8-hourly for 3 days
Clonorchis sinensis	Praziquantel 25 mg/kg 8-hourly for 1–3 days[b]
***Opisthorchis* spp.**	Praziquantel 25 mg/kg 8-hourly for 1–3 days[b]
Fasciolopsis buski	Praziquantel 25 mg/kg 8-hourly for 1 day
Fasciola hepatica	Triclabendazole 10 mg/kg single dose[c]

[a]May be split to minimize nausea.
[b]Depending on worm load.
[c]Repeated if necessary.

Prevention

Prevention of schistosomiasis is difficult and relies on a combination of approaches. Mass treatment of the population (especially children) decreases the egg load in the community. Health education programmes, the provision of latrines, and access to a safe water supply should decrease contact with infected water. Attempts to eradicate the snail host have generally been unsuccessful, although human-made bodies of water can often be made less 'snail friendly'. Travellers should be advised to avoid potentially infected water and attend for screening 3 months after if exposed.

Food-borne flukes

Many flukes infect humans via ingestion of an intermediate host, often freshwater fish or crustaceans.

Paragonimiasis

More than 20 million people are infected with lung flukes of the genus *Paragonimus*. It is common throughout South and East Asia and is also found in parts of West Africa and Latin America. *Paragonimus* spp. are principally parasites of a variety of mammals that feed on crustacea, and humans can become infected through eating uncooked or poorly prepared shellfish. The adult worms (of which the major species is *Paragonimus westermani*) live in the lungs, producing eggs that are either expectorated or swallowed and passed in the faeces. Miracidia emerging from the eggs penetrate the first intermediate host, a freshwater snail. Larvae released from the snail seek out the second intermediate host, freshwater crustacea, in which they encyst as metacercariae. After consumption by mammalian hosts, cercariae penetrate the small intestinal wall and migrate directly from the peritoneum to the lungs across

the diaphragm. Having established themselves in the lung, the adult worms may survive for 20 years.

The common clinical features are fever, cough, and mild haemoptysis. In heavy infections, the disease may progress, sometimes mimicking pneumonia or pulmonary TB. Ectopic worms may cause signs in the abdomen or the brain.

The diagnosis is made by detection of ova on sputum or stool microscopy. Radiological appearances are variable and non-specific. Treatment is with praziquantel or triclabendazole; the latter, which has a simpler regimen and is supplied free through the WHO, is generally preferred. Prevention involves avoidance of inadequately cooked shellfish.

Liver flukes

Humans can become infected with a variety of liver flukes. Terminology is confusing: three parasite species, *Clonorchis sinensis*, *Opisthorchis felineus*, and *O. viverrini*, are commonly referred to as the human liver flukes, although feline and other mammals are the principal hosts. *C. sinensis* and *O. viverrini* are almost entirely confined to East and South-east Asia, and the distribution of *O. felineus* extends across Central Asia as far as Eastern Europe. Adult worms live in the bile ducts, releasing eggs into the faeces. The parasite requires two intermediate hosts, a freshwater snail and a fish, and humans are infected by consumption of raw fish. The cycle is completed when excysted worms migrate from the small intestine into the bile ducts.

Infection is often asymptomatic, and the flukes can live in the biliary tree for 20 to 25 years. It sometimes causes cholangitis and is associated with biliary carcinoma. The diagnosis is made by identifying eggs on stool microscopy. Treatment is with praziquantel or albendazole, and infection can be avoided by preparing and cooking fish adequately.

Other food-borne flukes

Humans can also be infected with a variety of other animal flukes, notably, the liver fluke *Fasciola hepatica* and the intestinal fluke *Fasciolopsis buski*. Both require a water snail as an intermediate host; cercariae encyst on aquatic vegetation and then are consumed by animals or humans. After ingestion, *F. hepatica* penetrates the intestinal wall before migrating to the liver. During this stage, it causes systemic allergic symptoms. After reaching the bile ducts, it gives rise to similar problems to those caused by the other liver flukes. *F. buski* does not migrate after it excysts and causes mainly bowel symptoms.

Management of trematode infections

For drug treatment, see **Box 42.69**.

CESTODES

Cestodes (tapeworms) are ribbon-shaped worms, which vary from a few millimetres to several metres in length. Adult worms live in the human intestine, where they attach to the epithelium using suckers on the anterior portion (scolex). From the scolex arises a series of progressively developing segments, called proglottids. The mature distal segments contain eggs, which either may be released directly into the faeces or are carried out with an intact detached proglottid. The eggs are consumed by intermediate hosts, after which they hatch into larvae (oncospheres). These penetrate the intestinal wall of the host (pigs, cattle, or other animals) and encyst in the tissues. Humans ingest the cysts in undercooked meat, and the cycle is completed when the parasites excyst in the stomach and develop into adult worms in the small intestine. Infections are usually solitary, but several adult tapeworms may coexist. The exceptions to this life cycle are the dwarf tapeworm, *Hymenolepis nana*, which has no intermediate host and is transmitted from person to person by the faecal–oral route, and *Taenia solium*, which can cause either normal tapeworm infection (when humans are the definitive host) or cysticercosis (when humans are the intermediate host).

Taenia saginata

Taenia saginata, the beef tapeworm, may reach a length of several metres. It is found in all countries where undercooked beef is eaten, although human infection can largely be eradicated by good abattoir hygiene and inspection regimens, and the main burden of disease falls on economically low- and middle-income countries. The adult worm causes few, if any, symptoms and is not a significant cause of chronic health problems. Infection is usually discovered when proglottids are found in faeces or on underclothing, often causing considerable anxiety. Ova may also be seen on stool microscopy. Infection can be cleared with a single dose of praziquantel (10 mg/kg).

Taenia solium and cysticercosis

Taenia solium, the pork tapeworm, is generally smaller than *T. saginata*, although it can still reach 6 metres in length. It is particularly common in South America, South Africa, China, and parts of South-east Asia. As with *T. saginata*, infection is usually asymptomatic. The ova of the two species are identical, but the proglottids can be distinguished on inspection.

Pork tapeworm infection is acquired by eating uncooked pork. Treatment is with praziquantel or niclosamide. Drug treatment should not be accompanied by a purgative, as was previously believed.

Cysticercosis occurs when humans become the intermediate host of the parasite and is caused by cysts rather than the adult worm. It follows the ingestion of eggs from contaminated food and water, not from pork meat. Faecal–oral autoinfection can occur but is rare. Patients with tapeworms do not usually develop cysticercosis, and individuals with cysticercosis do not usually harbour tapeworms. After the ingestion of eggs, the larvae are liberated, penetrate the intestinal wall, and are carried to various parts of the body, where they develop into cysticerci. These are cysts, 0.5 to 1 cm in diameter, containing the scolex of a new adult worm. Common sites for cysticerci include subcutaneous tissue, skeletal muscle, and brain. Superficial cysts may be felt under the skin but usually cause no significant symptoms. Muscle cysts tend to calcify and are often visible on X-rays.

Neurocysticercosis refers to the presence of cysts in the brain. They are generally 5 to 20 mm in diameter and a range from a solitary cyst to many dozen. The cysts are mostly asymptomatic but can give rise to a variety of problems depending on their location, including epilepsy, personality change, hydrocephalus, and focal neurological signs. Contrast enhanced CT or MRI shows the evolution of brain cysts from active colloidal, ring-enhancing lesions with surrounding oedema to nodular, calcified cysts. Serological tests may support the diagnosis but may be negative, and the diagnosis is often clinical based on risk exposure and the characteristic appearances on scans.

Management of cysticercosis

After years of controversy, recent studies suggest that antihelminthic drugs are of benefit in most cases of neurocysticercosis, although their role in other forms of cysticercosis remains unproven. The priority is to control seizures with anticonvulsant medication. Antihelminthic treatment is never urgent and should always be accompanied by corticosteroids to reduce the inflammation caused by dying cysts. Albendazole is the drug of choice, with praziquantel as an alternative for 2 to 3 weeks. Surgery is occasionally required for patients with hydrocephalus.

Diphyllobothrium latum

Infection with the fish tapeworm *Diphyllobothrium latum* is common in northern Europe and Japan, owing to the consumption of raw fish. The adult worm reaches a length of several metres, but like the other tapeworms, usually causes no symptoms. A megaloblastic anaemia (caused by competitive use of vitamin B_{12} by the parasite) may occur. Diagnosis and treatment are the same as for *Taenia* spp.

Hydatid disease

Hydatid disease occurs when humans become an intermediate host of the dog tapeworm, *Echinococcus granulosus*. The adult worm lives in the gut of domestic and wild canines, and the larval stages are usually found in sheep, cattle, and camels. Humans may become infected either from direct contact with dogs or from food or water contaminated with dog faeces. After ingestion, the parasites excyst, penetrate the small intestine wall, and are carried to the liver and other organs in the bloodstream. A slow-growing, thick-walled cyst is formed, inside which further larval stages of the parasite develop. The life cycle cannot be completed unless the cyst is eaten by a dog. Hydatid disease is prevalent in areas where dogs are used in the control of livestock, especially sheep. It is common in Argentina, Peru, Central Asia, China, and parts of East Africa, and about 1 million people are infected worldwide.

Symptoms depend mainly on the site of the cyst. The liver is the most common organ affected (60%) followed by the lungs (20%), kidneys (3%), brain (1%), and bone (1%). The symptoms are those of a slowly growing benign tumour. Pressure on the bile ducts may cause jaundice. Rupture into the abdominal cavity, pleural cavity, or biliary tree may occur. A cyst rupturing into a bronchus may result in its expectoration and spontaneous cure, but if secondary infection supervenes, a chronic pulmonary abscess will form. Focal seizures can occur if cysts are present in the brain. Renal involvement produces lumbar pain and haematuria. Calcification of the cyst occurs in about 40% of cases. The diagnosis and treatment of hydatid liver disease are described in Chapter 23 ('Hydatid disease' section).

A related parasite of foxes, *Echinococcus multilocularis*, causes a similar but more severe infection, alveolar hydatid disease. These cysts are invasive, and metastases may occur; if untreated, the disease is usually fatal. Treatment requires radical surgery as well as antihelminthic treatment.

ARTHROPOD ECTOPARASITES

Arthropods, which include the arachnid ticks and mites as well as insects, may be responsible for human disease in several ways.

Local hypersensitivity reactions

Local lesions may be caused by hypersensitivity to allergens in arthropod saliva. This common reaction, known as papular urticaria, is non-specific and is seen in the majority of people in response to the bite of a variety of blood-sucking arthropods, including mosquitoes, bugs, ticks, lice, and mites (Fig. 42.35).

Occasionally, tick bites may cause a more severe systemic allergic response. In the USA and Australia but also elsewhere, ticks (e.g., the lone star tick that is also the vector for Rocky Mountain spotted fever) transmit 'alpha-gal' allergy (to alpha-galactose, a carbohydrate found in meat and dairy products). This is also known as ***mammalian meat allergy*** because the allergen is transmitted in tick saliva after feeding on mammals. Affected humans are sensitized to this allergen and react with urticaria and other atopic features after subsequent meat ingestion. The saliva of some tick species contains a neurotoxin, which causes flaccid paralysis in the victim after a bite; this condition is rare but occurs worldwide, most commonly in children.

Resident ectoparasite infections

Most ectoparasites alight on humans only to feed (although some species of lice live in very close proximity to the skin: body lice in clothing and head and pubic lice on human hairs; see Chapter 43, 'Pediculosis pubis' section). However, some types of parasite reside within the skin, causing more specific local lesions.

Scabies

See Chapter 45 ('Scabies' section).

Jiggers

Jiggers is caused by infection with the jigger flea, *Tunga penetrans*, and is common throughout South America and Africa. The pregnant female flea burrows into the sole of the foot, often between the toes. The egg sac grows to about 0.5 cm in size, and then the eggs are discharged on to the ground. The main danger is bacterial infection or tetanus. The flea should be removed with a needle or scalpel and the area kept clean until it heals.

Fig. 42.35 Papular urticaria caused by bedbug bites.

Myiasis

Myiasis is caused by invasion of human tissue by the larva of certain flies, principally the Tumbu fly *Cordylobia anthropophaga* (found in sub-Saharan Africa) and the human botfly *Dermatobia hominis* (Central and South America). The larvae, which hatch from eggs laid on laundry and linen, burrow into the skin to form boil-like lesions; a central breathing orifice may be visible. Secondary infection rarely occurs. Covering the larva with petroleum jelly usually brings it up in search of air, and it can then be easily extracted, although the American species may require surgical extraction.

Systemic envenoming

Many arthropods can cause local or systemic illness through envenoming, that is, injection of venom. A detailed discussion of spider, scorpion, and other bites is beyond the scope of this chapter (see Further reading and online topics).

Vectors of infection

By far the most important role of arthropods in causing human disease is as vectors of parasitic and viral infections. Some of these infections are shown in **Box 42.15** and are discussed in detail elsewhere.

CRIMEAN–CONGO HAEMORRHAGIC FEVER

Somia Iqtadar

Crimean–Congo haemorrhagic fever (CCHF) is a viral haemorrhagic fever caused by the Nairovirus of the Bunyaviridae family and is transmitted to humans by the bite of the *Hyalomma* tick or by direct contact with blood of an infected animal or human. CCHF is a severe disease with a high case fatality rate ranging from 10% to 40%. The disease was first described in the Crimea in 1944 and identified in 1956 in the Congo, hence the name.

Geographical distribution

CCHF is endemic in all of Africa, the Balkans, the Middle East, and Asia. CCHF is now spreading to other areas, including parts of Europe. The World Health Organization estimates that about 3 billion people live in areas at risk of the disease.

Transmission

Ticks are both a reservoir and a vector for the CCHF virus. Numerous wild and domestic animals, such as cattle, goats, sheep, and hares, serve as amplifying hosts for the virus. Animals become infected by the bite of infected ticks, and the virus remains in their bloodstream for about 1 week after infection, allowing the tick–animal–tick cycle to continue when another tick bites. Although a number of tick genera are capable of becoming infected with CCHF virus, ticks of the genus *Hyalomma* are the principal vector (Fig. E42.1).

Population migration with animals contributes to the higher probability of susceptible animals being bitten by infected ticks, thus increasing the risk of transmission to humans who handle the animals.

The CCHF virus is transmitted to people either by tick bites or through contact with infected animal blood or tissues during and immediately after slaughter. The majority of cases have occurred in people involved in the livestock industry, such as agricultural workers, slaughterhouse workers, and veterinarians.

Human-to-human transmission can result from close contact with the blood, secretions, organs, or other bodily fluids of infected persons. (Hospital-acquired infections can also occur because of improper sterilization of medical equipment, reuse of needles, and contamination of medical supplies.)

Fig. E42.1 **A tick.**

Clinical course

CCHF presents in four distinct stages: incubation, pre-haemorrhagic, haemorrhagic, and convalescence.

Incubation period

The length of the incubation period depends on the mode of acquisition. The incubation period after tick bite is usually 1 to 3 days, with a maximum of 9 virus days. The incubation period after contact with infected blood or tissues is usually 5 to 6 days, with a documented maximum of 13 days.

Pre-haemorrhagic stage

This stage lasts about 2 to 4 days on average (range, 1–7 days) and begins with sudden onset of fever (>38°C), chills, myalgia, dizziness, neck pain and stiffness, backache, headache, sore eyes, and photophobia. There may be nausea, vomiting, diarrhoea, abdominal pain, and sore throat early on followed by sharp mood swings and confusion. After 2 to 4 days, the agitation may be replaced by sleepiness, depression, and lassitude, and the abdominal pain may localize to the upper right quadrant, with clinically detectable hepatomegaly and jaundice. Other clinical signs include tachycardia, lymphadenopathy, and splenomegaly.

Haemorrhagic stage

The haemorrhagic stage is usually short (~2–3 days) but can be prolonged up to 2 weeks. It is characterized by petechial rash on internal mucosal surfaces, such as in the mouth and throat, and on the skin. The petechiae may give way to larger rashes called ecchymoses, as well as other haemorrhagic phenomena.

Haematology and blood chemistry commonly show thrombocytopenia, leucopenia and elevated levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactate dehydrogenase, and creatine phosphokinase along with elevated levels of inflammatory cytokines. Coagulation may be affected, with prolonged prothrombin and activated partial thromboplastin times accompanied by a decrease in fibrinogen levels and an increase in the levels of fibrinogen degradation products. The haemorrhagic stage is pronounced in severe cases, with rapid progression to disseminated intravascular coagulation (DIC), sudden liver failure, rapid kidney deterioration, or pulmonary failure and shock. If lethal, death usually occurs in the second week of illness.

Convalescence

In survivors, convalescence generally begins around 9 to 10 days after the onset of illness (range, 9–20 days) and is associated with a return to normal for laboratory parameters. This stage can be prolonged and may be associated with hypotension, tachycardia or bradycardia, polyneuritis, breathing issues, xerostomia, vision and hearing deficiencies, hair loss, and memory loss, among others.

Investigations

CCHF is confirmed by blood sample, performed in specially equipped laboratories with a high biosafety level, if any of the following tests is positive:

- Confirmation of the presence of immunoglobulin (Ig) M or IgG antibodies seroconversion by enzyme-linked immunosorbent assay

- Positive antigen detection test
- Detection of viral nucleic acid in the specimen by reverse transcription polymerase chain reaction (RT-PCR)
- Isolation of the virus.

Patients with fatal disease, as well as in those in the first few days of illness, do not usually develop a measurable antibody response, so diagnosis in these individuals is achieved by virus or RNA detection in blood or tissue samples. Later in the course of the disease, in people surviving, antibodies can be found in the blood, although at this stage, the antigen, viral RNA, and virus are no longer detectable.

Management

When CCHF is suspected, isolation precautions should start, health facility staff alerted, the case immediately reported, blood samples drawn for CCHF diagnostic confirmation, and the treatment protocol listed next started without waiting for confirmation.

Patients should be isolated and cared for using barrier-nursing techniques, including masks, goggles, gloves, gowns, and the proper removal and disposal of contaminated articles.

Treatment

General supportive therapy is the mainstay of patient management in CCHF. Intensive monitoring to guide volume and blood component replacement is recommended.

If there is clinical suspicion of CCHF, a ribavirin treatment protocol needs to be initiated immediately with the consent of the patient or relatives and the attending physician (**Box E42.1**).

Note that ribavirin is not a specific treatment for CCHF viral infection To date, the nucleoside analogue ribavirin is the only direct-acting antiviral that has been widely used clinically in patients with CCHF. However, the use of ribavirin is controversial, with continued debate about whether treatment improves outcome. Pregnancy should be prevented (whether the patient is the female or male partner) for a period 6 months after completing a course of ribavirin.

Favipiravir has also been studied in CCHF and has shown promise in preclinical animal models. However, efficacy data in humans infected with CCHFV are limited.

Prophylaxis

When there has been known direct contact with the blood or secretions of a probable or confirmed case (e.g., needle-stick injury or contact with mucous membranes such as in the eye or mouth), the recommended procedure is to perform baseline blood studies and start the person on the ribavirin protocol.

Household or other contacts of the case who may have had the same exposure to infected ticks or animals or who recall indirect contact with case body fluids should be monitored for 14 days from the date of last contact with the patient or other source of infection by having their temperature taken twice daily. If the patient develops a temperature of 38.5°C or higher, headache, and muscle pains, they should be admitted to hospital and started on ribavirin treatment.

Box E42.1 Treatment protocol for Crimean–Congo haemorrhagic fever disease

High-dose oral ribavirin therapy consists of:

- 2-g loading dose
- 4 g/day in four divided doses (6-hourly) for 4 days
- 2 g/day in four divided doses for 6 days

Prevention and control

It is difficult to prevent or control CCHF infection in animals and ticks because the tick–animal–tick cycle usually goes unnoticed, and the infection is usually not apparent in domestic animals. Furthermore, the tick vectors are numerous and widespread, so tick control with acaricides (chemicals intended to kill ticks) is only a realistic option for well-managed livestock production facilities.

Although an inactivated, mouse brain–derived vaccine against CCHF has been developed and used on a small scale in Eastern Europe, there is currently no safe and effective vaccine widely available for human use. Further research is needed to develop these potential vaccines, as well as to determine the efficacy of the different treatment options, including that of ribavirin and other antiviral drugs.

There is no safe and effective vaccine currently available for human use for CCHF. A new vaccine against deadly CCHF is being trialled in humans for the first time. The ChAdOx2 CCHF vaccine is based on the ChAdOx2 vector, a weakened version of a common cold virus (adenovirus) that has been genetically modified so it is impossible for it to replicate in humans.

In the absence of an approved vaccine, the only way to reduce infection in humans is by raising awareness of the risk factors and educating people about the measures they can take to reduce exposure to the virus.

Public health advice should focus on several aspects, as follows.

Reducing the risk of tick-to-human transmission

- Wear protective clothing (long sleeves, long trousers).
- Wear light-coloured clothing to allow easy detection of ticks on the clothes.
- Use approved acaricides on clothing.
- Use approved repellent on the skin and clothing.
- Examine clothing and skin regularly for ticks; if any are found, remove them safely.
- Seek to eliminate or control tick infestations on animals or in stables and barns.
- Avoid areas where ticks are abundant and seasons when they are most active.

Reducing the risk of animal-to-human transmission

- Wear gloves and other protective clothing while handling animals or their tissues in endemic areas, notably during slaughtering, butchering, and culling procedures in slaughterhouses or at home.
- Quarantine animals before they enter slaughterhouses or routinely treat animals with pesticides 2 weeks before slaughter.

Reducing the risk of human-to-human transmission in the community

- Avoid close physical contact with CCHF-infected people.
- Wear gloves and protective equipment when taking care of ill people.
- Wash hands regularly after caring for or visiting ill people.
- If the patient with CCHF dies, advise the family to follow safe burial practices (**Box E42.2**).

Controlling infection in healthcare settings

Healthcare workers caring for patients with suspected or confirmed CCHF or handling specimens from them should implement standard infection control precautions. These include basic hand hygiene, use of personal protective equipment, safe injection procedures, and safe burial practices.

DENGUE

Somia Iqtadar

Epidemiology

Dengue has emerged as one of the most important mosquito-borne viral diseases of humans. It can carry a significant morbidity and mortality, especially if improperly managed. It is predominantly a disease of urban and semi-urban areas in the tropics and subtropics. With climate change and global warming, the mosquito vector has extended its range from tropical regions deeper into subtropical zones. The spread of dengue fever therefore illustrates how global trade (e.g., allowing the transport of the mosquito vectors in used tyres), increasing travel within and between countries (permitting the movement of viraemic individuals), urban overcrowding (being conducive to multiple infections from a single infected mosquito), and ineffective vector-control strategies have supported a pandemic in the modern era.

Virology

Infection is caused by dengue virus, flavivirus of family Flaviviridae. It is transmitted by *Aedes aegypti* and *Aedes albopictus*. There are four distinct serotypes: DEN-1, -2, -3, and -4. Each episode of infection induces life-long protective immunity to the homologous serotype but confers only partial and transient protection against subsequent infection by the other three serotypes. Secondary infection (by another serotype) is a major risk factor for dengue haemorrhagic fever (DHF), mainly due to antibody-induced enhancement.

Epidemiological studies have identified young age, female sex, high body mass index, virus strain, and genetic variants of the human major histocompatibility complex class I–related sequence B and phospholipase C epsilon 1 genes as risk factors for severe dengue.

Spectrum of disease

The incubation period (time between viral invasion and onset of clinical disease) for dengue infection is generally between 4 and 7 days (range, 3–14 days). The spectrum of clinical manifestations varies from totally asymptomatic to undifferentiated febrile illness (viral syndrome), dengue fever (DF) and DHF, including dengue shock syndrome (DSS) (Fig. E42.2).

Box E42.2 Safe burial practices for patients with viral haemorrhagic fever

- Long, thick rubber gloves or two pairs of surgical gloves should be used for washing the body for burial.
- The dead body should be sprayed with 1:10 liquid bleach solution and then wrapped in the winding sheet.
- The winding sheet should be sprayed with bleach solution.
- The body should then be placed in a plastic bag, which should be sealed with adhesive tape.
- The transport vehicle should be disinfected, and all of the deceased person's clothing should be burned.

Revised dengue classification

Clinical course of dengue infection

After the incubation period, the illness begins abruptly. The subsequent clinical course of dengue disease can be highly variable but may be broadly divided into three phases: febrile, critical, and convalescent (Fig. E42.3).

Febrile phase

Typically, this begins with the sudden onset of high-grade fever. This acute febrile phase generally lasts for 2 to 7 days and is often accompanied by facial flushing, skin erythema, generalized body ache, myalgia, arthralgia, and headache. There is often associated anorexia, nausea, and vomiting. Some patients may have a sore throat with congested pharynx and conjunctivae. These initial

clinical features are common to both patients who have simple DF and those who will go on to develop DHF subsequently.

On physical examination, mild haemorrhagic manifestations such as mucosal bleeding, petechial hemorrhages and a positive tourniquet test result are equally common in both DF and DHF. Vaginal bleeding is also seen frequently in young adult females. Uncommonly, however, massive vaginal or gastrointestinal bleeding may occur during this phase. Hepatomegaly is common, but tender hepatomegaly is highly suggestive of DHF.

Investigations

The earliest haematological abnormality is a progressive decrease in the total white cell count (WCC). This non-specific viral response should alert the physician to the possibility of dengue, particularly during a dengue epidemic. Dengue virus protein (NS1 antigen) and PCR test results are generally positive during this early stage.

Critical phase

Toward the end of the febrile phase—around the time of defervescence (usually between the third and fifth days of illness but may be up to the seventh day)—a few patients enter a stage of increased capillary permeability. Unlike in other routine viral infections, in which the patient's condition tends to improve with defervescence, in DHF at this point, depending on the capillary leak, the patient can proceed in two different clinical directions. Those without significant plasma leak gradually convalesce, but those who develop major plasma leak may deteriorate in the face of critical loss of volume.

The critical phase typically lasts for about 24 to 48 hours. During this stage, varying degrees of circulatory disturbances can develop. In less severe cases, these changes are minimal and transient. Many of these patients recover with routine oral fluid and electrolytes or even with non-specific management at home. In more severe forms of plasma leakage, significant volume depletion occurs. A compensatory response in the form of increased sympathetic drive kicks in. Now the patient becomes restless, with cold, clammy skin; a rapid, thready pulse; and prolonged capillary refill time. As the diastolic blood pressure rises (increased sympathetic tone) in the face of unchanged systolic pressure (caused by vasoconstriction), the pulse pressure narrows. Abdominal pain; persistent vomiting; restlessness; altered conscious level; clinical fluid accumulation; mucosal bleed; and a tender, enlarged liver are the clinical warning signs of severe dengue, with an increased possibility of rapid progression to shock. In this stage, if fluid resuscitation is not instituted promptly and appropriately, the patient can progress rapidly to profound and irreversible shock. It is important to note that haemoconcentration (a rising trend of haematocrit [Hct] from the baseline value) and thrombocytopenia are usually detectable even before the subsidence of fever and the onset of shock. It gives credence to the notion that a low-grade plasma leak has started before haemodynamic compromise has become clinically apparent. The Hct level correlates well with the amount of plasma volume loss and disease severity. The Hct may not, however, truly represent the volume loss in cases of frank haemorrhage or early and excessive fluid replacement or when Hct determination is wrongly timed. The biochemical abnormalities usually observed include leucopenia with a relative lymphocytosis, prolonged prothrombin time or activated partial thromboplastin time, elevated transaminases (typically, aspartate AST more than three times alanine ALT), hypoproteinaemia, and hypoalbuminaemia.

Convalescent phase

Plasma leak stops within 24 to 48 hours of time of onset and is followed by reabsorption of extravascular fluid. The patient's general wellbeing improves, appetite returns, gastrointestinal symptoms abate, haemodynamic status stabilizes (WCCs improve followed

Fig. E42.4 **The convalescent rash of dengue fever.**

by improvement in platelet count), and a diuresis ensues. Some patients may have the classical rash of 'isles of white in a sea of red' (Fig. E42.4). Some may experience generalized pruritus. Bradycardia and electrocardiographic changes are not uncommon during this stage. It is important to note that during this phase, the Hct level may drop further because of resorption-associated haemodilution. The recovery of platelet count is typically preceded by recovery of WCC.

Pathophysiology of plasma leakage

The initial febrile phase of dengue disease mimics the picture of common acute viral illnesses. Toward the end of the febrile illness, however, features of increased capillary permeability and plasma leak are witnessed in a small subset of patients. Although it might well be speculated that increased plasma permeability is present in all cases of dengue disease, the plasma leak remains small and is clinically compensated in most patients. Only in a small percentage does this condition cross the critical threshold of compensatory mechanisms to become clinically significant.

This acute increase in vascular permeability beyond the critical limit of compensatory responses is the primary pathophysiological event that differentiates DHF and DSS from uncomplicated DF. This leak is responsible for loss of plasma into the extravascular compartment, giving rise to the haemoconcentration; hypovolaemic state; and, in extreme conditions, shock. In common with the classical volume-depleted state, it leads to reflex tachycardia and generalized vasoconstriction as a result of increased sympathetic activity. This compensated stage of shock is characterized by the responses initiated by the patient to overcome the stress of volume depletion. Physiological mechanisms (neural, hormonal, and biochemical) are triggered to compensate for the stress of hypovolaemia. The baroreceptors in the arteries detect a drop in blood pressure and cause the release of adrenaline (epinephrine) and noradrenaline (norepinephrine). These catecholamines cause vasoconstriction and tachycardia, the body's attempt to increase the blood pressure. Vasoconstriction results in tissue hypoxaemia and anaerobic glycolysis, which in turn give rise to acidosis. Acidosis-mediated respiratory centre stimulation causes hyperventilation (tachypnoea). By hyperventilating and washing out CO_2, the body is indirectly trying to correct the acidosis. Vasoconstriction can affect the kidneys, stimulating the renin–angiotensin–aldosterone axis to cause further vasoconstriction and conservation of fluid via increased renal reabsorption. Vasoconstriction that started in the splanchnic circulation can spread to kidneys, gastrointestinal tract, and other organs to divert blood preferentially to the heart, lungs, and brain. This reduction in renal circulation (glomerular filtration rate [GFR]) manifests itself in the form of reduced urine production.

Pathophysiological events that occur during DSS are exactly like those of 'classical hypovolaemic shock' caused by blood loss (or volume loss during gastroenteritis). The only difference is that in DHF, the volume lost to the serosal cavities is rich in proteins and is available for reabsorption (through the lymphatics) subsequently.

The clinical manifestations of vasoconstriction in various systems are as follows:

- ***Skin.*** This is cold and clammy, with pallor and a delayed capillary refill time (>2 seconds).
- ***Cardiovascular system.*** There are a raised diastolic blood pressure and a narrowing of pulse pressure, an effect of increased sympathetic outflow (≤30 mmHg).
- ***Renal system.*** As a result of reduced GFR, urinary output drops (<0.5 mL/kg per hour).
- ***Gastrointestinal system.*** There are nausea, vomiting, and abdominal pain.
- ***Central nervous system.*** As a function of reduced cerebral perfusion, there may be lethargy, restlessness, apprehension, impaired consciousness, and combative behaviour.
- ***Respiratory system.*** Tachypnoea (respiratory rate >20 breaths/min in adults) is a feature of shock.

The molecular mechanism responsible for the increased vascular permeability seen during DHF and DSS is still not well understood. It appears that immune hyperdrive results in massive overproduction of cytokines ('cytokine storm') caused by aberrant activation of T lymphocytes and disturbances of the homeostatic system involving regulatory T cells. High concentrations of mediators of inflammation, including C3a; C5a; tumour necrosis factor; interleukin (IL)-2, IL-6, and IL-10; interferon; and histamine have also been noted.

A second infection with a heterotypic dengue virus may impart an increased risk of developing DHF. Antibody-dependent enhancement of viral replication is believed to be responsible for this phenomenon. Dengue virus is released from the host cells in two forms. The immature form, unlike mature particles, is incapable of entering new host cells. Subneutralizing concentration of the cross-reacting antibody from the previous infection may opsonize these immature virus particles and allow the entry and replication of immature virion in the macrophage or mononuclear cells. This is mediated through Fc epitope-recognizing domains on the macrophages. T-cell activation is also enhanced. Profound T-cell activation with cell death during acute dengue infection may suppress or delay viral elimination, leading to the higher viral loads and enhanced immunopathology found in patients with DHF.

Expanded dengue syndrome

In recent years, with geographical spread and greater involvement of adults, the term 'expanded dengue syndrome' has been used to describe unusual manifestations of dengue infection. These include neurological, hepatic, renal, hematological, and other isolated organ involvement, which could be explained as complications of severe profound shock or associations with underlying host conditions, diseases, or co-infections. Some important manifestations are shown in Box E42.3.

Box E42.3 Expanded dengue syndrome (unusual or atypical manifestations of dengue)

System	Unusual manifestations
Neurological	Febrile seizures in young children Encephalopathy Encephalitis, aseptic meningitis Intracranial haemorrhages, thrombosis Mononeuropathies, polyneuropathies, Guillain–Barré syndrome Transverse myelitis
Gastrointestinal or hepatic	Hepatitis. fulminant hepatic failure Acalculous cholecystitis Acute pancreatitis
Renal	Acute renal failure Haemolytic uraemic syndrome Acute tubular necrosis
Cardiac	Conduction abnormalities Myocarditis Pericarditis
Respiratory	Acute respiratory distress syndrome Pulmonary haemorrhage Pleural effusion
Musculoskeletal	Myositis with raised creatine phosphokinase Rhabdomyolysis
Lymphoreticular/ bone marrow	Infection-associated haemophagocytic syndrome Haemophagocytic lymphohistiocytosis Idiopathic thrombocytopenic purpura Disseminated intravascular coagulation
Eye	Macular haemorrhage Conjunctival bleed Impaired visual acuity Optic neuritis
Others	Post-infectious fatigue syndrome, depression, hallucinations, psychosis Alopecia

Reproduced from Comprehensive Guidelines for Prevention and Control of Dengue and Dengue Haemorrhagic Fever, WHO (2011).

Box E42.4 Differential diagnosis of dengue haemorrhagic fever

Organism	Disease
Arboviruses	Chikungunya fever Zika
Other viral diseases	Crimean–Congo haemorrhagic fever (nairovirus) Measles Rubella Other viral exanthems Epstein–Barr virus Enteroviruses Influenza Hepatitis A Hantavirus
Bacterial diseases	Meningococcaemia Leptospirosis Typhoid fever Melioidosis Scarlet fever
Parasitic diseases	Malaria

Differential diagnosis of dengue illness

It is easy to misdiagnose dengue in non-endemic settings because the clinical features are non-specific and mimic many other diseases. Differential diagnoses are shown in **Box E42.4**.

Investigations

Laboratory investigations of DF include disease-monitoring laboratory tests and diagnostic tests.

