
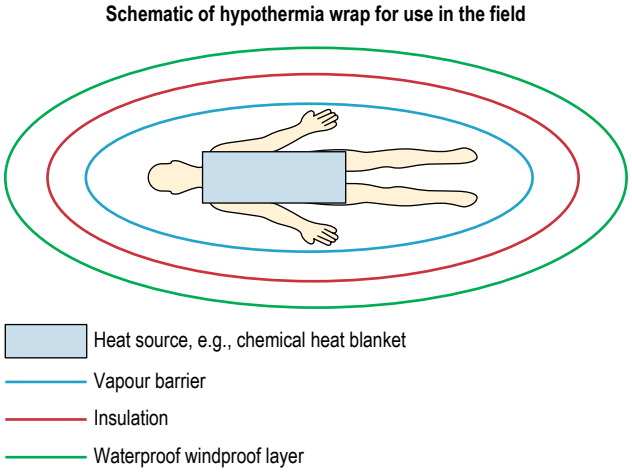

Fig. 16.6 Hypothermia wrap.

temperature. They should be evacuated in a multilayer wrap that provides shelter from the elements, insulation, and a vapour barrier (Fig. 16.6). The latter will minimize the energy loss from the heat used to evaporate water. Heat sources can be added to the wrap to minimize the temperature drop that occurs after insulation.

Swiss stage III

In severe hypothermia (T_{Core} < 28°C), people look dead with poor, difficult-to-detect vital signs. These patients are at risk of cardiopulmonary arrest. They should be transported in a hypothermia wrap with gentle movement to a hospital, preferably with rewarming and intensive care unit facilities.

Swiss stage IV

These patients have no discernible vital signs after 1 min of assessment. Start standard CPR and continue to hospital, preferably with extracorporeal cardiac life support (ECLS) facilities. The use of a mechanical cardiopulmonary resuscitation device will facilitate prolonged CPR during transfer. Survival is possible in some patients after prolonged resuscitation and active rewarming to good neurological outcome. The longest period of CPR for a hypothermic patient with full recovery is 6.5 hours in the context of an initial T_{Core} of 23.2°C.

Hospital treatment

In the hospital, core temperature should be measured. Patients should be rewarmed in a monitored environment. Passive rewarming with blankets, forced warm air, etc., is effective in mild and moderate cases. In severe hypothermia, rewarming has been successfully undertaken with invasive techniques such as peritoneal, thoracic, or bladder lavage when resources are limited. However, ECLS such as cardiac bypass or extracorporeal membrane oxygenation (ECMO) are preferred and improve survival. The Hypothermia Outcome Prediction after Extracorporeal life support (HOPE) score calculates the probability of survival for patients in hypothermic cardiac arrest and guides decision-making. Give warm intravenous fluids slowly. Correct metabolic abnormalities and check for underlying medical causes.

Avalanche medicine

In Europe and North America, avalanche kills 150 people each year. Many are the result of recreational activities (skiing, climbing, snowmobiles), but avalanches also bury people on roads and in villages.

A person is said to be buried if the head and chest are under the snow. Breathing may still be possible if the airway remains open, the chest can expand, and there is sufficient gas diffusion through the snowpack for oxygenation and CO_2 disbursal. Gas diffusion depends on snow density. Death in the first few minutes is due to asphyxia or trauma, and survival depends on immediate rescue by bystanders. Survival falls rapidly after 10 to 15 minutes, and these survivors often have poor neurological outcome because of hypoxia. As time progresses, hypoxia, hypercapnia, and hypothermia become increasingly important. However, if the victim has been able to breathe under the snow and become hypothermic before cardiac arrest occurs, then survival with good neurological outcome has been recorded more than an hour after burial.

Management

If the victim is in cardiac arrest in the first 60 minutes, asphyxia is the likely cause and standard CPR methods should be employed. After 60 minutes hypothermia is possible, and in cardiac arrest, continuous resuscitation and transfer to a facility with ECLS should be considered.

Peripheral cold injury

Extremity injury due to cold exposure is often associated with hypothermia.

Non-freezing cold injury

Non-freezing cold injury (NFCI) describes extremity injury caused by exposure to wet and cold conditions above freezing temperatures. It is seen in outdoor sportspersons and rough sleepers. In military personnel it has been recognized ('trench foot') from the time of Napoleon's campaigns (1812). The long-term sequelae can be very disabling.

Phases of injury

- Pre-hyperaemic: hours or days, when extremities are cold, pale, cyanotic, and oedematous, with sensory changes.
- Hyperaemic: 10 days, when there is sensory disturbance, weakness, atrophy, and anhidrosis.
- Post-hyperaemic: months or years, characterized by cold sensitivity, hyperhidrosis, infection, and trauma.

Chilblains (pernio) occur on exposed skin as blue plaques which may ulcerate and last for 1 to 2 months.

Management

- Treat underlying hypothermia
- Elevate limb
- Provide a cool, dry air flow
- Analgesia
- Long-term foot care and chronic pain management.

Freezing cold injury

This occurs in tissues exposed to freezing temperatures below 0°C.

Frostnip

A superficial injury with transient pallor, numbness, and pain that resolves on rewarming with no significant long-term damage.

Frostbite

The phases of injury are characterized as follows.

- Pre-freeze: cooling, vasoconstriction, and ischaemia
- Freeze/thaw: intra- or extracellular ice crystal formation causing cellular damage. Thawing initiates a reperfusion injury and inflammatory reaction
- Vascular stasis: sludging, coagulation, and ischaemia
- Late ischaemic: infarction, with an inflammatory cascade leading to microcirculatory damage and cell death

Prevention

Human tissue freezes at –5°C. Injury is determined by the type and duration of cold insult.

At-risk individuals should maintain their body core temperature, adequate nutrition, and hydration. Avoid restriction to blood flow caused by tight clothing or footwear and insulate all exposed skin. Supplementary oxygen can protect high-altitude climbers.

Clinical features

Frostbite is most common in the hands and feet (90%); the remainder is mostly on the face, buttocks, and thighs. The extremity is white and firm with numbness (75%) and sensory changes (10%). There is severe pain with reperfusion. Superficial clear fluid vesicles appear in 20% of frostbite and haemorrhagic bullae in 30%. Deep frostbite involves subcutaneous connective tissues, muscle, and bone.

Classification

Clinical classification describes the depth of injury. Plain radiographs will only show abnormalities after several weeks. Bone scintigraphy can help to predict outcome and monitor progress.

Management

- Treat hypothermia.
- Do not rewarm in the field if there is any possibility of refreezing, in order to prevent reperfusion injury. In a suitable environment, rewarm in a water bath with moving water at 37 to 39°C.
- Analgesia.
- Elevate.
- Dry, sterile, non-constricting dressings.
- Aloe vera topical cream decreases prostaglandin formation and improves superficial injury.
- Non-steroidal anti-inflammatory drugs block the arachidonic acid pathway and reduce inflammation; early low-molecular-weight dextran may decrease microthrombi; antibiotics are indicated if there are signs of infection.
- Tissue plasminogen activator (tPA) and the prostacyclin analogue iloprost have been used with some success and must be supervised by a frostbite expert.

Surgery

In the absence of life- or limb-endangering infection, surgery should be delayed. Tissue salvage often exceeds initial estimates. Consult with a surgeon with expertise in frostbite.

HOT ENVIRONMENTS

Physiology

Body core temperature is maintained at T_{Core} 37°C by the thermoregulatory centre in the hypothalamus, which integrates information from skin temperature sensors with core temperatures from receptors in the brain and in the walls of large blood vessels.

Heat is produced by cellular metabolism, is dissipated through the skin by vasodilatation and sweating, and is expired in air via the alveoli. Heat is lost to the environment by conduction, convection, radiation, and evaporation. Sweat evaporation is the principal mechanism for controlling temperature following exercise or in response to an increase in environmental temperature. The elderly and those with chronic disease, whose ability to adjust physiologically to heat is reduced due to diminished thermoregulatory capacity, are more susceptible. The rising global temperature has given rise to heat waves and increased mortality in these groups.

Heat acclimatization

Acclimatization occurs over several weeks and should be guided by workload. Sweat volume increases and the salt content falls. Cardiovascular and renal compensations also occur.

Heat illness

Exertional heat illness occurs when the body cannot regulate temperature in the prevailing environmental conditions or during heat-producing activity (e.g., sporting, work, and military events). In tropical areas other causes for fever, for example, malaria, may need to be excluded.

Prickly heat rash (miliaria rubra)

This is characterized by a pruritic, erythematous rash. Sweating may be limited by plugging or damage to the sweat ducts. It may be prevented by using loose cotton clothing and frequent cool showers. Treatment includes cool bathing and talcum powder.

Heat cramps

These are painful muscle cramps, usually in the legs, that often occur in fit people when they exercise excessively, especially in hot weather. Two theories have been proposed for heat cramps. The serum electrolyte and dehydration theory is traditional, but recent evidence supports the altered neuromuscular control theory. In a hot environment, fatigue and pain increase muscle spindle activity. Such cramps are self-limiting and respond to muscle stretching, massage, and rehydration.

Heat syncope

Peripheral vasodilatation can reduce central venous return and lead to syncope on standing or with effort. This recovers with rehydration and rest in the supine position.

Heat exhaustion

This is mild to moderate heat illness due to exposure to a high environmental temperature or strenuous exercise. Clothing that inhibits sweating, such as a wetsuit or military uniform, can cause an elevation in T_{Core} in less than 15 minutes. Clinical features are weakness, dizziness, syncope, nausea, and vomiting. The temperature can be normal or moderately elevated. Untreated heat exhaustion may progress to heat stroke which is a medical emergency.

Management

Reduce environmental temperature (T_{Env}) if possible, and cool the patient with sponging and fans. Oral rehydration is indicated, but in severe heat exhaustion, intravenous fluids may be needed. Monitor serum electrolytes.

Heat stroke

Heat stroke is an acute life-threatening condition in which neurological features are the main diagnostic features. T_{Core} usually rises above 40°C. There is headache, nausea, vomiting, and weakness, progressing to confusion, seizures, coma, and death. The skin feels intensely hot to the touch. Sweating is often but not invariably absent. Heat stroke can develop in unacclimatized people in hot, humid, windless conditions, even without exercise. Excessive exercise in inappropriate clothing can lead to heat injury in temperate climates. Diabetes, alcohol, and drugs such as antimuscarinics, diuretics, and phenothiazines can contribute. Heat stroke can lead to a fall in cardiac output, lactic acidosis and intravascular coagulation, and multiorgan failure. Morbidity and mortality are directly related to the duration of the high T_{Core}.

Prompt treatment is essential and can be curative, even with a T_{Core} higher than 40.5°C.

Complications are hypovolaemia, intravascular coagulation, cerebral oedema, rhabdomyolysis, and renal and hepatic failure.

Prevention

Acclimatization, fluids, appropriate clothing, and modifying activity are all required.

Management

The priority of treatment is to reduce the T_{Core} below 40.5°C as soon as possible.

No pharmacological agents are effective in lowering core temperature:

- Reduce the environmental temperature, if possible, by removing the patient to a cool and shady location.
- Reduce T_{Core} urgently—arrange cold water immersion if available. Otherwise, cool the patient with sponging, ice packs, or fanning.
- Move the patient to a medical facility. Manage in intensive care: monitor cardiac output and respiratory, renal, and hepatic function. Measure biochemistry, clotting, and muscle enzymes.
- Give fluids intravenously so that the intravascular volume remains normal.

Hyponatremia

This is recognized in endurance athletes and others who overhydrate in hot climates. Arginine and vasopressin promote fluid retention and there is a loss of sodium from natriuretic peptide. The clinical features are headache, nausea, and fatigue, followed by confusion, fitting, and encephalopathy. Early diagnosis and treatment with hypertonic fluid can be life saving. Prevention is helped by drinking to thirst.

WATER ENVIRONMENT

Oceans, lakes, and rivers are complex environments. Human interaction occurs at the water's edge or in the water. Water-borne infections such as schistosomiasis, onchocerciasis, and gastrointestinal infections affect millions of people around the world. Marine and bankside wildlife such as sharks, snakes, and crocodiles injure or kill people each year. This section reviews drowning, immersion, and diving emergencies.

Immersion

The first phase of immersion in cold water is the cold shock response. This is mediated by skin temperature receptors and causes involuntary gasping breaths, a loss of control of breathing, and an increased cardiac load. This lasts for about 90 seconds. Many victims inhale enough water (1.5–3 L of water) to die from early asphyxiation. In this phase, victims should be encouraged to 'float to survive'. Early rescue efforts should be by reaching or throwing buoyant objects and not by entering the water.

The second phase lasts 20 to 30 minutes and is the result of continuing superficial cooling of the peripheral nerves and muscles. There is a loss of muscle dexterity and strength so that the victim cannot help themselves. This period ends with swim failure.

The third phase is after 30 minutes and is the onset of hypothermia. There is progressive disorientation, a fall in level of consciousness, and ventricular fibrillation below 28°C.

Drowning

Drowning is defined as respiratory impairment from submersion in a liquid. The outcome is survival, with or without morbidity, or death. It is a global health problem, with 1000 deaths a day, mainly of children and adults less than 30 years old.

The majority of drowning deaths are due to asphyxia rather than hypothermia. Resuscitation from hypoxic drowning arrest is unlikely after 10 minutes and has not been recorded after 20 minutes. However, if the brain has cooled to below 30°C before cardiac arrest outcome this can improve the hypoxic survival time. The longest recorded underwater survival time with full recovery was recorded in a 7-year-old child with a temperature of 13.8°C who was immersed in icy water for 83 minutes.

A rescued patient may appear well but have continuing injury to the lungs for 4 to 6 hours after an event. In the presence of cough, chest pain, or any sign of aspiration, hospital observation for at least 6 hours post-event is recommended.

The difference between saltwater and freshwater immersion events does not alter the initial treatment. All patients are hypoxic and hypercapnic. Early rescue breaths and oxygen should be administered. Ventricular fibrillation only occurs in 10% of drowning events, and oxygenation and ventilation are essential initial treatment.

Of rescued victims, 20% die around the time of rescue, called circum-rescue collapse. If the victim is lifted vertically from the water, the relative hypovolaemia caused by cold water immersion can cause a collapse in arterial blood pressure and cardiac arrest. Victims should be lifted into the rescue boat or helicopter horizontally and transported in an orientation to assist venous return.

Diving

Diving below the surface of the water can be classified as follows.

- Free diving: this involves breath-holding usually to a depth of about 5 m; this has been practiced for more than 500 years.
- Snorkel diving: limited to 0.5 m by the inspiratory effort required to breathe through a tube reaching the surface at that depth.
- Open-circuit scuba diving: usually to depths above 30 m, breathing oxygen or oxygen–nitrogen mix from tanks. Mortality rate 1.5–9 per 100 000 dives.
- Technical diving: deeper or commercial diving involving complex gas mixtures or rebreathing circuits that allow deeper dives and longer time at depth.

Divers can suffer from heat illness, barotrauma, decompression illness, trauma, and drowning.

Decompression illness

Decompression illness (DCI) results from the volume–pressure changes within the air-filled cavities in the body and the dissolution of gases in the tissues. Water is denser than air, and each 0.3 m of seawater exerts an additional 0.021 bar on the diver. The gases in a diver's breathing mixture are dissolved in proportion to their partial pressures. The quantity is determined by the length of the dive and gas solubility. During descent, nitrogen and helium become dissolved in the tissues. If the diver ascends too rapidly, gas bubbles form in the intravascular or extravascular spaces. The bubbles initiate an inflammatory cascade, thrombosis, ischaemia, and hypoxia. This presents as clinical syndromes depending on the tissues affected. Decompression tables indicate the time required to return safety from a given depth to the surface. In general, decompression is unnecessary for dives above 30 m. The incidence of DCI is 2.8 cases per 10 000 dives. Classification is usually descriptive, although some countries classify Type I as affecting the musculoskeletal system, skin, and lymphatics and Type II as affecting all other systems. **Box 16.6** highlights the signs and symptoms of decompression illness.

Box 16.6 Signs and symptoms of decompression illness

Body system	Symptoms and signs of decompression problem
Musculoskeletal	Limb or joint pain: dull pain ('toothache') improved with activity
Lungs	Breathlessness
Central nervous	Seizures, hemiparesis, loss of consciousness (cerebral arterial gas embolism) Vertigo, nystagmus, vomiting
Spinal cord	Paraplegia, lower limb paralysis or weakness, a sensory level or bladder dysfunction
Cognitive	Behavioural and personality changes
Skin	Cutaneous itchy rash (cutis marmorata)
General systemic features	Fatigue, malaise, nausea, anorexia

Symptoms may occur within minutes or several hours after a dive. During the 24 hours after a dive, further ascent such as air travel can provoke DCI.

Treatment

- Basic resuscitation following an ABCDE approach.
- Give oxygen as close to 100% as possible.
- Lie flat.
- Keep cool but avoid hypothermia.
- Give oral or i.v. fluids for rehydration.
- Take expert advice.
- Arrange for emergency recompression as required.

Barotrauma

The volume of a gas-filled space varies inversely with pressure (Boyle's gas law). On descent, air-containing spaces such as the middle ear and facial sinuses will be compressed unless the pressure between the body cavity and the pressured gases breathed in can be equalized. **Box 16.7** describes signs and symptoms of barotrauma.

Arterial gas embolism

This severe form of barotrauma is the second leading cause of death in sports divers (30%).

Gas bubbles are forced across the alveolar-capillary membrane and into the pulmonary venous circulation. Embolization to the coronary arteries causes cardiac ischaemia, infarction, and dysrhythmias. Cerebral emboli cause symptoms and signs similar to acute stroke.

Gas problems

Hypoxia: This is usually caused by a failure of oxygen supply or during technical dives using rebreathers. Treatment is with oxygen.

Nitrogen narcosis: at depths below 30 m, nitrogen exerts a high partial pressure and has an effect similar to an anaesthetic. Symptoms include euphoria ('rapture of the deep'), loss of coordination, loss of motor control, loss of judgment, and loss of consciousness. This may be avoided by replacing air with a helium and oxygen mixture for deeper dives. It resolves on ascent to surface.

Box 16.7 Signs and symptoms of barotrauma

Anatomical area	Symptoms and signs of barotrauma
The middle ear	Pain due to failure to equalize pressures through the eustachian tube. The tympanic membrane may perforate
Injury to the inner ear	Injury to the vestibular apparatus gives rise to vertigo ('the staggers'), nausea, and tinnitus. Cochlea damage causes deafness
Facial sinus	Pain and epistasis
Dental	Pain beneath teeth that have cavities
Pulmonary	Pneumothorax (chest pain and breathlessness) and pneumomediastinum (chest pain, neck swelling, voice change). Gas entering the pulmonary vasculature causes coronary artery or cerebral gas embolus (see below)

Hypercapnia: breathing is normally controlled through the partial pressure of CO_2. Divers who are exercising and trying to conserve their oxygen supply can become hypercapnic, causing headache, palpitations, and drowsiness.

Oxygen toxicity: Oxygen breathed at high partial pressures for an extended time can be toxic to the central nervous system and lungs; therefore pure oxygen is not used for diving. Toxicity is rare if diving on air because the threshold for toxicity is 66 m. Pathologically, there is lung atelectasis, endothelial cell damage, and pulmonary oedema when alveolar pressure exceeds 1.5 atmospheres. Symptoms include visual problems, tinnitus, nausea, agitation, confusion, muscle twitching, and convulsions.

Recompression therapy

Advice is available from specialized diving emergency centres that give clinical advice and help to organize recompression. Recompression should be performed as soon as possible. Recompression follows standardized tables and is guided by clinical response. Recovery is usual. Rare long-term problems such as avascular necrosis of the hip from infarction can occur; some chronic focal neurological damage has been reported.

THE PHYSICAL WORLD

Ionizing radiation

Naturally occurring radon gas is produced from rocks and soil as the result of the breakdown of Uranium-238 and has been implicated in some lung cancers. Nuclear energy has many uses in medicine and industry. There is a good safety record, but when accidents occur, there is the potential for contamination and illness of large numbers of people, for example, Chernobyl (Soviet Union 1986) and Fukushima (Japan 2001). The devastating effects of nuclear warfare were witnessed in Hiroshima and Nagasaki (1945), and the possibility of a rogue nation or terrorist group using a nuclear weapon remains a concern.

Physics and physiology

Radiation is the transfer of energy by particles, waves, or rays. Non-ionizing radiation has a long wavelength, low frequency, and low energy, for example, microwaves, light, and radio. The main adverse effects are related to heat. Ionizing radiation has a short wavelength, high frequency, and high energy. Injury occurs at the cellular level and to DNA. Cellular repair is less effective when high doses are delivered rapidly. Tissues with a high rate of cellular division are more sensitive to radiation damage, for example, hematopoietic and gastrointestinal cells.

Ionizing radiation is either non-penetrating (α- or β-particles) or penetrating (X-rays, γ-rays, or neutrons). Non-penetrating radiation affects the skin alone, while penetrating radiation also affects the deeper tissues.

The unit of radiation absorbed in living tissues is the Gray (Gy). 1 Gy = 1 joule per kilogram (J/kg). Assuming good medical care, the lethal dose 50 (the dose given all at once that causes the death of 50% of subjects) is 4.5 Gy, and the maximal survivable dose is 10 Gy. Ionizing radiation is emitted by a radioactive substance (radionucleotide or radioisotope). When such radiation passes through a person, they have been irradiated but pose no hazard to other people.

Contamination

If a radioactive substance contaminates an exposed surface, its presence is of no immediate threat to the life of the patient or healthcare provider. The contaminated material emits radiation with an effect that depends on the type of substance, time of exposure, and distance from the source. This should not prevent treatment for associated illness or injury. The initial responders must take universal precautions and use respiratory protection if airborne contamination is a danger. The patient's clothes are removed and the skin is washed. All materials are collected in sealed containers and labelled for disposal as radioactive waste. Skin surfaces should be monitored using a suitable instrument.

Internal exposure

Radioactive material can be ingested, be inhaled, or enter through a wound. **Box 16.8** explains the management of internal radiation exposure.

External exposure

The individual is exposed to whole- or partial-body ionizing radiation. Even those with lethal dose exposure present no danger to other people.

Acute radiation sickness

Acute radiation sickness (ARS) is a syndrome that occurs after internal or external exposure. It varies with dose, dose rate, distribution, and tissue susceptibility. In mild ARS, nausea, vomiting, and malaise follow doses of approximately 1 Gy. Lymphopenia occurs within several days, followed 2 to 3 weeks later by a fall in all white cell and platelet counts. In more severe forms multiple organ systems are affected.

Haematopoietic syndrome. Absorption of 2 to 10 Gy is followed by transient vomiting in some individuals, followed by a period of improvement. Lymphocytes are particularly sensitive to radiation damage; severe lymphopenia develops over several days. A decrease in granulocytes and platelets follows 2 to 3 weeks later, because no new cells are formed in the marrow. Complications include bleeding and overwhelming infections, and there is a high mortality.

Gastrointestinal syndrome. Doses higher than 6 Gy cause vomiting several hours after exposure. This recurs some 4 days later, accompanied by diarrhoea. The villous lining of the intestine becomes denuded. Intractable bloody diarrhoea follows, with dehydration, secondary infection, and sometimes death.

Central nervous system syndrome. Exposures of more than 30 Gy are followed rapidly by nausea, vomiting, disorientation, and coma. Death due to cerebral oedema can follow, usually within 36 hours.

Radiation dermatitis. Skin erythema, purpura, blistering, and secondary infection occur. Total loss of body hair is a bad prognostic sign and usually follows an exposure of more than 5 Gy.

Management of ARS

Management is largely supportive: prevention and treatment of infection, haemorrhage, and fluid loss. The haemopoietic system can be supported using cytokine therapy and blood products.

Late effects of radiation exposure

Risks of acute myeloid leukaemia and cancer, particularly of skin, thyroid, and salivary glands, increase. Infertility, teratogenesis, and cataract are also late sequelae, developing years after exposure.

Medical radiation

There is a demonstrated risk of cancer from the use of therapeutic and diagnostic radiation.

Radiation differs in the density of ionization it causes. Therefore, a dose-equivalent called Sievert (Sv) is used. This is the absorbed dose weighted for the damaging effect of the radiation. The annual natural background radiation is approximately 2.5 mSv. A chest X-ray delivers 0.02 mSv, and CT of the abdomen/pelvis about 10 mSv. A dose of 100 mSv is known to have a significant long-term risk for solid tumours.

Focusing techniques are used to target therapeutic radiation towards the field being treated. Radiosensitive organs, such as the ovaries, are protected by shielding.

The risk from diagnostic imaging can be reduced by the use of imaging guided by valid decision-making rules, considering the benefit versus the risk for each patient, using alternative non-ionizing imaging, and consultation with radiological colleagues.

Children, younger adults, and pregnant women have a greater risk. Healthcare professionals should protect themselves with shielding and aprons when using ionizing radiation.

Box 16.8 Management of internal radiation exposure

Method of entry	Management
Ingestion	The use of a blocking or chelating agent may reduce uptake, e.g., Lugol's iodine
Inhalation	Bronchopulmonary lavage and chelating agents may be of benefit
Wounds	Decontamination and excision. Followed by tissue monitoring. Normal wound closure

Lightning strike

This describes cloud-to-ground lightning originating in thunderstorms. 1 in 10 victim strikes are fatal. Human tissues are directly damaged by the high-voltage direct current (DC) of more than 10 million volts that lasts only for a few milliseconds. Tissue resistance

determines the pathway through the body and the potential to generate heat. The heart is at risk of dysthymias and cardiac arrest is due to asystole. Respiratory muscles can be paralyzed. Blunt trauma occurs when the victim is thrown away from the strike.

Fern-shaped patterns seen on the skin are not thermal burns and require no treatment.

Management

Scene safety must be ensured and bystander cardiopulmonary resuscitation initiated for cardiopulmonary arrest. Respiratory muscle paralysis may persist for a considerable time and recover with support. Mortality is high and those who survive are left with variable CNS damage.

Electric shock

This describes injury from man-made electricity. Typically, this involves alternating current (AC), which is more dangerous than a similar DC current.

Electric shock can produce:

Minor Shock. The common domestic electric shock is typically painful but rarely fatal. A brief, immediate jerking episode can occur, which is not a seizure. A small burn is often present. There is usually no lasting neurological, cardiac, or skin damage.

Serious effects. These are rare following accidents in the home or in industry.

- **Cardiac, neurological, and muscle damage.** Ventricular fibrillation, muscular contraction, and spinal cord damage can follow a major shock.
- **Electrical burns.** These are commonly restricted to the skin. Muscle necrosis and spinal cord damage can also occur.

CORE SKILLS AND KNOWLEDGE

Heart disease remains the most common cause of death in the developed world and the third most common in low-income countries. Reducing this burden requires close collaboration between general practitioners, public health doctors, hospital specialists, and allied healthcare professionals, with interventions including reducing smoking rates, encouraging healthy eating choices, promoting aerobic exercise, and targeting hypertension (Chapter 18) and dyslipidaemia (Chapter 19).

In the outpatient setting patients with stable cardiac symptoms (e.g., exertional chest pain, palpitations, or peripheral oedema) are evaluated, and those with established cardiological disease are followed up in order to optimize lifestyle factors, titrate medications, and discuss timely percutaneous or surgical interventions.

Some cardiologists are trained in various interventional techniques (including direct current cardioversion, percutaneous coronary intervention (PCI), transcatheter valve procedures, cardiac ablation, or implantation of cardiac rhythm devices). Working closely with cardiac surgeons is pivotal to obtaining excellent outcomes. Cardiologists also look after patients with emergency cardiac presentations (e.g., acute coronary syndromes or heart block), often on coronary care units.

Key skills in cardiology include:

- Becoming familiar with the management of cardiac emergencies, including acute coronary syndrome (ACS) and life-threatening rhythm disorders

- Understanding cardiovascular risk reduction and the management of chronic cardiological conditions such as heart failure and atrial fibrillation
- Confidently interpreting electrocardiograms (ECGs) and echocardiogram reports and understanding the role of different forms of invasive cardiac intervention.

Cardiology can be best learned by observing cardiology outpatient clinics, attending ward rounds on the coronary care unit, observing invasive procedures such as coronary angiography or DC cardioversion, and seeing patients in the community with general practitioners or specialist cardiology nurses.

CLINICAL SKILLS

History

A full cardiological history covers the relevant symptoms and risk factors for cardiac disease in detail and is focused on establishing the cause of symptoms. Is this patient's chest pain likely to originate in the heart? Is their breathlessness more likely to be due to heart failure, lung disease, or something else? A fuller description of cardiac history-taking begins at the 'Clinical approach to the patient with heart disease' section, but **Box 17.1** provides a suggested structure to ensure that the relevant material is covered systematically.

Box 17.1 History-taking in cardiac disease

Symptoms

Chest pain

Think anatomically, about the type of pain caused by disease in different structures within the chest. The rapidity of onset is also informative.

- ***Heart***—central, squeezing or crushing in nature, radiation to left arm or jaw, with associated sweating or nausea
- ***Pericardium***—central, sharp in character, retrosternal, may radiate to back, worse sitting upright, associated viral symptoms or causative medication
- ***Aorta***—sudden onset, severe, tearing pain, can radiate to the back or legs (dissection)
- ***Oesophagus***—central, burning or tight in nature, worse on lying flat, worse after eating, with associated burping, epigastric discomfort or altered taste
- ***Lung/pleural***—localized and often peripheral, sharp in nature, worse on deep inspiration or coughing, with associated cough, fever, breathlessness, or haemoptysis (pleurisy, pneumonia, pulmonary embolus pneumothorax)
- ***Musculoskeletal***—often localized, intermittent, and related to movement; possible trigger event (e.g., abnormal activity); reproducible on palpation or movement
- ***Skin***—superficial pain often associated with a rash, for example, shingles
- ***Abdomen***—gall bladder, stomach, and pancreas pathology may present with upper abdominal or lower chest pain.

Breathlessness

Identify severity (see **Box 17.20**) and likely cause:

- ***Heart disease***—worse on lying flat, episodes of PND, peripheral oedema
- ***Lung disease***—associated respiratory symptoms, for example, cough, wheeze, pleuritic pain, fever, calf pain, or haemoptysis.

Lung disease and heart disease often coexist not least due to shared risk factors such as smoking.

Palpitations

These are usually episodic. Identify:

- ***Nature of symptoms***—fast or slow, feelings of 'missing a beat', associated chest pain or tightness, breathlessness, and dizziness
- ***Pattern of symptoms***—duration of problem, frequency of attacks, associations with exercise, caffeine or alcohol intake
- ***Severity of symptoms***—chest pain, dizziness, pre-syncope or loss of consciousness.

Dizziness or collapse

A full event history is required, ideally correlated by an eye-witness or video clip, if there was a loss of consciousness. Causes may include:

- ***Vasovagal syncope***—situational (intercurrent illness, dehydration, pain, emotional, postprandial, post micturition, post cough), antihypertensive medication, preceding pre-syncopal symptoms, rapid recovery
- ***Cardiac cause*** (malignant dysrhythmia or valve disease)—preceding chest pain or palpitations, sudden loss of consciousness, symptoms on exertion, lack of alternative explanation, family history of collapse or sudden death
- ***Neurological cause***—neurological aura, abnormal movements, urinary incontinence, tongue-biting, post-ictal phase.

Risk factors

- ***Previous cardiovascular disease***—enquire about or look up previous investigations and interventions
- ***Smoking***—quantified in pack years
- ***Diabetes***—time since diagnosis, degree of glycaemic control
- ***Hypertension***—time since diagnosis, degree of control
- ***Hyperlipidaemia***
- ***Chronic inflammatory disorders*** (e.g., rheumatoid arthritis)
- ***Family history of early-onset cardiovascular disease***
- ***Recreational drug use***—amfetamines, cocaine, cannabis.

Functional baseline and disability

- ***Social history***—who are the patient's social supports? What work do they do? What type of driving license do they have?
- ***Symptom-related disability***—exertional chest pain or breathlessness (try to quantify—how far can they walk? Can they climb a flight of stairs?). Does it limit their work performance? Are they house- or bed-bound?
- ***Self-care***—ranging from full functional independence to carer visits or full residential or nursing care.

Examination

Many features of cardiovascular disease can be elicited on physical examination (see figure opposite). They include:

- Evidence of life-threatening cardiac disease requiring emergency resuscitation: shock, dysrhythmias, pulmonary oedema
- Evidence of underlying conditions that contribute to cardiovascular disease (e.g., hyperlipidaemia or Marfan's syndrome)
- Evidence of heart failure
- Murmurs and specific signs associated with particular forms of valvular heart disease.

ECG interpretation

The ECG is an essential bedside test in the investigation of all patients with cardiac disease. A full guide to understanding the science behind it and its interpretation begins at the 'Electrocardiography' section, and **Box 17.2** offers a systematic approach to ensure that abnormalities are not missed.

Box 17.2 A systematic approach to interpreting the ECG

Step 1: Preliminaries

- Correct patient?
- Correct date and time?
- Standard speed (25 mm/sec)?
- Standard amplitude (10 mm/mV)?

Step 2: Heart structure

- Axis (left axis deviation if <–30 degrees, right axis deviation if >90 degrees)?
- Left ventricular hypertrophy (various criteria, see **Fig. 17.74**)?
- Evidence of atrial enlargement?

Step 3: Rate and rhythm

- Heart rate?
- Regular or irregular?
- Sinus rhythm (P–QRS–T)?
- Atrioventricular node delay/block (PR duration should be 120–200 ms)?
- Intraventricular conduction delay (QRS duration should be <120 ms)?
- Repolarization delay (QTc should be <450 ms)?

Step 4: Ischaemia

- Features include:
  - Q waves
  - ST elevation or depression
  - T-wave inversion.
- Anatomical regions:
  - Anterior (V_1/V_2)
  - Septal (V_3/V_4)
  - Lateral (V_5/V_6)
  - Interior (II, III, AVF)
  - High lateral (I, AVL).

Step 5: Global features

- Pericarditis (global saddle-shaped ST elevation)?
- Electrolyte abnormalities, for example, hyperkalaemia (peaked T waves)?
- Pre-excitation (upstroke before QRS complexes)?
- Rarer causes of global abnormalities include hypothermia, thyroid disease, and drug effects.

General
Breathless
Position - sitting up?
Colour - cyanosed (central)

ANATOMY, PHYSIOLOGY, AND EMBRYOLOGY OF THE HEART

The heart is made of four main cell types: cardiomyocytes, endothelial cells, fibroblasts, and smooth muscle cells. Cardiomyocytes (CMs) are designed to perform two fundamental functions: initiation and conduction of electrical impulses, and contraction. Although most CMs are able to perform both these functions, the vast majority are predominantly contractile cells and a small number are specifically designed as electrical cells. The latter, collectively known as the conducting system of the heart, are not nervous tissue but modified CMs lacking in myofibril components. They have the ability to generate electrical impulses, which are then conducted to the myocytes, leading to contraction by a process known as excitation–contraction coupling. The rate of electrical impulse generation and the force of myocardial contraction are modified by numerous factors, including autonomic input and stretch.

Three epicardial coronary arteries supply blood to the myocardium, and a more complex network of veins is responsible for drainage. In the face of continuous arterial pressure fluctuations blood vessels maintain constant tissue perfusion by a process known as ***'autoregulation'***; blood vessel control is, however, complex, involving additional local and central mechanisms.

Conduction system of the heart

Sinus node (sinoatrial node)

The sinus node is a complex, spindle-shaped structure that lies in the lateral and epicardial aspects of the junction between the superior vena cava and the right atrium (Fig. 17.1). Physiologically, it generates impulses automatically by spontaneous depolarization of its membrane at a rate quicker than any other cardiac cell type. It is therefore the ***natural pacemaker of the heart***.

A number of factors are responsible for the spontaneous decay of the sinus node cell membrane potential ('pacemaker potential'), the most significant of which is a small influx of sodium ions into the cells. This small sodium current has two components: the background inward (I_b) current and the 'funny' (I_f) current (or pacemaker current) (Fig. 17.2). The term 'funny' current denotes ionic flow through channels activated in ***hyperpolarized*** cells (–60 mV or greater), unlike other time- and voltage-dependent channels activated by ***depolarization***. The rate of depolarization of the sinus node membrane potential is modulated by autonomic tone (i.e., sympathetic and parasympathetic input), stretch, temperature, hypoxia, and blood pH and responds to other hormonal influences (e.g., tri-iodothyronine and serotonin).

Atrial and ventricular myocyte action potentials

Action potentials in the sinus node trigger depolarization of the atrial myocytes and subsequently the ventricular ones. These cells have a different action potential from that of sinus node cells (see Fig. 17.2). Their resting membrane potential is a consequence of a small flow of potassium ions into the cells through open 'inward rectifier' channels (I_{Kl}); at this stage, sodium and calcium channels are closed. The arrival of adjacent action potentials triggers the opening of voltage-gated, fast, self-inactivating sodium channels, resulting in a sharp depolarization spike. This is followed by a partial repolarization of the membrane due to activation of 'transient outward' potassium channels.

The plateau phase that follows is unique to myocytes and results from a small but sustained inward calcium current through L-type calcium channels (I_{CaL}) lasting 200 to 400 ms. This calcium influx is caused by a combined increase in permeability of the cell, especially the sarcolemmal membranes to calcium (Fig. 17.3). This plateau (or refractory) phase in myocyte action potential prevents early reactivation of the myocytes and directly determines the strength of contraction. The gradual inactivation of the calcium channels activates delayed rectifier potassium channels (I_K), repolarizing the membrane. Atrial tissue is activated like a 'forest fire', but the activation peters out when the insulating layer between the atrium and the ventricle—the annulus fibrosus—is reached. There is debate about whether impulses from the sinoatrial (SA) node travel over specialized conducting 'pathways' in the atrium or over ordinary atrial myocardium.

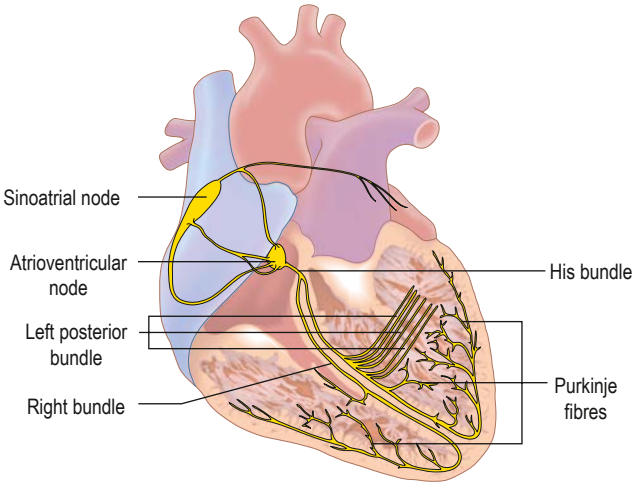

Fig. 17.1 The conducting system of the heart.

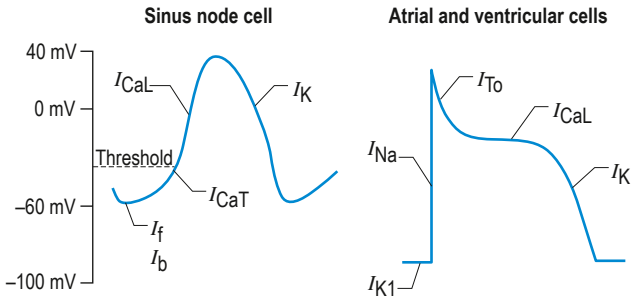

Fig. 17.2 Myocardial action potentials. I_b, Background inward sodium current; I_{CaL}, long-lasting (or 'L'-type) calcium channel; I_{CaT}, transient (or 'T'-type) calcium channel; I_f, 'funny' current; I_K, delayed rectifier potassium current; I_{K1}, inward rectifier potassium current; I_{Na}, inward sodium current; I_{To}, transient outward potassium current.

Atrioventricular node, His bundle, and Purkinje fibres

The depolarization continues to conduct slowly through the atrioventricular (AV) node. This is a small, bean-shaped structure that lies beneath the right atrial endocardium within the lower interatrial septum. The AV node continues as the His bundle, which penetrates the annulus fibrosus and conducts the cardiac impulse rapidly towards the ventricle. The His bundle reaches the crest of the interventricular septum and divides into the right bundle branch and the main left bundle branch.

The ***right bundle branch*** continues down the right side of the interventricular septum to the apex; from here, it radiates and divides to form the Purkinje network, which spreads throughout the subendocardial surface of the right ventricle. The ***main left bundle branch*** is a short structure, which fans out into many strands on the left side of the interventricular septum. These strands can be grouped into an anterior superior division (the anterior hemi-bundle) and a posterior inferior division (the posterior hemi-bundle), though there is large anatomical variation between patients. The anterior hemi-bundle supplies the subendocardial Purkinje network of the anterior and superior surfaces of the left ventricle, and the inferior hemi-bundle supplies the inferior and posterior surfaces. Impulse conduction through the AV node is slow and depends on action potentials, largely produced by slow transmembrane calcium flux. In the atria ventricles and His–Purkinje system, conduction is rapid and is due to action potentials generated by rapid transmembrane sodium diffusion.

Cellular basis of myocardial contraction–excitation–contraction coupling

Each myocyte, approximately 100 μm long, branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction to adjacent cells. Myocytes contain bundles of parallel myofibrils. Each myofibril is made up of a series of sarcomeres (Fig. 17.4). A sarcomere (the basic unit of contraction) is bound by two transverse Z lines, to each of which is attached a perpendicular filament of the protein actin. The actin filaments from each of the two Z bands overlap with thicker parallel protein filaments known as myosin. Actin and myosin filaments are attached to each other

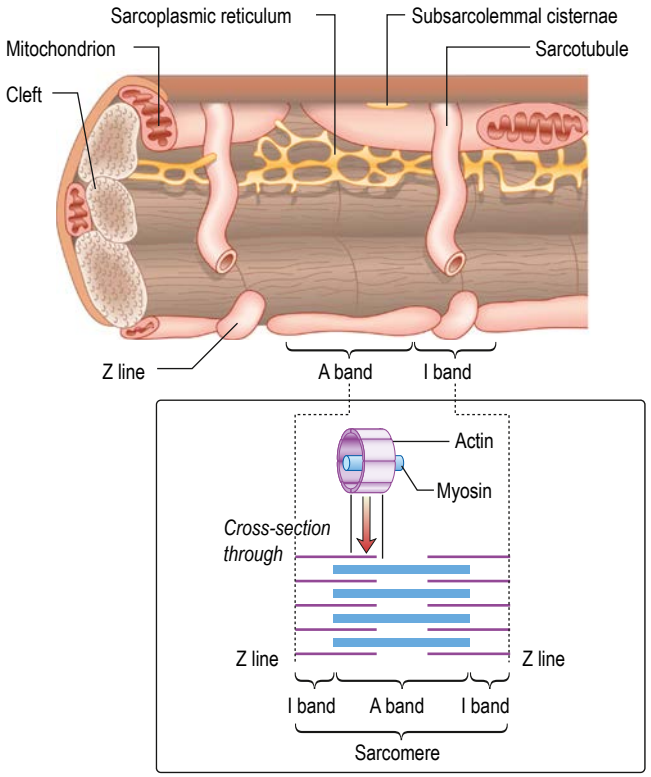

Fig. 17.4 The structure of a myofibril within a myocyte. The myofibrils are made up of a series of sarcomeres joined at the Z line.

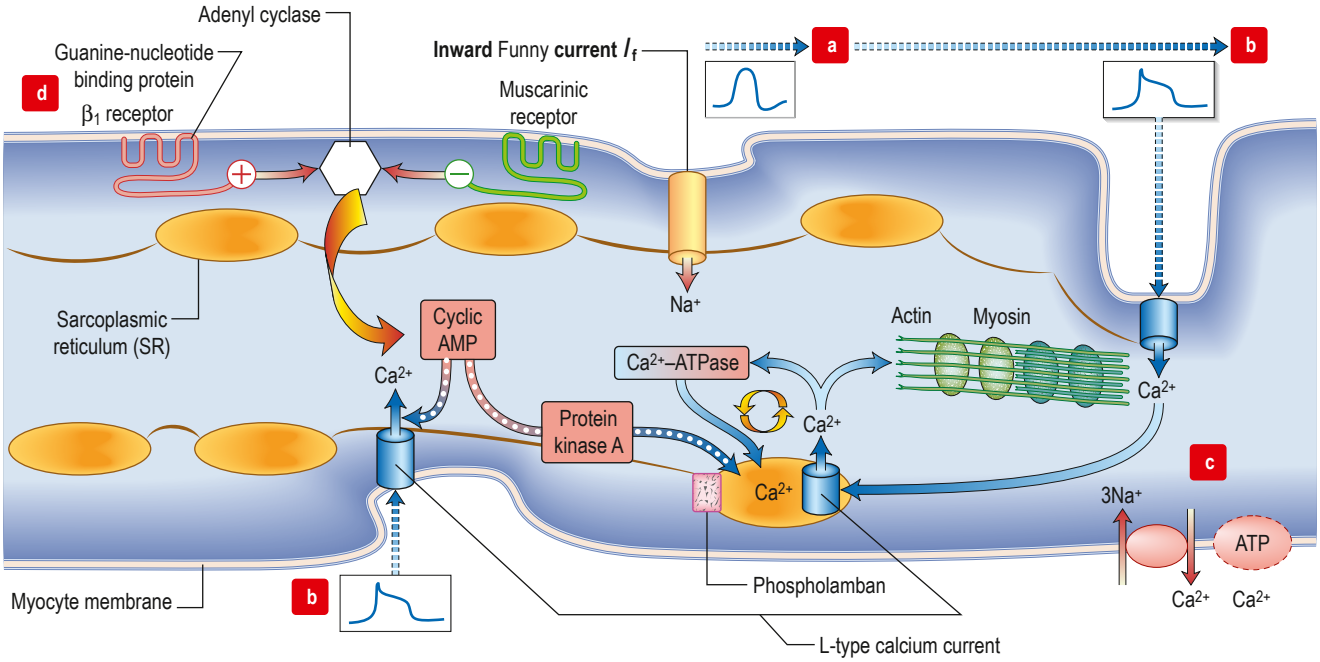

Fig. 17.3 The 'complete' cardiac cell. (a) *Spontaneous depolarization* in sinus node cells, due to sodium (Na) influx through the 'funny' current, generates the 'pacemaker' potential. **(b)** This activates other atrial and ventricular myocytes, triggering ***action potentials*** and activating L-type calcium (Ca) channels in the surface and transverse tubule membranes (at the top and bottom of the figure). **(c)** The resulting ***Ca influx*** acts on Ca-induced Ca release channels (RyR2) on the sarcoplasmic reticulum (SR); this causes the release of stored Ca, which acts on actin and myosin fibrils, leading to contraction. Ca reuptake pumps in the SR, regulated by phospholamban, replenish the stores; various exchange pumps also expel Ca from the cell. **(d)** ***Autonomic input*** has either a positive chronotropic/inotropic effect (β_1 receptors) or a negative chronotropic/inotropic effect (muscarinic receptors). *AMP,* Adenosine monophosphate; *ATPase,* adenosine triphosphatase.

by cross-bridges that contain adenosine triphosphatase (ATPase), which breaks down adenosine triphosphate (ATP) to provide the energy for contraction.

Two chains of actin molecules form a helical structure with another molecule, tropomyosin, in the grooves of the actin helix; a further molecule, troponin, is attached to every seven actin molecules. During cardiac contraction, the length of the actin and myosin monofilaments does not change. Rather, the actin filaments slide between the myosin filaments when ATPase splits a high-energy bond of ATP. To supply the ATP, the myocyte (which cannot stop for a rest) has a very high mitochondrial density (35% of the cell volume). As calcium ions bind to troponin C, the activity of troponin I is inhibited, which induces a conformational change in tropomyosin. This event unlocks the active site between actin and myosin, enabling contraction to proceed.

Calcium is made available during the plateau phase of the action potential when calcium ions enter the cell and are mobilized from the sarcoplasmic reticulum (SR) through the ryanodine receptor (RyR2) calcium-release channel. RyR2 activity is regulated by the protein calstabin 2 and nitric oxide (NO). The force of cardiac muscle contraction ('inotropic state') is thus regulated by the influx of calcium ions into the cell through calcium channels (see Fig. 17.3). T (transient) calcium channels open when the muscle is more depolarized, whereas L (long-lasting) calcium channels require less depolarization. The extent to which the sarcomere can shorten determines the stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or severe exercise.

Starling's law of the heart

The contractile function of an isolated strip of cardiac tissue can be described by the relationship between the velocity of muscle contraction, the load that is moved by the contracting muscle, and the extent to which the muscle is stretched before contracting. As with all other types of muscle, the velocity of contraction of myocardial tissue is reduced by increasing the load against which the tissue must contract. However, in the non-failing heart, pre-stretching of cardiac muscle improves the relationship between the force and velocity of contraction (Fig. 17.5).

This phenomenon was described in the intact heart as an increase of stroke volume (ventricular performance) with an enlargement of the diastolic volume (preload) and is known as 'Starling's law of the heart' or the 'Frank–Starling relationship'. It has been transcribed into more clinically relevant indices. Thus, stroke work (aortic pressure × stroke volume) is increased as ventricular end-diastolic volume is raised. Alternatively, within certain limits, cardiac output rises as left atrial pressure increases (this is assessed invasively by measuring the pulmonary capillary wedge pressure). This clinical relationship is described by the ventricular function curve (see Fig. 17.5), which also shows the effect of sympathetic stimulation.

Nerve supply of the myocardium

Adrenergic nerves supply atrial and ventricular muscle fibres, as well as the conduction system. Beta$_1$ receptors predominate in the heart, with both adrenaline (epinephrine) and noradrenaline (norepinephrine) having positive inotropic and chronotropic effects. Cholinergic nerves from the vagus supply mainly the SA and AV nodes via M_2 muscarinic receptors. The ventricular myocardium is sparsely innervated by the vagus. Under basal conditions, vagal inhibitory effects predominate over the sympathetic excitatory effects,

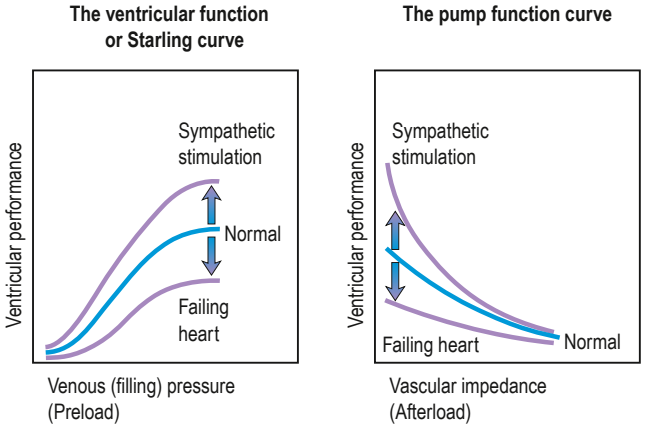

Fig. 17.5 The Frank–Starling mechanism. The effect on ventricular contraction of alteration in filling pressures and outflow impedance in the normal, failing, and sympathetically stimulated ventricle is shown.

resulting in a slow heart rate. Interestingly, post cardiac transplant, following which both sympathetic and parasympathetic nervous input to the heart is abrogated, resting heart rate increases to 90 to 100 beats per minute.

Adrenergic stimulation and cellular signalling

Beta$_1$-adrenergic stimulation enhances Ca^{2+} flux in the myocyte and thereby strengthens the force of contraction (see Fig. 17.3). Binding of catecholamines, such as adrenaline, to the myocyte β_1-adrenergic receptor stimulates membrane-bound adenylate kinases. These enzymes enhance production of cyclic adenosine monophosphate (cAMP), which activates intracellular protein kinases; these, in turn, phosphorylate cellular proteins, including L-type calcium channels within the cell membrane. Beta$_1$-adrenergic stimulation of the myocyte also enhances myocyte relaxation.

The return of calcium from the cytosol to the SR is regulated by phospholamban (PL), a low-molecular-weight protein in the SR membrane. In its dephosphorylated state PL inhibits Ca^{2+} uptake by the SR ATPase pump (see Fig. 17.3). However, β_1-adrenergic activation of protein kinase phosphorylates PL and blunts its inhibitory effect. The subsequently greater uptake of Ca^{2+} ions by the SR hastens Ca^{2+} removal from the cytosol and promotes myocyte relaxation.

The increased cAMP activity also results in phosphorylation of troponin I, an action that inhibits actin–myosin interaction and further enhances myocyte relaxation.

Cardiac cycle

The cardiac cycle (Fig. 17.6) consists of precisely timed rhythmic electrical and mechanical events that propel blood into the systemic and pulmonary circulations. The first event in the cardiac cycle is atrial depolarization (a P wave on the surface ECG), followed by right atrial and then left atrial contraction. Ventricular activation (the QRS complex on the ECG) follows after a short interval (the PR interval). Left ventricular contraction starts and, shortly thereafter, right ventricular contraction begins. The increased ventricular pressures exceed the atrial pressures and close first the mitral and then the tricuspid valves.

Until the aortic and pulmonary valves open, the ventricles contract with no change of volume (isovolumetric contraction). When ventricular pressures rise above the aortic and pulmonary artery

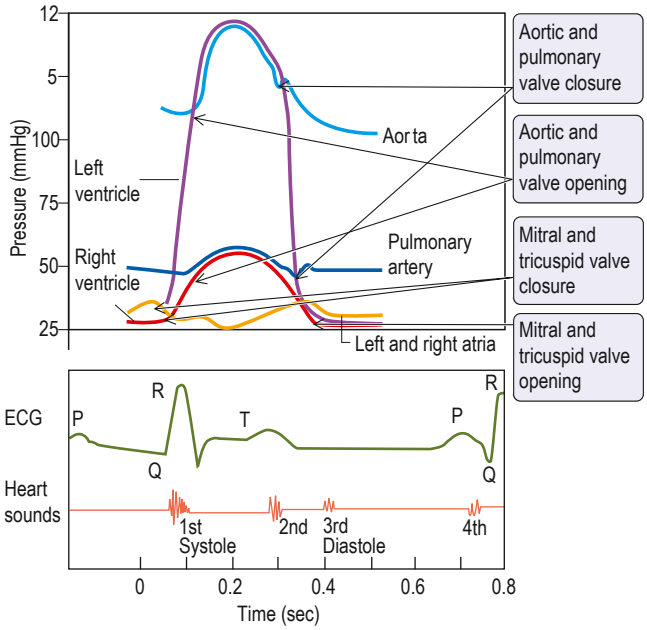

Fig. 17.6 The cardiac cycle.

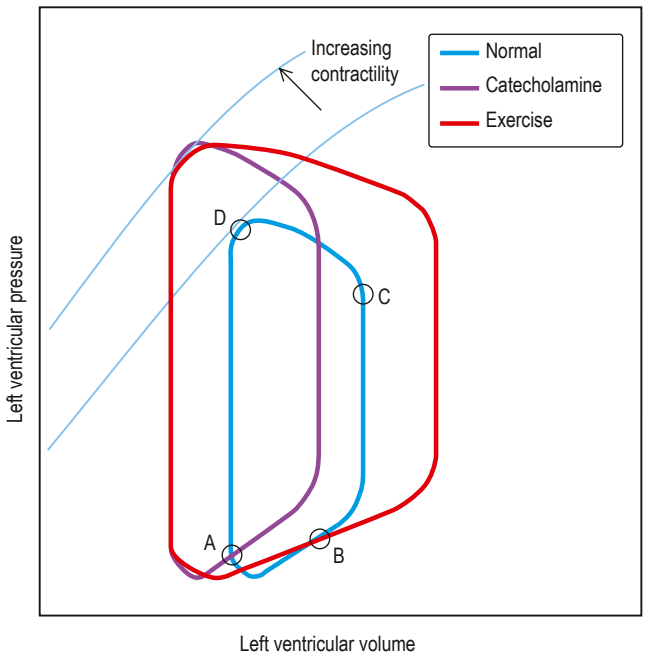

Fig. 17.7 Pressure–volume loop. AB, Diastole: ventricular filling; BC, systole: isovolumetric ventricular contraction; CD, systole: ventricular emptying; DA, diastole: isovolumetric ventricular relaxation.

pressures, the pulmonary valve and then the aortic valve open and ventricular ejection occurs. As the ventricles begin to relax, their pressures fall below the aortic and pulmonary arterial pressures, and aortic valve closure is followed by pulmonary valve closure. Isovolumetric relaxation then occurs. After the ventricular pressures have fallen below the right atrial and left atrial pressures, the tricuspid and mitral valves open. The cardiac cycle can be depicted graphically as the relationship between the pressure and volume of the ventricle (Fig. 17.7), illustrating the changing pressure–volume relationships in response to increased contractility and to exercise.

Coronary circulation

The coronary arterial system (Fig. 17.8) consists of the right and left coronary arteries. These arteries branch from the aorta, arising immediately above two cusps of the aortic valve. The right and left coronary arteries are unique in that they fill during diastole, when not occluded by valve cusps, and when not squeezed by myocardial contraction. The right coronary artery arises from the right coronary sinus and courses through the right side of the AV groove, giving off vessels that supply the right atrium and the right ventricle. The vessel usually continues as the posterior descending coronary artery, which runs in the posterior interventricular groove and supplies the posterior part of the interventricular septum and the posterior left ventricular wall.

Within 2.5 cm of its origin from the left coronary sinus the left main coronary divides into the left anterior descending (LAD) artery and the circumflex artery. The LAD artery runs in the anterior interventricular groove and supplies the anterior septum and the anterior left ventricular wall. The left circumflex artery travels along the left AV groove and gives off branches to the left atrium and the left ventricle (marginal branches).

The sinus node and the AV node are supplied by the right coronary artery in about 60% and 90% of people, respectively. Therefore disease in this artery may cause sinus bradycardia and AV nodal block. The majority of the left ventricle is supplied by the left coronary artery and disease in this vessel can cause significant myocardial dysfunction.

Some blood from the capillary beds in the wall of the heart drains directly into the cavities of the heart via tiny veins, but the majority returns by veins that accompany the arteries, to empty into the right atrium via the coronary sinus. An extensive lymphatic system drains into vessels that travel along the coronary vessels and then into the thoracic duct.

Blood vessel control and functions of the vascular endothelium

In functional terms the tunica intima with the vascular endothelium and the smooth muscle cell–containing tunica media are the main constituents of blood vessels. These two structures are closely interlinked by a variety of mechanisms to regulate vascular tone. The central control of blood vessels is achieved via the neuroendocrine system. Sympathetic vasoconstrictor and parasympathetic vasodilator nerves regulate vascular tone in response to daily activity. Where neural control is impaired or in various pathological states, such as haemorrhage, endocrine control of blood vessels, mediated through adrenaline (epinephrine), angiotensin, and vasopressin, takes over.

At a local level, tissue perfusion is maintained automatically and by the effect of various factors synthesized and/or released in the immediate vicinity. In the face of fluctuating arterial pressures blood vessels vasoconstrict independently of nervous input when blood pressure drops, and vice versa. This process of ***autoregulation*** is a consequence of:

- the ***Bayliss myogenic*** response—the ability of blood vessels to constrict when distended
- the ***vasodilator washout*** effect—the vasoconstriction triggered by a decrease in the concentration of tissue metabolites.

The vascular endothelium is a cardiovascular endocrine organ, which occupies a strategic interface between blood and other tissues. It produces various compounds (e.g., NO, prostacyclin [PGI_2], endothelin, endothelial-derived hyperpolarizing factor [EDHF],

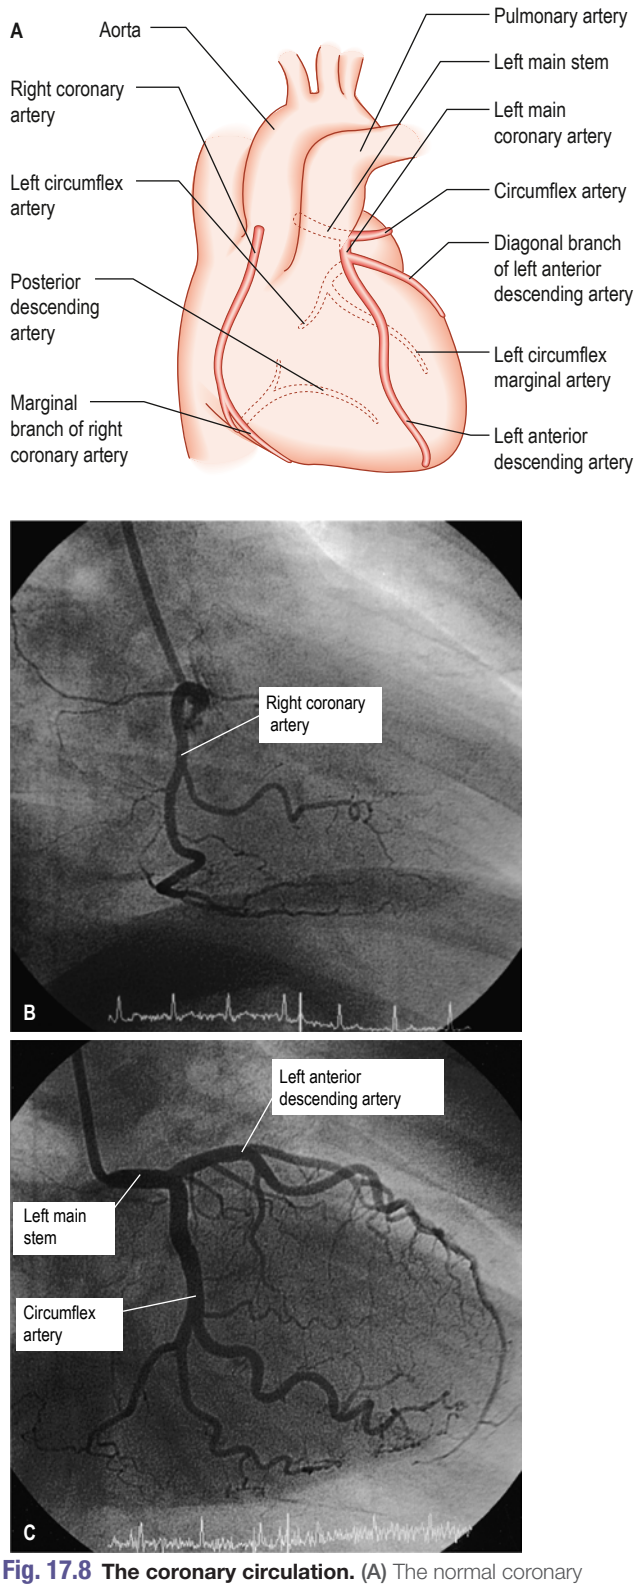

Fig. 17.8 The coronary circulation. (A) The normal coronary arterial anatomy. (B) Angiogram of the dominant right coronary system. (C) Angiogram of the left coronary system from the same patient (right anterior oblique projection).

adhesion molecules, vascular endothelial growth factor [VEGF]) and has enzymes located on the surface, controlling the levels of circulating compounds such as angiotensin, bradykinin, and serotonin. It has many regulatory roles.

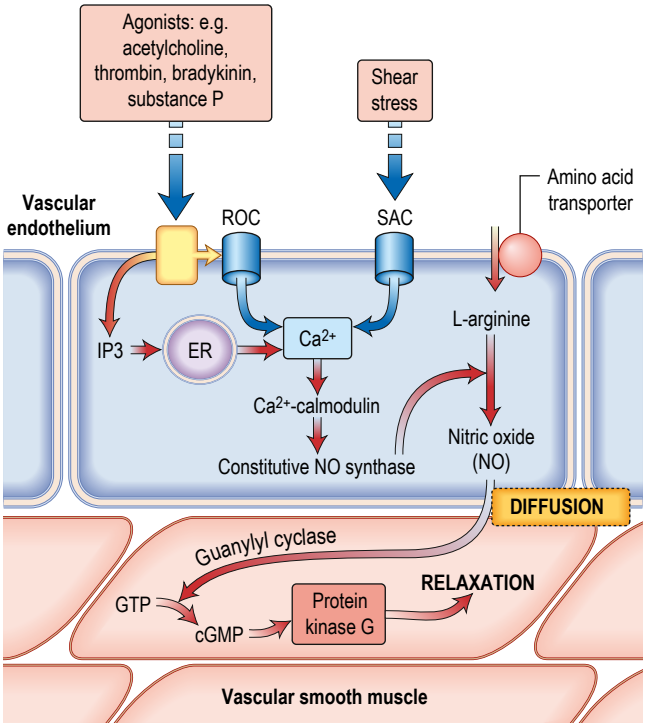

Fig. 17.9 The stimulus for production and function of nitric oxide (NO). Various stimuli lead to the production of NO via cytoplasmic calcium/calmodulin. NO triggers smooth muscle relaxation via the activation of guanylyl cyclase. *cGMP,* Cyclic guanine monophosphate; *ER,* endoplasmic reticulum; *GTP,* guanine triphosphate; *IP3,* inositol triphosphate; *ROC,* receptor-operated Ca^{2+} channel; *SAC,* stretch-activated Ca^{2+} channel.