Disease-monitoring laboratory tests

- Full blood count
  - WCC. At the beginning of the febrile phase, the WCC is usually normal but decreases rapidly as the disease progresses. It may show a relative lymphocytosis; this non-specific trend of leucopenia should raise the suspicion of possible dengue infection in appropriate settings.
  - Hct. Haemoconcentration, as depicted by a rising Hct, is a marker of plasma leakage in dengue infection and helps to differentiate between DF and DHF. Significant blood loss and early fluid replacement may mask this trend. It is of paramount importance to obtain a baseline Hct in the early febrile phase of disease. It will become useful later for early recognition of plasma leak (detection of a rising Hct level).
  - Platelet count. This is perhaps the most common (and most maligned) laboratory investigation in dengue infection. In the early febrile phase, the platelet count is usually within the normal range but decreases rapidly as the disease progresses to the late febrile phase or at defervescence and may remain low for the first few days of recovery. There is a significant correlation between disease severity and thrombocytopenia; however, thrombocytopenia does not directly predict bleeding.
- Liver function tests (LFTs). Abnormal LFTs in the form of elevated transaminases is common and is characterized by greater elevation of the AST compared with the ALT. The frequency and degree of elevation of the liver enzymes are higher with DHF than with DF.

  Key indicators are as follows:
- Leucopenia followed by progressive thrombocytopenia is suggestive of dengue infection.
- A rising Hct accompanying progressive thrombocytopenia is suggestive of DHF.
- In the absence of a baseline Hct level, a Hct value greater than 40% in adult females and greater than 46% in adult males should raise the suspicion of plasma leakage.

Diagnostic tests

Confirmatory laboratory tests include antibody detection (serology), virus isolation, detection of viral genetic materials (PCR), and detection of dengue virus protein (NS1 antigen). Dengue viraemia in a patient is short-lived, typically occurs 2 to 3 days before the onset of fever and lasts for 4 to 7 days of illness. During this period the dengue virus, its nucleic acid (PCR RNA) and circulating viral antigen (NS1) can be detected. In the early stages of the disease (within up to 6 days of onset), virus isolation or viral nucleic acid or antigen detection can be used to diagnose infection. At the end of the acute phase of infection, immunological tests (IgM and IgG antibodies) are the methods of choice for diagnosis.

Management of dengue infection

There is no currently available medication to combat the dengue virus after host invasion. The mainstay of dengue infection management remains symptomatic and supportive.

Box E42.5 Warning signs of impending severe dengue fever

- No clinical improvement or worsening of the patient's condition just before or during transition to the afebrile phase (defervescence) or as the disease progresses
- Persistent vomiting
- Severe abdominal pain
- Lethargy or restlessness
- Bleeding: epistaxis, melena, haematemesis, menorrhagia, dark-coloured urine (haemoglobinuria), or haematuria
- Dizziness
- Pale, cold, and clammy hands and feet
- Low or no urine output for 4–6 hours

Patients with DF should maintain an adequate oral intake of fluid to avoid dehydration. Paracetamol can be used for fever and myalgia. Aspirin and other non-steroidal anti-inflammatory agents should be avoided because of the risk of bleeding complications.

It is important to identify those who are at risk of developing severe disease and in need of hospitalization because prompt and appropriate management of severe cases in hospital can effectively reduce the mortality rate associated with dengue infections. The parameters that need to be monitored include general condition, vital signs, serial Hct, full blood count, urine output, and presence of any warning signs (**Box E42.5**).

In DHF, aggressive intravascular volume repletion with intravenous crystalloids and colloids is indicated to prevent or reverse hypovolaemic shock. In mild cases, oral rehydration may be sufficient. Intravenous fluids are indicated if the patient is vomiting or if the Hct continues to rise by 10% to 20% despite oral rehydration. Isotonic crystalloid solutions should be used throughout the critical period, except in very young infants in whom 0.45% saline may be used. In obese patients, ideal body weight should be used as a guide to calculating fluid requirements. Blood transfusions may be needed only for patients with severe bleeding manifestations. Most patients with DSS respond to 10 mL/kg fluid in children or 300 to 500 mL in adults given over 1 hour or as a bolus. The rate of fluid administration is then reduced gradually to 7, 5, 3, then 1.5 mL/kg/h with regular monitoring of clinical condition, vital signs, urine output, and Hct. In patients with profound shock, if shock is not reversible after the initial fluid bolus, this can be repeated, and colloids and blood transfusion should be considered. Fluid that is lost into tissue spaces during the period of plasma leakage is subsequently reabsorbed rapidly. Thus, care should be taken to avoid hypervolaemia and pulmonary oedema. Intravenous fluids should generally be discontinued after 24 to 48 hours. There is no evidence that corticosteroids are of benefit in patients with DSS.

Patients can be discharged from hospital when they have been afebrile for more than 24 hours and have normal oral intake and urine output, rising platelet counts, and stable Hct and vital signs.

Prevention

Prevention is dependent on control of the vector, *A. aegypti*. The most effective preventive strategy is mosquito control to avoid artificial stagnation of water to reduce breeding sites. Mosquito barriers, such as insecticide-impregnated mosquito nets and insect repellents, are needed for patients until fever subsides to prevent the vector mosquito from biting and acquiring the virus.

A novel technique in which selected strains of *Wolbachia* have been introduced into *A. aegypti* to prevent transmission of dengue virus by the vector is now used in many countries with good results. *Wolbachia* prevents dengue transmission by either directly blocking the virus or by decreasing the lifespan of the vector.

Two vaccines to protect against dengue are available for use. Dengvaxia a three-dose vaccine is approved for use in people of 9 to 16 years with laboratory confirmation of previous dengue virus infection in those living in dengue endemic areas.

Qdenga is approved in the EU, UK, Brazil, Argentina, Indonesia, and Thailand.

EBOLA VIRUS DISEASE

Somia Iqtadar

Ebola virus disease (EVD) and its late complication, Ebola haemorrhagic fever (EHF), are loosely grouped as belonging to the viral haemorrhagic fevers but are distinguished by their severity and fatality. EVD can infect humans and a range of non-human primates (monkeys, gorillas, and chimpanzees), dogs, and pigs.

The causative agent of EVD is Ebola virus, which belongs to the Filoviridae family, genus Ebola virus; it is a pleomorphic, negative-sense RNA virus. The first Ebola virus species was discovered in 1976 in what is now the Democratic Republic of the Congo near the Ebola River, hence its name. Since then, outbreaks have appeared sporadically around this geographical area. The 2014 outbreak in West Africa was the largest and most complex Ebola outbreak to date; it spread rapidly, causing many casualties.

Five subspecies of Ebola virus have been identified to date. Four of these have been implicated in human infection: Zaire Ebola virus, Sudan Ebola virus, Taï Forest Ebola virus (formerly Côte d'Ivoire Ebola virus), and Bundibugyo Ebola virus. The fifth, Reston Ebola virus, has been identified only in non-human primates and has not caused verified EVD in humans.

The natural reservoir host of Ebola viruses remains unknown. However, on the basis of available evidence and the nature of similar viruses, researchers believe that the virus is zoonotic (animal borne), with bats being the most likely reservoir.

Transmission

The manner in which the virus is first acquired by the index case at the start of an outbreak remains speculative. It appears to be through contact with an infected animal, but when the infection becomes established in a human host, it may spread from person to person very efficiently via faecal–oral, parenteral, or air-borne splashes. Ebola virus enters the host through:

- Direct contact with the blood or secretions (saliva, stools, vomitus) of an infected person
- Exposure to objects (e.g., needles) that have been contaminated with infected secretions
- Eating the meat of infected animals.

The viruses that cause EVD are often spread between families and friends because these individuals come into close contact with infectious secretions. During outbreaks of EVD, the disease can spread rapidly within healthcare settings and to healthcare professionals if barrier nursing and appropriate protective equipment, such as masks, gowns, and gloves, are not used.

Proper cleaning and disposal of instruments, such as thermometers, needles, and syringes, are also important, as is the disposal of highly infectious bodily waste and any bedding and equipment soiled with it. Without adequate sanitation, quarantine, and sterilization of items and instruments that cannot be disposed of, virus transmission can continue and amplify an outbreak.

Clinical features

When infection occurs, symptoms usually begin abruptly. Symptoms of EVD typically include fever, headache, joint and muscle aches, diarrhoea, vomiting, abdominal pain, rash, red eyes, cough, sore throat, and internal and external bleeding.

Clinical course

After the incubation period, which ranges from 2 to 21 days, the patient may show the following clinical features:

- ***Days 1 and 2.*** The patient often presents with non-specific flu-like symptoms with fever up to 39°C, profuse sweating, malaise, frontal and temporal headache, myalgia, retrobulbar pain, and conjunctival injection. Gastrointestinal symptoms dominate the clinical picture, with nausea, profuse vomiting, watery diarrhoea, and diffuse abdominal pain being the most common. Within 2 days, blood may appear both in vomitus and in stools. Respiratory symptoms such as sore throat and cough often follow the initial presentation. Relative bradycardia is the only sign at this stage.
- ***Days 3 and 4.*** A sore, tender throat with dysphagia becomes the predominant symptom in addition to the gastrointestinal features already described. The soft palate becomes erythematous. Dehydration usually starts to be clinically evident at this stage. Lymphadenopathy involving occipital, cervical, and axillary lymph nodes is seen in some patients.
- ***Days 5 to 7.*** By now, about 50% of patients begin to display a haemorrhagic diathesis with spontaneous epistaxis, gingival haemorrhage, gastrointestinal and genital bleeding (in females), haematuria, and bleeding at injection sites. Subconjunctival haemorrhages are also seen frequently. Signs include an erythematous, non-itchy rash, spreading from the face and buttocks to the trunk and arms, which may go on to become papular or maculopapular within 24 hours. Haemorrhagic lesions often become confluent within hours.
- ***Days 8 to 16.*** At this stage, dehydration and hypotension become severe in the absence of supportive care. Oedema may be present, and shock syndrome may prevail. Most deaths occur around day 12 with clinical evidence of multiorgan failure, involving the kidney and liver in particular. Central nervous system features, including fits and coma, may also be seen. Persistent hiccups, although rare, carry a poor prognosis. Among those who recover, the rash usually disappears around day 12; palmar and plantar desquamation occurs on days 14 to 16. Complications may include orchitis, residual hepatic dysfunction, transverse myelitis, or uveitis.

Differential diagnosis

Other viral haemorrhagic fevers, such as dengue and CCHF, and other conditions, such as acute surgical abdomen, malaria, leukaemia, and enteric fever, are the most important differential diagnoses.

Pathophysiology

Symptoms may appear anywhere from 2 to 21 days after exposure to Ebola virus, though an incubation period of 8 to 10 days is most common. Typically, Ebola virus infection runs its course within 14 to 21 days.

Cytokines are released when the virus invades reticuloendothelial cells, which initiates inflammatory responses that are not very protective. These cytokines produce initial non-specific flu-like symptoms such as fever, myalgia, and malaise. This early phase of infection is characterized by thrombocytopenia, leucopenia, and a pronounced lymphopenia. Neutrophilia develops after several days, as do elevations in AST and ALT. As the infection progresses, the cytopathic effects of infection and cytokine release result in DIC, bleeding, and capillary leak caused by microvascular endothelial cell damage and compromised vascular integrity. Bilirubin may be normal or slightly elevated. With the onset of anuria, blood urea nitrogen and serum creatinine increase. Terminally ill patients may develop a metabolic acidosis that may contribute to the often-observed tachypnoea.

Cutaneous manifestations are frequently marked. Bleeding from mucous membranes and puncture sites is reported in 40% to 50% of cases and maculopapular rashes in approximately 50%. Other cutaneous manifestations include petechiae, purpura, ecchymosis, and haematomas (especially around needle injection sites). All infected patients show some extent of coagulopathy and features of impaired perfusion. In general, the development of haemorrhagic symptoms is indicative of a poor prognosis.

However, contrary to popular belief, haemorrhage contributes little to the hypovolaemia and shock associated with EVD; instead, death supervenes because of multiple organ dysfunction syndrome caused by capillary leak, fluid redistribution, hypotension, DIC, and focal tissue necrosis.

Diagnosis

Diagnosing EVD in an individual who has been infected for only a few days is difficult because the early symptoms, such as fever, abdominal pain, red eyes, and a skin rash, are non-specific and are often seen in individuals with many different viral infections.

However, if a person demonstrates these symptoms along with a history of travel to an endemic area or contact with someone who has EVD, the individual must be considered as a suspected case of EVD. The patient should be isolated, appropriate investigations should be performed, and public health professionals should be notified. Samples from the patient can then be collected and tested to confirm infection.

Investigations

These are shown in **Box E42.6**.

Management

Therapeutics

There are currently two treatments approved by the US Food and Drug Administration (FDA) to treat EVD caused by the Ebola virus, species Zaire ebolavirus, in adults and children.

The first drug approved in October 2020, Inmazeb, is a combination of three monoclonal antibodies (mAbs) atoltivimab, maftivimab, and odesivimab.

The second drug, Ebanga, is a single mAb and was approved in December 2020.

Box E42.6 Laboratory tests used in the diagnosis of Ebola virus disease

Timeline of infection	Diagnostic tests available
Within a few days of symptom onset	NP-antigen capture ELISA testing IgM ELISA PCR (RT-PCR) Virus isolation
Later in the disease course or after recovery	IgM and IgG antibodies
Retrospectively in deceased patients	Immunohistochemistry testing RT-PCR Virus isolation

ELISA, Enzyme-linked immunosorbent assay; *Ig,* immunoglobulin; *NP,* nucleoprotein; *RT-PCR,* reverse transcription polymerase chain reaction.

mAbs are proteins produced in a laboratory or other manufacturing facility that act like natural antibodies to stop a germ such as a virus from replicating after it has infected a person. These particular mAbs bind to a portion of the Ebola virus's surface called the glycoprotein, which prevents the virus from entering a person's cells.

Both of these treatments were evaluated in a randomized controlled trial during the 2018 to 2020 Ebola outbreak in the Democratic Republic of the Congo. The overall survival rate was much higher for patients receiving either of the two treatments. Neither Inmazeb nor Ebanga has been evaluated for efficacy against species other than Zaire ebolavirus.

Supportive care

Whether or not other treatments are available, basic interventions can significantly improve chances of survival when provided early. These are referred to as supportive care, and include:

- Maintenance of fluid and electrolyte balance
- Maintenance of blood pressure and oxygen saturation to prevent tissue hypoxia
- Early detection and treatment of superimposed infections.

Patients can produce infectious virions for prolonged periods. Therefore, strict barrier isolation in a room away from traffic patterns must be maintained throughout the illness. Early notification of public health professionals and contact screening are essential. The patient's urine, stool, sputum, and blood, along with any objects that have come in contact with the individual or their bodily fluids (e.g., laboratory equipment), are all highly contagious and must be incinerated or disinfected with a 0.5% sodium hypochlorite solution. Those who have died of EVD should be buried promptly, with standard protocols observed for contagion limitation.

Prevention

Because the disease is highly infectious, prevention of EVD presents many challenges. Strict application of isolation measures and barrier nursing is the cornerstone of management of all contagious viral haemorrhagic fevers, including EVD.

A safe and effective vaccine is an important tool to protect and prevent the introduction and spread of Ebola.

There are two licensed Ebola vaccines. Both vaccines are safe and protective against the species Zaire ebolavirus only.

Ebola Zaire vaccine (rVSV-ZEBOV) Ervebo is genetically engineered to express a glycoprotein from Zaire ebolavirus to provoke a neutralizing immune response. It was licensed in November 2019 by the European Medicines Agency and prequalified by WHO. The US FDA licensed the vaccine in December 2019. It is recommended by the Strategic Advisory Group of Experts on Immunization as part as a broader set of Ebola outbreak response tools.

A second new vaccine is delivered in two doses called Zabdeno (Ad26.ZEBOV) and Mvabea (MVA-BN-Filo) for individuals 1 year and older.

The vaccine is delivered in two doses: Zabdeno is administered first, and Mvabea is given approximately 8 weeks later as a second dose. This prophylactic two-dose regimen is therefore not suitable for an outbreak response in which immediate protection is necessary.

For individuals at imminent risk of exposure to Ebola (e.g., healthcare professionals and those living in or visiting areas with an ongoing EBOV outbreak) who completed the Zabdeno and Mvabea two-dose vaccination regimen, a Zabdeno booster vaccination should be considered if more than 4 months have passed since the second dose was administered.

Specific infections 1525

CORE SKILLS AND KNOWLEDGE

Sexually transmitted infections (STIs) are among the most common causes of illness in the world and remain endemic in all societies. They rank among the top five disease categories for which adults seek healthcare worldwide.

The medical specialty of genitourinary medicine encompasses the diagnoses and treatment of STI and human immunodeficiency virus (HIV). It also includes the public health control of these infections through screening, partner notification and contract tracing, and health promotion, as well as provision of vaccines and other biomedical interventions to protect against STI and HIV acquisition in high-risk populations. The specialty is multidisciplinary and includes physicians, specialist nurses, health advisers, psychologists, microbiologists, virologists, pharmacists, and public health clinicians.

Key STI skills include:

- Taking a sexual history and obtaining information for partner notification
- Performing a sexual health examination and investigations and correctly interpreting results
- Discussing prevention interventions to ensure that people can avoid acquiring or transmitting STIs and HIV.

The best place to experience the care of people with STIs is in the sexual health clinic or via specialists services for those living with HIV (see Chapter 44).

CLINICAL SKILLS

History

Patients presenting with possible STIs may be anxious, embarrassed, and concerned about confidentiality. Clinicians must be alert to these issues and respond sensitively. The clinical setting must ensure privacy and confidentiality. The clinical history is tailored to the presentation encountered, but many of the points in **Box 43.1** are likely to be relevant.

Examination in the sexual health clinic

The purpose and procedure of the examination should be explained and informed consent obtained. Examination should be in a private room with a lockable door and a chaperone present. The patient should be provided with a gown or paper drapes to cover areas not being examined. Ensuring the patient is relaxed and in a comfortable position will result in a better experience and enable a thorough examination with properly taken swabs. The process of anogenital examination is shown in **Figs. 43.1 to 43.3**. If the person is asymptomatic, clinical examination may not be indicated.

Investigations

Although investigation is guided by the history and examination, multiple infections may coexist, and some may be asymptomatic. The minimum investigations are tests for chlamydia, gonorrhoea (including samples from extra-genital sites if indicated by the sexual history), syphilis, and HIV. HIV antibody testing should be performed on an 'opt-out' basis. Screening for hepatitis viruses should be performed in those at increased risk. The recommended investigations for different clinical presentations are shown in **Boxes 43.2 to 43.8**. The recommended tests for specific infections are detailed in this chapter.

SEXUALLY TRANSMITTED INFECTIONS

The World Health Organization (WHO) estimated in 2020 that more than 1 million people acquire an STI every day. Each year, there are an estimated 374 million new infections in people aged 15 to 49 years with one of the four major curable STIs (chlamydia, gonorrhoea, syphilis, and trichomoniasis) worldwide. These include 7.1 million cases of syphilis, 82 million cases of gonorrhoea, 129 million cases of chlamydia, and 156 million cases of trichomoniasis.

Box 43.1 Taking a clinical history in patients with a sexually transmitted infection

Symptom history relevant to sexually transmitted infections

- STIs may be asymptomatic
- Genital symptoms
  - Urethral discharge in males
  - Vaginal discharge in females
  - Lower abdominal pain in females
  - Genital lumps
  - Genital ulceration
  - Genital itching
  - Rectal symptoms
- Systemic symptoms: fever, skin rash, joint pains, eye symptoms

Sexual history

- Number and types of recent sexual contacts, with dates
- Sex of partners
- Regular or casual sexual contact. If regular, how long have they been having sex?
- Use of condoms
- Any known symptoms or STI diagnosis in the partner
- Sexual practices (e.g., insertive or receptive; vaginal, anal, pharyngeal, oro-anal)
- Whether the patient has ever paid or been paid for sex
- Country of origin of sexual partners

Previous history of STIs and ongoing risk exposure

- Previous STIs, including dates and treatment received
- HIV testing and results
- Hepatitis A and B, and HPV vaccination status
- Risk factors for ongoing acquisition of HIV and STIs
  - Frequent partner change
  - Unprotected sex
  - Use of drugs or alcohol to a level that reduces safer sex
  - Current or history of injecting drugs by patient and by any sexual partners
  - GBMSM
  - Sexual partners from countries with high HIV or other STI prevalence

Offer risk reduction advice and make patients aware of post-exposure HIV prophylaxis after sexual exposure and pre-exposure prophylaxis.

Wider history

- General medical history
- Medication history, including recent antibacterial or antiviral treatment
- Menstrual, obstetric, and cervical cytology screening histories
- Details of current contraception
- Any past or current drug or alcohol misuse

GBMSM, Gay, bisexual, and other males who have sex with males; *HIV,* human immunodeficiency virus; *HPV,* human papillomavirus; *STI,* sexually transmitted infection.

In 2016 more than 490 million people were estimated to be living with genital herpes, and more than 300 million females were estimated to have human papillomavirus (HPV) infections, the primary cause of cervical cancer. The estimates suggest that most of these infections are in low-income countries.

In England there has been an overall increasing trend in STIs over the past decade before a drop occurred in 2020 and 2021 during the COVID-19 pandemic. However, by 2022 cases of gonorrhoea and infectious syphilis (primary, secondary, and early latent) had exceeded numbers in 2019 to 79 268 (16.1% increase) and 8693 (8.1% increase) cases, respectively. There were further increases between 2022 and 2023 and the number of gonorrhoea diagnoses in 2023 was the largest annual number reported since records began in 1918, and the number of syphilis diagnoses was the largest since 1948. Gonorrhoea is increasing in people of all ages, but the increase is highest among people aged 15 to 24 years. Infectious syphilis is increasing in both heterosexual persons, as well as gay, bisexual, and other males who have sex with males (GBMSM) but in 2023 there was a larger proportional increase in syphilis diagnoses among heterosexual persons than GBMSM. Between 2021 and 2022, chlamydia diagnoses increased by 24.3% from 160 279 to 199 233, and diagnoses of first episode genital herpes increased 13.8% from 21 892 to 24 910. STIs are associated with frequent partner change and inconsistent use of condoms. Increased travel and recreational drug and alcohol use are also implicated. The only decreasing trend is in diagnoses of first episode genital warts which decreased by 8.5% from 28 497 to 26 079 between 2021 and 2022 due to the established HPV vaccination program. Amongst the largely vaccinated age group of 15 to 17 year olds diagnoses remained low at 104 in 2022 and 107 in 2023.

Despite high global incidence and substantial morbidity, STIs remain neglected in clinical practice, public health, and research. There have been rapid increases in antimicrobial resistance in *Neisseria gonorrhoeae* and *Mycoplasma genitalium*, with the possibility of untreatable cases. STIs often coexist, and the inflammation caused by one STI can increase the risk of acquisition of others; most infections increase the acquisition and transmission of HIV.

ASYMPTOMATIC SCREENING

All STIs can be asymptomatic, and multiple infections frequently coexist; hence, many people without symptoms attend sexual health clinics to seek sexual health checks and advice. Sexual health checks offer individual and public health benefits because treatment of asymptomatic infections reduces the period of infectivity, prevents long-term complications, and reduces onward transmission.

Increasingly, sexual health clinics are making asymptomatic sexual health checks available online because routine examination of those with no symptoms yields few additional diagnoses. A short electronic medical history is self-completed to confirm the absence of symptoms, and a sexual history and risk assessment for STIs, HIV, and other blood-borne viruses determines which investigations are needed. The self-sampling kit is posted to the person with instructions of how to take samples and package them safely. These are posted back to the service for testing, and results are returned electronically.

The minimum investigations, even if the person is asymptomatic, are tests for chlamydia, gonorrhoea (including samples from extragenital sites if indicated by the sexual history), syphilis, and HIV. HIV antibody testing should be performed on an 'opt-out' basis. If it is declined, the reasons why should be documented because it may need to be discussed again at a follow-up visit if the patient is at high risk for HIV infection.

Hepatitis A screening and vaccination

Screening for hepatitis viruses should be performed in those at increased risk.

A test for antibodies to hepatitis A, with vaccination if negative, should be performed in:

- GBMSM
- People who inject drugs (PWID)

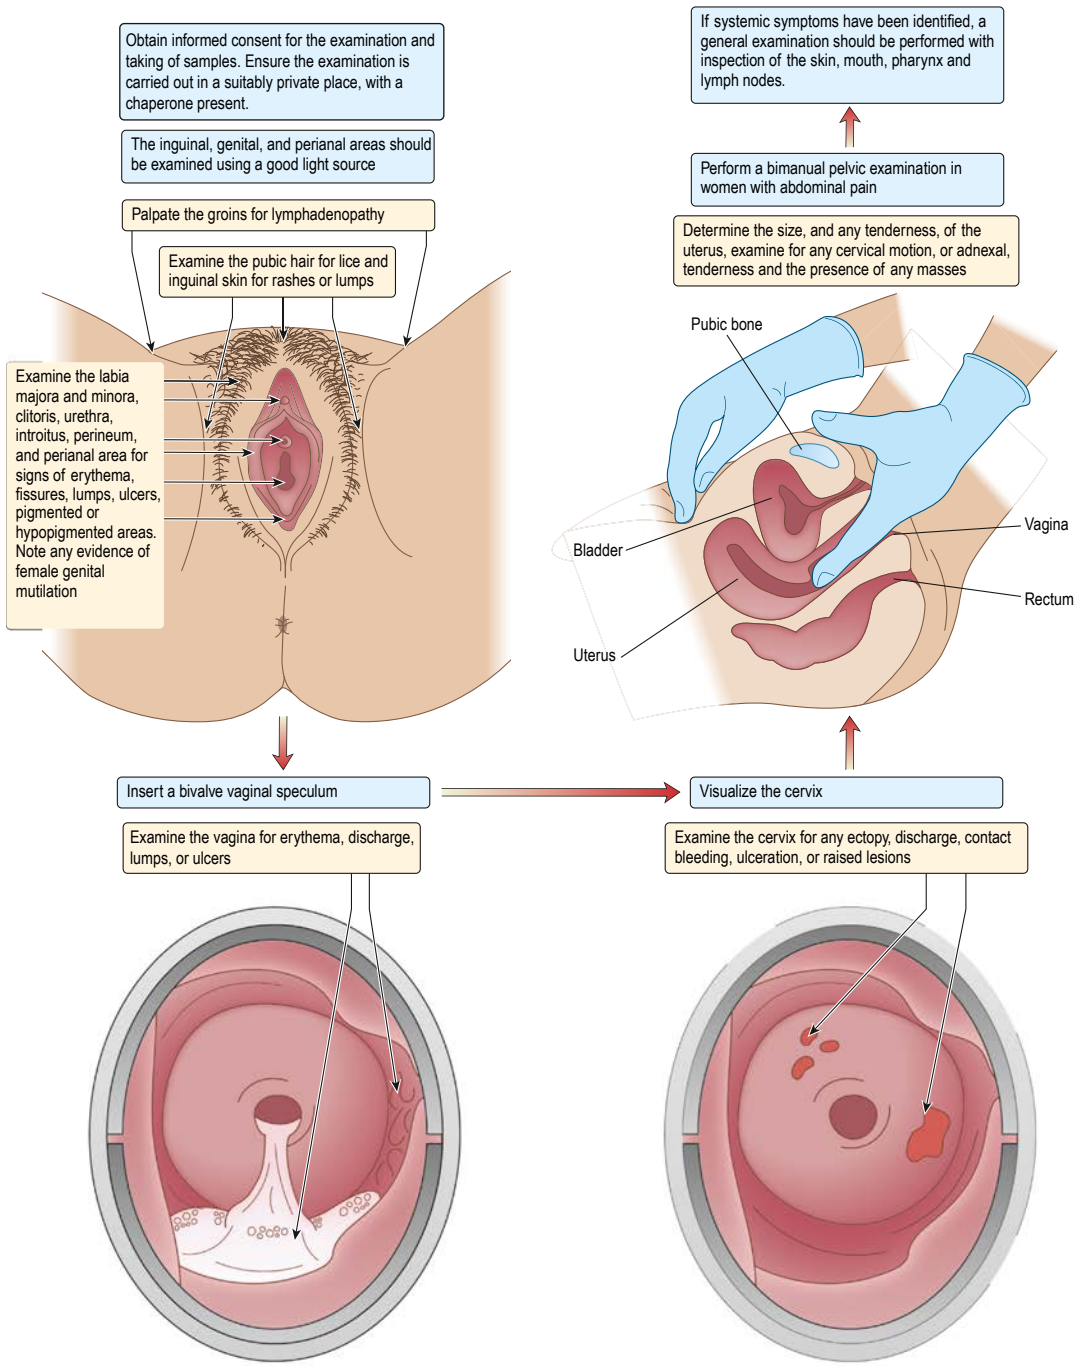

Fig. 43.1 **Examination of the vulva, vagina, and cervix.**

- People with chronic hepatitis B or C
- People living with HIV (PLWH)

Hepatitis B screening and vaccination

The recommended screening test in those who have not been immunized is hepatitis B core antibody (anti-HBc), which is a marker of past infection, or hepatitis B surface antigen (HBsAg), which identifies currently infected individuals. Screening is recommended for:

- Sexual partners of those who are HBsAg positive
- GBMSM and their sexual partners
- People who have been sexually assaulted
- Sex workers
- PWID and their sexual partners
- Individuals, or those with a partner, from countries with intermediate or high prevalence of chronic hepatitis B (defined as 2% or more and including all countries outside Western Europe, North America, and Australasia)
- Needle-stick injury recipients
- People with chronic hepatitis C
- PLWH
- Those born to mothers infected with hepatitis B.

Patients who are negative and have ongoing increased risk should be offered vaccination.

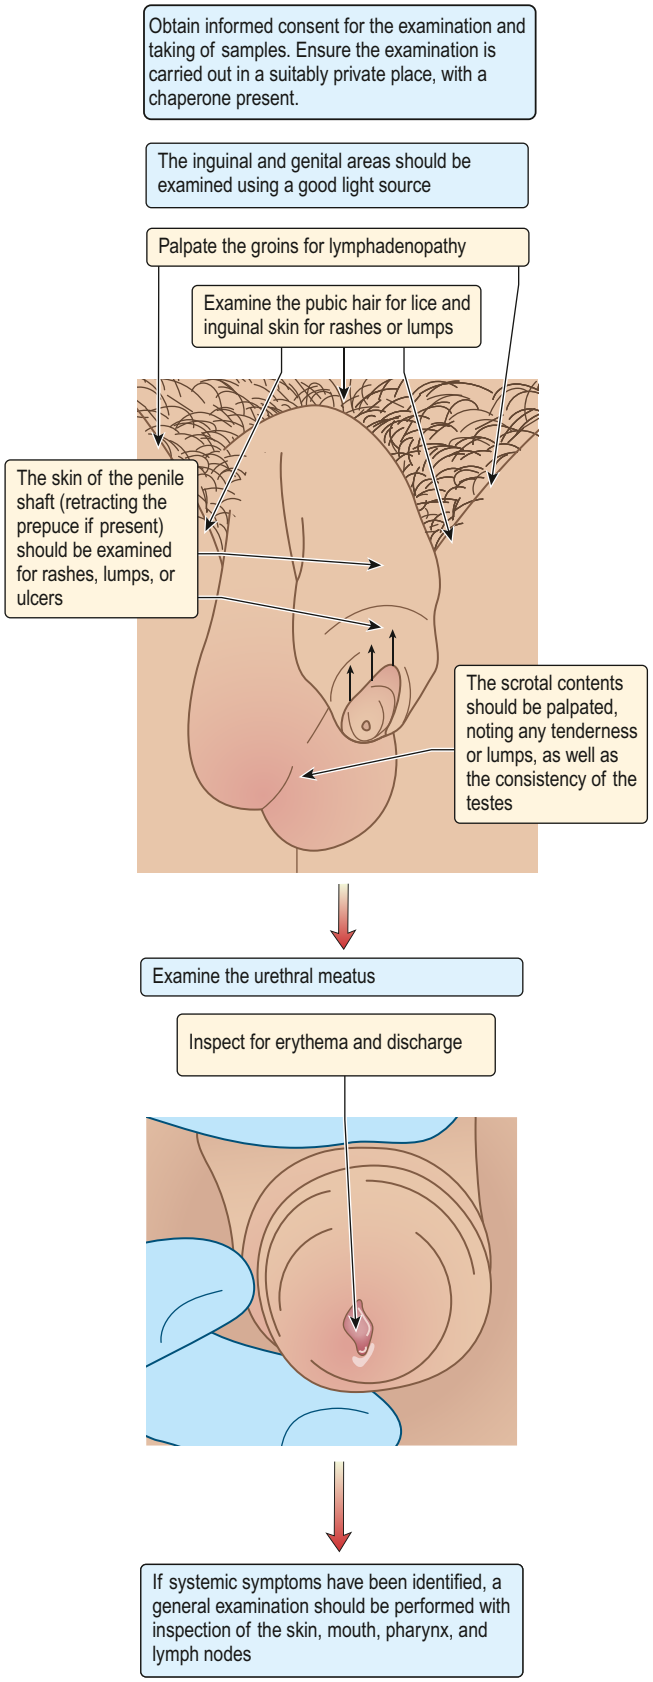

Fig. 43.2 **Examination of the penis, penile meatus, and scrotal contents.**

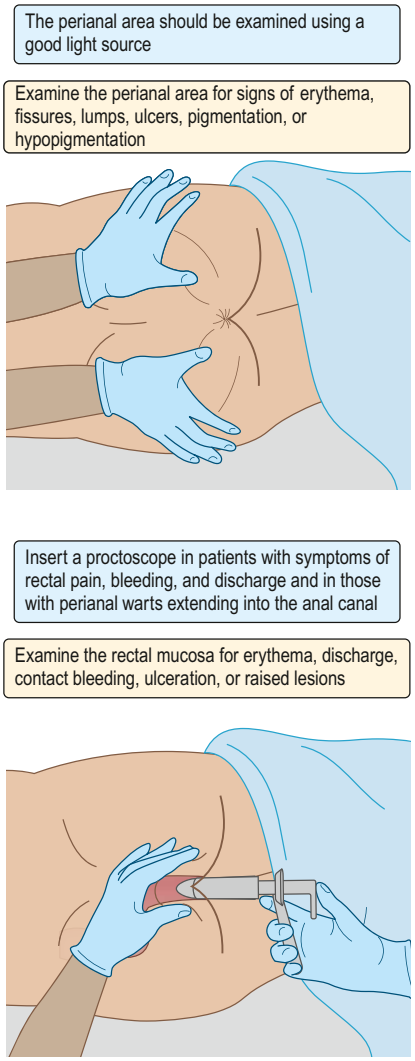

Fig. 43.3 **Examination of the perianal area and anal canal.**

Hepatitis C screening

Screening for antibodies to hepatitis C is recommended in:

- Sexual partners of persons who are hepatitis C virus (HCV) positive
- PWID
- GBMSM who are taking or are eligible for pre-exposure prophylaxis (PrEP) for HIV (see Chapter 44)
- GBMSM with additional risk factors, e.g., sex associated with trauma or injury, recreational drug use, rectal lymphogranuloma venereum (LGV)
- Sex workers
- Individuals from countries with intermediate or high prevalence of chronic hepatitis C (as defined earlier for hepatitis B)
- Needle-stick injury recipients
- People with chronic hepatitis B
- PLWH
- Those born to mothers infected with HCV.

Box 43.2 Urethritis

Presentation
- Males: urethral discharge and dysuria
- Females: usually asymptomatic; may cause mild dysuria

Infective causes

Usually divided into gonococcal (caused by *Neisseria gonorrhoeae*) or non-gonococcal
- *Chlamydia trachomatis*[a]
- *Mycoplasma genitalium*[b]
- *Ureaplasma urealyticum*
- *Neisseria gonorrhoeae*
- Trichomonas vaginalis[c]
- Herpes simplex virus[c]
- UTI[d]
- Adenoviruses (often associated with conjunctivitis)[c]

Non-infective causes
- Non-specific urethritis (where no cause can be identified)
- Physical or chemical trauma
- Urethral stricture

Features that help discriminate between causes
- Urethral stricture
- Colour of discharge: green-yellow with gonorrhoea
- Urinary symptoms: dysuria, urinary frequency, nocturia, or haematuria may suggest UTI
- Testicular pain or swelling: gonorrhoea, chlamydia, and UTI can cause epididymo-orchitis
- Other symptoms: genital sores suggest HSV, rash, or sore eyes suggest adenovirus

Investigations
- Microscopy of urethral discharge
- NAAT and culture for *N. gonorrhoeae*
- NAAT for *C. trachomatis*
- NAAT for *M. genitalium*
- Serology for syphilis and HIV
- Tests for *T. vaginalis* and HSV are not usually performed routinely
- No commercial tests are available for *U. urealyticum*
- A MSU if symptoms are suggestive of UTI

[a]The most common cause of non-gonococcal urethritis (NGU).
[b]The second most common cause of NGU.
[c]Rarer cause of NGU.
[d]Most frequent non-sexually transmitted cause of NGU.
HSV, Herpes simplex virus; *MSU,* midstream specimen of urine; *NAAT,* nucleic acid amplification test; *UTI,* urinary tract infection.

Box 43.3 Vaginal discharge

Infective causes

Vaginal infections
- BV[a]
- *Candida albicansa*[a]
- *Trichomonas vaginalis*[b]

Cervical infections
- *Chlamydia trachomatis*
- *Neisseria gonorrhoeae*
- Herpes simplex virus

Non-infective causes
- Physiological discharge or cervical ectopy[c]
- Cervical polyps
- Neoplasms
- Retained products (e.g., of conception, tampons)
- Chemical irritation

Features that help discriminate between causes
- Odour: BV and *T. vaginalis* can have an offensive odour.
- Vulval itching or soreness: *Candida* spp. and *T. vaginalis* can both cause vulval irritation.
- Other symptoms: dysuria suggests UTI, abdominal pain may suggest spread of gonorrhoea or chlamydia into the upper genital tract, and intermenstrual or postcoital bleeding that persists after treatment may warrant gynaecology assessment.

Investigations
- Microscopy of vaginal discharge for BV, *Candida* spp., and *T. vaginalis*
- Culture for *Candida* spp.
- NAAT for *T. vaginalis*
- NAAT for *N. gonorrhoeae* and *C. trachomatis*
- Serology for syphilis and HIV

[a]The most common causes of altered vaginal discharge, but *C. trachomatis* and *N. gonorrhoeae* infections must also be considered.
[b]The most common cause worldwide but rarer in high-income countries.
[c]Common diagnosis but requires exclusion of infective causes.
BV, Bacterial vaginosis; *HIV,* human immunodeficiency virus.

INVESTIGATIONS FOR SYMPTOMATIC PATIENTS

These depend on the clinical presentation but should always include tests for chlamydia, gonorrhoea, syphilis, and HIV. The recommended investigations for these presentations are shown in **Boxes 43.2 to 43.8**.

MANAGEMENT, PREVENTION, AND CONTROL OF STIs

The treatment of specific conditions is covered in the appropriate sections. Most sexual health clinics give directly observed therapy when possible or dispense medication directly to the patient to improve adherence and prevent onward transmission.

Tracing the sexual partners of patients (partner notification) is crucial in controlling spread of STIs. The aims are to identify and treat those with infections (particularly those with asymptomatic infections) to break the chain of transmission. Appropriate antibiotic therapy may be offered to recent sexual partners of those known to have active infections (epidemiological treatment). Interviewing people about their sexual partners requires tact and sensitivity, and specialist health advisers are available for this in sexual health clinics.

Many STI diagnoses are in young people (16–24 years). Prevention starts with education and information. People often begin sexual activity at young ages, so education programmes need to include school pupils, as well as young adults. Education of health professionals is also required. Primary public health programmes aimed at informing groups most at risk of STIs, including GBMSM, sex workers, young people, and Black and minority ethnic groups to help modify sexual behaviour, should be implemented at local and national levels. Vaccination against hepatitis A and B should be given to those at increased risk, and HPV vaccine should be given to those eligible through the national HPV vaccination programme for GBMSM delivered through sexual health clinics. Secondary interventions include prompt diagnosis and management of STIs to reduce complications and onward transmission. The National Chlamydia Screening Programme in England aims to provide earlier detection and treatment for chlamydia for sexually active females younger than 25 years old by providing easy access to chlamydia testing online and in community settings.

Reducing the numbers of sexual partners, avoiding overlapping relationships, using condoms correctly and consistently, and avoiding sex if symptoms are present can reduce the risks of acquiring

Box 43.4 Lower abdominal pain

Infective causes

- PID[a,b]
  - *Chlamydia trachomatis*[c]
  - *Neisseria gonorrhoeae*
  - *Mycoplasma genitalium*
  - BV
- UTI

Non-infective causes

- Ectopic pregnancy
- Acute appendicitis
- Endometriosis
- Irritable bowel syndrome
- Neoplasms
- Torsion or haemorrhage of ovarian cyst

Features that help discriminate between causes

- Site, character, and duration of pain
- Vaginal discharge, postcoital or intermenstrual bleeding, deep dyspareunia
- Date of last menstrual period and contraception. Is pregnancy possible?
- Dysuria, urinary frequency, nocturia or haematuria
- Nausea, vomiting, diarrhoea, or constipation

Investigations

- Microscopy of vaginal discharge for BV and *T. vaginalis*
- NAAT for *T. vaginalis*
- NAAT and culture for *N. gonorrhoeae*
- NAAT for *C. trachomatis*
- NAAT for *M. genitalium*
- Serology for syphilis and HIV
- Pregnancy test to exclude ectopic pregnancy
- MSU for culture if urinary symptoms

[a] Most common in sexually active individuals younger than 25 years of age.
[b] Symptoms of abnormal vaginal discharge or abnormal bleeding and bacterial vaginosis (BV) are usually present with pelvic inflammatory disease (PID).
[c] The most common cause of PID.
HIV, Human immunodeficiency virus; *MSU,* midstream specimen of urine; *NAAT,* nucleic acid amplification test; *UTI,* urinary tract infection.

Box 43.5 Genital lumps

Infective causes

- HPV, anogenital warts[a,b]
- Molluscum contagiosum[a,b]
- *Sarcoptes scabiei* (scabies): excoriated lesions
- *Treponema pallidum:* secondary condylomata lata[c]

Non-infective causes

- Normal anatomical variants: papillae, sebaceous glands, skin tags
- Sebaceous cysts
- Neoplasms or premalignant disease (e.g., perianal, vulval, and penile intraepithelial neoplasia)

Features that help discriminate between causes

- Lumps: anogenital warts can occur on mucous membranes and keratinized skin; molluscum contagiosum and scabetic papules only occur on keratinized skin.
- Single or multiple lesions: painful single lesions suggest malignant or premalignant conditions, anogenital warts, molluscum contagiosum and syphilitic condylomata lata are usually multiple
- Itch: scabetic itchy papules typically present on the scrotum, penile shaft, and labia majora, as well as classic body areas.
- Pain: neoplasms and premalignant conditions are often sore or painful.
- Length of time: if present before first sexual activity, likely to be a normal anatomical variant.
- Lumps or rashes elsewhere: scabetic itchy papules are usually visible on classic areas of body; widespread skin rash of secondary syphilis usually present with condylomata lata.

Investigations

- NAAT for *Neisseria gonorrhoeae*
- NAAT for *Chlamydia trachomatis*
- Serology for syphilis and HIV
- Clinical diagnoses of anogenital warts (HPV testing not appropriate) and molluscum contagiosum

[a] The most common infective cause followed by molluscum contagiosum.
[b] Mucous membrane lumps suggest anogenital warts; molluscum contagiosum does not occur on mucous membranes.
[c] Moist papules are rare in secondary syphilis but easily misdiagnosed as genital warts.
HPV, Human papillomavirus; *NAAT,* nucleic acid amplification test.

and transmitting an STI. For those who change their sexual partners frequently, regular sexual health checks (approximately 3-monthly) are advisable. If people develop symptoms, they should be encouraged to seek medical advice as soon as possible to reduce complications and spread to others.

Biomedical prevention

Prevention of HIV acquisition is part of a sexual health service. The universal offering of HIV testing contributes to reducing the pool of PLWH who are undiagnosed because many new infections are transmitted from people who are unaware of their HIV infection. It is possible to reduce acquisition of HIV infection after high-risk sexual exposure if triple anti-retroviral therapy (ART) is started as soon as possible. This is termed 'HIV post-exposure prophylaxis (PEP)'. Initiation within 72 hours reduces dissemination and replication of virus in tissues. The recommended first-line PEP regimen is tenofovir disoproxil 245 mg/emtricitabine 200 mg with raltegravir 1200 mg once daily for 28 days.

Tenofovir disoproxil 245 mg/emtricitabine 200 mg can also be used as HIV PrEP for people who are not infected with HIV. This has been shown to be highly effective at preventing HIV acquisition in a large real-world study conducted from sexual health clinics in England. With more than 24 000 participants, the PrEP Impact trial demonstrated that HIV PrEP can reduce HIV acquisition by 86% over several years of use. HIV PrEP has been routinely provided to people at higher risk of acquiring HIV at UK sexual health clinics since October 2020 (see also Chapter 44).

Box 43.6 Genital ulceration

Infective causes

HSV types 1 and 2[a]
- Primary
- Recurrent

Treponema pallidum[b]
- Primary chancre
- Secondary mucous patches
- Tertiary gumma

Herpes zoster[c]
LGV[d]
Mpox[d]
Chancroid[e]
Donovanosis (granuloma inguinale)[e]

Non-infective causes
- Trauma
- Aphthous ulceration (e.g., Behçet's syndrome)[f]
- Lichen sclerosus
- Erosive lichen planus
- Fixed drug eruptions
- Stevens–Johnson syndrome
- Crohn's disease
- Neoplasms

Features that help distinguish between causes
- Pain: HSV, herpes zoster, and non-infective causes are usually painful.
- Single or multiple: HSV and herpes zoster are usually multiple.
- Length of time: it is more likely to be non-infective if present for several weeks.
- External dysuria: this is a classic symptom of HSV in females.
- Ulcers or rash elsewhere: patients with syphilis, mpox, and non-infective dermatological causes usually have skin signs elsewhere.
- Systematic symptoms: these can occur with primary HSV, early syphilis, herpes zoster, mpox, non-infective dermatological causes, and Crohn's disease.

Investigations
- Ulcer swab for PCR for HSV-1, HSV-2, and *T. pallidum*
- NAAT for *Neisseria gonorrhoeae*
- NAAT for *Chlamydia trachomatis*
- Serology for syphilis and HIV (with repeat syphilis serology after a 3-month window period if appropriate)
- In GBMSM, consider:
  Ulcer swab for *C. trachomatis* NAAT with genotyping for LGV if positive mpox PCR

[a] The most common cause of multiple painful ulcers.
[b] Syphilis ulcers are usually single and non-painful.
[c] Rarer than herpes simplex virus (HSV); characterized by a unilateral presentation.
[d] Lymphogranuloma venereum (LGV) and mpox are rare except in gay, bisexual, and other males who have sex with males (GBMSM).
[e] Chancroid and donovanosis extremely rare.
[f] Most common non-infective cause, usually similar lesions in mouth.
HIV, Human immunodeficiency virus; *NAAT,* nucleic acid amplification test; *PCR,* polymerase chain reaction.

Box 43.7 Genital itching

Infective causes
- *Candida albicans*[a]
- *Trichomonas vaginalis*
- Phthirus pubis (pubic lice)[b]
- Sarcoptes scabiei (scabies)[c]

Non-infective causes[d]
- Irritant dermatitis
- Genital eczema
- Lichen sclerosus
- Lichen planus

Features that help distinguish between causes
- Site and duration of itch: itching confined to genital area with *Candida* spp. and *T. vaginalis.*
- Vaginal discharge, offensive odour, or vulval swelling: suggest *Candida* spp., *T. vaginalis*, or possibly irritant dermatitis.
- Itching or rash elsewhere or any known skin problems: pubic lice, scabies, and non-infective causes.

Investigations
- Microscopy of vaginal discharge for candida and *T. vaginalis*
- Culture for *Candida* spp.
- NAAT for *T. vaginalis*
- NAAT for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*
- Serology for syphilis and HIV

[a] The most frequent symptom in females is vulval itching rather than vaginal discharge.
[b] Relatively rare but easily visible in the hair area.
[c] May present with excoriated papules caused by excessive scratching.
[d] Genital dermatoses are common causes of genital itching, frequently misdiagnosed as *Candida* spp.
HIV, Human immunodeficiency virus; *NAAT,* nucleic acid amplification test.

SPECIFIC INFECTIONS

Human immunodeficiency virus and acquired immunodeficiency virus

This is discussed in Chapter 44.

Hepatitis B

This is discussed in Chapter 23. Sexual contacts should be screened and immunized if they are not immune.

Chlamydia trachomatis

Chlamydia trachomatis is the most common STI in the UK; up to 10% of sexually active people younger than the age of 25 years are infected. It infects the urethra, endocervix, rectum, pharynx, and conjunctiva. Up to 50% of males and 80% of females may be asymptomatic, so it is frequently unrecognized and therefore untreated. Pelvic inflammatory disease (PID) is the main complication of *C. trachomatis* in females, leading to tubal infertility, ectopic pregnancy, and chronic pelvic pain, causing significant morbidity and cost to health services.

Clinical features

The incubation period is up to 14 days.

In males, *C. trachomatis* can cause an anterior urethritis with a mucopurulent urethral discharge (worse on waking, when there may be crusting at the meatus) and dysuria. The infection can ascend along the vas deferens, leading to epididymo-orchitis.

In females, the most common site of infection is the endocervix, but the urethra can also be infected. Symptoms may include increased vaginal discharge, dysuria, postcoital or intermenstrual bleeding, and lower abdominal pain. Examination of the cervix may reveal mucopurulent cervicitis or contact bleeding. Ascending infection into the uterus and fallopian tubes causes endometritis and acute salpingitis (PID). In pregnancy, *C. trachomatis* is associated with preterm birth, postpartum infection, and neonatal mucopurulent conjunctivitis or pneumonia caused by vertical transmission during vaginal delivery.

Rectal infection, through receptive anal sex, or via spread from the cervix or via the vagina in females may be asymptomatic but

Box 43.8 Rectal symptoms

Presentation
- Symptoms of proctitis are rectal pain, mucopurulent anal discharge, rectal bleeding, constipation, and tenesmus

Infective causes

Rectal infections
- *Neisseria gonorrhoeae*[a]
- *Chlamydia trachomatis*[a]
- LGV[b]
- HSV[c]
- *Treponema pallidum*[c]
- Mpox[b]

Enteric infections
- *Shigella* spp.[b]
- *Campylobacter* spp.
- *Entamoeba histolytica*
- *Salmonella* spp.
- *Escherichia coli*

Non-infective causes
- Ulcerative colitis
- Crohn's disease
- Neoplasms

Features that help distinguish between causes
- Irritation or, pain around the anus or rectum: suggest infective causes of proctitis.
- Anal discharge or bleeding: suggest infective causes of proctitis or neoplasm.
- Abdominal pain, diarrhoea, or blood in stool: suggest infective causes of enteritis or inflammatory bowel disease.
- Feeling of incomplete bowel evacuation or constipation: suggest infective causes of proctitis or neoplasm.
- Systemic symptoms: occur with primary HSV, early syphilis, mpox, enteritis, and inflammatory bowel disease.

Investigations
- Proctoscopy: mucosal erythema, oedema, contact bleeding, mucopurulent discharge, ulceration in severe cases
- Microscopy of a rectal smear, rectal culture for *N. gonorrhoeae*
- NAAT for *N. gonorrhoeae*
- NAAT for *C. trachomatis* (if positive for *C. trachomatis*, genotyping for LGV should be requested)
- Swab for HSV-1, HSV-2
- *T. pallidum* PCR
- Serology for syphilis and HIV
- LGV should be considered in GBMSM with suspected inflammatory bowel disease, as the clinical presentation can be very similar
- Cultures for enteric pathogens should be performed if symptoms of enteritis are present

[a] The most common sexually transmitted causes of proctitis.
[b] Outbreaks occurring in Europe in gay, bisexual, and other males who have sex with males (GBMSM).
[c] Rarer causes than *N. gonorrhoeae* and *C. trachomatis*; mainly seen in GBMSM.
HSV, Herpes simplex virus; *LGV,* lymphogranuloma venereum; *NAAT,* nucleic acid amplification test; *PCR,* polymerase chain reaction.

can cause proctitis. Reactive arthritis (see Chapter 32) can occur with *C. trachomatis* infection, particularly in human leucocyte antigen B27–positive individuals.

Diagnosis

Nucleic acid amplification tests (NAATs) are the diagnostic tests of choice with sensitivities of 95% to 99%. In males, first-voided urine (FVU) samples are used. In females, vulvovaginal swabs (VVSs) are used. FVU samples in males and self-taken VVSs are non-invasive, meaning they can be obtained by the patient without the need for an examination, so they are ideal for asymptomatic chlamydia screening. GBMSM who practice receptive anal sex and receptive oral sex should have rectal and pharyngeal swabs for *C. trachomatis* NAAT performed.

Management

Doxycycline 100 mg orally twice daily for 7 days is recommended for uncomplicated infection; oral azithromycin 1 g stat followed by 500 mg/day for 2 days is used if doxycycline is contraindicated. Azithromycin is recommended in pregnancy and lactation in WHO, US, UK and Australian guidelines. Doxycycline is contraindicated in pregnancy. Longer courses of antibiotics are required for complicated infections (see PID and epididymo-orchitis later). Epidemiological treatment before test result availability is usually offered to those who have had recent sex with someone who has confirmed *C. trachomatis* infection because the infection rate can be up to 75%. Abstinence from sex for at least 7 days or until treatment is completed should be advised. Sexual contacts must be traced, notified, and treated because many infections are asymptomatic. A follow-up consultation (usually by telephone) should assess adherence to therapy and partner notification. A routine test of cure is not necessary except in pregnancy, in complicated infections, and if symptoms persist or re-infection is suspected. NAAT results may remain positive for some time after treatment because they detect non-viable organisms, so a test of cure should be deferred until 4 weeks after completion of treatment.

Gonorrhoea

Neisseria gonorrhoeae is a Gram-negative intracellular diplococcus (see Fig. 43.4) that infects the urethra, endocervix, rectum, pharynx, and conjunctiva. Up to 10% of males and 50% of females are asymptomatic. Co-infection with *C. trachomatis* is common, occurring in 20% to 40% of gonococcal infections.

Clinical features

The incubation period is 2 to 14 days, and most symptoms in males occur between 2 and 5 days.

In males, *N. gonorrhoeae* can cause anterior urethritis with mucopurulent or purulent urethral discharge and dysuria (Fig. 43.5). The discharge can be profuse, causing staining of underwear. Complications include ascending infection, leading to epididymo-orchitis.

In females, symptoms may include increased vaginal discharge, dysuria, postcoital or intermenstrual bleeding, and lower abdominal pain. Examination of the cervix may reveal mucopurulent or purulent cervicitis or contact bleeding. Complications include Bartholin's abscesses, and ascending infection into the uterus and fallopian tubes causes endometritis and acute salpingitis (PID). In pregnancy, *N. gonorrhoeae* is associated with preterm birth, postpartum infection, and neonatal purulent conjunctivitis caused by vertical transmission during vaginal delivery.

Rectal infection, through receptive anal sex, or via spread from the cervix or via the vagina in females, may be asymptomatic but can cause proctitis. *N. gonorrhoeae* septicaemia (disseminated gonococcal infection [DGI]) is a rare complication presenting as fever, tenosynovitis, arthritis, and characteristic erythematous skin lesions with necrotic centres.

Diagnosis

NAATs are the diagnostic test of choice for *N. gonorrhoeae* because they have better sensitivity than culture. However, as *N. gonorrhoeae* antimicrobial resistance is increasing and ceftriaxone-resistant isolates have been identified in the UK and globally, culture on selective media should be performed before any treatment for

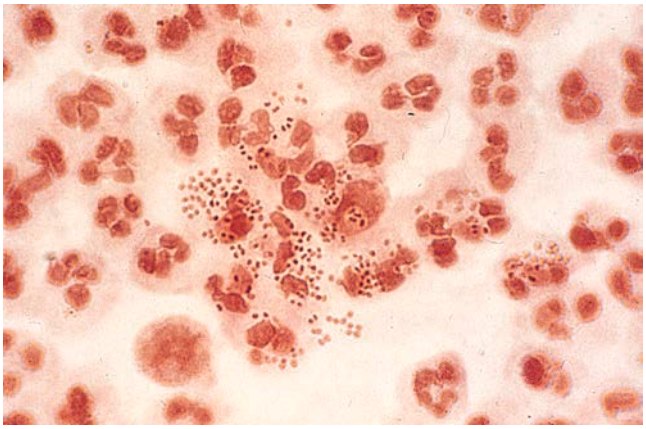

Fig. 43.4 ***Neisseria gonorrhoeae.*** Gram-negative intracellular diplococci. *(Courtesy Dr B. Goh.)*

Fig. 43.5 ***Neisseria gonorrhoeae.*** Mucopurulent urethral discharge.

N. gonorrhoeae being given. The specimens of choice for *N. gonorrhoeae* NAATs are FVU samples in males and VVSs in females. Self-taken VVSs are as sensitive at detecting *N. gonorrhoeae* as clinician-taken VVSs. FVU samples are less sensitive than VVSs in females. FVU samples in males and self-taken VVSs in females are non-invasive and therefore ideal for asymptomatic screening. GBMSM who practice receptive anal and receptive oral sex should have rectal and pharyngeal swabs for *N. gonorrhoeae* NAATs. Urethral swabs in males and endocervical swabs in females and rectal and pharyngeal swabs are used for culture.

Microscopy of Gram-stained urethral and endocervical secretions may demonstrate intracellular, Gram-negative diplococci, allowing rapid diagnosis (see Fig. 43.4). Sensitivity ranges from 90% to 95% in urethral specimens from symptomatic males to 37% to 50% in endocervical specimens. Microscopy should not be used for pharyngeal specimens because non-pathogenic *Neisseria* spp. colonize the mouth and look identical to *N. gonorrhoeae* microscopically. The sensitivity of blood and synovial fluid cultures is poor, so NAATs from the genital tract, rectum, and pharynx remain the tests of choice for investigations of DGI.

Management

Treatment should be given to those who have positive microscopy, a positive NAAT, or a positive culture for *N. gonorrhoeae*. Antibiotic-resistant strains of *N. gonorrhoeae* are increasing, so gonococcal culture for antibiotic susceptibility testing should be taken before treatment. Resistance to all the commonly used antibiotics has been reported in the UK, but ceftriaxone resistance is very rare. When antimicrobial susceptibility is not known before treatment, single-dose ceftriaxone 1 g intramuscularly (i.m.) is recommended in the UK. If confirmed susceptibility at all suspected sites of infection is known in advance of treatment, oral ciprofloxacin 500 mg single dose can be used. If there is a history of penicillin anaphylaxis or established cephalosporin allergy, gentamicin 240 mg i.m. should be used in combination with oral azithromycin 2 g. Ceftriaxone, gentamicin, and azithromycin can be used in pregnancy. Longer courses of antibiotics are required for complicated infections (see PID and epididymo-orchitis later) and DGI. Epidemiological treatment (treatment based on known exposure) pending test results can be offered to those who have had sex within the past 14 days with those who have confirmed *N. gonorrhoeae* infection. Abstinence from sex for at least 7 days or until treatment has been completed should be advised. All sexual contacts should be notified, tested, and treated if positive. A follow-up assessment and test of cure using *N. gonorrhoeae* NAAT should take place 14 days after treatment. This can be done using postal testing.

Non-gonococcal urethritis and *Mycoplasma genitalium*

Non-gonococcal urethritis (NGU) in males is characterized by a urethral discharge and dysuria. There are several causes, many of which are sexually transmitted; the most common of these is *C. trachomatis*, discussed earlier. Up to 25% of NGU cases may be caused by *Mycoplasma genitalium*. Other causes are *Ureaplasma urealyticum*, *Trichomonas vaginalis*, adenoviruses, and herpes simplex virus (HSV) 1 and 2, in that order of frequency. Studies investigating the cause of NGU have consistently identified no known cause in more than 60% of cases. Non–sexually transmitted causes of NGU include urinary tract infections (UTIs) and strictures.

Clinical features

The incubation period is usually 2 to 3 weeks. The main symptom is a mucopurulent urethral discharge (worse on waking when there may be crusting at the meatus). Dysuria is common but not universal. Discomfort or itching within the urethra may be present.

Diagnosis

Microscopy of Gram-stained urethral secretion showing five or more polymorphonuclear leucocytes per high-power (×1000 oil-immersion lens) field is diagnostic. Symptomatic males with no microscopic evidence of urethritis should be re-examined and tested after holding their urine overnight. Males with symptoms of urethritis should have NAATs for *N. gonorrhoeae*, *C. trachomatis*, and *M. genitalium* on an FVU sample. *M. genitalium*–positive specimens should be tested for macrolide resistance mutations because a high percentage of infections are macrolide resistant. Testing for *T. vaginalis* and HSV is only usually performed in persistent or recurrent NGU. There is no commercial test available for *U. urealyticum*. A midstream specimen of urine (MSU) should be taken if symptoms are suggestive of a UTI (urinary frequency, nocturia, urgency, haematuria).

Management

First-line therapy for NGU is oral doxycycline 100 mg twice daily for 7 days. Abstinence from sex for at least 7 days should be advised.

All sexual contacts should be notified, tested, and treated. If the patient is *M. genitalium* positive, and macrolide sensitive, azithromycin 1 g orally as a single dose followed by 500 mg/day for 2 days should be started within 2 weeks of finishing doxycycline. If the patient is *M. genitalium* positive and macrolide resistant, oral moxifloxacin 400 mg/day for 7 days should be given. This additional treatment is not needed if the *M. genitalium* NAAT result is negative. Follow-up is indicated if *C. trachomatis* or *M. genitalium* is confirmed or if symptoms persist.

Recurrent or persistent non-gonococcal urethritis

This is defined as persistent or recurrent symptomatic urethritis occurring 30 to 90 days after treatment of acute NGU and occurs in 10% to 20% of cases. The aetiology is probably multifactorial, but *M. genitalium* and *T. vaginalis* are likely causes. It is necessary to ensure that there is still microscopic evidence of urethritis, that there was good adherence to NGU treatment with sexual abstinence, and that sexual partners were also treated. If there is no microscopic evidence of urethritis, patients should be reassured and further antibiotic therapy avoided. If microscopy confirms persistent or recurrent NGU, subsequent treatment needs to cover *M. genitalium* and *T. vaginalis*. The recommended treatment is azithromycin 1 g orally as a single dose followed by 500 mg/day for 2 days with oral metronidazole 400 mg twice daily for 5 to 7 days. If the patient is *M. genitalium* positive and macrolide resistant or if treatment with azithromycin has already failed, oral moxifloxacin 400 mg/day for 7 days should be given. Current sexual partners of those infected with *M. genitalium* should also be tested and treated if positive with the same antibiotic regimen as their sexual partner. Abstinence from sex until both have finished their treatment should be advised. All who were *M. genitalium* positive should have a test of cure 5 weeks after the start of treatment.

Pelvic inflammatory disease

PID results when infections ascend from the cervix or vagina into the upper genital tract. It includes endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It is most frequent in sexually active females aged younger than 25 years. *C. trachomatis* and *N. gonorrhoeae* account for about 25% of UK cases and *M. genitalium* for 10% to 13% of cases. The anaerobic bacteria associated with bacterial vaginosis (BV) have also been implicated in incident PID. However, even in laparoscopically proven PID, often no bacterial cause is found. PID has serious long-term sequelae because of tubal damage and pelvic adhesions, resulting in infertility, increased risk of ectopic pregnancy, and chronic pelvic pain. The risk of sequelae increases with more severe and multiple episodes of PID. Tubal infertility occurs in 10% to 12% after one episode of PID and increases to 50% to 60% after three or more episodes. The risk of ectopic pregnancy is increased 6- to 10-fold, and abdominal or pelvic pain for longer than 6 months occurs in 18%.

Clinical features

The onset of symptoms often occurs in the first part of the menstrual cycle. Lower abdominal pain, which is usually bilateral, is the most common symptom. Other symptoms include increased vaginal discharge, irregular bleeding, deep dyspareunia, and dysuria. There may be a mucopurulent cervical discharge with contact bleeding. Lower abdominal tenderness and adnexal and cervical motion tenderness on bimanual examination are the most common signs.

Diagnosis

The diagnosis is usually made on the clinical findings of lower abdominal pain, with increased vaginal discharge, abnormal bleeding, and cervical motion or adnexal tenderness on bimanual examination supporting the diagnosis. However, clinical diagnosis has a specificity of only 65% to 70%. The differential diagnosis includes ectopic pregnancy, acute appendicitis, endometriosis, UTI, and irritable bowel disease.

Investigations should include:

- Microscopy of Gram-stained vaginal discharge for BV
- Microscopy of an endocervical specimen for evidence of inflammatory cells and intracellular, Gram-negative diplococci suggestive of gonorrhoea
- NAAT and culture for *N. gonorrhoeae*
- NAAT for *C. trachomatis* and *M. genitalium*
- Pregnancy test to exclude ectopic pregnancy
- An MSU sample if UTI symptoms (urinary frequency, nocturia, urgency, haematuria).

Management

Early diagnosis and treatment reduce the risk of long-term sequelae, so empirical treatment should be started before microbiology results are known. A broad-spectrum antibiotic regimen is needed to cover the main bacterial causes. The recommended first-line treatment is single-dose ceftriaxone 1 g by intramuscular injection, with oral doxycycline 100 mg twice daily and oral metronidazole 400 mg twice daily for 14 days. If *M. genitalium* positive, oral moxifloxacin 400 mg/day for 14 days is the first-line treatment. Abstinence from sex for at least 14 days should be advised. All sexual contacts should be notified, tested, and treated.

Those with moderate or severe clinical findings should be reviewed within 2 to 3 days to ensure that they are improving on treatment. Lack of response requires further investigation and possible admission for intravenous therapy, surgical intervention, or both. Symptom resolution, adherence to therapy, and partner notification should be reviewed after 2 to 4 weeks.

Epididymo-orchitis

Acute epididymo-orchitis is a clinical syndrome consisting of pain, swelling, and inflammation of the epididymis that can extend into the testis. It is caused mainly by extension of infection from the urethra or the bladder. In males younger than 35 years, *C. trachomatis* and *N. gonorrhoeae* are the main causes, and *M. genitalium* may also be implicated. In males older than 35 years, it is more commonly a complication of a UTI. Mumps is a cause of epididymo-orchitis in non-immune males. The most common differential diagnosis is torsion of the spermatic cord, which is a urological emergency.

Clinical features

The typical presentation is subacute onset of unilateral scrotal pain and swelling. Although there may be symptoms of urethral discharge and dysuria, these are often absent. On examination, there is tenderness and usually palpable swelling of the epididymis. There may also be tenderness and swelling of the testicle, with oedema and erythema of the overlying scrotal skin. A urethral discharge may be present.

Diagnosis

The diagnosis is usually based on clinical features. The main differential diagnosis is testicular torsion.

Investigations

These include a NAAT and culture for *N. gonorrhoeae* and a NAAT for *C. trachomatis* and *M. genitalium*. If microscopy of Gram-stained urethral secretions shows 5 or more polymorphonuclear leucocytes per high-power (×1000 oil-immersion lens) field, this indicates the diagnosis is NGU. If intracellular Gram-negative diplococci are present, this is suggestive of *N. gonorrhoeae*. A urine dipstick test and an MSU should be done to confirm or exclude UTI.

Management

Because empirical treatment should be started before microbiology results are known, a broad-spectrum antibiotic regimen is needed to cover the main bacterial causes. In younger males, in whom an STI is the likely diagnosis, the recommended regimen is single-dose ceftriaxone 1 g i.m. with oral doxycycline 100 mg twice daily for 14 days. If the patient is *M. genitalium* positive, oral moxifloxacin 400 mg/day for 14 days should be given. When a UTI is the more likely diagnosis, oral ofloxacin 200 mg twice daily for 14 days should be prescribed. Abstinence from sex for at least 14 days should be advised. All sexual contacts should be notified, tested, and treated. Patients should be reassessed after 3 days if there is no improvement in their symptoms because this requires further investigations. All should be seen after 2 weeks to assess symptom resolution, adherence to therapy, and partner notification.

Bacterial vaginosis

BV is the most frequent cause of vaginal discharge during reproductive years. The historical prevalences are 9% of those attending cervical cytology screening and 15% of pregnancies. BV develops when *Gardnerella vaginalis* and other BV-associated bacteria (BVAB) displace the normal lactobacilli-dominant vaginal flora. There is increasing evidence that BV is associated with sex with new and multiple partners and that reducing unprotected sex may reduce incident and recurrent infections. BV in pregnancy is associated with an increased risk of miscarriage and preterm birth. BV also increases the risk of acquisition and transmission of HIV and other STIs and is associated with incident PID. Up to 50% of those with BV have no symptoms. It is not necessary to look for or treat asymptomatic BV.

Clinical features

The symptoms are an increased vaginal discharge and offensive fishy odour. On examination, there is a creamy-white homogeneous discharge, which may be slightly frothy (caused by the volatile amine production by the bacteria, which is responsible for the characteristic odour) (Fig. 43.6). Visible inflammatory changes are not seen with BV.

Diagnosis

The most accurate method of diagnosis is microscopy of Gram-stained vaginal discharge because the characteristic pattern of the BV bacteria is easily distinguished from the normal lactobacilli-dominant vaginal flora.

Diagnosis using clinical criteria is possible but is less sensitive and specific. All three of the following should be present for the diagnosis to be made:

- Characteristic creamy-white homogeneous vaginal discharge
- Raised vaginal pH of greater than 4.5 (measured using narrow-range pH paper)
- Characteristic fishy odour (which can be released by mixing vaginal discharge with 10% potassium hydroxide)

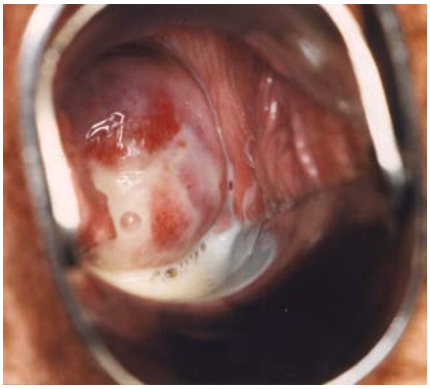

Fig. 43.6 Bacterial vaginosis. Homogeneous creamy-white vaginal discharge, which may be slightly frothy and adherent to the vaginal walls.

Commercial NAATS are available that detect combinations of BVAB, and these have similar sensitivity and specificity to microscopy. Many of the clinical symptoms and signs of BV are similar to *T. vaginalis*, so a *T. vaginalis* NAAT should be performed on those with recurrent BV to exclude undiagnosed *T. vaginalis* infection.