Vasomotor control

- ***Nitric oxide*** is a diffusible gas with a very short half-life; it is produced in endothelial cells from the amino acid L-arginine via the action of the enzyme NO synthase (NOS), which is controlled by cytoplasmic calcium/calmodulin (Fig. 17.9). It is produced in response to various stimuli (Box 17.3), triggering vascular smooth muscle relaxation through activation of guanylate cyclase; this leads to an increase in the intracellular levels of cyclic 3,5-guanine monophosphate (cGMP). Its cardiovascular effects protect against atherosclerosis, high blood pressure, heart failure, and thrombosis. NO is also the neurotransmitter in various 'nitrergic' nerves in the central and peripheral nervous systems and may play a role in the central regulation of vascular tone. The class of drugs used to treat erectile dysfunction, the phosphodiesterase (PDE_5) inhibitors, prevent the breakdown of cGMP and promote vasodilation.
- ***PGI_2*** is synergistic with NO and also plays a role in the local regulation of vasomotor tone.
- ***Endothelin (ET)*** is a 21-amino-acid peptide that counteracts the effects of NO. Its production is inhibited by shear stress—that is, the stress exerted on the vessel wall by the flowing blood—and it causes profound vasoconstriction and vascular smooth muscle hypertrophy. It is thought to play a role in the genesis of hypertension and atheroma.
- ***Angiotensin-converting enzyme (ACE)***, located on the endothelial cell membrane, converts circulating angiotensin I (synthesized by the action of renin on angiotensinogen) to angiotensin II, which has vasoconstrictor properties and leads to aldosterone release (see Fig. 17.6). Aldosterone promotes sodium

Box 17.3 Some of the products and functions of the vascular endothelium

Endothelial product	Function(s)	Stimulus
Nitric oxide	Vasodilation Inhibition of platelet aggregation Inhibition of transcription of adhesion molecules Inhibition of vascular smooth muscle proliferation	Shear stress, e.g., induced by exercise Agonists: thrombin, acetylcholine, endothelin, bradykinin, serotonin, substance P Inflammation/ endotoxin shock

absorption from the kidney and, together with the angiotensin-induced vasoconstriction, provides haemodynamic stability.

- ***Other factors*** that influence vasomotor tone include histamine (released by mast cells), bradykinin (synthesized from kininogen by the action of coagulation factor XIIa), and serotonin (released by platelets).

Anti- and prothrombotic mechanisms

PGI_2, produced from arachidonic acid in the endothelial cell membrane by the action of the enzyme cyclo-oxygenase, inhibits platelet aggregation. Low-dose aspirin prevents activation of the cyclo-oxygenase pathway in platelets but only to a degree that does not affect PGI_2 synthesis, unlike higher doses. Other antithrombotic agents, such as clopidogrel (an adenosine diphosphate [ADP] receptor antagonist) or abciximab and tirofiban (glycoprotein IIb/IIIa inhibitors), achieve their effects by acting directly on platelet receptors. The antithrombotic effect of PGI_2 is aided by NO, affecting platelets via activation of guanylate cyclase. The endothelial cell membrane also produces other anticoagulant molecules, such as thrombomodulin, heparin sulphate, and various fibrinolytic factors. Clinically used, fast-acting heparin preparations are identical to this naturally occurring molecule.

In addition to their ability to prevent clotting, endothelial cells also aid thrombosis. They are responsible for the production of von Willebrand factor through a unique organelle called the Weibel–Palade body, which not only acts as a carrier for factor VIII but also promotes platelet adhesion by binding to exposed collagen.

CLINICAL APPROACH TO THE PATIENT WITH HEART DISEASE

Clinical features of heart disease

The following symptoms occur with heart disease:

- chest pain
- dyspnoea (breathlessness)
- palpitations
- syncope
- fatigue
- peripheral oedema.

The severity of cardiac symptoms or fatigue is classified according to the New York Heart Association (NYHA) grading of cardiac status (see **Box 17.20**). The differential diagnosis of chest pain is given in **Box 17.4**.

Central chest pain

This is the most common symptom associated with heart disease. The pain of angina pectoris and myocardial infarction (MI) is due to myocardial hypoxia.

Types of pain include:

- a retrosternal heavy or gripping sensation with radiation to the left arm or neck that is provoked by exertion and eased with rest or nitrates—***angina*** (see 'Angina' section)
- similar pain at rest—***acute coronary syndrome*** (see 'Acute coronary syndromes' section)
- severe, tearing chest pain radiating through to the back—***aortic dissection*** (see 'Aneurysmal disease' section)
- sharp, central chest pain that is worse with movement or respiration but relieved with sitting forward—***pericarditis pain*** (see 'Pericardial disease' section)
- sharp, stabbing, left submammary pain associated with anxiety—***da Costa's syndrome.***

Dyspnoea

Left ventricular failure causes dyspnoea due to oedema of the pulmonary interstitium and alveoli. This makes the lungs stiff (less compliant), thus increasing the respiratory effort required to ventilate

Box 17.4 Differential diagnosis of chest pain

Central

Cardiac
- Ischaemic heart disease (infarction or angina)
- Coronary artery spasm
- Pericarditis/myocarditis
- Mitral valve prolapse
- Aortic aneurysm/dissection

Non-cardiac
- Pulmonary embolism
- Oesophageal disease

them. ***Tachypnoea*** (increased respiratory rate) is often present owing to stimulation of pulmonary stretch receptors.

Orthopnoea refers to breathlessness on lying flat. Blood is redistributed from the legs to the torso, leading to an increase in central and pulmonary blood volume. The patient uses an increasing number of pillows to sleep.

Paroxysmal nocturnal dyspnoea (PND) is when a patient is woken from sleep fighting for breath. It is caused by the same mechanisms as orthopnoea. However, as sensory awareness is reduced during sleep, pulmonary oedema can become quite severe before the patient is awoken.

Platypnea-orthodeoxia is paradoxical, worsening shortness of breath and hypoxia when the patient sits up. This is usually seen with intracardiac shunting, pulmonary arteriovenous connections, or hepatopulmonary syndrome.

Bendopnea is shortness of breath when bending over at the waist. This is typically seen in patients with reduced cardiac output and elevated right or left atrial pressure.

Hyperventilation with alternating episodes of apnoea ***(Cheyne–Stokes respiration)*** occurs in severe heart failure.

If hypopnoea occurs rather than apnoea, the phenomenon is termed 'periodic breathing', but the two variations are known together as ***central sleep apnoea syndrome (CSAS)***. This occurs due to malfunctioning of the respiratory centre in the brain, caused by poor cardiac output with concurrent cerebrovascular disease. The symptoms of CSAS, such as daytime somnolence and fatigue, are similar to those of obstructive sleep apnoea syndrome (OSAS, see Chapter 20, 'Obstructive sleep apnoea' section), and there is considerable overlap with the symptoms of heart failure. CSAS is believed to lead to myocardial hypertrophy and fibrosis, deterioration in cardiac function, and complex arrhythmias, including non-sustained ventricular tachycardia, hypertension, and stroke. Patients with CSAS have a worse prognosis than similar patients without CSAS.

Palpitations

These represent an increased awareness of the normal heartbeat or the sensation of slow, rapid, or irregular heart rhythms. The most common arrhythmias felt as palpitations are premature ectopic beats and paroxysmal tachycardias. A useful trick is to ask patients to tap out the rate and rhythm of their palpitations, as the different arrhythmias have different characteristics:

- ***Premature beats (ectopics)*** are felt by the patient as a pause followed by a forceful beat. This is because premature beats are usually followed by a pause before the next normal beat, as the heart resets itself. The next beat is more forceful, as the heart has had a longer diastolic period and therefore is filled with more blood before this beat.
- ***Paroxysmal tachycardias*** (see 'Tachycardias' section) are felt as a sudden, racing heartbeat.
- ***Bradycardias*** (see 'Bradycardia' section) may be appreciated as slow, regular, heavy, or forceful beats. Most often, however, they are simply not sensed.

Syncope

Syncope is a transient loss of consciousness due to inadequate cerebral blood flow. This is detailed further in Chapter 11 ('Dizziness and blackouts' section).

Fatigue

Fatigue may be a symptom of inadequate systemic perfusion in heart failure. Other contributing factors may include:
- poor sleep
- side-effects of medication, particularly beta-blockers
- electrolyte imbalance caused by diuretic therapy
- a systemic manifestation of infection (endocarditis) or anaemia.

Peripheral oedema

Heart failure results in salt and water retention due to renal underperfusion and consequent activation of the renin–angiotensin–aldosterone system (see Chapter 27). This leads to dependent pitting oedema. Non-cardiac causes of oedema include renal dysfunction, hepatic dysfunction, and medications such as calcium-channel blockers.

Examination of the cardiovascular system

General examination

General features of the patient's wellbeing should be noted, as well as the presence of conjunctival pallor, obesity, jaundice, and cachexia.
- Cardiac causes of ***clubbing*** (see Chapter 20, 'Examination of the respiratory system' section) include congenital cyanotic heart disease, particularly Fallot's tetralogy; less commonly, it is seen in patients with subacute infective endocarditis (IE) and atrial myxoma.
- ***Splinter haemorrhages*** are small, subungual linear haemorrhages that are frequently due to trauma but are also seen in IE.
- ***Cyanosis*** is a dusky blue discoloration of the skin (particularly at the extremities) or of the mucous membranes when the capillary oxygen saturation is below 85%. ***Central cyanosis*** is seen with shunting of deoxygenated venous blood into the systemic circulation, as in the presence of a right-to-left heart shunt, which is associated with congenital heart disease. ***Peripheral cyanosis*** is seen in the hands and feet, which are cold. It occurs in conditions associated with peripheral vasoconstriction and stasis of blood in the extremities, leading to increased peripheral oxygen extraction. Such conditions include congestive heart failure, circulatory shock, exposure to cold temperatures, and abnormalities of the peripheral circulation, such as Raynaud's phenomenon (see Chapter 32, 'Raynaud's phenomenon' section).

Arterial pulse

The first pulse to be examined is the right radial pulse. Timing should be synchronous with other peripheral pulses; delayed femoral

pulsation occurs because of a proximal stenosis, particularly of the aorta (coarctation).

Rate

The pulse rate should be between 60 and 80 beats per minute (b.p.m) when an adult patient is lying quietly in bed.

Rhythm

The rhythm is regular, except for a slight quickening in early inspiration and a slowing in expiration (sinus arrhythmia).

- ***Premature beats*** occur as occasional or repeated irregularities superimposed on a regular pulse rhythm. Similarly, intermittent heart block is revealed by occasional beats dropped from an otherwise regular rhythm.
- ***Atrial fibrillation*** produces an 'irregularly irregular' pulse. This irregular pattern persists when the pulse quickens in response to exercise, in contrast to pulse irregularity due to ectopic beats, which usually disappears on exercise.

Character

- ***Carotid pulsations*** are not normally apparent on inspection of the neck but may be visible (Corrigan's sign) in conditions associated with a large-volume pulse, including high-output states (such as thyrotoxicosis, anaemia, or fever) and in aortic regurgitation.
- ***A 'collapsing' or 'water hammer' pulse*** (Fig. 17.10) is a large-volume pulse characterized by a short duration with a brisk rise and fall. This is best appreciated by palpating the radial artery with the palmar aspect of four fingers while elevating the patient's arm above the level of the heart. A collapsing pulse is characteristic of aortic valvular regurgitation or a persistent ductus arteriosus.
- ***A small-volume pulse*** is seen in cardiac failure, shock, and obstructive valvular or vascular disease. It may also be present during tachyarrhythmias.
- ***A plateau pulse*** (see Fig. 17.10) is small in volume and slow in rising to a peak; it is due to aortic stenosis.
- ***An alternating pulse (pulsus alternans)*** (see Fig. 17.10) is characterized by regular alternate beats that are weak and strong. It is a feature of severe myocardial failure and is due to the prolonged recovery time of damaged myocardium; it indicates a very poor prognosis. It is easily noticed when taking the blood pressure because the systolic pressure may vary from beat to beat by as much as 50 mmHg.
- ***A bigeminal pulse (pulsus bigeminus)*** (see Fig. 17.10) is caused by a premature ectopic beat following every sinus beat. The rhythm is not regular because every weak pulse is premature.
- ***Pulsus bisferiens*** (see Fig. 17.10) is found in hypertrophic cardiomyopathy (HCM) and in mixed aortic valve disease (regurgitation combined with stenosis). The first systolic wave is the 'percussion' wave, produced by transmission of the left ventricular pressure in early systole. The second peak is the 'tidal' wave, caused by recoil of the vascular bed. This normally happens in diastole (the dicrotic wave), but when the left ventricle empties slowly or is obstructed and cannot empty completely, the tidal wave occurs in late systole. The result is a palpable double pulse.
- ***A dicrotic pulse*** (see Fig. 17.10) results from an accentuated dicrotic wave. It can occur in sepsis, hypovolaemic shock, tamponade, and in the immediate postoperative period after aortic valve replacement.
- ***Paradoxical pulse*** is a misnomer, as it is actually an exaggeration of the normal pattern. In normal subjects the systolic pressure and the pulse pressure (the difference between the systolic and diastolic blood pressures) fall during inspiration. The normal fall of systolic pressure is less than 10 mmHg, and this can be measured using a sphygmomanometer. It is due to increased pulmonary intravascular volume during inspiration. In severe airflow limitation (especially severe asthma) there is an increased negative intrathoracic pressure on inspiration, which enhances the normal fall in blood pressure. In patients with cardiac tamponade the fluid in the pericardium increases the intrapericardial pressure, thereby impeding diastolic filling of the heart. The normal inspiratory increase in venous return to the right ventricle is at the expense of the left ventricle, as both ventricles are confined by the accumulated pericardial fluid within the pericardial space. Paradox can occur via a similar mechanism in constrictive pericarditis but is less common.

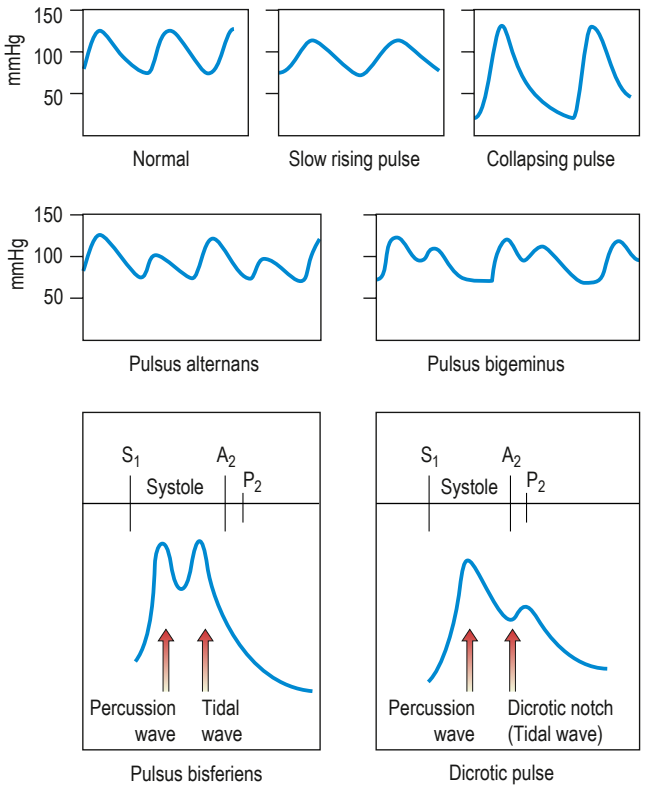

Fig. 17.10 Arterial waveforms. A_2, Aortic component of the second heart sound; P_2, pulmonary component of the second heart sound; S_1, first heart sound.

Blood pressure

The peak systemic arterial blood pressure is produced by transmission of left ventricular systolic pressure. Vascular tone and an intact aortic valve maintain the diastolic blood pressure. Instructions for taking the blood pressure using the auscultatory method are outlined in Box 17.5. See Chapter 18 for further details.

Jugular venous pressure

There are no valves between the internal jugular vein and the right atrium. Observation of the column of blood in the internal jugular system is therefore a good measure of right atrial pressure. The external jugular cannot be relied on because of its valves and because it may be obstructed by the fascial and muscular layers through which it passes; it can be used only if typical venous pulsation is seen, indicating no obstruction to flow.

Box 17.5 Taking the blood pressure

Use a properly calibrated machine.

1. Take the blood pressure in the (right) arm with the patient relaxed and comfortable.
2. Wrap the sphygmomanometer cuff around the upper arm and place the inflation bag over the brachial artery.
3. Inflate the cuff until the pressure exceeds the arterial pressure—when the radial pulse is no longer palpable.
4. Position the diaphragm of the stethoscope over the brachial artery just below the cuff.
5. Slowly reduce the cuff pressure until sounds (Korotkoff sounds) can be heard ***(phase 1).*** This is the systolic pressure.
6. Allow the pressure to fall further until the Korotkoff sounds suddenly become muffled ***(phase 4).***
7. Allow the pressure to fall still further until the sounds disappear ***(phase 5).***
8. The diastolic pressure is usually taken as ***phase 5*** because this phase is more reproducible and nearer to the intravascular diastolic pressure. The Korotkoff sounds may disappear ***(phase 2)*** and reappear ***(phase 3)*** between the systolic and diastolic pressures. Do not mistake ***phase 2*** for the diastolic pressure or ***phase 3*** for the systolic pressure.

Measurement of jugular venous pressure

See Box 17.6.

Elevation of the jugular venous pressure (JVP) occurs in ***heart failure***. An elevated JVP also occurs in:

- constrictive pericarditis and cardiac tamponade (increases in inspiration—***Kussmaul's sign***)
- renal disease with salt and water retention
- over-transfusion or excessive infusion of fluids
- superior vena cava obstruction.

A reduced JVP occurs in hypovolaemia.

Jugular venous pressure wave

This consists of three peaks and two troughs (Fig. 17.11). The peaks are described as ***a***, ***c***, and ***v*** waves and the troughs are known as ***x*** and ***y*** descents. The ***a*** wave and ***v*** wave are the only visible positive waves.

- ***The a wave*** is produced by atrial systole and is increased with right ventricular hypertrophy secondary to pulmonary hypertension or pulmonary stenosis. Giant cannon waves occur in complete heart block and ventricular tachycardia.
- ***The x descent*** occurs when atrial contraction finishes.
- ***The c wave*** occurs during the ***x*** descent and is due to transmission of right ventricular systolic pressure before the tricuspid valve closes.
- ***The v wave*** occurs with venous return filling the right atrium. Giant ***v*** waves occur in tricuspid regurgitation.
- ***The y descent*** follows the ***v*** wave when the tricuspid valve opens. A steep ***y*** descent is seen in constrictive pericarditis and tricuspid incompetence.

Precordium

- With the patient at 45 degrees, the cardiac apex is located in the fifth intercostal space mid-clavicular line. Left ventricular dilation will displace the apex downwards and laterally. It may be impalpable in patients with emphysema, obesity, or pericardial or pleural effusions.
- ***A tapping apex*** is a palpable first sound and occurs in mitral stenosis.
- ***A vigorous apex*** may be present in diseases with volume overload, for example, aortic regurgitation.

Box 17.6 Measurement of jugular venous pressure (JVP)

- The patient is positioned at about 45 degrees to the horizontal (between 30 and 60 degrees), wherever the top of the venous pulsation can be seen in a good light.
- The JVP is measured as the vertical distance between the manubriosternal angle and the top of the venous column.
- The normal JVP is usually <3 cmH_2O, which is equivalent to a right atrial pressure of 8 cmH_2O when measured with reference to a point midway between the anterior and posterior surfaces of the chest.
- The venous pulsations are not usually palpable (except for the forceful venous distension associated with tricuspid regurgitation).
- Compression of the right upper abdomen causes a temporary increase in venous pressure and makes the jugular venous pulse more visible (hepatojugular reflux).

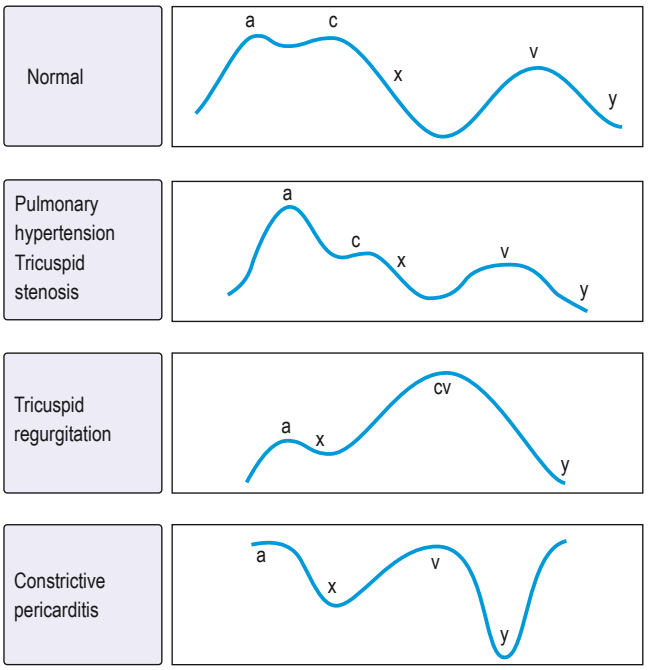

Fig. 17.11 Jugular venous waveforms.

- ***A heaving (sustained) apex*** may occur with left ventricular hypertrophy—aortic stenosis, systemic hypertension, and HCM.
- ***A double pulsation*** may occur in HCM.
- ***A sustained left parasternal heave*** occurs with right ventricular hypertrophy or left atrial enlargement.
- ***A palpable thrill*** may be felt overlying an abnormal cardiac valve, for example, systolic thrill with aortic stenosis.

Auscultation

The ***bell*** of the stethoscope is used for low-pitched sounds (heart sounds and mid-diastolic murmur in mitral stenosis). The ***diaphragm*** is used for high-pitched sounds (systolic murmurs, aortic regurgitation, ejection clicks, and opening snaps). The areas of auscultation are shown in Fig. 17.12. Left-sided valve murmurs may be more prominent in expiration and right-sided in inspiration. Mitral murmurs may be more audible with the patient reclining to the left. Left heart valve closure sounds usually precede their corresponding right heart valve closure sounds.

First heart sound (S1)

This is due to mitral and tricuspid valve closure. A loud S1 occurs in thin people, hyperdynamic circulation, tachycardias, and mild

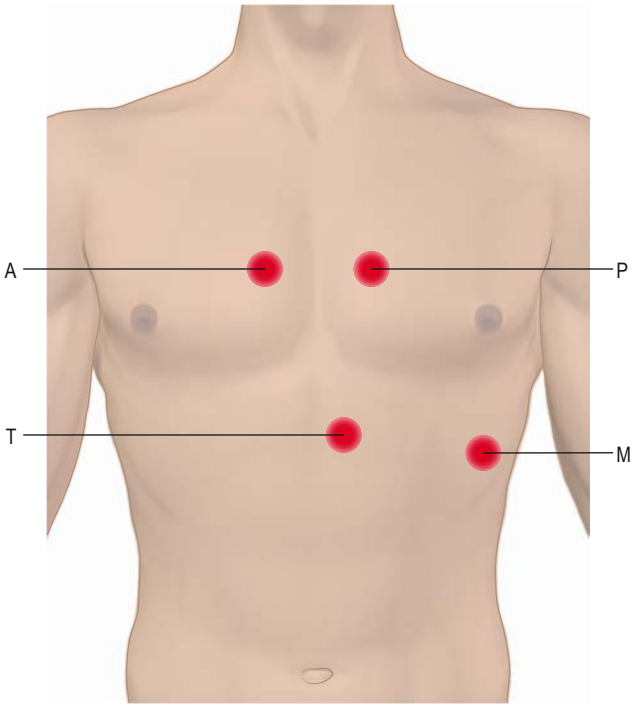

Fig. 17.12 Heart auscultation. Aortic area second intercostal space (ICS) right sternal edge **(A)**. Pulmonary area second ICS left sternal edge **(P)**. Mitral area fifth ICS mid-clavicular line **(M)**. Tricuspid area third to fifth ICS left sternal edge **(T)**.

to moderate mitral stenosis. A soft S1 occurs in obesity, emphysema, pericardial effusion, severe calcific mitral stenosis, mitral or tricuspid regurgitation, heart failure, shock, bradycardias, and first-degree block.

Second heart sound (S2)

This is due to aortic and pulmonary valve closure. Physiological splitting of S2 occurs during inspiration in children and young adults. Keen auscultators may identify additional abnormalities of S2, which may be described as:

- widely split (mitral regurgitation, ventricular septal defect (VSD), right bundle branch block)
- reversed split (aortic stenosis, HCM, left bundle branch block, patent ductus arteriosus)
- fixed split (secundum atrial septal defect)
- single (pulmonary stenosis, Eisenmenger's syndrome).

Third and fourth heart sounds

These are pathological:

- ***A third heart sound ('volume overload')*** is due to rapid ventricular filling and is present in significant heart failure. Reducing left atrial pressure with diuresis can diminish this sound.
- ***A fourth heart sound (pressure overload)*** occurs in late diastole and is associated with atrial contraction. Causes include aortic stenosis, severe systemic hypertension, and left ventricular outflow obstruction, as in HCM, that is, causes of significant left ventricular hypertrophy.

Singly or together, especially in a tachycardic state, they will produce a gallop rhythm.

Heart murmurs

These are due to turbulent blood flow and occur in hyperdynamic states or with abnormal valves. Audio recordings of common murmurs are available to be listened to online via the Elsevier eBooks+. Innocent or flow murmurs are soft, early systolic, short, and non-radiating. They are heard frequently in children and young adults. Heart murmurs can be graded:

- 1/6: very faint; not always heard in all positions
- 2/6: quiet but not difficult to hear
- 3/6: moderately loud
- 4/6: loud with or without thrills
- 5/6: very loud with or without thrills; heard with the stethoscope partly off the chest
- 6/6: with or without thrills; heard with the stethoscope completely off the chest.

The individual murmurs are discussed under valve disease (see 'Valvular heart disease' section).

Cardiac investigations

Blood tests

A panel of routine blood tests is typically carried out in patients with heart disease to exclude other conditions (e.g., kidney disease or anaemia) which may be relevant. Specialist blood tests in cardiology include:

- cardiac enzymes (troponin is used in the diagnosis of ACS, see 'Acute coronary syndromes' section; creatine kinase, aspartate aminotransferase [AST], and lactate dehydrogenase [LDH] may also be elevated in this context).
- B-type natriuretic peptide (BNP), which is used in the diagnosis of heart failure.

Chest radiograph

This allows gross inspection of cardiac size and associated lung pathology such as pulmonary oedema or effusions. This is discussed in more detail in Chapter 8 ('Chest radiography [chest X-ray]' section).

Electrocardiography

The ECG is a recording of the electrical activity of the heart. It is the vector sum of the depolarization and repolarization potentials of all myocardial cells (see **Fig. 17.2**). At the body surface, these generate potential differences of about 1 mV, and fluctuations in these potentials create the familiar P–QRS–T pattern. At rest, the intracellular voltage of the myocardium is polarized at –90 mV compared with that of the extracellular space. This diastolic voltage difference occurs because of the high intracellular potassium concentration, which is maintained by the sodium–potassium pump despite the free membrane permeability to potassium. Depolarization of cardiac cells occurs when there is a sudden increase in the permeability of the membrane to sodium. Sodium rushes into the cell and the negative resting voltage is lost (phase 0 on **Fig. 17.13**). The depolarization of a myocardial cell causes the depolarization of adjacent cells, and in the healthy heart, the entire myocardium is depolarized in a coordinated fashion. During repolarization, cellular electrolyte balance is slowly restored (phases 1, 2, and 3). Slow diastolic depolarization (phase 4) follows until the threshold potential is reached. Another action potential then follows.

The ECG is recorded from two or more simultaneous points of skin contact (electrodes). When cardiac activation proceeds towards the positive contact, an upward deflection is produced on the ECG. Correct representation of a three-dimensional spatial vector requires recordings from three mutually perpendicular (orthogonal) axes. The shape of the human torso does not make

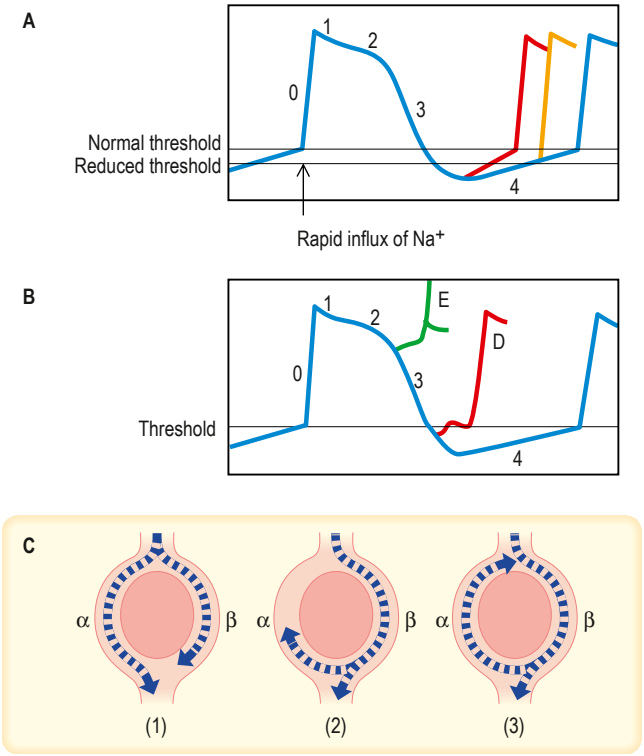

Fig. 17.13 Mechanisms of arrhythmogenesis. **(A–B)** Action potentials (i.e., the potential difference between intracellular and extracellular fluid) of ventricular myocardium after stimulation. **(A)** Increased (accelerated) automaticity due to reduced threshold potential or an increased slope of phase 4 depolarization. **(B)** Triggered activity due to early (E) or delayed (D) 'after-depolarizations' reaching threshold potential. **(C)** Mechanism of circus movement or re-entry. In panel 1 the impulse passes down both limbs of the potential tachycardia circuit. In panel 2 the impulse is blocked in one pathway (α) but proceeds slowly down pathway β, returning along pathway α until it collides with refractory tissue. In panel 3 the impulse travels so slowly along pathway β that it can return along pathway α and complete the re-entry circuit, producing a circus movement tachycardia.

this easy, so the practical ECG records 12 projections of the vector, called 'leads' (Fig. 17.14).

Six of the leads are obtained by recording voltages from the limbs (I, II, III, AVR, AVL, and AVF). The other six leads record potentials between points on the chest surface and an average of the three limbs: RA, LA, and LL. These are designated V_1–V_6 and aim to select activity from the right ventricle (V_1–V_2), interventricular septum (V_3–V_4), and left ventricle (V_5–V_6). Note that leads AVR and V_1 are oriented towards the cavity of the heart; leads II, III, and AVF face the inferior surface; and leads I, AVL, and V_6 face the lateral wall of the left ventricle. A V_4 on the right side of the chest (V_4R) is occasionally useful (e.g., for the diagnosis of right ventricular infarction).

Most ECG machines are simultaneous three-channel recorders, with output given either as a continuous strip or with automatic channel switching. Many modern ECG machines provide automatic interpretation which can be helpful, but many arrhythmias still defy automatic analysis.

ECG waveform

The shape of the normal ECG waveform (Fig. 17.15) has similarities, regardless of the orientation. The first deflection is caused by atrial depolarization; it is a low-amplitude, slow deflection called a ***P wave***. The ***QRS complex*** reflects ventricular activation or depolarization and is sharper and larger in amplitude than the P wave. An initial downward deflection is called the ***Q wave***. An initial upward deflection is called an ***R wave***. The ***S wave*** is the last part of ventricular activation. The ***T wave*** is another slow and low-amplitude deflection that results from ventricular repolarization.

The ***PR interval*** is the length of time from the start of the P wave to the start of the QRS complex. It is the time taken for activation to pass from the sinus node, through the atrium, AV node, and His–Purkinje system, to the ventricle.

The ***QT interval*** extends from the start of the QRS complex to the end of the T wave. This interval represents the time taken to depolarize and repolarize the ventricular myocardium. The QT interval varies greatly with heart rate and is often represented as a corrected QT interval (or QTc) for a given heart rate. There are a number of formulae for derivation of QTc, but the most widely accepted are Bazett's formula and Fridericia's correction (Box 17.7).

An abnormally prolonged QTc can predispose to a risk of dangerous ventricular arrhythmias. Prolongation of the QT interval may be congenital or can occur in many acquired conditions (see Box 17.15).

The ***ST segment*** is the period between the end of the QRS complex and the start of the T wave. In the normal heart all cells are depolarized by this phase of the ECG: that is, the ST segment represents ventricular repolarization.

A normal 12-lead ECG is shown in Fig. 17.16, and the normal values for the electrocardiographic intervals are indicated in Box 17.7. Leads that face the lateral wall of the left ventricle have predominantly positive deflections, and leads looking into the ventricular cavity are usually negative. Detailed patterns depend on the size, shape, and rhythm of the heart and the characteristics of the torso.

Cardiac vectors ('axis')

At any point in time during depolarization and repolarization, electrical potentials are being propagated in different directions. Most of these cancel each other out and only the net force is recorded. This net force in the frontal plane is known as the cardiac vector.

The mean QRS vector can be calculated from the six standard leads (Fig. 17.17):

- ***Normal:*** between –30 degrees and +90 degrees
- ***Left axis deviation:*** between –30 degrees and –90 degrees
- ***Right axis deviation:*** between +90 degrees and +150 degrees.

Calculation of this vector is useful in the diagnosis of some cardiac disorders.

Exercise electrocardiography

This is now rarely used to detect coronary ischaemia as the test has a low sensitivity. The ECG is recorded while the patient walks or runs on a motorized treadmill. The test is based on the principle that exercise increases myocardial demand on coronary blood supply, which may be inadequate during exercise and, at peak stress, can result in relative myocardial ischaemia. Most exercise tests are performed according to a standardized method, such as the Bruce protocol. Normally, there is little change in the T wave or ST segment during exercise.

The patient's exercise capacity (the total time achieved) will depend on many factors; however, individuals who can exercise for less than 6 minutes generally have a poorer prognosis.

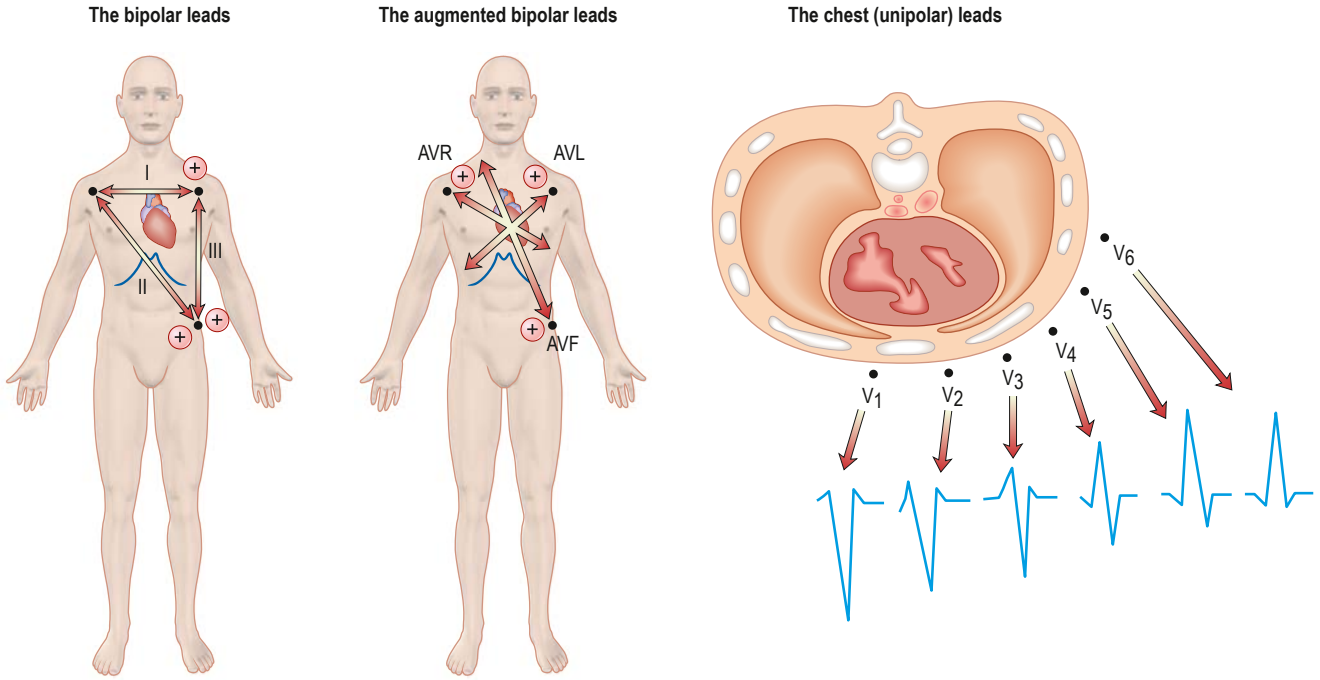

Fig. 17.14 **The connections or directions that comprise the 12-lead electrocardiogram.**

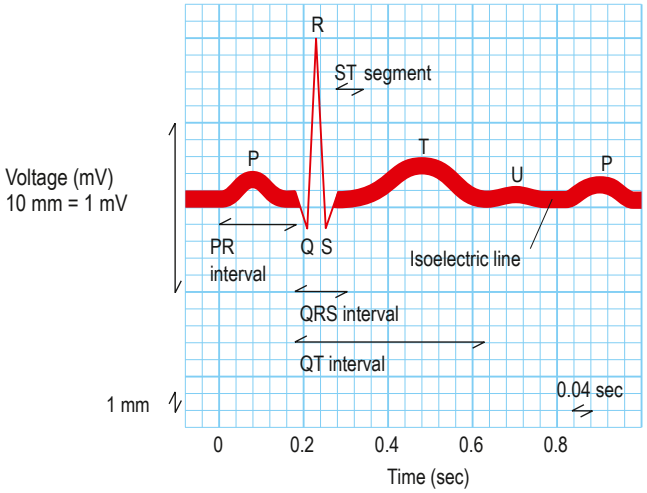

Fig. 17.15 **The waves and elaboration of the normal electrocardiogram.**

Box 17.7 Normal ECG intervals

Parameter	Interval
P wave duration	≤0.12 sec
PR interval	0.12–0.20 sec
QRS complex duration	≤0.11 sec
Corrected QT (QTc)	≤0.44 sec in males
	≤0.46 sec in females
$QT_{cB} = QT\sqrt{}^{2}$ (R–R)	Bazett's square root formula
$QT_{cF} = QT\sqrt{}^{3}$ (R–R)	Fridericia's cube root formula

Myocardial ischaemia provoked by exertion can result in ST-segment depression (>1 mm) in leads facing the affected area. The form of ST-segment depression provoked by ischaemia is characteristic: it either is planar or shows down-sloping depression (Fig. 17.18). Up-sloping depression is a non-specific finding. The degree of ST-segment depression is positively correlated to the degree of myocardial ischaemia.

ST-segment elevation during an exercise test is induced much less frequently than ST depression. When it does occur, it reflects transmural ischaemia caused by coronary spasm or critical stenosis.

Although most abnormalities are detected in lead V_5 (anterior and lateral ischaemia) or AVF (inferior ischaemia), it is best to record a full 12-lead ECG. During an exercise test, the blood pressure and rhythm responses to exercise are also assessed. Exercise normally causes an increase in heart rate and blood pressure. A sustained fall in blood pressure usually indicates severe coronary artery disease (CAD) or cardiomyopathy. A slow recovery of the heart rate to basal levels has also been reported to be a predictor of mortality.

Frequent premature ventricular depolarizations in the recovery stage (post exercise) are associated with an increased risk of death following adjustment for baseline risk factors.

Ambulatory monitoring of heart rhythm

Ambulatory taped electrocardiography

This records transient changes, such as a brief paroxysm of tachycardia, an occasional pause in the rhythm, or intermittent ST-segment shifts (Fig. 17.19). A conventional 12-lead ECG records 10 seconds of cardiac activity and usually samples fewer than 10 complexes. In a 24-hour period over 100 000 complexes are recorded. Such a large amount of data must be analyzed by automatic or semi-automatic methods. This technique is called ***Holter electrocardiography***, named after its inventor; 72-hour monitoring increases sensitivity for less frequent abnormalities and may be the standard monitoring period in some units, and occasionally longer period of event recording may be carried out where there is a high index of suspicion.

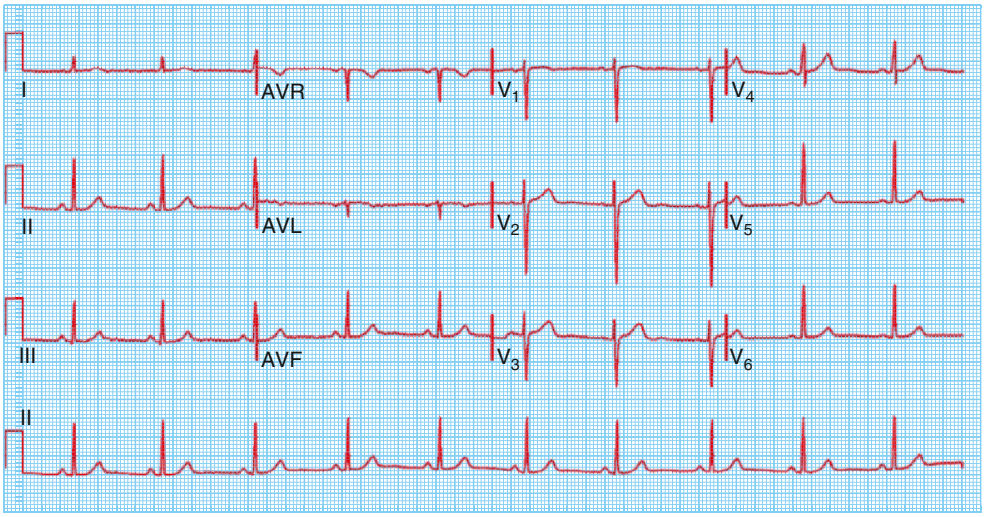

Fig. 17.16 **A normal 12-lead electrocardiogram.**

Implantable loop recording

A very small event recorder, known as an implantable loop recorder (ILR), can be implanted subcutaneously. It is useful in the management of infrequent syncope and has data supporting its use in the identification of paroxysmal atrial fibrillation in patients with unexplained embolic stroke.

Cardiac data from patient devices

Heart rate and single-lead ECG data are now increasingly available from personal, wearable, smart technology; integrating this into care for the individual patient requires a personalized approach.

Analysis of ambulatory heart rhythm recordings

Ambulatory cardiac rhythm recordings using any of the techniques above may reveal evidence of transient arrhythmias such as atrial fibrillation or heart block. In addition, the following techniques have been used to detect signs of cardiac disease from subtle abnormalities of the ECG trace:

- ***Heart rate variability (HRV)*** can be automatically assessed from a 24-hour ECG. HRV is decreased in some patients following MI and represents an abnormality of autonomic tone or cardiac responsiveness. It is not utilized in mainstream cardiology.
- ***Signal-averaged ECG (SAECG)*** is a technique that requires amplification and averaging of abnormal low-amplitude signals that occur beyond the end of the QRS complex and extend well into the ST segment. These signals are therefore also known as late potentials and are too small to be detected on a surface ECG. They arise in areas of slow conduction in the myocardium, such as the border zone of an infarct, where re-entrant ventricular arrhythmias can originate or from scar in patient with arrhythmogenic cardiomyopathy (ACM).
- ***T wave alternans (TWA)*** is a niche technique used as a non-invasive marker of susceptibility to ventricular arrhythmias and sudden cardiac death. TWA represents microvolt level changes in the morphology of the T waves in every other beat and can be detected during acute myocardial ischaemia using amplification techniques. Visible TWA on an ordinary surface ECG is quite a rare phenomenon, except in patients with long QT syndromes, particularly during emotion or exercise.

Tilt testing

Patients with suspected neurocardiogenic (vasovagal) syncope could be further investigated by upright tilt testing. The patient is secured to a table that is tilted to +60 degrees to the vertical for 45 minutes or more. The ECG and non-invasive blood pressure are continuously monitored throughout. If neither symptoms nor signs develop, isoprenaline may be slowly infused or glyceryl trinitrate administered and the tilt repeated. A positive test results in hypotension, sometimes bradycardia (**Fig. 17.20**), and pre-syncope/syncope, and supports the diagnosis of neurocardiogenic syncope. If symptoms and signs appear, placing the patient flat can quickly reverse them. The effect of treatment can be evaluated by repeating the tilt test, but it is not always reproducible. The overall sensitivity, specificity, and reproducibility are low. Tilt table testing can also support a diagnosis of postural orthostatic tachycardia syndrome (POTS, see 'Postural orthostatic tachycardia syndrome' section) if the heart rate increased more than 30 beats/min or increased to more than 120 beats/min after standing, especially if accompanied by symptoms.

Carotid sinus massage

Carotid sinus massage (**Box 17.8**) may lead to asystole (>3 sec) and/or a fall in systolic blood pressure (>50 mmHg). This hypersensitive response occurs in many of the normal (especially elderly) population but may also be responsible for loss of consciousness in some patients with carotid sinus syndrome (see 'Neurally mediated syndromes' section). In one-third of cases, carotid sinus massage is positive only when the patient is standing. Atherosclerosis can cause narrowing and stenosis of carotid arteries. Carotid sinus massage should thus be avoided in patients with carotid bruits.

Echocardiography

Echocardiography is a non-invasive diagnostic technique that is widely employed in clinical cardiology. It involves the use of ultrasound (either alone or with a contrast agent) to assess cardiac structure and function. A physician or technician performs the studies and a comprehensive examination takes 15 to 45 minutes. The ultrasound machines are either mobile on wheels or handheld.

Physics

Echocardiography uses transmitted ultrasound wavelengths of 1 mm or less, which correspond to frequencies of approximately 2

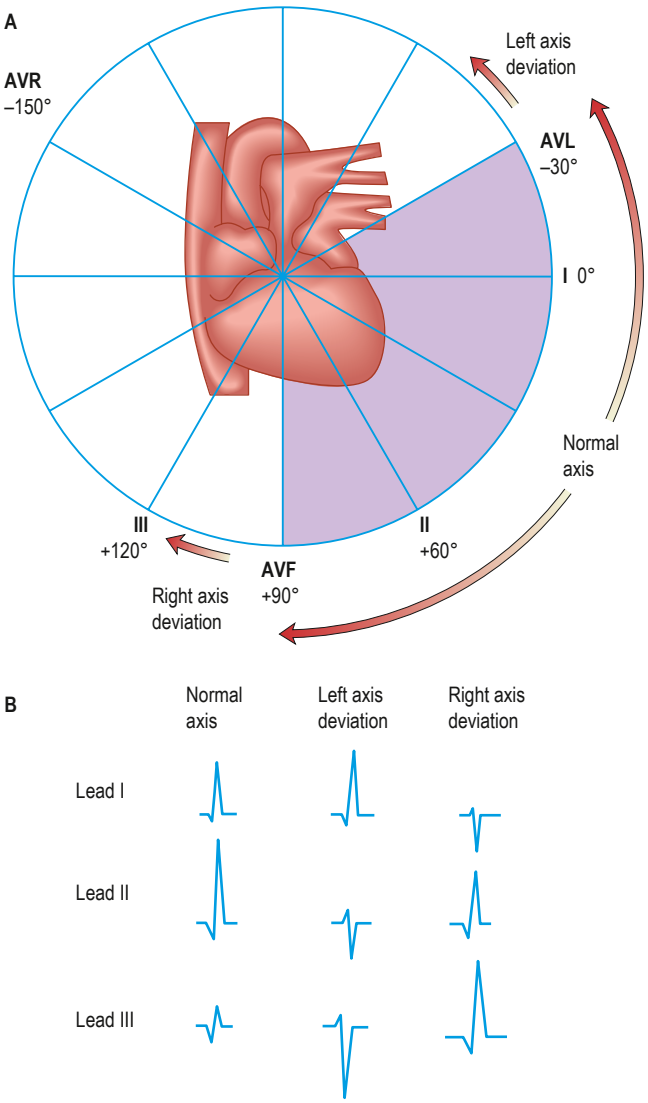

Fig. 17.17 Cardiac vectors. (A) The hexaxial reference system illustrating the six leads in the frontal plane; for example, lead I is 0 degrees, lead II is +60 degrees, and lead III is +120 degrees. **(B)** Calculating the direction of the cardiac vector. In the first column the QRS complex with zero net amplitude (i.e., when the positive and negative deflections are equal) is seen in lead III. The mean QRS vector is therefore perpendicular to lead III and is either −150 degrees or +30 degrees. Lead I is positive, so the axis must be +30 degrees, which is normal. In left axis deviation (second column) the main deflection is positive (R wave) in lead I and negative (S wave) in lead III. In right axis deviation (third column) the main deflection is negative (S wave) in lead I and positive (R wave) in lead III. The frontal plane QRS axis is normal only if the QRS complexes in leads I and II are predominantly positive.

MHz or more (2 million cycles per second or more). At such high frequencies, the ultrasound waves can be focused into a 'beam' and aimed at a particular region of the heart. The waves are generated in very short bursts or pulses a few microseconds long by a crystal transducer, which also detects returning echoes and converts them into electrical signals.

When the handheld crystal transducer is placed on the body surface, the emitted ultrasound pulses encounter interfaces between various body tissues as they pass through the body. In crossing each interface some of the wave energy is reflected, and if the beam

Fig. 17.18 Electrocardiographic changes during exercise testing. The upper traces show significant horizontal ST-segment depression during exercise. The lower traces show ST elevation during exercise.

path is approximately at right angles to the plane of the interface, the reflected waves return to the transducer as an echo. Since the velocity of sound in body tissues is almost constant (1550 m/s), the time delay for the echo to return measures the distance of the reflecting interface. Thus, if a single ultrasound pulse is transmitted, a series of echoes return, the first of which is from the closest interface.

Echocardiographic modalities

M-mode and two-dimensional echocardiography

M-mode echocardiography is a technique that details the changing motion of structures along the ultrasound beam with time. Thus the motion of the interventricular septum during the cardiac cycle (either towards or away from the transducer placed on the chest wall) can be assessed and quantified. Stationary structures thus generate horizontal straight lines; the distances of these lines from the top of the screen indicate the depth of the structures, and movements, such as those of heart valves, are indicated by zigzag lines (Fig. 17.21C). Alternatively, a series of views from different positions can be obtained in the form of a two-dimensional image (cross-sectional two-dimensional echocardiography; Fig. 17.21A and B). This method is useful for delineating anatomical structures and for quantifying volumes of the cardiac chambers.

Ejection fraction (EF) is best calculated from the difference in LV volumes from systole to diastole, derived from planimetered measurements of LV area in at least two planes. A normal EF is over 55%. This method is helpful in diagnosing heart failure as well as assessing the response of the patient to therapy. It also permits estimation of LV mass.

Three-dimensional echocardiography

Three-dimensional echocardiography is increasingly used in clinical practice and allows acquisition of a volumetric dataset using a multiplane probe rotating around a fixed axis. This allows more accurate volumetric analysis of ventricular function and mass, assessment of mitral and aortic valve disease, and assessment of adult congenital heart disease (Fig. 17.22).

Doppler echocardiography

Echocardiography utilizes echoes from tissue interfaces. Using high amplification, it is also possible to detect weak echoes scattered by small targets, including those from red blood cells. Blood velocity in

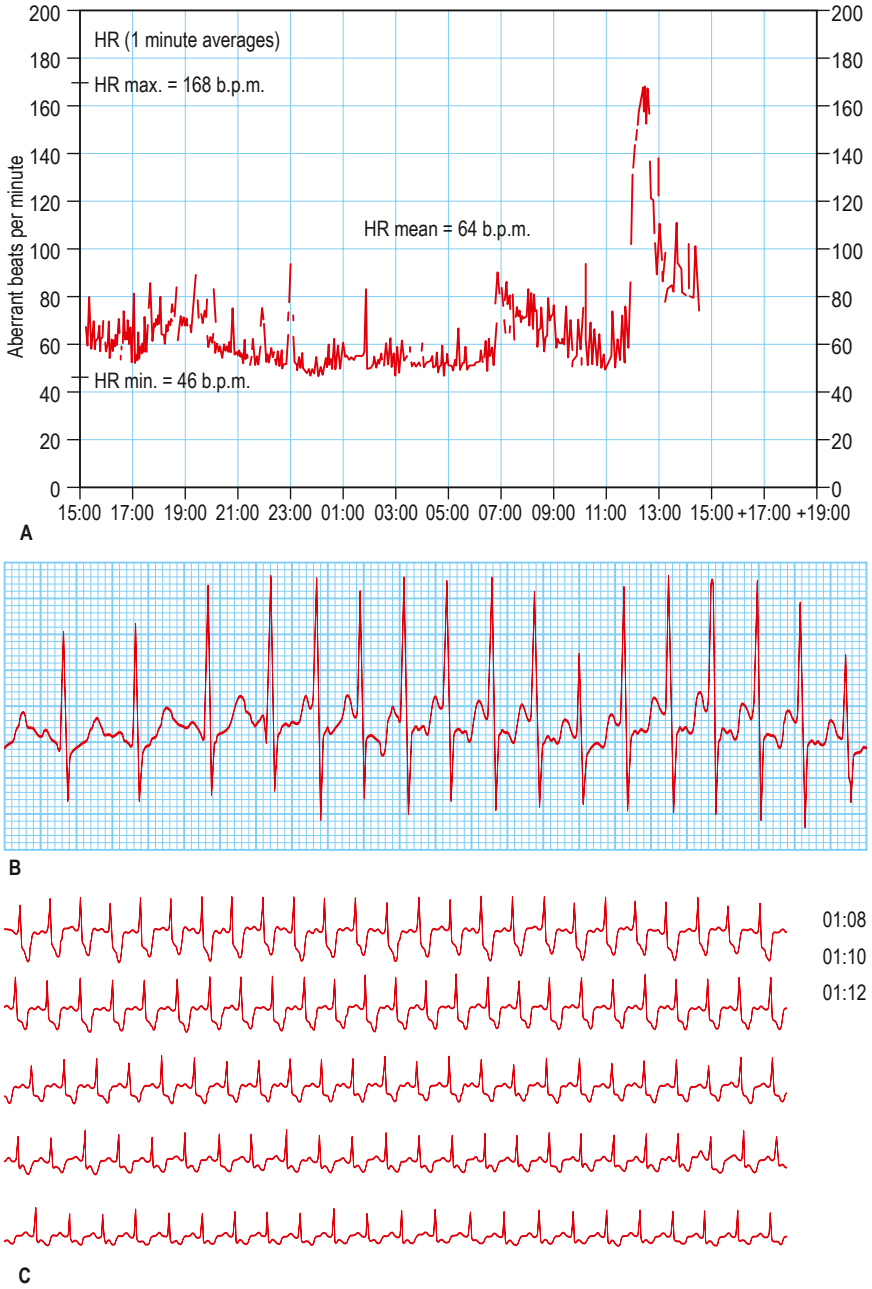

Fig. 17.19 Examples of Holter recordings. **(A)** A tachograph showing a sudden increase in heart rate (HR) between 11:00 and 13:00 hours. **(B)** An ambulatory ECG record of the same patient, revealing supraventricular tachycardia. **(C)** An ambulatory ECG showing ST depression in a patient with silent myocardial ischaemia.

the heart chambers is typically much more rapid (>1 m/s) than the movement of myocardial tissue. If the blood is moving in the same direction as the direction of the ultrasound beam, the frequency of the returning echoes will be changed according to the Doppler phenomenon. The Doppler shift frequency is directly proportional to the blood velocity. Blood velocity data can be acquired and displayed in several ways.

Pulsed-wave (PW) Doppler extracts velocity data from the pulse echoes used to form a two-dimensional image and gives useful qualitative information. PW echoes can be specified from locations within an image identified by a sample volume cursor placed on the screen. Such information from the left ventricular outflow tract (LVOT) and right ventricular outflow tract provides the stroke distance and is used to estimate cardiac output and also to quantify intracardiac shunts. Cardiac output can then be derived using the formula:

$$\text{CO} = \text{stroke volume} \times \text{heart rate}$$

Stroke volume is the stroke distance multiplied by the area of the LVOT, which can also be measured echocardiographically. PW Doppler of the flow across the mitral valve and into the left atrium through the pulmonary veins can be used as an element of the estimation of left ventricular filling pressure.

Colour flow Doppler imaging uses one colour (red) for blood flowing towards the transducer and another colour (blue) for blood flowing away. This technique allows the direction, velocity, and timing of the flow to be measured with a simultaneous view of cardiac

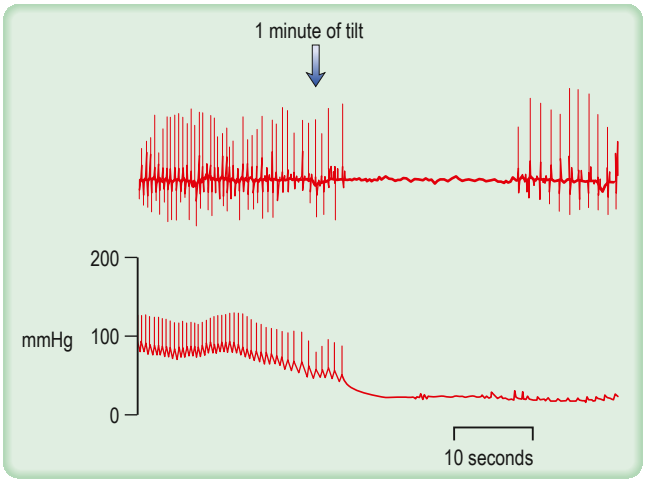

Fig. 17.20 Tilt test. The ECG *(top trace)* and arterial blood pressure *(bottom trace)* recorded during a tilt test. After 1 minute of tilt, hypotension, bradycardia, and syncope occur.

Box 17.8 Carotid sinus massage

- Explain the procedure to the patient and obtain informed consent.
- Ensure that there is no significant carotid artery disease (carotid bruits).
- Provide continuous electrocardiographic monitoring.
- Place the patient in the supine position with the head slightly extended.
- Start with right carotid sinus massage.
- Apply firm rotary pressure to the carotid artery at the level of the third cervical vertebra for 5 sec.
- Alternatively, apply steady pressure.
- If there is no response, massage the left carotid sinus.
- Generally, right carotid sinus massage decreases the sinus node discharge, and left carotid sinus massage slows atrioventricular conduction.
- Do not massage both carotid sinuses at the same time.
- Single application of carotid sinus pressure may be effective in about 20% to 30% of patients with paroxysmal supraventricular tachycardias; multiple applications can terminate tachycardia in about 50% of patients.
- Asystole is a potential but rare complication.

Fig. 17.21 Echocardiography. structure and function. Colour flow Doppler is used to help assess valvular regurgitation (Fig. 17.23) and may be helpful in the assessment of coronary blood flow.

Continuous-wave (CW) Doppler collects all the velocity data from the path of the beam and analyzes it to generate a spectral display. This is unlike PW Doppler, which provides information from a particular sample volume at one location along a line. Thus CW Doppler does not provide any depth information.

The outline of the envelope of the spectral display is used to estimate the value of peak velocity throughout the cardiac cycle. CW Doppler is typically used to assess valvular obstruction, which then causes increased velocities. For example, normal flow velocities are

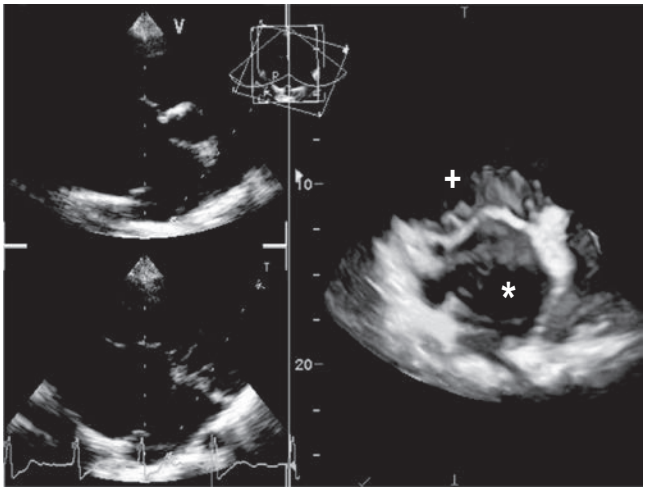

Fig. 17.22 Three-dimensional echocardiograph in a patient with an atrial septal defect (*). The mitral valve (+) and the left atrial anatomy are well delineated.

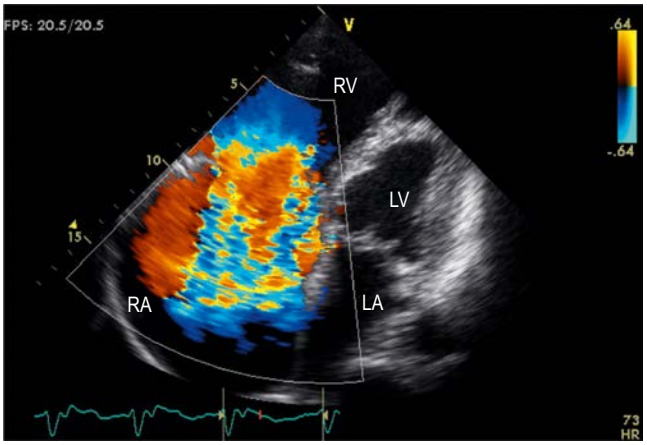

Fig. 17.23 Colour Doppler. Blood is shown flowing away from the echocardiography probe as a blue signal and towards the probe as a red signal. In this patient with tricuspid regurgitation blood leaks from the right ventricle (RV) to the right atrium (RA) during cardiac systole. *LA,* Left atrium; *LV,* left ventricle.

of the order of 1 m/s across the normal aortic valve, but if there is a severe obstructive lesion, such as a severely stenotic aortic valve, velocities of 4 m/s or more can occur. These velocities are generated by the pressure gradient that exists across the lesion.

According to the Bernoulli equation, the pressure difference between two chambers is calculated as: 4 multiplied by the square of the CW Doppler velocity between chambers. Thus a velocity of 5 m/s across the aortic valve suggests a peak gradient of 4 × 5 × 5 = 100 mmHg between the ascending aorta and the left ventricle. This equation has been validated in a wide variety of clinical situations, including valve stenoses, VSDs, and intraventricular obstruction (as in HCM). It is often clinically unnecessary to resort to invasive methods such as cardiac catheterization to measure intracardiac pressure gradients.

Similarly, pulmonary artery (PA) systolic pressure and right ventricular diastolic pressure can be calculated using the Bernoulli equation. In this case CW Doppler tracing of the tricuspid regurgitant jet is used to estimate the pressure gradient between the right ventricle and the right atrium. The pulmonary artery systolic pressure is then calculated by adding the estimated right atrial pressure to the pressure gradient between the right ventricle and the right atrium.

Tissue Doppler is similar to PW Doppler. It measures myocardial tissue velocities within a particular sample volume placed on the image. Such velocities are of the order of 1 cm/s. Currently, tissue Doppler of the mitral annulus is used as part of the estimation of left ventricular filling pressure.

Other ultrasound modalities include harmonic power Doppler, pulse inversion Doppler, and ultra-harmonics, which are used to detect and amplify microsphere-specific signals as part of the echocardiographic assessment of myocardial perfusion.

Transoesophageal echocardiography

In transoesophageal echocardiography (TOE, see **Fig. 17.75**), a transducer mounted on a flexible tube is placed into the oesophagus. This involves the use of local anaesthesia to suppress the gag reflex and, frequently, intravenous sedation. High-resolution images can be obtained because of the close proximity of the heart to the transducer in the oesophagus, and also because of the higher frequencies that are used relative to transthoracic imaging. TOE is most commonly used to assess valve structure and function (to assess for reparability of mitral valve prolapse or suitability of transcatheter repair), the features and complications of IE, and the aorta (for aortic dissection); it is also useful for seeking a cardiac source of embolus.