Management

The recommended treatment is oral metronidazole 400 mg twice daily for 7 days. A single dose of metronidazole 2 g can also be used but is less effective. Alternative topical treatments are intravaginal metronidazole 0.75% gel for 5 nights or intravaginal clindamycin 2% cream for 7 nights. High-dose metronidazole should be avoided in pregnancy, but the 7-day oral course can be safely prescribed, as can either of the intravaginal regimens.

BV recurrences are frequent, with about 50% experiencing a recurrence within 12 months of completing metronidazole therapy. Studies have identified male carriage of BVAB on the penis and urethra, suggesting that male partners may be re-infecting females with BVAB. A recent trial of simultaneous treatment of the male partner with oral metronidazole for 7 days did not reduce the rate of recurrence over placebo. However, small pilot trials of simultaneous treatment of the male partner with oral metronidazole for 7 days *plus* clindamycin cream applied to the penile skin have been associated with reduced recurrence in females; randomized trial data are awaited.

Candidiasis

Candida spp. are ubiquitous organisms and are not classified as STIs. Vulvovaginal *Candida* infection is extremely common with about 75% females having least one episode of symptomatic candidiasis in their lifetime. Predisposing factors for symptomatic infection include pregnancy, diabetes, broad-spectrum antibiotics, corticosteroids, and immunosuppression. *Candida albicans* causes 90% of vaginal yeast infections, with *Nakaseomyces glabrata* and other *Candida* species causing the remainder. Transient penile colonization (with penile rash) may occur following sex because of direct inoculation from the vagina.

Clinical features

In females, the main symptom is vulval itching. An increased thick, white vaginal discharge; vulval burning; external dysuria; and superficial dyspareunia may also be present. On examination, there may be the typical white, curdy, adherent plaques on the vaginal walls, but the amount and consistency of the discharge may look normal (Fig. 43.7).

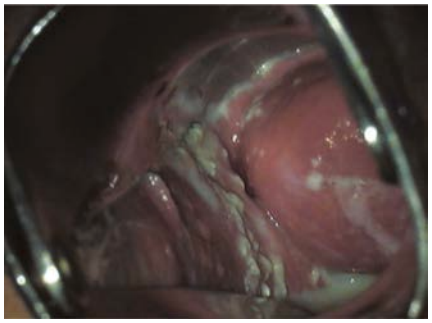

Fig. 43.7 Candidiasis. Adherent plaques of discharge on the vaginal walls.

In males, there may be a transient penile irritation and rash immediately after sex, but some experience more persistent balanoposthitis. On examination, there may be erythema of the foreskin and glans penis or a spotty, red, itchy rash on the glans with an accumulation of white discharge under the foreskin. In severe cases, there may be fissuring and phimosis of the foreskin.

Diagnosis

Microscopy of a Gram-stained vaginal or subpreputial smear identifies fungal pseudohyphae and spores in about 50% of cases of candidiasis. Culture of vaginal or subpreputial swabs has almost 100% sensitivity. Diabetes should be excluded in males with severe balanoposthitis.

Management

There are several short-course oral and intravaginal antifungal agents available, all with efficacies of 80% to 85%. Recommended treatments are the oral triazole drugs (e.g., fluconazole 150 mg as a single dose or itraconazole 200 mg twice daily for 1 day) and intravaginal imidazole pessaries or creams (e.g., clotrimazole pessary 500 mg as a single dose, miconazole vaginal ovule 1.2 g as a single dose, econazole pessary 150 mg nightly for 1–3 nights). These treatments can be supplemented with antifungal cream applied to the vulva. Males can be treated with either oral therapy or topical antifungal cream. Nystatin pessaries 200 000 units nightly for 14 nights are the treatment of choice for *N. glabrata* and other non-*albicans* yeasts. Intravaginal treatments are safe in pregnancy, but oral antifungal agents should be avoided.

Recurrent candidiasis (four or more symptomatic episodes in 1 year) occurs in up to 5% of females. It frequently requires weekly oral fluconazole 150 mg or clotrimazole pessary 500 mg for up to 6 months to prevent recurring symptoms. There is no evidence that treatment of sexual partners reduces recurrence, so partners do not need treatment unless they also have symptoms.

Trichomoniasis

T. vaginalis infection is the most common STI worldwide, though it is rarer in Western Europe and Australasia. The organism is a flagellated protozoon that is sexually transmitted. In females, it infects the vagina and urethra, and in males the urethra and subpreputial sac. *T. vaginalis* in pregnancy is associated with an increased risk of preterm birth and low birth weight, and it increases the risk of acquisition of HIV.

Clinical features

In females, 10% to 50% are symptomatic. The most common symptoms are an increased purulent vaginal discharge and malodour. There may also be vulval pruritus, external dysuria, and dyspareunia. On examination, there may be vulval erythema with inflamed vaginal mucosa. The discharge is yellow or grey and frothy and can be profuse. The cervix may have multiple small haemorrhagic areas, which have given rise to the description 'strawberry cervix'.

In males, the majority have no symptoms, although they may experience urethral discharge, irritation, and dysuria.

Diagnosis

Phase-contrast microscopy of vaginal discharge identifies the motile protozoa in up to 50% of infected females. The sensitivity of microscopy of urethral discharge in males is much lower. Culture detects 70% to 80% of infections. NAATs are the diagnostic tests of choice with VVSs in females and FVU in males detecting more than 90% of infections.

Management

The treatment of choice is oral metronidazole 400 mg twice daily for 7 days. Single-dose oral metronidazole 2 g can be used but is less effective. Because *T. vaginalis* infects areas beyond the vagina (e.g., the urethra), intravaginal metronidazole gel has poor cure rates and should not be used. Abstinence from sex for at least 7 days should be advised. All sexual contacts should be notified, tested, and treated. Tests of cure are recommended only if the patient remains symptomatic after treatment or if symptoms recur.

Occasionally, *T. vaginalis* can become resistant to metronidazole and other nitroimidazoles. This is usually relative rather than absolute resistance and may be overcome by high-dose metronidazole or tinidazole therapy.

Human papillomavirus (anogenital warts)

Anogenital warts are painless, benign, epithelial tumours, and a common STI. The causative agents are human papillomavirus (HPV) types 6 and 11. Genital HPV infection is acquired by direct skin-to-skin contact during sex with a person who has either clinical or subclinical infection. Subclinical infection is very common and 15% to 64% of those infected will develop warts.

Warts caused by HPV 6 and 11 do not undergo malignant transformation. The main oncogenic HPV types are 16 and 18. These lead to subclinical infection, not genital warts, and cause anogenital pre-malignant conditions and cancers. Neonates may acquire HPV from an infected birth canal, which may result either in anogenital warts or laryngeal papillomatosis.

Clinical features

Anogenital warts have a long incubation period; the average is 3 months, but it can extend to years. The warts first appear at sites of trauma during sex. In males, this is around the prepuce and glans; from there, they can spread to the urethra and down the penile shaft. In females, they usually start at the fourchette and then spread to the vulva and perineum (Fig. 43.8). Perianal lesions are common and not necessarily associated with receptive anal sex because subclinical HPV often affects the whole anogenital area. However, perianal lesions do occur most frequently in GBMSM. Warts on mucous membranes tend to be soft and non-keratinized, whereas those on the hair-bearing skin tend to be firm and keratinized. Warts tend to increase in size and number during pregnancy and in patients who are immunosuppressed.

Diagnosis

The diagnosis is made on clinical appearance. HPV testing is not indicated for diagnosing anogenital warts. The main differential

Fig. 43.8 **Genital warts on the fourchette and perineum.**

diagnoses are molluscum contagiosum and the condylomata lata of secondary syphilis. Atypical lesions should be biopsied, particularly in older patients, because pre-malignant and malignant lesions can look similar to warts. Investigations should include NAAT for *N. gonorrhoeae* and *C. trachomatis* and serology for syphilis and HIV because co-infection with other STIs is common.

Management

Several treatments are available for patients with anogenital warts but all have significant failure and relapse rates. Topical podophyllotoxin (0.5% solution or 0.15% cream used twice daily for 3 consecutive days per week) acts as a cytotoxic agent and is recommended first-line. If warts are still present after 8 weeks of treatment, imiquimod, which enhances the local immune response when applied to skin infected with HPV (5% cream used daily, three times a week), is recommended. If warts persist after 16 weeks of imiquimod, ablative treatments such as cryotherapy (1–2-weekly for a maximum of 4 treatments) or electrocautery should be used. Podophyllotoxin and imiquimod have the advantage of being self-applied home therapies.

Podophyllotoxin and imiquimod are not used in pregnancy. Poorer responses to treatment can occur in pregnancy, those living with HIV, and those who are immunosuppressed.

Smoking is associated with reduced clearance of HPV, so smoking cessation advice should be given. The use of condoms should be advised to protect against transmission of HPV infection and genital warts. Follow-up is recommended if warts are still present at the end of treatment.

Prevention and vaccination

There are very effective vaccines against HPV:

- A quadrivalent vaccine protects against types 6, 11, 16, and 18, which covers the most common high-risk types and those that cause genital warts.
- A vaccine protecting against nine virus types, which contains the same HPV antigens as the quadrivalent vaccine plus five additional high-risk types (31, 33, 45, 52, and 58), is currently used in the national vaccination programme in the UK.

In the UK, vaccination of females aged 12 to 13 years commenced in 2008 to prevent cervical cancer. Because the oncogenic genital HPVs are transmitted through sex, it also provided some indirect protection to males. However, increasing evidence of high levels of HPV-associated cancers and genital warts in GBMSM (who gain no indirect benefit from female vaccination) prompted a successful pilot study to assess the feasibility and cost-effectiveness of a national HPV vaccination programme for GBMSM delivered through sexual health clinics. In 2018 the programme for GBMSM aged 45 years or younger attending sexual health or HIV clinics was introduced, and in 2019 vaccination of males aged 12 to 13 years also commenced. HPV vaccines are highly effective, and only one dose is needed to confer life-long protection if given before the age of 25 years. If given between 25 to 45 years, two doses are needed 6 months to 2 years apart. People who are immunosuppressed (e.g., PLWH) require three doses ideally given within a 12-month period. Between 2015 and 2019, diagnoses of genital warts in 15- to 17-year-olds declined by 91% in females and 81% in males in England.

Molluscum contagiosum

Molluscum contagiosum is a large DNA virus. It causes small (typically 2–5 mm in diameter), benign, smooth papules with central umbilication. It is spread via direct skin-to-skin contact. When transmitted sexually, the lesions are usually multiple and present on the labia majora, penile shaft, pubic region, lower abdomen, and upper inner thighs.

Diagnosis

The diagnosis is made on the characteristic clinical appearance. Because this is a sexually acquired condition, investigations for other STIs should include NAAT for *N. gonorrhoeae* and *C. trachomatis* and serology for syphilis and HIV.

Management

Molluscum infection is often self-limiting, resolving naturally within 6 to 18 months on average in immunocompetent individuals. Treatment options, if required, are cryotherapy or podophyllotoxin cream, which has the advantage of being a self-applied home therapy. Patients should be advised about the risks of auto-inoculation of the virus and discouraged from shaving or waxing pubic hair to prevent further spread. No routine follow-up or partner notification is required unless other STIs are identified.

Herpes simplex

Genital herpes is the most common cause of genital ulceration in all countries worldwide. The peak incidence for primary infection is in 16- to 24-year-old individuals. Females acquire the infection more frequently, probably because of the larger surface area of susceptible mucous membrane on the vulva. Transmission occurs from the mucous membrane of a person who is shedding HSV, many of whom will be asymptomatic. Only about 20% of people with serological evidence of genital herpes give a clinical history of herpes, suggesting that many individuals have subclinical infection.

Genital herpes can be due to HSV type 1 or type 2. It is possible to be co-infected with both. HSV-1 infection may be spread from an infected genital tract or from orolabial lesions via orogenital sex. HSV-2 is almost always transmitted via genital-to-genital contact. In the UK, more than 50% of primary HSV cases are caused by HSV-1.

During the primary infection, the virus ascends the peripheral sensory nerves supplying the area of inoculation and establishes latency in the dorsal root ganglia, thus allowing future reactivation and recurrences.

Clinical features

The ***initial episode*** is the first occurrence of either HSV-1 or HSV-2. This is subdivided according to prior exposure to the other HSV type.

Primary genital infection is the first ever exposure to either HSV type 1 or 2. It typically presents with multiple painful, shallow ulcers (Fig. 43.9). There is usually tender inguinal lymphadenopathy and systemic symptoms of viraemia, including fever, myalgia, and headache. In females, vulval pain and external dysuria occur. Cervical ulcers may be present and can have the appearance of a malignancy. Rectal infection may lead to severe proctitis with pain and bleeding; this is mainly seen in GBMSM. The lesions start to heal over a period of 10 to 21days, even without treatment. Neurological complications can include aseptic meningitis and autonomic neuropathy, leading to urinary retention. Primary infection can also be asymptomatic.

Non-primary genital infection occurs in people with previous HSV-1 or HSV-2 who then acquire the other type of genital HSV. There is some cross-protection from the prior HSV infection, resulting in a milder illness than in primary infection. Non-primary genital infections are more likely to be asymptomatic than primary infections.

Recurrent genital herpes is due to reactivation of previous HSV-1 or HSV-2 infection. HSV-2 recurs more frequently than HSV-1. The median recurrence rate in the subsequent year after a primary or non-primary infection is about one recurrence for HSV-1 and about four recurrences for HSV-2. The recurrences may be preceded by a prodrome of tingling, itching, or pain in the area. On examination, there are usually a few ulcers confined to a small area, and systemic symptoms are rare. Recurrences are not always symptomatic but are potentially infectious because of subclinical viral shedding. Long-term studies show that symptomatic recurrences and subclinical viral shedding gradually decrease with time.

The clinical presentation of primary infection in patients who are immunosuppressed and in pregnancy is usually more severe, with increased frequency of symptomatic and subclinical recurrences. Rarely, the infection can disseminate, causing a systemic life-threatening condition.

Genital herpes increases the acquisition and transmission of HIV and is a significant attributable risk in the spread of HIV. Many people with recurrent HSV develop psychological and psychosexual problems and fear rejection on disclosure of their infection to sexual partners.

Diagnosis

HSV DNA detection using polymerase chain reaction (PCR) on a swab taken from the ulcer is the diagnostic method of choice. This can distinguish between HSV-1 and HSV-2. Tests for other STIs should be performed, including NAAT for *N. gonorrhoeae* and *C. trachomatis* and serology for syphilis and HIV.

Blood tests for HSV type-specific antibodies can be used to diagnose prior HSV-1 and HSV-2 infections when the clinical history is suggestive of genital herpes but confirmation by HSV DNA detection has not been possible. The presence of HSV-2 antibodies is indicative of genital herpes, but the presence of HSV-1 antibodies cannot differentiate between genital and orolabial infections.

Management

Initial episode

Recommended oral antiviral therapies are aciclovir 400 mg three times daily, valaciclovir 500 mg twice daily, or famciclovir 250 mg three times daily, all for 5 days. Aciclovir is the drug of choice in pregnancy and breast-feeding. Supportive measures include cleansing with saltwater; topical anaesthetic agents; and in females with multiple ulcers and severe dysuria, immersing the genitals in a bath or a bowl of warm water to urinate. If lesions are already healing, antiviral therapy will have little added effect. Secondary bacterial infection occasionally occurs and should be treated with antibiotics.

The natural history of HSV infection should be explained, including recurrences, subclinical viral shedding, and the potential for sexual transmission with both of these. Patients should be advised to avoid sex during the prodrome and recurrences. Subclinical viral shedding is most common during the first 12 months after initial HSV-2 infection and in those with frequent symptomatic recurrences. Condoms and suppressive treatment reduce the risk of transmission from subclinical viral shedding, but neither completely prevents it. Consequently, disclosure should be advised in all relationships.

Recurrence

The appropriate management depends on the number and severity of recurrences. Because recurrences tend to be less severe and self-limiting, they can sometimes be managed with saltwater bathing and topical anaesthetic agents.

When recurrences are infrequent but severe, episodic antiviral therapy, started early by the patient, reduces the duration and severity but does not reduce the number of recurrences. Recommended episodic regimens of oral agents are shorter: aciclovir 800 mg three times daily for 2 days, famciclovir 1 g twice daily for 1 day or valaciclovir 500 mg twice daily for 3 days. Alternatively, 5-day courses can be used: aciclovir 400 mg three times daily, valaciclovir 500 mg twice daily, or famciclovir 125 mg twice daily.

Suppressive treatment

All people with recurrent HSV experience a reduction in recurrences on suppressive therapy. The decision whether to start suppressive treatment depends on the number of recurrences and the physical and psychological impact of these versus the inconvenience of taking daily treatment. Recommended oral regimens are aciclovir 400 mg twice daily, valaciclovir 500 mg/day, or famciclovir 250 mg twice daily for 12 months. Therapy should then be discontinued to assess the frequency of recurrences. If they are still frequent, suppressive treatment can be restarted. It is safe to continue suppressive treatment over many years. Frequent recurrences are associated with psychological and psychosexual morbidity; support and counselling are often needed.

Herpes simplex virus in pregnancy

The main risk of HSV in pregnancy is vertical transmission. Despite antiviral treatment, neonatal HSV has high morbidity and mortality.

An initial episode of genital HSV in late pregnancy poses the highest risk of transmission, and elective caesarean delivery is recommended, particularly for infection within 6 weeks of the expected delivery date. Daily suppressive therapy (oral aciclovir 400 mg three times daily) is recommended from 32 weeks' gestation until birth for those with initial episodes earlier in pregnancy to reduce recurrence, subclinical viral shedding, and the need for a caesarean delivery. In those at high risk of preterm delivery, aciclovir 400 mg twice daily should be started from 22 weeks' gestation followed by aciclovir 400 mg three times daily from 32 weeks'. The risk of neonatal herpes with recurrent HSV is small, even if lesions are present at the time of delivery, therefore caesarean delivery is not indicated for recurrent RSV, but daily suppressive aciclovir throughout the third trimester is recommended.

Syphilis

Syphilis is a systemic disease caused by *Treponema pallidum*, a motile spirochaete. It is mainly transmitted by direct contact with an infectious lesion and enters the new host through breaches in squamous or columnar epithelium, usually during sex. Primary infection of non-genital sites may occur but is rare. It can also be transmitted by infected blood products and vertically during pregnancy. Syphilis is classified as acquired or congenital.

Acquired syphilis is further subdivided into primary, secondary, and early latent (all also referred to as early or infectious syphilis, indicating that infection has been acquired during the previous 2 years); late latent (infection for more than 2 years); and tertiary syphilis (the most destructive stage, which includes cardiovascular and neurological syphilis and gummatous lesions of any organ).

Congenital syphilis is subdivided into early (diagnosed within the first 2 years of life) and late (diagnosed after the age of 2 years).

The incidence varies significantly with geographical location. It is more common in low- and middle-income countries. In high-income countries, it is mainly confined to GBMSM. The number of cases of infectious syphilis in England increased by 260% between 2013 and 2022, with most cases in GBMSM. Syphilis still affects large numbers of pregnancies worldwide. In 2016 an estimated 988 000 pregnancies were infected with syphilis worldwide, resulting in more than 350 000 adverse birth outcomes, including 200 000 stillbirths and newborn deaths. The global rate of congenital syphilis was 425 cases per 100 000 livebirths in 2020, which is way above the WHO's target of 50 cases per 100 000 livebirths.

Clinical features

Primary syphilis

Between 9 and 90 days (mean, 21 days) after exposure, a papule develops at the site of inoculation. This ulcerates to become a painless, firm ulcer (chancre). There is usually also painless regional lymphadenopathy. The primary lesion may go unnoticed, especially if it is on the cervix or within the rectum. Healing occurs spontaneously within 3 to 8 weeks.

Secondary syphilis

This occurs in 25% with untreated primary syphilis. Between 3 and 10 weeks after the appearance of the primary lesion, septicaemia leads to constitutional symptoms, including fever, sore throat, malaise, and arthralgia, though any organ may be affected. Meningitis, cranial nerve palsies (particularly 8th nerve palsy with hearing loss), uveitis, interstitial keratitis, and retinal involvement may all occur and represent early neurological disease. Hepatitis, nephritis, and arthritis have all been described.

Common signs include:

- Widespread skin rash (present in 75%), which can involve the whole body, including the palms and soles, typically, a non-itchy, maculopapular rash that may have a coppery colour (**Fig. 43.10**)
- Generalized lymphadenopathy (present in 50%)
- Condylomata lata, which are moist, wart-like plaques found in the perianal area and other moist body sites
- Mucosal lesions in the mouth and on the genitalia presenting as distinct mucous patches or becoming confluent to form 'snail-track ulcers'.

Without treatment, the symptoms and signs of secondary syphilis resolve but may recur, especially in the first year of infection.

Latent syphilis

Latent syphilis is diagnosed based on reactive syphilis serology in someone who has no symptoms and has not been treated. It is divided into:

- Early latent: within 2 years of infection acquisition (1 year in the USA); sexual transmission is possible
- Late latent: present for 2 or more years; sexual transmission does not occur

Latent syphilis may persist for years or may even be life-long.

Tertiary syphilis

About one-third of people with untreated latent syphilis develop tertiary syphilis within 5 to 30 or more years of contracting the infection. Gummatous syphilis (with inflammatory, granulomatous, destructive lesions) is the most benign and commonly involves the skin and bones, but lesions can occur in any organ. Cardiovascular syphilis causes aortitis, aortic regurgitation, aneurysm of the ascending aorta, and stenosis of the coronary artery ostia. Neurosyphilis causes chronic meningovascular damage and endarteritis of the small vessels of the brain and spinal cord, presenting as 'general paralysis of the insane' and tabes dorsalis.

Syphilis in pregnancy and congenital syphilis

Syphilis can be transmitted across the placenta at any stage of pregnancy. The risk of transmission is dependent on the stage of maternal infection and can be up to 100% in early syphilis and even up to 10% with late infection. The WHO estimates that untreated early syphilis in pregnancy results in rates of second-trimester miscarriage or stillbirth of 25%, preterm birth before 32 weeks' gestation of 13%, neonatal death of 11%, and congenital syphilis among the infants born of 20%. Detection and treatment of syphilis early

Fig. 43.10 Rash of secondary syphilis on the palms. *(Courtesy Dr B. Goh.)*

in pregnancy can prevent congenital syphilis and neonatal death at term and reduce adverse pregnancy outcomes.

Signs of early congenital syphilis occur in the neonatal period and include a rash, condylomata lata, mucous patches, nasal discharge, hepatosplenomegaly, and periostitis. Late congenital syphilis (after 2 years of age) can present with neurological or gummatous lesions but also includes the 'stigmata of congenital syphilis' which occur because early damage to developing structures, particularly teeth and bones. These include Hutchinson's teeth, sabre tibia, bossing of the frontal and parietal bones, and saddle nose.

Diagnosis

T. pallidum infection cannot be cultured, but it can be identified by dark-ground microscopy of secretions from a primary chancre or condylomata lata. Sensitivity is dependent on highly skilled microscopists. Most laboratories can test swabs from these lesions for *T. pallidum* using PCR. However, serological testing remains the main laboratory diagnosis.

Most laboratories use a treponemal enzyme immunoassay to detect immunoglobulin (Ig) G and IgM as a screening test. If the result of this is positive, a further treponemal test and a non-treponemal test are performed.

Treponemal tests

T. pallidum haemagglutination and *T. pallidum* particle agglutination assays are highly specific for treponemal disease but usually remain positive for life, even after treatment, so they are unable to differentiate between prior treated infection and re-infection.

Non-treponemal tests

The Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests become positive after about 6 weeks of infection. They are quantifiable tests that can be used to monitor treatment response and evidence of re-infection. They are not specific to syphilis, and false-positive results may occur in other conditions, particularly in other infections and autoimmune diseases.

Examination of the cerebrospinal fluid for evidence of late neurosyphilis is indicated in patients with positive syphilis serology who demonstrate neurological signs and symptoms.

Management

Treponemicidal levels of an antibiotic are required for at least 7 days in patients with early syphilis to cover the slow division time of the organism (30 hours). In those with late syphilis, treponemes may divide even more slowly, so a longer duration therapy is required. Ideally, a long-acting penicillin should be given i.m.

Early syphilis (primary, secondary, and early latent)

- Benzathine penicillin G 2.4 MU i.m. single dose
- Penicillin allergy: oral doxycycline 100 mg twice daily for 14 days

Jarisch–Herxheimer reaction (mild fever, malaise, and headache) is caused by release of inflammatory cytokines and occurs within 8 hours of treatment in 50% of patients with primary syphilis and up to 90% with secondary syphilis.

Late latent, cardiovascular[a], and gummatous syphilis

- Benzathine penicillin G 2.4 MU i.m. three doses at weekly intervals
- Penicillin allergy: oral doxycycline 100 mg twice daily for 28 days

[a]Forty to 60 mg oral prednisolone daily for 3 days should be started 24 hours before antibiotic treatment for cardiovascular and neurosyphilis.

Neurosyphilis (both early and late stages of infection)[a]

- Procaine penicillin 2.4 MU i.m. daily plus probenecid 500 mg orally four times daily for 14 days
- Penicillin allergy: doxycycline 200 mg twice daily for 28 days

Pregnancy

- Penicillin can be safely used in pregnancy; doxycycline should be avoided.

Syphilis and human immunodeficiency virus

The diagnosis and management of syphilis in people living with HIV remains unaltered; however, if it is untreated, it may advance more rapidly than in HIV-negative patients, and there is a higher incidence of neurosyphilis.

Prognosis and follow-up

Those being treated for early syphilis should abstain from sex for at least 14 days, and sexual contacts must be traced and investigated. There should be regular follow-up within the first year using repeat VDRL/RPR titres to establish the 'fourfold fall', which demonstrates adequately treated syphilis.

The prognosis of syphilis depends on the stage at which the infection is treated. Early syphilis has an excellent outlook, but when permanent damage has occurred in those with tertiary syphilis, it is irreversible, though further progression will be halted.

Lymphogranuloma venereum

LGV is an STI caused by the invasive serovars L1, L2, and L3 of *C. trachomatis*. It is endemic in several tropical areas, including southern Africa, India, South-east Asia, and the Caribbean, where it accounts for 2% to 10% of cases of genital ulcer disease. It used to be rare in Western Europe but since 2003 has become endemic among GBMSM, particularly in those living with HIV. There is no evidence of transmission of LGV within heterosexuals in Europe. The main presentation in GBMSM is with rectal symptoms; genital infections are rarely seen. LGV should be considered in GBMSM with suspected inflammatory bowel disease because the clinical presentation can be very similar, and the histological findings of LGV proctitis are similar to those of other causes of granulomatous proctitis, such as Crohn's disease. It is frequently associated with other STIs and acute hepatitis C infection.

Clinical features

There are three clinical stages. The primary lesion may be transient and is frequently unnoticed. In the genital area, it takes the form of a painless papule or shallow ulcer appearing at the area of inoculation 7 to 30 days after exposure. The main presentation in GBMSM is proctitis with symptoms of rectal pain, mucopurulent discharge, rectal bleeding, constipation, and tenesmus. Systemic symptoms such as fever and malaise may occur.

Secondary lesions are enlarged, tender regional lymph nodes. With genital LGV, they are usually unilateral and affect the inguinal and femoral nodes. When both are involved, the 'groove sign' develops because of the inguinal ligament separating the two enlarged lymph node systems. The nodes may become matted with bubo formation, which may rupture. With rectal infection, the affected nodes are in the pelvis, so they are not usually clinically apparent.

The tertiary stage is a chronic inflammatory response with tissue destruction. In the rectum, it can cause fistulae, strictures, and granulomatous fibrosis, mimicking Crohn's disease. There may also

be scarring of the genital area, and destruction of local lymph nodes can lead to genital lymphoedema.

Diagnosis

A swab should be taken from the genital ulcer base or from the rectal mucosa for *C. trachomatis* NAAT. If this is positive, genotyping for LGV should be performed. Testing for the other causes of genital ulcers (see **Box 43.6**) or rectal symptoms (see **Box 43.8**) should include a swab for HSV and *T. pallidum* PCR and serology for syphilis, which should be repeated after the 3-month window period. An mpox PCR test should also be considered if there are other features suggestive of this such as rash elsewhere and marked inguinal lymphadenopathy. A NAAT for *N. gonorrhoeae* and *C. trachomatis* on FVU (or a VVS) and serology for HIV should be performed. Serology for hepatitis C should be considered in GBMSM in view of the frequent co-infection of acute hepatitis C with LGV.

Management

The first-choice treatment is oral doxycycline 100 mg twice daily for 21 days or azithromycin 1 g weekly for 3 weeks. Patients should be advised to abstain from sex until completion of treatment. Sexual contacts should be notified, examined, tested, and treated. Follow-up should continue until all symptoms and signs have resolved, which is usually by 3 to 6 weeks.

Mpox

Mpox is a zoonotic infection, caused by the monkeypox virus, which is endemic in West and Central Africa. Before 2022, cases in the UK and Europe had been very rare, limited to people travelling from countries where mpox is endemic or contacts of imported cases. In May 2022, a case of mpox was identified in London, UK, in someone with recent travel history from Nigeria, where mpox is endemic. Shortly afterward, several other cases were confirmed in London with no travel links to mpox endemic countries, and mpox was made a notifiable disease in England in June 2022. Further cases were confirmed throughout the UK, Europe, and North America, in GBMSM who had recent sexual contact with new or multiple partners but no travel to endemic countries. Soon many countries and regions had reported infections, and most were from Clade IIb, B 1 lineage. In July 2022 the WHO declared the outbreak a public health emergency of international concern (PHEIC) because of the rapid spread around the world through new modes of transmission, which were not well understood. This triggered a global response to the outbreak to reduce the spread of the infection by rapid diagnosis and partner notification and by increasing immunity through administering pre-exposure smallpox vaccination, where available, to GBMSM. Smallpox vaccines provide about 85% effectiveness against mpox. Some immunological response to the first vaccine occurs within 2 weeks, which is still within the mpox incubation period, so post-exposure vaccination was also offered within 4 days of exposure to try to modify the severity of disease.

In May 2023 the WHO declared an end to the PHEIC because there had been steady progress in controlling the spread of the disease. By December 2023 there had been 92 976 confirmed cases with 172 deaths in 116 countries. Although there has been a global decline in cases, the threat has not disappeared, and there is still a high risk of mpox being imported from one country to another.

Clinical features

Mpox is transmitted by skin-to-skin contact or from body fluids including respiratory secretions. It can also be spread through fomites (e.g., clothing, bedding, towels) used by someone with mpox.

After an incubation period of 5 to 21 days, a rash appears often starting on the face and then spreading elsewhere, including the mouth, genitals, and anal area. The rash evolves from papules to blisters or pustules to scabbing blisters. This is accompanied by fever and systemic symptoms such as headache, myalgia, and malaise. Inguinal lymphadenopathy is often present with the nodes being larger than is usually seen with genital herpes and syphilis (which are the main differential diagnoses).

Diagnosis

Suspected mpox lesions should be swabbed for mpox PCR test. Testing for the other causes of genital ulcers (see **Box 43.6**) should include a swab for HSV and *T. pallidum* PCR tests and serology for syphilis, which should be repeated after the 3-month window period. A NAAT for *N. gonorrhoeae* and *C. trachomatis* on FVU (or a VVS) and serology for HIV should be performed.

Management

The symptoms from mpox are usually self-limiting and clear after 2 to 4 weeks. They can be managed with supportive care and pain relief. The patient should be advised to isolate at home in a separate room from family and pets until the rash has healed. Mpox in people living with HIV and other immunocompromised people can be severe and hospital admission, and antivirals may be needed.

Close household and non-household contacts of confirmed cases do not need to isolate but should avoid sexual or intimate contact with others for 21 days. Post-exposure smallpox vaccination can be offered if within 4 days of the contact to reduce transmission.

Chancroid

Chancroid is caused by *Haemophilus ducreyi*. It used to be one of the most common causes of genital ulcers worldwide, but its incidence has now decreased markedly. It is extremely rare in most countries except for North India and Malawi.

Clinical features

Chancroid has a short incubation period of 3 to 7 days. Tender papules develop at the site of inoculation, which rupture into painful, ragged-edged ulcers with necrotic bases that bleed easily. The usual sites of infection are the prepuce, glans penis, labia minora, and vulval fourchette. There is often painful inguinal lymphadenopathy, which can develop into large buboes that suppurate.

Diagnosis and management

Detection of *H. ducreyi* DNA using PCR is the most sensitive diagnostic test, but there are no commercial assays available for this. A 'probable diagnosis' may be made if the patient has the appropriate clinical presentation, without evidence of syphilis or HSV.

Testing for the other causes of genital ulcers should be undertaken (see **Box 43.6**) and should include an ulcer swab for HSV and *T. pallidum* PCR, an ulcer swab for *C. trachomatis* NAAT with genotyping for LGV if positive and serology for syphilis, which should be repeated after the 3-month window period. A NAAT for *N. gonorrhoeae* and *C. trachomatis* on FVU (or a VVS) and serology for HIV should also be performed.

Single-dose regimens include ceftriaxone 250 mg i.m. or azithromycin 1 g orally. Multiple-dose regimens are oral ciprofloxacin 500 mg twice daily for 3 days or oral erythromycin 500 mg four times daily for 7 days. Multiple-dose regimens should be used in PLWH because treatment failures have been reported with single-dose therapy. Patients should be advised to abstain from sex for at least

7 days and be followed up at 3 to 7 days, when the ulcers should be healing. PLWH should be monitored closely because healing may be slower. Sexual partners should be notified, examined, tested, and treated epidemiologically because asymptomatic carriage has been reported.

Donovanosis

Donovanosis (also known as granuloma inguinale) is exceedingly rare and is confined to a few countries in South-east Asia, southern Africa, parts of India, and South America. It is caused by *Klebsiella granulomatis*.

Clinical features

Nodules at the site of inoculation develop into friable, non-painful ulcers or hypertrophic lesions that increase in size.

Diagnosis and management

The diagnosis is made on the presence of Donovan bodies using Giemsa or silver stains in scrapings or biopsies of the lesions. Donovan bodies are the encapsulated intracellular Gram-negative rods of *K. granulomatis* visible within mononuclear cells. Screening for all other STIs should be undertaken.

Antibiotic treatment should be given for a minimum of 3 weeks and until the lesions have completely healed. Oral regimens include azithromycin 1 g weekly or 500 mg/day or doxycycline 100 mg twice daily. Patients should be advised to abstain from sex for at least 3 weeks and be followed up until the lesions have fully resolved. Sexual partners should be notified, examined, and treated if necessary.

Pediculosis pubis

The pubic louse *(Phthirus pubis)* can attach tightly to the pubic and coarse body hair. It can also attach to the eyelashes and eyebrows. It is host specific and is transferred by close bodily contact. Although infestation may be asymptomatic, the most common complaint is of itch caused by hypersensitivity to the louse bites.

Diagnosis and management

Lice may be seen on the pubic and body hairs. They resemble small scabs or freckles but can be seen moving. The eggs (nits) are laid at the hair base and are strongly adherent to the hairs. Screening for other STIs should include NAAT for *N. gonorrhoeae* and *C. trachomatis* and serology for syphilis and HIV.

Treatment should be applied to all areas of the body, including facial hair if present. Permethrin 1% should be left on for 10 minutes, and malathion 0.5% should be left on for 12 hours. A second application is usually advised after 7 days. Permethrin is safe in pregnancy. Sexual partners should be examined and treated if infected.

CORE SKILLS AND KNOWLEDGE

Major advances in the treatment of patients living with HIV infection have led to an increase in global prevalence, even as rates of new infection fall. Where people have consistent access to effective anti-retroviral therapy (ART), HIV infection has been transformed from a progressively debilitating life-limiting illness characterized by opportunistic infections into a chronic condition requiring life-long multidisciplinary care.

Key skills in this specialty include:

- Assessing people living with HIV and its consequences, including level of immunosuppression, as well as recognition of opportunistic infection and AIDS-defining conditions
- Understanding the principles of ART and the holistic approach to management of people living with HIV infection
- Understanding the role of coexisting clinical conditions on morbidity and mortality and health-related quality of life
- Discussing prevention interventions to ensure that people can avoid acquiring or transmitting HIV.

The best place to experience the care of people living with HIV is within specialist HIV services. In the UK, these are in secondary and tertiary care settings, commonly co-located with sexual health, genitourinary medicine, and infectious diseases. People hospitalized with HIV related conditions (e.g., people with late-stage HIV infection and opportunistic infections) offer opportunities to learn about advanced disease.

CLINICAL SKILLS

History

History taking in human immunodeficiency virus (HIV) medicine encompasses a patient's risk factors for HIV, including sexual history, current health status, and medications, as well as an understanding of barriers to healthcare access and treatment adherence. Presenting symptoms may include those of acute disease and advanced infection (**Box 44.1**).

Examination

Clinical examination focuses on overall health status and the detection of HIV-related complications when immunosuppression is present. Examination is likely to be dictated by the presenting symptoms but may also include examination of the following:

- Skin for dermatological manifestations of HIV (e.g., fungal infection, Kaposi's sarcoma [KS])
- Lymph nodes for lymphadenopathy caused by infection or malignancy
- Mouth for oral lesions associated with HIV (e.g., candidiasis, hairy leukoplakia, cytomegalovirus ulcers)
- Cardiovascular system for signs of cardiovascular disease that can be exacerbated by HIV and its treatments
- Respiratory system for infection
- Abdomen for organomegaly
- Genitourinary tract for genital lesions (e.g., ulcers, warts, or signs of other sexually transmitted disease)
- Neurological examination for cognition and for clinical signs of opportunistic disease in the central nervous system

Box 44.1 Symptoms relevant to HIV

Acute HIV infection

- Fever
- Malaise
- Myalgia
- Lethargy
- Sore throat
- Maculopapular rash

Advanced HIV with immunosuppression

- Systemic symptoms: fever, weight loss, anorexia
- Symptoms related to HIV end-organ damage: cognitive impairment, skin disease, weight loss, gastrointestinal disturbance, heart failure, kidney failure
- Symptoms of immunosuppression and associated infection or malignancy: fever, cough, breathlessness, diarrhoea, skin changes

- Mental health which can affect risk and adherence (e.g., depression, anxiety, substance abuse)
- Overall health: malnutrition and wasting can be seen in advanced disease.

Investigation

- Testing for HIV in the UK is:
  - Targeted (to those with risk factors for HIV and clinical presentations consistent with HIV)
  - Universal (e.g., all presentations to the emergency department, all pregnancies)
- Investigations for people living with HIV include:
  - Assessment of immunosuppression (viral load, CD4 count)
  - Tests of drug resistance
  - Investigations for complications of immunosuppression (e.g., infection, malignancy)
  - Investigations for side-effects of the medications used in HIV (e.g., liver function, kidney function, diabetes, and cardiovascular disease screening)

BACKGROUND

Human immunodeficiency virus (HIV) is a retrovirus that preferentially invades and destroys cells of the immune system by replication, in particular T lymphocytes. If untreated, the result is a state of profound immunodeficiency, leaving the individual susceptible to potentially fatal infections and neoplasms, acquired immunodeficiency syndrome (AIDS), and death. After it is acquired, HIV cannot be removed from the body, and no cure currently exists. Effective anti-retroviral treatment suppresses viral replication, preserves immune function, and prevents onward transmission. Although commonly used, the imprecise and potentially confusing term 'HIV/AIDS' should be avoided. AIDS is a clinical syndrome and HIV the causative agent. Most people diagnosed with HIV in the UK take effective treatment and do not have AIDS. A person-first approach to language is important, especially in HIV care. 'People living with HIV' is the preferred terminology.

HISTORY OF HIV

The history of HIV is shown in **Box 44.2**.

Box 44.2 The history of HIV

1981: Five reports made of *Pneumocystis carinii* pneumonia in California.
1982: First documentation made of AIDS.
1983: Causative agent identified and named lymphadenopathy-associated virus (LAV) in France. (Francoise Barre Sinnoussi and Luc Montagnier were later awarded the Nobel Prize for Medicine.)
1984: HTLV-III identified and shown to be identical to LAV.
1985: First commercial blood tests for the virus licensed in the UK, enabling better understanding of the major routes of transmission. This led to public health messaging and interventions, including condoms, heat treatment of blood products, needle exchange, and opiate replacement programmes.
1986: The International Committee on the Taxonomy of Viruses term the causative virus human immunodeficiency virus (HIV), replacing the interchangeable use of LAV and HTLV-III.
1987: The first HIV-specific drug, AZT (zidovudine), an inhibitor of reverse transcriptase, is licensed and introduced.
Early 1990s: Trials show that using two antiviral drugs in combination improves outcomes.
1994: Use of AZT in pregnancy is shown to significantly reduce vertical transmission of HIV.
1996: Three-drug combination therapy (HAART) using compounds from different drug classes (reverse transcriptase inhibitors and PIs) is shown to effectively suppress viral replication, reducing AIDS and mortality.
1999: Universal offer of an HIV test to all pregnant females is implemented in the UK.
2000: Universal access to effective therapy to combat HIV worldwide is adopted by the UN General Assembly.
2000–2010: Emphasis on HIV testing, shifting toward an opt-out model rather than an opt-in one. Equitable and universal access to diagnosis and treatment becomes a focus of global attention.
2014: UNAIDS set the 90-90-90 targets: 90% of those living with HIV know their HIV status, 90% of those diagnosed are taking effective therapy, and 90% of those on effective therapy having fully suppressed virus, aiming to end the global epidemic by 2030. These targets remain unachieved.
2019: UK national HIV Action Plan establishes the goals of achieving zero new HIV infections, AIDS, and HIV-related deaths in England by 2030. Key components are prevention of acquisition, prompt diagnosis, and improving the health and quality of life of people living with HIV.

AIDS, Acquired Immunodeficiency syndrome; *HAART,* highly active anti-retroviral therapy; *HTLVT-III,* human T-lymphotropic virus type III; *PI,* protease inhibitor; *UNAIDS,* United Nations Programme on HIV/AIDS.

EPIDEMIOLOGY

Since the first description of AIDS in 1981, more than 85.6 million people are estimated to have acquired HIV globally, and at least 40 million people have died. At the start of 2023, 39 million people worldwide were living with HIV infection of whom 29.8 million were accessing ART, up from 7.7 million in 2010.

Highly active ART has dramatically reduced mortality and morbidity for those who are able to access consistent care, transforming HIV from a universally fatal infection into a long-term, manageable condition. Additionally, those taking effective ART in whom viral suppression is maintained below the limits of detection ('undetectable') cannot pass the virus on to sexual partners, characterized as undetectable = untransmissible (U = U).

In 2014, the United Nations Programme on HIV/AIDS (UNAIDS) set global targets for a scale up in HIV diagnosis and treatment with the ambition of ending the AIDS epidemic by 2030. These '90-90-90' ambitions are that:

- 90% of all people living with HIV know their HIV status.

- 90% of people with diagnosed HIV infection receive sustained ART.
- 90% of all people receiving ART achieve viral suppression.

Very few countries reached the 90-90-90 by 2020, when the targets were revised upward to '95-95-95'. Data from 2022 show that of people living with HIV across the world, 86% (73%–98%) knew their status, 76% (65%–89%) were receiving treatment, and 71% (60%–83%) had suppressed viral loads. Despite significant scale up of diagnosis and treatment, the global response remains suboptimal with HIV continuing to have an impact, including some of the world's most vulnerable populations.

Globally, UNAIDS data show that new HIV infections have been reduced by 59% since the peak in 1995, and deaths by 38% since 2010. In 2022, around 1.3 million people newly acquired HIV compared with approximately 3.2 million people in 1995.

Although HIV is a global pandemic, there is considerable geographical variation, particularly in populations most affected, mode of transmission, and viral subtypes. Globally, 46% of all new HIV infections were in females in 2022. There remains considerable geographical diversity: across Eastern Europe, Central Asia, North Africa, and the Middle East, new infection rates continue to rise. HIV is a major contributor to the global burden of disease and remains in the top 10 causes of disability-adjusted life-years and death.

HIV in sub-Saharan Africa

Sub-Saharan Africa remains the region most significantly affected by HIV. Although southern and eastern Africa are home to 6.2% of the global population, this figure includes more than half of the world's population living with HIV, and 43% of new HIV infections each year occur in this region. The predominant route of HIV transmission in the region is through heterosexual sexual intercourse, with females being disproportionately affected. In 2022 females aged 15 to 24 years were more than three times more likely to acquire HIV than their male peers.

HIV in high-income countries

Although the rate of new diagnoses is falling in many high-income countries, the overall prevalence of HIV is rising. In the UK, new diagnoses declined from a peak in 2005 and plateaued in 2021 during the COVID-19 (severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2]) pandemic, with an uptick of new HIV diagnoses in 2022. Falling death rates coupled with continuing new infections mean that the total number of people living with HIV continues to rise. In 2021, 107 000 people in the UK were estimated to be living with HIV of whom around 5000 remain undiagnosed. Of those diagnosed, 99% were on treatment and 98% virally suppressed. Of those diagnosed with HIV in the UK, gay, bisexual, and other males who have sex with males (GBMSM) and heterosexual populations from sub-Saharan Africa are the two largest groups of people living with the infection; 30% are female.

Declining infection rates are largely driven by reductions in the GBMSM community because of a combination of factors, including condom use, increased and repeat testing, rapid initiation of effective therapy for those with positive HIV test results, and greater use of pre-exposure prophylaxis (PrEP) (see later). In heterosexual males and females, the rates of decline are not as impressive.

As mortality rates fall, the population living with HIV is becoming older. In the UK in 2022, 50% of adults accessing HIV care were aged 50 years or older compared with 28% in 2013. With increasing age, HIV care is complicated by multimorbidity and polypharmacy.

Late diagnosis is the most common cause of HIV-related morbidity and mortality in the UK. Although the number of people diagnosed late (CD4 count <350 cells/mm^3 within 3 months of diagnosis) declined from 52% in 2004 to 44% in 2022, this figure remains high. Reducing late diagnosis and undiagnosed HIV is critical to both individuals and public health. Increasing testing access in both sexual health and other care settings such as emergency medicine and primary care is a critical intervention, as is HIV testing in patients presenting with clinical conditions that are associated with HIV (indicator conditions). The UK Government HIV Action Plan has mobilized resources to expand HIV testing, although at the time of writing, this remains confined to areas of high HIV prevalence.

The changing face of the epidemic

With effective ART, increasing numbers of people living with HIV are living with long-term, sustained viral suppression. In countries where ART is consistently accessible, AIDS-defining illnesses have given way to non-communicable conditions as the major health problems for people living with HIV. Although chronic health conditions accumulate during the life course, higher levels of multimorbidity and polypharmacy occur in people living with HIV at a younger age compared with the general population, including frailty and its associated disabilities. Leading causes of hospital admission of people living with HIV are respiratory, psychiatric, cardiovascular, renal, and neurological disorders. Data from the UK show that 75% of those living with HIV have at least one other long-term condition, including mental health conditions, hypertension, lipid disorders, and diabetes. The prevention, identification, and treatment of co-morbidities through an integrated, outcomes-focused, person-centred approach are central to HIV care.

ACQUISITION

Routes of acquisition

Even though HIV can be isolated from a wide range of body fluids and tissues, most infections are transmitted either sexually via semen and cervical secretions or via blood. Transmission risk correlates to the HIV viral load, which is highest in acute infection and can be decreased to undetectable by effective ART. HIV-associated stigma and discrimination; gender-based violence; and in some countries, the legal position with respect to LGBTQ+ and other human rights for those at high risk can restrict access to appropriate services and increase the risks of transmission and disengagement from care.

There is no evidence that HIV is spread by casual social contact (kissing, holding hands), household contact (plates, cutlery, towels), or insects such as mosquitoes and bed bugs.

Sexual transmission (vaginal and anal)

Heterosexual sexual transmission accounts for most global infections. HIV is readily transmitted from male to female genital tracts and through anal sex. Coexistent sexually transmitted infections (STIs), especially genital ulceration, enhance transmission. However, when the viral load is undetectable there is zero risk of sexual transmission. Male circumcision has been shown to reduce both acquisition and transmission. In the UK, 29% of new diagnoses in 2022 were reported among GBMSM and 28% among females who have sex with males. In central and sub-Saharan Africa, the epidemic has always been heterosexual with most adults living with HIV in these regions being female. Central Asia, Eastern Europe,

the Middle East, and North Africa continue to see expanding epidemics, largely through heterosexual transmission and opioid use, exacerbated by high rates of STIs and cultural and legal constraints affecting those at most risk.

Vertical transmission (transplacental, perinatal, breast-feeding)

Globally, vertical transmission remains the most common route of HIV acquisition in children. European studies suggest that with no intervention, 15% of babies born to mothers living with HIV are likely to acquire HIV, although rates of up to 40% have been reported in Africa and the USA. Increased likelihood of transmission is associated with advanced disease in the mother, higher maternal viral load, prolonged rupture of membranes, and chorioamnionitis. Although transmission can occur *in utero*, most transmissions take place perinatally. Breast-feeding has been shown to double the risk of vertical transmission in the pre-treatment era; however, the risk is very low for females using effective ART. In high-income countries, combined interventions to reduce transmission, including opt out HIV screening during pregnancy, early use of ART, and replacement infant feeding have led to a dramatic fall in the numbers of children acquiring HIV. The vertical transmission rate has been below 0.4% in England since 2012, reducing from 2.86% in 2000 to 2001. The lack of universal access to these interventions in resource-poor countries where 90% of vertical infections occur is a major health inequality. Vertical transmission rates are now included in global monitoring frameworks to assess progress toward eliminating the HIV epidemic.

Contaminated blood, blood products, and organ donation

Screening of blood and blood products was introduced in 1985 in Europe and North America. Before this, HIV infection was associated with the therapeutic use of blood transfusion and clotting factors (in haemophilia). In some parts of the world where blood products may not be screened and in areas where the rate of new HIV infections is very high, transfusion-associated transmission continues to occur.

Contaminated needles

The practice of sharing needles and syringes for intravenous (i.v.) drug use continues to be a major route of HIV transmission in parts of South-east Asia, Latin America, and Eastern Europe. Successful education and needle exchange schemes have significantly reduced the rate of transmission by this route in the UK.

Iatrogenic transmission from reuse of needles and syringes in low- and middle-income countries is reported. Healthcare workers have a risk of approximately 0.3% after a single needle-stick injury from a person living with HIV, although data were obtained before widespread use of effective ART and the associated reduction in viral load.

VIRAL STRUCTURE

HIV belongs to the lentivirus group of retroviruses. There are two types, HIV-1 and HIV-2. HIV-1 is the most frequently occurring strain globally. HIV-2 is almost entirely confined to West Africa and European countries with colonial links to West Africa, particularly France and Portugal. HIV-2 has only 40% structural homology with HIV-1. Although associated with immunosuppression and AIDS, HIV-2 is more indolent than HIV-1. It is also less responsive to ART. The structure of HIV is shown in Fig. 44.1.

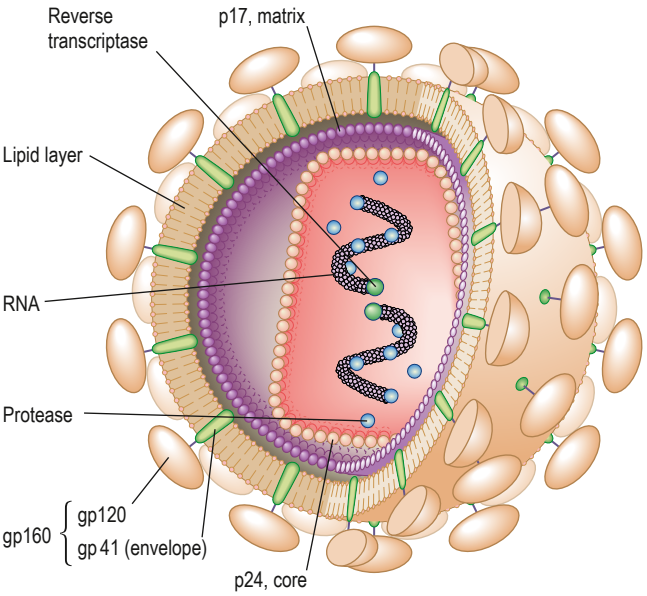

Fig. 44.1 Structure of HIV. Two molecules of single-stranded RNA are shown within the nucleus. The reverse transcriptase polymerase converts viral RNA into DNA (a characteristic of retroviruses). The protease includes integrase (p32 and p10). p24 (core protein) concentrations can be used to monitor HIV disease. p17 is the matrix protein. Glycoprotein 120 (gp120) is the outer envelope glycoprotein, which binds to cell surface CD4 molecules. gp41, a transmembrane protein, influences infectivity and cell fusion capacity.

Retroviruses are characterized by possession of the enzyme reverse transcriptase, which allows viral mRNA to be transcribed into DNA and incorporated into the host genome. Reverse transcription is an error-prone process that when combined with high viral turnover leads to considerable genetic variation and a diversity of viral subtypes or clades across the world. Based on DNA sequencing, HIV-1 is divided into four distinct strains, which represent four independent cross-species transfers: three (M, N, and O) are based on the chimpanzee-related strains of simian immunodeficiency virus (SIV), and one (P) may represent chimpanzee-to-gorilla-to-human transmission.

Group M (major) is the lineage that accounts for at least 98% of infections worldwide. Within the M group, there is a high degree of diversity, with subtypes (or clades), denoted A to K. Whereas there is a predominance of subtype B in Europe, North America, and Australia, areas of Central and sub-Saharan Africa have multiple M subtypes, clade C being most common. Recombination of viral material generates an array of circulating recombinant forms, which increase the genetic diversity. Recombinant forms are more common than non-recombinant forms in certain areas.

PATHOGENESIS

The relationship between the virus and the host defines pathogenesis. At the time of initial exposure, the virus is transported by dendritic cells from mucosal surfaces to regional lymph nodes where permanent infection is established, usually by one ‘founder virus’. The HIV surface glycoprotein 120 (gp120) is recognized by the CD4 T-cell, which is the main cell susceptible to infection. The interaction

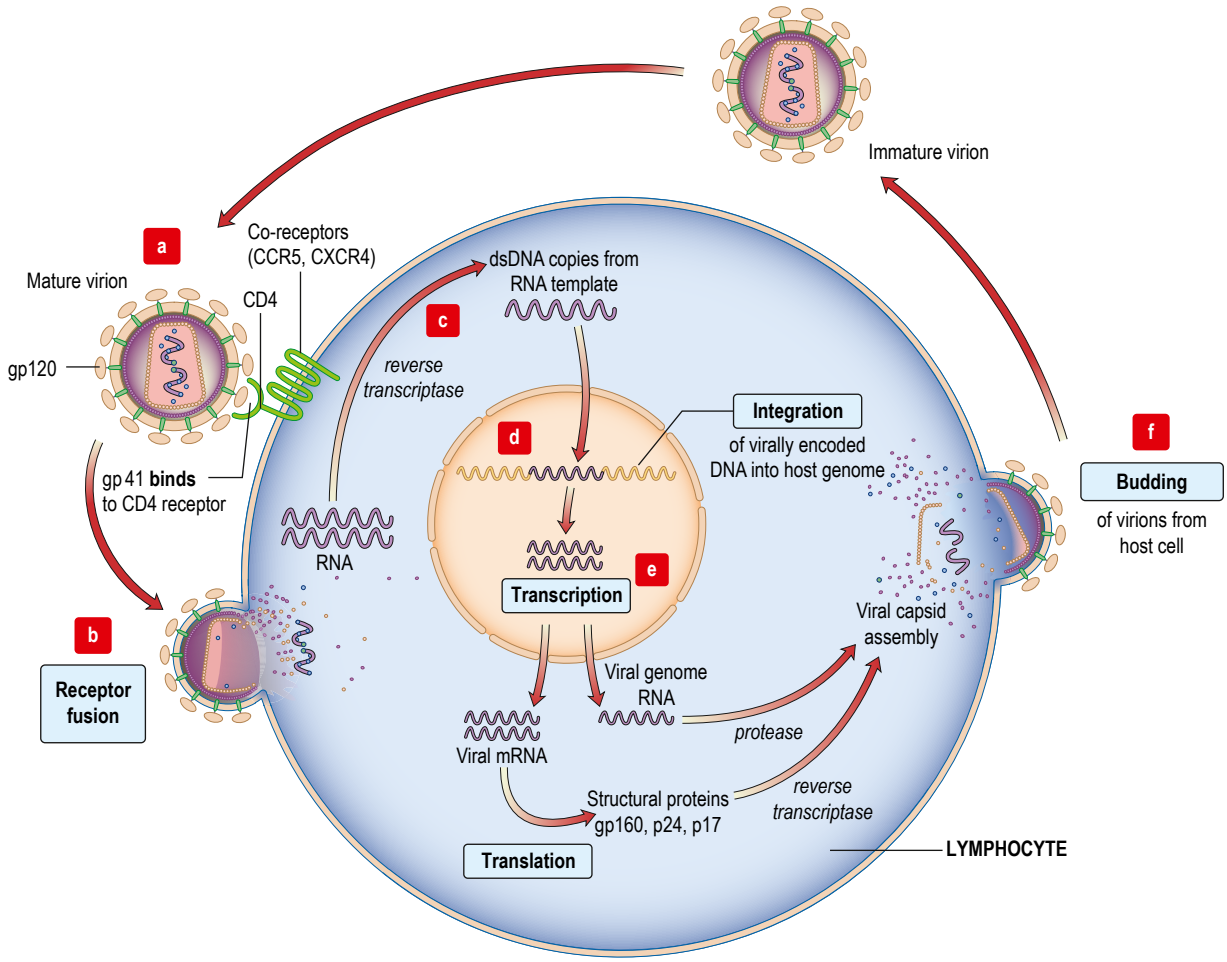

Fig. 44.2 Human immunodeficiency virus entry and replication in CD4 T lymphocytes. (a) ***Binding:*** the virus binds to host CD4 receptor molecules via the envelope glycoprotein gp120 and co-receptors CCR5 and CXCR4. **(b)** ***Fusion:*** a subsequent conformational change results in fusion between glycoprotein 41 (gp41) and the cell membrane. **(c)** ***Reverse transcription:*** entry of the viral capsid is followed by uncoating of the RNA. DNA copies are made from both RNA templates. DNA polymerase from the host cell leads to the formation of double-stranded DNA (dsDNA). **(d)** ***Integration:*** in the nucleus, virally encoded DNA is inserted into the host genome. **(e)** ***Transcription:*** regulatory proteins control transcription (an RNA molecule is now synthesized from the DNA template). **(f)** ***Budding:*** the virus is re-assembled in the cytoplasm and budded out from the host cell.

between CD4 and HIV gp120 surface glycoprotein, together with host chemokine CCR5 or CXCR4 co-receptors, facilitates entry into host cells (Fig. 44.2). Early infection is characterized by CCR5 CD4 memory T lymphocytes infection and depletion in the gastrointestinal (GI) tract. This compromises mucosal immune function, allowing microbial lipopolysaccharides to enter the circulation. HIV infection independent of CD4 receptors can occur in glial cells, monocytes, macrophages, and renal epithelial cells, leading to end-organ manifestations.

Studies of viral turnover have demonstrated a virus half-life of approximately 6 hours. To maintain plasma viraemia, 10^8 to 10^9 virus particles are released and cleared daily. Virus production by infected cells lasts for about 2 days and is probably limited by the death of the cell.

Progressive loss of activated CD4 T-cells due to killing by CD8 T-cells is a key factor in the immunopathogenesis of HIV. The production of broadly neutralizing antibodies occurs between 12 and 20 weeks after infection. These are usually clade specific but, in some people can be effective against several viral subtypes. Cell-mediated immunodeficiency from CD4 T-cell depletion leaves the person open to infections with intracellular pathogens, especially encapsulated bacteria.

HIV is also associated with immune activation, which leads to a long-term inflammatory state and is a key driver of co-morbidity. T-cell activation is observed from the earliest stages of infection, which leads to an increase in the numbers of CD4-bearing target cells susceptible to destruction. HIV itself is considered a pro-inflammatory state, with co-pathogens (e.g., cytomegalovirus [CMV]) and microbial translocation also implicated. Inflammation is demonstrated by raised concentrations of inflammatory cytokines (e.g., interleukin-6, D-dimer, and coagulation cascade activation). These pro-inflammatory phenomena contribute to HIV-associated end-organ damage, and co-morbidities, including cardiovascular disease, neuro-inflammation, and certain malignancies.

The spectrum of untreated HIV disease is broad; manifestations result from HIV-associated immune dysfunction, inflammation, co-morbidity, and co-infection. Most people living with HIV in high-income settings begin treatment early in the course of infection. With early initiation of ART and without immunosuppression, progression to an AIDS-defining event is rare. Without treatment,

Box 44.3 AIDS-defining conditions

- Candidiasis of the bronchi, trachea, or lungs
- Candidiasis, oesophageal
- Cervical carcinoma, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (1-month duration)
- CMV disease (other than of the liver, spleen, or nodes)
- CMV retinitis (with loss of vision)
- Encephalopathy, HIV-related
- Herpes simplex, chronic ulcers (1-month duration), or bronchitis, pneumonitis, or oesophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (1-month duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma (primary) of brain
- *Mycobacterium avium-intracellulare* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jirovecii* pneumonia
- Pneumonia, recurrent
- Progressive multifocal leucoencephalopathy
- *Salmonella* septicaemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome caused by HIV

CMV, Cytomegalovirus.

Box 44.4 Summary of the Centers for Disease Control and Prevention classification of HIV

Absolute CD4 count (/mm³)	A	B	C
	Asymptomatic or persistent generalized lymphadenopathy or acute seroconversion illness	HIV-related conditions[a], not A or C	Clinical conditions listed in AIDS surveillance case definition (see Box 44.3)
>500	A1	B1	C1
200–499	A2	B2	C2
<200	A3	B3	C3

[a]Examples of category B conditions include bacillary angiomatosis, candidiasis (oropharyngeal), constitutional symptoms, oral hairy leukoplakia, herpes zoster involving more than one dermatome, idiopathic thrombocytopenic purpura, listeriosis, pelvic inflammatory disease (especially if complicated by tubo-ovarian abscess), and peripheral neuropathy.
AIDS, Acquired immunodeficiency syndrome.

immunosuppression is progressive, opportunistic infections and tumours that meet the criteria for the diagnosis of AIDS (Box 44.3) are invariable, and the disease is fatal.

Several international HIV classifications exist, the two most frequently used being the WHO and Centers for Disease Control and Prevention classifications (Box 44.4). These classifications are used in public health monitoring and surveillance. Both classifications include a combination of immunological markers (e.g., CD4 count) correlated to the presence or absence of clinical AIDS-defining conditions.

Early disease: incubation and acute seroconversion illness

Early infection refers to the 6-month period after HIV acquisition and is marked by significant viral replication, resulting in very high concentrations of viraemia in the plasma and genital tract and consequently by high infectivity. This time is increasingly recognized as a key period for intervention, both to reduce long-term sequelae and to cut onward transmission.

The 2 to 4 weeks immediately after infection may be silent, both clinically and serologically. Alternatively, some people present with a self-limiting acute viral illness, which may be indistinguishable from glandular fever, which occurs 3 to 12 weeks after exposure. Symptoms include headache; fever; arthralgia; myalgia; lethargy; lymphadenopathy; sore throat; mucosal ulcers; and occasionally, a transient, faint pink, maculopapular rash. Neurological symptoms include photophobia; myelopathy; neuropathy; Guillain-Barré syndrome; and in rare cases, aseptic meningitis. The illness lasts up to 3 weeks, and recovery is usually complete. This is a crucial point for diagnosis of HIV; however, HIV is frequently not considered in the differential diagnosis in patients presenting with such non-specific viral symptoms, which is why in the UK routine HIV testing is recommended for presentations of acute mononucleosis.

Laboratory abnormalities in the early phase of infection include:

- Lymphopenia
- Atypical reactive lymphocytes on blood film
- Thrombocytopenia
- Raised liver transaminases
- Low CD4 lymphocytes
- Reversed CD4-to-CD8 ratio

Viral testing

Although antibodies to HIV may be absent during the earliest stages of infection, concentrations of circulating viral RNA are high, and p24 core protein may be detectable. HIV RNA polymerase chain reaction (PCR) may be positive within 10 days of exposure, with p24 antigen emerging a few days later. With increasingly sensitive assays, most people develop detectable antibodies within the first 2 to 4 weeks of early infection. Immunoglobulin (Ig) M antibodies followed by IgG antibodies usually appear at 2 to 6 weeks after infection. If early or acute HIV infection is suspected but standard diagnostic antibody test results are negative, repeat testing in 7 days and referral for expert advice are recommended.

In infants born to females living with HIV, maternal HIV antibody is passively transferred to the infants across the placenta and may persist in the absence of infection for up to 18 months. Nucleic acid testing is the preferred approach in infants younger than 18 months of age.

HIV antibody responses in early infection may be altered in people using antiviral PrEP, making RNA detection a more reliable indicator of early infection.

Clinical latency

The rate of clinical progression of untreated HIV is variable. Most people living with HIV are asymptomatic for years. While undiagnosed and untreated, the virus continues to replicate, leading to immunosuppression and risk of onward transmission. In most people, a gradual decline in CD4 count occurs over a period of approximately 10 years before progression to symptomatic disease or AIDS (Fig. 44.3). Others progress much more rapidly, with high concentrations of viral RNA and a rapid decline in CD4 count over 2 to 5 years. 'Long-term non-progressors' may continue with a normal CD4 count for decades. Within this group, a small subpopulation of 'elite suppressors' maintain a persistently undetectable viral load (usually defined as below 50 cpml) and a high CD4 count without taking ART. Older age is associated with more rapid progression. Sex and pregnancy do not appear to influence progression.

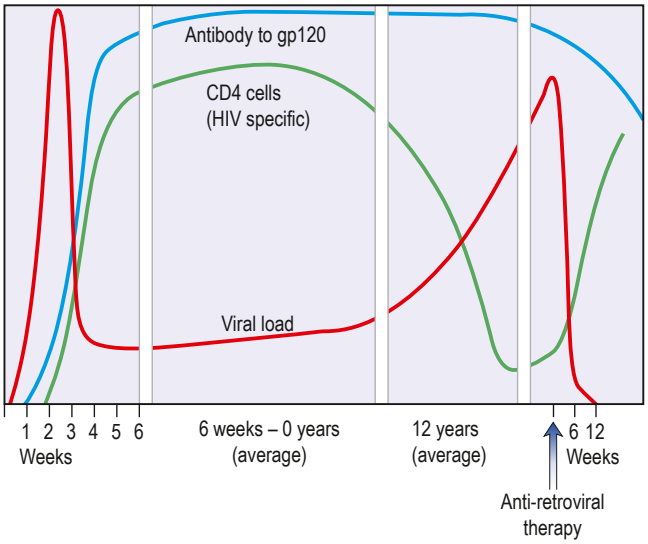

Fig. 44.3 The immune response to HIV (seroconversion).
gp120, Glycoprotein 120.

Persistent generalized lymphadenopathy

A subgroup of patients with asymptomatic infection has persistent generalized lymphadenopathy (PGL). This is defined as lymphadenopathy at two or more extra-inguinal sites for more than 3 months in the absence of other causes. The nodes are usually symmetrical, firm, mobile, and non-tender and may be accompanied by splenomegaly. Biopsy is rarely indicated but if undertaken reveals an architecture of follicular hyperplasia and endothelial proliferation. The presence of PGL does not seem to affect disease progression, although as the disease progresses, nodes may disappear.

SYMPTOMATIC HIV INFECTION

As immunosuppression worsens and the viral load rises, an array of symptoms and signs occurs. The clinical picture is caused by

- HIV-related end-organ disease
- HIV-associated immunosuppression

HIV-related end-organ disease

Neurological disease

Infection of the nervous tissue occurs at an early stage, and the likelihood of clinical neurological involvement increases with advanced disease. Manifestations include the following:

- AIDS dementia complex (ADC)
- HIV-associated neurocognitive disorder
- Progressive multifocal leucoencephalopathy (PML)
- Neuropathy
- Aseptic meningitis

These conditions have become much less frequent since the introduction of ART. The pathogenesis is thought to be caused by the release of neurotoxic products by HIV and cytokine abnormalities secondary to immune dysregulation. Viral suppression in the plasma is essential to control central nervous system (CNS) manifestations. Very unusually resistance may develop in the CNS compartment, necessitating switching or intensifying ART.

Box 44.5 Mucocutaneous manifestations of HIV infection

Cutaneous

- Dry skin and scalp
- Onychomycosis
- Seborrhoeic dermatitis
- Tinea: cruris, pedis
- Pityriasis: versicolor, rosea
- Folliculitis
- Acne
- Molluscum contagiosum
- Warts
- Herpes zoster: multidermatomal, disseminated
- Papular pruritic eruption
- Scabies
- Ichthyosis
- Kaposi's sarcoma

Mucous membranes

- Candidiasis: oral, vulvovaginal
- Oral hairy leukoplakia
- Aphthous ulcers
- Herpes simplex: genital, oral, labial
- Periodontal disease
- Warts: oral, genital

ADC has varying degrees of severity, ranging from mild memory impairment and poor concentration to severe cognitive deficit, personality change, and psychomotor slowing. Changes in affect are common, and depressive or psychotic features may be present. In severe cases, cerebral atrophy is shown on computed tomography (CT). T2-weighted magnetic resonance imaging (MRI) shows white matter lesions of increased density. Electroencephalography shows non-specific changes consistent with encephalopathy. The cerebrospinal fluid (CSF) is usually normal, although the protein concentration may be raised. Histologically, the spinal cord may show vacuolar myelopathy. Patients with mild neurological dysfunction may be more sensitive to a superimposed insult: fever, metabolic disturbance, or psychotropic medication may lead to a marked deterioration in cognitive functioning.

Sensory polyneuropathy is seen in advanced HIV infection, mainly in the legs and feet, although the hands may also be affected. Severe forms cause intense pain, which disrupts sleep, impairs mobility, increases frailty, and reduces quality of life. ***Autonomic neuropathy*** leads to postural hypotension and diarrhoea.

Eye disease

Ocular manifestations are common with advanced disease:

- Cytomegalovirus (CMV) retinitis is sight threatening and has a characteristic 'pizza retina' appearance on fundoscopy (see Fig. 44.4).
- Benign retinal cotton wool spots are rarely troublesome and should not be confused with CMV retinitis.
- Anterior uveitis can present as an acute red eye. It can occur *de novo* but also secondary to drugs (e.g., rifabutin therapy for mycobacterial infection) and infection (e.g., syphilis).
- Retinal disease can occur with *Pneumocystis* infection, toxoplasmosis, syphilis, and lymphoma, and the eye may be the site of first presentation.