Stress echocardiography

Echocardiography can be used clinically to evaluate the patient for the presence of myocardial scars and reversible ischaemia. Since ultrasound cannot directly detect red blood cells in capillaries, myocardial wall motion is used as a surrogate for perfusion. Myocardial segments that demonstrate a change in function (defined as a change or reduction in thickening) from rest to stress can be assumed to be supplied by a flow-limiting stenosis in the epicardial artery or graft.

Stress for this indication needs to be inotropic to induce true ischaemia. Physiological stress includes treadmill exercise, which requires rapid image acquisition, at high heart rates as the patient comes off the treadmill, to maintain sensitivity of the test. Alternatively, pharmacological stress can be induced with dobutamine at graded doses. This is relatively safe but complications such as ventricular arrhythmia have been reported. This technique can also assess viability of the myocardium and hibernating or stunned myocardium (see 'Hibernating myocardium and myocardial stunning' section).

Myocardial perfusion 'contrast' echocardiography

In order to assess myocardial perfusion by echocardiography (MPE), microspheres of similar size to red blood cells are used as an intravenous contrast agent. Microsphere-specific ultrasound modes, such as harmonic power Doppler, can be used for detection. Intravenous contrast infusion is employed to fill the myocardium. A pulse of ultrasound then destroys microspheres within the capillaries (and not the left ventricular cavity), and the time taken to replenish the capillaries is a measure of myocardial blood flow. The time taken to fill should be significantly shorter at stress than at rest.

Intravascular coronary ultrasound

Intravascular ultrasound (IVUS) probes can be used to obtain images of proximal coronary arteries as part of a percutaneous transluminal coronary angioplasty (PTCA) procedure, for example, to assess adequacy of deployment of intracoronary stents.

Nuclear imaging

Nuclear imaging is used to detect MI or to measure myocardial function, perfusion, or viability, depending on the radiopharmaceutical agent employed and the imaging technique chosen. These data are particularly valuable when used in combination. All involve a significant radiation dose.

Image type

Gamma cameras produce a planar image in which structures are superimposed, as in a standard X-ray. Nowadays, single-photon emission computed tomography (SPECT) imaging is preferred and uses similar raw data to construct tomographic images, just as a computed tomography (CT) image is reconstructed from X-rays. This gives finer anatomical resolution. These methods may be used with any of the radiopharmaceutical agents.

Myocardial perfusion and viability

Thallium-201 is rapidly taken up by the myocardium, so an image taken immediately after injection reflects the distribution of blood flow to the myocardium. Areas of ischaemia or infarction receive less ^{201}Tl and appear dark. Between 2 and 24 hours after injection, ^{201}Tl is redistributed so that all cardiac myocytes contain a comparable concentration. Images obtained at this time show dark areas where the myocardium has infarcted but normal density in ischaemic areas. Comparison of early and late images is one method of predicting whether an ischaemic area of myocardium contains enough viable tissue to justify coronary bypass or angioplasty. Technetium-99-labelled tetrofosmin (Fig. 17.24) is also taken up rapidly by cardiac myocytes but does not undergo redistribution. When this substance is injected during exercise, its distribution in the myocardium reflects the distribution of blood at the time of the exercise, even if the image is taken several hours later. This is a sensitive method of detecting myocardial viability. Images produced following injection of [^{99m}Tc]tetrofosmin during exercise can be compared to images produced following injection at rest to decide which areas of ischaemia are reversible. In patients unable to exercise the heart can be stressed with drugs, such as dipyridamole or dobutamine.

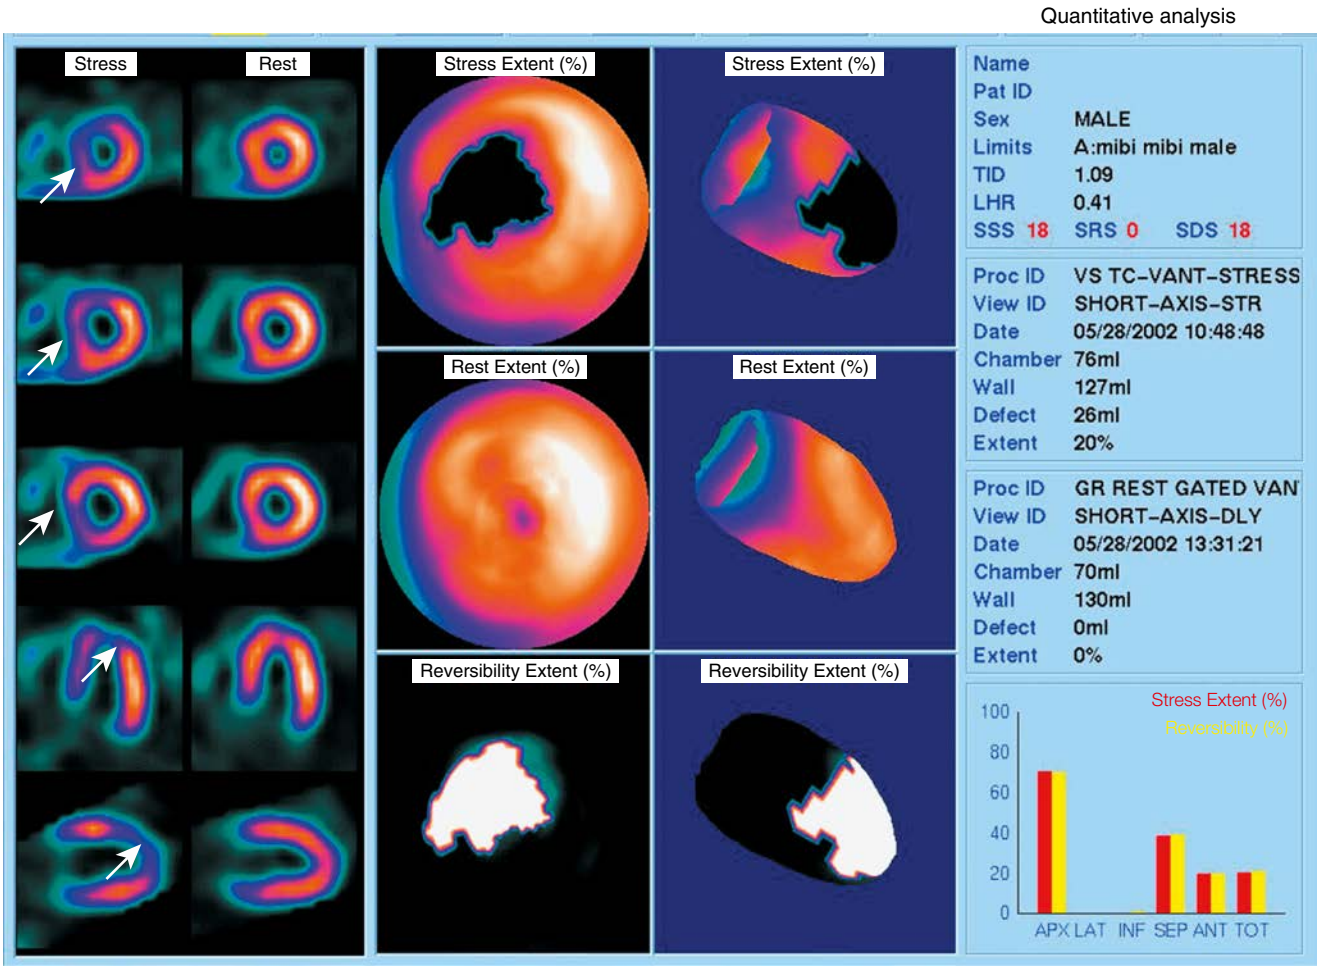

Fig. 17.24 Myocardial single-photon emission computed tomography (SPECT) study acquired with [^{99m}Tc]tetrofosmin tracer. ***Left panel:*** Three short-axis slices and a horizontal and a vertical axis plane of the left ventricle after stress and following a resting re-injection of tracer. The rest images demonstrate normal tracer uptake (orange signal) in the whole of the left ventricle. The stress images demonstrate reduced tracer uptake (*arrows*; purple-blue signal) in the anterior and septal walls, consistent with a significant stenosis in the left anterior descending artery. ***Middle panel:*** Polar maps of the whole myocardium can localize the ischaemic territory. ***Right panel:*** Quantitative analysis can help define the extent and reversibility of the ischaemia.

Infarct imaging

Perfusion images produced using compounds labelled with ^{201}Tl or [^{99m}Tc]sestamibi show a MI as a perfusion defect or 'cold spot'. These methods are sensitive for detecting and localizing the infarct but give no information about its age.

Imaging for amyloid disease

[^{99m}Tc]Pyrophosphate scintigraphy (DPD scan) is now frequently used in the diagnosis of cardiac amyloidosis, in particular transthyretin-type, obviating the need for a cardiac biopsy.

Cardiac computed tomography

CT is useful for assessment of the thoracic aorta and mediastinum. The development of 512-slice multidetector CT (MDCT) scanners has enabled accurate, non-invasive imaging of the coronary arteries.

Coronary artery calcification

Calcium is absent in normal coronary arteries but is present in atherosclerosis and increases with age. Studies have demonstrated a positive correlation between calcification and the presence of coronary artery stenoses, although the relationship is non-linear. MDCT scanners and electron beam CT (EBCT) are used to obtain multiple thin axial slices through the heart, allowing a calcium score to be calculated. The calcium score is based on the X-ray attenuation coefficient or CT number measured in Hounsfield units. Meta-analyses have demonstrated that a higher calcium score is associated with a higher event rate and higher relative risk ratios, although no study to date has shown a net effect on health outcomes of calcium scoring. The calcium score can be used to reclassify intermediate-risk patients to either low-risk or higher-risk. US guidelines support the initiation of statin therapy if the calcium score is more than 100. Guidelines on how to incorporate calcium score in primary prevention do vary between the USA, Europe, the UK, and Australasia.

CT coronary angiography

CT coronary angiography (CTCA) is performed with a supine patient connected to a three-lead ECG for cardiac synchronization. Image quality is optimal with a slow and steady heart rate (<65 b.p.m), which can be obtained with the use of oral or intravenous beta-blockers. Sublingual nitroglycerin (0.4–0.8 mg dose) may improve visualization of the coronary artery lumen. A volume dataset containing the whole heart is acquired during a single breath-hold with the injection of 60 to 80 mL of iodinated contrast agent at 4 to 6 mL/sec. The radiation dose during the scan can consistently be reduced to less than 5 milli-Sieverts (mSv) with ECG-controlled dose modulation; this compares favourably with 2.5 to 5.0 mSv for diagnostic coronary angiography and 15 to 20 mSv for SPECT. The volume dataset is then analyzed with multiplanar reformatting for the presence of coronary artery stenoses (Fig. 17.25). Studies have reported high sensitivity (>85%) and specificity (>90%) for the detection of CAD, with a very high negative predictive value (NPV) (>95%). CTCA has been adopted as an investigation for acute chest pain service in the emergency medicine department to exclude aortic dissection, pulmonary embolism, and CAD.

CT has also established its role in the planning of transcatheter valve procedures and left atrial ablation.

Cardiovascular magnetic resonance

Cardiovascular magnetic resonance (CMR) is a non-invasive imaging technique that does not involve potentially harmful radiation.

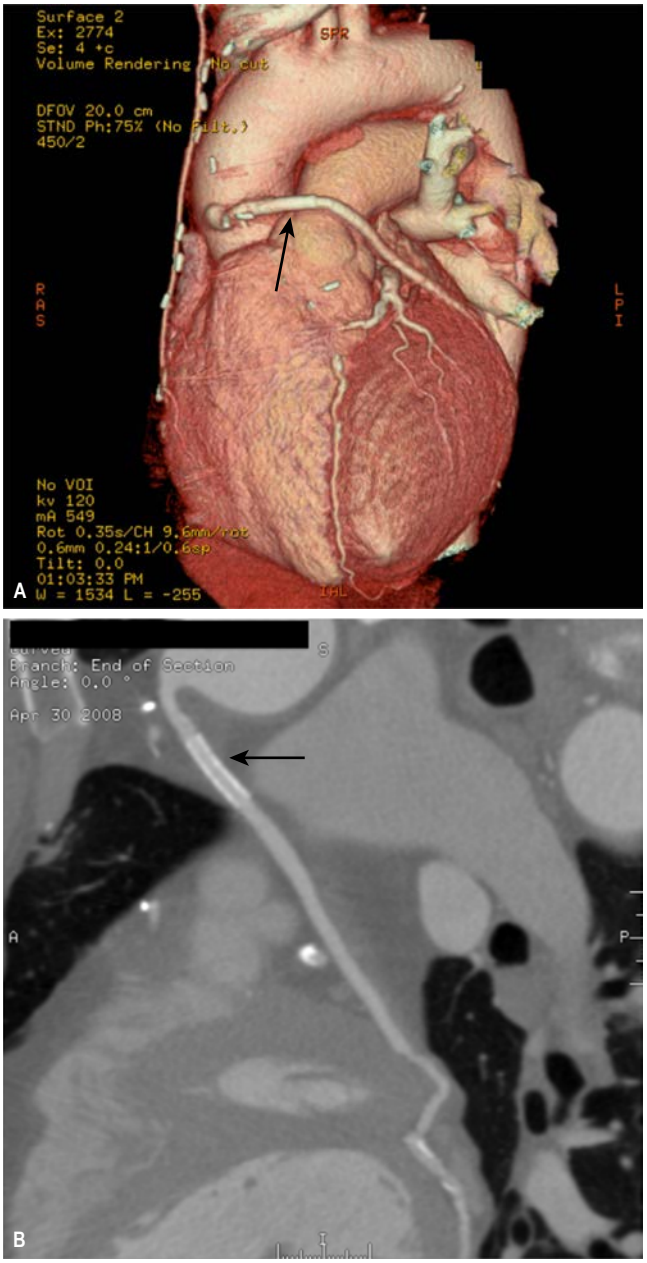

Fig. 17.25 Multislice computed tomography: coronary artery stent. (A) A volume-rendered image in a patient with coronary artery stent insertion *(arrowed)* in a saphenous vein graft to the native circumflex coronary artery. **(B)** The multiplanar reformatted image demonstrates stent patency *(arrowed)* and insertion of the graft to the circumflex coronary artery.

CMR is usually performed with multiple breath-holds to minimize respiratory motion artefacts and cardiac gating to reduce blurring during the cardiac cycle. Several different sequences provide anatomical and functional information. Most sequences do not require a contrast agent but intravenous gadolinium may be needed for magnetic resonance angiography and myocardial perfusion, infarct, and fibrosis imaging. The major contraindications are intracerebral clips, residual metallic fragments (e.g., foreign bodies), and significant claustrophobia. Previously, pacemakers or defibrillators were a strong contraindication to magnetic resonance imaging; however, newer devices are now compatible. Patients with coronary stents and prosthetic valves can be safely scanned.

Clinical use

The current indications for CMR are summarized in Box 17.9 and include:

- ***Congenital heart disease:*** CMR provides additional and complementary information to echocardiography in patients with congenital heart disease. Cine imaging can accurately assess systemic and non-systemic ventricular function and mass. Extracardiac conduits, anomalous pulmonary venous return, and aortic coarctations before and after repair can be studied by CMR and the studies repeated for long-term follow-up without the risk of ionizing radiation.
- ***Cardiomyopathies, pericardial disease, and cardiac masses:*** In HCM, CMR accurately defines the extent and distribution of myocardial hypertrophy and can be used in patients with suboptimal echocardiograms. Intravenous gadolinium can be utilized to demonstrate regional myocardial fibrosis, which is associated with an adverse prognosis. In patients with suspected arrhythmogenic right ventricular cardiomyopathy CMR is the imaging investigation of choice to detect global and regional wall motion abnormalities of the right ventricle and right ventricular outflow tract and to detect fatty or fibro-fatty infiltration of the right and left ventricles. In constrictive pericarditis and restrictive cardiomyopathy (RCM), CMR can demonstrate the effects of the impaired ventricular filling common to both conditions (dilated right atrium and inferior vena cava) and can also determine the thickness of the pericardium (usually 4 mm in normal individuals) (Fig. 17.26). In patients with dilated cardiomyopathy (DCM) CMR can accurately quantify biventricular function and, with gadolinium, can demonstrate myocardial fibrosis. In inflammatory and infiltrative conditions of the myocardium, such as myocarditis, sarcoidosis, and amyloidosis, CMR is increasingly used as a diagnostic investigation due to the different patterns of signal enhancement seen with gadolinium. In patients with thalassaemia CMR can detect iron deposition within the myocardium and guide chelation therapy. CMR can be useful in patients with cardiac masses to differentiate benign from malignant tumours and to identify thrombus not visualized on echocardiography.
- ***Diseases of the aorta:*** CMR is an excellent technique for assessing patients with aortic dissection and can detect the clinical features of an aortic dissection: the intimal flap, thrombosis in a false lumen, aortic regurgitation, pericardial effusion, and aortic dilation. As it does not involve radiation or need contrast, CMR is an ideal method of surveillance of patients with dilated thoracic aortas or repaired coarctation.
- ***Valvular heart disease:*** Valvular stenosis produces signal void on gradient-echo CMR. CMR can quantify the velocity across a stenosed valve using phase-contrast velocity mapping. Valvular regurgitation can be accurately quantified using phase-contrast velocity mapping across the valve, or by calculating the stroke volumes of the left and right ventricles, which are equal in the absence of significant regurgitation. However, in most patients transthoracic and TOE should provide sufficient information.
- ***Coronary artery disease:*** CMR can be used to evaluate coronary artery origin, left ventricular function, myocardial perfusion, and viability in a 'one-stop' approach to the assessment of patients with CAD. Coronary artery origin can be identified with ultra-fast breath-hold or respiratory-gated sequences with high accuracies. Global left ventricular function and wall motion abnormalities can be detected with cine-imaging performed at rest and during dobutamine stress. Myocardial perfusion can be assessed with gadolinium and first-pass imaging; ischaemia can be demonstrated with adenosine for coronary vasodilation. Myocardial viability can be determined using gadolinium and 'delayed enhancement' images. With these techniques, CMR is increasingly used to assess both ischaemia in patients with suspected coronary disease, and myocardial viability prior to revascularization in individuals with impaired cardiac function (Figs. 17.27 and 17.28). The CE-MARC study suggested a higher diagnostic yield for CMR over SPECT in the diagnosis of coronary disease.

Box 17.9 Indications for cardiovascular magnetic resonance (CMR)

- Congenital heart disease (CHD):
  - Anatomical assessment, particularly in patients with complex CHD
  - Follow-up/surveillance studies, particularly post procedures
  - Anomalous pulmonary or systemic venous return
  - Assessment of right or left ventricular function/dilation
- Cardiomyopathies/cardiac infiltration/pericardial disease/myocarditis
  - Disease of the aorta, including aortic dissection, aneurysm, coarctation
  - Valvular heart disease (quantification of stenosis and regurgitation)
  - Cardiac masses (tumours, thrombus, normal structures)
- Coronary artery disease:
  - Ischaemia (wall motion/perfusion assessment)
  - Coronary artery origins
  - Myocardial infarct imaging and viability assessment with delayed enhancement

Positron emission tomography

Positron emission tomography (PET) is based on detection of high-energy emissions caused by annihilation of positrons released from unstable isotopes. PET has several advantages over other techniques, such as improved spatial resolution, accurate quantification,

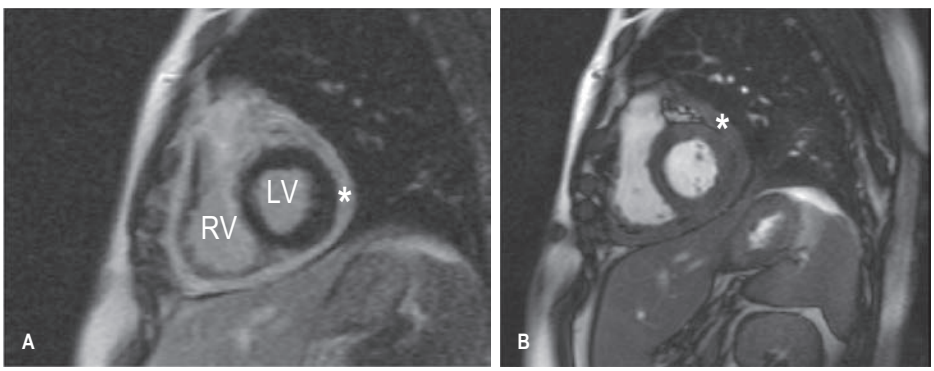

Fig. 17.26 Short-axis cardiac magnetic resonance (CMR) in a patient with constrictive pericarditis. Both images show thickening of the pericardium (*). *LV,* Left ventricle; *RV,* right ventricle.

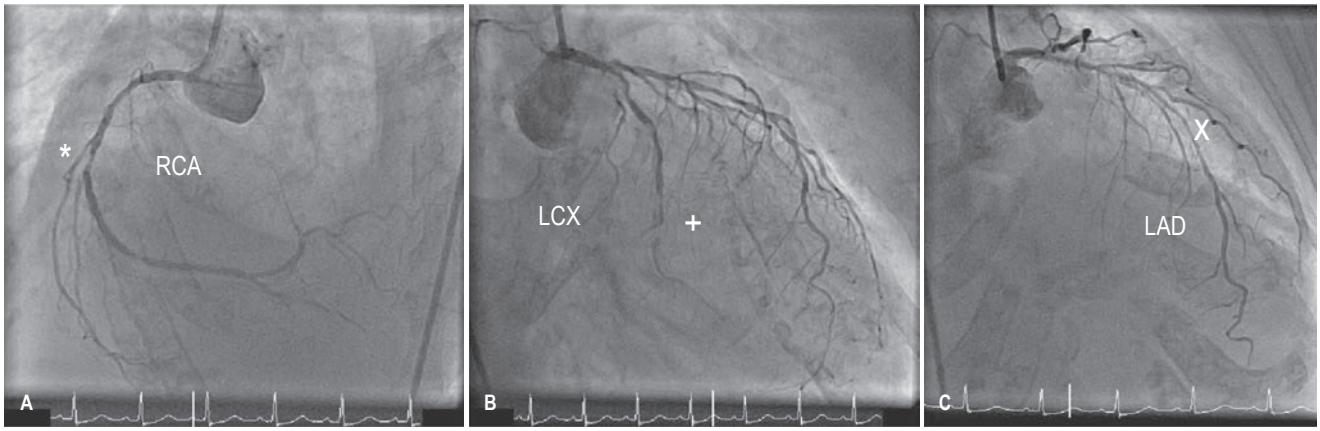

Fig. 17.27 Coronary angiogram (CMR) in a patient with type 2 diabetes mellitus and exertional breathlessness. **(A)** Diagnostic coronary angiography demonstrates a severe stenosis (*) in the right coronary artery (RCA). **(B)** There is a subtotally occluded (+) circumflex coronary artery (LCX). **(C)** A long diseased segment (X) is also seen in the left anterior descending (LAD) coronary artery.

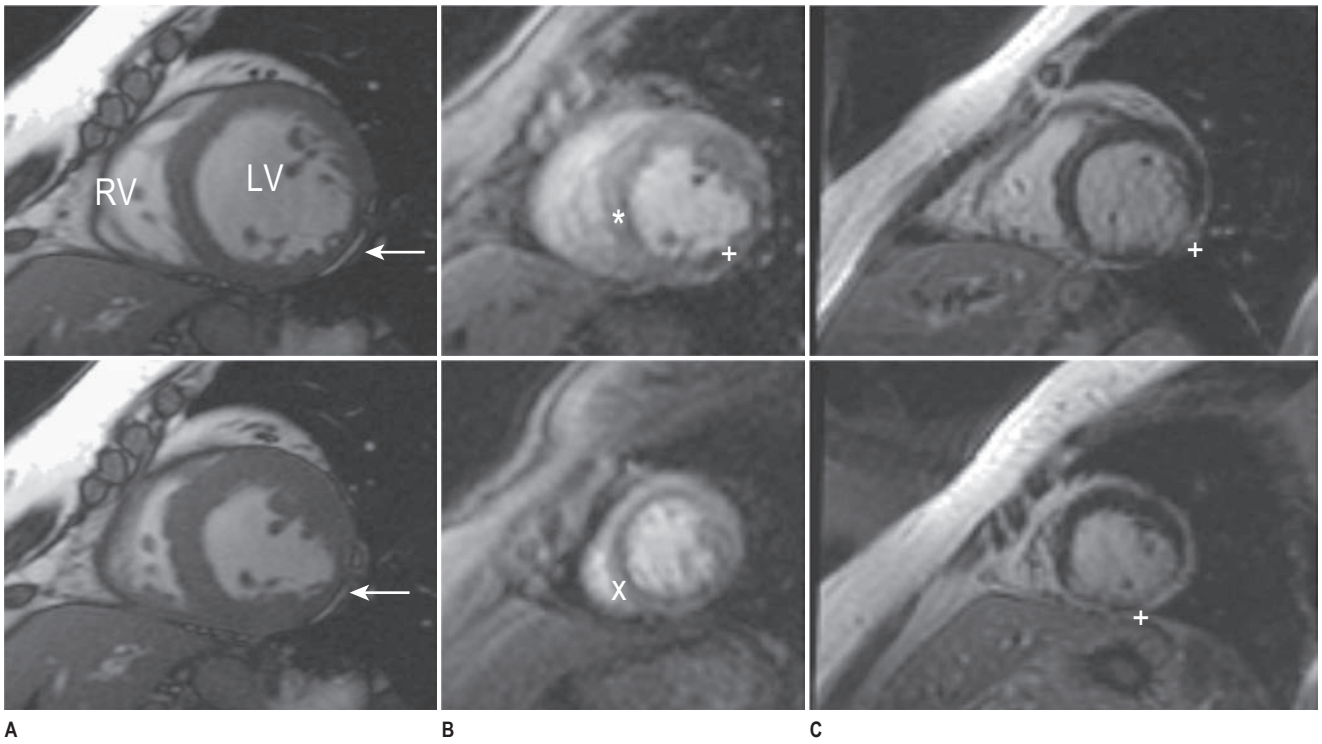

Fig. 17.28 Cardiac magnetic resonance (CMR). **(A)** Short-axis CMR FIESTA cine-imaging (diastole top, systole bottom) demonstrates thinning and hypokinesia of the inferolateral wall *(arrowed)* but preserved function of the rest of the myocardium. *LV,* Left ventricle; *RV,* right ventricle. **(B)** First-pass perfusion CMR (mid-top, apex bottom) demonstrates subendocardial perfusion defects in the inferolateral wall (+), infero-septum (*), and apical segments (X). **(C)** Delayed-enhancement CMR confirms a transmural myocardial infarction of the mid-apical inferolateral wall (+) secondary to a previous infarction from the circumflex coronary artery and demonstrates inducible ischaemia in the right and left coronary territories.

and use of biological isotopes of carbon, nitrogen, and oxygen. However, it is expensive and requires a cyclotron to produce the short-lived tracers. PET/CT has become a useful investigation in the detection of viable myocardium in patients who are suitable for revascularization.

Myocardial perfusion and ischaemia can be determined using PET with ^{13}N-ammonia or ^{15}oxygen with greater sensitivity than SPECT. Myocardial metabolism and viability can be detected with the use of ^{18}F-fluorodeoxyglucose (FDG), which the cardiac myocyte utilizes for energy production in the presence of reduced oxygen supply and blood flow. There may be reduced perfusion to infarcted or fibrotic myocardium, but also reduced FDG uptake. In hibernating myocardium, with viable but dysfunctional myocardium, PET can demonstrate reduced myocardial perfusion but with preserved or increased FDG uptake. FDG PET has a specific role in the diagnosis of active cardiac sarcoidosis and patient evaluation when infection of pacemaker leads or prosthetic valves is thought possible.

Cardiac catheterization

Cardiac catheterization is the introduction of a thin radio-opaque tube (catheter) into the circulation. The right heart is catheterized by introducing the catheter into a peripheral vein (usually the right femoral or internal jugular vein) and advancing it through the right atrium and ventricle into the pulmonary artery. The pressures in the right heart chambers and in the pulmonary artery can be measured directly. An indirect measure of left atrial pressure can be obtained by 'wedging' a balloon-tipped catheter into the distal pulmonary artery (see Fig. 13.13). In this position the pressure from the right ventricle is obstructed by the catheter, and only the pulmonary venous and left atrial pressures are recorded.

Left heart catheterization is usually performed via the right femoral or radial artery. A pigtail catheter is advanced up the aorta and manipulated through the aortic valve into the left ventricle. Pressure tracings are taken from the left ventricular cavity. The end-diastolic pressure is invariably elevated in patients with left ventricular dysfunction. A power injection of radio-opaque contrast material opacifies the left ventricular cavity (left ventriculography) and thereby assesses left ventricular systolic function. The catheter is then withdrawn across the aortic valve into the aorta and the 'pullback' gradient across the valve is measured. Aortography (a power injection into the aortic root) can be performed to assess the aortic root and the presence and severity of aortic regurgitation. Specially designed catheters are then used to engage the left and right coronary arteries selectively, and contrast cine-angiograms are taken in order to define the coronary circulation and identify the presence and severity of any CAD. During the procedure, intracoronary nitrate or adenosine may be used to dilate the coronary arteries. During cardiac catheterization, blood samples may be withdrawn to measure the oxygen content. These estimations are used to quantify intracardiac shunts and measure cardiac output.

If a significant coronary artery stenosis is discovered during a coronary angiogram this can be treated with a stent as an adjunct procedure.

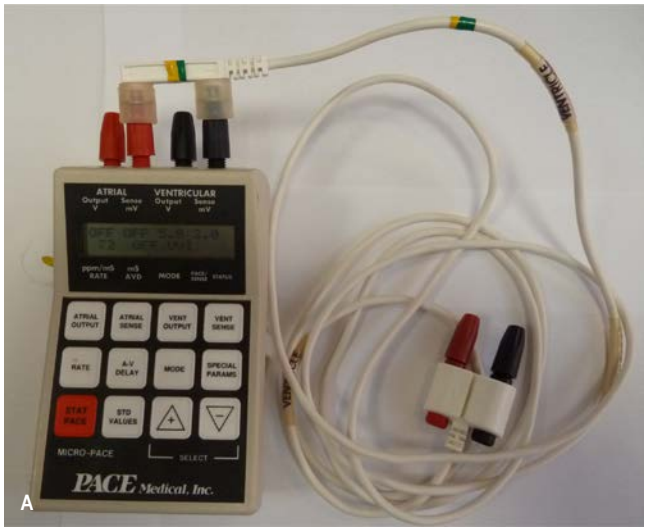

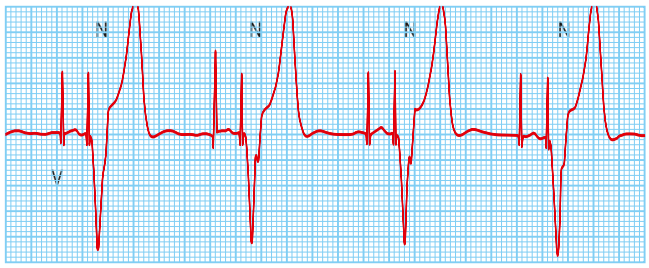

Fig. 17.29 Pacemakers. **(A)** A temporary pacemaker unit. **(B)** A permanent pacemaker with atrial and ventricular leads. **(C)** An electrocardiogram showing dual (atrial and ventricular) chamber pacing. A wide QRS complex results from abnormal activation of the ventricles from the right ventricular apex.

THERAPEUTIC PROCEDURES

Resuscitation, defibrillation, direct current cardioversion, and temporary cardiac pacing are discussed in the Acute Medicine section (see Chapter 11, 'Palpitations' section).

Permanent pacing

Permanent pacemakers are fully implanted in the body and connected to the heart by one or three electrode leads (Fig. 17.29B). The pacemaker is powered by solid-state lithium batteries, which usually last 5 to 10 years. Pacemakers are 'programmable', in that their operating characteristics (e.g., the pacing rate) can be changed by a programmer that transmits specific electromagnetic signals through the skin. The pacemaker leads are passed transvenously to the right heart chambers. Leadless pacemakers have been developed and can be considered in patients without upper extremity venous access or at high risk of device infection (Fig. 17.30). They are implanted via the femoral vein. The uptake of this technology is limited due to cost, single chamber pacing only, and the need to abandon existing device in the right ventricle at the time of battery expiration.

Implantation

Permanent pacemakers are inserted under local anaesthetic using fluoroscopy to guide the insertion of the electrode leads via the cephalic, axillary, or subclavian vein. Perioperative prophylactic antibiotics are routinely prescribed. The pacemaker is usually positioned subcutaneously on top of the pectoral muscle. Following surgery, which usually takes 60 to 90 minutes, the patient rests in bed for 6 to 12 hours before being discharged. Patients may not drive for at least 1 week after implantation and must inform the licensing authorities and their motor insurers.

Complications are rare and can be challenging to manage. Patients with these devices should be periodically reviewed in a pacemaker clinic. Complications include the following:

- Early: Pneumothorax, tamponade, lead displacement, haematoma, infection
- Late: Infection, erosion, lead failure, battery depletion.

Types of pacemaker

Pacemakers are designed both to pace and to sense either the ventricles, the atria, or, more commonly, both chambers. A single-chamber ventricular pacemaker is described as a 'VVI' unit because it paces the ventricle (V), senses the ventricle (V), and is inhibited (I) by a spontaneous ventricular signal. Occasionally (e.g., in symptomatic sinus bradycardia), an atrial pacemaker (AAI) may be implanted. Pacemakers that are connected to both the right atrium and ventricle ('dual-chamber' pacemakers) are used to simulate the natural pacemaker and activation sequence of the heart. This form of pacemaker is called DDD because it paces the two (dual) chambers, senses both (D), and reacts in two (D) ways: pacing in the same chamber is inhibited by spontaneous atrial and ventricular signals, and ventricular pacing is triggered by spontaneous atrial events (Fig. 17.29C).

In addition, pacemakers may be 'rate-responsive' (R). A rate-responsive pacemaker detects motion (level of vibration or acceleration), respiration, or changes in QT interval; by employing one or more biosensors, it changes its rate of pacing so that it is appropriate to the level of exertion.

The choice of pacemaker mostly depends on the underlying rhythm abnormality and the general condition of the patient. For example, complete heart block in patients with sinus rhythm should be treated with a dual-chamber device in order to maintain AV synchrony, whereas inactive or infirm patients may not benefit from the most sophisticated units.

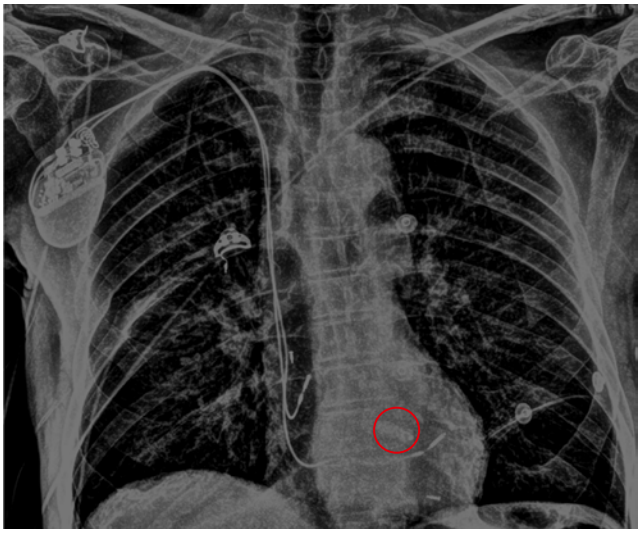

Fig. 17.30 Leadless pacemaker. Chest radiograph showing a right-sided dual chamber pacemaker. The *red circle* shows a leadless pacemaker implanted into the right ventricle that, in this case, was implanted as the transvenous pacemaker has failed leads and the superior vena cava was occluded.

Cardiac resynchronization therapy

In patients with heart failure and, in particular, left bundle branch block (LBBB) another ventricular lead may be implanted via the coronary sinus to the epicardial surface of the left ventricle. More recently, conduction system pacing has become vogue, whereby a lead is torqued deeper into the RV septum such that the electrode can directly capture a branch of the left bundle, thereby effecting a narrower paced QRS on ECG and a more synchronized ventricular activation pattern compared to standard RV endocardial pacing (Fig. 17.31). The longer-term implications of pacing using this technique are currently under evaluation.

Implantable cardiac defibrillators

An implantable cardioverter–defibrillator (ICD) may be considered in a survivor of a ventricular fibrillation or ventricular tachycardia arrest, or as a primary prevention device to abort sudden cardiac death in patients at high risk of developing ventricular arrhythmia (see 'Implantable cardioverter–defibrillator' section).

Pericardiocentesis

A pericardial effusion is an accumulation of fluid between the parietal and visceral layers of pericardium. Fluid is removed for relief of symptoms that are due to haemodynamic embarrassment, or for diagnostic purposes. This can be a technically difficult procedure,

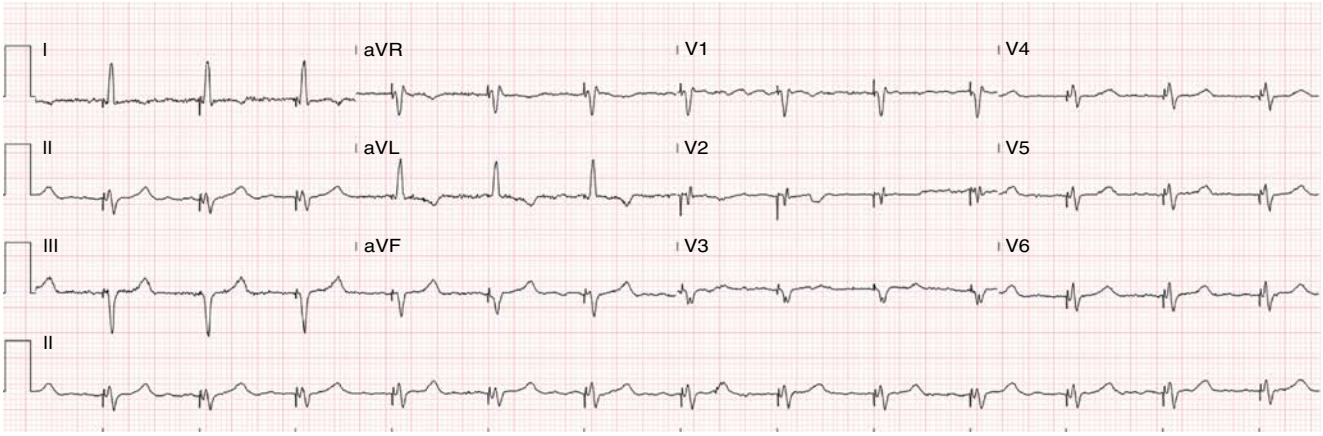

Fig. 17.31 An ECG showing atrial fibrillation and a 'narrower' or more physiologic ventricular paced complex. The pacing lead is capturing the conduction system of the heart.

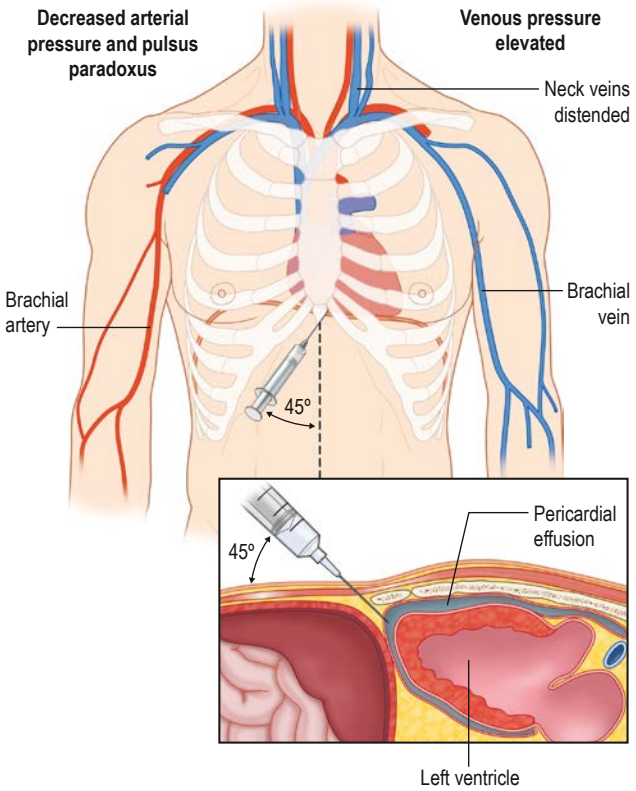

Fig. 17.32 Pericardiocentesis.

particularly in the acute setting, and should be performed in a cardiac laboratory. In an emergency it can be performed at the bedside.

Pericardial aspiration or pericardiocentesis (Fig. 17.32) is performed by inserting a needle into the pericardial space, usually via a subxiphisternal route, under ultrasound guidance. Certain effusions, particularly posterior ones, require surgical drainage under a general anaesthetic. If a large volume of fluid is to be removed, a wide-bore needle and cannula are inserted. The needle may be removed and the cannula left *in situ* to drain the fluid. Fluid that is removed is sent for chemical analysis, microscopy, including cytology, Gram stain, and culture. If reaccumulation of pericardial fluid is anticipated, the cannula may be left in place for several days, or an operation can be performed to cut a window in the parietal pericardium (fenestration) or to remove a large section of the pericardium.

Temporary mechanical cardiac support

Patients with cardiogenic shock have an inpatient mortality of 50%. Definitions of shock vary but include persistent hypotension (systolic blood pressure ≤90 mmHg), with elevated filling pressures, reduced cardiac output, and evidence of end-organ hypoperfusion. Temporary mechanical support should not be used when there is no remediable cause of cardiac dysfunction. It is also unsuitable in patients with moderate or severe aortic regurgitation, aortic dissection, and severe peripheral vascular disease.

Techniques used to provide temporary mechanical cardiac support in the cardiac-intensive care unit setting include:

- ***Miniature cardiac pumps.*** The Impella® device is a miniaturized axial flow device that is delivered across the aortic valve usually from the femoral artery and drives blood from the left ventricle to the aorta. Flow rates of up to 5 L/min can be achieved while the heart is revascularized and recovers from an acute event (see Fig. 17.33). It cannot be used if there is left ventricle thrombus.
- ***Extracorporeal membrane oxygenation (ECMO)*** provides biventricular support in the veno-arterial configuration. Blood is removed from a large (>15 Fr), usually femoral, venous cannula via an external centrifugal pump and, after oxygenation, is returned via a large femoral arterial cannula capable of delivering flows of 4 to 6 L/min. Physiologically, ECMO increases afterload and increases LV end-diastolic pressure and can potentiate pulmonary oedema.
- ***Intra-aortic balloon pumping*** is now infrequently used to assist the failing left ventricle. A catheter with a long, sausage-shaped balloon at its tip is introduced percutaneously into the femoral artery and manipulated under X-ray control so that the balloon lies in the descending aorta just below the aortic arch (Fig. 17.34). The balloon is rhythmically deflated and inflated with carbon dioxide gas. Using the ECG or intra-aortic pressure changes, the inflation is timed to occur during ventricular diastole to increase diastolic aortic pressure and, consequently, to improve coronary and cerebral blood flow. During systole the balloon is deflated, resulting in a reduction in the resistance to left ventricular emptying. Complications occur in about 20% of patients and include aortic dissection, leg ischaemia, emboli from the balloon, and balloon rupture. Embolic complications are reduced by anticoagulation with heparin.

Fig. 17.33 Chest radiograph showing an Impella cardiac pump. The pump propels blood from an entry point near the tip of the left ventricle across the aortic valve and into the aorta.

CARDIAC ARRHYTHMIAS

An abnormality of the cardiac rhythm is called a cardiac arrhythmia. Arrhythmias may cause sudden death, syncope, heart failure, chest pain, dizziness, palpitations, or no symptoms at all. There are two main types of arrhythmia:

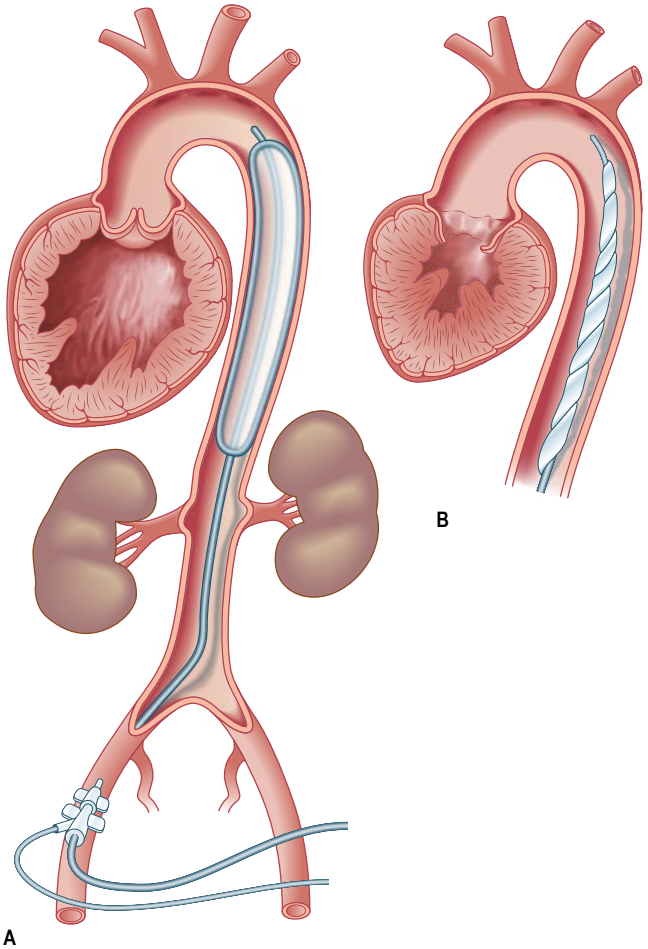

Fig. 17.34 Intra-aortic balloon pump. **(A)** The pump is inflated in the aorta during diastole. **(B)** The balloon is deflated during systole.

- ***Bradycardia:*** the heart rate is slow (<60 b.p.m during the day or <50 b.p.m at night).
- ***Tachycardia:*** the heart rate is fast (>100 b.p.m).

Tachycardias are more symptomatic when the arrhythmia is fast and sustained. Tachycardias are subdivided into ***supraventricular tachycardias (SVTs)***, which arise from the atrium or the AV junction, and ***ventricular tachycardias***, which arise from the ventricles.

Some arrhythmias occur in patients with apparently normal hearts; in others arrhythmias originate from diseased tissue, such as scar, as a result of underlying structural heart disease. When myocardial function is poor, arrhythmias are more symptomatic and are potentially life-threatening.

Sinus node function

The biological cardiac pacemaker is the sinus node (see 'Sinus node [sinoatrial node]' section), and, like most cardiac tissue, it depolarizes spontaneously.

The rate of sinus node discharge is modulated by the autonomic nervous system. Normally, the parasympathetic system predominates, resulting in slowing of the spontaneous discharge rate from approximately 100 to 70 b.p.m. A reduction of parasympathetic tone or an increase in sympathetic stimulation leads to tachycardia; conversely, increased parasympathetic tone or decreased sympathetic stimulation produces bradycardia. The sinus rate in women is slightly faster than in men. Normal sinus rhythm is characterized by P waves that are upright in leads I and II of the ECG (see Fig. 17.16) but inverted in lead AVR.

Sinus arrhythmia

Fluctuations of autonomic tone result in phasic changes of the sinus discharge rate. During inspiration, parasympathetic tone falls and the heart rate quickens; on expiration, the heart rate falls. This variation is normal, particularly in children and young adults. Typically, sinus arrhythmia results in predictable irregularities of the pulse.

Sinus bradycardia

A sinus rate of less than 60 b.p.m (European guidelines) or less than 50 b.p.m (US guidelines) is known as sinus bradycardia. It is usually asymptomatic unless the rate is very slow. Sinus bradycardia is normal in athletes owing to increased vagal tone. Other causes may be divided into systemic or cardiac and are discussed in the 'Bradycardia' section.

Sinus tachycardia

Sinus rate acceleration to more than 100 b.p.m is known as sinus tachycardia. Again, causes may be divided into systemic or cardiac and are discussed in the 'Inappropriate sinus tachycardia' section.

Mechanisms of arrhythmia production

Abnormalities of automaticity, which could arise from a single cell, and abnormalities of conduction, which require abnormal interaction between cells, account for both bradycardia and tachycardia. Sinus bradycardia is a result of abnormally slow automaticity, while bradycardia due to AV block is caused by abnormal conduction within the AV node or the intraventricular conduction system. The mechanisms generating tachycardia are shown in Fig. 17.13.

Accelerated automaticity

The normal mechanism of spontaneous cardiac rhythmicity is slow depolarization of the transmembrane voltage during diastole until the threshold potential is reached and the action potential of the pacemaker cells takes off. This mechanism may be accelerated by increasing the rate of diastolic depolarization or changing the threshold potential (Fig. 17.13A). For example, sympathetic stimulation releases adrenaline (epinephrine), which enhances automaticity. Such changes are thought to produce sinus tachycardia, escape rhythms, and accelerated AV nodal (junctional) rhythms.

Triggered activity

Myocardial damage can result in oscillations of the transmembrane potential at the end of the action potential. These oscillations, called 'after-depolarizations', may reach threshold potential and produce an arrhythmia. If they occur before the transmembrane potential reaches its threshold (at the end of phase 3 of the action potential), they are called 'early after-depolarizations' (E in Fig. 17.13B). When they develop after the transmembrane potential is completed, they are called 'delayed after-depolarizations' (D in Fig. 17.13B).

The abnormal oscillations can be exaggerated by pacing, catecholamines, electrolyte disturbances, hypoxia, acidosis, and some medications, which may then trigger an arrhythmia. The atrial tachycardias produced by digoxin toxicity are due to triggered activity. The initiation of ventricular arrhythmia in the long QT syndrome (see 'Long QT syndrome' section) may be caused by this mechanism.

Re-entry (or circus movements)

The mechanism of re-entry (Fig. 17.13C) occurs when a 'ring' of cardiac tissue surrounds an inexcitable core (e.g., in a region of scarred

myocardium). Tachycardia is initiated if an ectopic beat finds one limb refractory (α), resulting in unidirectional block and the other limb excitable. Provided conduction through the excitable limb (β) is slow enough, the other limb (α) will have recovered and will allow retrograde activation to complete the re-entry loop. If the time to conduct around the ring is longer than the recovery times (refractory periods) of the tissue within the ring, circus movement will be maintained, producing a run of tachycardia. The majority of regular paroxysmal tachycardias are produced by this mechanism.

BRADYCARDIAS AND HEART BLOCK

Bradycardias may be due to failure of impulse formation (sinus bradycardia) or failure of impulse conduction from the atria to the ventricles (AV block).

Bradycardia

Sinus bradycardia

Sinus bradycardia is due either to extrinsic factors that influence a relatively normal sinus node or to intrinsic sinus node disease. The mechanism can be acute and reversible, or chronic and degenerative.

Common ***extrinsic causes*** of sinus bradycardia include:

- hypothermia, hypothyroidism, cholestatic jaundice, and raised intracranial pressure
- drug therapy including beta-blockers, digitalis, non-dihydropyridine calcium-channel blockers
- neurally mediated syndromes (see next section).

Common ***intrinsic causes*** include:

- acute ischaemia and infarction of the sinus node (as a complication of acute MI)
- chronic degenerative changes, such as fibrosis of the atrium and sinus node (sick sinus syndrome).

Sick sinus syndrome or ***sinoatrial disease*** is usually caused by idiopathic fibrosis of the sinus node. Other causes of fibrosis, such as ischaemic heart disease, cardiomyopathy, or myocarditis, can also cause the syndrome. Patients develop episodes of sinus bradycardia or sinus arrest (Fig. 17.35B) and commonly experience paroxysmal atrial tachyarrhythmias (tachy-brady syndrome) owing to diffuse atrial disease.

Neurally mediated syndromes

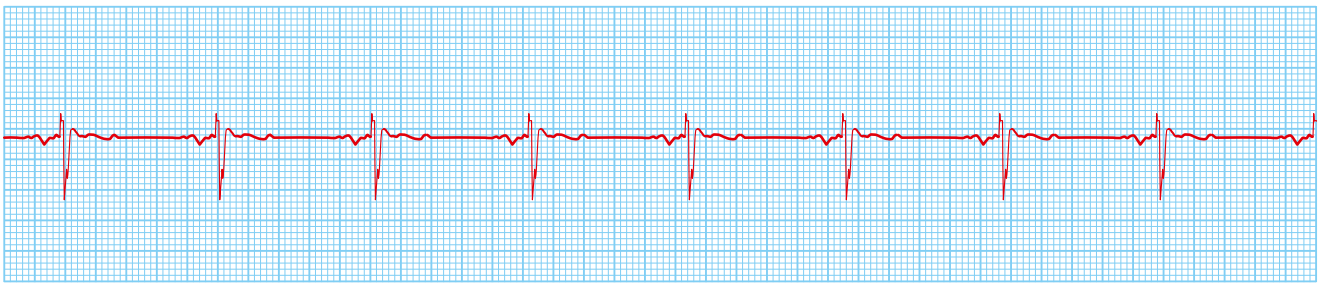
Neurally mediated syndromes are due to a reflex (Bezold–Jarisch) that may result in bradycardia (sinus bradycardia, sinus arrest, and AV block), hypotension, and peripheral vasodilation. These syndromes usually present as syncope or pre-syncope (dizzy spells).

- ***Carotid sinus syndrome*** occurs in the elderly and mainly leads to bradycardia.
- ***Neurocardiogenic (vasovagal) syncope*** usually presents in young adults but may present for the first time in elderly patients. It results from a variety of situations (physical and emotional) that affect the autonomic nervous system. The efferent output may be predominantly bradycardic, predominantly vasodilatory, or mixed.

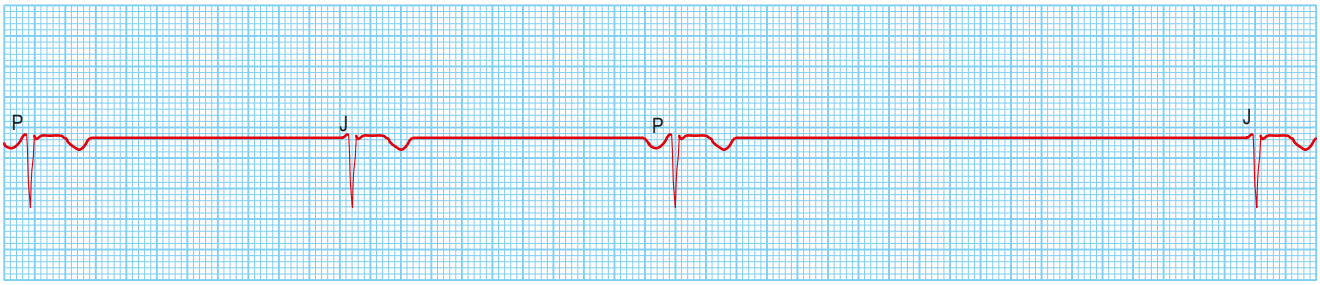
Many medications, such as antihypertensives, tricyclic antidepressants, and neuroleptics, can be the cause of syncope, particularly in the elderly. Careful dose titration and avoidance of combination of two agents with the potential to cause syncope help to prevent iatrogenic syncope.

Management

The management of sinus bradycardia is first to identify and then, if possible, remove any extrinsic causes. Temporary pacing may be employed in patients with reversible causes until a normal sinus rate is restored, and in individuals with chronic degenerative conditions until a permanent pacemaker is implanted.



A



B

Fig. 17.35 Sinus node. **(A)** An ECG showing normal sinus rhythm (PR interval <0.2 sec). A P wave precedes each QRS complex. **(B)** A patient with sick sinus syndrome. The ECG shows sinus arrest (only occasional sinus P waves) and junctional escape beats (J). P waves are inverted in the cavity leads shown.

Chronic symptomatic sick sinus syndrome may require permanent dual chamber pacing (DDD). In patients afflicted by both tachycardias and bradycardias (tachy-brady syndrome), a pacemaker can allow the safe introduction of antiarrhythmic drugs (or ablation therapy) to manage the tachycardic element.

Patients with carotid sinus hypersensitivity (who experience asystole >3 sec), especially if symptoms are reproduced by carotid sinus massage, may also benefit from pacemaker implantation.

Treatment options in vasovagal attacks include avoidance, if possible, of situations known to cause syncope in a particular patient and sitting/lying down and applying counter-pressure manoeuvres (pushing the palms together or crossing the legs) if an attack threatens. Increased salt intake, compression of the lower legs with compression stockings, and drugs such as beta-blockers, alpha-agonists (e.g., midodrine), or myocardial negative inotropes (e.g., disopyramide) may be helpful.

In selected patients, particularly those older than 40 years of age, with symptomatic neurocardiogenic syncope, permanent pacemaker therapy with a dual-chamber pacemaker is helpful. Some devices have features that can help in neurocardiogenic syncope, such as 'rate drop response', which, once activated, paces the heart at a fast rate for a set period of time in order to prevent syncope, or 'closed loop stimulation', which is a proprietary algorithm that increases pacing rate if a reduction in estimated right ventricle contractility is sensed.

Heart block

Heart block or conduction block may occur at any level in the conducting system. Block in either the AV node or the His bundle results in AV block; block lower in the conduction system produces a bundle branch block pattern on ECG.

Atrioventricular block

There are three forms.

First-degree AV block

This is simple prolongation of the PR interval to more than 0.20 seconds. Every atrial depolarization is followed by conduction to the ventricles but with delay (Fig. 17.36).

Second-degree AV block

This occurs when some P waves conduct and others do not. There are several forms (Fig. 17.37):

- ***Mobitz I block*** (Wenckebach block phenomenon) is progressive PR interval prolongation until a P wave fails to conduct. The PR interval before the blocked P wave is much longer than the PR interval after the blocked P wave.
- ***Mobitz II block*** occurs when a dropped QRS complex is not preceded by progressive PR interval prolongation. Usually, the QRS complex is wide (>0.12 sec).
- ***2:1 AV block*** occurs when every second P wave conducts to the ventricles. This form of second-degree block is neither Mobitz I nor Mobitz II.

Advanced or high-degree AV block occurs when only every third P wave (or higher ratio) conducts to the ventricles. ***Wenckebach AV block***, in general, is due to block in the AV node, whereas Mobitz II block signifies block at an infranodal level, such as the His bundle. The risk of progression to complete heart block is greater and reliability of the resultant escape rhythm is less with Mobitz II block. Therefore pacing is usually indicated urgently in Mobitz II block, whereas patients with Wenckebach AV block are usually monitored.

Acute MI may produce ***second-degree, 2:1***, or ***higher-degree heart block***. In inferior MI close monitoring and transvenous temporary backup pacing are all that is required. In anterior MI second-degree heart block is associated with a high risk of progression to complete heart block, and permanent pacemaker implantation is usually indicated. If cardiac function is severely depressed, biventricular pacing may be employed (see 'Cardiac resynchronization therapy or implantable cardioverter–defibrillator' section).

Third-degree (complete) AV block

Complete heart block occurs when all atrial activity fails to conduct to the ventricles (Fig. 17.38). In patients with complete heart block the aetiology needs to be established (Box 17.10). In this situation life is maintained by a spontaneous escape rhythm.

A narrow-complex escape rhythm (<0.12 sec QRS complex) originates from the His bundle and therefore implies that the region of block lies more proximally in the AV node. The escape rhythm occurs with an adequate rate (50–60 b.p.m.) and is relatively reliable. Treatment depends on the aetiology. Recent-onset,

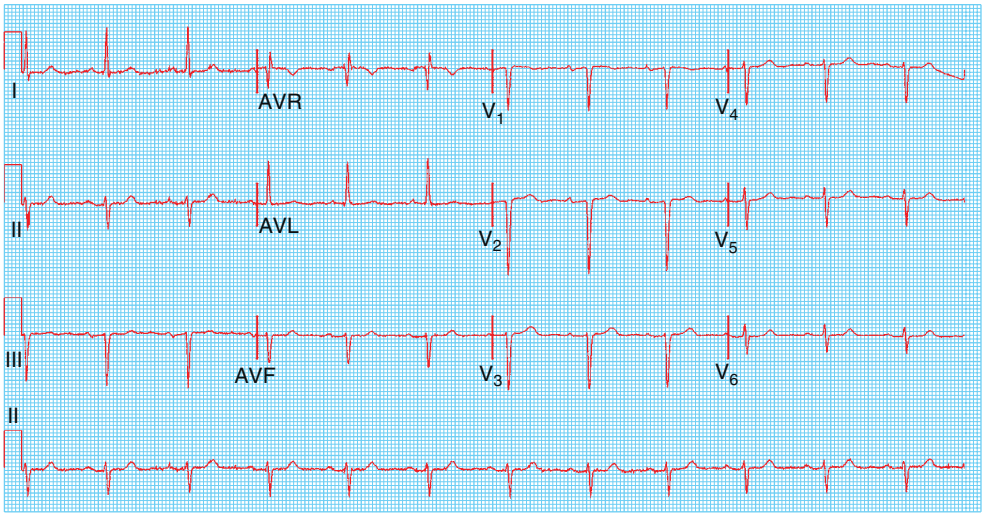


Fig. 17.36 **An ECG showing first-degree atrioventricular block with a prolonged PR interval.**

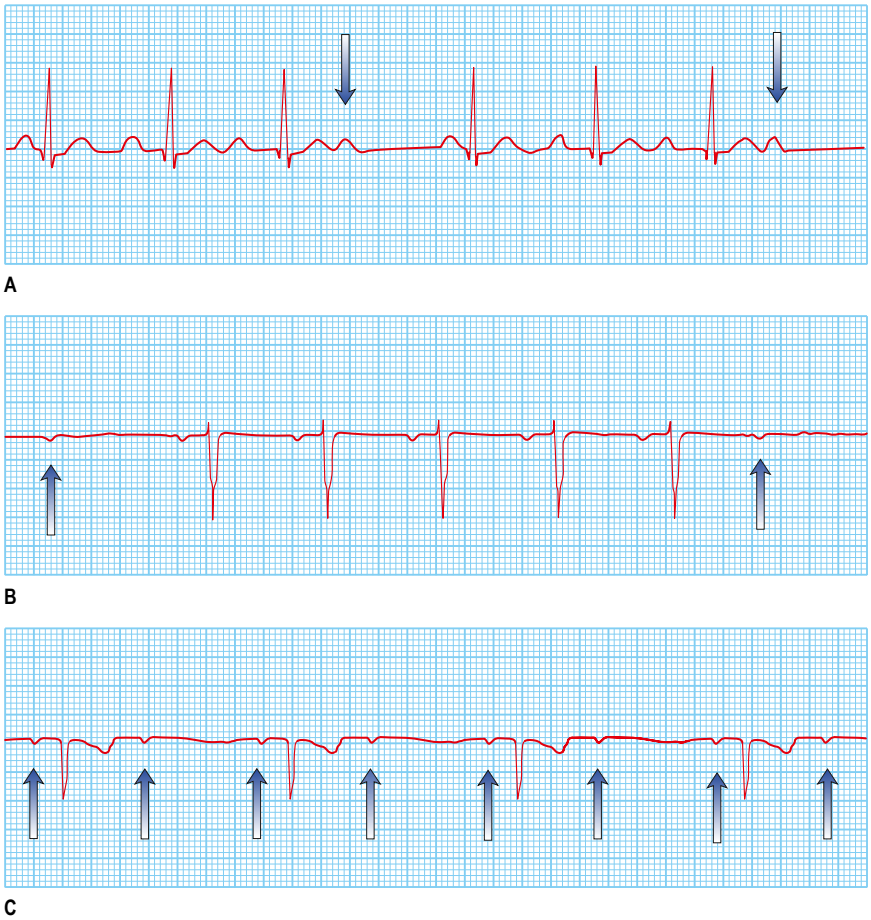

Fig. 17.37 Three varieties of second-degree atrioventricular (AV) block. **(A)** Wenckebach (Mobitz type I) AV block. The PR interval gradually prolongs until the P wave does not conduct to the ventricles *(arrowed)*. **(B)** Mobitz type II AV block. The P waves that do not conduct to the ventricles *(arrowed)* are not preceded by gradual PR interval prolongation. **(C)** Two P waves to each QRS complex. The PR interval prior to the dropped P wave is always the same. It is not possible to define this type of AV block as type I or type II Mobitz block, and it is therefore a third variety of second-degree AV block (*arrows* show P waves).

narrow-complex AV block that has transient causes may respond to intravenous atropine, but temporary pacing facilities should be available for the management of these patients. Chronic narrow-complex AV block requires permanent pacing (dual-chamber; see 'Permanent pacing' section) if it is symptomatic or associated with heart disease. Pacing can be considered in isolated, congenital AV block, even if asymptomatic.