Referral to ophthalmology for ocular manifestations is an urgent priority.

Mucocutaneous manifestations

The skin is commonly affected in people living with HIV (Box 44.5) because both dendritic and Langerhans cells are target cells for HIV:

- Pruritus is common at all stages of HIV. Generalized dry, itchy, flaky skin is typical, and hair may become thin and dry. An intensely pruritic papular eruption favouring the extremities may be found, particularly in patients of African ethnicities.
- Eosinophilic folliculitis presents with urticarial lesions, particularly on the face, arms, and legs.
- Otitis externa may be recurrent.

- Cutaneous drug reactions are common (e.g., rashes secondary to sulphur-containing drugs; Fig. 45.33).
- Delayed hypersensitivity is a good indicator of cell-mediated immunity. It is frequently reduced or absent, even before clinical immunosuppression.
- Aphthous ulceration can be severe, recurrent, and refractory to treatment. It can impair the patient's ability to eat. Biopsy may be needed to exclude other causes of ulceration. Topical steroids are used, and resistant cases may respond to thalidomide.

Haematological complications

These are common in advanced HIV infection:

- Lymphopenia progresses as the CD4 count falls.
- Anaemia of chronic HIV infection is usually mild, normochromic, and normocytic.
- Neutropenia is common and usually mild.
- Isolated thrombocytopenia may occur early in infection and be the only manifestation of HIV. Platelet counts are often moderately reduced but can fall dramatically to 10 to 20 × 10^9/L leading to easy bleeding and bruising. Megakaryocytes are increased in the bone marrow, but their function is impaired. Circulating antiplatelet antibodies lead to peripheral destruction. Effective ART alone usually resolves thrombocytopaenia. However, in some cases, it is refractory and may require additional therapies such as i.v. immunoglobulin therapy, corticosteroids, and platelet transfusion.
- Pancytopenia may occur because of underlying opportunistic infections (e.g., *Mycobacterium avium-intracellulare* [MAI], disseminated CMV) or malignancies (e.g., lymphoma).
- Myelotoxic drugs used in HIV include ganciclovir and valganciclovir (neutropenia), systemic chemotherapy (pancytopenia), co-trimoxazole (agranulocytosis), and rifabutin (neutropenia, thrombocytopenia).

Gastrointestinal effects

Weight loss and diarrhoea are common in people with advanced HIV. Wasting is attributed to a direct effect of viraemia on metabolism but may also be a consequence of anorexia. People living with HIV who are not on ART have lower body mass indexes (BMIs) than people on HIV treatment.

HIV enteropathy with varying degrees of villous atrophy causes chronic diarrhoea in the absence of other pathogens. Achlorhydria is reported in people with advanced HIV disease, affecting absorption, nutrition, and drug pharmacodynamics; the mechanism is unclear.

Kidney complications

HIV-associated nephropathy (HIVAN) is a cause of significant kidney disease. It is most frequently seen in people of Black ethnicities. It causes a collapsing variant of focal segmental glomerulosclerosis, along with a tubulopathy due to direct viral infection of tubular cells. The kidneys may be hyperechoic on ultrasound examination. HIVAN requires urgent ART and specialist renal care. The course is usually progressive, and dialysis may be required. Other kidney pathology in HIV includes ***HIV-immune complex kidney disease***, which can present with a range of glomerular abnormalities, IgA nephropathy, and thrombotic microangiopathy.

Many nephrotoxic drugs are used in the management of opportunistic infections, for example, foscarnet, amphotericin B, pentamidine, and sulfadiazine. Tenofovir (an anti-retroviral drug) is associated with renal impairment and very rarely with Fanconi's syndrome (dysfunction of the proximal renal tubule leading to glycosuria, phosphaturia, and aminoaciduria).

Respiratory complications

Pneumocystis jiroveci pneumonia (PJP) is the commonest pulmonary complication in advanced HIV (see later). Pneumonia is more common in HIV compared than in the general population (see Box 44.13). Pneumococcal, influenza, and SARS-CoV-2 vaccinations are recommended (see Box 44.14).

Lymphoid interstitial pneumonitis is very uncommon in adults but occurs in children. There is an infiltration of lymphocytes, plasma cells, and lymphoblasts in alveolar tissue. Epstein–Barr virus (EBV) may also be present. Lymphocytic, lymphoblastic, and plasma cell infiltration leads to a dry cough, which may be confused with *Pneumocystis* infection based on comparable reticulonodular radiograph findings. ART and corticosteroids are the mainstays of treatment.

Sinusitis is seen in advanced infection. Antibacterial therapy and topical steroids are usually effective, but some patients require surgical intervention. A similar process is seen in the middle ear, which can lead to chronic otitis media.

Endocrine complications

Endocrine abnormalities have been reported in people living with HIV and include reduced concentrations of testosterone, early menopause, and adrenal insufficiency. The latter mainly occurs in those with advanced disease and is also associated with CMV co-infection. Gluco- and mineralocorticoid replacement may be needed.

Cardiac complications

People living with HIV are twice as likely to develop cardiovascular disease as the general population. Ischaemic heart disease is associated with viraemia and occurs when ART is taken intermittently. The increased risk in postmenopausal females may be overlooked. Management of cardiovascular risk factors, including hyperlipidaemia, hypertension, diabetes, obesity, and smoking, is required. The use of statins has been shown to reduce the incidence of major cardiac events and death in people living with HIV even when atherosclerotic cardiovascular disease risk is low. Statins (preferably pitavastatin or atorvastatin) should be offered to all people living with HIV aged older than 40 years, irrespective of lipid profile or estimated CVD risk. Statin provision is a priority for those aged older than 40 with a 10-year cardiovascular disease risk greater than 5%.

Cardiomyopathy is associated with HIV and may progress to congestive cardiac failure. Lymphocytic and necrotic myocarditis are described. In untreated disease, direct infection of the myocardium, opportunistic infections, and nutritional disorders all contribute. For people on ART, ischaemic cardiomyopathy is more common. Specialist cardiology assessment is useful in determining the aetiology.

Conditions associated with immunosuppression

Immunodeficiency leads to opportunistic disease (Box 44.6). Many of the organisms causing clinical disease in HIV are latent or ubiquitous in the environment. Opportunistic illnesses are frequently caused by organisms that

- Are not considered pathogenic in the absence of HIV
- Cause unusually severe disease in HIV

Box 44.6 Major HIV-associated pathogens

Protozoa
- *Toxoplasma gondii*
- *Cryptosporidium parvum*
- *Microsporidia* spp.
- *Leishmania donovani*
- *Isospora belli*

Viruses
- Cytomegalovirus
- Herpes simplex
- Varicella zoster
- Human papillomavirus
- Human herpes virus-8
- JC polyomavirus

Fungi and yeasts
- Pneumocystis jirovecii
- *Cryptococcus neoformans*
- *Candida* spp.
- Dermatophytes (*Trichophyton* spp.)
- *Aspergillus fumigatus*
- *Histoplasma capsulatum*
- *Coccidioides immitis*

Bacteria
- *Salmonella* spp.
- *Mycobacterium tuberculosis*
- *Mycobacterium avium-intracellulare*
- *Streptococcus pneumoniae*
- *Staphylococcus aureus*
- *Haemophilus influenzae*
- *Moraxella catarrhalis*
- *Rhodococcus equi*
- *Bartonella quintana*
- *Nocardia* spp.

- Are oncogenic, e.g., tumours with a viral aetiology.

Susceptibility increases with advancing immunosuppression. Mechanisms of increasing susceptibility to infection include:
- Defective T-cell function against protozoa, fungi, and viruses
- Impaired macrophage function against intracellular bacteria such as *Mycobacteria* and *Salmonella* spp.
- Defective B-cell immunity against capsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus* spp.

CD4 T-lymphocyte numbers are used as markers to predict risk of infection. For example, PJP and toxoplasmosis occur with CD4 counts less than 200 cells/mm^3, and *M. avium* complex (MAC) and CMV occur with CD4 counts less than 100 cells/mm^3. People with CD4 counts of more than 200 cells/mm^3 are at low risk of ***AIDS-defining conditions*** (see **Box 44.3**). This hierarchy of infection allows for appropriate intervention with prophylactic drugs.

Presentations may be atypical in advanced HIV because the inflammatory response is impaired. Examples are the absence of meningism (neck stiffness) in cryptococcal meningitis or a paucity of clinical findings in early PJP. Multiple pathogens may coexist. Radiological findings may be helpful because indirect serological tests are frequently unreliable. Diagnosis may require specimens from the appropriate site for culture or histology.

The clinical consequences of HIV-related immune dysfunction depend on at least three factors:
- ***Previous microbial exposure.*** Many clinical infections are caused by reactivation of latent infection.
- ***Pathogenicity of organisms encountered.*** High-grade pathogens, such as *Mycobacterium tuberculosis*, *Candida* spp., and the herpesviruses, are clinically relevant even when immunosuppression is mild. Less virulent organisms cause disease in those with more advanced immunodeficiency. Organisms usually controlled by intact cell-mediated immunity are a particular clinical problem.
- ***Degree of host immunosuppression.*** When patients are severely immunocompromised (CD4 count <100 cells/mm^3), disseminated infections with organisms of low virulence (e.g., MAI, *Cryptosporidium* spp.) can establish themselves. These infections are very resistant to treatment, mainly because there is no functioning immune response to clear organisms. The mpox mortality rate in people with advanced HIV infection (CD4 count <100 cells/mm^3) is 27%.

HIV TESTING

HIV testing is a key intervention in treatment and prevention of HIV. A range of settings and modalities helps maximize testing opportunities. Infection is diagnosed either by detection of virus-specific antibodies (anti-HIV) or by direct identification of viral material. Modern 'fourth-generation' tests, which are now the standard of care in many countries, test for anti-HIV antibodies and the p24 antigen simultaneously.

HIV antibodies

This is the most used marker of infection. Routine tests are based on enzyme-linked immunosorbent assay techniques. An initial screening test should be with a high-sensitivity fourth-generation assay and then confirmed using a second high specificity diagnostic platform of equivalent sensitivity. Rapid diagnostic tests are frequently used as point-of-care testing (POCT). All positive HIV POCT results must be followed by laboratory testing for confirmation. Up to 3 months (mean 6 weeks) may elapse between infection and antibody detection (serological latency, 'window period'). Antibodies to HIV have no protective function and persist for life.

As with all IgG antibodies, anti-HIV cross the placenta. Babies born to females living with HIV have detectable maternal antibodies at birth; these antibodies are lost gradually over the first 18 months of life in babies without HIV. Anti-HIV antibody is therefore not a reliable marker vertical transmission before 18 months of age.

The Serological Testing Algorithm for Recent HIV Seroconversion (STARHS) (also termed Recent Infection Treatment Algorithm [RITA]) identifies recently acquired infections by pairing a more sensitive and a less sensitive (detuned) test. A positive result on the sensitive test and a negative 'detuned' test are indicative of recent infection, and positive results on both tests point to an infection that is more than 130 days old. The major application of this is in epidemiological surveillance and monitoring.

Viral p24 antigen

The p24 antigen (p24ag) is a HIV viral capsid protein that can be detected in blood shortly after infection. It usually disappears 8 to 10 weeks after infection (see **Fig. 44.3**). It is helpful in identifying individuals with recent infection who have not yet mounted an antibody response. Anti-p24 antibodies (anti-p24) can be detected in the early weeks of infection and through the asymptomatic phase. They are frequently lost as the disease progresses.

In people using PrEP, the detection of viral antigens or antibody responses may be delayed, masking early infection.

Genome detection assays

Nucleic acid–based assays are used to aid diagnosis in situations in which serological tests are not reliable. These include use in the babies of those living with HIV in pregnancy and in early infection when antibody may not be present. They are also used for subtyping HIV variants, including for medicolegal reasons.

CLINICAL APPROACH TO THE PERSON LIVING WITH HIV

Initial assessment

People are newly diagnosed with HIV in many clinical settings. Referral should be made to the clinical team responsible for HIV care. In the UK, HIV care is usually undertaken by infectious disease

Box 44.7 Baseline assessment of asymptomatic, newly-diagnosed HIV

History
- Coexisting conditions: medical, sexual, and reproductive, psychiatric
- Knowledge and beliefs about HIV, including treatment and transmission
- Full drug history, including recreational drug use
- Vaccination history
- Social circumstances: relationships, disclosure, support

Examination
- General physical examination including weight, height, BMI, blood pressure, and waist circumference

Investigations

Haematology
- Full blood count, differential count, and film

Biochemistry
- Kidney function, including eGFR
- Liver blood tests
- Fasting serum lipid profile: total cholesterol, HDL
- Fasting blood glucose and haemoglobin A_{1c}
- Serum bone profile
- Urinalysis
  - Dipstick for blood, protein, and glucose
  - Urine protein:creatinine ratio

Immunology
- Lymphocyte subsets
- HLA-B*5701 status

Virology
- HIV antibody (confirmatory)
- HIV viral load
- HIV genotype and subtype determination
- Hepatitis A IgG
- Hepatitis B surface antigen and full profile
- Hepatitis C antibody (followed by hepatitis C RNA testing if antibody-positive, and confirmation of antibody-positive status if RNA-negative)

Microbiology
- Toxoplasmosis serology
- Syphilis serology
- Tuberculosis status
- Screen for other STIs

Other
- Cervical cytology
- Chest X-ray if indicated
- 10-year cardiovascular risk assessment
- Fracture risk assessment

BMI, Body mass index; *eGFR*, estimated glomerular filtration rate; *HDL*, high-density lipoprotein; *HLA*, human leucocyte antigen; *Ig*, immunoglobulin; *STI*, sexually transmitted infection.

or sexual health services. An HIV specialist clinician should review all patients with new diagnoses within 2 weeks or on the same day if the patient is unwell.

A full medical history, physical examination, and laboratory evaluation should be undertaken at diagnosis to determine the stage of infection, evaluate co-morbidities and co-infections, and assess mental health. The initial assessment should include the patient's socioeconomic situation, relationships, family and social support networks, and substance misuse. Contact tracing and partner notification should be initiated and managed by the HIV team in all cases, including children who require testing. Baseline investigations depend on the clinical setting, but those appropriate for an asymptomatic person in the UK are shown in **Box 44.7**.

HIV resistance testing (genotyping)

Sequencing of the viral genotype at diagnosis establishes the viral subtype and identifies resistance to ART. The results are used to guide the selection of ART agents. Genotyping cannot be performed in people with an undetectable viral load because replicating virus is needed.

Monitoring

Regular monitoring is required with the schedule determined by clinical, virological, and treatment stages. All reasonable efforts should be made to encourage people to take ART, but in rare cases when people choose not to initiate therapy, monitoring should take place according to the degree of immunosuppression and no less frequently than two to four times per year.

Immunological monitoring

CD4 lymphocyte counts and the **CD4:CD8 ratio** are monitored. The absolute CD4 count and its percentage of total lymphocytes fall as HIV progresses, conferring risk of HIV-related pathology; patients with CD4 counts less than 200 cells/mm^3 or CD4 percentage less than 10% are at greatest risk. Rapidly falling CD4 counts are an indication for urgent referral and initiation of ART. Factors other than HIV (e.g., smoking, exercise, intercurrent infections, diurnal variation) also affect CD4 numbers. When stable on ART with a CD4 above 350 cells/mm^3, CD4 counts are performed annually.

Virological monitoring

The **HIV viral load** (HIV RNA) is the number of copies of HIV RNA in the blood. It is monitored at least twice per year. The aim of therapy is to suppress viral replication to achieve an undetectable viral load defined as less than 50 copies/mL. Viral load tests include quantitative branched DNA (bDNA) and reverse transcriptase PCR. Very sensitive tests can report 'target not detected (0 copies/mL)'. For the purposes of HIV transmission risk, the World Health Organization's 'Say Zero' campaign uses a threshold viral load less than 200 copies/mL; there is negligible risk of transmission at less than 1000 copies/mL.

Transient increases in viral load (viral blips) may occur after immunizations (e.g., against influenza, SARS-CoV-2 and pneumococcus) or during episodes of acute intercurrent infection (e.g., tuberculosis [TB]). Repeat viral load measurements should not be carried out within 1 month of these events. People should be reassured about the risks of transmission to partners according to the values given earlier.

HIV RNA is the standard marker of anti-retroviral treatment efficacy (see later). An uncontrolled viral load in a person on ART indicates either problems with adherence or viral resistance.

HIV viral load should be measured when ART is initiated and again at 1, 3, and 6 months after starting. Ideally, the viral load falls 10-fold after 1 month, with maximum effect at 10 to 12 weeks. When switching ART, viral load should be monitored within 6 weeks. Viral load should be monitored three monthly in the first year and 6 monthly for people stable on ART.

By about 6 months after seroconversion to HIV, the viral set-point for an individual is established. There is a correlation between HIV RNA concentration and long-term prognosis, independent of the CD4 count. People with a viral load consistently above 100 000 copies/mL have a 10 times higher risk of progression to clinical AIDS over the next 5 years than those with counts consistently below 10 000 copies/mL.

Monitoring other aspects of health

Regular assessment is required, including intercurrent medical problems (including mental health), medications, vaccinations, recreational drug use, sexual history, reproductive decision-making, cervical cytology, and social situation (including support networks, employment, benefits, food security, and accommodation). Regular review includes advice on reducing HIV transmission, sexual and reproductive health, testing opportunities for STIs and blood-borne viruses, and cervical screening. Information is required to allow people to make informed choices about childbearing and breastfeeding. Diagnostic testing should be offered to sexual partners and existing family members as necessary.

Regular assessments of BMI, waist circumference, metabolic and bone markers, blood pressure, and cardiovascular risk are required. Dietary advice should be available when weight problems exist. General health promotion advice including exercise, smoking cessation, alcohol, diet, and drug misuse should be given, considering the increased risk of cardiovascular and metabolic co-morbidities associated with HIV and its treatment. Hormone replacement therapy should be considered for menopausal females.

Life expectancy for people who are diagnosed early during HIV infection and have life-long access to effective ART life approaches that of the general population. Yet **health-related quality of life** reported by people living with HIV is consistently lower than that of the general population and below that of people with other long-term conditions. Lower health-related quality of life scores are associated with poor clinical and virological outcomes. Underlying causes are multiple and complex with contributors including pain; anxiety and depression; impaired cognitive function; sleep disturbance; co-morbidity; and social, welfare, and spiritual concerns. Both internalized and external HIV associated stigma have a detrimental impact on quality of life. Effective healthcare approaches must recognize and address the full range of symptoms and wellbeing challenges faced by people living with HIV. HIV-validated patient-reported outcome measures are useful tools to achieve person-centred care that addresses the diversity and complexity of the concerns of people living with HIV.

HIV-associated stigma is a major driver of health inequalities globally, undermining every aspect of HIV-related prevention, treatment, and care. **Stigma** and **discrimination** are experienced at many levels ranging from discriminatory policies and laws; prejudice; social exclusion; and internalized stigma that leads to feelings of shame, low self-esteem, and fear of discrimination. HIV-associated stigma frequently intersects with other forms of stigma, including that associated with sexual orientation, gender, race, migration status, and age, compounding impact on mental and physical wellbeing. In females, gender-based violence should be explicitly discussed. Stigma within health and care settings is regularly reported by people living with HIV, preventing people from seeking care and getting timely and appropriate treatment. Examples include refusal of treatment, disrespect from healthcare providers, longer waiting times, and excessive infection control measures. Interventions to combat stigma are essential and include educational, empowerment, and skills-building approaches. At a health systems level, it is crucial to recognize, report, and investigate examples of discrimination, including lack of privacy and breaches of confidentiality. Designing and delivering health and care services in partnership with service users and ensuring that services are accessible to those who may already be underserved and marginalized will further improve outcomes for people living with HIV.

Ageing brings distinctive challenges to the experience of living with HIV with **frailty** developing earlier than for those without HIV. Higher rates of age-related co-morbidities occurring at an earlier age in people living with HIV add complexity to clinical care, increase rates of polypharmacy, and have an impact on physical and mental wellbeing. Higher rates of social isolation, loneliness, and economic hardship are experienced by older people living with HIV, who are also often dealing with intersectional stigma. Providers of care for older adults have limited knowledge and experience of the needs of older people living with HIV. At the same time, HIV clinical services need to evolve to meet the needs of their patients as they age, including the inclusion of frailty assessments in HIV care pathways.

MANAGEMENT OF HIV

Effective ART has transformed outcomes for people living with HIV, extending life expectancy toward that of the general population for those who are diagnosed before the onset of immunosuppression, reducing morbidity, and eliminating onward transmission for people who are virally suppressed. The aims of current management are to maintain viral suppression while maximizing long-term wellbeing, with focused prevention and treatment of HIV-associated co-morbidities (**Box 44.8**).

People living with HIV have a chronic, potentially stigmatizing, and sometimes unpredictable condition. Specialist clinical management must address co-morbidities, medication side-effects, complex drug interactions, and adherence (including the emergence of resistant viral strains when adherence has not been optimal). Even with complete viral suppression, ART does not fully restore health; treated infection is associated with a variety of co-morbidities, including cardiovascular disease, cancer, and impaired mental health.

There is no cure for HIV. Cure related research is still in its infancy with a focus on eliminating the viral reservoirs that current ART therapy is unable to achieve.

ANTI-RETROVIRAL THERAPY

The key practical principles of prescribing ART are given in **Box 44.9**.

ART continues to evolve and improve. Increased potency, reduced toxicity, single-tablet formulations, compounds with different mechanisms of action, and an improved understanding of drug resistance have all incrementally improved outcomes.

In people without drug resistance, the combined use of three drugs has been the gold-standard ART regimen. However, emerging evidence supports the use of certain two-drug therapies in people without drug resistance as a way of reducing cumulative toxicity while maintaining viral suppression. The first long-acting two-monthly injectable two-drug therapy is now available in some countries, including the UK, for some people who are virally suppressed. This regimen is less robust with respect to drug resistance but safe with careful selection based on clinical criteria and is preferred by some people who find it less stigmatizing and more convenient. Better clinical outcomes have been closely linked to physician expertise and the numbers of patients under direct care.

With increasing numbers of medication available as generics ('off-patent'), drug costs are falling. This necessitates cost-effectiveness assessment of novel agents to justify use. Regularly updated treatment guidelines are produced by the British HIV

Box 44.8 An approach to the sick patient living with HIV

Potential problems
- Adverse drug reactions
- Drug–drug interactions
- Presentation or complications of malignancy
- Immune reconstitution phenomenon
- Infection in an immunocompromised host
- Acute opportunistic infections
- Organic or functional brain disorders
- Non–HIV-related pathology

History
- Anti-retroviral drugs and prophylaxis
- Previous HIV-related pathology
- Potential sources of infectious agents: food hygiene, pets, contacts with acute infections, contact with tuberculosis, STIs
- Recreational drugs, travel
- Secure confidentiality: ask who is aware of HIV diagnosis

Examination
- Signs of adverse drug reactions (e.g., skin rashes, oral ulceration)
- Signs of disseminated sepsis
- Clinical evidence of immunosuppression (e.g., oral *Candida* infection, oral hairy leukoplakia)
- Neurological signs or meningism
- Evidence of altered mental state: organic or functional
- Genitalia (e.g., herpes simplex, syphilis, gonorrhoea)
- Fundi (e.g., cytomegalovirus retinitis)
- Mouth (e.g., *Candida* infection)
- Lymphadenopathy

Investigation
- Full blood count and differential count (lymphocyte subsets and viral load may be affected by intercurrent illness)
- Kidney function tests
- Liver blood tests
- Plasma glucose
- Blood gases, including acid–base balance
- Blood cultures, including specimens for mycobacterial culture
- Microscopy and culture of available or appropriate specimens: stool, sputum, urine, cerebrospinal fluid
- Malaria screen in recent travellers from endemic areas
- Serological tests for cryptococcal antigen, toxoplasmosis; save serum for viral studies
- Chest X-ray
- CT or MRI scan of the brain if there are focal neurological signs and *always* before lumbar puncture

CT, Computed tomography; *MRI,* magnetic resonance imaging; *STI,* sexually transmitted infection.

Association (BHIVA), European AIDS Society, and the Department of Health and Human Services in the USA. Up-to-date treatment guidance should always be used.

Starting anti-retroviral therapy

ART should be offered to everyone diagnosed and living with HIV irrespective of CD4 count. It should be started as soon as the patient is ready, which may be on the day of diagnosis. There is clear evidence of the benefits of ART on morbidity and mortality at any CD4 count, together with the impact of treatment on prevention, reducing onward transmission to zero when there is viral suppression.

ART should be offered and ideally started immediately in all people presenting with symptomatic acute HIV, especially if they have neurological symptoms. This stage of disease may represent a unique opportunity for therapy because there is less viral diversity, and the host immune capacity is still intact. There is evidence to show that the viral load can be reduced substantially by effective therapy at this point.

In people with an AIDS-defining condition or an opportunistic illness, ART should be initiated as soon as possible and within 2 weeks of starting treatment for intercurrent conditions except when there is the potential for or diagnosed TB meningitis or cryptococcal meningitis.

The (U=U campaign is based on evidence that people who are virally suppressed cannot transmit HIV. This should be clearly communicated with every person living with HIV because it has been shown to improve mental health and adherence to treatment. Language is important, and clinician should say ‘zero risk’, not ‘negligible risk’.

Involving people living HIV fully in therapeutic decision-making is essential for success. Treatment-support resources, including local, independent, and peer-support resources, are available and should be provided. Although HIV specialists manage and prescribe ART, it is advisable for people living with HIV to share their status with their general practitioners and other healthcare professionals. When an individual prefers not to do this, the benefits and potential harm (especially drug–drug interactions) should be clearly explained and the decision revisited regularly.

Although the benefits of ART in HIV infection are indisputable, treatment is life-long and requires a commitment to take daily oral treatment or to attend on-time for injectable treatment. Contemporary ART regimens are tolerable and safe. Multimorbidity and polypharmacy occur earlier than in the general population.

Not all people living with HIV choose to take ART. In this case, capacity and mental health should be assessed and support offered when needed. Sexual partners of people choosing not to take ART should be advised of prevention interventions, including PrEP (see later).

Which anti-retroviral therapy to start

ART uses a combination of drugs. Recommended treatments contain either three or two different drugs. In many instances, these drugs are co-formulated.

Three drug regimens include two nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) in combination, with a drug from another class, usually an integrase inhibitor. In specific circumstances, a boosted protease inhibitor (bPI) or a non-nucleoside reverse transcriptase inhibitor (NNRTI) is used. Recommendations for first-line ART are summarized in **Box 44.10**.

Nucleoside/nucleotide reverse transcriptase inhibitors

NRTIs are nucleoside analogues that inhibit the synthesis of DNA by reverse transcription and act as DNA chain terminators. They require three phosphorylation steps for activity. They were the earliest drug class to be used against HIV (e.g., zidovudine [AZT]). Nucleotide reverse transcriptase inhibitors (NtRTIs) have a similar mechanism of action but require only two intracellular phosphorylation steps for activity.

Historically, two N(t)RTIs have been combined to provide the ‘backbone’ of an ART regimen together with a third drug. Fixed-dose NRTI-containing drug combinations are available, reducing pill burden. More recently, oral, and injectable NRTI-sparing two-drug therapies have now been developed for people who are virally suppressed. The choice of which NRTIs should form the backbone of therapy is influenced by efficacy, toxicity, and cost.

Common NRTIs include:

Box 44.9 Prescribing anti-retroviral drugs: practice points

Characteristics of anti-retroviral drugs	Practice points
Long-term adherence is key to success	Make treatment decisions in partnership with the patient. Check for factors that may compromise accurate adherence. Ensure that the proposed drug regimen fits with the patient's lifestyle. Clarify that the patient understands requirements and reasons for strict adherence. Check access to appropriate storage conditions for some agents.
Should not be stopped suddenly	Make sure that mechanisms are in place to ensure adequate drug supplies (e.g., regular clinic appointments, repeat prescriptions, home delivery of medications). Be aware of unexpected time away from home (e.g., holidays, intercurrent hospital admissions, immigration detention, police detention). If there is an urgent medical indication to stop, obtain advice from a specialist physician or pharmacist.
Can be compromised by the introduction of other medications, including other ARVs and vice versa	Always check potential interactions before adding new agents (see www.hiv-druginteractions.org). Use care with DAA therapies in hepatitis C (expert advice required). Use care with enzyme inducers (e.g., rifampicin, rifabutin, warfarin, and nevirapine), which reduce effective concentrations. Remember that methadone levels may be reduced by efavirenz. Some ART may block metabolism of other agents causing toxicity (e.g., steroids, statins. Therapeutic drug monitoring may be necessary
Can interact adversely with some herbal, complementary, and recreational agents	Check potential interactions before adding new agents; see www.hiv-druginteractions.org. Herbal remedies that induce cytochrome P450 (e.g., St. John's wort and Chinese herbal remedies may reduce ART concentrations. Therapeutic drug monitoring may be necessary.
May produce additive toxicities when given with other medications	For example: • Corticosteroid (inhaled and systemic) concentrations may be elevated • Muscle toxicity with statins • Hepatotoxicity with anti-tuberculosis medication • Increased myelosuppression with chemotherapy or high-dose co-trimoxazole
Are associated with a range of adverse drug reactions, which may be confused with other pathology	For example, rash, fever, nausea, and diarrhoea may all be caused by intercurrent pathology or anti-retroviral drugs.
May exacerbate co-morbidities	Examples include hepatic dysfunction caused by hepatitis B and C, increased cardiovascular risk, and osteoporosis.

ART, Anti-retroviral therapy; *ARV,* anti-retroviral; *DAA,* direct-acting antiviral.

- *Tenofovir disoproxil fumarate (TDF)* has been the mainstay of most ART regimens for many years. It is metabolized in the kidneys. Side-effects include renal impairment, osteopenia, and osteoporosis, especially in older adults. Fanconi's syndrome is very rare. Monitoring includes kidney function (serum creatinine, estimated glomerular filtration, urine protein:creatinine ratio), and serum phosphate (for hypophosphatemia). It has a low liability for drug interactions, with the exception of drugs that reduce creatinine clearance.
- *Tenofovir alafenamide (TAF)* is a prodrug of tenofovir. Its use results in lower plasma concentrations of tenofovir than TDF, which reduces the potential for kidney and bone toxicity. Many different fixed-dose formulations incorporate TAF with other anti-retroviral classes. TAF comes in two doses (10 and 25 mg) because it can interact with drugs metabolized by the CYP3A4 pathway. When given with an enzyme inhibitor (e.g., ritonavir), the dose must be lowered. It should not be co-administered with enzyme-inducing drugs such as rifampicin.
- *Emtricitabine (FTC)* and *lamivudine (3TC)* can be considered interchangeably. They are very well-tolerated but have uncommonly been known to cause nail and skin darkening in those with dark skin.
- *Abacavir* is associated with hypersensitivity in at-risk individuals (human leucocyte antigen [HLA]-B*5701)

Co-formulated NRTI-containing combinations include:

- Truvada: TDF/FTC or TDF/lamivudine
- Descovy: TAF/FTC
- Kivexa: abacavir plus lamivudine

Older NRTI and NtRTIs have been associated with mitochondrial toxicity because of their effect on human mitochondrial DNA polymerase. This manifests as myopathy, neuropathy, and hepatic steatosis with lactic acidosis.

Integrase strand transfer inhibitors

These drugs act as selective inhibitors of HIV integrase, blocking viral replication by preventing insertion of HIV DNA into the human DNA genome. They are gold-standard first-line therapy and are effective in viral resistance. They have superior tolerability and safety profiles to those of other classes (e.g., NNRTIs and bPIs; see later). Integrase strand transfer inhibitors (INSTIs) such as bictegravir and dolutegravir are therefore agents of choice. Older integrase inhibitors include raltegravir and elvitegravir.

- *Bictegravir* is a second-generation INSTI with a good side-effect profile and has a higher genetic barrier to resistance than raltegravir. A fixed-dose tablet of bicgravir co-formulated with TAF and FTC is available (Biktarvy).
- *Dolutegravir* is a second-generation INSTI with a good side-effect profile and a higher genetic barrier to resistance than raltegravir. Dolutegravir is associated with a small increase in serum creatinine because it blocks tubular secretion. It is an important

Box 44.10 Initial anti-retroviral therapy regimens: choice of initial therapy and preferred regimens

Recommended as initial treatment for most people living with HIV (grade 1A)	
Regimen	**Specific details**
Bictegravir/emtricitabine/tenofovir AF	
Dolutegravir plus emtricitabine/tenofovir AF or emtricitabine/tenofovir DX	Bone and renal caveats for tenofovir DX
Dolutegravir/lamivudine	No baseline lamivudine resistance Baseline viral load <500 000 copies/mL and CD4 count >200 cells/mm^3
	No active hepatitis B infection and if at risk of hepatitis B, hepatitis B virus immune
Dolutegravir/lamivudine/abacavir	HLA-B*5701 negative and estimated 10-year risk of CVD <10%
Recommended as initial treatment in certain clinical situations (grade 1A)	
Regimen	**Specific details**
Darunavir plus cobicistat or ritonavir plus emtricitabine plus tenofovir AF or tenofovir DX	Bone and renal caveats for tenofovir DX
Doravirine plus emtricitabine or lamivudine plus tenofovir AF or tenofovir DX	Bone and renal caveats for tenofovir DX
Efavirenz plus emtricitabine or lamivudine plus abacavir or tenofovir AF or tenofovir DX	May be a first-line choice in pregnancy and for people on TB treatment but not recommended outside these scenarios
Raltegravir plus emtricitabine plus tenofovir AF or tenofovir DX	Baseline viral load <100 000 copies/mL Bone and renal caveats for tenofovir DX

CVD, Cardiovascular disease; *HLA,* human leucocyte antigen; *TB,* tuberculosis; *Tenofovir AF,* tenofovir alafenamide; *tenofovir DX,* tenofovir disoproxil.

component of regimens in drug resistance when it is dosed twice daily. Fixed-dose tablets co-formulated with lamivudine (Dovato) and with abacavir and lamivudine (Triumeq) are available.

- *Cabotegravir* is a second-generation INSTI with a good side-effect profile and a higher genetic barrier to resistance than raltegravir. It forms part of a complete injectable 2-monthly regimen together with rilpivirine (NNRTI; see later). There is also an oral formulation available, which can be used during the month of oral-lead in before injection together with oral rilpivirine.
- *Elvitegravir* is metabolized via the cytochrome P450 (CYP450) pathway, requiring co-administration of a CYP450 blocker to secure adequate plasma concentrations, thus increasing drug interaction potential. Single-tablet co-formulations exist with tenofovir, FTC, and cobicistat (Stribild) and with TAF, FTC, and cobicistat (Genvoya).
- *Raltegravir* was the first licensed compound in this drug class. It can be used as first-line therapy and as part of a regimen to treat people with resistance to other classes. It has a favourable side-effect profile and few drug interactions with the exception of cation-containing compounds and antacids. Newer generation drugs have higher genetic barriers to resistance.

Co-formulated NRTI-containing combinations also containing an INSTI include the following:

- Biktarvy (TAF/FTC plus bictegravir)
- Dovato: lamivudine plus dolutegravir
- Triumeq (abacavir/lamivudine and dolutegravir)

Non-nucleoside analogues

NNRTIs bind to reverse transcriptase to inhibit its function. Older NNRTIs are metabolized through the CYP450 pathway, including CYP3A4 and CYP2D6, and consequently have a high liability for drug interactions. Older NNRTIs are associated with rashes (including Stevens–Johnson syndrome) and elevation of liver enzymes.

- *Doravirine* is a second-generation NNRTI with a better tolerability profile, fewer drug interactions, and retention of some activity against viruses resistant to other NNRTIs. As a result, it is a recommended option for first-line treatment in the European AIDS Clinical Society guidelines.
- *Rilpivirine* is a second-generation NNRTI with a low generic barrier. It needs to be taken with a meal and cannot be taken with antacids or proton pump inhibitors. Its predominant clinical use is as part of the 2-monthly regimen together with cabotegravir, though fixed-dose single-tablet oral combinations containing rilpivirine together with FTC and TAF (Odefsey) or TDF (Eviplera) are available.
- *Etravirine* is a second-generation NNRTI with some activity against drug-resistant NNRTI strains. It is sometimes useful in the treatment of ART-experienced patients. Rash is the most common adverse effect.

Other older NNRTIs such as efavirenz and nevirapine are not recommended in the UK, but people who attend from abroad may be taking them.

- *Efavirenz* has CNS side-effects, including dysphoria and insomnia. It is associated with an increased risk of suicide.
- *Nevirapine* carries a small risk of CD4-related serious hepatic or cutaneous toxicity. It is not used in females with a CD4 count above 250 cells/mm^3 or males with a CD4 count of more than 400 cells/mm^3.

Protease inhibitors

Protease inhibitors (PIs) inhibit the production of functional viral proteins and enzymes and impede viral maturation, leading to production of dysfunctional viral particles. PIs have high potency and high genetic barriers and can be co-prescribed with reverse transcriptase inhibitors. However, these drugs must be prescribed with 'boosters' such as ritonavir or cobicistat to increase drug exposure because of significant metabolism via CYP450 and CYP3A4. The main disadvantages of PIs are the increased risks of drug interactions and lipid abnormalities.

- Boosted ***atazanavir*** and ***darunavir*** are generally dosed once a day. They are most often used in people with resistance; darunavir may be used twice a day to overcome phenotypic resistance. Both can cause diarrhoea and lipid abnormalities. Atazanavir

increases unconjugated bilirubin levels and may produce icterus.
- ***Symtuza*** is a once-daily, fixed-dose single tablet containing darunavir, cobicistat, FTC, and TAF and is the only PI-based single-tablet regimen.

Entry inhibitors, co-receptor blockers, and capsid inhibitors

Drugs from these mechanistic groups are used when there is a need to construct an unusual regimen because of virological resistance or intolerance.
- *Maraviroc* is a chemokine receptor antagonist that blocks cellular CCR5 receptor entry by CCR5 tropic strains of HIV. Tropism assays must be done to establish that the patient is carrying a CCR5 tropic virus. It is dosed twice daily, and the dose must be adjusted based on other co-prescribed ART because it is a substrate of the CYP450 CYP3A4 pathway.
- *Enfuvirtide* is a fusion inhibitor. It is an injectable peptide derived from HIV gp41 that inhibits gp41-mediated fusion of HIV with the target cell. It has a low genetic barrier. It must be injected twice daily, which limits utility. Side-effects relate to the subcutaneous route of administration in the form of injection site reactions.
- *Fostemsavir* is an entry inhibitor that binds to the viral envelope protein gp120 adjacent to the gp120-CD4+ binding site. It is dosed orally twice daily and is a very useful adjunct in patients who are highly treatment experienced with triple class resistance. Its use has significantly improved likelihood of success in this situation and has a low adverse event rate.
- *Lenacapavir* is a first-in-class capsid inhibitor with a triphasic mechanism of action. It can be dosed orally daily or weekly or can be injected 6 monthly. It is licensed for the treatment of people with three-class resistance in whom a regimen cannot otherwise be constructed. It has few side-effects and has produced excellent outcomes for people with no other treatment options. The genetic barrier appears to be low.
- *Ibalizumab* is a post-attachment inhibitor that prevent the HIV gp120 protein from changing its shape to engage with co-receptors. It is a monoclonal antibody that requires i.v. administration every 14 days. It has been shown to be effective in people with multidrug-resistant HIV, for which it is licensed.

Monitoring anti-retroviral therapy

Success rates for initial therapy using modern ART are very high. By 4 weeks of therapy, the viral load should have dropped by at least 1 log 10 copies/mL and by 12 to 24 weeks should be fully suppressed (<50 copies/mL). Slower immunological recovery is seen when treatment is initiated in advanced infection (low CD4 count and late diagnosis) and in older adults.

People are reviewed 2 to 4 weeks after starting therapy to check adherence and for adverse effects. The viral load is measured at 1, 3, and 6 months after starting ART, and a suboptimal response at any time point demands a full assessment and possible change in therapy.

When clinically stable and virologically suppressed on therapy, the viral load should be routinely measured every 6 months. When the viral load is below 50 copies/mL and the CD4 count has been above 350 cells/mm^3 for at least 12 months, monitoring frequency falls to annually or even longer (**Box 44.11**).

Regular clinical assessment (6–12-monthly) should include adherence, tolerability, BMI, waist diameter, blood pressure, and urinalysis. Patients should be monitored for drug toxicity and co-morbidities: liver blood tests, kidney function, bone profile, and a metabolic assessment that includes fasting lipids and haemoglobin A_{1C}. Males who have sex with males (MSM) should be tested for syphilis and offered sexual health screening three-monthly or if symptomatic. Cervical screening should be annual.

Box 44.11 Monitoring patients on anti-retroviral therapy

History
- Adherence to medication
- Evidence of ART toxicity or intolerance
- Documentation of any new clinical conditions since last assessment
- Drug history, including all co-medications: prescribed, recreational, over the counter, complementary, and herbal

Physical examination
- Blood pressure
- Weight
- HIV viral load
- Lymphocyte subsets
- Full blood count
- Urinalysis if tenofovir is being used
- Liver blood tests
- Kidney function
- Fasting lipid profile
- Fasting blood glucose or haemoglobin A_{1c}

Additional investigations (depending on the clinical picture)
- HIV genotype if there is evidence of virological failure
- Therapeutic drug monitoring in certain situations
- DEXA scan and calculation of fracture risk (e.g., FRAX score)
- Cardiovascular risk assessment

ART, Anti-retroviral therapy; *DEXA,* dual-energy X-ray absorptiometry; *FRAX,* Fracture Risk Assessment Tool.

Drug resistance

Resistance to ART (**Box 44.12**) results from mutations in the viral genome. HIV has a rapid turnover, with 10^8 replications occurring per day. The error rate is high, resulting in genetic diversity within the population of virus in an individual, which includes drug-resistant mutants when drug pressure is insufficient. When drugs only partially inhibit virus replication, there is selection pressure for the emergence of drug-resistant strains. The rate at which resistance develops depends on the genetic barrier of the drug (how many mutations are needed before resistance occurs). Drugs such as NNRTIs and some NRTIs have low genetic barriers, and a single mutation will confer high-level resistance. Conversely, PIs and second-generation INSTIs have high genetic barriers. It is possible to transmit drug-resistant virus and for someone to be diagnosed with a highly resistant virus, though this is very uncommon.

HIV anti-retroviral drug resistance testing is routine at diagnosis and before starting therapy and when therapy is failing (viral load > 200 copies/mL on more than one consecutive occasion). The tests involve PCR sequencing of areas of the viral genome that indicate drug susceptibility. Such assays are limited by the starting concentration of virus and their ability to detect minority strains. For results to be useful when therapy is failing, samples must be analyzed when the patient is on therapy because when the selection pressure of therapy is withdrawn, wild-type virus becomes the predominant strain, and resistance mutations may no longer be detectable.

Box 44.12 Mechanisms and implications of HIV drug resistance

1. HIV replicates rapidly and inaccurately. Replication in the presence of ARV drugs leads to a selection pressure for mutations that can survive (i.e., select for drug resistance).
2. Specific point mutations in the viral reverse transcriptase, protease, and integrase genes correlate with reduced drug sensitivity and can be identified by virus genotyping.
3. Inadequate drug concentrations fail to suppress viral replication and viral load and precipitate drug resistance.
4. Inadequate drug concentrations can result from poor adherence, altered GI tract absorption, increased drug breakdown, and drug–drug interactions.
5. Some drugs, especially NNRTIs and integrase inhibitors, have a low genetic barrier (i.e., a small number of mutations can result rapidly in high levels of resistance).
6. Stopping drugs with long half-lives can leave a subtherapeutic drug tail for long enough for resistant strains to develop.
7. In patients on stable therapy, the introduction of new drugs that impact cytochrome P450 pathways can lead to dangerous alterations in ARV drug concentrations.
8. Therapeutic drug monitoring may be a useful investigation for some drugs in some circumstances.
9. Without drug selection pressure, wild-type virus reasserts itself, and resistant variants no longer make up the major circulating viral strains and may not be found on investigation. Genotyping should, if possible, be carried out on specimens obtained while the patient is on therapy.
10. Resistant variants survive and are archived. They reappear if the drug selection pressure is re-introduced. This means that all previous genotypes need to be considered when assessing virological failure and planning new therapy.

ARV, Anti-retroviral; *GI,* gastrointestinal; *NNRTI,* non-nucleoside reverse transcriptase inhibitor.

Databases containing nearly all published HIV and protease sequences, with their associated resistance patterns, are maintained in real time by Stanford University (see Further reading). Phenotypic assays provide a more direct measure of susceptibility, but the complexity of these assays is a barrier to clinical use.

Drug interactions with anti-retroviral therapy

Many ART drugs are victims, perpetrators, or substrates of drug–drug interactions.

Although chelators and chemotherapy may affect first-line INSTI concentrations, there is a lower risk of drug interactions because they largely are metabolized via glucuronidation.

Boosted PIs are potent inhibitors of CYP450 and CYP3A4 pathways, and some NNRTIs are potent inducers. When the drugs are victims, this can lead to subtherapeutic ART concentrations and resistance to treatment. Conversely, when ART leads to enzyme inhibition, supra-therapeutic or subtherapeutic concentrations of concomitant medication may lead to toxicity or under-dosing (e.g., hormone replacement therapy, contraception). This effect applies to naturopathic (e.g., St John's wort) and allopathic medications (e.g., statins, chemotherapy, anticoagulants, rifamycin). An exhaustive list of potential interactions can be found using the online drug interaction tool maintained by Liverpool University (see Further reading).

Therapeutic drug monitoring of peak and trough plasma concentrations may be useful in certain settings.

Adherence

People's beliefs about their own immune systems, trust in 'Western medicine', stigma, faith, and fear of disclosure may affect their perceptions about the personal need for medicines. Adherence to treatment is pivotal to success. With the older drugs, adherence below 95% was associated virological and failure. However, newer ARTs are more forgiving. Irregular adherence facilitates the emergence of drug-resistant variants and virological treatment failure.

Factors implicated in poor adherence may be associated with the medication, the individual, or the provider:

- ***Medication-related factors:*** side-effects, pill burden, inconvenience
- ***Patient factors:*** motivation, psychological wellbeing, family and social support, fear of disclosure, trust in allopathic medicine, health beliefs
- ***Provider factors:*** health literacy around HIV and ART, education of clinicians in adherence support techniques

Supporting adherence is a key part of clinical care, and peer mentorship is very useful.

Acceptability, tolerability, and an assessment of adherence over the previous 2 weeks should be documented at each visit. Adherence over previous 2 weeks is a good proxy for general adherence. Questions about adherence should be phrased in a neutral non-judgmental way to facilitate discussions about difficulties. Provision of multidisciplinary support for adherence is an expected standard of care. Digital aids such as apps, alarms, and dosette boxes can be helpful.

Anti-retroviral therapy failure

Persistent viral replication, CD4 decline, and disease progression indicate ART failure. It is caused by a variety of factors, including poor adherence, limited drug potency, and drug or food interactions compromising drug absorption or effectiveness. Penetration into compartments such as the CNS can occasionally be an issue and necessitate a change in ART regimen.

Switching anti-retroviral therapy

A rise in viral load, toxicity, tolerability concerns, co-morbidities, coinfections, and emergence of better therapies are all reasons to review current treatment. If the patient has a viral load below the limit of detection and a change needs to be made because of intolerance to a particular drug, then within-class switches should be considered before cross-class switches. Simplification to recommended two-drug therapies can be considered.

Virological failure is defined as two consecutive viral loads of more than 200 copies/mL in a previously fully suppressed patient on ART. It requires testing for drug resistance while the person continues to take ART. If resistance occurs, a prompt change in treatment is warranted because maintaining a regimen that is failing leads to resistance. At least two drugs to which there is no resistance should be prescribed, if possible from new classes. The use of bPIs used twice daily in a regimen for multidrug resistance is common.

Stopping anti-retroviral therapy

Stopping ART is not recommended unless there is severe toxicity. Switching therapy is preferable to stopping ART. It is important to note that some drugs may have long half-lives. Injectable cabotegravir and rilpivirine can persist for many months and up to 1 year. Treatment interruptions are not helpful to cardiovascular or virological outcomes.

Complications and long-term safety of anti-retroviral therapy

As efficacy and tolerability of anti-retroviral drugs (ARVs) have improved and longevity for people living with HIV has increased to approximate that of the general population, long-term safety has

become increasingly important. Although the side-effect profiles of modern ART have significantly improved, unwanted effects still sometimes occur. Whereas some are acute and associated with initiation of medication, others emerge after longer-term exposure.

Allergic reactions

Allergic reactions occur with greater frequency in people living with HIV infection, especially in the context of advanced disease in which there is immune dysregulation. Abacavir is associated with a potentially fatal hypersensitivity reaction, strongly linked to the presence of HLA-B*5701, usually within the first 6 weeks of treatment. Rechallenge with abacavir can be fatal and is contraindicated. In the UK, routine screening for the HLA-B*5701 allele has reduced the incidence of abacavir hypersensitivity. Allergies to first-generation NNRTIs such as nevirapine and efavirenz (often in the second or third week of treatment) usually present with a widespread maculopapular pruritic rash, often with a fever and disordered liver blood tests. Reactions can resolve, even with continuing therapy, but drugs should be stopped immediately in any patient with mucous membrane involvement or severe hepatic dysfunction.

Lipodystrophy and metabolic syndrome

A syndrome of lipodystrophy occurred in people who received older ART drugs, including NRTIs such as D4T (stavudine), DDI (didanosine), and AZT (zidovudine), together with first-generation PIs in the 1980s and early 1990s. It was characterized by:

- A loss of subcutaneous fat in the arms, legs, and face (lipoatrophy)
- Deposition of visceral, breast, and local fat
- Raised total cholesterol, high-density lipoprotein cholesterol, and triglycerides
- Insulin resistance with hyperglycaemia
- An increased risk of cardiovascular events.

Management includes dietary advice, an increase in exercise, and statins and fibrates reduce circulating lipids. Simvastatin is contraindicated because of drug interactions with PIs. Injections with facial fillers can help with facial fat loss and fat loss that is painful (e.g., feet, buttocks).

This syndrome does not occur with contemporary ART.

Mitochondrial toxicity and lactic acidosis

Mitochondrial toxicity from older drugs in the nucleoside analogue class (mainly stavudine and didanosine) leads to increased lactate and lactic acidosis, with fatalities reported. NRTIs inhibit gamma-DNA polymerase and other enzymes that are necessary for normal mitochondrial function. Symptoms are often vague and insidious and include anorexia, nausea, abdominal pain, and general malaise. Venous lactate concentration is raised, and the anion gap is typically widened. This is a serious condition, requiring immediate cessation of ART and provision of appropriate supportive measures until normal biochemistry is restored. All patients should be alerted to the possible symptoms and encouraged to attend hospital promptly.

Bone metabolism

Although untreated HIV is believed to have a direct impact on bone metabolism, a fall in bone mineral density is associated with starting ART and is most noticeable in tenofovir-containing regimens. Prevalence varies between study populations, geographical locations, and with dietary intake. Hypothesized mechanisms include direct effects of ART on bone or an indirect renal-mediated effect. Elevated urinary phosphate or low serum phosphate is indicative. Fragility fractures can occur. TAF is preferred when a decrease in bone mineral density has occurred because this appears to have less effect on bone health. Fracture risk (e.g., Fracture Risk Assessment Tool [FRAX] score) should be assessed at baseline in patients older than 50 years of age and postmenopausal females or when other risk factors for bone loss exist. Dual-energy X-ray absorptiometry scans can be used where available.

Immune reconstitution inflammatory syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a paradoxical inflammatory reaction that occurs on initiating ART, usually in people who are profoundly immunosuppressed when beginning therapy. As their immune systems recover, they mount an inflammatory response to a range of pathogens with exacerbation of symptoms and new or worsening clinical signs. Examples include unusual mass lesions or lymphadenopathy associated with mycobacteria, deteriorating radiological appearances associated with TB infection, inflammatory retinal lesions in association with CMV, deterioration in liver function in chronic hepatitis B carriers, and vigorous vesicular eruptions with herpes zoster. Most concerning are IRIS lesions that can obstruct the airway and CNS disease, especially TB and cryptococcal meningitis. To avoid this situation, certain pathogens, in particular *M. tuberculosis* and *Cryptococcus* spp., should be treated for several weeks to reduce the microbiological burden before ART is initiated. Corticosteroids may be needed. In the recent multi-country mpox outbreak, cases of IRIS in advanced HIV disease were reported.

Pregnancy

In the UK, the overall vertical HIV transmission rates are 1% for females diagnosed before delivery and 0.1% for females on ART with a viral load of less than 50 copies/mL. Risk of vertical transmission increases with higher maternal viral load. Management of HIV in pregnancy requires close collaboration between obstetrical, medical, and paediatric teams. The aim is to deliver a healthy baby without HIV to a healthy parent, without prejudicing future treatment options. Effective ART in pregnancy is important to both maternal and fetal outcomes. Drug concentrations may change because of changes in volume of distribution so ART guidelines in pregnancy may differ.

Females who are taking an effective ART regimen at conception should continue this treatment. Pregnant females not already on ART, including elite controllers, should start an effective three-drug ART during pregnancy and be advised to continue life-long treatment with appropriate monitoring and support. For the small numbers of females with HIV who do not wish to take ART treatment for their own health, ART should be offered to reduce transmission to the fetus from the beginning of the second trimester if the viral load is greater than 30 000 copies/mL. Consideration should be given to starting ART earlier in pregnancy if the viral load is greater than 100 000 copies/mL. Stopping ART after delivery is not recommended. Mode of delivery is reviewed with viral load results at 36 weeks' gestation. Pre-ART and delivery by caesarean section to reduce vertical transmission risk have been recommended. This is no longer the case, and for females on effective ART with a viral load below 50 copies/mL at 36 weeks' gestation, vaginal delivery can be supported in the absence of obstetric contraindications. If the viral load is 400 copies/mL or greater at 36 weeks' gestation, caesarean delivery is recommended. The baby should receive post-exposure prophylaxis with zidovudine for 2 weeks postpartum.

Guidelines still advise that replacement infant feeding in people living with HIV should be offered to reduce transmission to the fetus; however, the risk of transmission through breastmilk for females with an undetectable viral load is very low. BHIVA advises supporting people who wish to breast-feed or chest-feed with information and frequent clinical and viral load monitoring for both the mother and baby.

Post-exposure prophylaxis

It is possible to prevent HIV acquisition after exposure and before infection is established. This includes the occupational exposure of healthcare workers and sexual exposure. Animal models provide biological plausibility for use of ART as post-exposure prophylaxis (PEP), but there have been no prospective trials to inform the best approach. Each exposure is evaluated on a case-by-case basis, weighing risk of infection with treatment benefit. The risk of acquisition of HIV after exposure is dependent on the viraemia in the person with HIV. When the source person has an undetectable viral load (<200 copies/mL), then PEP is not indicated because HIV cannot be transmitted.

PEP is most beneficial within the first 24 hours but may be useful up to 72 hours after possible exposure. In the UK, the recommended first-line PEP regimen is tenofovir disoproxil 245 mg/FTC 200 mg with raltegravir 1200 mg once daily for a minimum of 28 days with monitoring for side-effects. A blood test for HIV test should be done at the time that PEP is dispensed. Rapid POCT can also be useful in this setting. PEP after sexual exposure should be a trigger for discussion of PrEP (see later).

Toward a cure

There is increasing interest in the possibilities of a cure for HIV. This could be either:

- Functional: long-term control of the virus without the use of drugs
- Sterilizing: elimination of the HIV reservoir

Reports of therapeutic possibilities exist, including a small number of people living with HIV who underwent stem cell transplants for treatment of coexisting malignancies. Cure studies involving kick-and-kill strategies and the use of monoclonal antibodies are being explored. These approaches are in the early clinical phases.

HIV-ASSOCIATED DISEASE

Opportunistic infections occur with immunosuppression evidenced by a CD4 count below 200 cells/mm^3. This occurs in people who are diagnosed late, people who have disengaged with HIV care or are not adherent with ART, people who have chosen not to take ART, and in regions without access to ART.

In the UK, improved HIV outcomes because of early diagnosis and widespread uptake of ART mean that the types of infection seen in the context of HIV have altered with a lower prevalence of 'classic' opportunistic infections, such as *Pneumocystis* pneumonia and CMV (**Box 44.13**), but an increase in community-acquired infections such as *S. pneumoniae* and *Haemophilus influenzae*.

Immune reconstitution with ART may produce unusual responses to opportunistic pathogens and confuse the clinical picture. Thus, prevention and treatment of opportunistic infections remain integral to the management of HIV infection.

Avoidance of infection

Exposure to certain organisms can be avoided. Food hygiene to reduce exposure to *Salmonella* spp., toxoplasmosis, and *Cryptosporidium* spp. Condom use reduce exposure to HSV, hepatitis B and C viruses, and human papillomaviruses (HPVs). Use of CMV-negative blood products reduces CMV infections. Travel-related infection can be minimized with appropriate prophylaxis and vaccinations.

Immunization strategies

Guidance on the appropriate use of vaccines in HIV is shown in **Box 44.14**. Immunization may be less effective in immunosuppressed persons.

Chemoprophylaxis

In the absence of a normal immune response, many opportunistic infections are difficult to eradicate using antimicrobials, and the recurrence rate is high. Primary and secondary chemoprophylaxis can be used to reduce the incidence of some opportunistic infections. Advantages must be balanced against potential toxicity, drug interactions, treatment burden, and cost.

Primary prophylaxis is effective in reducing the risk of *Pneumocystis jirovecii*, TB, cryptococcus, toxoplasmosis, and MAI.

Primary prophylaxis is *not* usually recommended against CMV, herpesviruses, and fungi other than cryptococcus.

With the introduction of ART and immune reconstitution, ongoing chemoprophylaxis can be discontinued when the CD4 counts is above 200 cells/mm^3 and the viral load is undetectable (<200 copies/mL). Long-term secondary prophylaxis may be needed after cryptococcal and herpes zoster infections.

Fungal infections

Pneumocystis jirovecii infection

P. jirovecii is the most common opportunistic infection causing pneumonia (see **Box 44.13**). It can also rarely cause extrapulmonary disease. Disseminated PJP infection occurs when the CD4 count falls below 200 cells/mm^3. The introduction of effective ART and primary prophylaxis in people with CD4 counts of less than 200 cells/mm^3 has significantly reduced the incidence in the UK.

The organism damages the alveolar epithelium, which impedes gas exchange and reduces lung compliance. The onset is often insidious over a period of weeks, with increasing shortness of breath (usually on exertion), non-productive cough, fever, and malaise. Clinical signs include tachypnoea and tachycardia. The patient is usually hypoxic and desaturates on exercise. Fine crackles are heard on auscultation, although in mild cases, there may be no auscultatory abnormality. Although the chest radiograph may be normal in early infection, typical appearances are of bilateral perihilar interstitial infiltrates progressing to confluent alveolar shadows throughout the lungs. High-resolution CT scans of the chest demonstrate a characteristic ground-glass appearance even when there is little to see on the chest radiograph. Definitive diagnosis is obtained through bronchoalveolar lavage and by PCR amplification of the fungal DNA or microscopic identification with silver staining or immunofluorescent techniques.

Treatment should be instituted as early as possible. First-line therapy for severe infection (P_aO_2 <8 kPa or type 2 respiratory failure) is with i.v. co-trimoxazole (120 mg/kg daily in divided doses) for 21 days. Up to 40% of people will have an adverse

Box 44.13 Some causes of pneumonia in immunocompromised patients

Pathogen	Affected patient population	Clinical features
Pneumocystis jirovecii	Impaired cell-mediated immunity: CD4 count <200 cells/mm^3, long-term corticosteroid use, immunosuppressant drugs	*Pneumocystis* pneumonia, hypoxia on exertion Chest radiograph: perihilar ground-glass shadowing, cysts
Non-tuberculous mycobacterial species	Impaired cell-mediated immunity: CD4 count usually <200 cells/mm^3 Structural lung disease: bronchiectasis, cystic fibrosis, severe COPD	Varied clinical presentation (see Chapter 20): Non-specific fevers, cough, malaise Lymphadenopathy or hepatosplenomegaly Chest CT: nodules, cavitation, thickened airways, 'tree-in-bud' small airways
***Nocardia* spp.**	Impaired cell-mediated immunity: CD4 count usually <150 cells/mm^3, chronic corticosteroid use, after solid organ transplantation, after stem cell transplantation Structural lung disease: bronchiectasis, cystic fibrosis, severe COPD	Acute, subacute, or chronic pneumonia Multiple radiographic presentations, including lobar infiltrates, abscesses, cavities, pleural effusion, pulmonary nodules
***Aspergillus* spp.** ***Zygomycetes* spp.** ***Penicillium* spp.**	Prolonged neutropenia: after chemotherapy for haematological malignancy, after stem cell transplant (myeloablative transplants are at particular risk) Impaired cell-mediated immunity: graft-versus-host disease, immunosuppressant therapy Chronic granulomatous disease	Invasive fungal pneumonia: cough ± haemoptysis, pleuritic pain, fever CT findings: cavitating consolidation, 'tree-in-bud', nodules with ground-glass halo, air-crescent sign (caused by lung necrosis in late stages)
***Cryptococcus* spp.**	Impaired cell-mediated immunity: CD4 count usually <200 cells/mm^3, chronic corticosteroid use, after solid organ transplantation, after stem cell transplantation	Non-specific respiratory symptoms: fever, cough, breathlessness Usually associated with neurological involvement, but isolated pulmonary disease does occur Progresses to disseminated disease in immunocompromised patients Chest CT: cavities, nodules, infiltrates
Histoplasma capsulatum	Impaired cell-mediated immunity: CD4 count usually <50 cells/mm^3	Fever, fatigue, weight loss Cough and dyspnoea are the most common respiratory symptoms Chest radiograph can be normal in disseminated disease Chest CT: diffuse reticular or reticulonodular infiltrates, miliary infiltrates, occasionally mediastinal lymphadenopathy
***Coccidioides* spp.** ***Paracoccidioides* spp.** ***Blastomyces* spp.**	Impaired cell-mediated immunity: CD4 count usually <50 cells/mm^3	Often presents as disseminated disease (chest radiograph frequently normal) Focal or diffuse pneumonia CT findings: diffuse reticulonodular infiltrates, consolidation, nodules (multiple or single), cavities, mediastinal lymphadenopathy
Cytomegalovirus (uncommon; usually presents with retinitis or colitis)	Impaired cell-mediated immunity: CD4 count usually <50 cells/mm^3, after transplantation on immunosuppressant therapy	Cough, dyspnoea, and fever Chest CT: reticular or ground-glass opacities, alveolar infiltrates, nodules or nodular opacities, pleural effusions
Respiratory syncytial virus, human metapneumovirus, influenza, parainfluenza	Impaired cell-mediated immunity: CD4 count usually <200 cells/mm^3, chronic corticosteroid use, after solid organ transplantation, after stem cell transplantation	Cough, dyspnoea, fever Chest CT: ground-glass opacification, air-space shadowing, 'tree-in-bud', airway dilation and wall thickening
Toxoplasma gondii	Impaired cell-mediated immunity: CD4 count usually <100 cells/mm^3	Isolated pulmonary or disseminated disease Dry cough, fever, dyspnoea Chest CT: appearance similar to that of *Pneumocystis jirovecii* or fungal pneumonia, pleural effusion

COPD, Chronic obstructive pulmonary disease; *CT,* computed tomography.

drug reaction, including a typical allergic rash. If the patient is sensitive to co-trimoxazole, i.v. pentamidine (4 mg/kg per day), clindamycin and primaquine, atovaquone, or dapsone and trimethoprim can be given for the same duration. In severe disease, systemic corticosteroids reduce mortality rates. Deterioration can be rapid. Continuous positive airways pressure (CPAP) or mechanical ventilation may be required. Pneumothorax is a common complication of invasive ventilation, and CPAP is preferable where feasible. When ventilation occurs, the course is often protracted. ART should be initiated as early as possible because IRIS is not a feature of PJP.

Secondary prophylaxis is required when the CD4 count is below 200 cells/mm^3. The usual regimen is co-trimoxazole 960 mg three times a week or 480 mg/day. Patients sensitive to sulphonamide are given dapsone, pyrimethamine, or nebulized pentamidine. The last protects only the lungs and does not penetrate the upper lobes particularly efficiently; hence, if relapses occur on this regimen, they may be either atypical or extrapulmonary.

Box 44.14 Use of vaccines in adults living with HIV

Vaccine	Type	Regimen[a]
SARS-CoV-2	All are suitable	Initial doses: two (increase to three doses if CD4 count <200 cells/mm^3, HIV-related illness in the preceding 12 months, if not on ART, or on ART with detectable viral load); boosters as available
Hepatitis A	Inactivated	Non-immune, at-risk patients
Hepatitis B	Subunit	All non-immune patients
Human papillomavirus	Virus-like particle	Three doses for GBMSM (or equivalent risk, i.e., females and heterosexual males living with HIV) to age 45 years
Influenza	Inactivated	Annual vaccination for all
Meningococcus	Conjugated or recombinant protein	At-risk groups, age criteria
Pneumococcus	Conjugated and polysaccharide	Conjugated vaccine for all, polysaccharide additionally for at-risk groups
Pertussis	Acellular multicomponent	Pregnancy
Measles, mumps, and rubella[b]	Live attenuated	All non-immune patients
Varicella (chickenpox)[b]	Live attenuated	All non-immune patients
Herpes zoster (shingles)[b]	Live attenuated	At-risk groups (age criteria)

[a]Vaccination regimens are different in people living with human immunodeficiency virus (HIV) because of suboptimal immune responses requiring higher or more frequent dosage.
[b]Live attenuated viruses should not be given to patients with CD4 counts <200 cells/mm^3 and should be used with caution in those with CD4 counts <350 cells/mm^3.
GBMSM, Gay, bisexual, and other males who have sex with males; *SARS-CoV-2,* severe acute respiratory syndrome coronavirus 2.
Adapted from British HIV Association. Guidelines on the use of vaccines in adults living with HIV.

Cryptococcosis

The most common presentation of cryptococcal infection in the context of HIV is meningitis, although pulmonary and disseminated infections can also occur. The organism *Cryptococcus neoformans* is widely distributed, often in bird droppings, and is usually acquired by inhalation. The onset may be insidious with non-specific fever, nausea, and headache. As the infection progresses, raised intracranial pressure occurs with cranial nerve palsies, visual symptoms, confusion, and loss of consciousness. Seizures or other focal neurological presentations may occur. Neck stiffness and photophobia may be absent because these signs depend on the inflammatory response of the host, which, in this setting, is abnormal.

Diagnosis is made on examination of the CSF (after exclusion space-occupying pathology on CT or MRI imaging scan). Manometry should be performed at the time of lumbar puncture is done because raised intracranial pressure can be life-threatening. Indian ink staining shows the organisms directly. CSF cryptococcal antigen is positive at variable titre and remains present after treatment, although concentrations decrease. Culture should be sent.

Factors associated with a poor prognosis include a high organism count in the CSF, a low white blood cell count in the CSF, and impaired consciousness at presentation.

Usual treatment includes:

- Induction: i.v. liposomal amphotericin B (4.0 mg/kg per day) plus oral flucytosine (25 mg/kg per day) for 14 days. i.v. fluconazole (400 mg/day) is useful if kidney function is impaired or if amphotericin side-effects are troublesome. Steroids should be avoided.
- Consolidation: fluconazole (400 mg once daily) for 8 weeks.

ART initiation should be deferred for at least 4 weeks after the start of treatment because of the risk of IRIS. Long-term maintenance therapy with fluconazole should be continued for 12 months. This can be reviewed if the viral load is consistently undetectable and the CD4 count is consistently above 100 cells/mm^3 over a period of at least 3 months.

Candidiasis

Mucosal infection with *Candida* spp. occurs in the mouth and oesophagus and may be severe enough to cause odynophagia and dysphagia. *Candida albicans* is the usual organism, although infections with *Candida krusei* and *Candida glabrata* also occur. Pseudomembranous candidiasis, consisting of creamy plaques in the mouth and pharynx, is easily recognized, but erythematous *Candida* appears as reddened areas on the hard palate or as atypical areas on the tongue. Angular cheilitis can occur in association with either form. Vulvovaginal *Candida* infection may be difficult to treat.

Fluconazole or itraconazole is the agent of choice for treatment. Liquid formulations may be useful if swallowing is painful or impaired. Nystatin pastilles may also be helpful in managing pain. Disseminated *Candida* infection is uncommon in the context of HIV infection, but if present, fluconazole is the preferred drug; amphotericin, voriconazole, posaconazole, or caspofungin can also be used. Effective ART is the most successful strategy for managing candidiasis in persons living with HIV.

Aspergillosis

Infection with *Aspergillus fumigatus* is rare in people living with HIV unless there are coexisting factors such as lung pathology, neutropenia, transplantation, or glucocorticoid use. Spores are air borne and ubiquitous. After inhalation, lung infection proceeds to haematogenous spread to other organs. Sinus infection can occur. Voriconazole is the preferred treatment, with liposomal amphotericin B (3 mg/kg i.v. daily) an alternative. Caspofungin is also effective.

Histoplasmosis, blastomycosis, coccidioidomycosis, and *Talaromycosis* spp.

These fungal infections are geographically restricted but should be considered in patients who have travelled to areas of high risk. The most common manifestation is with pneumonia, which may

be confused with *P. jirovecii* in its presentation (see earlier). Systemic infections are also reported, particularly with *Talaromyces* (previously *Penicillium marneffei*), which can produce papular skin lesions. Treatment is with amphotericin B.

Protozoal infections

Toxoplasmosis

Toxoplasma gondii most commonly causes encephalitis and cerebral abscess in the context of HIV, usually as a result of reactivation of latent asymptomatic infection. The incidence depends on seropositivity to toxoplasmosis in the population. High antibody levels are found in France (90% of the adult population). About 25% of the adult UK population is seropositive to *Toxoplasma* spp.

Clinical features include focal neurology, seizures, fever, headache, and confusion. Focal neurological signs occur in more than 50% of cases. Eye involvement with chorioretinitis may also be present. In most cases of IgM, serology is positive as well as IgG. Typically, contrast-enhanced MRI of the brain shows ring-enhancing lesions and is more sensitive than CT.