Broad-complex escape rhythm (>0.12 sec) implies that the escape rhythm originates below the His bundle and therefore that the region of block lies more distally in the His–Purkinje system. The resulting rhythm is slow (15–40 b.p.m.) and relatively unreliable. Dizziness and blackouts ***(Stokes–Adams attacks)*** often occur. It is usually caused by degenerative fibrosis and calcification of the distal conduction system ***(Lenegre–Lev's disease)***. Broad-complex AV block may also be caused by ischaemic heart disease, myocarditis, cardiomyopathy, or genetic mutations. Permanent pacemaker implantation (see 'Permanent pacing' section) is indicated, as pacing considerably reduces the mortality. An ICD (see 'Implantable cardioverter–defibrillator' section) may be indicated in those at higher risk of ventricular arrhythmia, such as with severe left ventricular dysfunction or pathogenic gene mutations.

Bundle branch block

The His bundle gives rise to the right and left bundle branches. The left bundle subdivides into the anterior and posterior divisions of the left bundle (though it is debated whether anatomically there are two discrete divisions or just arborisation of the system). Various conduction disturbances can occur.

Bundle branch conduction delay

This produces slight widening of the QRS complex (up to 0.12 sec). It is known as incomplete bundle branch block.

Complete block of a bundle branch

This is associated with a wider QRS complex (≥0.12 sec). The shape of the QRS depends on whether the right or the left bundle is blocked.

Right bundle branch block (Fig. 17.39A) produces late activation of the right ventricle. This is seen as deep S waves in leads I and V_6 and as a tall late R wave in lead V_1 (late activation moving towards right-sided leads and away from left-sided leads).

LBBB (Fig. 17.40) produces the opposite: a deep S wave in lead V_1 and a tall late R wave in leads I and V_6. Because left bundle branch conduction is normally responsible for the initial ventricular activation, LBBB also produces abnormal Q waves.

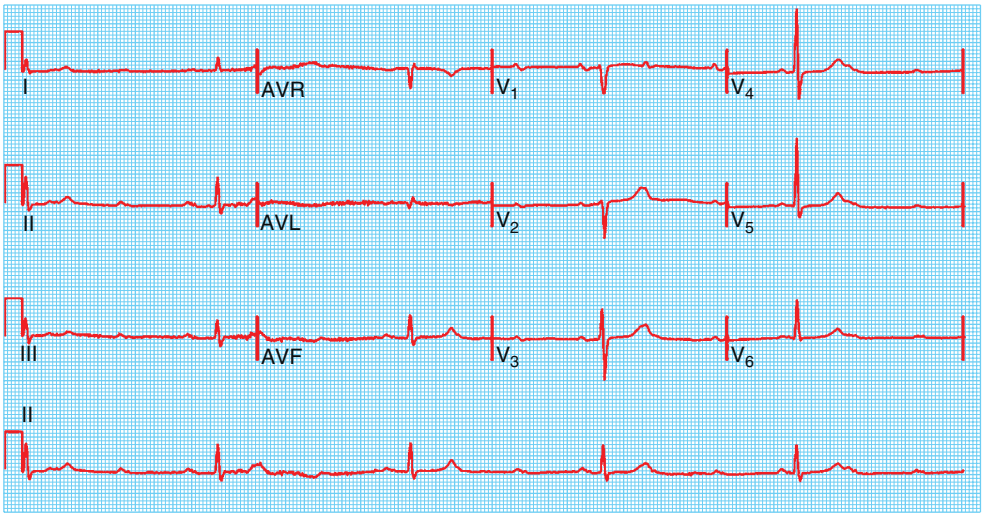

Fig. 17.38 Complete heart block. In this example, the QRS complexes are narrow (0.08 sec) and there is complete dissociation of atrial and ventricular complexes.

? Box 17.10 Causes of complete heart block

Congenital
- Autoimmune (e.g., maternal SLE)
- Structural heart disease (e.g., transposition of great vessels)

Idiopathic fibrosis
- Lev's disease (progressive fibrosis of distal His–Purkinje system in elderly patients)
- Lenegre's disease (proximal His–Purkinje fibrosis in younger patients)

Ischaemic heart disease
- Acute myocardial infarct
- Ischaemic cardiomyopathy

Non-ischaemic heart disease
- Calcific aortic stenosis
- Idiopathic dilated cardiomyopathy
- Infiltrations (e.g., amyloidosis, sarcoidosis, neoplasia)

Cardiac surgery
- For example, following aortic valve replacement, CABG, VSD repair

Iatrogenic
- Radiofrequency AV node ablation and pacemaker implantation

Drug-induced
- e.g., Digoxin, beta-blockers, non-dihydropyridine calcium-channel blockers, amiodarone

Infections
- Endocarditis
- Lyme disease
- Chagas' disease

Autoimmune rheumatic disease
- For example, SLE, rheumatoid arthritis

Neuromuscular diseases
- For example, Duchenne muscular dystrophy

Hemiblock

Delay or block in the divisions of the left bundle branch produces a swing in the direction of depolarization (electrical axis) of the heart. When the anterior division is blocked (left anterior hemiblock), the left ventricle is activated from inferior to superior. This produces a superior and leftward movement of the axis (left axis deviation). Delay or block in the postero-inferior division swings the QRS axis inferiorly to the right (right axis deviation).

Bifascicular block

Bifascicular block (see Fig. 17.39B) is a combination of a block of any two of the following: the right bundle branch, the left antero-superior division, and the left postero-inferior division. Block of the remaining fascicle will result in complete AV block.

Trifascicular block

This term is commonly and incorrectly used when there is a combination of bifasicular block and first-degree block (prolongation of the PR interval). The correct definition of this term is when all three fascicles are blocked, resulting in complete heart block with right bundle branch block and either left anterior fascicular block or left posterior fascicular block. Trifasicular block is also present where there is alternating left and right bundle branch block. The rate of progression to complete heart block in a patient with bifasicular and bifasciular block with prolonged PR interval are similar at 1%/year.

Clinical features of heart blocks

Bundle branch blocks are usually asymptomatic. Right bundle branch block causes wide but physiological splitting of the second heart sound. LBBB may cause reverse splitting of the second sound. Patients with intraventricular conduction disturbances may complain of syncope. This is due to intermittent complete heart block or ventricular tachyarrhythmias. ECG monitoring (which can include implantable loop monitors) and electrophysiological studies can determine the cause of syncope in these patients.

Aetiology

Right bundle branch block occurs as an isolated congenital anomaly, present in 5% of healthy individuals, or is associated with cardiac or pulmonary conditions. Conditions commonly associated with right bundle branch block include congenital cardiac disorders, such as atrial and ventricular septal defects, pulmonary stenosis and Fallot's tetralogy, pulmonary embolism, pulmonary hypertension, MI, fibrosis of conduction tissue, and Chagas' disease. Block in the right bundle alone does not tend to alter the electrical axis of the heart unless accompanied by right ventricular hypertrophy (RV overload) or coexistent fascicular block. The combination of right bundle branch block with left axis deviation is seen in patients with ostium primum atrial septal defects but more often signifies diffuse

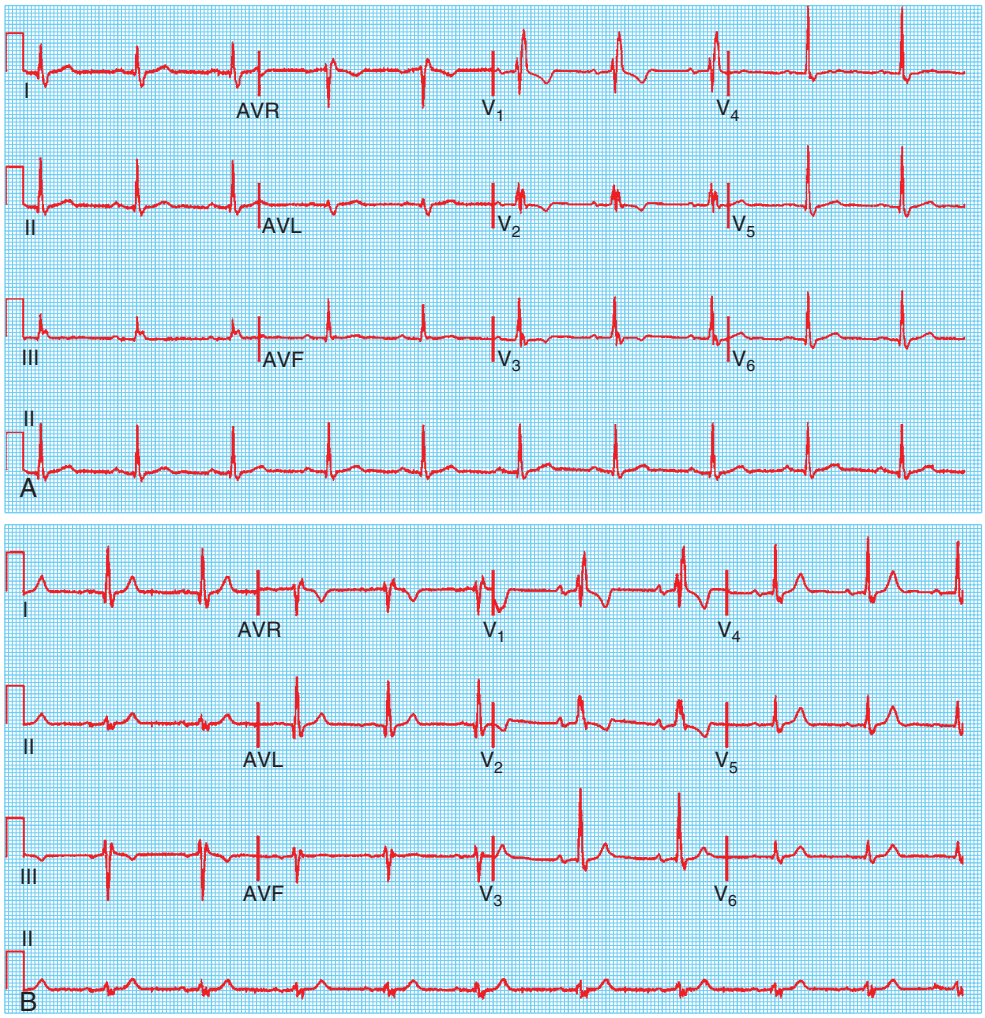

Fig. 17.39 Right bundle branch block versus bifascicular block. (A) A 12-lead ECG showing right bundle branch block. Note an rsR′ pattern with the tall R′ in lead V_1–V_2 and the broad S waves in leads I and V_5–V_6. **(B)** Compare with this ECG showing bifascicular block. In addition to right bundle branch block, note the left axis deviation and deep S waves in leads III and AVF, which are typical of left anterior hemiblock.

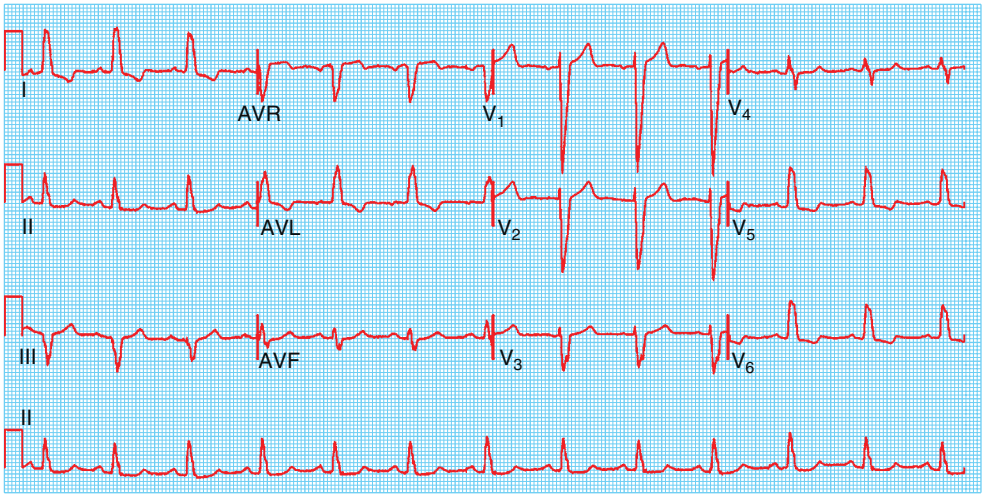

Fig. 17.40 A 12-lead ECG showing left bundle branch block. The QRS duration is more than 0.12 seconds. Note the broad, notched R waves with ST depression in leads I, AVL, and V_6, and the broad QS waves in V_1–V_3.

conduction tissue disease affecting the right bundle and the left anterior fascicle.

Complete LBBB is often associated with extensive left ventricular disease. The most common causes include aortic stenosis, hypertension, MI, and severe coronary disease, similar to the causes of complete heart block.

Management

Any patient with evidence of conduction delay should be assessed for the likely aetiology. Drugs contributing to bradycardia should be stopped if it is safe to do so. Echocardiography is helpful to assess the structure and function of the heart.

The management of different ECG findings is set out in **Box 17.11** and varies considerably between simple reassurance and urgent admission to a monitored area for cardiac pacing.

Box 17.11 The management of various ECG abnormalities frequently associated with bradycardia

Rhythm	Management
First-degree AV block	Reassurance, generally no further monitoring unless symptomatic
Second-degree AV block, Mobitz I	Address reversible causes, outpatient monitoring, permanent pacemaker if syncope
Second-degree AV block, Mobitz II, or higher-degree block	Close monitoring in a high dependency area; temporary pacing if likely short-term (reversible) cause; otherwise permanent pacemaker
Complete (third-degree) block	Close monitoring in a high dependency area; permanent pacemaker
Right bundle branch block	Exclude pathological causes; reassurance
Left bundle branch block	Identify cause; if associated with pre-syncope or syncope consider an extended period of rhythm monitoring (e.g., 24 h Holter or implantable loop device)
Higher-degree block with LV dysfunction	Cardiac resynchronization therapy with a biventricular pacemaker/defibrillator

TACHYCARDIAS

Supraventricular tachycardias

Supraventricular tachycardias (SVTs) arise from the atrium or the AV junction. Conduction is via the His–Purkinje system; therefore the QRS shape during tachycardia is usually similar to that seen in the same patient during baseline rhythm. A classification of SVT is given in **Box 17.12**. Some of these tachycardias are discussed in more detail in the sections that follow.

Inappropriate sinus tachycardia

Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated to, or out of proportion with, the level of physical or emotional stress. It is found predominantly in young women. Sinus tachycardia due to intrinsic sinus node abnormalities, such as enhanced automaticity, or abnormal autonomic regulation of the heart with excess sympathetic and reduced parasympathetic input, is extremely rare.

In general, sinus tachycardia is a secondary phenomenon and the underlying causes need to be actively investigated. Depending on the clinical setting, acute causes include exercise, emotion, pain, fever, infection, acute heart failure (AHF), acute pulmonary embolism, and hypovolaemia. Chronic causes include pregnancy, anaemia, hyperthyroidism, and catecholamine excess. The underlying cause should be found and treated rather than treating the compensatory physiological response. If necessary, beta-blockers may be used to slow the sinus rate—in hyperthyroidism, for example (see **Box 34.30**); ivabradine, an I_F (pacemaker current) blocker, may be useful when beta-blockade cannot be tolerated.

Postural orthostatic tachycardia syndrome

This is a sudden and significant increase in heart rate (usually >130 beats per minute) associated with normal or mildly reduced blood pressure and produced by standing. There is sinus tachycardia with a structurally normal heart. The underlying mechanism is a failure of the peripheral vasculature to constrict appropriately in response to orthostatic stress, which is compensated by an excessive increase in heart rate. Management begins with supportive measures aimed

Box 17.12 Causes of supraventricular tachycardia (SVT)

Tachycardia	ECG features	Comment
Sinus tachycardia	P wave morphology similar to sinus rhythm; P waves always precede QRS	Need to determine underlying cause
Atrioventricular nodal re-entrant tachycardia (AVNRT)	No visible P wave, or inverted P wave immediately before or after QRS complex	Most common cause of palpitations in patients with normal hearts
Atrioventricular re-entrant tachycardia (AVRT) complexes	P wave visible between QRS and T wave	Due to an accessory pathway; if pathway conducts in both directions, ECG during sinus rhythm may be pre-excited
Atrial fibrillation	'Irregularly irregular' RR intervals and absence of organized atrial activity	Most common tachycardia in patients >65 years
Atrial flutter	Visible flutter waves at 300 b.p.m. (sawtooth appearance), usually with 2:1 AV conduction	Suspect in any patient with regular SVT at 150 b.p.m.
Atrial tachycardia	Organized atrial activity with P wave morphology different from sinus rhythm preceding QRS	Usually occurs in patients with structural heart disease or following extensive ablation within atria
Multifocal atrial tachycardia	Multiple P wave morphologies (≥3) and irregular RR intervals	Rare arrhythmia; most commonly associated with significant chronic lung disease
Accelerated junctional tachycardia	ECG similar to that in AVNRT	Rare in adults

at identifying triggers and avoiding situations (such as suddenly rising from sitting) that are associated with pre-syncope. Medications including beta-blockers and serotonin-selective reuptake inhibitors are sometimes used.

Atrioventricular junctional tachycardias

AV nodal re-entrant and AV re-entrant tachycardias are usually referred to as paroxysmal SVTs and are often seen in young patients with no or little structural heart disease, although congenital heart abnormalities can coexist in a small proportion of patients with these arrhythmias. The first presentation is commonly between ages 12 and 30, and the prevalence is approximately 2.5/1000.

In these tachycardias the AV node is an essential component of the re-entry circuit.

Atrioventricular nodal re-entrant tachycardia

Atrioventricular nodal re-entrant tachycardia (AVNRT) is twice as common in women. Clinically, the tachycardia often strikes suddenly without obvious provocation, but exertion, emotional stress, coffee, tea, and alcohol may aggravate or induce it. An attack may stop spontaneously or may continue indefinitely until medical intervention.

In AVNRT there are two functionally and anatomically different pathways predominantly within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and conducts faster. In sinus rhythm the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g., an atrial premature beat) occurs early when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles. It then travels back through the fast pathway, which has already recovered its excitability, thus initiating the most common 'slow–fast', or typical, AVNRT.

The rhythm is recognized on ECG from normal regular QRS complexes, usually at a rate of 140 to 240/min (Fig. 17.41A). Sometimes, the QRS complexes will show typical bundle branch block. P waves either are not visible or are seen immediately before or after the QRS complex because of simultaneous atrial and ventricular activation. It is less common (5%–10%) to observe a tachycardia when the atrial impulse conducts anterogradely through the fast pathway and returns through the slow pathway, producing a long RP′ interval ('fast–slow').

Atrioventricular re-entrant tachycardia

This large circuit comprises the AV node, the His bundle, the ventricle, and an abnormal connection of myocardial fibres from the ventricle back to the atrium. It is called an accessory pathway or bypass tract and results from an incomplete separation of the atria and the ventricles during fetal development.

In contrast to AVNRT, atrioventricular re-entrant tachycardia (AVRT) is due to a macro re-entry circuit and each part of the circuit is activated sequentially. As a result, atrial activation occurs after ventricular activation and the P wave is usually seen clearly between the QRS and T waves (Fig. 17.41B).

Accessory pathways are most commonly situated on the left but may occur anywhere around the AV groove. The most common accessory pathways, known as ***Kent bundles***, are in the free wall or septum. In about 10% of cases multiple pathways occur. ***Mahaim fibres*** are atriofascicular or nodofascicular fibres that enter the ventricular myocardium in the region of the right bundle branch. Accessory pathways that conduct from the ventricles to the atria only are not visible on the surface ECG during sinus rhythm and are therefore 'concealed'. Accessory pathways that conduct bidirectionally usually are 'manifest' on the surface ECG. If the accessory pathway conducts from the atrium to the ventricle during sinus rhythm, the electrical impulse can conduct quickly over this abnormal connection to depolarize part of the ventricles abnormally (pre-excitation). A pre-excited ECG is characterized by a short PR interval and a wide QRS complex that begins as a slurred part known as the ***δ wave*** (Fig. 17.41C). Patients with a history of palpitations and a pre-excited ECG have a condition known as ***Wolff–Parkinson–White (WPW) syndrome***.

During AVRT, the AV node and ventricles are activated normally ***(orthodromic AVRT)***, usually resulting in a narrow QRS complex. Less commonly, the tachycardia circuit can be reversed, with activation of the ventricles via the accessory pathway, and atrial activation via retrograde conduction through the AV node ***(antidromic AVRT)***. This results in a broad-complex tachycardia.

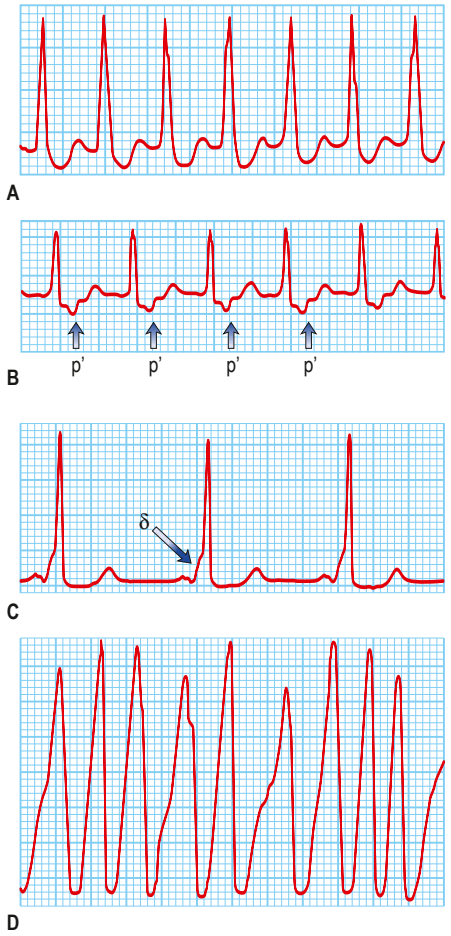

Fig. 17.41 Atrioventricular junctional tachycardia. (A) Atrioventricular nodal re-entrant tachycardia (AVNRT). The QRS complexes are narrow and the P waves cannot be seen. **(B)** Atrioventricular re-entrant tachycardia (AVRT) (Wolff–Parkinson–White syndrome, WPW). The tachycardia P waves *(arrowed)* are clearly seen after narrow QRS complexes. **(C)** An ECG taken in a patient with WPW syndrome during sinus rhythm. Note the short PR interval and the δ wave *(arrowed)*. **(D)** Atrial fibrillation in the WPW syndrome. Note the tachycardia with broad QRS complexes and the fast and irregular ventricular rate.

These patients are also prone to atrial fibrillation. During atrial fibrillation, the ventricles may be depolarized by impulses travelling over both the abnormal and the normal pathways. This results in pre-excited atrial fibrillation, a characteristic tachycardia that is typified by irregularly irregular broad QRS complexes (Fig. 17.41D). If an accessory pathway has a short antegrade effective refractory period (<250 ms), it may conduct to the ventricles at an extremely high rate and may cause ventricular fibrillation. The incidence of sudden death is 0.15% to 0.39% per patient-year and it may be a first manifestation of the disease in younger individuals. Verapamil and digoxin may allow a higher rate of conduction over the abnormal pathway and precipitate ventricular fibrillation. Therefore neither verapamil nor digoxin should be used to treat atrial fibrillation associated with WPW syndrome.

Acute management

This is reviewed in Chapter 11 ('Atrial fibrillation/Acute management' section).

Long-term management

Patients with suspected cardiac arrhythmias should be referred to a cardiologist for electrophysiological evaluation and long-term management. Both pharmacological and non-pharmacological treatments, including ablation of an accessory pathway, are readily available. Verapamil, diltiazem, and beta-blockers have proven efficacy in 60% to 80% of patients. Sodium-channel blockers (flecainide and propafenone), potassium repolarization current blockers (sotalol, dofetilide, azimilide) and the multichannel blocker amiodarone may also prevent the occurrence of tachycardia.

Refinement of catheter ablation techniques has rendered many AV junctional tachycardias entirely curable. Modification of the slow pathway is successful in 96% of patients with AVNRT, although a 1% risk of AV block is present. In AVRT the target for catheter ablation is the accessory pathway(s). The success rate of ablation of a single accessory pathway is approximately 95%, with a recurrence rate of 5%, requiring a repeat procedure.

Atrial tachyarrhythmias

Atrial tachyarrhythmias, including atrial fibrillation, atrial flutter, atrial tachycardia, and atrial ectopic beats, all arise from the atrial myocardium. They share similar aetiologies, of which the most commonly encountered in clinical practice are increasing age, MI, hypertension, obesity, diabetes mellitus, HCM, heart failure, valvular heart disease, myocarditis, pericarditis, cardiothoracic surgery, electrolyte imbalance, alcohol use, obstructive airway disease, chest infections, and hyperthyroidism.

Atrial fibrillation

This is the commonest sustained arrhythmia, occurring in 1% to 2% of the general population and 5% to 15% of patients over 75 years of age. It also occurs, particularly in a paroxysmal form, in younger patients.

Aetiology

Any condition resulting in raised atrial pressure, increased atrial muscle mass, atrial fibrosis, or inflammation and infiltration of the atrium may cause atrial fibrillation.

Hypertension and heart failure are the most common causes in the developed world. Hyperthyroidism may provoke atrial fibrillation, sometimes as virtually the only feature of the disease, and thyroid function tests are mandatory in any patient with atrial fibrillation that is unaccounted for. Atrial fibrillation occurs in one-third of patients after cardiac surgery. Alcohol, but not caffeine, is also a trigger. Mitral stenosis caused by rheumatic heart disease is a major cause in the developing world.

A genetic predisposition to AF has been proposed. About 30% to 40% of patients with AF, especially those who present at a young age, have at least one parent with the arrhythmia, and genes associated with the sodium channel, the potassium channel, gap junction proteins, and right–left isomerism have been implicated. Gene defects linked to chromosomes 10, 6, 5, and 4 have been associated with familial atrial fibrillation.

Pathophysiology

Atrial fibrillation is maintained by continuous, rapid (300–600/min) activation of the atria by multiple meandering re-entry wavelets, often driven by rapidly depolarizing automatic foci, located predominantly within the pulmonary veins. The atria respond electrically at this rate but there is no coordinated mechanical action, and only a proportion of the impulses are conducted to the ventricles. The ventricular response depends on the rate and regularity of atrial activity, particularly at the entry to the AV node, the refractory properties of the AV node itself, and the balance between sympathetic and parasympathetic tone.

Clinical features

Symptoms attributable to atrial fibrillation are highly variable. In some patients (about 30%) it is an incidental finding, while others attend hospital as an emergency with rapid palpitations, dyspnoea, and/or chest pain following the onset of atrial fibrillation. Most patients with on-going atrial fibrillation experience some deterioration of exercise capacity or wellbeing, but this may be appreciated only once sinus rhythm is restored. When caused by rheumatic mitral stenosis, the onset of atrial fibrillation results in considerable worsening of cardiac failure.

The patient has an 'irregularly irregular' pulse, as opposed to a basically regular pulse with an occasional irregularity (e.g., extrasystoles) or recurring irregular patterns (e.g., Wenckebach block). The irregular nature of the pulse in atrial fibrillation is maintained during exercise.

The ECG shows fine oscillations of the baseline (so-called fibrillation or *f* waves) and no clear P waves (Fig. 17.42A). The QRS rhythm is rapid and irregular. Untreated, the ventricular rate is usually 120 to 180/min.

The clinical classification of atrial fibrillation includes:

- ***first diagnosed episode***—irrespective of duration or severity of symptoms
- ***paroxysmal***—stops spontaneously or with intervention within 7 days
- ***persistent***—continuous for more than 7 days, including episodes terminated by cardioversion
- ***longstanding persistent***—continuous for more than 1 year, where the long-term treatment goal remains to achieve sinus rhythm
- ***permanent***—continuous, with a joint decision between the patient and the physician to cease further attempts to regain sinus rhythm.

The classification is helpful in choosing between rhythm restoration and rate control. Atrial fibrillation may be asymptomatic and the 'first diagnosed episode' should not necessarily be regarded as the true onset.

Management

Acute management

This is reviewed in Chapter 11 ('Atrial fibrillation' section).

Fig. 17.42 Twelve-lead ECGs showing atrial fibrillation and atrial flutter. **(A)** Atrial fibrillation. Note the absolute rhythm irregularity. The ECG shows fine oscillations of the baseline (so-called fibrillation or *f* waves) and no clear P waves. **(B)** Atrial flutter, showing regular sawtooth-like atrial flutter waves (F waves) between QRS complexes. The flutter frequency is 300/min. Every fourth flutter wave is transmitted to the ventricles and the ventricular rate is therefore 75/min.

Long-term management

An integrated approach to the management of AF is recommended, which prioritizes stroke prevention, symptom control with rate, and/or rhythm control and optimization of co-morbidities.

Stroke prevention

Atrial fibrillation increases the risk of stroke fivefold and anticoagulation reduces this risk by two-thirds. However, the risk of stroke is not uniform, and it is only patients who are at higher risk of stroke who are likely to benefit overall from anticoagulation, since treatment increases the risk of haemorrhage. A scoring system known as CHA_2DS_2VASc is used (**Box 17.13**) as the first step in determining the need for anticoagulation. The Australian guidelines have removed the sex (male or female) component of this score for simplicity.

The HAS-BLED score as recommended by European, Canadian, and UK (NICE) guidelines is used to identify possible modifiable risk factors for bleeding (e.g., hypertension control) rather than a tool to deny anticoagulation to patients at high risk of stroke (**Box 17.14** and **Fig. 17.43**)

When oral anticoagulation is required, a direct oral anticoagulant (DOAC) is first-line treatment. Warfarin may still be preferred where AF is secondary to valvular abnormalities (e.g., in rheumatic heart disease or following mitral valve replacement).

DOACs fall into two classes: direct thrombin inhibitors (e.g., dabigatran) and oral direct factor Xa inhibitors (e.g., rivaroxaban, apixaban, edoxaban). Their mechanism of action is described in Chapter 40 ('Anticoagulant agents' section). In comparison with warfarin, the DOACs have a rapid onset of action, shorter half-life, and fewer food and drug interactions and do not require INR blood test monitoring. Trial data have shown them to be equally effective as warfarin but safer, with a 52% reduction in intracerebral haemorrhage.

Antiplatelet agents should not be used to reduce stroke risk. Percutaneous left atrial appendage occlusion (LAAO) may be offered where anticoagulation is contraindicated or not tolerated.

Rate control

Ventricular rate control can improve symptoms of AF in the majority of patients. As a primary strategy, this is appropriate in patients who:

Box 17.13 CHA_2DS_2-VASc scoring system for non-valvular atrial fibrillation

	Risk factors	Score/points
C	Congestive heart failure Includes patients with heart failure with reduced ejection fraction; recently decompensated heart failure with preserved ejection fraction; hypertrophic cardiomyopathy	1
H	Hypertension or on treatment	1
A_2	Age ≥75	2
D	Diabetes mellitus or fasting glucose >7 mmol/L	1
S_2	Stroke/TIA/thromboembolism	2
V	Vascular disease (aorta, coronary or peripheral arteries)	1
A	Age 65–74	1
Sc	Sex category: female	1
Annual risk of stroke		
0 points = 0% risk: No prophylaxis 1 point = 1.3% risk: Consider anticoagulation in men 2+ points = 2.2% risk: Oral anticoagulant A score of 1 (for being female alone) is not enough to warrant anticoagulation.		

TIA, Transient ischaemic attack.

Box 17.14 HAS-BLED score for bleeding risk on oral anticoagulation in atrial fibrillation

Clinical characteristic	Score/points
Hypertension (systolic ≥ 160 mmHg)	1
Abnormal renal function (creatinine >200 μmol/L)	1
Abnormal liver function (liver enzymes >×3 upper limit of normal)	1
Stroke in past	1
Previous major bleeding	1
Labile INRs (in range <60% of time)	1
Elderly: age ≥65years	1
Drugs as well (antiplatelets/non-steroidal anti-inflammatory drugs)	1
Alcohol intake at same time (>14 units/week)	1

Yearly risk of developing major bleeding with anticoagulation rises with increasing score, from 1% with a score of 0 (low risk) to around >5% with a score of 3 or more (high risk).
INR, International Normalized Ratio.
(Adapted From European Society of Cardiology Clinical Practice Guidelines. Eur Heart J *2020; 42:373–498.)*

- have the permanent form of AF associated with no symptoms, or symptoms that have improved by slowing heart rate;
- are older than 65 years with recurrent atrial tachyarrhythmias ('accepted' atrial fibrillation); and
- have persistent tachyarrhythmias and have failed cardioversion(s) and serial prophylactic antiarrhythmic drug therapy, and in whom the risk/benefit ratio from using specific antiarrhythmic agents is shifted towards increased risk.

Rate control is usually achieved with a combination of ***digoxin***, ***beta-blockers***, or ***non-dihydropyridine calcium-channel blockers*** (***verapamil*** or ***diltiazem***). Beta-blockers are the preferred therapy. Digoxin monotherapy is sometimes sufficient for elderly, non-ambulant patients (the catecholamine effect of ambulation easily overwhelms the vagotonic effect of digoxin).

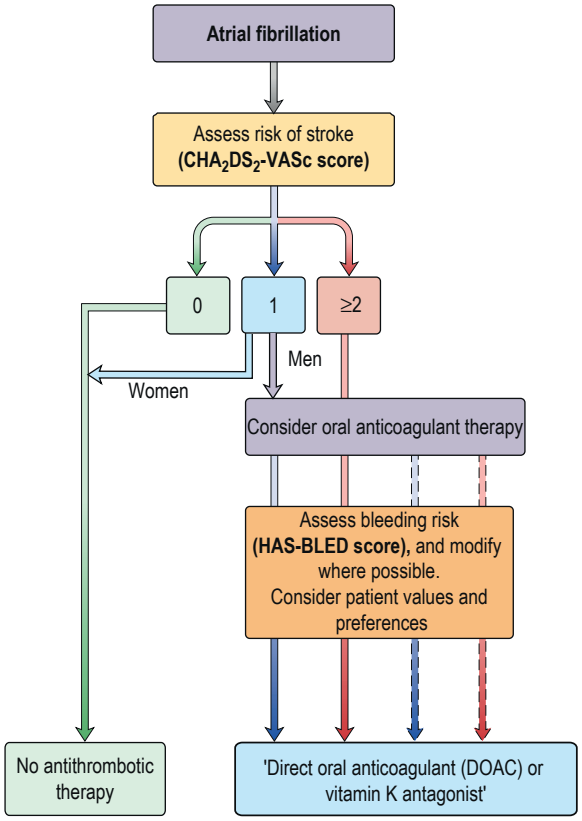

Fig. 17.43 Anticoagulation in atrial fibrillation.

The ventricular rate response is generally considered to be controlled if the resting heart rate is below 110 b.p.m., but stricter control (between 60 and 80 b.p.m. at rest and below 110 b.p.m. during moderate exercise) may be needed if symptoms persist. To assess the adequacy of rate control, an ECG rhythm strip may be sufficient but ambulatory 24-hour Holter monitoring or an exercise stress test are more informative. Older patients with poor rate control despite optimal medical therapy should be considered for pacemaker implantation followed by AV node ablation ***('ablate and pace' strategy)***.

Rhythm control

This refers to a strategy that seeks to maintain sinus rhythm. Historic randomized studies in patients predominantly over the age of 65 years (AFFIRM) or in patients with heart failure (AF-CHF) have shown that there is no net mortality benefit to be gained from rhythm control strategy compared with rate control. Newer data support the early use of rhythm control in all patients with a new diagnosis of AF, particularly when there is a concurrent diagnosis of heart failure. Which strategy to adopt needs to be assessed for each individual patient. Factors to consider include the likelihood of maintaining sinus rhythm, symptoms of AF, and the safety/tolerability of antiarrhythmic drugs or cardiac ablation.

Antiarrhythmic medications

Recurrent paroxysms may be prevented with oral medication. In general, patients with no significant heart disease can be treated with any class Ia, Ic, or III antiarrhythmic drug, although it is recommended that amiodarone (because of its substantial extracardiac adverse effect profile) should be reserved until other drugs have

failed. For patients with ***heart failure*** or ***left ventricular hypertrophy*** only amiodarone is recommended. Patients with ***coronary artery disease*** may be treated with sotalol or amiodarone.

Ablation

Patients with ***paroxysmal atrial fibrillation*** or with early ***persistent atrial fibrillation***, who have little left atrial dilation, may be treated with left atrial ablation. The ectopic triggers for atrial fibrillation are generally found in the pulmonary veins, which can be isolated from the atria using radiofrequency, cryothermal, or pulsed-field energy. Occasionally, more extensive ablation within the left atrium is needed. These techniques are more successful than antiarrhythmic drugs and may represent a 'cure' in some patients. However, the procedure is invasive and carries hazard of serious complications such as stroke and bleeding in about 2% of cases. In the long term, recurrence is not uncommon, and an apparently successful ablation does not remove the obligation for appropriate anticoagulation. Ablation has not been shown to improve long-term cardiovascular outcome but it does successfully treat symptoms due to atrial fibrillation.

Atrial flutter

Atrial flutter is often associated with atrial fibrillation and frequently requires a similar initial therapeutic approach. Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 b.p.m. Typical or 'isthmus-dependent' atrial flutter involves a macro re-entrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the Eustachian ridge between the tricuspid annulus and the inferior vena cava, and up the interatrial septum, giving rise to the most frequent pattern, referred to as counterclockwise flutter. Re-entry can also occur in the opposite direction (clockwise or reverse flutter).

The ECG shows regular sawtooth-like atrial flutter waves (F waves) between QRS complexes (see **Fig. 17.42B**). In typical counterclockwise atrial flutter the F waves are negative in the inferior leads and positive in leads V_1 and V_2. In clockwise atrial flutter the deflection of the F waves is the opposite. If F waves are not clearly visible, for diagnostic clarification they can be revealed by slowing AV conduction by carotid sinus massage or by administering AV nodal-blocking drugs such as adenosine or verapamil.

Symptoms are largely related to the degree of AV block. Most often, every second flutter beat conducts, giving a ventricular rate of 150 b.p.m. When patients are receiving rate-controlling treatment, AV conduction block reduces the heart rate to approximately 75 b.p.m.

Management

The acute management of atrial flutter is discussed in Chapter 11 ('Atrial flutter' section). Recurrent paroxysms may be prevented by ***class III*** antiarrhythmic agents (sotalol, amiodarone). ***AV nodal blocking agents*** may be used to control the ventricular rate if the arrhythmia persists. However, the treatment of choice for patients with recurrent atrial flutter is catheter ***ablation*** (see 'Catheter ablation' section), which permanently interrupts re-entry by creating a line of conduction block within the isthmus between the inferior vena cava and the tricuspid valve ring. This technique offers patients whose only arrhythmia is typical atrial flutter an almost certain chance of a cure, although the later occurrence of atrial fibrillation is not uncommon.

Atrial tachycardia

This is an uncommon arrhythmia. Its prevalence is believed to be less than 1% in patients with arrhythmias. It is usually associated with structural heart disease, but in many cases it is referred to as idiopathic. Atrial tachycardia with block can be seen with digitalis poisoning.

The mechanisms of atrial tachycardia are attributed to enhanced automaticity, triggered activity, or intra-atrial re-entry. Atrial re-entrant tachycardia is usually relatively slow (125–150 b.p.m.) and can be initiated and terminated by atrial premature beats. The P′P′ intervals are regular. The PR interval depends on the rate of tachycardia and is longer than in sinus rhythm at the same rate.

Automatic tachycardia usually presents with higher rates (125–250 b.p.m.) and is often characterized by a progressive increase in the atrial rate with onset of the tachycardia ('warm-up') and progressive decrease prior to termination ('cool-down'). Atrial tachycardia is typically caused by a focus that is frequently located along the crista terminalis in the right atrium, adjacent to a pulmonary vein in the left atrium, or around one of the atrial appendages. Automatic atrial tachycardia may also present as an incessant variety leading to tachycardia-induced cardiomyopathy. Short runs of atrial tachycardia may provoke more sustained episodes of atrial fibrillation.

Carotid sinus massage may increase AV block during tachycardia, thereby facilitating the diagnosis, but does not usually terminate the arrhythmia. Management options include ***cardioversion***, ***antiarrhythmic drug therapy*** to maintain sinus rhythm, ***AV nodal slowing agents*** to control rate, and, in selected cases, radiofrequency catheter ***ablation***. Anticoagulation for isolated atrial tachycardia is not required.

Atrial ectopic beats

These often cause no symptoms, although they may be sensed as an irregularity or heaviness of the heartbeat. On the ECG, they appear as early and abnormal P waves and are usually, but not always, followed by normal QRS complexes. Treatment is not normally required unless the ectopic beats provoke more significant arrhythmias, when ***beta-blockers*** may be effective.

Ventricular tachyarrhythmias

The acute management of sustained ventricular tachycardia is discussed in Chapter 11 ('Paroxysmal supraventricular tachycardia' section). Conditions that may predispose to or commonly present with ventricular tachycardia are discussed below.

Brugada's syndrome

This inheritable condition accounts for part of a group of patients with idiopathic ventricular fibrillation who have no evidence of causative structural cardiac disease. It is more common in young male adults and in South-east Asia. The diagnosis is made by identifying the classic ECG changes that may be present spontaneously or may be provoked by the administration of a class I antiarrhythmic (flecainide or ajmaline—principally used as a diagnostic agent in patients where the diagnosis is suspected): right bundle branch block with coved ST elevation in leads V_1–V_3 (**Fig. 17.44**). Atrial fibrillation may occur.

In 20% of cases this is a monogenic inheritable condition associated with loss of sodium-channel function due to a mutation in the *SCN5A* gene. It can present with sudden death during sleep, resuscitated cardiac arrest, and syncope, or the patient may be asymptomatic and diagnosed incidentally or during familial assessment.

Management

Patients should be instructed to treat fevers aggressively (non-pharmacological measures, as well as paracetamol ± NSAIDs); high

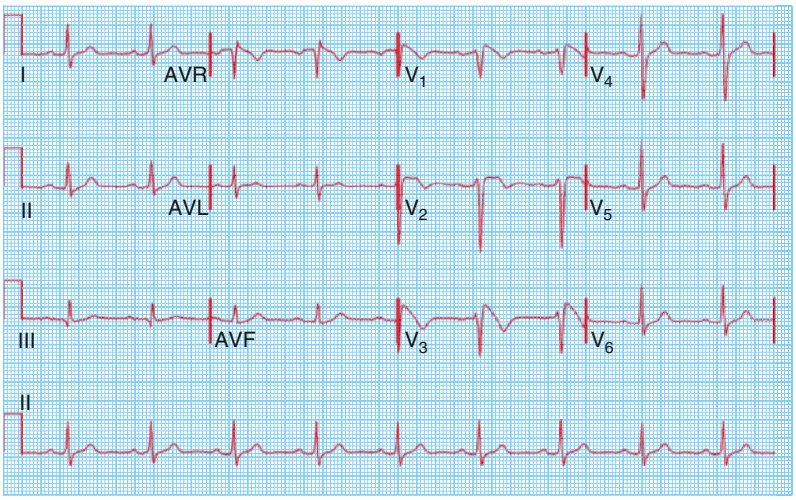

Fig. 17.44 The Brugada ECG. ST elevation (V_1, V_2, V_3) with right bundle branch block.

body temperatures are pro-arrhythmogenic. Certain prescribed medications are contraindicated (see https://www.brugadadrugs.org). An ICD should be considered in individuals with suspected arrhythmic syncope and a spontaneous type 1 Brugada ECG. There is an evolving role of quinidine to reduce the risk of ventricular fibrillation in this population. Beta-blockade is not helpful and may be harmful.

Long QT syndrome

This describes an ECG where the ventricular repolarization (QT interval) is greatly prolonged. The causes of long QT syndrome are listed in **Box 17.15**.

Congenital long QT syndrome

Two major syndromes have been described, one associated with congenital deafness (Jervell–Lange–Nielsen' syndrome) and one that is not (Romano–Ward' syndrome).

The molecular biology of the congenital long QT syndromes has been shown to be heterogeneous. It is usually a monogenic disorder and has been associated with mutations in cardiac potassium and sodium channel genes. The different genes involved appear to correlate with different phenotypes (**Fig. 17.45A**) that can exhibit such variable penetrance that carriers may have completely normal ECGs. Multiple long QT (LQT) subtypes have been identified but three major ones account for the majority of cases. These are:

- ***LQT1*** (*KCNQ1* gene mutation affecting the $I_{ks}\alpha$ subunit), in which the arrhythmia is usually provoked by exercise, particularly swimming
- ***LQT2*** (*KCNH2* gene mutation affecting the $I_{kr}\alpha$ subunit), in which arrhythmia provocation is associated with emotion and acoustic stimuli
- ***LQT3*** (*SCN5A* gene mutation affecting the $I_{Na}\alpha$ subunit), in which the arrhythmias occur during rest or when asleep.

It is likely that identification of the mutation involved will not only improve diagnostic accuracy, particularly with cascade screening in affected families, but also guide future therapy for the congenital long QT syndrome.

Acquired long QT syndrome

QT prolongation and torsades de pointes are usually provoked by bradycardia.

? Box 17.15 Causes of long QT syndrome

Congenital
- Jervell–Lange-Nielsen syndrome (autosomal recessive)
- Romano–Ward syndrome (autosomal dominant)

Acquired

Electrolyte abnormalities
- Hypokalaemia
- Hypomagnesaemia
- Hypocalcaemia

Drugs
- Quinidine, disopyramide
- Sotalol, amiodarone
- Tricyclic antidepressants, e.g., amitriptyline
- Phenothiazine drugs, e.g., chlorpromazine
- Antipsychotics, e.g., haloperidol, olanzapine
- Macrolides, e.g., erythromycin
- Quinolones, e.g., ciprofloxacin
- Methadone

Poisons
- Organophosphate insecticides

Miscellaneous
- Bradycardia
- Mitral valve prolapse
- Acute myocardial infarction
- Diabetes
- Prolonged fasting and liquid protein diets (long-term)
- Central nervous system diseases, e.g., dystrophia myotonica

Clinical features

Patients with a long QT are at risk of developing syncope and palpitations as a result of polymorphic ventricular tachycardia (torsades de pointes). They usually terminate spontaneously but may degenerate into ventricular fibrillation, resulting in sudden death.

Torsades de pointes is characterized on the ECG by rapid, irregular, sharp complexes that continuously change from an upright to an inverted position (**Fig. 17.45B**).

Between spells of tachycardia or immediately preceding the onset of tachycardia, the ECG shows a prolonged QT interval; the corrected QT (see **Box 17.9**) is usually over 0.50 seconds.

Management

Acute (acquired) long QT syndrome is treated as follows:
- Any electrolyte disturbance is corrected.
- Causative drugs are stopped.
- Magnesium sulphate 8 mmol (Mg^{2+}) is given over 10 to 15 min for acquired long QT.
- Intravenous isoprenaline may be effective when QT prolongation is acquired (isoprenaline is contraindicated for congenital long QT syndrome).

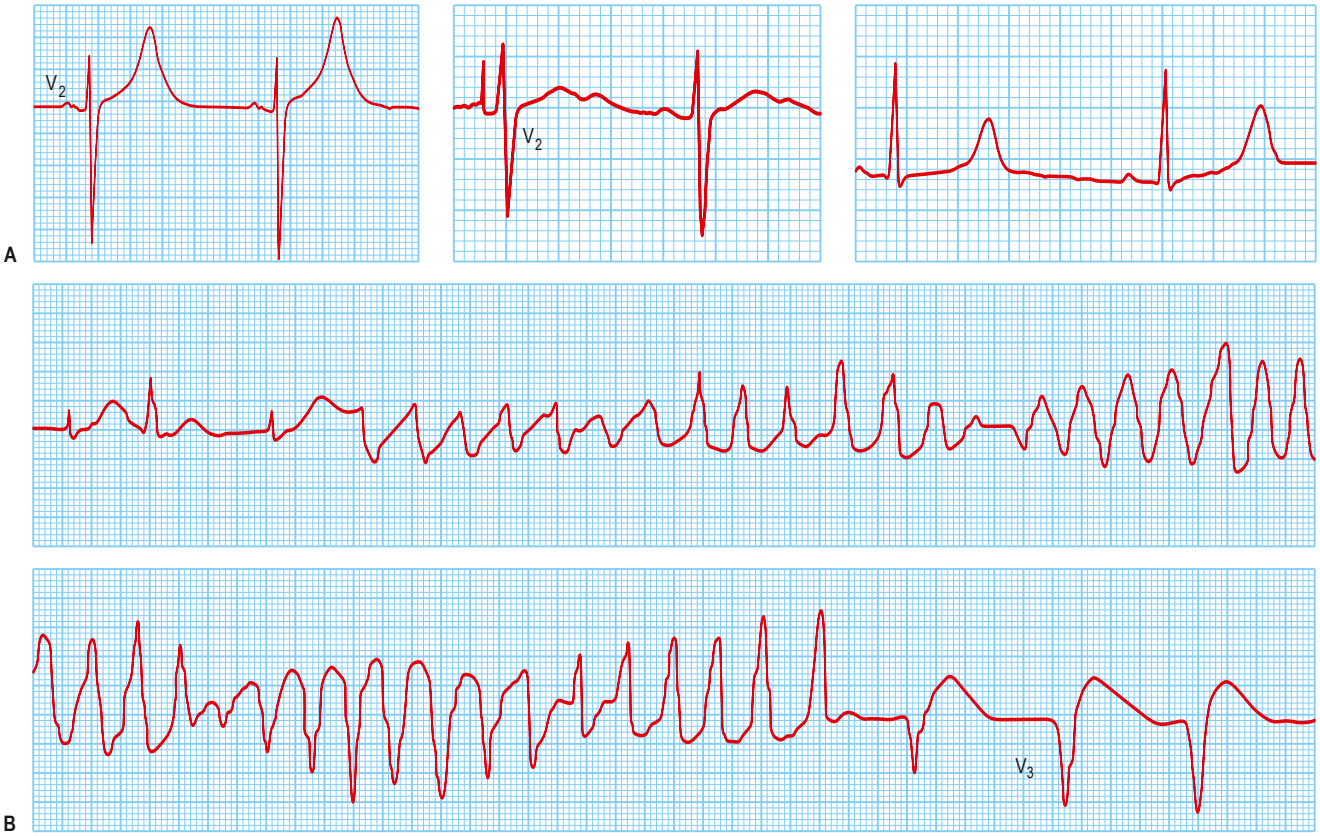

Fig. 17.45 Prolonged QT syndrome. **(A)** Three examples of a prolonged QT interval corresponding to three different types of long QT syndrome. **(B)** An ECG demonstrating a supraventricular rhythm with a long QT interval giving way to atypical ventricular tachycardia (torsades de pointes). The tachycardia is short lived and is followed by a brief period of idioventricular rhythm.

- A higher heart rate may need to be maintained with atrial or ventricular pacing.

Long-term, all patients with the syndrome should avoid drugs known to prolong the QT interval (see www.crediblemeds.org). Non-selective beta-blockade (nadolol or propranolol) reduces the risk of arrhythmic events. LQT3 patients respond additionally to sodium-channel blockers, such as mexiletine. Patients who have survived a cardiac arrest, syncope despite beta-blockers, or those with marked QT prolongation with a genetic mutation usually benefit from ICD therapy and are best evaluated in inherited cardiomyopathy clinics. Left cardiac sympathetic denervation can be considered in patients receiving ICD therapy despite optimal medical treatment or in those in whom ICD implant cannot be performed.

Short QT syndrome

This rare channelopathy is usually diagnosed in the presence of a QTC less than 320 ms or a QTC less than 360 ms with a family history of the syndrome or pathogenic mutation. Three definite genetic abnormalities predominately affecting potassium channels have been identified. Ventricular arrhythmias and sudden death may occur. ICD implantation is recommended for survivors of cardiac arrest and patients with either arrhythmic syncope or sustained ventricular tachycardia. Quinidine may be useful to reduce the burden of ventricular arrhythmia.

Normal heart ventricular tachycardia

Monomorphic ventricular tachycardia in patients with structurally normal hearts (idiopathic ventricular tachycardia) is usually a benign condition with an excellent long-term prognosis. Occasionally, it is incessant (so-called Gallavardin's tachycardia) and, if untreated, may lead to cardiomyopathy. An echocardiogram and CMR are frequently used to define 'structurally normal'.

Normal heart ventricular tachycardia arises from a focus in either the right ventricular outflow tract or the left ventricular septum. Treatment of symptoms is usually with beta-blockers. There is a special form of verapamil-sensitive tachycardia that responds well to non-dihydropyridine calcium antagonists. In symptomatic patients radiofrequency catheter ablation is highly effective, resulting in a cure in over 90% of cases. It is important to distinguish the more benign right ventricular outflow tract ventricular tachycardia from the more pathogenic ACM (see 'Hypertrophic cardiomyopathy' section) due to some similarities on ECG.

Non-sustained ventricular tachycardia

Non-sustained ventricular tachycardia (NSVT) is defined as ventricular tachycardia that is 5 consecutive beats or more but lasts for less than 30 seconds (Fig. 17.46A). NSVT can be found in 6% of patients with normal hearts and usually does not require treatment. It is documented in up to 60% to 80% of patients with heart disease. Antiarrhythmic suppression of NSVT is not usually advocated but beta-blockers may improve quality of life in symptomatic individuals.

Ventricular premature beats (ectopics)

These may be uncomfortable, especially when frequent. The patient complains of extra beats, missed beats, or heavy beats because it may be the premature beat, the post-ectopic pause, or the next

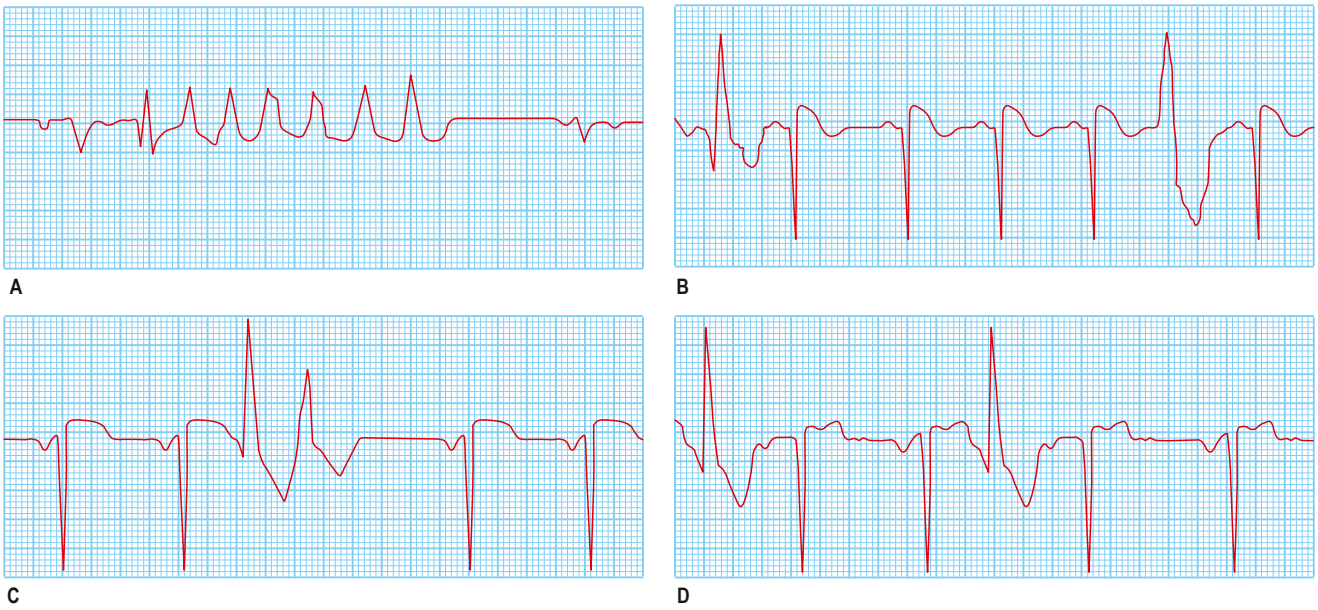

Fig. 17.46 Varieties of ventricular ectopic activity. **(A)** A brief run of ventricular tachycardia (*non*-sustained ventricular tachycardia) that follows previous ectopic activity. **(B)** Two ventricular ectopic beats of different morphology (multimorphological). **(C)** Two ventricular premature beats (VPBs) occurring one after the other (a pair or couplet of VPBs). **(D)** Frequently repetitive ventricular ectopic activity of a single morphology.

sinus beat that is noticed. The pulse is irregular owing to the premature beats. Some early beats may not be felt at the wrist. When a premature beat occurs regularly after every normal beat, 'pulsus bigeminus' may occur.

These premature beats (Fig. 17.46B–D) have a broad (>0.12 sec) and bizarre QRS complex because they arise from an abnormal (ectopic) site in the ventricular myocardium. Following a premature beat, there is usually a complete compensatory pause because the AV node or ventricle is refractory to the next sinus impulse. Early 'R-on-T' ventricular premature beats (occurring simultaneously with the upstroke or peak of the T wave of the previous beat) may induce ventricular fibrillation in patients with heart disease, particularly following MI.

Ventricular premature beats are usually treated only if symptomatic. Simple measures, such as reassurance and beta-blocker therapy, are normally all that is required. In patients with a 24-hour burden of ventricular ectopics of more than 10% and heart failure symptoms, an ablation could be considered to prevent further deterioration in symptoms and cardiac function.

Long-term management of cardiac tachyarrhythmias

Options for the long-term management of all cardiac tachyarrhythmias include:

- antiarrhythmic drug therapy
- ablation therapy
- device therapy.

Antiarrhythmic drugs

Drugs that modify the rhythm and conduction of the heart are used to treat cardiac arrhythmias. Antiarrhythmic drugs may aggravate or produce arrhythmias (proarrhythmia), and they may also depress ventricular contractility and must therefore be used with caution. They are classified according to their effect on the action potential (Vaughan Williams classification; Box 17.16 and Fig. 17.47).

Box 17.16 Vaughan Williams classification of antiarrhythmic drugs

Class/action	Drugs
Class I	Membrane-depressant drugs (sodium-channel blockers)
Ia Lengthen action potential	Disopyramide
Ib Shorten action potential	Lidocaine, mexiletine
Ic No effect on action potential	Flecainide, propafenone
Class II Block β-adrenoceptors	Atenolol, acebutolol, bisoprolol, propranolol, esmolol
Class III Lengthen action potential	Amiodarone, dronedarone, sotalol, dofetilide, ibutilide, vernakalant
Class IV Reduce plateau phase of action potential	Calcium-channel blockers, e.g., verapamil, diltiazem
Other	Adenosine, digoxin

Class I drugs

These are membrane-depressant drugs that reduce the rate of entry of sodium into the cell (sodium channel blockers). They may slow conduction, delay recovery, or reduce the spontaneous discharge rate of myocardial cells. Class I agents have been found to increase mortality compared to placebo in post-MI patients with ventricular ectopy (Cardiac Arrhythmia Suppression Trial [CAST] trials—class Ic agents) and in patients treated for atrial fibrillation (class Ia agent, quinidine). In view of this class Ic agents, such as flecainide, and all other class I drugs should be reserved for patients who do not have symptomatic CAD, left ventricular dysfunction, or other forms of significant structural heart disease.

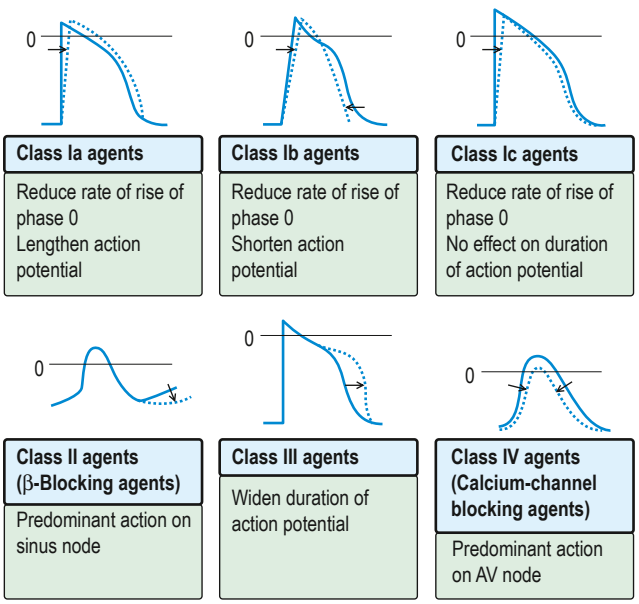

Fig. 17.47 Vaughan Williams classification of antiarrhythmic drugs based on their effect on cardiac action potentials (see also Fig. 17.13). (0 = 0 mV. The *dotted curves* indicate the effects of the drugs.) *AV,* Atrioventricular.

Class II drugs

These drugs prevent the effects of catecholamines on the action potential. Most are β-adrenoceptor antagonists. Cardioselective beta-blockers (β_1) include metoprolol, bisoprolol, atenolol, and acebutolol. Beta-blockers suppress AV node conduction, which may be effective in preventing attacks of junctional tachycardia and may help to control the ventricular rate during paroxysms of other forms of SVT (e.g., atrial fibrillation). In general, beta-blockers are anti-ischaemic and antiadrenergic and have proven beneficial effects in patients post MI (by preventing ventricular fibrillation) and in those with congestive heart failure. It is therefore advisable to use beta-blocker therapy either alone or in combination with other antiarrhythmic drugs in patients with symptomatic tachyarrhythmias, particularly those with CAD.

Class III drugs

These prolong the action potential, usually by blocking the rapid component of the delayed rectifier potassium current (I_{Kr}), and do not affect sodium transport through the membrane. The drugs in this class are amiodarone, dronedarone, and sotalol. Sotalol is also a beta-blocker.

Sotalol may result in acquired long QT syndrome and torsades de pointes, particularly in women. The risk of torsades is increased in the setting of renal dysfunction and hypokalaemia; particular care should be taken in patients taking diuretic therapy. Amiodarone therapy, in contrast to most other antiarrhythmic drugs, carries a low risk of proarrhythmia in patients with significant structural heart disease, but its use may be limited due to toxic and potentially serious side-effects. Dronedarone is a multichannel-blocking drug that suppresses the recurrence of atrial fibrillation and reduces hospital admissions in patients with cardiovascular risk. However, it has proven harmful in patients with left ventricular dysfunction and is contraindicated in heart failure.

Vernakalant is a multichannel blocker that is approved for the rapid intravenous medical cardioversion of new-onset atrial fibrillation.

Class IV drugs

The non-dihydropyridine calcium-channel blockers are particularly effective at slowing conduction in nodal tissue. These drugs can prevent attacks of junctional tachycardia (AVNRT and AVRT) and may help to control ventricular rates during paroxysms of other forms of SVT (e.g., atrial fibrillation).

Clinical use of antiarrhythmic drugs

Antiarrhythmic drugs have not been shown to prolong life. Patient safety is the main factor in determining the choice of antiarrhythmic therapy, and proarrhythmic risks need to be carefully assessed prior to initiating therapy. As a generalization, class Ic agents are employed in patients with structurally normal hearts, and class III agents are used in those with structural heart disease, although exceptions exist.

Patients with structurally normal hearts and normal QT intervals, or those with implantable defibrillators, either are at very low risk of proarrhythmia or are protected from any life-threatening consequences; in these individuals it is possible to persevere with drug therapy.

Catheter ablation

Catheter ablation (radiofrequency, cryoablation, and, more recently, pulse field) is frequently employed in the management of symptomatic tachyarrhythmias. Ablations are performed percutaneously by placing electrode catheters into the heart chambers, usually via femoral vessels. Successful ablation depends on accurate identification of either the site of origin of a focal tachycardia or a critical component of a macro re-entry tachycardia. Catheter ablation has been found to be highly effective in the following tachyarrhythmias:

- AVNRT
- AVRT with an accessory pathway, including WPW syndrome
- atrial fibrillation
- atrial flutter
- normal heart ventricular tachycardia
- atrial tachycardia.

Symptomatic patients with a ***pre-excited*** ECG because of accessory pathway conduction (WPW syndrome) are advised to undergo catheter ablation as first-line therapy, owing to the risk of sudden death should sustained atrial arrhythmia occur. Patients with accessory pathways that only conduct retrogradely from the ventricles to the atrium are not at increased risk of sudden death but experience symptoms due to AVRT. These individuals are commonly offered an ablation procedure if simple measures, such as AV nodal slowing agents, fail to suppress tachycardia. Asymptomatic patients with the WPW ECG pattern are now frequently offered an ablation procedure for prophylactic reasons. The main risk associated with accessory pathway ablation is thromboembolism in patients with left-sided accessory pathways.

Patients with ***normal hearts and documented ventricular tachycardia*** should be referred for specialist evaluation. Unlike ventricular tachycardia in patients with structural heart disease, normal heart ventricular tachycardia is not associated with increased risk of sudden death, and long-term success can be achieved by catheter ablation.

Catheter ablation is recommended in patients with ***atrial flutter*** that is not easily managed medically. Ablation of typical flutter is effective in 90% to 95% of cases. In the direct comparison of catheter ablation and antiarrhythmic therapy the rate of recurrence was significantly lower following ablation. ***Atrial tachycardia***, especially in patients with structurally normal hearts, may also be treated by catheter ablation. In atrial fibrillation adequate control of ventricular rates is sometimes not possible, despite optimal medical therapy. These patients experience

a marked symptomatic improvement following AV node ablation (which leads to complete heart block) and pacemaker implantation.

In ***younger patients*** with structurally normal hearts, ***atrial ectopic beats***, which commonly arise from a focus situated in the pulmonary veins, may trigger atrial fibrillation. Catheter ablation of this ectopic focus includes the application of radiofrequency energy around the pulmonary veins in order to abolish the connection between the sleeves of arrhythmogenic atrial myocardium surrounding or extending into the veins from the atrium (pulmonary vein isolation). The trigger is therefore eliminated, and the arrhythmia does not recur. These techniques appear to be highly effective, especially in young patients with paroxysmal atrial fibrillation, normal atrial size, and no underlying heart disease (70%–80% long-term success) but are presently time-consuming procedures (3 h or more) and carry a risk of serious complications such as stroke, tamponade, pulmonary vein stenosis, and atrio-oesophageal fistula in a small minority of patients (in experienced centres <2% altogether).

Implantable cardioverter–defibrillator

Up to 40% of patients diagnosed with life-threatening ventricular arrhythmias (ventricular fibrillation or rapid ventricular tachycardia with hypotension) will die within 1 year of diagnosis. Large multicentre prospective trials, such as the Antiarrhythmics Versus Implantable Defibrillator (AVID) trial (which compared an implantable defibrillator to amiodarone therapy), have proven that implantable defibrillators improve overall survival in patients who have experienced an episode of life-threatening ventricular tachyarrhythmia.

The ICD recognizes ventricular tachycardia or fibrillation and automatically delivers pacing or a shock to the heart to cause cardioversion to sinus rhythm. Modern ICDs are larger than a pacemaker and the generator is usually implanted in a pre- or subpectoral position (Fig. 17.48). The device may have leads to sense and pace both the right atrium and ventricle, and the lithium batteries employed are able to provide energy for over 100 shocks, each of around 40 J.

As an alternative to the traditional ICD with transvenous leads, there is also a subcutaneous device (S-ICD) where the generator is sited intramuscularly in the axilla, and a subcutaneous lead is tunnelled adjacent to the sternum. This option is increasingly favoured in the younger patient cohort as it minimizes the long-term complication of a defibrillator lead in the heart (infection, vascular obstruction, lead failure needing extraction, tricuspid valve dysfunction), but it does have limitations, requiring an individualized approach to patient selection.

ICD discharges are painful if the patient is conscious. However, ventricular tachycardia may often be terminated by overdrive pacing the heart, which is painless.

The ICD is superior to all other treatment options for preventing sudden cardiac death, and their use has cut the sudden death rate in patients with a history of serious ventricular arrhythmias to approximately 2% per year. However, the majority of these people have significant structural heart disease and overall cardiac mortality due to progressive heart failure remains high. As a result, the ICD is now first-line therapy in the secondary prevention of sudden death.

ICDs are also employed in the primary prevention of sudden cardiac death. The chances of surviving an out-of-hospital cardiac

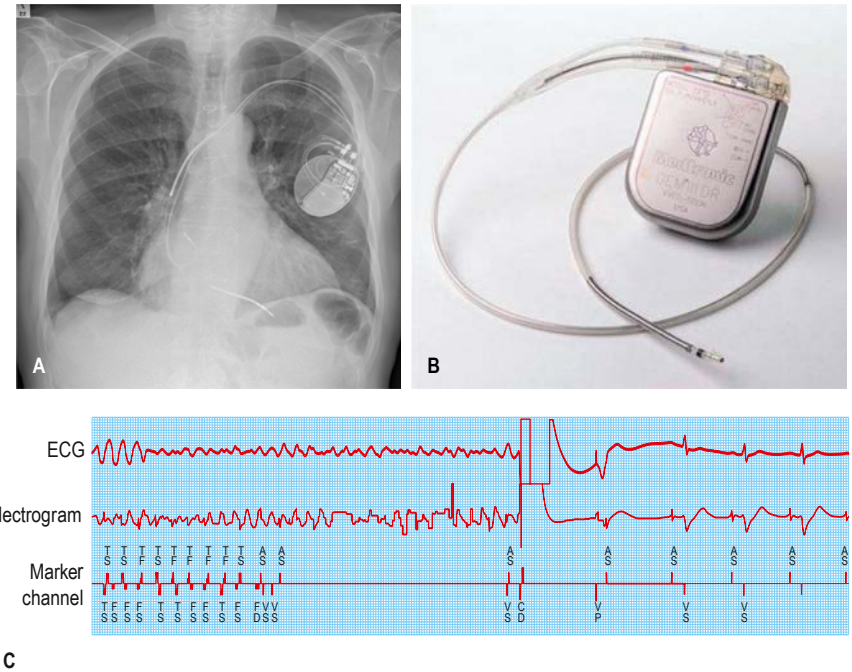

Fig. 17.48 Implantable cardioverter–defibrillator. **(A)** X-ray of a 'dual-chamber' defibrillator in a left pectoral position with atrial and ventricular leads. **(B)** Medtronic GEM® III DR defibrillator. **(C)** ECG showing the termination of ventricular fibrillation by a direct current shock at 20 J. The electrogram, recorded internally from the ventricular lead of an ICD, reveals chaotic ventricular activity consistent with ventricular fibrillation. This is confirmed by an electrocardiogram (lead V_2). The marker channel demonstrates that the device detects ventricular fibrillation correctly (FS, fibrillation sensing, lower line) and delivers an appropriate shock (CD) that terminates the arrhythmia and restores normal sinus rhythm (VS, ventricular sensing, lower line). Incidentally, atrial fibrillation is also detected before shock delivery (upper line on the marker channel).

arrest are as low as 10%. Therefore selected patients who have never experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia but who are assessed to be at high risk of sudden death are advised to undergo ICD implantation. In two large primary prevention ICD trials Multicenter Automated Defibrillator Implantation Trial (MADIT II) and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), therapy with an ICD reduced mortality by 23% to 31% on top of conventional treatment, which included revascularization, beta-blockers, and ACE inhibitors. ICD combined with cardiac resynchronization therapy may improve both symptoms and life expectancy of patients with any degree of heart failure (the COMPANION, CARE-HF, and MADIT-CRT trials).

The following groups of patients may merit prophylactic ICD placement for primary prevention:

- Patients with heart failure, with a left ventricular EF of 35% or less and NYHA functional class ≤3 (see **Box 17.20**). In such patients who also have LBBB (QRS > 120 ms) there is additional benefit in combining ICD with cardiac resynchronization therapy (CRT-D; see 'Cardiac resynchronization therapy or implantable cardioverter–defibrillator' section). In patients with DCM and low EF, scar on cardiac MRI (late gadolinium enhancement) identifies a subgroup of patients who are more likely to benefit from a primary prevention ICD.
- Those with a familial condition and high risk of sudden death, such as DCM and HCM, long QT syndrome, Brugada's syndrome, or other channelopathies, along with other high-risk factors.

HEART FAILURE

Heart failure is a complex syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the heart to function as a pump to support a physiological circulation. Worldwide, the incidence of heart failure is variable but increases with advancing age, with approximately 26 million people affected. In the UK overall incidence is about 2 in 1000. The prognosis of heart failure has improved over the past 10 years with evidence-based therapy, but the mortality rate remains high and approximately 50% of patients are dead at 5 years. Heart failure is the leading cause of medical hospital admissions in over 65-year-olds and accounts for 5% of admissions to hospital medical wards. The cost of managing heart failure in the UK exceeds £1 billion per year. CAD is the most common cause of heart failure in Western countries.

The causes of heart failure are shown in **Box 17.17**.

Pathophysiology

The physiological changes in heart failure are initially compensatory and maintain cardiac output and peripheral perfusion. However, as heart failure progresses, these mechanisms are overwhelmed and become pathological (**Box 17.18**). Peripheral vasoconstriction and sodium retention in heart failure by activation of the renin–angiotensin–aldosterone system entails a loss of beneficial compensatory mechanisms and contributes to the spiral of cardiac decompensation. Evaluation of cardiac function requires assessment of preload, afterload, and contractility.

? Box 17.17 Causes of heart failure

Main causes

- Ischaemic heart disease (35%–40%)
- Cardiomyopathy (dilated) (30%–34%)
- Hypertension (15%–20%)

Other causes

- Inherited: e.g., hypertrophic
- Valvular heart disease (mitral, aortic, tricuspid)
- Infiltrative: amyloidosis, sarcoidosis, haemochromatosis, Fabry's disease
- Congenital heart disease (atrial septal defect, ventricular septal defect)
- Alcohol and recreational drugs
- Prescribed medication related (trastuzumab, anthracyclines, tyrosine kinase inhibitors, checkpoint inhibitors, clozapine)
- Hyperdynamic circulation (anaemia, thyrotoxicosis, Paget's disease)
- Right heart failure (right ventricular infarct, pulmonary hypertension, pulmonary embolism, chronic obstructive pulmonary disease)
- Arrhythmias (atrial fibrillation, bradycardia [complete heart block, sick sinus syndrome])
- Pericardial disease (constrictive pericarditis, pericardial effusion)
- Infections: e.g., Chagas' disease
- Myocarditis (lymphocytic, eosinophilic, giant cell)

i Box 17.18 Pathophysiological changes in heart failure

- Ventricular dilation
- Myocyte hypertrophy
- Increased collagen synthesis
- Altered myosin gene expression
- Altered sarcoplasmic Ca^{2+}-adenosine triphosphatase density
- Increased atrial natriuretic peptide secretion
- Salt and water retention
- Sympathetic stimulation
- Peripheral vasoconstriction

Venous return (preload)

In the intact heart myocardial failure leads to a reduction of the volume of blood ejected with each heartbeat and an increase in the volume of blood remaining after systole. This increased diastolic volume stretches the myocardial fibres and, as Starling's law of the heart (see 'Starling's law of the heart' section) would suggest, myocardial contraction is restored. However, the failing myocardium results in depression of the ventricular function curve (cardiac output plotted against the ventricular diastolic volume) (see **Fig. 13.8**).

Mild myocardial depression is not associated with a reduction in cardiac output because it is maintained by an increase in venous pressure (and hence diastolic volume). However, the proportion of blood ejected with each heartbeat (EF) is reduced early in heart failure. Sinus tachycardia also ensures that any reduction of stroke volume is compensated for by the increase in heart rate; cardiac output (stroke volume × heart rate) is therefore maintained.

When there is more severe myocardial dysfunction, cardiac output can be maintained only by a large increase in venous pressure and/or marked sinus tachycardia. The increased venous pressure contributes to the development of dyspnoea, owing to the accumulation of interstitial and alveolar fluid, ascites with hepatic enlargement, and dependent oedema from increased systemic venous

pressure. However, the cardiac output at rest may not be much depressed, but myocardial and haemodynamic reserve is so compromised that a normal increase in cardiac output cannot be produced by exercise. In very severe heart failure the cardiac output at rest is depressed, despite high venous pressures. The inadequate cardiac output is redistributed to maintain perfusion of vital organs, such as the heart, brain, and kidneys, at the expense of the skin and muscle.

Outflow resistance (afterload)

Outflow resistance (afterload) (see Fig. 17.5) is the load or resistance against which the ventricle contracts. It is formed by:

- pulmonary and systemic resistance
- physical characteristics of the vessel walls
- the volume of blood that is ejected.

An increase in afterload decreases the cardiac output, resulting in a further increase of end-diastolic volume and dilation of the ventricle, which further exacerbates the problem of afterload. This is expressed by Laplace's law: the tension of the myocardium (T) is proportional to the intraventricular pressure (P) multiplied by the radius of the ventricular chamber (R)—that is, T∝PR. Systemic blood pressure correlates with afterload and is used as a surrogate measure.

Myocardial contractility (inotropic state)

The state of the myocardium also influences performance. The sympathetic nervous system is activated in heart failure via baroreceptors as an early compensatory mechanism, which provides inotropic support and maintains cardiac output. Chronic sympathetic activation, however, has deleterious effects by further increasing neurohormonal activation and myocyte apoptosis. This is compensated by a downregulation of β-receptors. Increased contractility (positive inotropism) can result from increased sympathetic drive, and this is a normal part of the Frank–Starling relationship (see Fig. 17.5). Conversely, myocardial depressants (e.g., hypoxia) decrease myocardial contractility (negative inotropism).

Neurohormonal and sympathetic system activation: salt and water retention

The increase in venous pressure that occurs when the ventricles fail leads to retention of salt and water as diminished renal perfusion, which activates the renin–angiotensin system (see Fig. 27.5). Salt and water accumulates in the interstitium, producing many of the physical signs of heart failure and further increasing venous pressure (Fig. 17.49). The retention of sodium is, in part, compensated by the action of circulating atrial natriuretic peptides and antidiuretic hormone.

Myocardial remodelling in heart failure

Left ventricular remodelling is a process of progressive alteration of ventricular size, shape, and function owing to the influence of mechanical, neurohormonal, and possibly genetic factors in several clinical conditions, including MI, cardiomyopathy, hypertension, and valvular heart disease. Its hallmarks include hypertrophy, loss of myocytes, and increased interstitial fibrosis. Remodelling continues for months after the initial insult, and the eventual change in the shape of the ventricle becomes responsible for the impairment of overall function of the heart (Fig. 17.50A). In cardiomyopathy the process of progressive ventricular dilation or hypertrophy takes place without ischaemic myocardial injury or infarction (Fig. 17.50B).

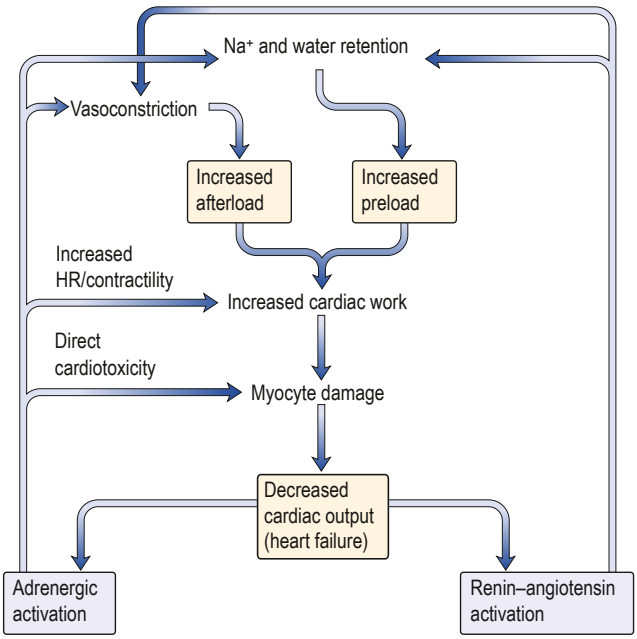

Fig. 17.49 The compensatory physiological response to heart failure. Chronic activation of the renin–angiotensin and adrenergic systems results in a 'vicious circle' of cardiac deterioration that further exacerbates the physiological response. *HR,* Heart rate.

Abnormal calcium homeostasis

Calcium ion flux within myocytes plays a pivotal role in the regulation of contractile function. Excitation of the myocyte cell membrane causes the rapid entry of calcium into myocytes from the extracellular space via calcium channels. This triggers the release of intracellular calcium from the SR and initiates contraction (see Fig. 17.3). Relaxation results from the uptake and storage of calcium by the SR (see Fig. 17.9), controlled by changes in nitric oxide. In heart failure there is a prolongation of the calcium current in association with prolongation of contraction and relaxation.

Natriuretic peptides (ANP, BNP, and CNP)

- ***Atrial natriuretic peptide (ANP)*** is released from atrial myocytes in response to stretch. ANP induces diuresis, natriuresis, vasodilation, and suppression of the renin–angiotensin system. Levels of circulating ANP are increased in congestive cardiac failure and correlate with functional class, prognosis, and haemodynamic state.
- ***B-type natriuretic peptide (BNP)*** is predominantly secreted by the ventricles in response to increased myocardial wall stress. N-terminal (NT)-proBNP is an inactive protein that is cleaved from proBNP to release BNP. Both BNP and NT-proBNP are increased in patients with heart failure, and levels correlate with ventricular wall stress and the severity of heart failure. BNP and NT-proBNP are good predictors of cardiovascular events and mortality, although monitoring levels are not routinely used to guide heart failure management.
- ***C-type natriuretic peptide (CNP)***, which is limited to vascular endothelium and the central nervous system, has similar effects to those of ANP and BNP.

Endothelial function in heart failure

The endothelium has a central role in the regulation of vasomotor tone. In patients with heart failure endothelium-dependent vasodilation in peripheral blood vessels is impaired and may be one mechanism of exercise limitation. The cause of abnormal endothelial

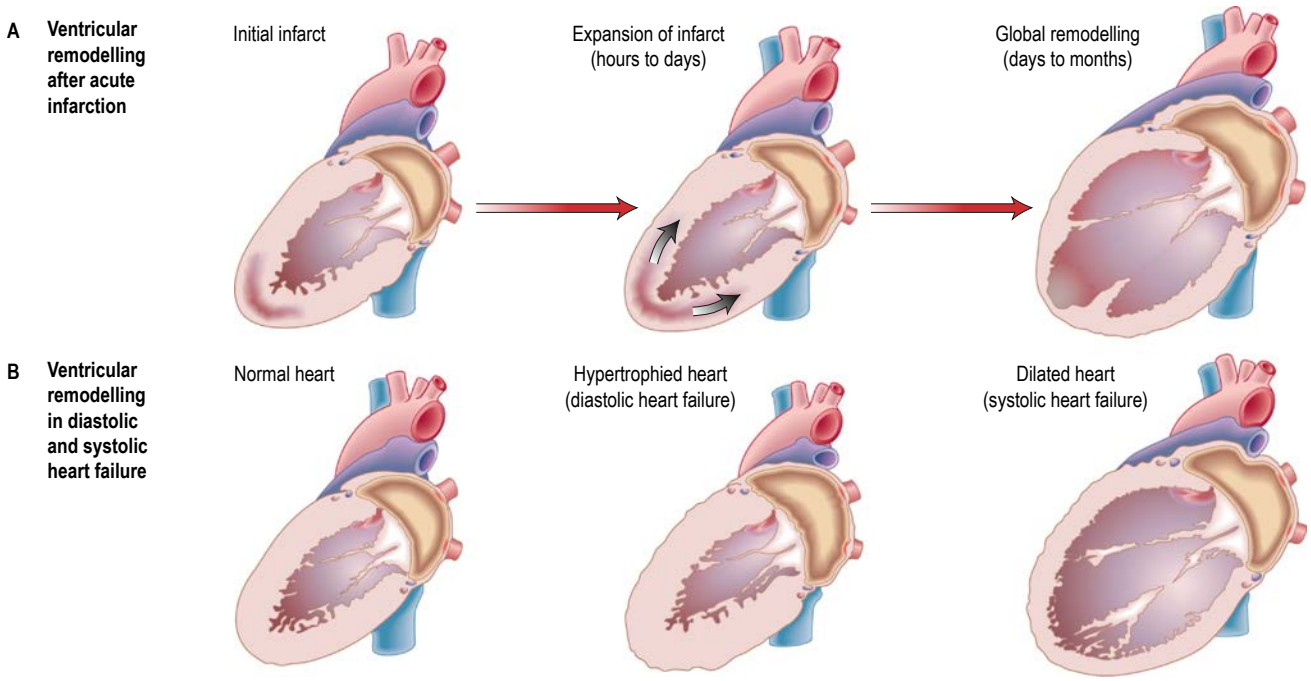

Fig. 17.50 Ventricular remodelling. **(A)** In ischaemic (myocardial infarction) heart failure. **(B)** In non-ischaemic heart failure (e.g., in cardiomyopathy).

responsiveness relates to abnormal release of both nitric oxide and vasoconstrictor substances, such as ET. The activity of nitric oxide, a potent vasodilator, is blunted in heart failure. ET secretion from a variety of tissues is stimulated by many factors, including hypoxia, catecholamines, and angiotensin II. The plasma concentration of ET is elevated in patients with heart failure, and levels correlate with the severity of haemodynamic disturbance.

ET has many actions that potentially contribute to the pathophysiology of heart failure: vasoconstriction, sympathetic stimulation, renin–angiotensin system activation, and left ventricular hypertrophy. Acute intravenous administration of ET antagonists improves haemodynamic abnormalities in patients with congestive cardiac failure, but oral ET antagonists have not shown long-term benefit in heart failure.

Arginine vasopressin (vasopressin)

Arginine vasopressin (AVP) is raised in severe chronic heart failure (CHF), particularly in patients on diuretic treatment. A high AVP concentration precipitates hyponatraemia, which is an ominous prognostic indicator. Oral short-term vasopressin antagonists can be considered in the management of patients with hospitalized decompensated heart failure.

Clinical syndromes of heart failure

There are many causes of heart failure (see **Box 17.17**) that can present suddenly, with AHF, or more insidiously, with CHF. One common classification of heart failure uses the left ventricular ejection fraction (LVEF):

- ***Heart failure with reduced ejection fraction (HFrEF)*** (EF ≤ 40%) is commonly caused by ischaemic heart disease but can also occur with valvular heart disease and hypertension.
- ***Heart failure with preserved ejection fraction (HFpEF)*** is a syndrome consisting of symptoms and signs of heart failure with an LVEF of 50% or greater. There is increased stiffness in the ventricular wall and decreased left ventricular compliance, leading to impairment of diastolic ventricular filling and hence decreased cardiac output. Echocardiography may demonstrate an increase in left ventricular wall thickness, increased left atrial size, and abnormal left ventricular relaxation with normal or near-normal left ventricular volume. HFPEF, which was historically described as ‘diastolic heart failure’, is more common in elderly hypertensive patients but may occur with primary cardiomyopathies (hypertrophic, restrictive, infiltrative).
- ***Heart failure with mildly reduced ejection fraction (HFmrEF)*** is a recently introduced classification for those patients in the ‘grey zone’ with an LVEF of 41% to 49%.
- ***Right ventricular systolic dysfunction (RVSD)*** may be secondary to chronic left-sided heart disease but can occur with primary and secondary pulmonary hypertension, right ventricular infarction, arrhythmogenic right ventricular cardiomyopathy, and adult congenital heart disease.

Clinical features of heart failure

The symptoms and signs of heart failure are shown in **Box 17.19**.

The NYHA classification of heart failure (**Box 17.20**) can be used to describe the symptoms of heart failure and limitation of exercise capacity and is useful for assessing response to therapy.

Diagnosis of heart failure

The diagnosis of heart failure should be based on a detailed history, clinical findings, natriuretic peptide levels, and objective evidence of cardiac dysfunction using measures of left ventricular structure and function (usually echocardiography). The underlying cause of heart failure should be established in all patients (**Box 17.21** and **Fig. 17.51**).

Investigations in heart failure

- ***Blood tests.*** Full blood count, serum creatinine and electrolytes, liver biochemistry, thyroid function, iron studies, fasting glucose, HbA_{1C}, and lipid profile should be considered. Cardiac enzymes (e.g., troponin) should be measured in AHF to assess for myocardial injury, and BNP or NT-proBNP may be used to diagnose CHF.
- ***Chest X-ray.*** Features of heart failure include cardiomegaly, pulmonary congestion with upper lobe diversion, fluid in fissures, Kerley B lines, and pulmonary oedema.

Box 17.19 Clinical features of heart failure

Symptoms
- Exertional dyspnoea
- Orthopnoea
- Paroxysmal nocturnal dyspnoea
- Fatigue

Signs
- Tachycardia
- Elevated jugular venous pressure
- Cardiomegaly
- Third and fourth heart sounds
- Bi-basal crackles
- Pleural effusion
- Peripheral ankle oedema
- Ascites
- Tender hepatomegaly

Box 17.20 New York Heart Association (NYHA) classification of heart failure

Class	Features
Class I	No limitation. Normal physical exercise does not cause fatigue, dyspnoea, or palpitations
Class II	Mild limitation. Comfortable at rest but normal physical activity produces fatigue, dyspnoea, or palpitations
Class III	Marked limitation. Comfortable at rest but gentle physical activity produces marked symptoms of heart failure
Class IV	Symptoms of heart failure occur at rest and are exacerbated by any physical activity

Box 17.21 Diagnosis of heart failure (European Society of Cardiology guidelines)

Diagnosis of HF-REF requires two conditions to be satisfied
1. Symptoms and/or signs typical of heart failure
2. Ejection fraction ≤ 40%

Diagnosis of HF-mREF requires two conditions to be satisfied
1. Symptoms and/or signs typical of heart failure
2. Ejection fraction 41%–49%

Diagnosis of HF-PEF requires three conditions to be satisfied
1. Symptoms and/or signs typical of heart failure
2. Ejection fraction ≥50%
3. Normal-sized LV with relevant structural heart disease (LV hypertrophy/left atrial enlargement) and/or diastolic dysfunction, including elevated natriuretic peptides

- ***ECG.*** Identify features of ischaemia, ventricular hypertrophy, or arrhythmia.
- ***Echocardiography.*** Assess cardiac chamber dimension, systolic and diastolic function, regional wall motion abnormalities, valvular disease, and cardiomyopathies.
- ***Stress echocardiography.*** Assess for ischaemia (and myocardial viability).
- ***Nuclear cardiology.*** Radionucleotide angiography (RNA) can quantify ventricular EF; SPECT or PET can demonstrate myocardial ischaemia and viability in dysfunctional myocardium. PET can be useful in diagnosing inflammatory cardiomyopathies.
- ***Cardiac MRI (CMR).*** Recommended for assessing cardiac structure, function, and viability, as well as myocardial characterization in suspected sarcoidosis, amyloidosis, haemochromatosis, Fabry's disease, and HCM.
- ***Coronary angiogram.*** For patients with angina and symptomatic ventricular arrhythmias.
- ***Right heart catheterization.*** This technique measures right atrial and pulmonary artery pressure (the 'wedge' pressure), a surrogate for left atrial pressure. It is valuable in assessment of pulmonary hypertension, prior to mitral or tricuspid valve intervention, in evaluation of patients with HFPEF, in heart transplant work-up, and in the management of cardiogenic shock.

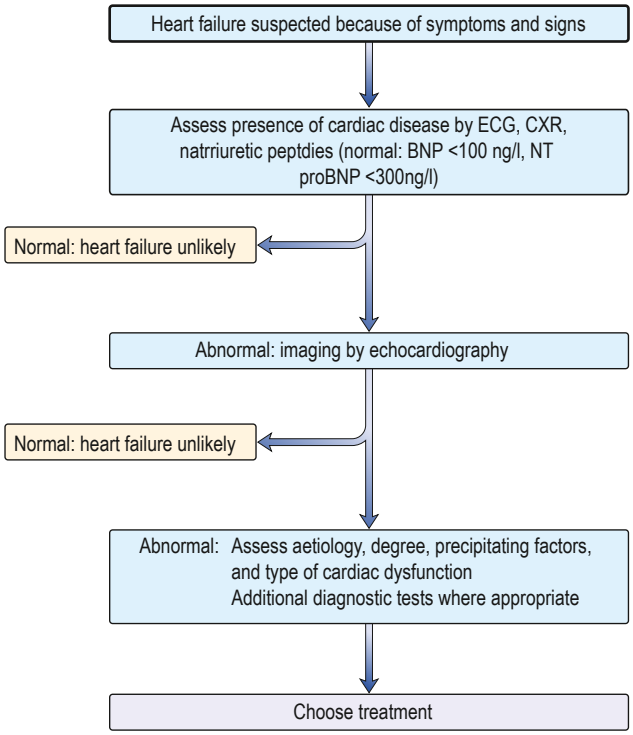

Fig. 17.51 Algorithm for the diagnosis of heart failure. *(Based on the European Society of Cardiology and NICE guidelines.)*

- ***Cardiac biopsy.*** This is used for diagnosis of cardiomyopathies, such as amyloid, myocarditis, and sarcoidosis, and for follow-up of transplanted patients to assess rejection.
- ***Cardiopulmonary exercise testing.*** Peak oxygen consumption (VO_2) is predictive of hospital admission and death in heart failure. A 6-minute exercise walk is an alternative. These assessments are clinically used in patients being assessed for heart transplant candidacy.
- ***Ambulatory 24-hour ECG monitoring (Holter).*** This is used in patients with suspected arrhythmia and may be employed in those with severe heart failure or inherited cardiomyopathy to determine whether a defibrillator is appropriate (non-sustained ventricular tachycardia).

Management of heart failure

The management of acute heart failure, presenting with pulmonary oedema, is discussed in Chapter 11 ('Acute heart failure' section). Management of CHF is aimed at relief of symptoms, prevention and control of disease leading to cardiac dysfunction, slowing disease progression, and improving quality and length of life.

Measures to prevent heart failure include cessation of smoking, alcohol, and illicit drugs, effective treatment of hypertension, diabetes and hypercholesterolaemia, and pharmacological therapy following MI.

The management of heart failure requires any factor involved in its aetiology to be identified and treated. Community nursing programs to help with drug compliance and detect early deterioration may prevent acute hospitalization.

General lifestyle advice

- ***Education.*** Effective counselling of patients and family, emphasizing weight monitoring and dose adjustment of diuretics, may prevent hospitalization. This is usually guided by primary care physicians and specialist community heart failure nurses.

- ***Dietary modification.*** Salt restriction is required, and foods rich in salt or salt added in cooking and at the table should be avoided. In severe heart failure fluid restriction is necessary and patients may need to weigh themselves daily. Alcohol has a negative inotropic effect and heart failure patients should moderate consumption.
- ***Smoking.*** Smoking should be stopped with help from anti-smoking clinics if necessary.
- ***Physical activity, exercise training, and rehabilitation.*** Low-level endurance exercise (e.g., 20–30 min walking 3–5 times per week or 20 min cycling at 70%–80% of peak heart rate 5 times per week) is actively encouraged in patients with compensated heart failure in order to reverse 'deconditioning' of peripheral muscle metabolism. Strenuous isometric activity should be avoided. For hospitalized patients with exacerbations of congestive cardiac failure, limiting activity reduces the demands on the heart; however, prolonged bed rest should be avoided, and consideration should be given to prophylaxis against venous thromboembolism in patients with reduced mobility.
- ***Vaccination.*** It is recommended that patients with heart failure be vaccinated against pneumococcal disease, influenza, and COVID-19.
- ***Sexual activity.*** Can be continued according to physical capabilities. Phosphodiesterase type 5 inhibitors (e.g., sildenafil) can be considered but are contraindicated in patients using nitrate medication as the combination may induce profound hypotension.
- ***Driving.*** Driving of cars and motorcycles may continue, provided that there are no symptoms that distract the driver's attention. Symptomatic heart failure or an LVEF of less than 40% disqualifies patients from holding a commercial driving license and driving large lorries and buses in the UK.

Monitoring

The clinical condition of a person with heart failure fluctuates; lengthy and repeated hospital admissions are common, with an average inpatient stay of between 5 and 10 days. Monitoring of clinical status is necessary and this responsibility should be shared between primary and secondary healthcare professionals.

Essential monitoring includes assessment of:

- functional capacity (e.g., NYHA functional class, exercise tolerance test, echocardiography)
- fluid status (body weight, clinical assessment, and serum creatinine and electrolytes)
- cardiac rhythm (ECG, Holter monitoring).

Multidisciplinary team approach

Heart failure care should be delivered by a multidisciplinary team with an integrated approach across the healthcare community. The team should involve specialist healthcare professionals: cardiologist or physician with a specialist interest in heart failure, heart failure nurse, dietician, pharmacist, occupational therapist, physiotherapist, and palliative care adviser. Understanding the information needs of patient and carers is vital. Good communication is essential for best clinical management and should include advice on anxiety, depression, and 'end-of-life' issues.

Drug management

Box 17.22 and **Fig. 17.52** show the treatment options. Four classes of medicine have been shown to reduce premature mortality and heart failure hospitalization in patients with heart failure with reduced EF (sometimes called the 'four pillars' of heart failure management):

- ***inhibitors of the renin–angiotensin system*** (ACE inhibitors, angiotensin receptor antagonists, or combined angiotensin receptor-neprilysin inhibitors)
- ***beta-blockers***
- ***aldosterone receptor antagonists*** (such as spironolactone or finerenone)
- ***sodium-glucose co-transporter 2 inhibitors***.

Systematic network meta-analysis has shown that patients with heart failure who are administered all four classes of agents benefit from a 73% reduction in all-cause mortality over 2 years. The guidelines also support the use of these agents in patients with heart failure with mildly reduced EF.

Prioritizing rapid simultaneous initiation of all four foundational therapies at low doses (Fig. 17.52) precedes individual drug dose optimization, as initiating a new drug class generally provides greater benefits than increasing the dose of existing medications. In the hospital setting, this can reduce absolute mortality risk by up to 25% over 1 year, compared to patients not receiving guideline directed therapy (STRONG-HF trial). This translates to a number needed to treat (NNT) of 4 to prevent one death.

Inhibitors of the renin–angiotensin system

Angiotensin-converting enzyme inhibitors

The use of ACE inhibitors in patients with heart failure has been demonstrated in multiple large randomized controlled trials (CONSENSUS, SOLVD) to improve symptoms and reduce mortality significantly. ACE inhibitors also benefit patients with asymptomatic heart failure following MI. Thus ACE inhibitors improve survival in patients in all functional classes (NYHA I–IV) and are recommended in all patients at risk of developing heart failure. The main adverse effects of ACE inhibitors are cough, hypotension, hyperkalaemia, and renal dysfunction. Contraindications to their use include bilateral renal artery stenosis, pregnancy, and previous angio-oedema. In patients with heart failure ACE inhibitors should be introduced at a low initial dose and gradually titrated, with regular monitoring of blood pressure and renal function.

Elevated creatinine is frequently cited as a reason not to start RAS receptor blockers in patients with heart failure due to concerns of these classes of drugs effecting a further deteriorating renal function. However, the STOP ACEi trial demonstrated that in chronic kidney disease patients with an estimated GFR of less than 30 mL/min/1.73 m^2, discontinuation of RAS did not impact the natural deterioration in estimated GFR over 3 years.

Angiotensin II receptor antagonists

The angiotensin II receptor antagonists (ARAs; candesartan, losartan, valsartan) are indicated as second-line therapy in patients intolerant of ACE inhibitors. Unlike ACE inhibitors, they do not affect bradykinin metabolism and do not produce a cough. The CHARM Alternative Trial showed that candesartan reduced the risk of heart failure hospitalization compared to placebo in patients intolerant of ACE inhibitors. Other trials (Val-HeFT and ELITE II) have assessed other ARAs. However, unlike ACE inhibitors ARAs have not been shown to reduce all-cause mortality in clinical trials.

Angiotensin receptor–neprilysin inhibitor

Angiotensin receptor–neprilysin inhibitors (ARNIs) are a new class of drug that produce dual inhibition of the angiotensin (AT_1) receptor and the natriuretic system. The PARADIGM-HF trial studied sacubitril/valsartan in patients with established symptomatic heart failure and reduced EF and demonstrated superiority over ACE inhibitor therapy in lowering morbidity and mortality. Symptomatic ambulatory patients who are on ACE inhibitors or ARA should be swapped to ARNIs. Patients on ACE inhibitors should have this drug discontinued at least 36 hours prior to commencement of ARNI to reduce the risk of angioedema. Further trial data (PIONEER-HF and TRANSITION) support the commencement of *de novo* ARNI in hospitalized patients with heart failure.

Box 17.22 Drugs used in heart failure

Drug	Dose (initial/maximum)	Precautions
Drugs blocking the renin-angiotensin system		
ACE inhibitors		
Captopril	6.25 mg ×3 daily/50 mg ×3 daily	
Enalapril	2.5 mg ×2 daily/10–20 mg ×2 daily	
Lisinopril	2.5–5 mg daily/20–40 mg daily	
Perindopril	2 mg daily/8–16 mg daily	
Ramipril	1.25–2.5 mg ×2 daily/5 mg ×2 daily	Monitor renal function and use with caution if baseline serum creatinine >250 μmol/L or baseline blood pressure <90 mmHg
ARAs		
Candesartan	4 mg daily/32 mg daily	
Losartan	50 mg daily/100 mg daily	
Valsartan	40 mg ×2 daily/160 mg ×2 daily	
ARNIs		
Angiotensin receptor neprilysin inhibitor Sacubitril/valsartan	24/26–49/51 mg ×2 daily/97/103 mg × daily	Monitor renal function, check for hyperkalaemia. Discontinue ACE inhibitor 3 days prior to starting, discontinue ARA the day of starting
Beta-adrenoceptor-blocking drugs		
Bisoprolol	1.25 mg daily/10 mg daily	Use with caution in obstructive airways disease, bradyarrhythmias
Carvedilol	3.125 mg ×2 daily/50 mg ×2 daily	Avoid in acute heart failure until patient is cardiovascularly stable
Metoprolol succinate (CR/XL)	12.5–25 mg daily/200 mg daily	
Nebivolol	1.25 mg daily/10 mg daily	
Aldosterone antagonists		
Eplerenone	25 mg daily/50 mg daily	
Spironolactone	12.5–25 mg daily/50 mg daily	Monitor renal function, check for hyperkalaemia, gynaecomastia with spironolactone
Sodium-glucose co-transporter 2 inhibitor (SGLT2i)		
Dapagliflozin	10 mg daily	Advise genital hygiene post urination to reduce risk of candida
Empagliflozin	10 mg daily	
Other drugs used in heart failure		
Diuretics		
Bendroflumethiazide	2.5 mg daily	Rarely need more than 2.5 mg daily. Reduced efficacy when eGFR<30 mL/min/1.73 m^2
Bumetanide	0.5–1.0 mg daily/5–10 mg daily	
Furosemide	20–40 mg daily/250–500 mg daily	Monitor renal function and check for hypokalaemia and hypomagnesaemia
Metolazone	2.5 mg daily/10 mg daily	Use in severe heart failure
Cardiac glycosides		
Digoxin	0.125–0.25 mg daily (reduce dose in elderly or in renal impairment)	Use with caution in renal impairment or conduction disease, and with amiodarone
Vasodilators		
Hydralazine	37.5–75 mg ×3 daily	
Isosorbide dinitrate	20–40 mg ×3 daily	
I_F *channel blocker*		
Ivabradine	5 mg daily/7.5 mg ×2 daily	Use with caution in sick sinus syndrome; AV block
Soluble guanylate cyclase inhibitor		
Vericiguat	2.5 mg/10 mg daily	

ACE, Angiotensin-converting enzyme; *ARA*, angiotensin II receptor antagonist; *AV*, atrioventricular.

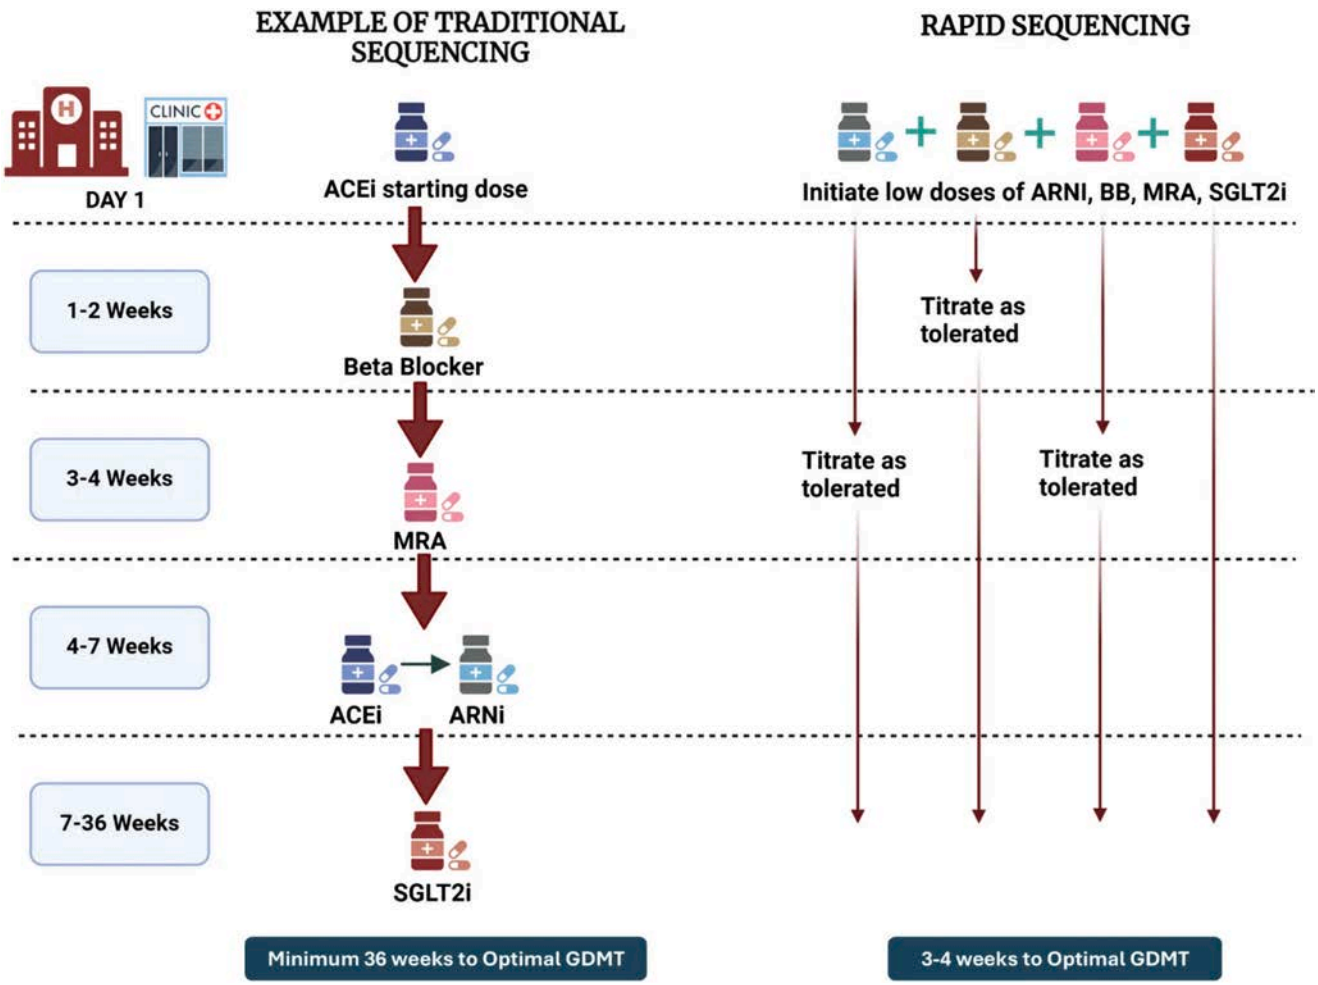

Fig. 17.52 Traditional versus rapid sequence initiation of guideline-directed medical therapy in heart failure with reduced ejection fraction. *(Shahid, I., Khan, M.S., Butler, J. et al. Initiation and sequencing of guideline-directed medical therapy for heart failure across the ejection fraction spectrum.* Heart Fail Rev *[2025]. https://doi.org/10.1007/s10741-025-10481-7.)*

Beta-blockers

Beta-blockers have been shown to improve functional status and reduce cardiovascular morbidity and mortality in patients with heart failure. Several trials (CIBIS II, MERIT-HF, COMET, SENIORS) have assessed the effects of beta-blockers in varying degrees of heart failure. Bisoprolol, carvedilol, and sustained-release metoprolol reduce mortality in heart failure. Nebivolol is used in the treatment of stable mild to moderate heart failure in patients over 70 years old. In practice, beta-blockers are started once a patient is euvolaemic at a low dose and gradually increased, with monitoring of heart rate and blood pressure.

Aldosterone antagonists

The aldosterone antagonists spironolactone and eplerenone have been shown to improve survival in patients with symptomatic heart failure. In the RALES study spironolactone reduced total mortality by 30% in severe heart failure. However, gynaecomastia or breast pain occurred in 1 in 10 men taking spironolactone. In EPHESUS eplerenone given to patients with an acute MI and heart failure reduced total mortality by 15% and sudden cardiac death by 21%, with no gynaecomastia.

Sodium-glucose co-transporter 2 inhibitors

Sodium-glucose co-transporter 2 inhibitors (SGLT2i) reduce the risk of heart failure admission and cardiovascular mortality (DAPA-HF, EMPEROR-reduced and SOLOIST-WHF). This class of drug, though initially used in the management of diabetes, is now widely accepted as a prognosis-altering heart failure medication that can be used in the absence of diabetes. SGLT2i are the only drugs that reduce the risk of heart failure hospitalization and cardiovascular mortality in patients with heart failure with preserved ejection fraction (HFPEF). Patients should be counselled about hygiene post urination to reduce the risk of genital candida. This drug should be withheld in situations of prolonged fasting to reduce the risk of euglycaemic ketoacidosis.

Other medication used in heart failure

The following agents lack the clear prognostic benefits for the four classes of agents above but may still have benefit in selected patients.

Diuretics

These act by promoting the renal excretion of salt and water by blocking tubular reabsorption of sodium and chloride (see Chapter 26). Loop diuretics (e.g., furosemide and bumetanide) should be given in patients with fluid overload. Although diuretics provide symptomatic relief of dyspnoea and improve exercise tolerance, there is limited evidence (due to lack of a clinical trial) that they affect survival. In patients with severe heart failure the combination of a loop and thiazide/thiazide-type diuretic (e.g., bendroflumethiazide, metolazone) may be required. There is emerging data for the use of acetazolamide (carbonic anhydrase inhibitor) or tolvaptan

(vasopressin receptor antagonist) as an add-on therapy to loop diuretics in acute decompensated heart failure. Serum electrolytes and renal function must be monitored regularly (risk of hypokalaemia and hypomagnesaemia).

Cardiac glycosides

Digoxin is a cardiac glycoside that is indicated in patients with atrial fibrillation with heart failure. Although the DIG study demonstrated that digoxin reduced hospital admissions in patients with heart failure, a subanalysis in the ROCKET AF trial suggested that mortality may, in fact, be increased. It is now infrequently used as add-on therapy in symptomatic heart failure patients already receiving ACE inhibitors and beta-blockers. If it is used, digoxin levels (6 hours post dose) should be measured, with the knowledge that a concentration of more than 1 ng/mL is associated with excess mortality.

Vasodilators and nitrates

The combination of hydralazine and nitrates reduces preload and afterload and is used in patients intolerant of ACE inhibitors or ARAs. The Veterans Administration Cooperative Study demonstrated that it improved survival in patients with CHF. The A-HeFT trial showed that the same combination reduced mortality and hospitalization for heart failure in black patients with heart failure.

Ivabradine

Ivabradine selectively decreases heart rate without affecting blood pressure by inhibiting the I_F channels in the SA node. An elevated heart rate in patients with heart failure is associated with worse cardiovascular outcomes; in the first instance it is important to exclude fluid overload. The SHIFT study reported a reduction in cardiovascular death and heart failure hospitalization in patients in sinus rhythm with CHF and left ventricular dysfunction (LVEF ≤ 35%). Ivabradine can be used in patients in sinus rhythm with a heart rate of more than 70 beats per minute despite beta-blocker treatment or in those who are unable to tolerate beta-blockers.

Vericiguat

Vericiguat is a stimulator of soluble guanylate cyclase and increases the functionality of nitric oxide, causing vasodilation, reduction in inflammation, and subsequent improvement in cardiac and vascular function. In the VICTORIA study, in patients with an EF of less than 45% and a recent decompensation requiring intravenous diuretics, vericiguat, as compared to placebo, reduced the frequency of heart failure hospitalizations but had no effect on mortality. The drug was also associated with a slightly higher incidence of anaemia and symptomatic hypotension.

Intravenous iron

Iron deficiency is common in heart failure and is multifactorial. Oral iron substitution is ineffective due to ineffective absorption in heart failure and hepcidin block (see Fig. 38.11). Multiple studies (IRONMAN, AFFIRM-AHF) have shown that intravenous iron therapy improves symptoms and quality of life irrespective of the presence of anaemia in patients with heart failure and reduced or mildly reduced EF and iron deficiency (transferrin saturation <20% or serum ferritin <100 μg/L).

Inotropic and vasopressor agents

Intravenous inotropes and vasopressor agents (see **Box 17.29**) are used in patients with AHF or cardiogenic shock (see Chapter 13, 'Cardiogenic shock' section). They have a limited role in the management of CHF and in this context are restricted to bridging therapy while awaiting heart transplantation.

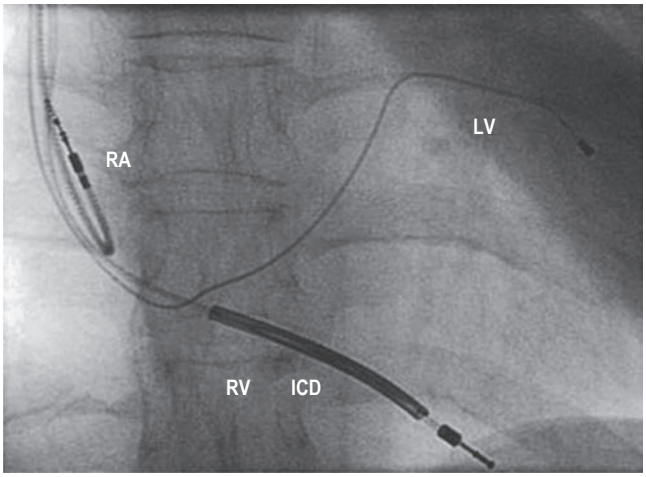

Fig. 17.53 Implanted biventricular pacemaker with implantable cardioverter–defibrillator device (CRT-D). *LV,* Left ventricle; *RA,* right atrium; *RV,* right ventricle.

Non-pharmacological treatment

Cardiac resynchronization therapy or implantable cardioverter–defibrillator

Cardiac resynchronization therapy (CRT) entails simultaneous pacing of both ventricles (biventricular pacing) using a lead placed in the right ventricle and another in the coronary sinus to pace the left ventricle (**Fig. 17.53**). It is an effective therapy in addition to optimal tolerated medical treatment in patients with significant left ventricular impairment and a prolonged QRS interval (data supporting benefit is predominately in patients with LBBB). Resynchronization may reverse the process of ventricular remodelling, reduce functional mitral regurgitation, and improve left ventricular function. The CARE-HF and COMPANION trials reported symptomatic benefit and a reduction in heart failure events and mortality following CRT implantation in patients with heart failure in NYHA classes III and IV. Similar findings have been noted in more recent trials in patients with mild heart failure or no symptoms (RAFT, MADIT-CRT). Resynchronization is now also attempted with conduction system pacing.

Most patients with heart failure who receive CRT also meet the criteria for use of an ICD and could receive a combined device (CRT-D, 'D' denoting 'defibrillator'). Patients with end-stage heart failure (NYHA IV) or other co-morbidities that may significantly reduce lifespan are generally not candidates for an ICD.

Ablation

There is increasing evidence that catheter ablation to achieve sinus rhythm in patients with atrial fibrillation/flutter is effective in reducing risk of death or worsening heart failure compared to placebo in patients with an EF of less than 35% (CASTLE-AF).

In patients with frequent ventricular ectopics (>10% burden) and impaired systolic burden, catheter ablation to reduce the burden of ectopics can improve cardiac function.

Revascularization

While CAD is the most common cause of heart failure, the role of revascularization in patients with heart failure is unclear. Patients with angina and left ventricular dysfunction have a higher mortality from surgery (10%–20%) but have the most to gain in terms of improved symptoms and prognosis. Factors that must be considered before recommending surgery include symptoms, age, co-morbidities, and evidence of reversible myocardial ischaemia.

Hibernating myocardium and myocardial stunning

'Hibernating' myocardium can be defined as reversible left ventricular dysfunction due to chronic CAD that responds positively to inotropic stress and indicates the presence of viable heart muscle that may recover after revascularization. It is caused by reduced myocardial perfusion, which is just sufficient to maintain viability of the heart muscle. Myocardial hibernation results from repetitive episodes of cardiac stunning that occur, for example, with repeated exercise in a patient with CAD.

Myocardial stunning is reversible ventricular dysfunction that persists following an episode of ischaemia when the blood flow has returned to normal: that is, there is a mismatch between flow and function.

The prevalence of hibernating myocardium in patients with CAD can be estimated from the frequency of improvement in regional abnormalities in wall motion after revascularization. Techniques to try to identify hibernating myocardium include stress echocardiography, nuclear imaging, CMR, and PET.

The clinical relevance of the hibernating and stunned myocardium is that ventricular dysfunction due to these mechanisms may be wrongly ascribed to myocardial necrosis and scarring, which seems untreatable, whereas reversible hibernating and stunned myocardium respond to coronary revascularization.

The evidence supporting revascularization as a treatment for patients with heart failure and reduced ejection in the absence of angina or ACS is very limited (REVIVED-BCIS2).

Advanced heart failure

Advanced heart failure therapies comprise both cardiac transplantation and durable mechanical circulatory supports (or ventricular assist devices).

Cardiac transplantation

Cardiac transplantation is the treatment of choice for younger patients with severe intractable heart failure. Identifying patients who might benefit from advanced heart failure treatments is challenging and the acronym '*I NEED HELP*' in **Box 17.23** may help. With careful recipient selection, the expected 1-year survival for patients following transplantation is over 90%, and median survival is 14 years. Irrespective of survival, quality of life is dramatically improved for the majority. The availability of organs for heart transplantation is limited.

Heart allografts do not function normally (but are still better than a severely diseased one), as cardiac denervation results in a high resting heart rate, loss of diurnal blood pressure variation, and impaired renin–angiotensin–aldosterone regulation. Some patients develop a 'stiff heart' syndrome, caused by rejection, denervation, and ischaemic injury during organ harvest and implantation.

The complications of heart transplantation are summarized in **Box 17.24**. Many (infection, malignancy, hypertension, and hyperlipidaemia) are related to immunosuppression. Allograft coronary atherosclerosis is the major cause of long-term graft failure and is present in 30% to 50% of patients at 5 years. It is due to a 'vascular' rejection process in conjunction with hypertension and hyperlipidaemia.

There are specific contraindications to cardiac transplantation (**Box 17.25**); notably, high pulmonary vascular resistance (PVR) and active malignancy are absolute contraindications.

Durable ventricular assist devices

Ventricular assist devices (VADs) are mechanical systems that replace or help the failing ventricles in delivering blood around the body and are powered by a driveline that exits the abdomen. The Heartmate 3™ (Abbott) is currently the main left ventricular assist device (LVAD) by market share (**Fig. 17.54**); it receives blood from the left ventricle and delivers it to the aorta in a continuous, non-pulsatile flow; these devices can also be implanted to receive blood from the right atrium and deliver it to the pulmonary artery, effectively a right ventricular assist device (RVAD). The Syncardia Total Artificial Heart™ has independently pumping right and left chambers that are surgically implanted in the place of the existing ventricles and deliver total cardiac support with pulsatile flow. Both devices are intracorporeal (suitable for long-term support as a bridge to transplantation or in some countries as destination therapy in patients with end-stage heart failure who are not candidates for transplantation). The main problems with VADs include thromboembolism, bleeding, infection, and device malfunction.

Box 17.23 Acronym for clinical indicators that should trigger possible referral to an advanced heart failure unit: I NEED HELP

I Intravenous inotropes (previous or on-going)
N New York Heart Association (NYHA) class IIIb to IV or persistently elevated natriuretic peptides
E End-organ dysfunction (worsening renal or liver dysfunction)
E EF ≤20%
D Defibrillator shocks (recent appropriate shocks)
H Hospitalizations (>1 in the last 12 months)
E Oedema despite escalating diuretics
L Low systolic BP (≤90 mmHg)
P Prognostic medication (progressive intolerance or down-titration of GDMT)

(Adapted from Baumwol J 'I Need Help'—A mnemonic to aid timely referral in advanced heart failure. J Heart Lung Transplant *2017;36:593-594.)*

Box 17.24 Complications of cardiac transplantation

- Allograft rejection:
  - 'Humoral'
  - 'Vascular'
  - 'Cell-mediated'
- Infections:
  - Early: hospital-acquired organisms—staphylococci; Gram-negative bacteria
  - Late (2–6 months): opportunistic (toxoplasmosis, cytomegalovirus, fungi, *Pneumocystis*)
- Allograft vascular disease
- Hypertension
- Hypercholesterolaemia
- Malignancy

Box 17.25 Contraindications to cardiac transplantation

- Age >60 years (some variations between centres)
- Alcohol/drug misuse
- Uncontrolled psychiatric illness
- Uncontrolled infection
- Severe renal/liver failure
- High pulmonary vascular resistance
- Systemic disease with multiorgan involvement
- Treated cancer in remission but with <5 years' follow-up
- Recent thromboembolism
- Other disease with a poor prognosis

CORONARY ARTERY DISEASE

Coronary artery disease (CAD) is the largest single cause of death in Europe, the USA, and many other parts of the world. It is estimated that 2.3 million people in the UK are living with coronary heart disease. Cardiovascular diseases were responsible for 168 030 deaths

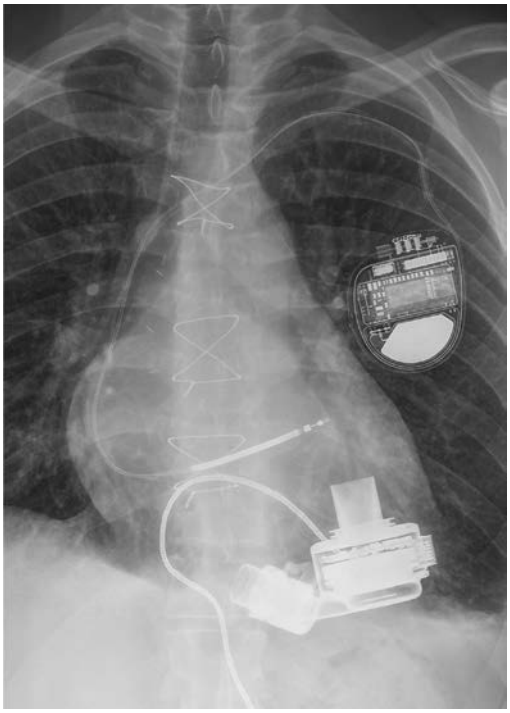

Fig 17.54 Radiograph of a HeartMate 3 left ventricular assist device.

in the UK, with 1 in 8 men and 1 in 14 women dying from coronary heart disease. This equates to one person dying from coronary heart disease every 8 minutes.

Myocardial ischaemia occurs when there is an imbalance between the supply of oxygen (and other essential myocardial nutrients) and the myocardial demand for these substances.

Coronary blood flow to a region of the myocardium may be reduced by a mechanical obstruction that is due to:

- atheroma
- thrombosis
- spasm
- embolus
- coronary ostial stenosis (seen after cardiac surgery)
- coronary arteritis (e.g., in systemic lupus erythematosus).

Myocardial ischaemia can also be caused or exacerbated by a decrease in the flow of oxygenated blood to the myocardium due to:

- anaemia
- carboxyhaemoglobulinaemia
- hypotension, causing decreased coronary perfusion pressure.

A higher demand for oxygen may cause myocardial ischaemia due to an increase in cardiac output (e.g., thyrotoxicosis) or myocardial hypertrophy (e.g., from aortic stenosis or hypertension).

Myocardial ischaemia most commonly arises as a result of obstructive CAD in the form of coronary atherosclerosis. In addition to this fixed obstruction, variations in the tone of smooth muscle in the wall of a coronary artery may add another element of dynamic or variable obstruction.

Pathophysiology of coronary atherosclerosis

Coronary atherosclerosis is a complex inflammatory process characterized by the accumulation of lipid, macrophages, and smooth muscle cells in intimal plaques in the large and medium-sized epicardial coronary arteries. The vascular endothelium plays a critical role in maintaining vascular integrity and homeostasis. Mechanical shear stresses (e.g., from hypertension), biochemical abnormalities (e.g., elevated low-density lipoprotein [LDL] or diabetes mellitus), immunological factors (e.g., free radicals from smoking), inflammation, and genetic alteration may contribute to the initial endothelial 'injury' or dysfunction, which is believed to trigger atherogenesis.

The ***development of atherosclerosis*** follows endothelial dysfunction, with increased permeability to and accumulation of oxidized lipoproteins, which are taken up by macrophages at focal sites within the endothelium to produce lipid-laden foam cells. Macroscopically, these lesions are seen as flat yellow dots or lines on the endothelium of the artery and are known as ***'fatty streaks'***. The 'fatty streak' progresses with the appearance of extracellular lipid within the endothelium ***('transitional plaque')***. Release of cytokines, such as platelet-derived growth factor and transforming growth factor beta (TGF-β), by monocytes, macrophages, or the damaged endothelium promotes further accumulation of macrophages, as well as smooth muscle cell migration and proliferation. The proliferation of smooth muscle with the formation of a layer of cells covering the extracellular lipid separates it from the adaptive smooth muscle thickening in the endothelium. Collagen is produced in larger and larger quantities by the smooth muscle and the whole sequence of events cumulates as an '***advanced*** or ***raised fibrolipid plaque***'. The 'advanced plaque' may grow slowly and encroach on the lumen or become unstable, undergo thrombosis, and produce an obstruction ***('complicated plaque')***.

Two different mechanisms are responsible for thrombosis on the plaques (Fig. 17.55):

- ***The first process*** is superficial endothelial injury, which involves denudation of the endothelial lining of the plaque. Subendocardial connective tissue matrix is then exposed and platelet adhesion occurs because of reaction with collagen. The thrombus is adherent to the surface of the plaque.
- ***The second process*** is deep endothelial fissuring, which involves an advanced plaque with a lipid core. The plaque cap tears (ulcerates, fissures or ruptures), allowing blood from the lumen to enter the inside of the plaque itself. The plaque core contains lamellar lipid surfaces, tissue factor (which triggers platelet adhesion and activation) produced by macrophages, and exposed collagen, which are highly thrombogenic. Thrombus forms within the plaque, expanding its volume and distorting its shape. Thrombosis may then extend into the lumen.

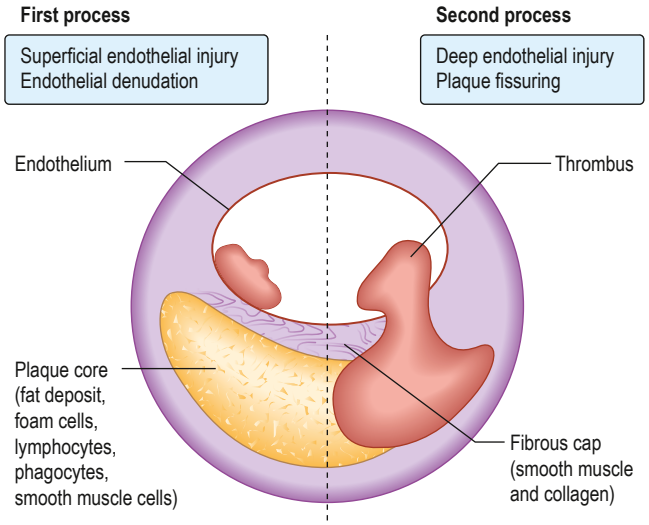

Fig. 17.55 Mechanisms underlying the development of thrombosis on plaques.