Diagnosis is by characteristic radiological findings on MRI. Single-photon emission CT may also help differentiate toxoplasmosis from primary CNS lymphoma. Empirical anti-toxoplasmosis therapy is indicated when toxoplasmosis is suspected, and radiological improvement within 3 weeks is considered diagnostic. The differential diagnosis includes cerebral lymphoma, PML tuberculoma, and cryptococcal infection.

Treatment is with pyrimethamine for at least 6 weeks (loading dose, 200 mg; then 50 mg/day), combined with sulfadiazine (2–4 g/day for 2 days followed by 500–1000 mg four times per day) and folinic acid (leucovorin) (5–25 mg with each dose of pyrimethamine). Clindamycin is used if sulfa drugs cause hypersensitivity. Alternatives include trimethoprim plus sulfamethoxazole, atovaquone, and pyrimethamine plus azithromycin.

ART should be initiated as soon as the patient is clinically stable, approximately 2 to 4 weeks after acute treatment has begun, to minimize the risk of IRIS.

Cryptosporidiosis

Cryptosporidium parvum cysts attach to the epithelium of the small bowel wall, causing secretion of fluid into the gut lumen and failure of fluid absorption. Self-limiting acute diarrhoea may be seen in an immunocompetent individual. In advanced HIV infection, it can cause severe and progressive watery diarrhoea, which may be associated with anorexia, abdominal pain, and nausea and vomiting. It is also associated with sclerosing cholangitis. The cysts are seen on stool specimen microscopy using Kinyoun acid-fast stain and are readily identified in small bowel biopsy specimens. Nitazoxanide and paromomycin may have some effect; however, immune restoration with effective ART is the treatment of choice and usually leads to remission. In the ART era, infection is rare.

Microsporidiosis

Enterocytozoon bieneusi and *Septata intestinalis* are causes of diarrhoea. Spores can be detected in stools using a trichrome or fluorescent stain that attaches to the chitin of the spore surface. Immune restoration with ART is the treatment of choice and can have a dramatic effect.

Leishmaniasis

Leishmaniasis occurs in immunosuppressed individuals who have been in endemic areas, including South America, tropical Africa, and much of the Mediterranean. Symptoms are frequently nonspecific and consist of fever, malaise, diarrhoea, and weight loss. Splenomegaly, anaemia, and thrombocytopenia are significant findings. Leishmania amastigotes live and multiple in tissues and may be seen on bone marrow biopsy or splenic aspirates. Serological tests for *Leishmania* are not reliable, and biopsy may be required. Treatment is with liposomal amphotericin plus ART. Relapse is common without ART, and long-term secondary prophylaxis may be required in this setting.

Viral infections

Hepatitis B

Hepatitis B infection does not appear to influence the natural history of HIV or responses to anti-HIV treatment. However, in HIV co-infected patients:

- Rates of hepatitis B e antigen (HBeAg) clearance and anti-E (HBeAb) seroconversion are significantly reduced.
- HBV viral load is higher.
- The risk of developing chronic infection is increased.
- Disease may reactivate if treatment for hepatitis B is withdrawn in resolved or controlled hepatitis B infection.

Liver disease occurs most commonly in those with high HBV DNA levels indicative of continuing replication. Detection and quantification of HBV DNA are markers of viral activity and predictive of responses to treatment. Baseline HBV resistance testing may guide interventions in those previously exposed to antiviral drugs. Hepatitis B is treatable, and people living with HIV and hepatitis B should always receive ART that contains either TDT/TAF plus FTC/3TC (see earlier). Initiation of ART may result in a flare of HBV because of improved immune function.

Hepatitis C

Hepatitis C co-infection is associated with:

- More rapid progression of HIV infection
- Blunted CD4 responses to ART
- More likely and more rapid hepatitis C progression
- Higher hepatitis C viral load
- Worse drug-related hepatotoxicity.

Assessment of those with both HIV and hepatitis C virus (HCV) requires full clinical and laboratory evaluation, as well as ultrasound and FibroScan to stage the liver disease. For HCV, both viral load and genotype will influence therapeutic decision-making.

Potent direct-acting antivirals (DAAs) have revolutionized HCV care, and the infection can be cured with short courses of oral therapy. All people living with HIV and HCV should commence ART. ART should be started first in most instances, ideally 4 to 6 weeks before starting treatment for HCV. NRTIs and INSTIs are compatible with DAAs for HCV, but drug interactions should be monitored with other ART classes. The Liverpool website provides comprehensive advice on drug interactions with ART (see Further reading). HCV cure outcomes are similar in individuals with co-infection and are dependent on stage of disease, HCV genotype, and co-administered ART, with response rates of more than 90%.

Acute hepatitis C has increased in people living with HIV, particularly MSM. Epidemics have been reported in several countries, including the UK. UK guidelines recommend that patients are offered DAAs for HCV in acute infection if:

- Decrease in HCV RNA is less than $2^{\log 10}$ at week 4 after diagnosis
- HCV RNA is positive at week 12 after diagnosis.

Immune responses to HCV do not protect against re-infection, and high rates of re-infection have been reported after both therapeutic and spontaneous clearance. Patients who initially clear HCV but have evidence of re-emergent virus should be assessed for relapse or re-infection. Relapse is treated as for chronic HCV, and re-infection is managed as for acute hepatitis C.

Hepatitis B and C virus co-infection

Because of the comparable routes of transmission of hepatitis viruses and HIV, co-infection is common, particularly in MSM, people who inject drugs, and those who acquired HIV through blood products. A higher prevalence of hepatitis viruses is found in those living with HIV infection compared with the general population: of 38 million people living with HIV worldwide, about 12% (5 million) also have chronic viral hepatitis. All those with newly diagnosed HIV should be screened for hepatitis A, B, and C. Hepatitis A and B vaccination should be offered to those without immunity.

As treatment advances have improved HIV prognosis, hepatitis virus co-infection has become an increasingly significant cause of morbidity and mortality, making the management of HIV and hepatitis co-infection a key aspect of clinical care. People living with HIV and hepatitis co-infection are more likely to have rapid liver disease progression than people with mono-infection. Liver disease should be staged. Appropriate monitoring for complications of portal hypertension and hepatocellular carcinoma screening should be performed in those with cirrhosis. People living with HIV and liver disease should be jointly managed by HIV clinicians together with hepatologists. For people with end-stage liver disease, care should be based in specialist centres, ideally with links to a transplant unit.

In co-infected patients, the hepatotoxicity associated with specific ART may be potentiated.

Cytomegalovirus (CMV)

CMV has historically been the cause of considerable morbidity, especially in later stages of disease when the CD4 count is consistently below 100 cells/mm^3. The availability of ART has dramatically altered the epidemiology of CMV in those living with HIV: most people start ARVs early and are therefore not at risk. Disease presentations include retinitis, colitis, oesophageal ulceration, encephalitis, and pneumonitis. CMV also causes polyradiculopathy and adrenalitis. Arteritis may be the major pathogenic mechanism.

CMV retinitis occurs when the CD4 count is below 50 cells/mm^3. Routine fundoscopy should be carried out to look for evidence of early infection. Although usually unilateral to begin with, the infection may progress to involve both eyes. Presenting features depend on the area of retina involved. Loss of vision is most common when there is macular involvement. Other symptoms include floaters, field loss, scotomata, orbital pain, and headache. Examination of the fundus (Fig. 44.4) reveals haemorrhages and exudates, which follow the vasculature of the retina: a so-called 'pizza pie' appearance. Retinal detachment and papillitis may occasionally occur. Features are highly characteristic, and the diagnosis is made clinically. If untreated, retinitis spreads within the eye, destroying the retina within its path. All persons with symptoms of visual disturbance should have a thorough examination with the pupils dilated; if no evident pathology is seen, a specialist ophthalmological opinion should be sought.

Treatment for CMV retinitis should be started as soon as possible, with either oral valganciclovir (900 mg twice daily), i.v. ganciclovir (5 mg/kg twice daily), or i.v. foscarnet (90 mg/kg twice daily) given for at least 3 weeks or until retinitis is quiescent. Ganciclovir can be given directly into the vitreous cavity, but regular injections are required. A sustained-release implant of ganciclovir is available that can be surgically inserted into the affected eye. Cidofovir is available for use if other drugs are contraindicated. The major side-effect of ganciclovir is myelosuppression; foscarnet and cidofovir are nephrotoxic. If immunosuppression is not reversed, reactivation is common, leading to blindness. Maintenance therapy may be required until ART is instituted and immune competence restored.

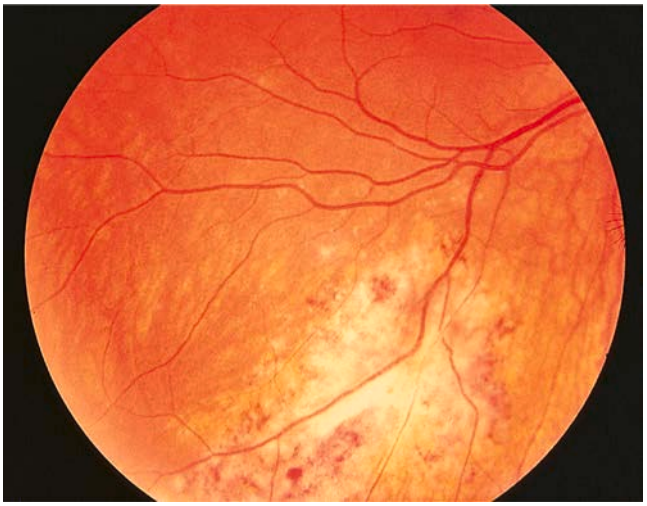

Fig. 44.4 **Untreated cytomegalovirus retinitis.**

CMV colitis presents with abdominal pain (generalized or in the left iliac fossa), diarrhoea that may be bloody, generalized abdominal tenderness, and a low-grade fever. Dilated large bowel may be seen on and abdominal radiograph. Sigmoidoscopy shows a friable or ulcerated mucosa. Histology shows characteristic 'owl's eye' cytoplasmic inclusion bodies (Fig. 20.14). Treatment is with i.v. ganciclovir (5 mg/kg twice daily) for 14 to 28 days. When the patient is stable, optimization of ART improves symptoms, and the histological changes are reversed. Restoration of immune competence with ART removes the need for maintenance therapy.

CMV oesophagitis occurs because non-colonic sites along the GI tract are prone to CMV infection, leading to ulceration of the oesophagus, usually in the lower third, and causing odynophagia.

CMV encephalopathy has clinical similarities to that caused by HIV itself, though with a more aggressive course. ***CMV polyradiculopathy*** can affect the lumbosacral roots, leading to muscle weakness and sphincter disturbance. CSF has an increase in white blood cells, which, surprisingly, are almost all neutrophils. Although progression may be arrested by anti-CMV medication, functional recovery may not occur. The diagnosis is based on MRI and CSF viral PCR. Treatment is with ganciclovir. ART should be started within 2 weeks of CMV treatment.

Herpes infections

Herpes simplex primary infection occurs with greater frequency and severity, presenting in an ulcerative rather than vesicle form in immunosuppressed individuals. Genital, oral, and occasionally disseminated oral or genital infection can occur. Viral shedding may be prolonged in comparison with immunocompetent patients.

Varicella zoster infection can occur at any stage of HIV but tends to be more aggressive and longer lasting in patients who are immunosuppressed. Multidermatomal zoster may occur.

Treatment with valaciclovir is usually effective. Frequent recurrences need suppressive therapy. Aciclovir-resistant strains (usually caused by thymidine kinase-deficient mutants) may respond to foscarnet.

Human herpesvirus 8 (HHV-8) is the causative agent of KS (see later).

EBV is more likely to be latent in people living with HIV. There are increased EBV titres in oropharyngeal secretions and high numbers of EBV-infected B cells. The normal T-cell response to EBV is depressed in HIV. EBV is associated with *primary cerebral lymphoma* and *non-Hodgkin's lymphoma* (see later). *Oral hairy leukoplakia* caused by EBV is a sign of immunosuppression first noted in HIV but now recognized in other conditions. It appears intermittently on the lateral borders of the tongue or the buccal mucosa as a pale, ridged lesion. Although it is usually asymptomatic, patients may find it unsightly and occasionally painful. The virus can be identified histologically and on electron microscopy. ART is helpful. There is a variable response to treatment with aciclovir.

Human papillomavirus infection

HPV produces genital, plantar, and occasionally oral warts, which may be slow to respond to therapy and recur repeatedly. HPV is also associated with cervical, vaginal, and anal intraepithelial neoplasia, which in time may progress to squamous cell carcinomas of the cervix, vulvo-vagina, and rectum. HPV vaccination should be offered to those living with HIV.

Polyomavirus infection

JC virus, a member of the papovavirus family, infects oligodendrocytes, leading to demyelination particularly within the white matter of the brain, causing PML. Clinical features are progressive neurological or intellectual impairment, often including hemiparesis or aphasia. The condition is usually inexorably progressive, but a stuttering course may be seen. Radiologically, the lesions are usually multiple and confined to the white matter. They do not enhance with contrast and do not produce a mass effect. MRI (Fig. 44.5) reveals enhanced signal on T2-weighted images of the lesions. MRI appearance and JC virus detection by PCR in a CSF sample are usually sufficient for diagnosis and avoid the need for brain biopsy for tissue diagnosis. There is no specific treatment. Effective ART leads to clinical and radiological remission.

SARS-CoV-2 (COVID-19) infection

The incidence of SARS-CoV-2 appears to be equivalent that of the general population. Adverse outcomes are more commonly reported in association with CD4 counts below 350 cell/mm^3, people with untreated HIV, and those with a detectable viral load. Patients living with HIV who are hospitalized because of COVID-19 infection are younger and have more co-morbidities than the general population. Early anti-SARS-CoV-2 treatment may be indicated for people living with HIV, especially if untreated or with a poor immune response to ART. Pre-existing ART should be continued during hospital admissions, although the route of administration may need to change if oral treatment is not possible in critical illness. Drug–drug interactions must be considered. Viral blips may be seen, and the CD4 count may fall, necessitating consideration of appropriate prophylaxis for other opportunistic infections.

Vaccination against SARS-CoV-2 is recommended for all those living with HIV. Vaccine choice is dependent on local availability and guidelines. In situations in which vaccine supplies may be limited, those with CD4 counts below 350 cells/mm^3 should be prioritized. Securing continuity of HIV treatment and care in the event of isolation or lockdown measures is crucial. Long-term symptoms after COVID-19 should be addressed as for the general population with appropriate referrals to specialist services.

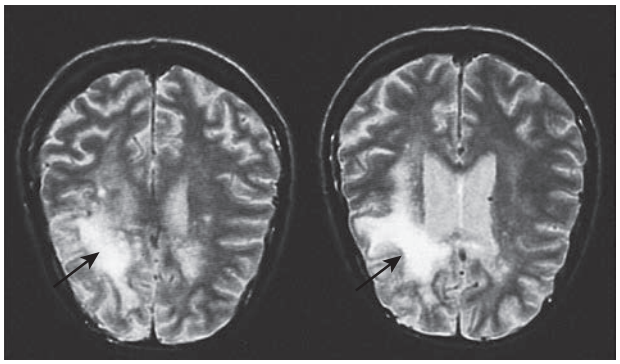

Fig. 44.5 Magnetic resonance imaging scans showing progressive multifocal leucoencephalopathy *(arrows)*.

Mpox infection

Mpox is caused by an *Orthopoxvirus* related to variola. It is transmitted by person-to-person contact and occasionally by fomites. An outbreak in 2022 occurred outside the usual endemic areas of central and west Africa, disproportionately affecting MSM and linked with sexual contact. All those with mpox should have a full STI screen including HIV testing.

Cutaneous, mucosal, and anogenital vesicular or ulcerating lesions are accompanied by fever, lymphadenopathy, and a generalized rash. In people with uncontrolled HIV or a CD4 count below 200 cells/mm^3, the clinical picture may be more severe with multisystem manifestations. PCR detection of mpox DNA from lesions is the diagnosis test of choice.

Treatment is symptomatic for pain and fever alongside skin lesion care, isolation, and contact tracing. In severe cases, hospitalization and antiviral therapy may be indicated. Oral tecovirimat (600 mg twice daily for those weighing 40–120 kg; three time daily for those weighing >120 kg). Brincidofovir and cidofovir may also be effective. Vaccinia immune globulin i.v. has been used for people who are unable to mount an adequate immune response. Mpox IRIS has been seen with the introduction of ART, and care must be taken with the introduction of ART in those who are not yet taking or restarting ART. Vaccination should be offered to all people living with HIV. PEP with mpox vaccination should be given as soon as possible and ideally within 4 days of exposure.

Influenza infection

Influenza virus A is no more frequent in persons living with HIV but has been associated with an increased severity and complication rate when the CD4 counts are less than 200 cells/mm^3. People living with HIV should be vaccinated annually. Prophylaxis with oseltamivir is used in unvaccinated individuals with CD4 counts below 200 cells/mm^3.

Bacterial infections

Bacterial infection in HIV is common. Cell-mediated immune responses normally control infection against intracellular bacteria such as mycobacteria. The abnormalities of B-cell function associated with HIV lead to infections with encapsulated bacteria because reduced production of IgG2 cannot protect against the

polysaccharide coat of such organisms. These functional abnormalities may be present well before there is a significant decline in CD4 numbers so bacterial sepsis may be seen in the early stages of HIV infection. *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* infections are examples. Bacterial infection is often disseminated and although usually amenable to standard antibiotic therapy, may recur. Long-term prophylaxis may be required for frequently recurring infection.

Mycobacterium tuberculosis

Many parts of the world that have a high prevalence of TB also have a high prevalence of HIV infection, both of which are increasing. TB can cause disease with minimal immunosuppression, so it can appear in both early and advanced HIV. HIV-related TB frequently represents reactivation of latent TB, but there is also clear evidence of newly acquired infection and hospital-acquired spread in populations living with HIV.

The pattern of disease differs with the degree of immunosuppression:

- People with relatively well-preserved CD4 counts have a clinical picture comparable to that in the general population with predominantly pulmonary infection.
- In advanced HIV, pulmonary disease may be atypical, and extrapulmonary disease is more common, including CNS, lymph nodes, bone marrow, and liver infection. TB bacteraemia may be present. CNS disease is the most severe and concerning presentation and can be intracranial or affect the spinal cord.

The diagnosis depends on demonstrating the organisms in appropriate tissue specimens. The response to tuberculin testing is blunted in individuals living with HIV and is unreliable. Sputum microscopy results may be negative even in those with pulmonary infections; culture techniques are the best diagnostic tool.

M. tuberculosis infection usually responds well to standard treatment regimens. Multi- and extensive drug-resistant TB are emerging problems; adherence to anti-tuberculous therapy is crucial. Secondary prophylaxis may be required after treatment.

Testing for latent TB infection with interferon-gamma release assays (IGRAs) should be offered to all people living with HIV in areas of high TB prevalence and to all those with additional risk factors for TB regardless of local prevalence. Testing for TB should take place irrespective of CD4 count. For those who are IGRA positive and in whom active TB has been excluded, latent TB infection should be treated with 6 months of isoniazid plus pyridoxine or 3 months of isoniazid plus rifampicin plus pyridoxine.

Drug–drug interactions between anti-retroviral and anti-tuberculous medications are complex and caused by enzyme induction or inhibition. Rifampicin is a potent inducer of CYP450. PIs are contraindicated with rifampicin. Drugs that can be used with rifampicin include efavirenz and dolutegravir (twice daily). FTC/3TC and TDF can also be used, but TAF-containing drugs should be avoided. Rifabutin has a weaker effect on CYP450 and may be substituted for rifampicin if PIs are required for HIV therapy; rifabutin can be used with reduced doses of PIs given three times per week. Co-prescribing for HIV and TB is complex and should always been done with an HIV specialist.

IRIS can occur because of the improvement in immune function in patients with TB starting ART. Paradoxical inflammatory reactions include exacerbation of symptoms, new or worsening clinical signs, and deteriorating radiological appearances. This usually occurs in the first few weeks after initiation of ART. In people living with HIV and TB:

- Allowing at least 2 weeks of anti-tuberculous therapy before commencing ART reduces the risk of IRIS.
- ART should then be started as soon as is practicable and within 4 weeks of initiation of TB treatment.
- In people with a CD4 counts less than 50 cells/mm^3, ART should be offered within 2 weeks.
- In CNS disease, ART should be delayed until 8 weeks after initiation of TB treatment because worsening of CNS disease could lead to fatality.
- Steroids may be needed to manage IRIS.

Mycobacterium avium-intracellulare infection

Atypical mycobacteria, particularly MAI, generally appear only in the very late stages of HIV infection with profound immunosuppression. MAI is a saprophytic organism of low pathogenicity that is ubiquitous in soil and water. Entry may be via the GI tract or lungs with dissemination via infected macrophages.

Clinical features include fever, malaise, weight loss, anorexia, sweats, and anemia. GI symptoms may be prominent with diarrhoea and malabsorption. Abnormal liver blood test results and a low haemoglobin may be seen. A high index of suspicion is needed. Direct examination and culture of blood, lymph node, bone marrow, or liver indicate the diagnosis most reliably. MAI is typically resistant to standard anti-tuberculous treatment. Rifabutin in combination with clarithromycin or azithromycin can reduce the burden of organisms and ameliorate symptoms in some. Ethambutol, rifabutin, and clarithromycin is a common combination. Addition of amikacin may be needed. Primary prophylaxis with rifabutin or azithromycin may delay the appearance of MAI in people with CD4 counts below 50 cells/mm^3, but no corresponding increase in survival has been shown.

Salmonella spp.

Salmonella infections are much less frequent with the advent of ART. Organisms are usually acquired orally and cause GI disease or disseminated infection. *Salmonella* osteomyelitis and cystitis have been reported. The diagnosis is from blood and stool cultures. Most isolates are sensitive to oral ciprofloxacin 500 mg twice daily for 5 days. Education on food hygiene should be provided.

Other bacterial infections

Folliculitis, abscesses, and cellulitis are common and are usually caused by ***S. aureus***.

Periodontal disease is a chronic disease mediated by immunoinflammatory factors. In the early stages, oral bacteria interact with periodontal tissue, triggering an inflammatory response that leads to destruction of the periodontium, with pain and damage to the gums. It is more common in smokers. Therapy is with local debridement and systemic antibiotics.

Infections caused by other organisms

Strongyloides infection is caused by a nematode found in tropical areas and may cause a hyper-infection syndrome in people living with HIV. Larvae are produced, which invade through the bowel wall and migrate to the lung and occasionally to the brain. Albendazole or ivermectin is used for treatment.

Scabies may be much more severe in HIV infection and cause disseminated atypical, crusted papular lesions known as 'Norwegian scabies', from which mites are readily demonstrated. Superadded staphylococcal infection may occur. Treatment with conventional agents, such as lindane, may fail. Ivermectin has been used to good effect.

HIV-associated cancers

HIV is pro-inflammatory state that increases the risk of cancer. In the UK, the incidence and prevalence of malignancies are higher in people living with HIV, with cancers occurring at younger ages and with higher rates of mortality compared with the general population. The most tightly associated malignancies are KS, non-Hodgkin's lymphoma, and cervical cancer, which are AIDS-defining illnesses. Hepatoma and Hodgkin's lymphoma, although not AIDS defining, are significantly more common. Anal cancer is also more common than in the general population.

Although AIDS-defining malignancies have significantly decreased with the advent of ART, the increased longevity of people living with HIV increases the risks for development of cancers that are associated with older age. Non–AIDS-defining cancers (NADCs) are now among the leading causes of death among people living with HIV. ART may provide some prevention benefits for NADCs.

Kaposi's sarcoma

KS in association with HIV (epidemic KS) behaves more aggressively than in the general population (endemic KS). The incidence has fallen significantly since the introduction of ART. HHV-8 is implicated in the pathogenesis. KS skin lesions are characteristically purple and well circumscribed, occurring in multiple sites with a predilection for the tip of the nose, the genitals, and the feet. KS is a multicentric tumour consisting of spindle cells and vascular endothelial cells, which together form slit-like spaces in which red blood cells become trapped. This process is responsible for the characteristic purple hue of the tumour. In addition to the skin lesions, KS affects the lymph nodes, the lung, and the GI tract, giving rise to a wide range of symptoms and signs. Most people with visceral involvement also have skin or mucous membrane lesions. Visceral KS carries a worse prognosis than disease confined to the skin. KS can affect the eyelids and conjunctiva, causing periorbital oedema (Fig. 44.6).

ART is the treatment for KS. Local radiotherapy gives good results in discrete skin lesions and is helpful in lymph node disease. In aggressive disease, systemic chemotherapy with liposomal anthracyclines is indicated.

Lymphoma

Lymphomas are relatively common in people living with HIV, especially those with low CD4 counts and in whom the viral load has been uncontrolled for a substantial period. Non-Hodgkin, large B-cell type is most common. Lymphomas are frequently extranodal and often affect the brain, lung, and GI tract. Many of these tumours are strongly associated with EBV, with evidence of expression of latent gene antigens such as Epstein–Barr nuclear antigens (EBNA 1–6), some of which are involved in the immortalization of B cells and drive a neoplastic pathway. HIV-associated lymphomas are commonly aggressive. Patients often present with systemic 'B' syndromes and progress rapidly despite chemotherapy. Primary cerebral lymphoma is variably responsive to radiotherapy but overall carries a poor prognosis.

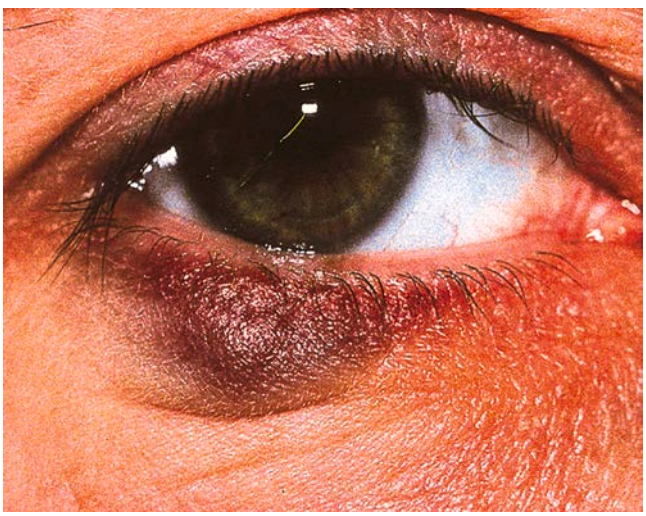

Fig. 44.6 **Kaposi's sarcoma of the eyelid.**

Cervical cancer

For females with HIV, there is an increased risk of cervical cancer caused by oncogenic subtypes of HPV. The risk is significantly reduced by effective ART. Enhanced surveillance and early intervention are indicated with annual cervical cytology to monitor for pre-malignant changes.

Anal cancer

Anal cancer risk is significantly elevated in people living with HIV, particularly among MSM. Females with precancerous cervical changes and cervical cancer are also at increased risk. Anal cancer is strongly linked to infection with HPV, with HPV 16 and 18 being the most common subtypes detected in almost 90% of cases. The incidence of precancerous change is reduced by HPV vaccination. Early detection and treatment of high grade anal intraepithelial neoplasia through high-resolution anoscopy has been shown to modify progression to invasive cancer.

PREVENTION AND CONTROL OF HIV

HIV is a treatable chronic condition with a life expectancy that can match that of the general population in those who start treatment early. Initiating treatment when infection is more advanced compromises clinical outcomes and is the most important predictor of morbidity and mortality. In 2020, people diagnosed late in England were found to be 17 times more likely to die within 1 year of their diagnosis compared with prompt diagnosis. Of the 100 000 people living with HIV in 2022, about 5% were undiagnosed, and 44% of people newly diagnosed were diagnosed late (CD4 count <350 cells/mm^3).

Long-term engagement with effective treatment delivers the best clinical outcomes for people living with HIV and when the viral load is undetectable prevents onward transmission. In 2022, the UK Health Security Agency estimated around 15 000 people in England had transmissible levels of virus, of whom 24% were undiagnosed, 35% were not retained in care, and 24% were on treatment with no reported viral load.

Expanding HIV testing

Expansion of testing within and beyond sexual health services is a key intervention to achieve good clinical outcomes and a reduction in new infections. In 2021, the UK government committed to end new HIV transmissions in the UK by 2030 with expansion of HIV testing as a key intervention

UK guidelines list clinical settings where HIV testing should be universally offered. Guidance also includes a list of clinical situations and diagnoses **(indicator conditions)** that are highly predictive of HIV infection and in which HIV testing is recommended (Box 44.15). Testing is recommended for all new registrants in primary

Box 44.15 HIV testing: where and who to test

Universal HIV opt-out testing is recommended for all patients attending the following settings:

- Sexual health services
- Antenatal services
- Termination of pregnancy services
- Addiction and substance misuse services
- Healthcare services for tuberculosis, hepatitis B, hepatitis C, and lymphoma
- Primary and secondary healthcare, including emergency departments, in areas of high and extremely high HIV seroprevalence
- Individuals commencing chemotherapy or immunosuppressive or immunomodulatory therapy in line with speciality guidelines

HIV testing should be routinely recommended to the following individuals:

- All patients diagnosed with an STI
- Sexual partners of those living with HIV
- Males who have disclosed sexual contact with other males
- Female sexual contacts of males who have sex with males
- People of Black African heritage
- People reporting current or prior history of injecting drug use
- Sex workers
- Transwomen
- People in prison
- Persons from a country of high HIV prevalence (>1%)
- Persons who report sexual contact abroad or in the UK with individuals from countries of high HIV prevalence
- Individuals known to have or have had a mother living with HIV and who do not have documented HIV-negative status
- Patients presenting for healthcare when HIV is a differential diagnosis

HIV-associated indicator conditions

Respiratory

- Tuberculosis, *Pneumocystis jirovecii* pneumonia, bacterial pneumonia, aspergillosis

Neurology

- Cerebral toxoplasmosis, primary cerebral lymphoma, cryptococcal meningitis, progressive multifocal leucoencephalopathy, aseptic meningitis or encephalitis, cerebral abscess, space-occupying lesion of unknown cause, Guillain–Barré syndrome, transverse myelitis, peripheral neuropathy, dementia

Dermatology

- Kaposi's sarcoma, severe or recalcitrant seborrhoeic dermatitis, severe or recalcitrant psoriasis, multidermatomal or recurrent herpes zoster

Gastroenterology

- Persistent cryptosporidiosis, oral candidiasis, oral hairy leukoplakia, chronic diarrhoea of unknown cause, weight loss of unknown cause, *Salmonella* spp. infection, *Shigella* spp. infection, *Campylobacter* spp. infection, hepatitis B infection, hepatitis C infection

Oncology

- Non-Hodgkin's lymphoma, anal cancer, anal intraepithelial dysplasia, lung cancer, seminoma, head and neck cancer, Hodgkin's lymphoma, Castleman's disease

Gynaecology

- Cervical cancer, vaginal intraepithelial neoplasia, cervical intraepithelial neoplasia (grade 2 or above)

Haematology

- Any unexplained blood dyscrasia, including thrombocytopenia, neutropenia, and lymphopenia

Ophthalmology

- Cytomegalovirus retinitis; infective retinal diseases, including herpesviruses and *Toxoplasma* spp.; any unexplained retinopathy

Ear, nose, and throat

- Lymphadenopathy of unknown cause, chronic parotitis, lymphoepithelial parotid cysts

Other

- Mononucleosis-like syndrome (primary HIV infection), pyrexia of unknown origin, any lymphadenopathy of unknown cause, any STI

STI, Sexually transmitted infection.

care and for patients admitted to acute medical care in areas where HIV seroprevalence is more than 2 per 1000 population.

Expanded opt-out testing for blood-borne viruses (HIV, hepatitis B and C) in emergency departments in areas of high HIV prevalence was implemented in 2022 to reach communities underserved by existing testing opportunities. Early results show a significant number of people newly diagnosed with all three viruses, as well as people already diagnosed but not accessing effective care. Opt-out testing for blood-borne viruses is implemented in all adult prisons in England for new arrivals.

Point-of-care HIV antibody tests that are sensitive, specific, and easy to use; are readily available; can test either blood or oral fluids; and give results within minutes. Home sampling and home testing approaches have increased testing rates in some populations.

All reactive POCTs should be followed up with confirmatory serological assays, and arrangements must be in place to ensure that people who are found to be HIV positive have rapid routes into specialist clinical care and to peer support.

Strategies for reducing HIV transmission

HIV is a preventable infection, yet new infections continue to occur. Combinations of behavioral, biomedical, and structural approaches are required, with specific interventions appropriate for the population at risk.

Models of the epidemic in the UK suggest that most new infections are transmitted from people who are unaware of their HIV status or have recently acquired HIV. Reduction of the high rates of undiagnosed infection through scale-up of testing and early initiation of effective treatment is therefore central to an effective prevention response.

For those at high risk of acquisition, additional emphasis on the need for repeat testing is required because those with early infection and a high viral load are particularly infectious.

Vaccine development has been hampered by the genetic variability of the virus and the complex immune response that is required from the host, with disappointing results from trials of candidate agents.

Consistent, correct condom use and education for behavior change are key strategies.

Provision of clean injecting equipment for people who inject drugs has been successful in the countries where it has been implemented.

Medically performed circumcision in heterosexual males without HIV has been demonstrated in studies in Africa to reduce female-to-male transmission of HIV by at least 50% and reduce male-to female transmission.

Use of effective ART to maintain a viral load below the limits of detection by people living with HIV has been demonstrated to reduce onward transmission risk to zero. These data have been used to support the 'U=U' message campaign, reinforcing the benefits of testing and early treatment.

Partner notification schemes are important in ensuring appropriate testing and interventions are available for those who may be at risk of HIV acquisition. Availability and accessibility of confidential HIV testing provide an opportunity for health education to reduce risk.

Pre-exposure prophylaxis

The use of ART by people who are not living with HIV but who are at risk of acquisition is called PrEP. This consists of oral TDF/FTC taken either daily or on demand before potential HIV exposure. TAF/FTC can also be used. Injectable PREP using cabotegravir every 2 months has been developed, but this not available on the National Health Service (NHS) at the time of writing. It is superior to oral PrEP and preferred by those who entered clinical trials. When used consistently, PrEP has been shown to be highly successful and safe, with a reduction in the risk of HIV acquisition by up to 90%. Based on these results, PrEP, with appropriate safety monitoring, is recommended as an effective HIV prevention strategy. Work is still ongoing to scale up access for all those who could benefit from PrEP within the NHS. PrEP uptake rates are highest among gay and bisexual males and lowest for females and heterosexuals of Black African and Asian ethnicities.

Global strategies

Understanding and changing behaviour is crucial but notoriously difficult; sex, HIV, and AIDS carry many taboos. Stigma, poverty, punitive homophobic and transphobic legislation, social unrest, and war all contribute to the spread of HIV. Ongoing investment in and prioritization of HIV requires political will (not always readily available) if progress is to be sustained.

CORE SKILLS AND KNOWLEDGE

Skin diseases are common, and their burden on a population level is significant. Across Europe, they have an annual incidence of more than 40% with the commonest being fungal infection, acne, and eczema. In the UK, skin cancers are more common than the sum total of every other type of cancer. Skin diseases cause considerable distress, and some can be life-threatening.