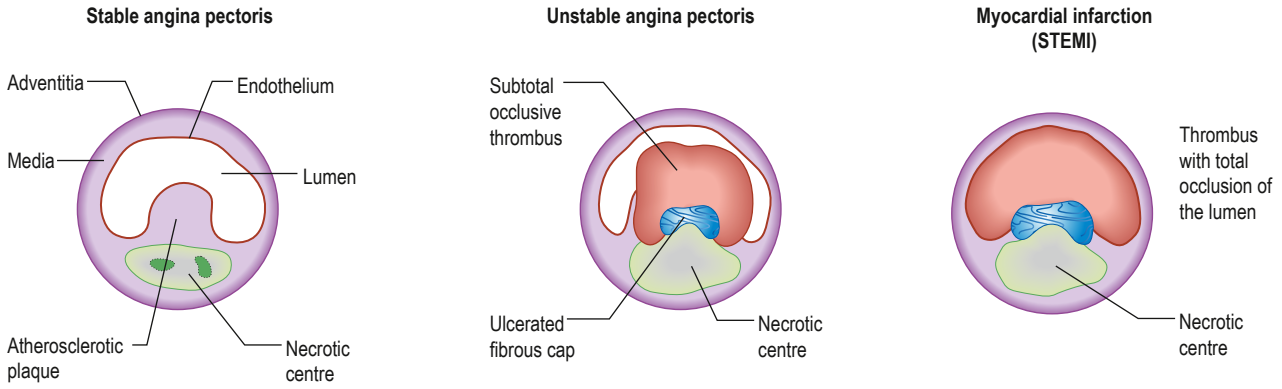

Fig. 17.56 Mechanisms underlying the development of thrombosis on plaques in various clinical syndromes. Relationship between the state of the coronary artery vessel wall and the various syndromes. *STEMI,* ST-elevation myocardial infarction.

A 50% reduction in luminal diameter (producing a reduction in luminal cross-sectional area of approximately 70%) causes a haemodynamically significant stenosis. At this point, coronary autoregulation through dilatation of the distal arterioles maintains adequate resting blood flow to the myocardium, but any further increase in myocardial oxygen demand would provoke ischaemia.

CAD gives rise to a wide variety of clinical presentations, ranging from relatively stable angina through to the ACSs of unstable angina (UA) and MI (Fig. 17.56). Fig. 17.57 shows a plaque rupture.

Risk factors for coronary artery disease

CAD is an atherosclerotic disease that is multifactorial in origin, giving rise to the risk factor concept. Certain living habits promote atherogenic traits in genetically susceptible persons, and more than 90% of coronary heart disease events will occur in individuals with at least one 'risk' factor (Box 17.26). Some of these, such as age, gender, race, and family history, cannot be modified, whereas other major risk factors, such as serum cholesterol, smoking habits, diabetes, and hypertension, can.

Atherosclerotic disease manifest in one vascular bed is often advanced in other territories. Patients with peripheral vascular disease (intermittent claudication) have a two- to fourfold increased risk of CAD, stroke, or heart failure. After a first MI, there is a three- to sixfold increase in the risk of heart failure and stroke. After stroke, the risk of heart failure and MI is increased twofold, and following a diagnosis of heart failure, risk of stroke is increased two- to threefold.

The disease can be asymptomatic even in its most severe form, with 1 in 3 MIs going unrecognized. Some 30% to 40% of individuals who present with an ACS have had no prior warning symptoms to suggest the presence of underlying disease.

Diagnosis

Cardiovascular risk assessment for primary and secondary prevention of cardiovascular disease

Primary prevention can be defined as prevention of the atherosclerotic disease process and ***secondary prevention*** as treatment of the atherosclerotic disease process (i.e., treatment of the disease or its complications). The objective of prevention is to reduce the incidence of first or recurrent clinical events due to CAD, ischaemic stroke, and peripheral artery disease.

In the UK, NICE guidelines recommend that primary care should use the QRISK®3 risk assessment tool (see Further reading) to identify people who are likely to be at high risk (10-year risk of cardiovascular disease ≥10%).

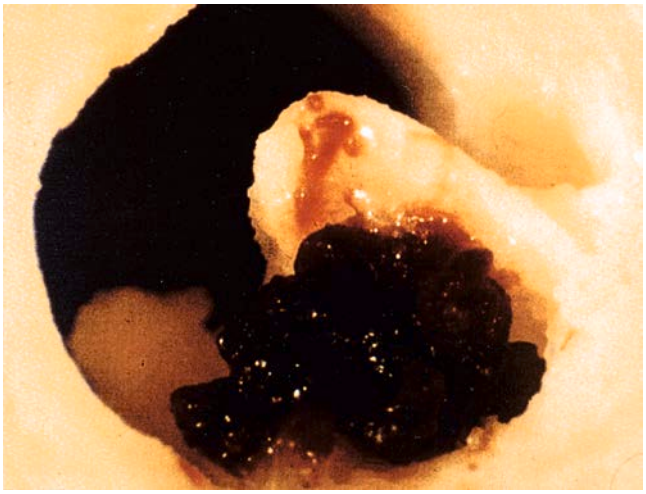

Fig. 17.57 Acute coronary thrombus. Cross-section (×30) of the epicardial coronary artery, demonstrating a rupture of the shoulder region of the plaque with a luminal thrombus.

Box 17.26 Risk factors for coronary disease

Fixed
- Age
- Male sex
- Positive family history
- Deletion polymorphism in the angiotensin-converting enzyme *(ACE)* gene (DD)

Potentially changeable
- Hyperlipidaemia
- Cigarette smoking
- Hypertension
- Diabetes mellitus
- Sedentary lifestyle
- Blood coagulation factors—high fibrinogen, factor VII
- Elevated C-reactive protein
- Homocysteinaemia
- Obesity
- Gout
- Soft water
- Drugs, e.g., contraceptive pill, nucleoside analogues, cyclo-oxygenase 2 (COX-2) inhibitors, rosiglitazone
- Heavy alcohol consumption

Lipids

A full lipid profile should be obtained, including total cholesterol, high-density lipoprotein (HDL) cholesterol, non-HDL cholesterol, and triglyceride concentrations. Total cholesterol concentration of more than 7.5 mmol/L and a family history of premature coronary heart disease may have ***familial hypercholesterolaemia***; in the UK those with a QRISK®3 score of more than 10% should be offered statin therapy regardless of their serum cholesterol (see Chapter 19, 'Risk prediction tables' section).

Lifestyle modifications

It is recommended that patients should eat a healthy, balanced diet with at least five portions of fruit and vegetables per day, ideally varying the type of fruit that is eaten, along with unsalted nuts, seeds, and legumes. Processed and ultra-processed foods should be minimized, as they contain fewer nutrients and fibre but more energy than whole foods. With each 10% increase in daily intake of ultra-processed food, there is a 6% increase in heart disease risk. Similarly, foods high in sugar or containing refined sugars such as fructose should be avoided, as should sugar-sweetened beverages, which contain a significant number of calories but are of limited nutritional benefit. Animal-based foods, particularly red meat and processed meats, are linked with a higher risk of cardiovascular disease, whereas fish intake is associated with a lower risk. At least two portions of fish weekly are recommended, one of which should be oily (e.g., sardines, salmon). Food containing trans fatty acids (TFAs) should be avoided and those with saturated fatty acids (SFAs) should preferably be replaced by polyunsaturated fatty acids (rapeseed and olive oils) to lower CVD risk.

Eating habits, however, are difficult to influence, and change via transformation of the whole food system, from production to consumption, is required with government legislation. For example, sugar taxes have now been introduced by various countries and have been shown to have a meaningful impact.

Regular exercise reduces blood pressure and has favourable effects on lipid profile. It has been shown to reduce cardiovascular events and death. The weekly exercise recommendations are 150 minutes or more of moderate-intensity aerobic activity or 75 minutes of vigorous-intensity aerobic activity. Weight/body mass index (BMI) should be less than 25 kg/m^2 (see Chapter 37).

In the UK the recommendation is not to drink more than 14 units of alcohol per week (men and women), ideally spread evenly over 3 or more days, and smoking should be discontinued. Blood pressure and diabetes should be managed according to guidelines (see Chapter 18).

Statin treatment

NICE guidance recommends atorvastatin 20 mg for the primary prevention of cardiovascular disease in people with a 10-year risk of cardiovascular disease of 10% or higher if lifestyle modification is ineffective or inappropriate. In patients with established cardiovascular disease atorvastatin 80 mg is recommended, unless there are potential drug interactions, a high risk of adverse effects, or a different patient preference.

ANGINA

Myocardial ischaemia in patients with stable CAD occurs when there is a mismatch between blood supply and metabolic demand. This results in cardiac ischaemic pain or angina and ST–T changes on the 12-lead ECG and may cause regional wall motion abnormalities on echocardiography. Ischaemic metabolites, including adenosine, stimulate nerve endings and produce pain.

Epidemiology

The prevalence of angina increases with age in both sexes: in women it is 5% to 7% at 45 to 64 years as opposed to 10% to 12% at 65 to 84 years, while in men it is 4% to 7% at 45 to 64 years as opposed to 12% to 14% at 65 to 84 years. The annual mortality rate ranges from 1.2% to 2.4% and there is an annual incidence of cardiac death of 0.6% to 1.4%.

Diagnosis

The diagnosis of angina is largely based on the clinical history.

- ***Classical angina*** or ***typical angina*** is characterized by chest pain, which is usually predictable and reproducible:
  - 'Heavy', 'tight', 'constricting', or 'gripping' central or retrosternal discomfort that may radiate to the jaw and/or arms.
  - Pain occurs with exercise or emotional stress or may be exacerbated by the cold.
  - Pain eases rapidly with rest or with GTN.
- ***Atypical angina*** is described as chest pain with 2 out of 3 of the features above.
- ***Non-angina chest pain*** is described as chest pain with 1 out of 3 of the features above. Contemporary data now suggest that only 15% of patients suspected of having CAD present with typical symptoms.
- ***Stable angina*** can be classified according to the Canadian Cardiovascular Society guidelines (**Box 17.27**).
- ***Unstable angina*** refers to angina of recent onset (<24 h) or deterioration in previous stable angina, with symptoms frequently occurring at rest. The utilization of high-sensitivity troponins has transformed the diagnosis of patients who previously would have been labelled as having UA to having an NSTEMI in most cases.
- ***Refractory angina*** refers to patients with severe coronary disease in whom revascularization is not possible and angina is not controlled by medical therapy.
- ***Vasospastic*** or ***variant (Prinzmetal's) angina*** refers to angina that occurs without provocation, usually at rest, as a result of coronary artery spasm. It occurs more frequently in women. Characteristically, there is ST-segment elevation on the ECG during the pain.
- ***Microvascular angina*** patients have exercise-induced angina but normal or unobstructed coronary arteries (on coronary angiography, CTCA). Intracoronary acetylcholine may cause coronary spasm. While they have a good prognosis, they are often highly symptomatic and can be difficult to treat. In women with this syndrome the myocardium shows an abnormal metabolic response to stress, consistent with the suggestion that the myocardial ischaemia results from abnormal dilator responses of the coronary microvasculature to stress.

Examination

There are usually no abnormal findings in angina. Signs to suggest anaemia, thyrotoxicosis, or hyperlipidaemia (e.g., lipid arcus,

Box 17.27 Canadian Cardiovascular Society functional classification of angina

Class	Description
Class I	No angina with ordinary activity; angina with strenuous activity
Class II	Angina during ordinary activity, e.g., walking up hills, walking rapidly upstairs, with mild limitation of activities
Class III	Angina with low levels of activity, e.g., walking 50–100 m on the flat, walking up one flight of stairs, with marked restriction of activities
Class IV	Angina at rest or with any level of exercise

xanthelasma, tendon xanthoma) should be sought. It is essential to exclude aortic stenosis (i.e., slow-rising carotid impulse and ejection systolic murmur radiating to the neck) as a possible cause of the angina. The blood pressure should be taken to identify coexistent hypertension. BMI or waist circumference should be measured.

Investigations

Patients with suspected angina should have initial investigations (Box 17.28). The diagnosis of stable angina can be made on clinical assessment alone *or* by clinical assessment combined with anatomical (cardiac catheterization or CTCA) or functional imaging (SPECT, stress echocardiography, stress MRI).

Patients *without known CAD* presenting with chest pain can be categorized as having typical angina, atypical angina, or non-anginal chest pain.

- Patients with typical or atypical angina or patients with non-anginal chest pain but with ST changes or Q waves should be referred for CTCA.
- If the results from CTCA are inconclusive, the patient should be referred for non-invasive functional tests (SPECT, stress echocardiography, stress MRI).
- Patients with ***non-anginal chest pain*** (e.g., if the pain is continuous, unrelated to exertion, exacerbated by respiration, or associated with dizziness, palpitations, or difficulty in swallowing), where the ECG and cardiac biomarkers are normal, should be considered for alternative diagnoses and investigated appropriately.
- It is important to note that up to 30% of ACS presentations can have very atypical or non-anginal symptoms, particularly in women.

Box 17.28 Initial investigations in stable angina

Laboratory tests
- Full blood count
- Thyroid function tests
- Fasting glucose
- HbA_{1c}
- Fasting lipid profile
- Glomerular filtration rate
- Troponin if unstable

12-Lead ECG
- Exclude coronary syndrome, pathological Q waves, left ventricular hypertrophy, left bundle branch block

Echocardiography
- Regional wall motion abnormalities
- Left ventricular ejection fraction
- Diastolic function
- Alternative causes of chest pain

Ambulatory ECG
- Paroxysmal arrhythmia
- Vasospastic angina

Chest X-ray
- Atypical presentation
- Pulmonary disease
- Heart failure

Management of stable angina

Patients should be informed of the nature of their condition and reassured that the prognosis is good (annual mortality <2%). Lifestyle management should be instigated, as for prevention of CAD. The stable angina algorithm in Fig. 17.58 should be used to guide initial patient management, while Box 17.29 outlines pharmacological therapy.

Revascularization

Revascularization with PCI or coronary artery bypass surgery is indicated for patients with on-going angina symptoms despite appropriate medical therapy and/or to improve prognosis.

Percutaneous coronary intervention

PCI is the process of dilating a coronary artery stenosis by introducing an inflatable balloon and metallic stent (Fig. 17.59) into the arterial circulation via the femoral, radial, or brachial artery (Fig. 17.60); the radial artery is the best (see later).

- Fractional flow reserve (FFR) is an invasive intracoronary measurement that can be used to assess the haemodynamic significance of a coronary stenosis prior to PCI using intracoronary adenosine. A normal FFR value is 1, and values less than 0.80 are associated with ischaemia, while if greater than 0.8, medical treatment (i.e., no stent) is associated with improved patient outcomes.
- PCI can also be guided by IVUS and optical coherence tomography (OCT) to assess coronary lesions both before and after angioplasty.

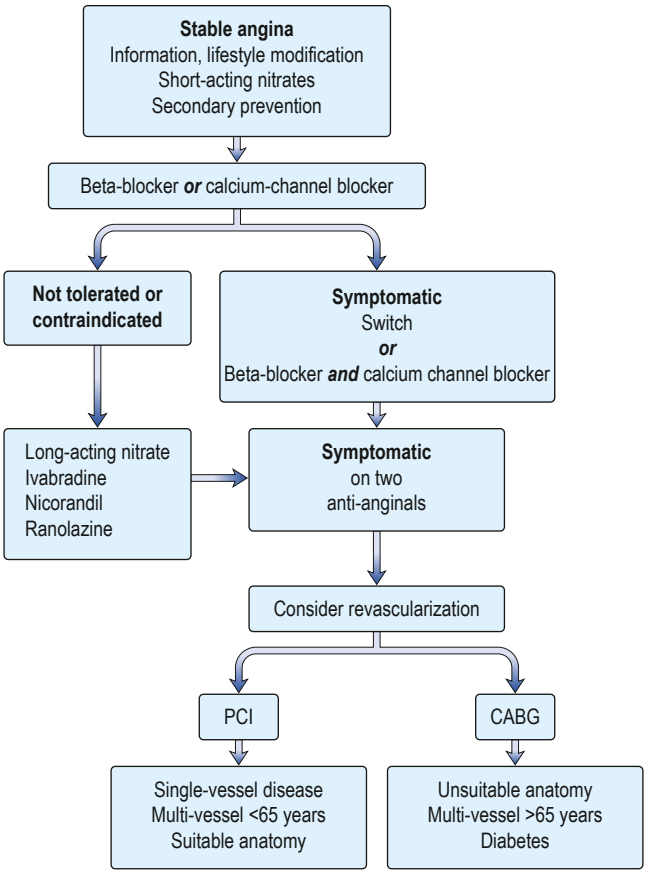

Fig. 17.58 Algorithm for treatment of patients with stable angina. *CABG,* Coronary artery bypass grafting; *PCI,* percutaneous coronary intervention. *(From National Institute for Health and Care Excellence. Clinical Guideline CG126L: Management of Stable Angina. NICE July 2011, with permission.)*

- Adjunct tools that can be used in PCI to treat highly calcified lesions include cutting balloon, laser atherectomy, rotational atherectomy, and intravascular lithotripsy.

Complications of PCI include bleeding, haematoma, dissection, and pseudo-aneurysm from the arterial puncture site, although use of the radial artery reduces these risks and is the standard technique in the UK. Serious complications include acute MI (2%), stroke (0.4%), and death (1%).

Bare metal stents (BMSs) are associated with a 20% to 30% risk of coronary artery restenosis within 6 to 9 months of

Box 17.29 Pharmacological therapy in stable angina

Drug	Dose	Indications/mechanism of action/cautions
Vasodilators		
Glyceryl trinitrate	0.3–1.0 mg sublingual 2.0–3.0 mg buccal	Prophylaxis and treatment of angina—rapid onset Repeat after 5 min if symptomatic Vasodilation (causes headache and flushing)
Isosorbide mononitrate	10–60 mg ×2 daily (slow-release preparations available)	Prophylaxis of angina Side-effects—headache and flushing Contraindicated with phosphodiesterase type 5 inhibitors
Beta-blocker		
Bisoprolol	2.5–10 mg daily	Inhibits β-adrenoceptors, reduces heart rate and BP, reduces myocardial oxygen consumption Caution—COPD, acute heart failure, AV conduction Side-effects—fatigue, peripheral vasoconstriction (cold peripheries), sexual dysfunction, bronchospasm
Calcium-channel blockers		
Verapamil (phenylalkylamines)	80–120 mg ×3 daily (or 240–480 mg daily slow-release)	Inhibit calcium channels in myocardium, cardiac conductive tissue, and vascular smooth muscle Diltiazem and verapamil—contraindicated in severe bradycardia, left ventricular failure with pulmonary congestion, second- or third-degree AV block Side-effects—constipation (verapamil), ankle oedema (amlodipine, diltiazem), reflex tachycardia (amlodipine)
Diltiazem (benzothiazepines)	60–120 mg ×3 daily (longer-acting preparations available)	
Amlodipine (dihydropyridines)	5–10 mg daily	
Other anti-anginal drugs		
Ivabradine	2.5–7.5 mg ×2 daily	Inhibits pacemaker I_f current in SA node Use in sinus rhythm ± beta-blocker Side-effects—bradycardia, phosphenes Contraindications—sick sinus syndrome, AV block
Nicorandil	5–30 mg ×2 daily	Activates ATP-sensitive potassium channels and has nitrate properties—peripheral and coronary vasodilation Use as adjunctive therapy Side-effects—headache, flushing, oral ulceration
Ranolazine	375–750 mg ×2 daily	Inhibits late sodium channels into cardiac cells Use as adjunctive therapy Metabolized by cytochrome P450 3A4 Side-effects—constipation, dizziness, lengthened QT
Event-reducing drugs		
Antiplatelet	Aspirin 75–100 mg daily	Reversible inhibition of platelet COX-1 and thromboxane production
	Clopidogrel 75 mg daily	Thienopyridine that antagonizes platelet ADP receptor P2Y12. Use in aspirin intolerance
ACE inhibitor or ARB	Enalapril 10 mg daily	Indicated if treating other condition, e.g., hypertension, heart failure, chronic kidney disease
Statins	Atorvastatin 80 mg daily	Use to reduce LDL cholesterol to <1.8 mmol/L

ACE, Angiotensin-converting enzyme; *ADP,* adenosine diphosphate; *ARB,* angiotensin receptor blocker; *ATP,* adenosine triphosphate; *AV,* atrioventricular; *BP,* blood pressure; *COPD,* chronic obstructive pulmonary disease; *COX-1,* cyclo-oxygenase-1; *LDL,* low-density lipoprotein; *SA,* sinoatrial.

implantation and are now infrequently used. First-generation ***drug-eluting stents*** (DESs) with ***sirolimus*** and ***paclitaxel*** reduced restenosis but suffered from late and very late stent thrombosis. Second-generation DESs (with thinner struts and biodegradable or biocompatible polymers) demonstrated better safety and efficacy and are recommended for most patients. BMSs may be preferred in patients requiring early non-cardiac surgery or who have active bleeding at the time of PCI or significant future bleeding risk on antiplatelet therapy. An alternative is the use of drug-eluting balloons (DEBs) which can be used to expand lesions while delivering antiproliferative agents locally, suppressing neointimal hyperplasia. These can be used in smaller coronary vessels which may not be amenable to stenting and also lessen the duration of dual antiplatelet therapy, which is particularly helpful in patients predisposed to bleeding. Dual antiplatelet therapy (aspirin and a P2Y12 inhibitor, e.g., clopidogrel) should continue for 6 to 12 months, and most patients will then continue on a single antiplatelet agent life-long.

Coronary artery bypass grafting

With CABG, autologous arteries or veins are anastomosed to the ascending aorta and to the native coronary arteries distal to the area of stenosis (Fig. 17.61). Arterial grafts (with *in situ* internal mammary or transposed radial arteries grafted onto the stenosed coronary arteries) demonstrate improved long-term patency compared to vein grafts. Operative mortality is ~1% in patients with normal left ventricular function but increases with age and co-morbidities.

PCI versus CABG

A multidisciplinary team (made up of interventional and non-interventional cardiologists, cardiac surgeons, cardiac anaesthetists, and intensivists) should review whether patients should

continue with medical therapy or be referred for PCI or CABG. The STS score and/or EuroSCORE II (see Further reading) can be utilized to determine in-hospital mortality and morbidity in patients referred for surgery. The SYNTAX score should be used for complex CAD to determine long-term mortality and morbidity in patients referred for PCI. In the current European Society of Cardiology (ESC) guidelines for revascularization (see Further reading), PCI is preferred to CABG in patients with single- or double-vessel disease not involving the proximal LAD or left main stem (LMS) vessel. CABG and PCI are both appropriate in patients with proximal LAD stenosis, LMS, or three-vessel disease (without diabetes mellitus) and a low SYNTAX score (0–22). CABG is preferred to PCI in patients with three-vessel disease and diabetes or elevated SYNTAX score

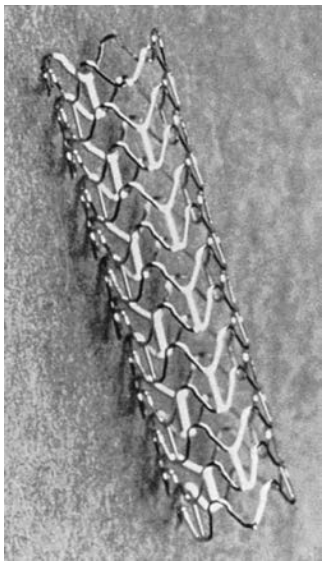

Fig. 17.59 **An intracoronary stent.**

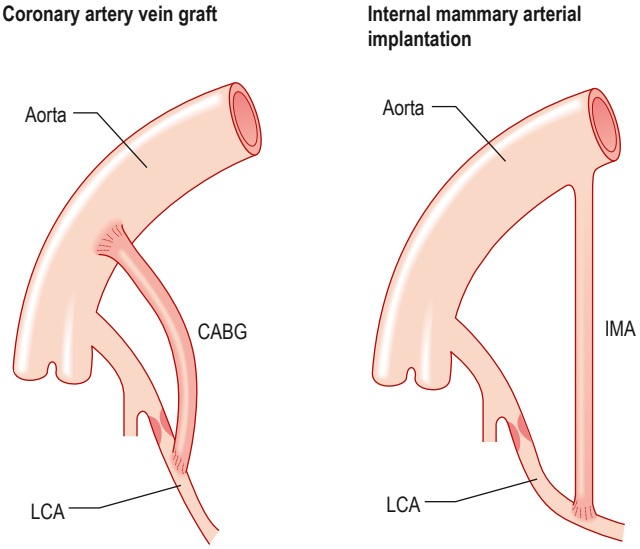

Fig. 17.61 **Relief of coronary obstruction by surgical techniques: coronary artery bypass grafting (CABG) and internal mammary arterial implantation (IMA).** In both of these examples the graft bypasses a coronary obstruction in the left coronary artery (LCA).

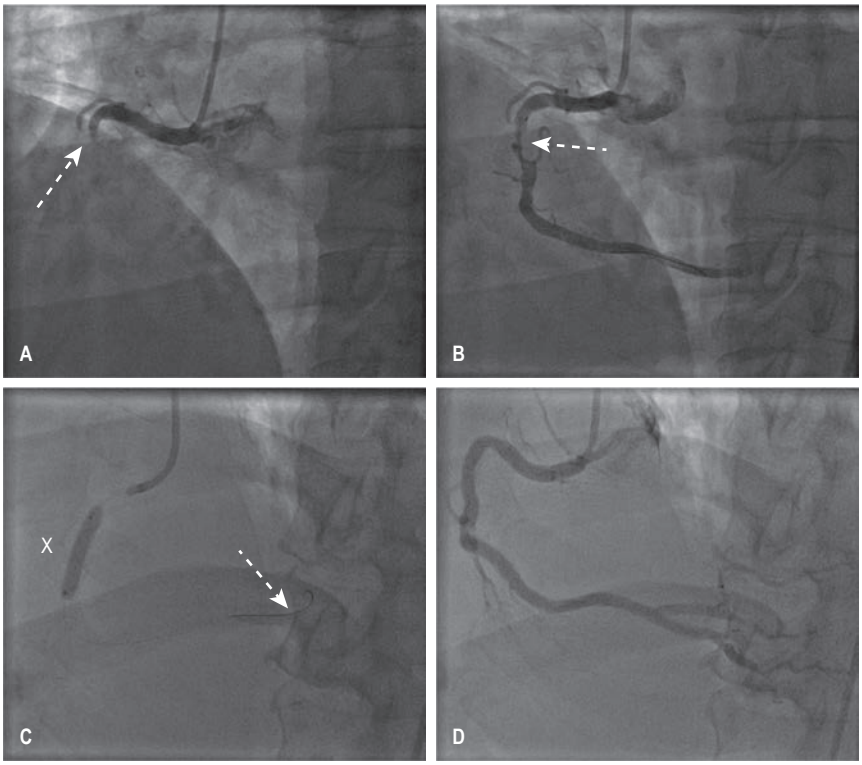

Fig. 17.60 **Percutaneous transluminal coronary angioplasty (PTCA).** **(A)** Coronary angiography demonstrates an occluded right coronary artery *(arrowed)*. **(B)** A soft wire passed through the guide catheter reopens the artery but a severe stenosis remains *(arrowed)*. **(C)** A balloon (X) is inflated to dilate the stenosis. The soft guidewire can be seen in the distal posterior descending artery *(arrowed)*. **(D)** The right coronary artery has now been successfully reopened with good antegrade flow.

(>22) and in patients with LMS and SYNTAX score of more than 22. Some patients may undergo a hybrid procedure with a combination of minimally invasive bypass surgery with an arterial graft and PCI. Patient clinical characteristics (severe co-morbidities, reduced life expectancy, 'porcelain' [heavily calcified] aorta, or the need for additional surgery to the aorta or valves) may alter the modality of revascularization.

Patients with refractory angina

Some patients remain symptomatic despite medication and are not suitable for (further) revascularization. These individuals need ongoing lifestyle advice and a pain management programme. Spinal cord stimulation and coronary sinus reducing devices show some promise.

ACUTE CORONARY SYNDROMES

Acute coronary syndromes (ACSs) comprise a spectrum of clinical presentations ranging from UA to non-ST-elevation myocardial infarction (NSTEMI) and ST-elevation myocardial infarction (STEMI). Each of these underlying conditions typically present with similar symptoms and signs (most commonly with sudden-onset 'heavy' or 'tight' feeling chest pain), and are managed similarly until subsequent tests (ECG, cardiac biomarkers and different imaging modalities) provide the ultimate diagnosis.

Pathophysiology

ACSs result from an imbalance between myocardial oxygen supply and demand, primarily due to a sudden reduction in coronary blood flow. This is commonly caused by the rupture or erosion of an atherosclerotic plaque, leading to thrombus formation and arterial occlusion. The extent of myocardial ischaemia and necrosis depends on the location and duration of the obstruction, the adequacy of collateral blood flow around the occluded vessel, and myocardial oxygen demand.

Partial occlusion or transient complete occlusion can result in NSTEMI or UA, where the ischaemia is typically subendocardial with less myocardial damage.

- UA represents myocardial ischaemia in the absence of myocardial damage. Patients may have prolonged (>20 mins) angina at rest, new onset severe angina, or rapidly worsening angina (increased frequency and/or longer duration).
- In patients with NSTEMI there is occluding thrombus, which leads to myocardial necrosis and a rise in serum troponin levels. The use of high-sensitivity troponins (see 'Biomarkers' section) has made the distinction between UA and NSTEMI more challenging, as minor troponin elevations can now be detected.
- STEMI (see section below) occurs in the setting of complete coronary artery occlusion and is characterized by transmural ischaemia and extensive myocardial injury.

The pathophysiological process of ACS is dynamic, and the clinical presentation can evolve, underscoring the importance of early recognition and intervention to restore coronary perfusion and minimize myocardial damage.

Diagnosis

A rise and/or fall in troponin levels above the 99th percentile of healthy individuals suggests a diagnosis of MI, based on the criteria in the fourth universal definition of MI developed jointly by European and American cardiological associations, provided that the clinical presentation is consistent with myocardial ischaemia. There are five different types, each with distinct pathological, clinical, and prognostic features:

- **Type 1 MI:** this is the traditional clinical picture, characterized by atherosclerotic plaque disruption complicated by thrombosis. It involves reduced blood supply to the myocardium due to coronary atherothrombotic obstruction to blood flow.
- **Type 2 MI:** there is reduced oxygen supply or increased demand secondary to other causes unrelated to acute coronary atherothrombosis, for example, coronary artery spasm, coronary embolism, anaemia, arrhythmias, hypertension, or hypotension.
- **Type 3 MI:** refers to a cardiac event resulting in death before measurement of biomarkers.
- **Type 4 MI:** increase in troponin in the setting of coronary angioplasty (PCI) (4a), stent thrombosis (4b), or in-stent restenosis (4c).
- **Type 4b MI:** increase in troponin in the setting of coronary angioplasty (PCI).
- **Type 5 MI:** increase in troponin related to coronary artery bypass grafting (CABG)

Clinical features

The primary symptom of ACS is substernal chest pain, often described as a crushing or pressure-like feeling, which may radiate to the jaw and/or left arm. This pain may come on quickly, come and go, or get worse with exercise. Unlike stable angina, it is not usually predictable.

Other symptoms can include dyspnoea, diaphoresis, nausea or vomiting, and unexplained fatigue. Some patients may also experience light-headedness, syncope, or a racing heartbeat. Atypical presentations are more common in women, elderly patients, and those with diabetes, who may experience more vague and subtle symptoms such as isolated jaw or left arm pain, epigastric pain, and weakness. These patients are often misdiagnosed and undertreated, and they have a higher mortality across the spectrum of ACS. Physical examination may note general distress and diaphoresis. Heart sounds are frequently normal. It is important to identify adverse clinical signs, such as hypotension, basal crackles, fourth heart sounds, and cardiac murmurs. A new pansystolic murmur may represent mitral regurgitation from papillary muscle dysfunction or rupture, or a VSD from septal rupture.

Investigations

Electrocardiogram

A resting 12-lead ECG is the initial diagnostic tool in assessing patients with suspected ACS, and it should be repeated, as required, if the patient has chest pain. In UA and NSTEMI there may

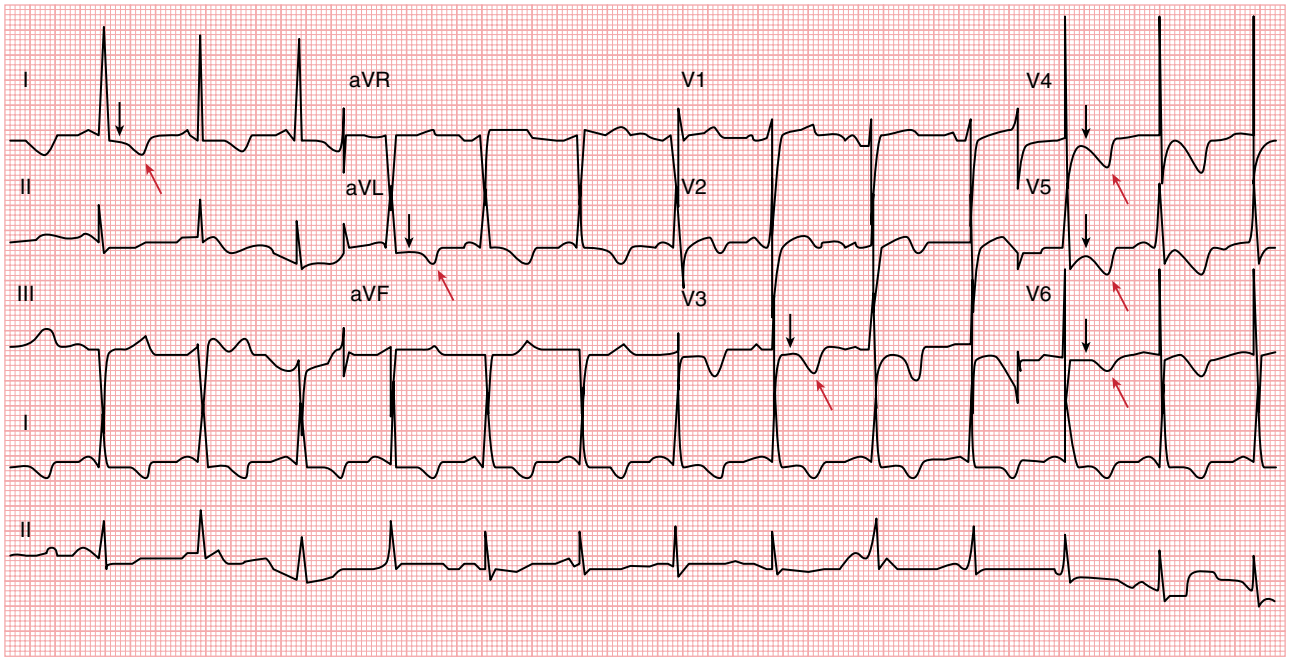

Fig. 17.62 NSTEMI with ST depression *(black arrows)* and T-wave inversion *(red arrows)* in anterior and lateral leads (V_3–V_6, aVL, I). *(Harding, M., et al. (2019). Coronary artery disease and acute coronary syndrome. In:* Lewis's Medical-Surgical Nursing: Assessment and Management of Clinical Problems, *11th ed. Elsevier.)*

be ST depression and/or T-wave inversion due to subendocardial ischaemia, occurring with a particular vascular territory (see Fig. 17.62), although about one-third of patients may have a normal ECG. Dynamic ECG changes, such as intermittent ST-segment elevations or depressions and T-wave inversions, are highly suggestive of ongoing ischaemia. In STEMI the hallmark ECG finding is persistent ST-segment elevation, typically in the leads facing the ischaemic zone, as a result of transmural ischaemia. Additionally, new onset of LBBB is considered a STEMI equivalent and may be indicative of acute coronary artery occlusion. Transient ST elevation can be seen in coronary vasospasm (Prinzmetal's angina), pericarditis, and aortic dissection involving the coronary arteries.

Biomarkers

Cardiac troponins are the cornerstone biomarkers for the diagnosis of ACS as they are highly specific and sensitive indicators of myocardial injury. Previous biomarkers (creatine kinase-MB [CK-MB], LDH, and aspartate transaminase [AST]) were once widely used, but due to their lower specificity and sensitivity for cardiac injury, they have been supplanted by troponins.

The cardiac troponin complex is composed of three subunits: troponin T (cTnT), troponin I (cTnI), and troponin C. Troponin T and I are cardiac specific, and their presence in the bloodstream is indicative of myocardial damage.

- Troponin T attaches the troponin complex to the actin filament.
- Troponin I inhibits the interaction with myosin heads in the absence of sufficient calcium ions.
- Troponin C acts as the calcium-binding site during excitation–contraction coupling.

High-sensitivity troponin assays have improved the early detection of myocardial injury, with elevations detectable within 60 minutes of an indexed cardiac event. The NPV for MI in those with normal troponin concentrations exceeds 99%. This high NPV indicates that a 'rule out' pathway is highly effective in correctly identifying patients who do not have an MI, thus allowing for safe discharge and reducing unnecessary hospital admissions and further testing. However, such an approach increases the likelihood of detecting minor troponin elevations that may not be related to acute ischaemic heart disease. If the initial troponin assay is negative, it should be repeated 1 to 3 hours later, with rising concentrations suggesting myocardial ischaemia.

The troponin assay provides prognostic information: that is, a high serum troponin level carries an increased mortality risk in ACS (Box 17.30). It also defines which patients may benefit from aggressive medical therapy and early coronary revascularization.

NSTEMI and unstable angina

Risk stratification

Both the Thrombolysis in Myocardial Infarction (TIMI) score (Box 17.31) and the Global Registry of Acute Coronary Events (GRACE) prediction score can be used in patients with ACS to define risk. The GRACE score is based on age, heart rate, systolic blood pressure, serum creatinine, and the Killip score (Boxes 17.32 and 17.33).

Investigations and management

All patients require immediate management of their chest pain, as outlined in Chapter 11 ('Chest pain' section) and in Box 17.34.

Antiplatelet drugs

Platelets play a crucial role in the thrombosis cascade associated with ACS. When an atheromatous plaque ruptures, circulating platelets are exposed to various substances such as ADP, thromboxane A2 (TxA2), adrenaline (epinephrine), thrombin, and collagen tissue factor. This exposure triggers platelet activation, with thrombin being a particularly potent stimulant. Activated platelets express glycoprotein (GP) IIb/IIIa receptors on their surface, which facilitate the bridging of fibrinogen between adjacent platelets, leading to the formation of platelet aggregates (see Fig. 38.33).

ACS patients should be treated with dual antiplatelet agents to inhibit different pathways of platelet activation and aggregation, to significantly reduce the risk of recurrent ischaemic events:

- ***aspirin 300 mg*** loading dose, then 75 to 100 mg daily *and*
- ADP-receptor $P2Y_{12}$ inhibitor (choice depends on bleeding risk and local guidelines):
  - **clopidogrel 300 to 600 mg** loading then 75 mg daily *or*
  - **prasugrel 60 mg** loading then 10 mg daily *or*
  - **ticagrelor 180 mg** loading then 90 mg twice daily.

Anticoagulants

Anticoagulant drugs inhibit thrombin, a key enzyme involved in both platelet and coagulation system activation, and should be prescribed with dual antiplatelets in ACS. Parenteral anticoagulants are essential to mitigate the risk of thrombus propagation and new thrombus formation. The choice of anticoagulant is influenced by the patient's characteristics and clinical setting:

- ***Low-molecular-weight heparin (LMWH),*** for example, enoxaparin—preferentially inhibits factor Xa while having a lesser effect on thrombin and has a predictable anticoagulant response, usually not requiring laboratory monitoring.

Box 17.30 Relationship between troponin I and risk of death in acute coronary syndrome

Serum troponin levels (ng/mL)	Mortality at 42 days (% of patients)
0 to <0.4	1.0
0.4 to <1.0	1.7
1.0 to <2.0	3.4
2.0 to <5.0	3.7
5.0 to <9.0	6.0
>9.0	7.5

Box 17.34 Pharmacological therapy in acute coronary syndrome

Drug	Dose	Notes
Antiplatelet drugs		
Aspirin	150–300 mg chewable or soluble aspirin, then 75–100 mg orally daily	Caution if active peptic ulceration
Clopidogrel	300 mg orally loading dose, then 75 mg orally daily	Caution: increased risk of bleeding; avoid if CABG planned
Prasugrel	60 mg oral loading dose, then 10 mg orally daily (5 mg daily if <60 kg or >75 years old)	
Ticagrelor	Initially 180 mg, then 90 mg ×2 daily	
Antithrombin drugs		
Heparin	5000 units i.v. bolus, then 0.25 units/kg per hour	Measure anticoagulant effect with APTT at 6 h
Low-molecular-weight heparins, e.g., enoxaparin	1 mg/kg s.c. ×2 daily	Risk of bleeding
Bivalirudin	0.75 mg/kg i.v. bolus, then 1.75 mg/kg per hour for 4 h post PCI	
Fondaparinux	2.5 mg s.c. daily, for up to 8 days	
Rivaroxaban	Oral 2.5–10 mg daily	
Glycoprotein IIb/IIIa inhibitors[a]		
Abciximab	0.25 mg/kg i.v. bolus, then 0.125 μg/kg per min up to 10 μg/min i.v. ×12 h	Indicated if coronary intervention likely within 24 h
Eptifibatide	180 μg/kg i.v. bolus, then 2 μg/kg per min ×18 h	Indicated in high-risk patients managed without coronary intervention or during PCI
Tirofiban	25 μg/kg over 5 min, then 0.15 μg/kg per min for up to 18 h	Indicated in high-risk patients managed without coronary intervention or during PCI
Analgesia		
Diamorphine or morphine	2.5–5.0 mg i.v.	Prescribe with antiemetic, e.g., metoclopramide 10 mg i.v.
Myocardial energy consumption		
Atenolol	5 mg i.v. repeated after 15 min, then 25–50 mg orally daily	Avoid in asthma, heart failure, hypotension, bradyarrhythmias
Metoprolol	5 mg i.v. repeated to a maximum of 15 mg, then 25–50 mg orally ×2 daily	
Coronary vasodilation		
Glyceryl trinitrate	2–10 mg/h i.v./buccal/sublingual	Maintain systolic BP >90 mmHg
Plaque stabilization/ventricular remodelling		
HMG-CoA reductase inhibitors (statins)		
Rosuvastatin	20–40 mg orally	Combine with dietary advice and modification
Pravastatin	20–40 mg orally	
Atorvastatin	80 mg orally	
ACE inhibitors		
Ramipril	2.5–10 mg orally	Monitor renal function
Lisinopril	5–10 mg orally	

[a]Not now used in patients pre-treated with clopidogrel and aspirin prior to coronary intervention.
ABG, Arterial blood gases; *ACE*, angiotensin-converting enzyme; *APTT*, activated partial thromboplastin time; *BP*, blood pressure; *CABG*, coronary artery bypass graft; *COPD*, chronic obstructive pulmonary disease; *i.v.*, intravenous; *PCI*, percutaneous coronary intervention; *s.c.*, subcutaneous.

- ***Unfractionated heparin (UFH):*** a fast-acting anticoagulant with a short half-life, which can be advantageous for potential rapid reversal. It acts by binding to antithrombin and potentiating its effect, primarily inhibiting thrombin and factor Xa. UFH requires monitoring of the activated partial thromboplastin time (aPTT) to ensure therapeutic anticoagulation.
- ***Fondaparinux:*** fondaparinux is a synthetic pentasaccharide that selectively inhibits factor Xa. It has a longer half-life and does not inhibit thrombin directly. Fondaparinux is associated with a lower risk of heparin-induced thrombocytopenia (HIT) compared to heparin.
- Bivalirudin: as a direct thrombin inhibitor, bivalirudin directly inhibits both circulating and clot-bound thrombin. It has a rapid onset and offset of action and may be preferred in patients at high risk of bleeding or those with HIT.

Anti-ischaemia agents

In patients with no contraindications (asthma, AV block, acute pulmonary oedema) beta-blockers are administered orally, to reduce myocardial ischaemia by blocking circulating catecholamines. This will lower the heart rate and blood pressure, reducing myocardial

oxygen consumption. The dose can be titrated to produce a resting heart rate of ~60 b.p.m.

In patients with on-going angina, nitrates should be given either sublingually or intravenously. They effectively reduce preload and produce coronary vasodilation. However, tolerance can become a problem and patients should be weaned off intravenous administration if symptoms resolve.

Plaque stabilization/remodelling

HMG-CoA reductase inhibitor drugs (statins) and ACE inhibitors are routinely administered to patients with ACS. These agents may produce plaque stabilization, improve vascular and myocardial remodelling, and reduce future cardiovascular events. Starting the drugs while the patient is still in hospital increases the likelihood of these individuals receiving long-term therapy.

Coronary angiography and intervention

Very high-risk patients require urgent coronary angiography (<2 h). This includes those individuals with persistent or recurrent chest pain not responding to medical therapy, clinical signs of heart failure, haemodynamic instability or cardiogenic shock, or life-threatening arrhythmias (ventricular fibrillation, ventricular tachycardia).

High-risk patients with rising or falling cardiac troponin levels, dynamic ST- or T-wave changes, or elevated GRACE scores (>140) require coronary angiography within 24 hours.

Intermediate-risk patients with diabetes mellitus, renal impairment (estimated glomerular filtration rate <60), LVEF below 40%, congestive cardiac failure, early post-infarction angina, previous PCI or CABG, or a GRACE score of over 109 but less than 140 require coronary angiography within 72 hours.

Low-risk patients can be managed initially with medical therapy, but an invasive strategy with cardiac catheterization is preferred in most patients.

ST-elevation myocardial infarction

MI occurs when cardiac myocytes die due to prolonged myocardial ischaemia. In Europe approximately 1.8 million people die annually from ischaemic heart disease.

Pathophysiology

Rupture or erosion of a vulnerable coronary artery plaque can produce prolonged occlusion of a coronary artery, leading to myocardial necrosis within 15 to 30 minutes. The subendocardial myocardium is initially affected but, with continued ischaemia, the infarct zone extends through to the subepicardial myocardium, producing a transmural 'Q wave' MI. Early reperfusion may salvage regions of the myocardium, reducing future mortality and morbidity.

The in-hospital mortality rate is between 6% and 14%. Several risk factors can be identified that predict death rate at 30 days (GRACE ACS score, **Box 17.35**).

Clinical features

Any patient presenting with severe chest pain lasting more than 20 minutes may be suffering from MI. The pain may not respond to sublingual glyceryl trinitrate. The pain may radiate to the left arm, neck, or jaw. However, many patients present atypically (particularly females, the elderly, those with diabetes, or those from ethnic minorities), and symptoms in these groups may include dyspnoea, fatigue, pre-syncope, or syncope. Autonomic symptoms are common, and on examination, the patient may be pale and clammy, with marked sweating. In addition, the pulse may be thready with significant hypotension, bradycardia, or tachycardia.

Investigations

Electrocardiography

An ECG in patients with chest pain should be performed within 10 minutes of first contact with the emergency medical team (ambulance or emergency department). The baseline ECG is rarely normal, but if it is, it should be repeated every 15 minutes while the patient remains in pain. Continuous cardiac monitoring is required because of the high likelihood of significant cardiac arrhythmias. ECG changes (**Box 17.36**) are usually confined to the ECG leads that 'face' the infarction. The presence of new ST elevation (due to opening of the K^+ channels) of 0.2 mV or more at the J-point in leads V_1–V_3 and 0.1 mV or more in other

Box 17.35 TIMI risk score in ST-elevation myocardial infarction (STEMI)

Risk factor	Score

BP, Blood pressure; *LBBB,* left bundle branch block; *MI,* myocardial infarction; *TIMI,* thrombolysis in myocardial infarction.

Box 17.36 Typical ECG changes in myocardial infarction (STEMI)

Infarct site	Leads showing ST elevation
Anterior	
Small	V_3–V_4
Extensive	V_2–V_5
Anteroseptal	V_1–V_3
Anterolateral	V_4–V_6, I, AVL
Lateral	I, AVL
Inferior	II, III, AVF
Posterior	V_1, V_2 reciprocal changes, i.e., ST depression
Subendocardial	Any lead
Right ventricle	VR_4

leads suggests anterior MI (Fig. 17.63). An inferior wall MI is diagnosed when ST elevation is seen in leads II, III, and AVF (Fig. 17.64). Lateral MI produces changes in leads I, AVL, and V_5/V_6. In patients with a posterior MI there may be ST depression in leads V_1–V_3 with a dominant R wave and ST elevation in lead V_5/V_6. New (or presumed new) LBBB is compatible with coronary artery occlusion requiring urgent reperfusion therapy. It may not be possible to exclude MI in patients with a paced rhythm or right bundle branch block, and patients with symptoms compatible with MI should be triaged in the MI pathway. The evolution of the ECG during the course of STEMI is illustrated in Fig. 17.65.

Blood tests and other imaging

Blood samples should be taken for cardiac troponin I or T levels, although treatment should not be deferred until the results are available. Full blood count, serum electrolytes, glucose, and lipid profile should be obtained. Transthoracic echocardiography (TTE) may be helpful to confirm an MI, as wall-motion abnormalities are detectable early in STEMI. TTE may detect alternative diagnoses, such as aortic dissection, pericarditis, or pulmonary embolism.

Management

Initial assessment involves rapid triage for chest pain *('time is muscle')* and referral for reperfusion therapy (primary PCI or thrombolysis). Initial medical therapy includes aspirin (300 mg), nitrates, and, if refractory pain, intravenous opioids for relief. Routine oxygen administration is not recommended unless oxygen saturations are less than 90% (see Box 17.34).

Primary percutaneous coronary intervention

The preferred reperfusion therapy for STEMI in interventional cardiology centres is primary PCI with a target of 60 minutes for wire crossing of the culprit vessel. Recent updated ESC guidelines recommend performing complete revascularization during the index hospital admission. Data from the RIVAL and RIFLE STEACS studies

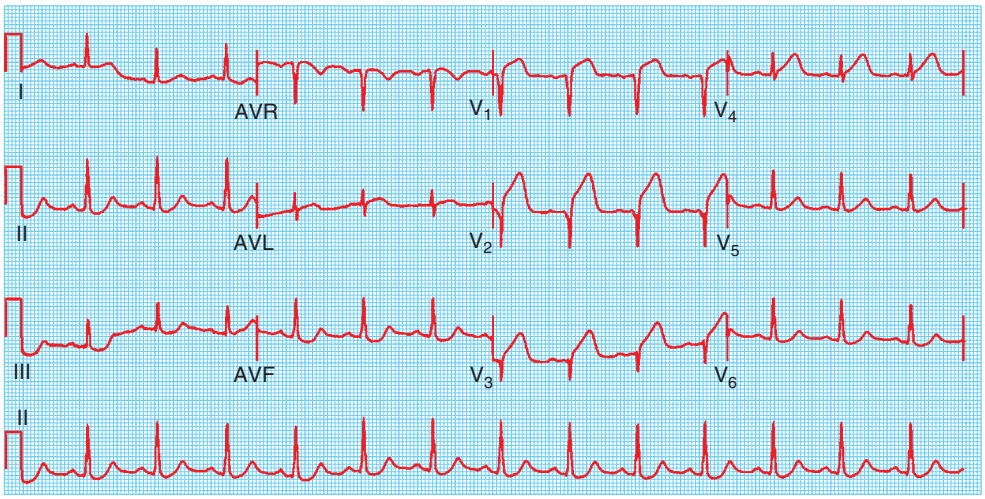

Fig. 17.63 An acute anteroseptal myocardial infarction, shown by a 12-lead ECG. Note the ST-segment elevation and pathological Q waves in leads V_1–V_3. Ischaemic changes with ST-segment depression are also seen in the inferior leads (II, III, and AVF).

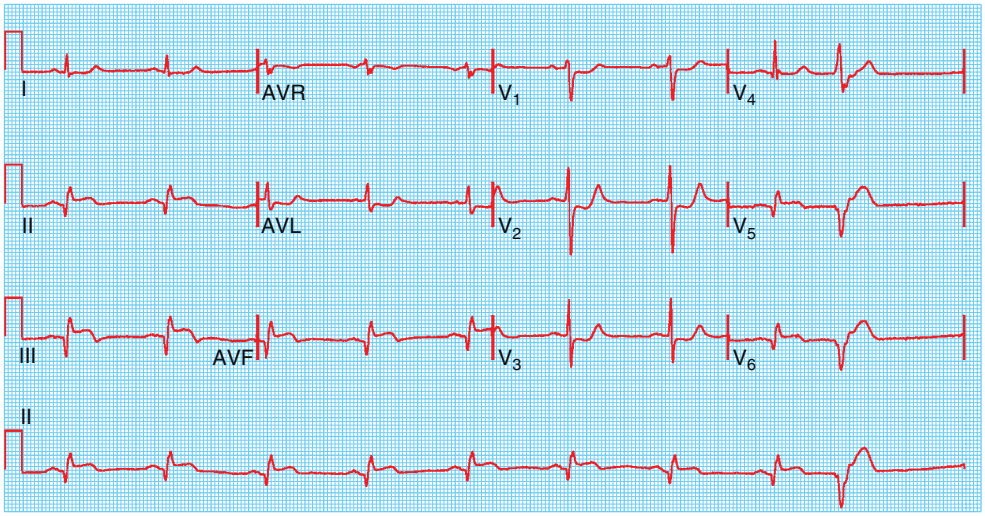

Fig. 17.64 An acute inferior wall myocardial infarction, shown by a 12-lead ECG. Note the raised ST segment and Q waves in the inferior leads (II, III, and AVF).

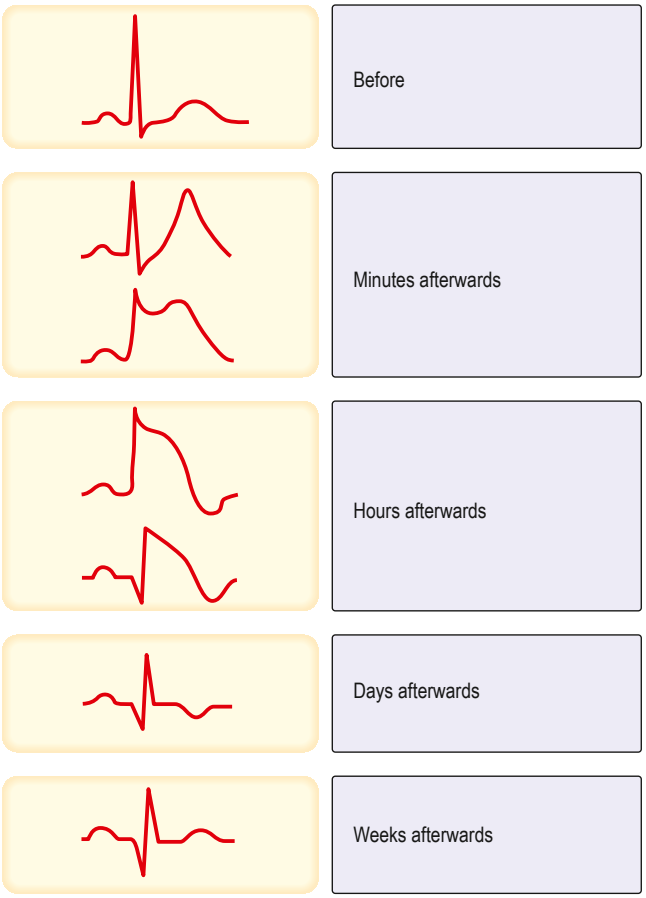

Fig. 17.65 Electrocardiographic evolution of myocardial infarction (STEMI). After the first few minutes, the T waves become tall, pointed, and upright, and there is ST-segment elevation. After the first few hours, the T waves invert, the R-wave voltage is decreased and Q waves develop. After a few days, the ST segment returns to normal. After weeks or months the T wave may return to upright but the Q wave remains.

demonstrate that radial access is the preferred route, as this reduces complications and may improve survival. Primary PCI performed with drug-eluting stents is preferred to BMSs. Dual antiplatelet therapy is with aspirin and an ADP-receptor blocker (prasugrel or ticagrelor). Anticoagulant options include UFH, enoxaparin, or bivalirudin. The routine use of GP IIb/IIIa inhibitors is no longer recommended.

Thrombolysis

Thrombolytic agents enhance the breakdown of occlusive thromboses by the activation of plasminogen to form plasmin. Thrombolysis is appropriate if transfer to a primary PCI-capable centre is not possible within 120 minutes of STEMI diagnosis. A meta-analysis showed that thrombolysis within 6 hours of STEMI or LBBB MI prevented 30 deaths in every 1000 patients treated. Between 7 and 12 hours, 20 in every 1000 deaths were prevented. After 12 hours the benefits are limited, and there is evidence to suggest less benefit for older patients, possibly because of the increased risk of strokes. For patients who fail to reperfuse 60 to 90 minutes following thrombolysis administration, as demonstrated by 50% resolution of the ST-segment elevation, re-thrombolysis or referral for rescue coronary angioplasty is recommended. The contraindications to thrombolysis are provided in **Box 17.37**. Aspirin and clopidogrel are recommended in patients undergoing thrombolysis. Anticoagulant options include UFH, enoxaparin, or fondaparinux.

Box 17.37 Contraindications to thrombolysis

Absolute contraindications
- Haemorrhagic stroke or stroke of unknown origin at any time
- Ischaemic stroke in the preceding 3 months
- Central nervous system damage/neoplasm/vascular malformation
- Recent major trauma/surgery/head injury (within the preceding 3 weeks)
- Gastrointestinal bleeding within the last month
- Known bleeding disorder
- Aortic dissection

Relative contraindications
- Ischaemic stroke in the preceding 3 months
- Oral anticoagulant therapy
- Pregnancy or within 1 week postpartum
- Non-compressible vascular punctures
- Traumatic resuscitation
- Refractory hypertension (systolic blood pressure >180 mmHg)
- Advanced liver disease
- Internal bleeding, e.g., active peptic ulcer
- Dementia

Coronary artery bypass surgery

Cardiac surgery is reserved for a small proportion of patients with unsuitable anatomy for PCI or for those with complications of MI, such as VSD or mitral regurgitation. Operative mortality is highest in the first 72 hours after STEMI.

Complications of myocardial infarction

Heart failure

Cardiac failure following STEMI is a poor prognostic feature that necessitates medical and invasive therapy to reduce the death rate. The Killip classification is used to assess patients with heart failure post MI:

- ***Killip I***—no crackles and no third heart sound
- ***Killip II***—crackles in less than 50% of the lung fields or a third heart sound
- ***Killip III***—crackles in more than 50% of the lung fields
- ***Killip IV***—cardiogenic shock.

Patients may develop AHF and should be managed with diuretics (e.g., intravenous furosemide 40–80 mg) and vasodilators. ACE inhibitors can be given within 24 to 48 hours if the blood pressure is satisfactory. Oxygen may be required, with regular oxygen monitoring. Intravenous inotropes, such as dobutamine or milrinone, are used in severe heart failure. If the patient is in cardiogenic shock, revascularization with or without temporary mechanical circulatory support may be required (see 'Temporary mechanical cardiac support' section). Patients with cardiogenic shock may require intracardiac pressure from right heart catheterization to guide treatment.

Myocardial rupture and aneurysmal dilation

Rupture of the free wall of the left ventricle is usually an early, catastrophic, and fatal event from haemopericardium. The patient will have a haemodynamic collapse, then an electromechanical cardiac arrest. A subacute rupture may allow for pericardiocentesis, followed by surgical repair of the rupture. Aneurysmal dilation of the infarcted myocardium (**Fig. 17.66**) is a late complication that may require surgical repair. Left ventricular thrombus may develop and as a result of blood stasis within the aneurysmal segment, necessitating anticoagulation.

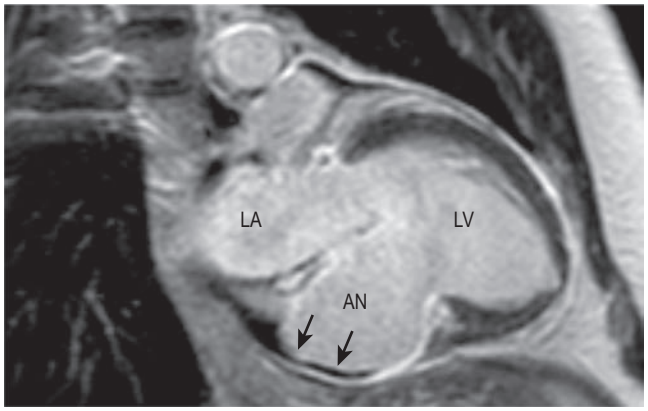

Fig. 17.66 Cardiac magnetic resonance image (vertical long axis) showing an inferior left ventricular aneurysm (*arrowed*, AN). The aneurysm was successfully resected surgically. *LA,* Left atrium; *LV,* left ventricle.

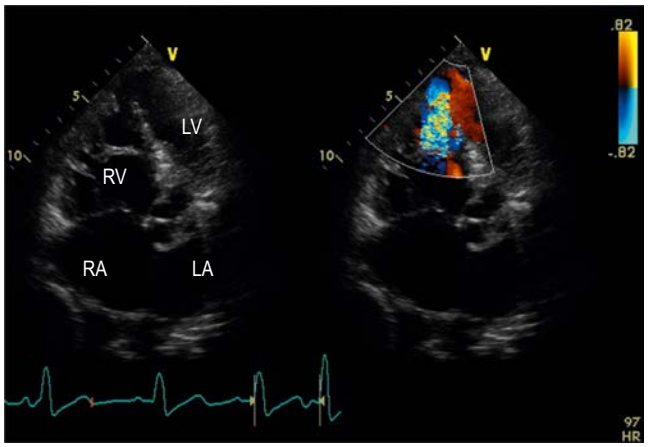

Fig. 17.67 Post-infarct ventricular septal defect. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

Ventricular septal defect

A ventricular septal defect (VSD) (Fig. 17.67) may occur in 1% to 2% of patients with STEMI and may be associated with delayed or failed revascularisation. However, mortality is very high and there is a 12-month non-operated mortality of 92%. Temporary mechanical cardiac support and coronary angiography may allow patient optimization prior to surgery (usually deferred till >7 days post infarction). In those not fit for surgery percutaneous VSD closure may be attempted.

Mitral regurgitation

Severe mitral regurgitation can occur early in the course of STEMI. Three mechanisms may be responsible, and a TOE may be necessary to confirm the aetiology:

- severe left ventricular dysfunction and dilation, causing annular dilation of the valve and subsequent functional regurgitation;
- MI of the inferior wall, producing dysfunction of the papillary muscle that may respond to coronary intervention; and
- MI of the papillary muscles (usually the posteromedial papillary muscle), producing sudden severe pulmonary oedema and cardiogenic shock.

Diagnosis is confirmed with echocardiography and patients may be managed with diuretics, nitrates, inotropic agents, and temporary mechanical support while they are stabilized for early mitral valve surgical repair or replacement.

Cardiac arrhythmias

Ventricular tachycardia and ventricular fibrillation are common in STEMI, particularly with reperfusion. Cardiac arrest requires defibrillation. Ventricular tachycardia that is haemodynamically tolerated should be treated with intravenous amiodarone 300 mg or lidocaine 50 to 100 mg. If the patient is hypotensive, synchronized cardioversion may be performed. Serum potassium should be maintained at >4.0 mmol/L and magnesium should be replenished. Refractory ventricular tachycardia or fibrillation may respond to magnesium 8 mmol/L over 15 minutes i.v.

Atrial fibrillation may occur in 1 in 6 patients and requires rate control with beta-blockers, anticoagulation, and consideration of rhythm control with antiarrhythmics such as amiodarone or synchronized DC cardioversion, especially for patients who are unstable.

Bradyarrhythmias can be treated initially with atropine 0.5 mg i.v. repeated up to six times in 4 hours. Temporary transcutaneous or transvenous pacemaker insertion may be necessary in patients with symptomatic heart block.

Heart block

Sinus bradycardia and varying levels of heart block including complete heart block may occur following acute MI, particularly with inferior MIs, as the right coronary artery supplies the SA and AV nodes. When associated with haemodynamic compromise, complete heart block can be managed with atropine and temporary transvenous pacing and may recover after a few days. Permanent pacing will be needed if complete heart block persists and is more common in anterior MI because of extensive infarction.

Post-MI pericarditis and Dressler's syndrome

See 'Pericardial disease' section.

Post-ACS lifestyle modification

After recovery from an ACS, patients should be encouraged to participate in a cardiac rehabilitation programme that provides education and information appropriate to their requirements. An exercise programme forms part of the rehabilitation.

- Patients should be physically active (30 min of moderate aerobic exercise five times per week).
- Dietary recommendations include calorie control of obesity, increased fruit and vegetables, reduced *trans* and saturated fats, and reduced salt intake in patients with hypertension.
- Alcohol consumption should be maintained within safe limits (≤14 units per week for both men and women), avoiding binge drinking.
- Patients should stop smoking (nicotine patches and buprenorphine are safe).
- A healthy weight (BMI < 25 kg/m^2) should be maintained.
- Blood pressure should be reduced to a systolic measurement of less than 130 mmHg.
- Patients with diabetes should be treated to maintain HbA_{1c} of less than 53 mmol/moL.

Post-ACS drug therapy and assessment

Extensive clinical trial evidence has been gathered in post-MI patients, demonstrating that a range of pharmaceuticals is advantageous in reducing mortality. Therefore patients who have suffered an MI should be taking most of the following medications:

- aspirin 75 mg daily (life-long)
- ADP-receptor blocker, for example, clopidogrel, prasugrel, and ticagrelor (at least for the first year)
- high-intensity statin (e.g., atorvastatin 80 mg) with target LDL cholesterol of less than 1.8 mmol/L
- beta-blocker (e.g., bisoprolol titrated to heart rate and blood pressure), particularly if there is heart failure with EF < 40%
- ACE inhibitor or angiotensin receptor blocker, particularly if LVEF is less than 40%
- aldosterone antagonist, if there is clinical evidence of heart failure and LVEF is less than 40%; the serum creatinine is less than 221 μmol/L (men) or less than 177 μmol/L (women); and the serum potassium is less than 5.0 mEq/L, for example, eplerenone 25 to 50 mg
- proton pump inhibitor for patients at high risk of bleeding while on dual antiplatelet therapy

The role of colchicine remains uncertain and requires careful patient selection. While earlier trials demonstrated benefits in reducing hospitalization for angina and revascularization, the largest trial to date (CLEAR SYNERGY) did not confirm these benefits.

Patients with permanent atrial fibrillation receiving medical therapy or CABG should be treated with dual therapy: aspirin or clopidogrel and anticoagulation.

Patients with permanent atrial fibrillation receiving stenting should be assessed for their bleeding risk using the HAS-BLED score (see **Box 17.14**):

- If this is 0 to 2, they can receive triple therapy for 6 months (aspirin and clopidogrel and warfarin) and then dual therapy (aspirin or clopidogrel and anticoagulation with warfarin or a DOAC).
- If it is over 2, they can receive triple therapy for 4 weeks (aspirin and clopidogrel and warfarin) and then dual therapy (aspirin or clopidogrel and anticoagulation with warfarin or a DOAC) for a further 11 months.

VALVULAR HEART DISEASE

MITRAL VALVE

The mitral valve consists of the fibrous annulus, anterior and posterior leaflets, chordae tendineae, and the papillary muscles (**Fig. 17.68**).

Mitral stenosis

Mitral stenosis is mostly due to rheumatic heart disease following previous rheumatic fever due to infection with a group A beta-haemolytic streptococcus; in low- to medium-income countries this affects nearly 20 million people. Genetically determined immune markers influence susceptibility to the initial infection and play a role in the risk of developing chronic rheumatic disease. The condition is more common in those with a history of multiple episodes of pharyngitis and also in women. Inflammation leads to commissural fusion and a reduction in mitral valve orifice area, causing the characteristic doming pattern on echocardiography. It is a progressive condition over many years with valve thickening, cusp fusion, and calcium deposition leading to increasing immobility of the valve cusps and a severely narrowed (stenotic) valve orifice.

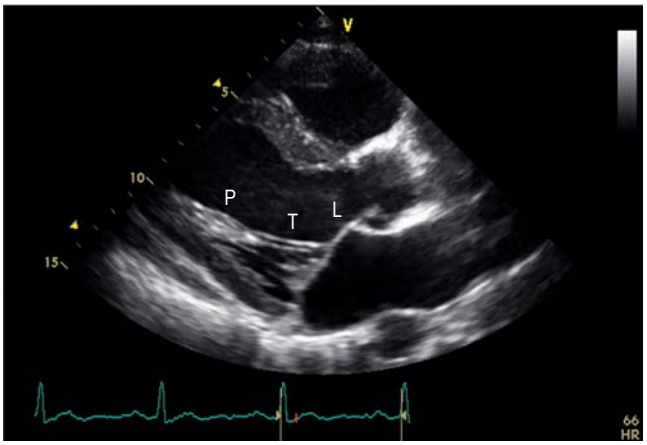

Fig. 17.68 Mitral valve apparatus—parasternal long axis. *L,* Leaflets; *P,* papillary muscle; *T,* chordae tendineae.

Other causes of mitral stenosis include:

- congenital mitral stenosis
- Lutembacher's syndrome (the combination of acquired mitral stenosis and an atrial septal defect)
- mitral annular calcification; rarely, this may lead to mitral stenosis if extensive, particularly in elderly patients and those with end-stage renal disease
- carcinoid tumours metastasizing to the lung, or primary bronchial carcinoid.

Pathophysiology

When the normal valve orifice area of 4 to 6 cm^2 is reduced to less than 1 cm^2, severe mitral stenosis is present. In order for sufficient cardiac output to be maintained, the left atrial pressure increases and left atrial hypertrophy and dilation occur, leading to increases in pulmonary venous, pulmonary arterial, and right heart pressures. Increases in the pulmonary capillary pressure can lead to the development of pulmonary oedema, particularly with the onset of atrial fibrillation with tachycardia and loss of coordinated atrial contraction. This is partially prevented by alveolar and capillary thickening and pulmonary arterial vasoconstriction (reactive pulmonary hypertension). Pulmonary hypertension leads to right ventricular hypertrophy, dilation, and failure, with subsequent functional tricuspid regurgitation.

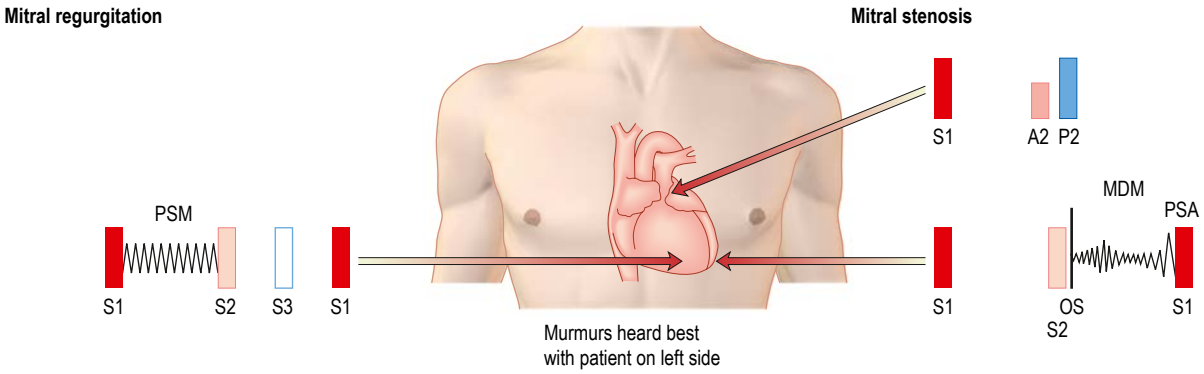
Clinical features

Symptoms

Usually, there is a long asymptomatic phase until the valve orifice is moderately stenosed (area <2 cm^2). This does not usually occur until several decades after the first attack of rheumatic fever, but in low- to medium-income countries, severe stenosis may occur at 10 to 20 years of age.

Progressive ***dyspnoea*** and ***reduced exercise tolerance*** develop from the elevation in left atrial pressure, vascular congestion, and interstitial pulmonary oedema. A cough productive of blood-tinged, frothy sputum or frank haemoptysis may occur. The development of pulmonary hypertension eventually leads to ***right heart failure*** and its symptoms of weakness, fatigue, and abdominal and lower limb swelling. The left ventricle, however, is safeguarded as it lies downstream of the mitral valve.

As the left atrium progressively enlarges, this predisposes to ***atrial fibrillation***, giving rise to symptoms such as palpitations.



Mitral regurgitation	
Pulse:	Sinus rhythm or atrial fibrillation
Apex:	Forceful, displaced, systolic thrill
Sounds:	Soft S1, S3
Murmurs:	Pansystolic

Mitral stenosis	
Face:	Mitral facies
Pulse:	Atrial fibrillation
RV:	Heaving, sustained
Apex:	Localized, tapping
Sounds:	Loud S1, loud P2 (if pulmonary hypertension), opening snap
Murmurs:	Mid-diastolic rumble at apex

Fig. 17.69 Features associated with mitral regurgitation and mitral stenosis. *A2,* Aortic component of the second heart sound; *MDM,* mid-diastolic murmur; *OS,* opening snap; *P2,* pulmonary component of the second heart sound (loud with pulmonary hypertension); *PSA,* pre-systolic accentuation; *PSM,* pansystolic murmur; *RV,* right ventricle; *S1,* first heart sound; *S2,* second heart sound; *S3,* third heart sound.

Atrial fibrillation may result in ***systemic emboli***, most commonly to the cerebral vessels, producing stroke, but mesenteric, renal, and peripheral emboli are also seen.

Signs

See the 'Clinical memo' in Fig. 17.69.

Face

Severe mitral stenosis with pulmonary hypertension is associated with 'mitral facies' or malar flush. This is a bilateral, cyanotic, or dusky pink discoloration over the upper cheeks arising from arteriovenous anastomoses and vascular stasis.

Pulse

A small-volume pulse may be present in severe mitral stenosis due to diminished left ventricular filling. The rhythm may be regular (sinus rhythm), but as the disease progresses, an 'irregularly irregular' pulse (atrial fibrillation) may occur and lead to symptomatic clinical deterioration.

Jugular veins

Right heart failure may develop with jugular venous distension. When pulmonary hypertension or tricuspid stenosis is present, the 'a'-wave will be prominent, provided that atrial fibrillation has not supervened.

Palpation

There is a tapping impulse felt parasternally on the left side which is the result of a palpable first heart sound combined with left ventricular backward displacement produced by an enlarging right ventricle. A sustained parasternal impulse due to right ventricular hypertrophy may also be felt.

Auscultation

Auscultation (see Fig. 17.69) reveals a loud first heart sound (S1) and an opening snap (OS) as the valve suddenly opens with the force of the increased left atrial pressure. With increasing severity, the OS moves closer to the second heart sound (S2), and with heavy calcification, the first heart sound softens and the OS may be absent. This is followed by a low-pitched, 'rumbling', mid-diastolic murmur, best heard with the bell of the stethoscope held lightly at the apex and the patient lying on the left side in expiration. If the patient is in sinus rhythm, the murmur becomes louder at the end of diastole as a result of atrial contraction (pre-systolic accentuation). Pulmonary hypertension may result in pulmonary valvular regurgitation, which causes an early diastolic murmur in the pulmonary area, known as a Graham Steell murmur.

Investigations

Chest X-ray

The chest X-ray may show left atrial enlargement with straightening of the left heart border and a 'double shadow' on the border of the right and left atria. Late in the course of the disease, a calcified mitral valve may be seen on a penetrated or lateral view. Pulmonary vascular congestion and enlargement of the main pulmonary arteries may also be present in severe disease.

ECG

In sinus rhythm the ECG may show a bifid P wave ('P mitrale') from delayed left atrial activation (Fig. 17.70). However, atrial fibrillation is frequently present. In the presence of pulmonary hypertension there may be features of right ventricular hypertrophy (right axis deviation and tall R waves in lead V_1) (Fig. 17.71).

Echocardiogram

Transthoracic echocardiography is able to determine the degree of thickening, calcification, and mobility of the mitral leaflets and the extent of commissural fusion and assess left atrial size (Fig. 17.72). The severity of the mitral stenosis (Box 17.38) can be defined by mitral valve area on two-dimensional echocardiography, with continuous wave (CW) Doppler to

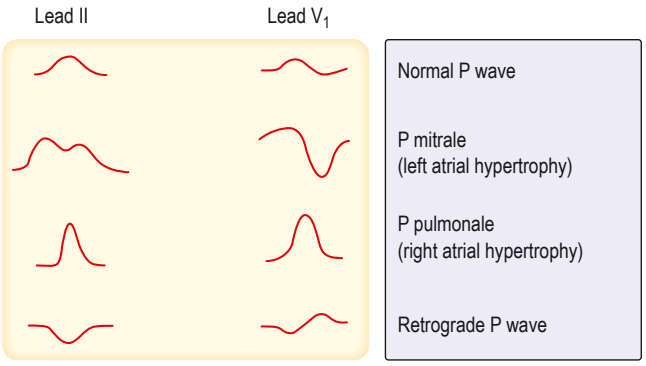


Fig. 17.70 A bifid P wave, as seen on the ECG in mitral stenosis (P mitrale). Other P wave abnormalities are also shown for comparison.

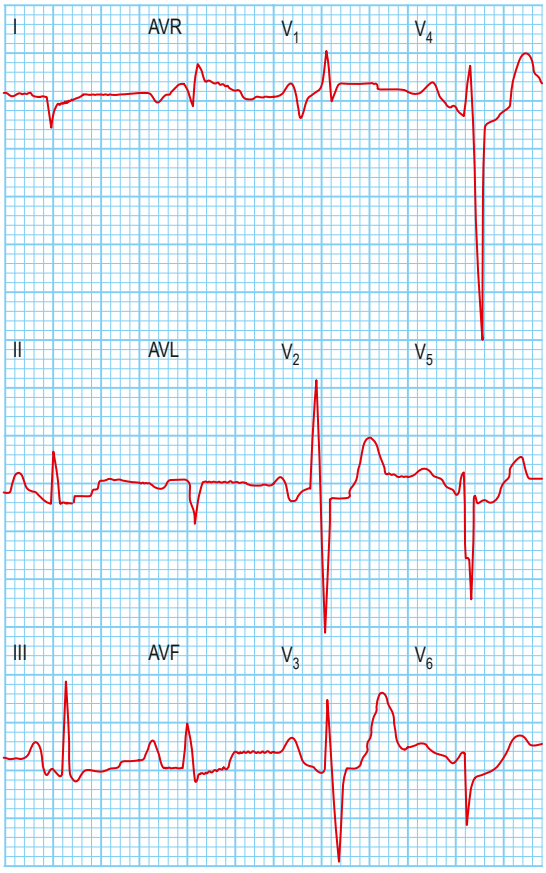

Fig. 17.71 Severe mitral stenosis, shown by a 12-lead ECG. Note the right axis deviation (frontal plane axis = +120 degrees), the left atrial conduction abnormality (large terminal negative component of the P wave in V_1), and the right ventricular hypertrophy (R wave in V_1 and right axis deviation).

measure the pressure half-time (the time taken for the pressure to halve from the peak value) and mean pressure drop across the valve. CW Doppler may also be used to estimate pulmonary artery pressure through measurement of the degree of tricuspid regurgitation.

TOE enables a detailed assessment of the mitral valve and other valves prior to consideration of surgical or percutaneous intervention and is able to detect thrombus in the left atrium or left atrial

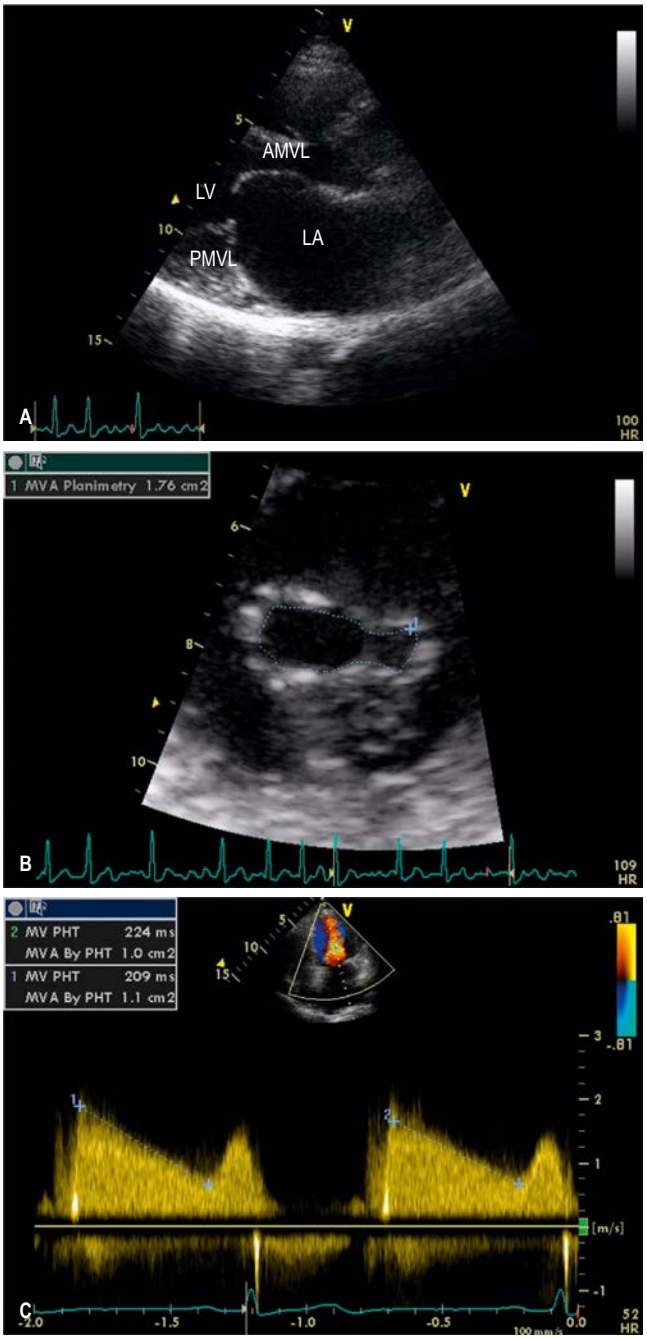

Fig. 17.72 Echocardiograms in rheumatic mitral valve disease. **(A)** A two-dimensional long-axis view, showing an enlarged left atrium and the 'hooked' appearance of the mitral valve leaflets, resulting from commissural fusion. **(B)** A magnified short-axis view, showing the mitral valve orifice as seen from the left atrium. The orifice area can be planimetered to assess the severity; in this case it is 1.5 cm^2, indicating moderately severe disease. **(C)** A continuous-wave (CW) Doppler recording, showing the slow rate of decay of flow velocity from the left atrium to the left ventricle during diastole. It is also possible to derive the valve orifice area from the velocity decay rate. *AMVL,* Anterior mitral valve leaflet; *LA,* left atrium; *LV,* left ventricle; *PMVL,* posterior mitral valve leaflet.

appendage. The Wilkins score is an echocardiographic assessment of the mitral valve (leaflet mobility, valve thickening, valve calcification, and subvalvular apparatus) and is helpful to determine suitability for percutaneous mitral valvuloplasty.

Cardiac catheterization

Left and right heart catheterization may be required in patients with severe mitral stenosis referred for intervention.

Management

Early symptoms of mitral stenosis, such as mild dyspnoea, can usually be treated with loop diuretics, although the presence of symptoms is an indication of surgical intervention. The onset of atrial fibrillation requires rate control (e.g., with beta-blockers or calcium-channel blockers) and consideration of DC cardioversion and anticoagulation with warfarin rather than a direct oral anticoagulant (DOAC), to prevent atrial thrombus and systemic embolization. Patients with severe mitral stenosis who develop symptoms, new-onset atrial fibrillation, or pulmonary hypertension are appropriate for intervention. Earlier prophylactic intervention may be indicated if the valve is amenable to balloon valvotomy and in pregnancy. There are four operative measures.

Trans-septal balloon valvotomy

This procedure is associated with low morbidity and mortality and involves introduction of a catheter into the right atrium via the femoral vein under local anaesthesia in the cardiac catheter laboratory. The interatrial septum is punctured and the catheter advanced into the left atrium and across the mitral valve. A balloon is passed over the catheter to lie across the valve and then inflated briefly to split the valve commissures. As with other valvotomy techniques, significant mitral regurgitation may result, necessitating valve replacement (see later). This procedure is ideal for patients with pliable valves in whom there is little involvement of the subvalvular apparatus and minimal mitral regurgitation (Wilkins score ≤8). TOE is required to exclude contraindications such as heavy calcification, more than mild mitral regurgitation, and left atrial thrombus.

Closed valvotomy

This operation is advised for patients with mobile, non-calcified, and non-regurgitant mitral valves. The fused cusps are forced apart by a dilator introduced through the apex of the left ventricle and guided into position by the surgeon's finger inserted via the left atrial appendage. Cardiopulmonary bypass is not required for this operation. Closed valvotomy may produce a good result for 10 years or more, but the valve cusps often re-fuse, and another operation may be necessary.

Open valvotomy

This operation is often preferred to closed valvotomy and requires cardiopulmonary bypass. The cusps are carefully dissected apart under direct vision, reducing the likelihood of traumatic mitral regurgitation,

Mitral valve replacement

Replacement with a mechanical or bioprosthetic mitral valve is necessary if:

- more than mild mitral regurgitation is present
- the valve is significantly calcified and stenotic and cannot be dissected open without producing significant mitral regurgitation
- there is severe mitral stenosis and thrombus in the left atrium despite anticoagulation
- there is a concomitant indication for surgery, for example, coronary artery bypass required.

Box 17.38 Echocardiographic severity of mitral stenosis

Parameter	Normal	Mild	Moderate	Severe
Pressure half-time (ms)	40–70	71–139	140–219	>219
Mean pressure drop (mmHg)		<5.0	5–10	>10
Valve area (cm^2)	4.0–6.0	1.5–2.0	1.0–1.5	<1.0

(Source: British Society of Echocardiography.)

Mitral regurgitation

Mitral regurgitation can occur due to a primary abnormality of the valvular apparatus involving the leaflets, mitral annulus, chordae tendineae, or papillary muscles or be secondary due to abnormalities of the left ventricle. The most frequent causes of mitral regurgitation are degenerative (mitral valve prolapse or myxomatous) disease, ischaemic heart disease, rheumatic heart disease, and infectious endocarditis. Mitral regurgitation may also be present in diseases of the myocardium (DCM and HCM), rheumatic autoimmune diseases (e.g., systemic lupus erythematosus), collagen diseases (e.g., Marfan's and Ehlers–Danlos syndromes), and disorders caused by drugs, including the centrally acting serotonin-releasing agent fenfluramine and the dopamine agonist cabergoline.

Pathophysiology

Regurgitation into the left atrium leads to left atrial dilation but little increase in left atrial pressure if the regurgitation is longstanding, as the regurgitant flow is accommodated by the enlarged left atrium. With acute mitral regurgitation (e.g., following MI, chordal rupture, or IE), the normal compliance of the left atrium does not allow dilation and the left atrial pressure rises. The left atrial *v*-wave is greatly increased and pulmonary venous pressure rises, leading to pulmonary oedema. Since a proportion of the stroke volume is regurgitated, the stroke volume increases to maintain the forward cardiac output and the left ventricle dilates with eccentric hypertrophy.

The Carpentier classification (Fig. 17.73) uses mitral leaflet motion to divide patients into different classes according to the mechanism of regurgitation, which can be useful when considering surgical intervention.

Clinical features

Symptoms

Mitral regurgitation can be present for many years and the cardiac dimensions greatly increased before any symptoms occur.

- ***Dyspnoea*** and ***orthopnoea*** develop because of pulmonary venous hypertension that arises as a direct result of mitral regurgitation and secondarily as a consequence of left ventricular failure.
- ***Fatigue*** and ***lethargy*** develop because of the reduced cardiac output.

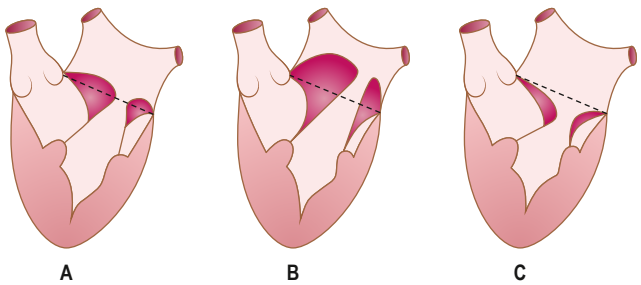

Fig. 17.73 Carpentier classification of mitral regurgitation and its causes. **(A)** Normal leaflet motion. **(B)** Increased leaflet motion/prolapse. **(C)** Restricted leaflet motion. *(Reproduced from Tuladhar SM, Punjabi PP. Surgical reconstruction of the mitral valve.* Heart *2006; 92:1373–1377, with permission.)*

- In the late stages of the disease the symptoms of ***right heart failure*** also occur and eventually lead to congestive cardiac failure.
- ***Cardiac cachexia*** may develop.
- **Palpitations** may occur from atrial fibrillation.

Signs

See Fig. 17.69.

The physical signs of uncomplicated mitral regurgitation are:

- ***Laterally displaced (forceful) diffuse apex beat*** and ***a systolic thrill*** (if severe)
- ***Soft first heart sound***, owing to the incomplete apposition of the valve cusps and their partial closure by the time ventricular systole begins
- ***Pansystolic murmur***, as regurgitation occurs throughout the whole of systole, being loudest at the apex but radiating widely over the precordium and into the axilla
- ***Mid-systolic click***, which may be present with a floppy mitral valve (see later); it is produced by the sudden prolapse of the valve and the tensing of the chordae tendineae that occurs during systole. This may be followed by a late systolic murmur owing to some regurgitation.
- ***Prominent third heart sound*** (S3), owing to the sudden rush of blood back into the dilated left ventricle in early diastole (sometimes a short mid-diastolic flow murmur may follow the third heart sound).

The signs related to atrial fibrillation, pulmonary hypertension, and left and right heart failure develop later in the disease. The onset of atrial fibrillation may have a much less dramatic effect on symptoms than in mitral stenosis.

Investigations

Chest X-ray

The chest X-ray may show left atrial and left ventricular enlargement. There is an increase in the cardiothoracic ratio and valve calcification may be present.

ECG

The ECG shows the features of left atrial delay (bifid P waves) and left ventricular hypertrophy (Fig. 17.74), as manifested by tall R waves in the left lateral leads (e.g., leads I and V_6) and deep S waves in the right-sided precordial leads (e.g., leads V_1 and V_2). Left ventricular hypertrophy occurs in about 50% of patients with mitral regurgitation. Atrial fibrillation may be present.

Echocardiogram

The echocardiogram (Fig. 17.75) shows a dilated left atrium and left ventricle. There may be specific features of chordal or papillary muscle rupture. The severity of regurgitation can be assessed with the use of colour Doppler, looking at the narrowest jet width (vena contracta) and area and calculating the regurgitant fraction, volume, or orifice area. Useful information regarding the severity of the condition can be obtained indirectly by observing the dynamics of ventricular function. ***TOE*** is used to identify the mechanism of regurgitation, the structural valve abnormalities, and the likelihood of successful surgical valve repair (see Fig. 17.75). Echocardiography during exercise is sometimes required in symptomatic individuals with discordant regurgitation severity at rest.

Cardiac catheterization

Left and right heart catheterization is appropriate in patients with suspected CAD and for assessment of pulmonary hypertension prior to surgery.

Management

Mild to moderate mitral regurgitation can be managed conservatively by following the patient with serial echocardiograms. Prophylaxis against endocarditis is discussed in the 'Prevention' section.

Current ESC guidelines recommend surgical intervention in patients with primary symptomatic severe chronic mitral regurgitation. Mitral valve repair is the preferred surgical technique as this preserves the functional components of the mitral apparatus, but mitral valve replacement may be required in those with advanced disease. ***Asymptomatic individuals*** should undergo regular surveillance in a Heart Valve Clinic, as certain echocardiographic parameters (LVEF ≤ 60%, LV end-systolic dimension > 40 mm, left atrium > 55 mm or pulmonary hypertension) are associated with a worse prognosis and should prompt surgical evaluation. The advantages of surgical intervention are diminished in more advanced disease. Sudden torrential mitral regurgitation, as seen with chordal or papillary muscle rupture or IE, necessitates emergency mitral valve surgery. When patients are not suited to surgical intervention or when surgery will be performed at a later date, management involves treatment with diuretics, ACE inhibitors, and anticoagulation if atrial fibrillation is present. A percutaneous mitral valve repair (MitraClip) may be appropriate in selected patients who are unsuitable for mitral surgery.

Mitral valve prolapse

This is also known as Barlow's syndrome or floppy mitral valve and is a common cause of mitral regurgitation. It is characterized by excessively large mitral valve leaflets, an enlarged mitral annulus, abnormally long chordae, or disordered papillary muscle contraction and can be diagnosed with echocardiography. Histology may demonstrate myxomatous degeneration of the mitral valve leaflets. Prolapsing mitral valve is more commonly seen in women than in men, and although most cases are sporadic, some have a familial preponderance. Its cause is unknown, but it may be associated with connective tissue disorders (Marfan's syndrome, Ehlers–Danlos syndrome, and pseudoxanthoma elasticum). Symptoms are usually due to mitral regurgitation, and some may experience atypical chest pain and develop atrial fibrillation. On auscultation, there is a systolic click from sudden stretch of the mitral chordae as the leaflets prolapse into the left atrium, and if regurgitation is present, this is late-systolic in the early phase and may progress to a pansystolic murmur.

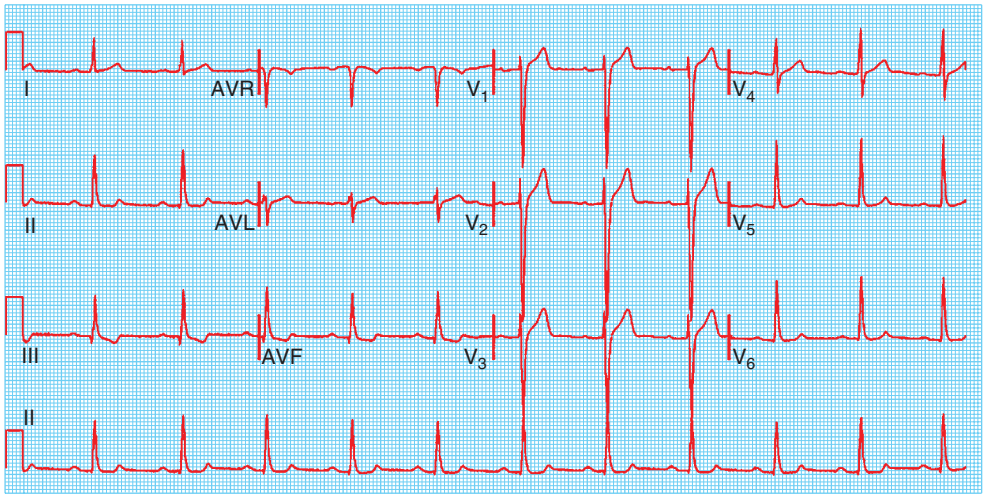
Secondary mitral regurgitation

Secondary mitral regurgitation refers to this abnormality in the presence of normal leaflet morphology and subvalvular apparatus. This is seen when there is either LV dysfunction and dilatation (due to cardiomyopathy) or atrial/annular dilatation (commonly seen with chronic AF). Unlike with primary mitral regurgitation, a clear benefit for surgical valve intervention has not been established. Treatment options for the individual patient in this instance are best decided by the Heart Valve team and may include medical treatment of the underlying cause, cardiac surgery, transcatheter intervention, heart transplant assessment, or palliation.

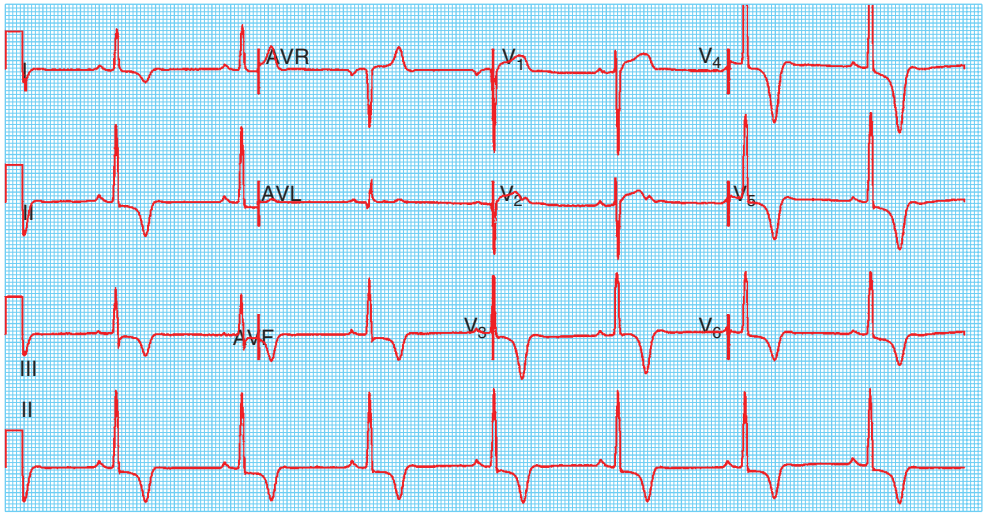
AORTIC VALVE

Aortic stenosis

Aortic stenosis is a chronic progressive disease that limits left ventricular outflow, leading to symptoms of chest pain, breathlessness, syncope, pre-syncope (exertional dizziness), and fatigue.

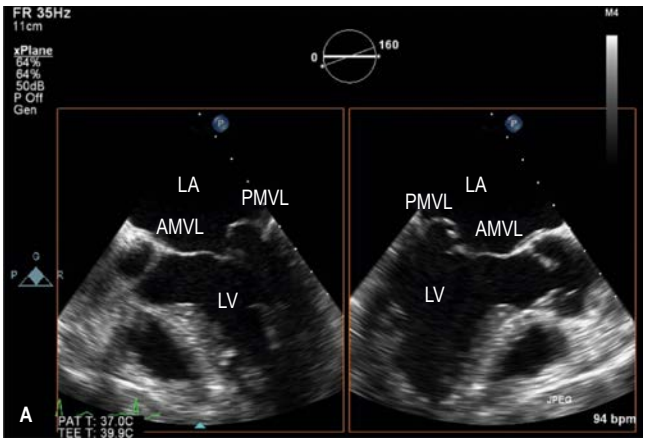


A



B

Fig. 17.74 Left ventricular hypertrophy, shown in 12-lead ECGs. **(A)** Note the size of the S wave seen in V_1 (26 mm); S in V_1 + R in V_6 = >35 mm. **(B)** Left ventricular hypertrophy in a patient with hypertrophic cardiomyopathy, with additional repolarization changes of deep T-wave inversion in leads V_3–V_6 and leads I, II, III, and AVF.



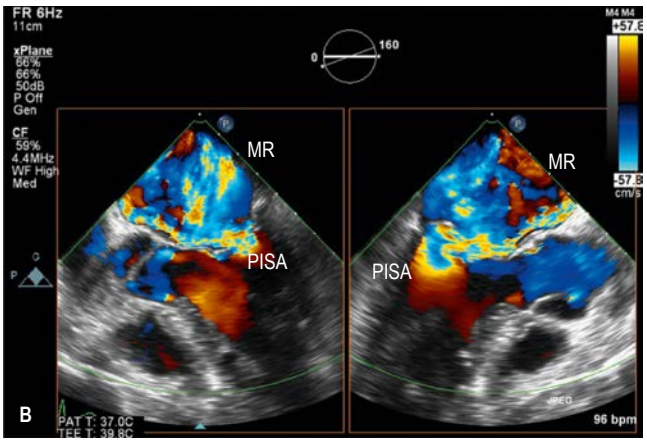


Fig. 17.75 Mitral regurgitation. **(A)** Transoesophageal echocardiography with marked prolapse of part of the posterior mitral valve leaflet (PMVL). **(B)** Image A with colour Doppler demonstrating severe mitral regurgitation (MR) into the left atrium (LA). *AMVL,* Aortic mitral valve leaflet; *LV,* left ventricle; *PISA,* proximal isovelocity surface area.

Aortic valve stenosis includes calcific stenosis of a trileaflet aortic valve, stenosis of a congenitally bicuspid valve, and rheumatic aortic stenosis. The prevalence of aortic stenosis increases with age and is primarily due to calcific disease in Europe, but worldwide, the commonest cause is rheumatic.

Calcific aortic valvular disease (CAVD) is the most common cause of aortic stenosis and occurs mainly in the elderly. This is an inflammatory process involving macrophages and T lymphocytes, initially with thickening of the subendothelium and adjacent fibrosis. The lesions contain lipoproteins, which calcify, increasing leaflet stiffness and reducing systolic opening. This can occur in a tri- or bileaflet aortic valve.

Bicuspid aortic valve (BAV) (Fig. 17.76) is the most common form of congenital heart disease, occurring in 1% to 2% of live births; in about 9% of cases it is familial. Patients with familial bicuspid valve tend to present at an earlier age. BAV is associated with aortic coarctation, root dilation, and, potentially, aortic dissection, and patients should have regular follow-up echocardiography.

Rheumatic fever can produce progressive fusion, thickening, and calcification of the aortic valve. In rheumatic heart disease the aortic valve is affected in about 30% to 40% of cases and there is usually associated mitral valve disease.

Other causes of valvular stenosis include chronic kidney disease, Paget's disease of bone, previous radiation exposure, and systemic lupus erythematosus. ***Valvular aortic stenosis*** should be distinguished from other causes of obstruction to left ventricular emptying (Fig. 17.77), which include:

- supravalvular obstruction—a congenital fibrous diaphragm above the aortic valve, often associated with learning difficulties and hypercalcaemia (Williams' syndrome)
- subvalvular aortic stenosis—a congenital condition in which a fibrous ridge or diaphragm is situated immediately below the aortic valve
- HCM—septal muscle hypertrophy obstructing left ventricular outflow.

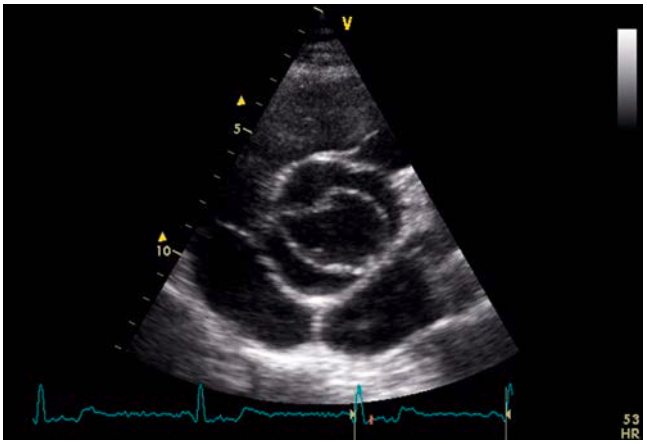

Fig. 17.76 **Bicuspid aortic valve.**

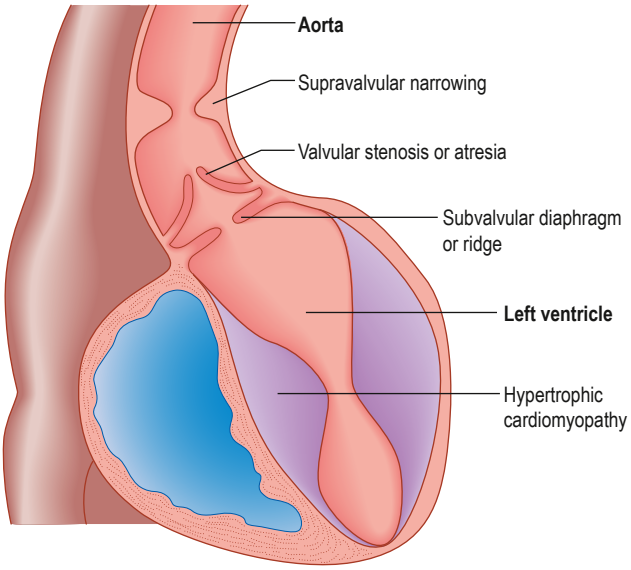

Fig. 17.77 **Several forms of left ventricular outflow tract obstruction.**

Pathophysiology

Obstructed left ventricular emptying leads to increased left ventricular pressure and compensatory left ventricular hypertrophy. In turn, this results in relative ischaemia of the left ventricular myocardium and consequent angina, arrhythmias, and left ventricular failure. The obstruction to left ventricular emptying is relatively more severe on exercise. Normally, exercise causes a many-fold increase in cardiac output, but when there is severe narrowing of the aortic valve orifice, the cardiac output can hardly increase. Thus, the blood pressure falls, coronary ischaemia worsens, the myocardium fails, and cardiac arrhythmias may develop. Left ventricular systolic function is typically preserved in patients with aortic stenosis.

Clinical features

Symptoms

There are usually no symptoms until aortic stenosis is moderately severe (when the aortic orifice is reduced to one-third of its normal size). At this stage, ***exercise-induced syncope***, ***angina***, and ***dyspnoea*** develop. When symptoms occur, the prognosis is poor: on average, death occurs within 2 to 3 years if there has been no valvular intervention.

Signs

See Fig. 17.78.

Pulse

The carotid pulse is small-volume and slow-rising or plateau in nature (see 'Character' section).

Precordial palpation

The apex beat is not usually displaced because hypertrophy (as opposed to dilation) does not produce noticeable cardiomegaly. However, the pulsation is sustained and obvious. A double impulse is sometimes felt because the fourth heart sound or atrial contraction ('kick') may be palpable. A systolic thrill may be felt in the aortic area.

Auscultation

There is an ejection systolic murmur that is usually crescendo–decrescendo ('diamond-shaped'), harsh in quality, and best heard in the second right intercostal space (aortic area). It may radiate into the carotid arteries and also the precordium. The murmur is usually longer when the disease is more severe, as a longer ejection time is required. Importantly, a soft or absent second heart sound reflects severe aortic stenosis. The intensity

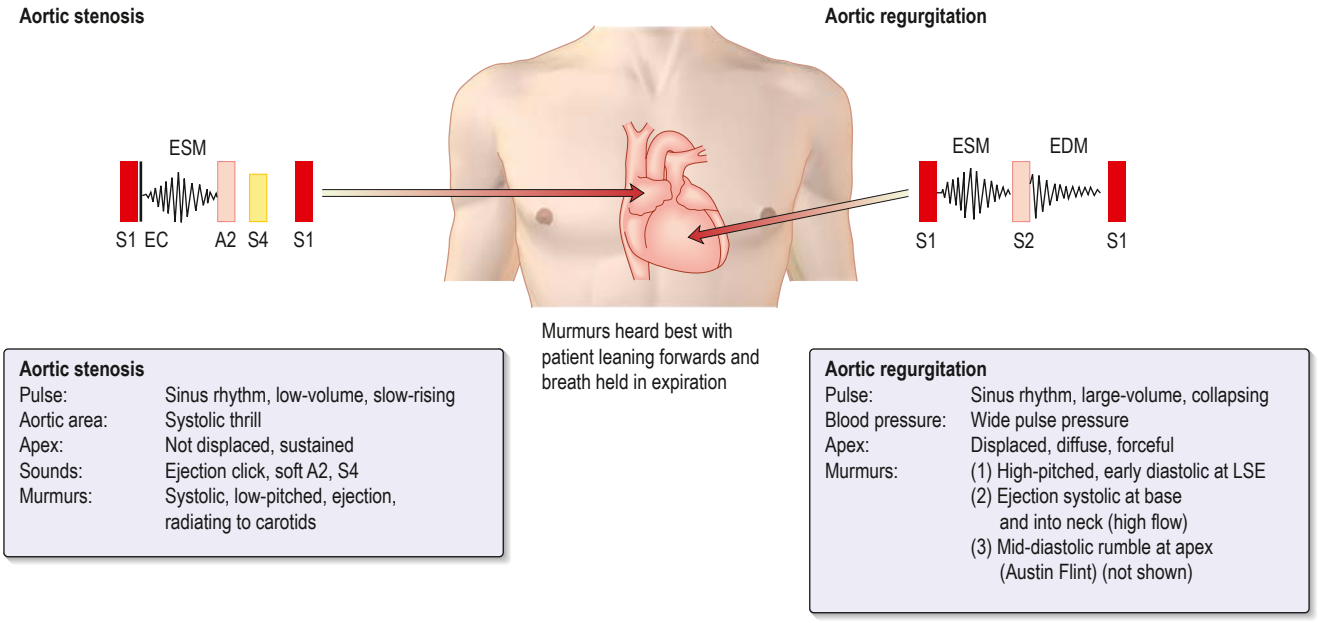

Fig. 17.78 Features of aortic stenosis and aortic regurgitation. *A2,* Aortic component of the second heart sound; *EC,* ejection click; *EDM,* early diastolic murmur; *ESM,* ejection systolic murmur; *LSE,* left sternal edge; *S1,* first heart sound; *S4,* fourth heart sound.

of the murmur is not a good guide to the severity of the condition because it is lessened by a reduced cardiac output. In severe cases the murmur may be inaudible.

Other findings include:

- ***systolic ejection click***, unless the valve has become immobile and calcified
- ***soft or inaudible aortic second heart sound*** when the aortic valve becomes immobile
- ***reversed splitting of the second heart sound*** (splitting on expiration) (see 'Second heart sound [S2]' section)
- ***prominent fourth heart sound***, caused by atrial contraction and heard unless coexisting mitral stenosis prevents this.

Investigations

Chest X-ray

The heart size is usually normal, although the cardiothoracic ratio increases as heart failure occurs. The aortic valve may be calcified. There may be a prominent, dilated, ascending aorta as a result of turbulent blood flow above the stenosed aortic valve leading to post-stenotic dilation.

ECG

The ECG shows left ventricular hypertrophy and left atrial delay. A left ventricular 'strain' pattern due to 'pressure overload' (depressed ST segments and T-wave inversion in leads orientated towards the left ventricle, i.e., leads I, AVL, V_5, and V_6) is common when disease is severe. Usually, sinus rhythm is present but atrial fibrillation and ventricular arrhythmias may be noted.

Echocardiogram

Echocardiography readily demonstrates the thickened, calcified, and immobile aortic valve cusps and can differentiate between a trileaflet and bicuspid valve. The severity of aortic stenosis is measured using the pressure gradient across the valve and the calculated valve area (Box 17.39 and Fig. 17.79). It can also assess for the presence of left ventricular hypertrophy, concomitant valve disease, and aortic coarctation.

Box 17.39 Echocardiographic severity of aortic stenosis

Parameter	Normal	Mild	Moderate	Severe
Peak velocity (m/s)	<1.7	1.7–2.9	3.0–4.0	>4.0
Peak pressure drop (mmHg)		<36	36–64	>64
Mean pressure drop (mmHg)		<25	25–40	>40
Valve area (cm^2)	>2.0	1.5–2.0	1.0–1.4	<1.0

(Source: British Society of Echocardiography.)

CMR and cardiac CT

These techniques are indicated for assessing the thoracic aorta for the presence of aneurysm, dissection, or coarctation. Cardiac CT has a key role in individuals being considered for transcatheter aortic valve replacement (TAVR, see below), but it can also measure the aortic valve calcium score to confirm stenosis severity if non-invasive testing is inconclusive.

Cardiac catheterization

Cardiac catheterization is mainly required to identify coexistent CAD prior to surgery but may be used to assess the pressure gradient across the aortic valve if further confirmation of severity is required.

Management

In patients with aortic stenosis symptoms are a good index of severity, and all symptomatic, appropriate patients should have ***aortic valve replacement***. Patients with a BAV and ascending aorta of over 50 mm or expanding at more than 5 mm per year should be considered for surgical intervention. Asymptomatic patients should be under regular review in a valve clinic for assessment of symptoms and serial echocardiography. Surgical intervention for asymptomatic people with severe aortic stenosis is recommended in those with:

- symptoms or fall in blood pressure during an exercise test
- very high peak velocity across aortic valve of more than 5.0 m/s

- rapid increase in velocity through the valve at more than 0.3 m/s/year
- the need for concurrent cardiac surgery, for example, CABG, ascending aorta, or other cardiac valve replacement.

Antibiotic prophylaxis against IE is discussed in the 'Prevention' section. Provided that the valve is not severely deformed or heavily calcified, critical aortic stenosis in childhood or adolescence can be treated by valvotomy (performed under direct vision by the surgeon or by balloon dilation using X-ray visualization). This produces temporary relief from the obstruction and aortic valve replacement will usually be required later. Balloon dilation (valvuloplasty) has been tried in adults, especially in the elderly, as an alternative to surgery, but results are poor and such treatment is reserved for patients unfit for surgery or as a 'bridge' to TAVR or surgery.

Transcatheter aortic valve replacement (TAVR or TAVI)

This is a minimally invasive procedure involving insertion of a new valve within the narrowed aortic valve, usually reserved for those at higher risk and not suitable for traditional surgical valve replacement due to frailty or underlying co-morbidities. A catheter is inserted into an artery in the groin and guided to the heart, and once in position, a balloon stent valve is expanded into place (Fig. 17.80). Compared with open heart surgery, procedural complications and mortality are lower, recovery time is quicker, and new-generation valves have been shown to be durable in follow-up studies; as such, the indications for this intervention are likely to expand to lower risk groups except in those who require concomitant cardiac surgery, for example, bypass grafting.

Aortic regurgitation

Aortic regurgitation can occur in diseases affecting the aortic valve, such as calcific valve disease or rheumatic valve disease, and diseases leading to aortic root dilatation, such as hypertension and Marfan's syndrome (MFS; Box 17.40).

Pathophysiology

Aortic regurgitation is reflux of blood from the aorta through the aortic valve back into the left ventricle during diastole. If net

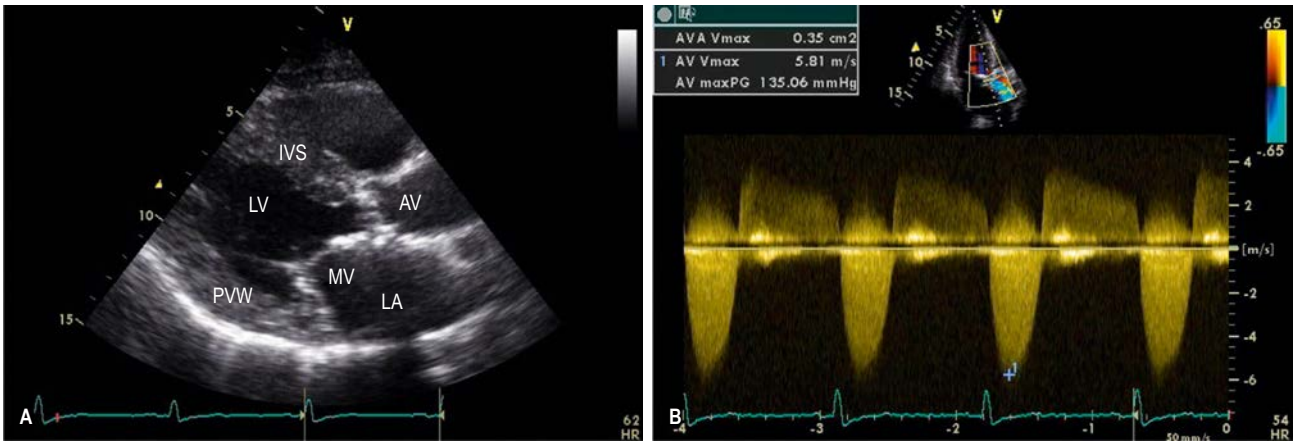

Fig. 17.79 Cardiac echograms. **(A)** Two-dimensional echocardiogram (long-axis view) in a patient with calcific aortic stenosis. The calcium in the valve generates abnormally intense echoes. There is some evidence of associated left ventricular hypertrophy. **(B)** Continuous-wave (CW) Doppler signals obtained from the right upper parasternal edge, where the high-velocity jet from the stenotic valve is coming towards the transducer. *AV,* Aortic valve; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle; *MV,* mitral valve; *PVW,* posterior ventricular wall.

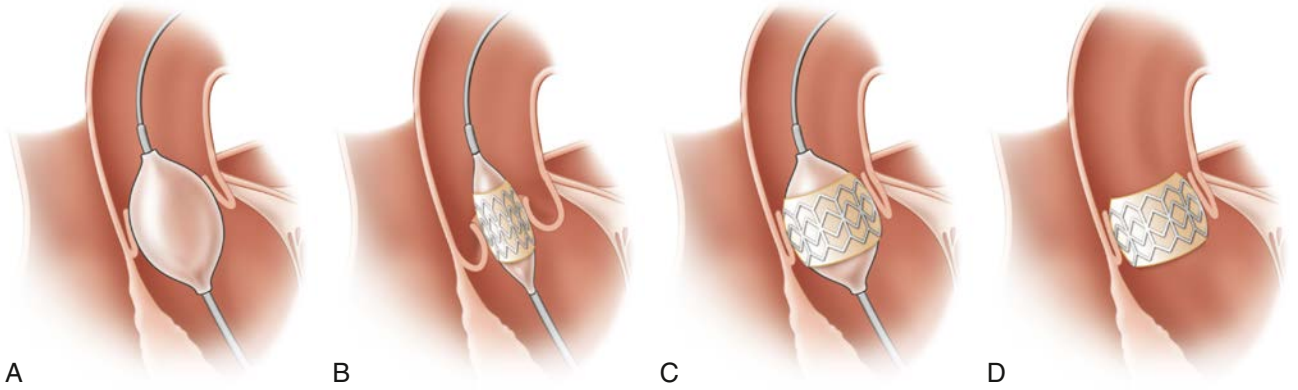

Fig. 17.80 Transcatheter aortic valve replacement (TAVR) procedure. **(A)** Balloon aortic valvuloplasty. **(B)** New valve placed around balloon. **(C)** Balloon inflated, deploying valve. **(D)** Catheter removed, valve in place. *(Concepts of Care for Patients With Cardiac Conditions. Medical-Surgical Nursing: Concepts for Clinical Judgment and Collaborative Care, Eleventh Edition. 2024. ISBN 978-0-323-87826-5.)*

cardiac output is to be maintained, the total volume of blood pumped into the aorta must increase and, consequently, left ventricular size must enlarge. Because of the aortic runoff during diastole, diastolic blood pressure falls, and coronary perfusion is decreased, whereas the increased stroke volume increases the systolic pressure, thereby also increasing the pulse pressure. In addition, the larger left ventricular size is mechanically less efficient, so the demand for oxygen is greater and cardiac ischaemia develops.

Clinical features

Symptoms

Patients may remain asymptomatic for many years until ***left ventricular failure*** develops with gradual exertional ***dyspnoea*** and lethargy, depending on the extent of left ventricular dilation and dysfunction. ***Angina pectoris*** may arise. ***Arrhythmias*** are relatively uncommon.

Signs

See Fig. 17.78. The signs of aortic regurgitation are many and are due to the high stroke volume, rapid return of blood back into the left ventricle, and increased left ventricular size.

The pulse is bounding or collapsing ('water hammer pulse') and there is a wide arterial pulse pressure (see 'Arterial pulse' section). The following signs, which are rare, also indicate a hyperdynamic circulation:

- ***Quincke's sign***—capillary pulsation in the nail beds
- ***de Musset's sign***—head nodding with each heartbeat
- ***Duroziez's sign***—a to-and-fro murmur heard when the femoral artery is auscultated with pressure applied distally (if found, it is a sign of severe aortic regurgitation)
- ***pistol shot femorals***—a sharp bang heard on auscultation over the femoral arteries in time with each heartbeat.

The apex beat is displaced laterally and downwards and is forceful in quality. On auscultation, there is a high-pitched early diastolic murmur best heard at the left sternal edge in the fourth intercostal space (Erb's point), with the patient leaning forwards and the breath held in expiration. Because of the volume overload there is commonly an ejection systolic flow murmur. The regurgitant jet can partially close the anterior mitral valve leaflet, causing a soft mid-diastolic murmur (Austin Flint rumble).

Investigations

Chest X-ray

The chest X-ray features are those of left ventricular enlargement and, possibly, dilation of the ascending aorta with calcification. The aortic valve may be calcified if valvular disease is responsible for the regurgitation.

ECG

The ECG reflects changes in the left ventricle with left ventricular hypertrophy due to 'volume overload': tall R waves and deeply inverted T waves in the left-sided chest leads, and deep S waves in the right-sided leads. Normally, sinus rhythm is present.

Echocardiogram

The severity of aortic regurgitation is assessed with a combination of colour Doppler (extent and width of the regurgitant jet; Fig. 17.81) and continuous-wave Doppler looking for diastolic flow reversal in the descending thoracic aorta, with characteristic pressure half-time measurements. Left ventricular volumes are increased and cardiac contraction is dynamic due to the increased stroke volume. The aortic root may also be enlarged. Diastolic fluttering of the mitral leaflets or septum occurs in severe aortic regurgitation (producing the Austin Flint rumble). TOE may provide additional information about the valves and aortic root.

Cardiac catheterization

Cardiac catheterization is appropriate for patients requiring valvular intervention, although CTCA or CT angiography may be an alternative in younger patients.

CMR and cardiac CT

These techniques may be indicated for assessing the thoracic aorta in cases of aortic dilation or dissection. CMR can be used to quantify left ventricular volumes and regurgitation severity.

Management

The underlying cause of aortic regurgitation (e.g., IE or syphilitic aortitis) may require specific treatment. Patients with acute aortic regurgitation may need treatment with vasodilators and inotropes. Patients should receive treatment for hypertension. ACE inhibitors are indicated in patients with left ventricular dysfunction and beta-blockers may slow aortic dilation in patients with MFS by reduction in shear stress. Patients should be followed by serial echocardiography as part of a valve clinic. As symptoms do not develop until the

? Box 17.40 Causes and associations of aortic regurgitation

Acute aortic regurgitation
- Acute rheumatic fever
- Infective endocarditis
- Dissection of the aorta
- Ruptured sinus of Valsalva aneurysm
- Failure of prosthetic valve

Chronic aortic regurgitation
- Rheumatic heart disease
- Syphilis
- Arthritides:
  - Reactive arthritis
  - Ankylosing spondylitis
  - Rheumatoid arthritis
- Hypertension (severe)
- Bicuspid aortic valve
- Aortic endocarditis
- Marfan's syndrome
- Osteogenesis imperfecta

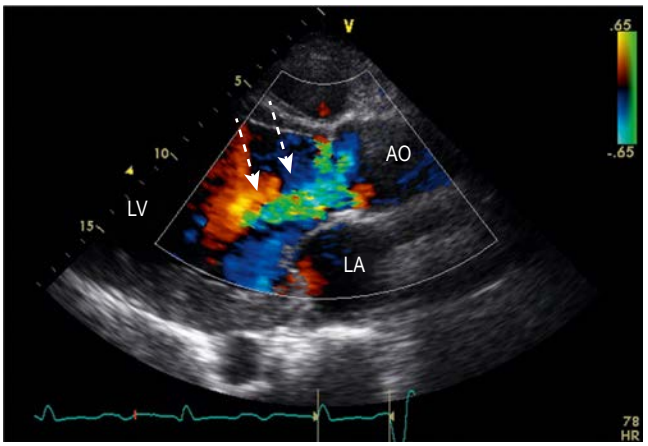

Fig. 17.81 Aortic regurgitation: colour Doppler. A regurgitant jet *(green)* can be seen passing retrogradely into the left ventricle from the aorta. *AO,* Aorta; *LA,* left atrium; *LV,* left ventricle.

myocardium fails, and because the myocardium may not recover fully after surgery, operative valve replacement may be performed before significant symptoms occur.

Aortic surgery is indicated in:

- acute severe aortic regurgitation, for example, as a result of endocarditis
- symptomatic patients (dyspnoea, NYHA class II–IV, angina) with chronic severe aortic regurgitation
- asymptomatic patients with an LVEF of less than or equal to 50%
- asymptomatic patients with an LVEF of more than 50% but with a dilated left ventricle (end-systolic dimension >50 mm)
- those undergoing CABG or surgery of the ascending aorta or other cardiac valve.

Both mechanical prostheses and tissue valves are used. Tissue valves are preferred in the elderly and in cases where anticoagulants must be avoided but are contraindicated in children and young adults because of the rapid calcification and degeneration of the valves.

Antibiotic prophylaxis against IE (see 'Prevention' section) is not recommended.

TRICUSPID VALVE

Tricuspid stenosis

This uncommon valve lesion, which is seen much more often in women than in men, is usually due to rheumatic heart disease and is frequently associated with mitral and/or aortic valve disease. Tricuspid stenosis is also seen in carcinoid syndrome and ergotamine treatment.

Pathophysiology

Tricuspid valve stenosis results in a reduced cardiac output, which is restored towards normal when the right atrial pressure increases. The resulting systemic venous congestion leads to hepatomegaly, ascites, and dependent oedema.

Clinical features

Symptoms

Patients with tricuspid stenosis are likely to have left-sided rheumatic valve disease that may be the main driver of symptoms which include abdominal pain (hepatomegaly), abdominal distension (ascites), and peripheral oedema.

Signs

See Fig. 17.82. The patient usually is in sinus rhythm and there is a prominent jugular venous *a*-wave. This pre-systolic pulsation may also be felt over the liver. There is usually a rumbling mid-diastolic murmur, which is heard best at the lower left sternal edge and is louder on inspiration. It may be missed because of the murmur of coexisting mitral stenosis. A tricuspid OS may occasionally be heard. Hepatomegaly, abdominal ascites, and dependent oedema may be present.

Investigations

Chest X-ray may show a prominent right atrial bulge. ECG demonstrates an enlarged right atrium as shown by peaked, tall P waves (>3 mm) in lead II. Echocardiography may show a thickened and immobile tricuspid valve and can quantify the severity of stenosis and other valvular lesions.

Management

Medical management consists of diuretic therapy and salt restriction. Tricuspid valvotomy is occasionally possible but tricuspid valve replacement is often necessary. Usually, other valves also need replacement because tricuspid valve stenosis is rarely an isolated problem.

Tricuspid regurgitation

Functional tricuspid regurgitation (see Fig. 17.23) may occur whenever the right ventricle dilates: for example, in cor pulmonale, MI, or pulmonary hypertension.

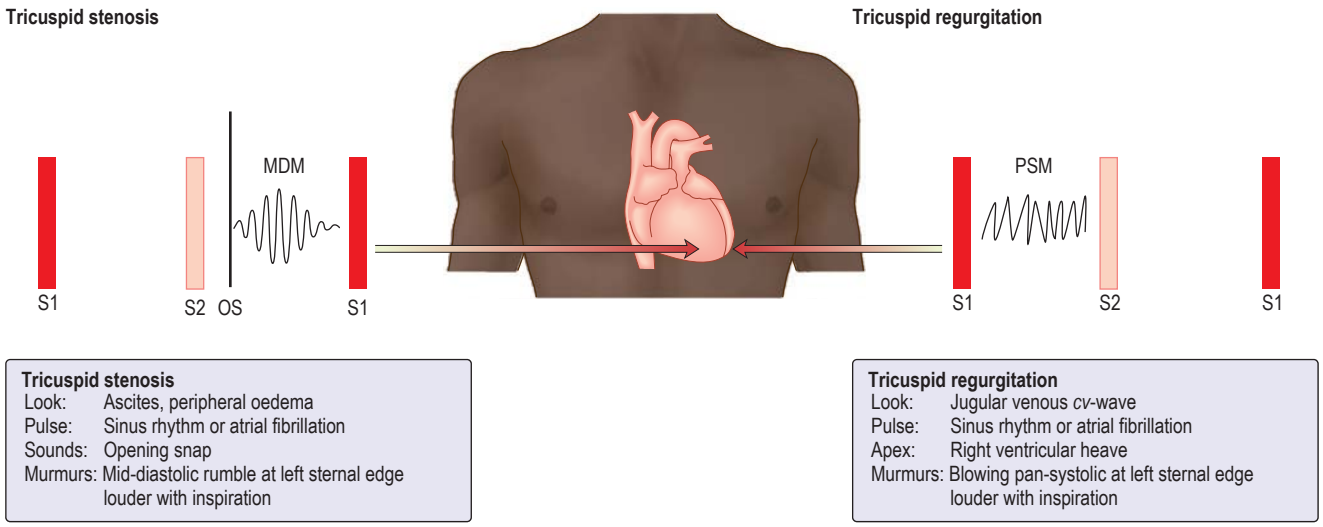

Fig. 17.82 Features of tricuspid stenosis and tricuspid regurgitation. *MDM,* Mid-diastolic murmur; *OS,* opening snap; *PSM,* pansystolic murmur; *S1,* first heart sound; *S2,* second heart sound.

Organic tricuspid regurgitation may occur with rheumatic heart disease, IE, carcinoid syndrome, Ebstein's anomaly (a congenitally malpositioned tricuspid valve), and other congenital abnormalities of the AV valves.

Clinical features

The valvular regurgitation gives rise to high right atrial and systemic venous pressures. Patients may experience the symptoms of ***right heart failure***.

Signs (see Fig. 17.82) include a large jugular venous '*cv*'-wave and a palpable liver that pulsates in systole. Usually, a right ventricular impulse may be felt at the left sternal edge, and there is a blowing pansystolic murmur, best heard on inspiration at the lower left sternal edge. Atrial fibrillation is common.

Investigations

An ***echocardiogram*** can assess the tricuspid leaflets (e.g., displaced in Ebstein anomaly, thickened in carcinoid, vegetations in endocarditis) and quantify dilation of the right ventricle.

Management

Functional tricuspid regurgitation usually improves with medical management. Severe organic tricuspid regurgitation may require operative repair of the tricuspid valve (annuloplasty or annuloplication) and very occasionally, tricuspid valve replacement may be necessary. In intravenous drug users with IE of the tricuspid valve, surgical removal of the valve is recommended to eradicate the infection. This is usually well tolerated in the short term. The insertion of a prosthetic valve for this condition is sometimes necessary.

PULMONARY VALVE

Pulmonary stenosis

This is usually a congenital lesion but may rarely result from rheumatic fever or from the carcinoid syndrome. Congenital pulmonary stenosis may be associated with Fallot's tetralogy, Noonan's syndrome, or congenital rubella syndrome. Pulmonary stenosis may be valvular, subvalvular, or supravalvular.

Clinical features

The obstruction to right ventricular emptying results in right ventricular hypertrophy, which, in turn, leads to right atrial hypertrophy. Severe ***pulmonary obstruction*** may be incompatible with life, but lesser degrees of obstruction give rise to ***fatigue***, ***syncope***, and the symptoms of ***right heart failure***. Mild pulmonary stenosis may be asymptomatic.

Physical signs (Fig. 17.83) are characterized by a harsh midsystolic ejection murmur, best heard on inspiration, to the left of the sternum in the second intercostal space. This murmur is often associated with a thrill. The pulmonary closure sound is usually delayed and soft. There may be a pulmonary ejection sound if the obstruction is valvular. A right ventricular fourth sound and a prominent jugular venous *a*-wave are present when the stenosis is moderately severe. A right ventricular heave (sustained impulse) may be felt.

Investigations

The chest X-ray usually shows a prominent pulmonary artery owing to post-stenotic dilation. The ECG demonstrates both right atrial and right ventricular hypertrophy, although it may sometimes be normal, even in severe pulmonary stenosis. Echocardiography can quantify the stenosis, assess the right heart, and look for other valve lesions or congenital cardiac abnormalities.

Management

Management of severe pulmonary stenosis requires pulmonary valvotomy (balloon valvotomy or direct surgery).

Pulmonary regurgitation

Physiological or mild pulmonary regurgitation is a common finding. Secondary pulmonary regurgitation is seen from dilation of the pulmonary valve ring, which occurs in pulmonary hypertension (Graham Steell murmur). It may also occur following tetralogy of Fallot repair. It is characterized by a decrescendo diastolic murmur, beginning

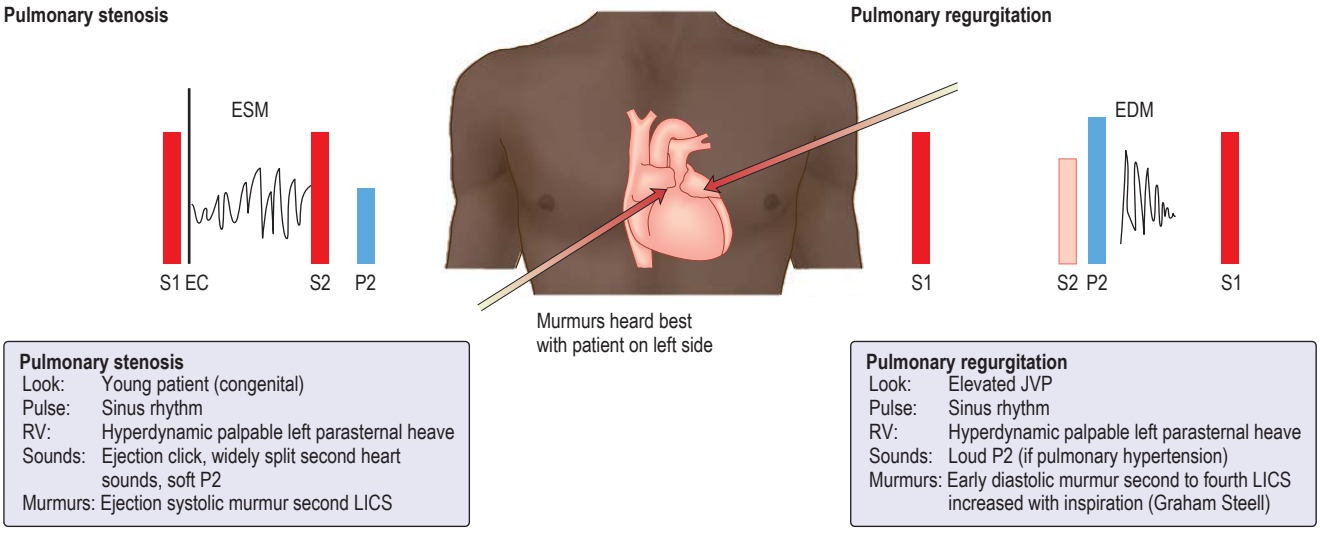

Fig. 17.83 Features of pulmonary stenosis and pulmonary regurgitation. *EC,* Ejection click; *EDM,* early diastolic murmur; *ESM,* end-systolic murmur; *ICS,* intercostal space; *LICS,* left intercostal space; *JVP,* jugular venous pulse; *P2,* pulmonary component of the second heart sound; *S1,* first heart sound; *S2,* second heart sound.

with the pulmonary component of the second heart sound that is difficult to distinguish from the murmur of aortic regurgitation ('Clinical memo', Fig. 17.83). Pulmonary regurgitation usually causes no symptoms and treatment is rarely necessary.

PROSTHETIC VALVES

There is no ideal replacement for our own normally functioning, native heart valves. There are two options for valve prostheses: mechanical (Fig. 17.84) or tissue (bioprosthetic).

The valves consist of two basic components: an opening to allow blood to flow through and an occluding mechanism to regulate the flow. Mechanical prostheses rely on artificial occluders: double tilting disc (St Jude), tilting disc (Björk–Shiley), or a ball and cage (Starr–Edwards). Tissue prostheses are derived from human (homograft) or porcine or bovine (xenograft) sources. A valve replacement from within the same patient (i.e., pulmonary to aortic valve position) is termed an autograft.

Mechanical versus tissue valves

Mechanical valves, being artificial structures, are more durable than their tissue counterparts, which tend to degenerate after 10 years. However, artificial structures are more thrombogenic. Mechanical valves require formal anticoagulation for the lifetime of the prosthesis. The target INR is determined by what type of valve is inserted, where it is positioned (risk of thrombosis higher for mitral than aortic valves), and whether the patient has additional risk factors for thromboembolism (mitral, tricuspid, and pulmonary disease is higher risk than aortic valve disease; previous thromboembolism; atrial fibrillation; left atrial diameter >50 mm; mitral stenosis; LVEF < 35%; hypercoagulable states, see Chapter 40).

All mechanical valves require anticoagulation, the precise strategy being dictated by the specifics of the prosthesis and other factors:

- ***low-thrombogenicity prosthesis*** (Carbomedics [aortic position], Medtronic Hall, St Jude Medical [without silzone]): INR 2.5 without and 3.0 with additional risk factors
- ***medium-thrombogenicity prosthesis*** (Björk–Shiley, other bileaflet valves): INR 3.0 without and 3.5 with additional risk factors
- ***high-thrombogenicity prosthesis*** (Lillehei–Kaster, Omniscience, Starr–Edwards): INR 3.5 without and 4.0 with additional risk factors.

Tissue valves require anticoagulation for a limited postoperative period only, while the suture lines endothelialize (the ESC recommends 3 months with a target INR of 2.5, although some centres use low-dose aspirin 75–100 mg daily). This can then be discontinued unless another risk factor for thromboembolism (e.g., atrial fibrillation) persists. There is currently no role for DOACs.

On auscultation, tissue valve heart sounds are comparable to those of a native valve. Mechanical valve heart sounds are generally louder, and both opening and closing sounds can be heard.

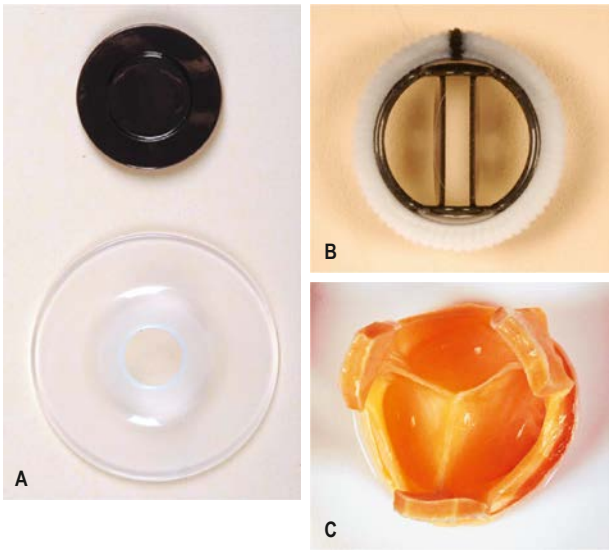

Fig. 17.84 Prosthetic valves. **(A)** Björk–Shiley mechanical prosthetic valve. **(B)** St Jude double tilting disc. **(C)** Aortic valve tissue prosthesis (aortic view).

Complications

All prostheses carry a risk of infection. Prosthetic valve endocarditis is associated with significant morbidity and mortality, and prevention is the cornerstone of management. Patient education regarding dental hygiene, avoidance of piercings and tattoos, and antibiotic prophylaxis is vital and should be reinforced at clinic visits. Details of antibiotic prophylaxis indicated in patients undergoing different types of interventional procedures are given in Box 12.8. Additional prophylaxis indicated in patients at higher risk of endocarditis is discussed in the 'Prevention' section. This must be borne in mind when managing a patient with a prosthetic heart valve, and steps should be taken to minimize the risk involved.

The prosthetic valve occluding mechanism can be interrupted by vegetations but also by thrombosis and calcification, resulting in either stenosis or regurgitation. The prosthesis can become detached from the valve ring, resulting in a ***para-prosthetic leak***. Haemolysis and anaemia from damage to red blood cells have become less common with current valves but may be seen in paravalvular regurgitation. Evidence of structural failure can be detected by simple auscultation, with echocardiography as the initial investigation of choice. TTE is non-invasive but scattering of echoes by mechanical valves makes assessment difficult. TOE provides alternative views and higher image resolution, making it the preferred investigation when prosthetic valve endocarditis is suspected.

Interruption of anticoagulant therapy

For minor surgical procedures, including dental extraction and diagnostic endoscopy, anticoagulation should not be interrupted, and the target INR may be reduced to 2.0 dependent on the valve. Percutaneous arterial puncture is safe with an INR below 2.0, although radial catheterization is safe at higher INR levels. For major surgical procedures, anticoagulation should be discontinued 5 days before the procedure and intravenous UFH or subcutaneous LMWH commenced when the INR is below 2.0.

Pregnancy and prosthetic heart valves

The types of valve prosthesis for use in women of childbearing age are as follows:

- ***Bioprosthetic valves*** are preferable during pregnancy, as they are less thrombogenic and do not require anticoagulation. However, valve degradation in women of childbearing age has been shown to be as high as 50% at 10 years and 90% at 15 years; women with a bioprosthetic valve are likely to require redo valve surgery.

- ***Mechanical heart valves*** have excellent durability but are thrombogenic and require life-long anticoagulation with warfarin. Pregnancy is a hypercoagulable state due to increased levels of fibrinogen and factors VII, VIII, and X; decreased levels of protein S activity; venous hypertension; and stasis.

Pregnancy in women with a mechanical heart valve is associated with increased maternal mortality (1%–4%) due to valve thrombosis. There is no anticoagulation regime that is ideal in these patients, so care should be managed by a pregnancy Heart Team who can balance the risks and benefits to the fetus and mother. Warfarin crosses the placenta and is associated with a 5%–12% risk of embryopathy during the first trimester. Warfarin also has an anticoagulant effect in the fetus, which may lead to spontaneous fetal intracranial haemorrhage. UFH or LMWH is preferable, particularly if doses of warfarin higher than 5 mg are required, as these drugs do not cross the placenta or cause fetal embryopathy. However, UFH may not provide consistent therapeutic anticoagulation during pregnancy, and there is a high incidence (25%) of valve thrombosis. LMWH provides a more consistent anticoagulant effect when given twice daily, with dose adjustment depending on the type of valve prosthesis to maintain anti-Xa levels.

INFECTIVE ENDOCARDITIS

Infective endocarditis is an endovascular infection of cardiovascular structures, including cardiac valves, the atrial and ventricular endocardium, the large intrathoracic vessels, and intracardiac foreign bodies, such as prosthetic valves, pacemaker leads, and surgical conduits. The annual incidence in the UK is 6 to 7/100 000 but higher in low- and middle-income countries. Without treatment, mortality approaches 100%; even with treatment, there is significant morbidity and mortality.

Aetiology

Endocarditis is usually the consequence of two factors: the presence of organisms in the bloodstream and abnormal cardiac endothelium that facilitates their adherence and growth.

Bacteraemia may arise for patient-specific reasons (poor dental hygiene, intravenous drug use, soft tissue infections) or may be associated with diagnostic or therapeutic procedures (dental treatment, intravascular cannulae, cardiac surgery, or permanent pacemakers).

Damaged endocardium promotes platelet and fibrin deposition, which allows organisms to adhere and grow, leading to an infected vegetation. Valvular lesions may create non-laminar flow, and jet lesions from septal defects or a patent ductus arteriosus (PDA) result in abnormal vascular endothelium. Aortic and mitral valves are most commonly involved in IE; intravenous drug users are the exception, as right-sided lesions are more common in these patients.

Organisms

Common organisms and the sources of infection are shown in **Fig. 17.85**.

Rare causes

These include the HACEK group of organisms, which tend to run a more insidious course (**Box 17.41**).

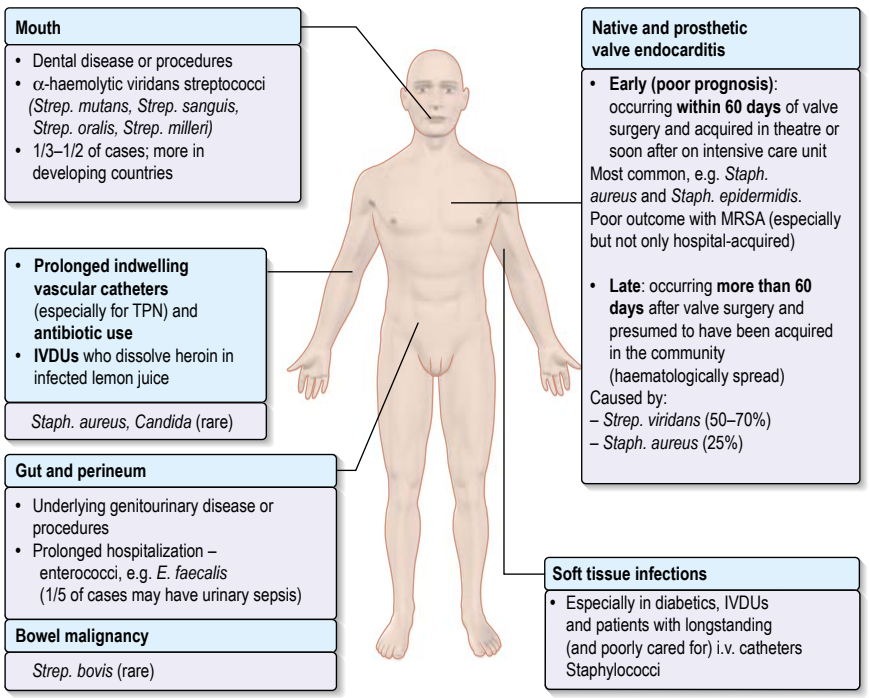

Fig. 17.85 Infective endocarditis: aetiology and sources of infection. *IVDU,* Intravenous drug user; *MRSA,* methicillin-resistant *Staphylococcus aureus*; *TPN,* total parenteral nutrition.

Box 17.41 Modified Duke criteria for endocarditis[a]

I. MAJOR CRITERIA
- **A. Microbiologic Major Criteria**
  - (1) Positive blood cultures
    - i. Microorganisms that commonly cause IE isolated from 2 or more separate blood culture sets (Typical)
    - *or*
    - ii. Microorganisms that occasionally or rarely cause IE isolated from 3 or more separate blood culture sets (Nontypical)
  - (2) Positive laboratory tests
    - i. Positive polymerase chain reaction (PCR) or other nucleic acid-based technique for *Coxiella burnetii*, *Bartonella* species, or *Tropheryma whipplei* from blood
    - *or*
    - ii. *C. burnetiid* antiphase I immunoglobulin G (IgG) antibody titer >1:800, or isolated from a single blood culture
    - *or*
    - iii. Indirect immunofluorescence assays (IFAs) for detection of IgM and IgG antibodies to *Bartonella henselae* or *Bartonella quintana* with immunoglobulin G (IgG) titer ≥1:800
- **B. Imaging Major Criteria**
  - (1) Echocardiography and cardiac computed tomography (CT) imaging
    - i. Echocardiography and/or cardiac CT showing vegetation, valvular/leaflet perforation, valvular/leaflet aneurysm, abscess, pseudoaneurysm, or intracardiac fistula
    - or
    - ii. Significant new valvular regurgitation on echocardiography as compared with previous imaging. Worsening or changing of pre-existing regurgitation is not sufficient.
    - or
    - iii. New partial dehiscence of prosthetic valve as compared with previous imaging
  - (2) Positron emission computed tomography with ^{18}F-fluorodeoxyglucose ([^{18}F]FDG PET/CT imaging)
    Abnormal metabolic activity involving a native or prosthetic valve, ascending aortic graft (with concomitant evidence of valve involvement), intracardiac device leads, or other prosthetic material
- **C. Surgical Major Criteria**
  Evidence of IE documented by direct inspection during heart surgery neither Major Imaging Criteria nor subsequent histologic or microbiologic confirmation

II. **MINOR CRITERIA**
- A. Predisposition
  - Previous history of IE
  - Prosthetic valve
  - Previous valve repair
  - Congenital heart disease
  - More than mild regurgitation or stenosis of any aetiology
  - Endovascular intracardiac implantable electronic device (CIED)
  - Hypertrophic obstructive cardiomyopathy
  - Injection drug use
- B. Fever
  Documented temperature greater than 38.0°C (100.4°F)
- C. Vascular Phenomena
  Clinical or radiological evidence of arterial emboli, septic pulmonary infarcts, cerebral or splenic abscess, mycotic aneurysm, intracranial haemorrhage, conjunctival haemorrhages, Janeway lesions, purulent purpura
- D. Immunologic Phenomena
  Positive rheumatoid factor, Osler nodes, Roth spots, or immune complex-mediated glomerulonephritis
- E. Microbiologic Evidence, Falling Short of a Major Criterion
  1) Positive blood cultures for a microorganism consistent with IE but not meeting the requirements for Major Criterion
  or
  2) Positive culture, PCR, or other nucleic acid-based test (amplicon or shotgun sequencing, *in situ* hybridization) for an organism consistent with IE from a sterile body site other than cardiac tissue, cardiac prosthesis, or arterial embolus; or a single finding of a skin bacterium by PCR on a valve or wire without additional clinical or microbiological supporting evidence
- F. Imaging Criteria
  Abnormal metabolic activity as detected by [^{18}F]FDG PET/CT within 3 mo of implantation of prosthetic valve, ascending aortic graft (with concomitant evidence of valve involvement), intracardiac device leads, or other prosthetic material
- G. Physical Examination Criteria
  New valvular regurgitation identified on auscultation if echocardiography is not available. Worsening or changing of pre-existing murmur not sufficient

[a]The diagnosis of infective endocarditis is definite when: (1) a microorganism is demonstrated by culture of a specimen from a vegetation, an embolism or an intracardiac abscess; (2) active endocarditis is confirmed by histological examination of the vegetation or intracardiac abscess; (3) two major clinical criteria, one major and three minor criteria, or five minor criteria are met.
Table 2. 2023 Duke-International Society for Cardiovascular Infectious Diseases Infective Endocarditis (IE) Criteria for the Diagnosis of IE, With Proposed Changes in Bold Type.
(From https://academic.oup.com/cid/article/77/4/518/7151107?login=true#415413859.*)*

Culture-negative endocarditis

This accounts for 5% to 10% of endocarditis cases. The usual cause is prior antibiotic therapy (good history-taking is vital), but some cases are due to a variety of fastidious organisms that fail to grow in normal blood cultures. These include *Coxiella burnetii* (the cause of Q fever), *Chlamydia* species, *Bartonella* species (organisms that cause trench fever and cat scratch disease), and *Legionella*.

Clinical features

The clinical presentation of IE (**Box 17.42**) is dependent on the organism and the presence of predisposing cardiac conditions. IE may occur as an acute, fulminating infection but also as a chronic or subacute illness with low-grade fever and non-specific symptoms. A high index of clinical suspicion is required to identify patients with IE, and certain criteria should alert the physician.

Box 17.42 Clinical features of infective endocarditis

Clinical feature	Approximate %
General	
Malaise	95
Clubbing	10
Cardiac	
Murmurs	90
Cardiac failure	50
Arthralgia	25
Pyrexia	90
Skin lesions	
Osler nodes	15
Splinter haemorrhages	10
Janeway lesions	5

High clinical suspicion

- New valve lesion/(regurgitant) murmur
- Embolic event(s) of unknown origin
- Sepsis of unknown origin
- Haematuria, glomerulonephritis, and suspected renal infarction
- 'Fever' plus:
  - Prosthetic material inside the heart
  - Other high predisposition for IE, for example, intravenous drug use
  - Newly developed ventricular arrhythmias or conduction disturbances
  - First manifestation of congestive cardiac failure
  - Positive blood cultures (with typical organism)
  - Cutaneous (Osler, Janeway) or ophthalmic (Roth) lesions (Fig. 17.86)
  - Peripheral abscesses (renal, splenic, spine) of unknown origin
  - Predisposition and recent diagnostic/therapeutic interventions known to result in significant bacteraemia.

Diagnosis

The 2023 Duke-ISCVID criteria are used for the clinical diagnosis of endocarditis (see Box 17.41). These reflect the changing epidemiology of IE and the utility of the latest microbiologic testing and advanced imaging tools. Confirmation of 'Definite IE' requires pathological confirmation of active endocarditis from cardiac tissue, cardiac device, or an arterial embolus or clinical criteria from a combination of major and/or minor criteria. Major microbiological criteria include positive blood cultures or polymerase chain reaction (PCR) testing used alongside major imaging criteria with echocardiography, CT, or CT/PET.

Investigations

Blood cultures are the mainstay of diagnosis of IE to identify the organism and ensure appropriate targeted antimicrobial therapy (Box 17.43).

Echocardiography is the first-line imaging technique if used appropriately and can identify vegetations and paravalvular infection. It is not an appropriate screening test for patients with just a fever or an isolated positive blood culture when the pretest probability of endocarditis is low. A negative echocardiogram does not exclude a diagnosis of endocarditis.

Transoesophageal echocardiography (TOE) is invariably used to confirm the diagnosis and clarify the extent of infection with a higher specificity and sensitivity.

^{18}F-FDG PET/CT is particularly helpful in confirming infection in patients with prosthetic valves, cardiac devices, grafts, and individuals with congenital heart disease and can also assess distant infection, for example, discitis and septic emboli to the abdomen.

Other tests: The ECG may note a prolonged PR interval, or there may be heart block suggesting paravalvular infection, for example, aortic root abscess. Chest X-ray may demonstrate septic emboli to the lungs from right-sided lesions. CT may also confirm emboli to the lungs, kidneys, liver, and spleen or distant arterial emboli to the brain or peripheries.

Box 17.43 Investigations and findings in endocarditis

Investigation	Findings and notes
Blood cultures	Three sets from different venepuncture sites
Serological tests	Consider in culture-negative cases for *Coxiella*, *Bartonella*, *Legionella*, *Chlamydia*
Full blood count	Reduced haemoglobin, increased white cells, increased or reduced platelets
Serum creatinine and electrolytes	Increased urea and creatinine
Liver biochemistry	Increased serum alkaline phosphatase
Inflammatory markers	Increased erythrocyte sedimentation rate and C-reactive protein (CRP reduces in response to therapy and increases with relapse)
Complement proteins	C3 and C4 complement proteins commonly consumed due to immune complex formation.
Urine	Proteinuria and haematuria
Electrocardiogram	PR prolongation/heart block is associated with aortic root abscess
Chest X-ray	Pulmonary oedema in left-sided disease, pulmonary emboli/abscess in right-sided disease
Transthoracic echocardiography	First-line non-invasive imaging test with sensitivity of 60%–75%; demonstrates vegetations, valvular dysfunction, ventricular function, abscesses
Transoesophageal echocardiography	Second-line invasive imaging test with greater sensitivity (>90%) and specificity; useful in suspected aortic root abscess and essential in prosthetic valve endocarditis

Management

The location of the infection means that prolonged courses of antibiotics are usually required. The combination of antibiotics may be synergistic in eradicating microbial infection and minimizing resistance. Blood cultures should be taken prior to empirical antibiotic therapy (but this should not delay therapy in unstable patients). Antibiotic treatment should continue for 4 to 6 weeks and, in some cases, may be longer. Typical therapeutic regimens are shown in **Box 17.44**, but advice on specific therapy should be sought from the local microbiology department, according to the organism identified and current sensitivities. Serum levels of gentamicin and vancomycin need to be monitored to ensure adequate therapy and prevent toxicity. In patients with penicillin allergy one of the glycopeptide antibiotics, vancomycin or teicoplanin, can be used. Penicillins, however, are fundamental to the therapy of bacterial endocarditis; allergies therefore seriously compromise the choice of antibiotics. It is essential to confirm the nature of a patient's allergy to ensure that the appropriate treatment is not withheld needlessly. Anaphylaxis would be much more influential on antibiotic choice than a simple gastrointestinal disturbance.

Persistent fever

Most patients with IE should respond within 48 hours of initiation of appropriate antibiotic therapy, as evidenced by a resolution of fever, reduction in serum markers of infection, and relief of systemic symptoms of infection. Failure of these factors to occur needs to be taken very seriously. The following should be considered:

- perivalvular extension of infection and possible abscess formation
- drug reaction (the fever should resolve promptly after drug withdrawal)
- hospital-acquired infection (i.e., venous access site, urinary tract infection)
- pulmonary embolism (secondary right-sided endocarditis or prolonged hospitalization).

In such cases samples for culture should be taken from all possible sites and evidence sought of the above causes. A change of antibiotic dosage or regimen should be avoided unless there are positive cultures or a drug reaction is suspected. Emergence of bacterial resistance is uncommon. Close liaison with the microbiology department is recommended and a cardiothoracic surgical opinion should be sought.

Box 17.44 Recommended antibiotic regimens in infective endocarditis[a]

Clinical situation	Suggested antibiotic regimen to start[b,c,d]
Clinical endocarditis, culture results awaited, no suspicion of staphylococci (native valve or late prosthetic valve >12 months after surgery)	Amoxicillin 2 g 4-hourly Ceftriaxone 2 g 12-hourly Gentamicin 3 mg/kg 24-hourly
Suspected staphylococcal endocarditis (recent intravascular devices or cardiac surgery <12 months, intravenous drug user)	Amoxicillin 2 g 4-hourly Flucloxacillin 2 g 4-hourly Gentamicin 3 mg/kg 24 hourly
Streptococcal endocarditis (penicillin-sensitive) (4 weeks native; 6 weeks prosthetic)	Amoxicillin 2 g 4-hourly Gentamicin 3 mg/kg 24 hourly (2 weeks)
Enterococcal endocarditis (amoxicillin-susceptible Enterococci, usually *Enterococcus faecalis*) (at least 6 weeks for native and prosthetic)	Amoxicillin 2 g 4-hourly and ceftriaxone 2 g for 6 weeks OR Amoxicillin 2 g 4-hourly for 6 weeks and gentamicin 3 mg/kg 24 hourly for 2 weeks
Staphylococcal endocarditis (native valve) (4–6 weeks)	Flucloxacillin 2 g 4-hourly (first line) *or* Vancomycin (high dose 15–20 mg/L)
Staphylococcal endocarditis (prosthetic valve) (6 weeks)	Flucloxacillin 2 g 4-hourly and Rifampicin 600 mg orally 12-hourly and Gentamicin 3 mg/kg 24-hourly
Staphylococcal endocarditis (prosthetic valve; meticillin resistant organism) (6 weeks)	Vancomycin (high dose 15–20 mg/L) and Rifampicin 600 mg orally 12-hourly and Gentamicin 3 mg/kg 24-hourly

[a] Adapted from 2023 ESC Guidelines for the management of endocarditis.
[b] Optimum choice and duration of therapy needs close liaison with microbiology department. All antibiotics given intravenously except rifampicin. If penicillin allergic may require alternative. OPAT management possible in selected cases following discussion with microbiology.
[c] Monitor vancomycin and gentamicin levels and adjust if necessary. Gentamicin, trough (pre-dose) concentrations should be <1 mg/L and peak (1 hour post dose) concentrations should be 10–12 mg/L. Vancomycin trough (pre-dose) concentration should be 15–20 mg/L.
[d] Choice of antibiotic depends on sensitivities.

Surgery

Decisions about surgical intervention in patients with IE should be made by specialist endocarditis teams involving cardiologists, cardiothoracic surgeons, and microbiologists, taking into account patient-specific features (age, non-cardiac morbidities, presence of prosthetic material or cardiac failure) and IE features (infective organism, vegetation size, presence of perivalvular infection, systemic embolization).

Prevention

In 2023 the ESC produced guidelines for the management of IE. They identified patients who are at higher risk of developing IE, including:

- those with a prior history of previous endocarditis
- those with prosthetic valves (including transcatheter devices) or material used for valve repair
- those with congenital heart disease including cyanotic congenital heart disease, repair with prosthetic material, or those with palliative shunts
- those with VADs.

The ESC recommends that these groups should receive antibiotic prophylaxis during high-risk procedures. This includes dental procedures that involve manipulation of the gingival or periapical part of the teeth or perforation of the oral mucosa. (The American Heart Association also considers that cardiac transplant patients with valvular heart disease should be included as highest-risk patients.) This is not in line with NICE guidance, which states that 'antibiotic prophylaxis against IE is not *routinely* recommended for people undergoing dental procedures'.

The ESC also provided additional recommendations applicable to all patients with valvular heart disease (including the highest-risk patients). These include:

- regular dental check-ups (6 months for the highest-risk groups and 12 months for all others)
- disinfection of wounds and eradication of chronic bacterial carriage (skin, urine)
- curative antibiotics for any focus on bacterial infection
- no self-medication with antibiotics
- strict infection control during at-risk procedures
- avoidance of piercing or tattoos
- limitation of the usage of infusion catheters, preferring peripheral versus central catheters; peripheral catheters should be changed every 3 to 4 days.

CONGENITAL HEART DISEASE

Fetal circulation

Oxygenated blood and nutrients are supplied to the developing fetus via the placenta and the umbilical vein (Fig. 17.87). Half of that blood is directed to the fetal ductus venosus and carried to the inferior vena cava and the remainder enters the liver. Blood moves from the inferior vena cava to the right atrium of the heart. In the fetus there is an opening between the right and left atrium (the foramen ovale), and most of the blood flows from the right into the left atrium, bypassing the pulmonary circulation. This blood goes into the left ventricle and is pumped through the aorta into the fetal body. Some of the blood flows from the aorta through the internal iliac arteries to the umbilical arteries and re-enters the placenta, where carbon dioxide and other waste products from the fetus are taken up and enter the woman's circulation.

Some of the blood from the right atrium does not enter the left atrium but rather enters the right ventricle and is pumped into the pulmonary artery. In the fetus there is a connection between the pulmonary artery and the aorta, the ductus arteriosus, which directs most of this blood away from the lungs. With the first breath after delivery, the lungs expand, vascular resistance in the pulmonary arteries falls, more blood moves from the right atrium to the right ventricle and pulmonary arteries, and oxygenated blood travels

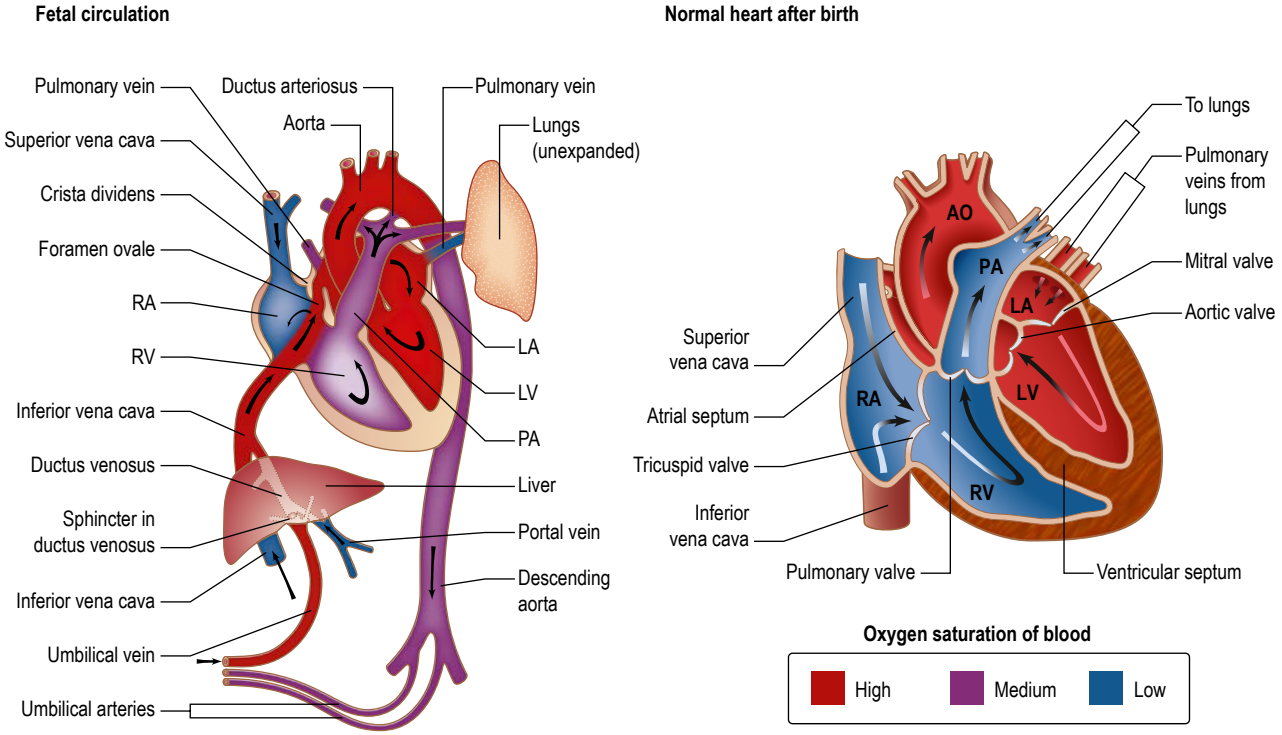

Fig. 17.87 Anatomy showing the circulation. *AO,* Aorta; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle.

back to the left atrium through the pulmonary veins. The decrease in right atrial pressure and relative increase in left atrial pressure result in closure of the foramen ovale.

The ductus arteriosus usually closes off within 1 or 2 days of birth, completely separating the left and right systems. The umbilical vein and the ductus venosus close off within 2 to 5 days of birth, leaving behind the ligamentum teres and the ligamentum venosus of the liver, respectively.

Adult congenital heart disease

Congenital heart defects (CHDs) are structural problems with the heart that are present at birth. The prevalence of CHD worldwide is estimated to be about 9 per 1000 newborns, with significant geographic variation. The prevalence of severe CHD is declining in many high income countries due to fetal screening and pregnancy termination (although migration from countries with higher rates of CHD to more economically high-income countries may offset this decline). However, the overall prevalence of CHD is increasing on a global scale, due to several factors, including:

- Increased survival of children with CHD due to medical, surgical, and technological advances; over 90% of individuals with CHD who are born now survive into adulthood.
- Ageing population: The global population is ageing, and CHD is more common in older adults who are surviving into late adulthood, having families, and leading active lifestyles.

Patients with congenital heart disease require life-long multidisciplinary specialist care and surveillance, as many need further intervention, surgery, and electrophysiological input in adulthood. In the UK the majority of these patients will be reviewed in designated specialist centres, at intervals depending on clinical need; however, non-specialists may also look after them in local hospitals, so all physicians should have a practical understanding of congenital heart disease.

Ventricular septal defect

VSD is the most common congenital cardiac malformation. They can occur just below the pulmonary and aortic valves, or in the perimembranous or muscular septum. The haemodynamic consequences of the VSD are dependent on the size and number of defects and resultant shunt size. In an otherwise structurally normal heart left ventricular pressure is higher than right and blood will shunt from left to right through a VSD (Fig. 17.88).

- In small defects the shunt velocity is high and the actual volume of blood shunting across the defect is small with no haemodynamic consequence.
- In larger defects the shunt, which is directed into the right ventricular outflow tract and the pulmonary vasculature and then back to the left heart, may lead to dilation of the ***left atrium and left ventricle***, and this is an indication for intervention or repair.
- In large, non-restrictive defects, a large volume of blood shunts into the pulmonary vasculature, leading to remodelling of the pulmonary vessels and pulmonary hypertension. Eventually, when the right ventricular pressure becomes suprasystemic (higher than left), blood starts to shunt from right to left, causing cyanosis. This is referred to as ***Eisenmenger's syndrome***.

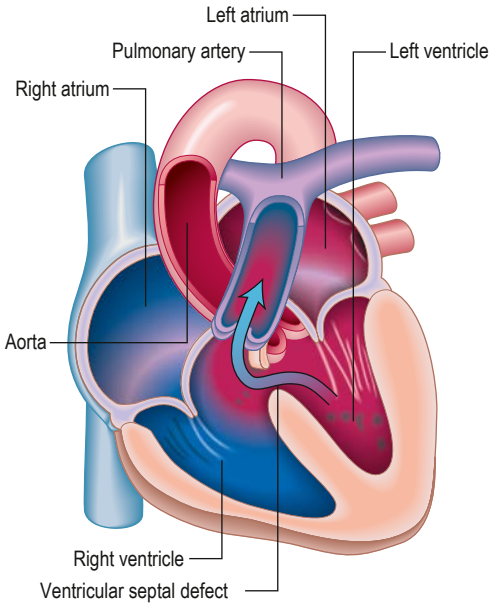
Clinical features

- ***Restrictive VSDs*** ('maladie de Roger') are often found incidentally, as patients are asymptomatic. These defects are associated with a loud pansystolic murmur best heard in the left third and fourth intercostal spaces. A systolic thrill may be present. The majority close spontaneously by the age of 10 years.
- ***Large (non-restrictive) VSDs*** usually present with heart failure symptoms in childhood and eventually lead to pulmonary hypertension and Eisenmenger's syndrome. As pressures equalize, the murmur becomes softer. With established Eisenmenger's syndrome, patients will be cyanosed and have evidence of clubbing.

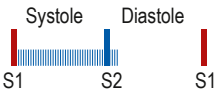
Investigations and treatment

A small VSD produces no abnormal X-ray or ECG findings. This is often a clinical diagnosis and echocardiography is used to confirm the VSD and assess for left heart dilation. If there is none, these lesions are managed conservatively, though there remains an increased risk of endarteritis or endocarditis.

In larger defects echocardiography is used to assess the size and location of the VSD and its haemodynamic consequences. Interventional options are either surgical repair or device closure. Closure (surgical or interventional) is offered for a significant shunt causing left atrial and ventricular enlargement with no evidence of irreversible pulmonary hypertension.



Heart sounds and murmurs



Harsh pansystolic murmur heard at the left sternal edge, accompanied by a systolic thrill ± left parasternal heave
Possible signs of pulmonary hypertension

Pathophysiology

- Left-to-right shunt
- When the left ventricle contracts, it ejects some blood into the aorta and some across the ventricular septal defect into the right ventricle and pulmonary artery
- **Small** VSDs ('maladie de Roger'): loud and sometimes long systolic murmur
- **Moderate** VSDs: loud, 'tearing' pansystolic murmur
- **Large** VSDs: cause pulmonary hypertension and soft murmur
  Eisenmenger's complex may result

Fig. 17.88 Ventricular septal defect (VSD). Pathophysiology and auscultatory findings.

Atrial septal defect

The diagnosis of an atrial septal defect (ASD) is often made in adulthood, as patients often remain asymptomatic through childhood and clinical signs can be subtle.

There are three main types of ASD (Fig. 17.89):

- ***Secundum defects*** (most common type): located in the mid-septum (fossa ovalis)
- ***Sinus venosus defects:*** located in the superior part of the septum near the superior vena cava (superior sinus venosus defect) or the inferior part of the septum near the inferior vena cava (inferior sinus venosus defect) entry point
- ***Ostium primum (atrioventricular septal) defects*** (15%): located in the lower part of atrial septum at the level of, and often involving, the AV valves.

An ASD with a significant left-to-right shunt causes right heart volume overload and right atrial and ventricular dilation. This may lead to arrhythmia, which is often the presenting symptom, along with breathlessness and exercise intolerance. There is raised pulmonary pressure due to increased blood flow through the pulmonary vessels, but significant pulmonary vascular disease develops in less than 5% of patients.

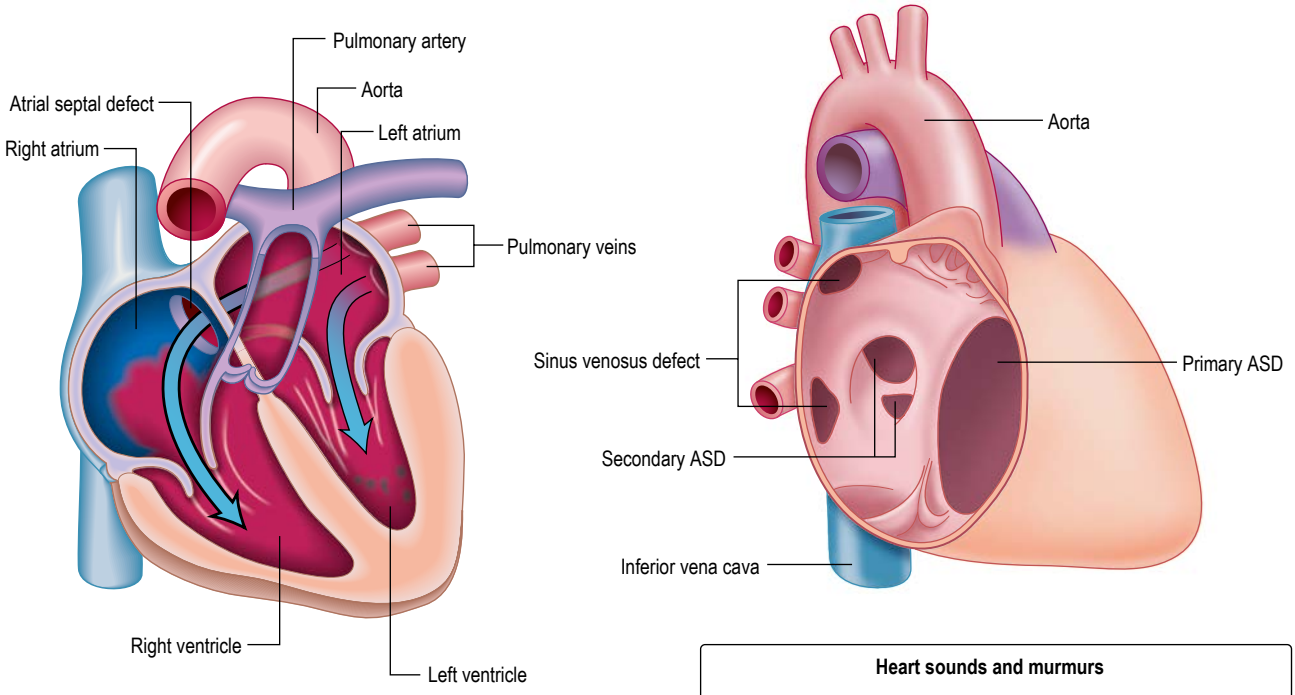
Clinical features

With larger ASDs, there may be a systolic flow murmur over the second and third left parasternal spaces from increased blood flow across the pulmonary valve and a wide, fixed, split-second heart sound (see Fig. 17.89).

Investigations and treatment

- ***Chest X-ray*** may demonstrate prominent pulmonary arteries and cardiomegaly due to right heart dilation.
- ***ECG*** usually shows complete or incomplete right bundle branch block and right axis deviation. Some patients with late diagnosis may have atrial arrhythmia.
- ***Echocardiography*** is used to demonstrate the defect in the septum and shunt direction is evaluated with colour Doppler. The right atrium and ventricle are assessed for dilation and the pulmonary pressure is measured. It is also important to assess the left heart, as if there is significant left ventricular or mitral pathology, this needs to be considered during closure of the defect (Fig. 17.90). TOE allows better imaging of the defect and guides device closure of the ASD.
- ***CMR and CT*** are helpful for assessing anomalous pulmonary venous drainage and confirming sinus venous defects which may not be seen on echocardiography.

Closure of an ASD is indicated if there is a significant left-to-right shunt, resulting in right atrial and ventricular enlargement with normal PVR and oxygen saturations. Secundum defects can often be closed with a device by an interventionalist if the defect is not too large and there are adequate rims of atrial septal tissue (Fig. 17.91).



Pathophysiology

- Left-to-right shunt through the defect in the interatrial septum
- Dilation of the pulmonary artery resulting from the shunt
- The murmur is produced by increased flow across the pulmonary valve and an increased stroke volume

Heart sounds and murmurs

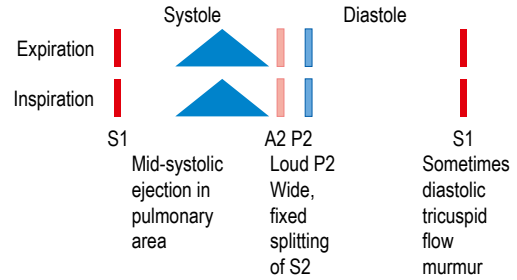


Fig. 17.89 Atrial septal defect (ASD). Pathophysiology and auscultatory findings.

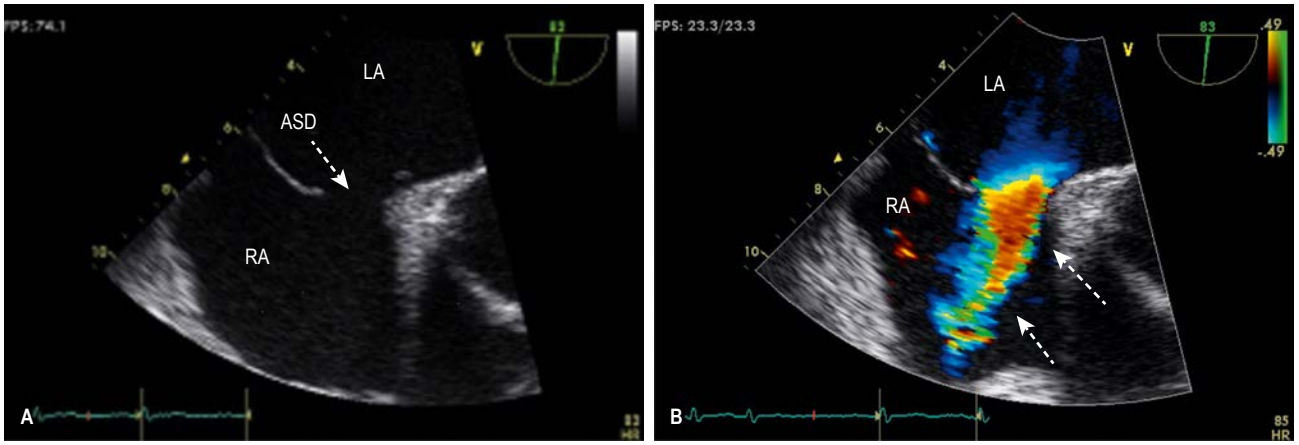

Fig. 17.90 Ostium secundum atrial septal defect (ASD, *arrowed*) in a young girl. **(A)** The defect is shown in a two-dimensional echocardiogram subcostal four-chamber view. **(B)** Colour Doppler can demonstrate the left-to-right shunt. *LA,* Left atrium; *RA,* right atrium.

Fig. 17.91 Angiographic appearance of a fully deployed atrial septal defect (ASD) closure device. The device bridges the ASD and wedges against the surfaces of the right and left atrial septa, occluding flow. The metal object in frame is the distal end of a transoesophageal echocardiography probe. *(Courtesy of Dr D Ward, St George's, University of London.)*

All other ASDs are closed surgically, and if there is anomalous pulmonary venous drainage, it is redirected to the left atrium at the same time.

Patent ductus arteriosus

A patent ductus arteriosus (PDA) is a persistent communication between the proximal left pulmonary artery and the descending aorta, resulting in a continuous left-to-right shunt (Fig. 17.92). Normally, the ductus arteriosus closes within a few hours of birth in response to decreased pulmonary resistance; however, in some cases (particularly in premature babies and in cases with maternal rubella) the ductus persists. Indomethacin (a prostaglandin inhibitor) is given to stimulate duct closure. The shunt size is dependent on the size of the duct and the pressure difference between the pulmonary arteries and aorta. If the left-to-right shunt is significant, it will result in left heart volume overload. Those with large unrestrictive defects may present with congestive heart failure in infancy and, if untreated, may develop pulmonary vascular disease; with time, Eisenmenger's syndrome will develop.

Clinical features

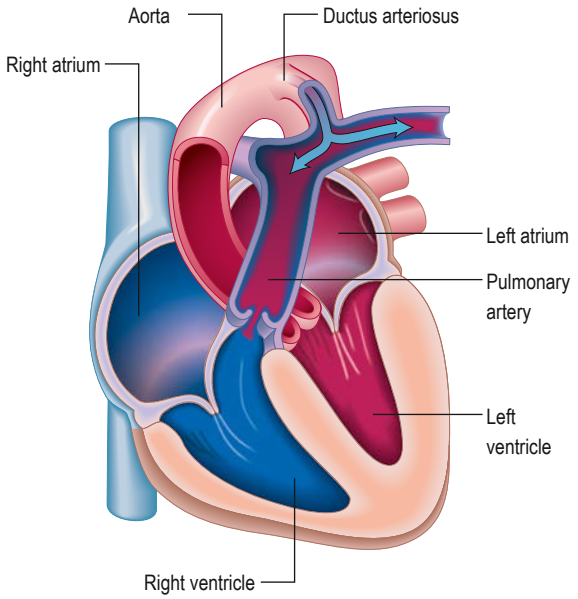
In adults, PDAs are graded as:

- ***Silent:*** tiny PDA, no murmur—incidental finding on echo.
- ***Small:*** no haemodynamic effect or significant shunt but audible systolic or continuous murmur.
- ***Moderate:*** bounding pulses (wide pulse pressure) and continuous murmur in the left infraclavicular region radiating to the back; displaced apex beat from left heart dilation and volume overload.
- ***Large:*** in adults these present with pulmonary hypertension; the murmur quietens and has often disappeared due to equalized pressures between the pulmonary artery and aorta. Patients with Eisenmenger's PDA may have more pronounced clubbing and lower saturations in their toes than in their fingers.

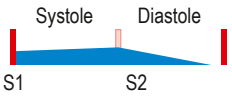
Investigations and treatment

- ***Chest X-ray*** in an adult with a significant left-to-right shunt will show enlarged pulmonary arteries and an increased cardiothoracic ratio (left heart dilation).
- ***ECG*** may demonstrate left atrial abnormality (broad P waves) and high-voltage QRS complexes related to left heart overload. If there is right axis deviation and a tall R in V_1, this may represent established Eisenmenger's syndrome.
- ***Echocardiography*** colour and CW Doppler imaging of the proximal pulmonary arteries may demonstrate the shunt. Echocardiography may show a dilated left atrium and left ventricle if there is a significant left-to-right shunt. Pulmonary pressure can be assessed. If there is pulmonary hypertension, the right ventricle will be hypertrophied.
- ***A right heart catheter study*** may be necessary in the adult who is diagnosed with a PDA and significantly raised pulmonary pressure to estimate the shunt and PVR.

Life expectancy is normal in silent PDAs and patients who have had appropriate and timely closure of a PDA. Indications for intervention (usually with percutaneous devices) include left ventricular dilation with significant shunt and no significant pulmonary vascular disease (assessed by PVR at right heart catheter). Small defects may predispose to endarteritis and should be considered for device closure unless clinically silent.



Heart sounds and murmurs

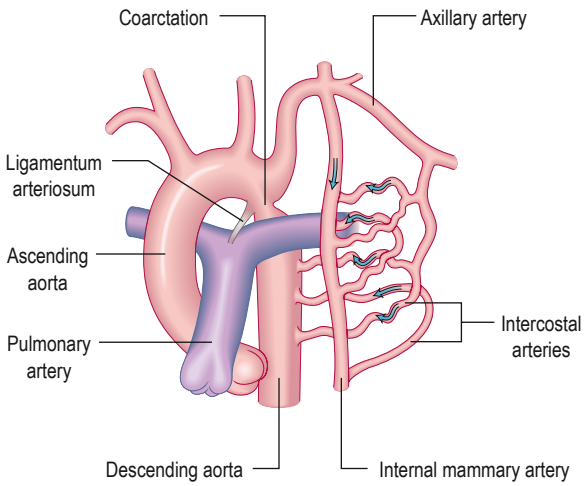


Continuous 'machinery' murmur best heard below the left clavicle in the first interspace or over the first rib
A thrill can often be felt

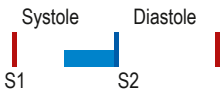
Pathophysiology

- Left-to-right shunt
- Some of the blood from the aorta crosses the ductus arteriosus and flows into the pulmonary artery
- The murmur is produced by the turbulent aortic-to-pulmonary artery shunting in both systole and diastole
- Dilation of the pulmonary artery, left atrium and left ventricle
- As pulmonary hypertension (Eisenmenger's reaction) develops, the murmur becomes quieter, may be confined to systole or may even disappear, causing central cyanosis

Fig. 17.92 Patent ductus arteriosus. Pathophysiology and auscultatory findings.



Heart sounds and murmurs



Mid–late systolic murmur may be heard over the upper precordium or the back
Vascular bruits from the collateral circulation may also be heard

Pathophysiology

Coarctation causes severe obstruction of blood flow in the descending thoracic aorta
The descending aorta and its branches are perfused by collateral channels from the axillary and internal thoracic arteries through the intercostal arteries

Fig. 17.93 Coarctation of the aorta. Pathophysiology and auscultatory findings.

Coarctation of the aorta

A coarctation of the aorta is a narrowing of the aorta at, or just distal to, the insertion of the ductus arteriosus (distal to the origin of the left subclavian artery; Fig. 17.93). Rarely, it can occur proximal to the left subclavian. In 80% of cases the aortic valve is bicuspid. There is an association with circle of Willis aneurysms (affecting approximately 10%) and Turner's syndrome. Severe narrowing of the aorta encourages the formation of a collateral arterial circulation involving the intercostal arteries.

Coarctation of the aorta may be asymptomatic for many years. Adults with undetected coarctation may present with hypertension, headaches, nosebleeds, and, in severe coarctation, ***claudication*** and cold legs may be present.

Clinical features

Physical examination of patients with significant coarctation reveals hypertension in the upper limbs and weak, delayed (radio-femoral delay) pulses in the legs. If coarctation is present in the aorta, proximal to the left subclavian artery, there will be asynchronous radial pulses in the right and left arms; often, the arch itself is hypoplastic and the blood pressure in the right arm is higher than in the left. For heart sounds and murmurs in coarctation of aorta, see Fig. 17.93. Those who have had surgery to correct coarctation may have a thoracotomy scar.

Investigations and treatment

- ***Chest X-ray*** may reveal a dilated aorta indented at the site of the coarctation. This kink in the aortic contour in the upper left

mediastinum is shaped like a number 3 and known as the '3 sign'. In adults tortuous and dilated collateral intercostal arteries may cause rib notching.

- ***ECG*** may demonstrate left ventricular hypertrophy.
- ***Echocardiography*** of suprasternal aortic arch windows can be difficult in adults but may demonstrate aortic luminal narrowing with turbulence in the descending aorta. Continuous Doppler of the descending aorta in significant coarctation will show high-velocity flow and slow diastolic runoff (diastolic tail) due to the obstruction.
- ***CT and MRI*** (Fig. 17.94) demonstrate the coarctation and the proximity to the aortic branch vessels, which need to be considered in intervention. MRI is preferable for surveillance, as it does not use radiation. If the aortic valve is bicuspid, it is also important to obtain images of the ascending aorta for associated aortopathy.

Fig. 17.94 Severe aortic coarctation in an adult. The coarctation is shown on cardiac magnetic resonance angiography. The *solid arrow* indicates the jump bypass graft; the *dotted arrow* indicates severe aortic coarctation.

Intervention/repair

Intervention is indicated if there is a peak–peak gradient across the coarctation of more than 20 mmHg in the cardiac catheter laboratory or greater than 50% luminal narrowing with associated hypertension or left ventricular hypertrophy. If there is significant collateralization, there may be minimal gradient, even in the setting of significant coarctation. In neonates coarctation is treated with surgical repair. In older children and adults the preferred option is balloon dilation and stenting. Balloon dilation is preferred for re-coarctation.

Tetralogy of Fallot

Tetralogy of Fallot (Fig. 17.95) consists of:

- a large, malaligned VSD
- an overriding aorta
- right ventricular outflow tract obstruction
- right ventricular hypertrophy.

The term tetralogy of Fallot represents a spectrum of disease: some patients will have only mild pulmonary stenosis, whereas the more severe extreme is pulmonary atresia, in which the pulmonary vasculature can also develop abnormally. Symptoms depend on the degree of pulmonary stenosis, but the majority of patients with tetralogy present in childhood. In infancy cyanosis usually develops due to increased right-sided pressures, resulting in a right-to-left shunt. Fallot's spells are episodes of severe cyanosis noted in children due to spasm of the subpulmonary muscle; these can be relieved by increasing systemic resistance using postural manoeuvres, such as squatting. In babies with severe pulmonary stenosis systemic-to-pulmonary artery shunts (i.e., a Blalock–Taussig subclavian-to-pulmonary artery shunt) may have been used initially to increase pulmonary blood flow until the pulmonary arteries are large enough for repair. Most adults with tetralogy of Fallot will have undergone complete repair but repair in childhood will often leave them with significant pulmonary regurgitation, which is generally well tolerated into early adulthood; the majority, however, will need pulmonary valve replacement with time.

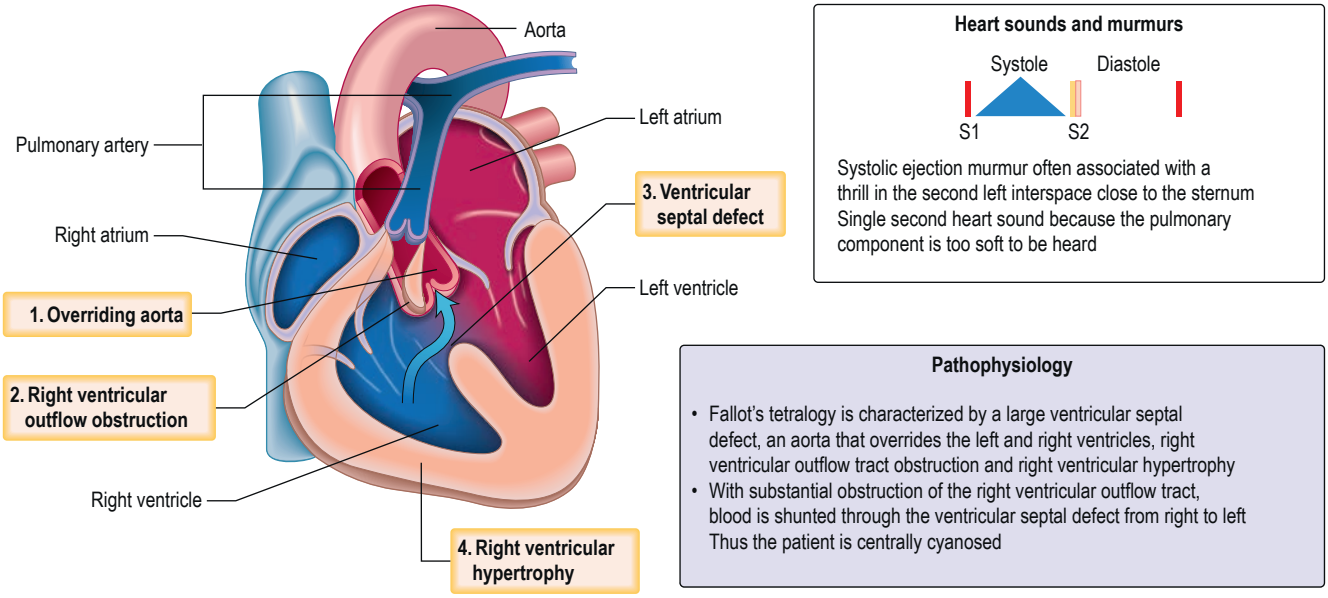


Fig. 17.95 Fallot's tetralogy. Pathophysiology and auscultatory findings.

The overall survival of those who have had operative repair is excellent. Many patients with repaired tetralogy of Fallot lead unlimited active lives. They do require on-going specialist follow-up as, in those with transannular patch repair (surgical or interventional), pulmonary valve replacements are needed during follow-up, and late complications include ventricular and atrial arrhythmias, heart failure, and sudden death.

Transposition of the great arteries

In transposition of the great arteries (TGA) the right atrium connects to the morphological right ventricle, which gives rise to the aorta, and the left atrium connects to the morphological left ventricle, which gives rise to the pulmonary artery (Fig. 17.96). This is incompatible with life, as blood circulates in two parallel circuits: that is, deoxygenated blood from the systemic venous return passes into the right heart and then, via the aorta, back to the systemic circulation. Babies with transposition are born cyanosed and rely on an ASD, VSD, or PDA, allowing oxygenated and deoxygenated blood to be mixed. In those without an adequate shunt an atrial septostomy is performed: a Rashkind's balloon is deployed to dilate the foramen ovale and is used to maintain saturations at 50% to 80% until a definitive procedure can be performed.

The majority of adult patients with TGA who were born between the 1960s and mid-1980s will have had an 'atrial switch' operation. In this procedure systemic venous blood was baffled across into the left atrium and then pumped via the left ventricle into the pulmonary artery; the pulmonary venous (oxygenated blood) returning to the left atrium was redirected via a baffle into the right atrium and right ventricle, and into the aorta. This palliation allowed patients a good quality of life into their fourth decade, but the right ventricle remains the systemic ventricle and with time starts to fail. Atrial arrhythmia is also common in this group.

The first arterial switch procedure was performed in 1975, and it is now routinely performed in babies with TGA in the first 2 weeks of life. The aorta is reconnected to the left ventricle and the pulmonary artery is connected to the right ventricle. The coronary arteries are re-implanted. Late complications include coronary complications, narrowing of the pulmonary arteries, which are stretched around the aorta, and neovalvular regurgitation.

Congenitally corrected transposition of the great arteries

In congenitally corrected transposition of the great arteries (ccTGA) systemic venous return to the right atrium enters a morphological left ventricle, which pumps deoxygenated blood into the pulmonary arteries. Pulmonary venous blood returns to the left atrium and then, via the morphological right ventricle, to the aorta. The circulation is physiologically corrected and these babies are not typically cyanosed, but the systemic circulation is supported by a morphological right ventricle. ccTGA is often associated with cardiac lesions:

- systemic (tricuspid) AV valve abnormalities with valve insufficiency
- VSD
- subpulmonary stenosis
- complete heart block
- WPW syndrome
- dextrocardia.

Some patients with ccTGA may live a normal life, while others develop progressive tricuspid regurgitation and systemic ventricular failure or require pacemaker insertion (the AV node is abnormal, leading to heart block).

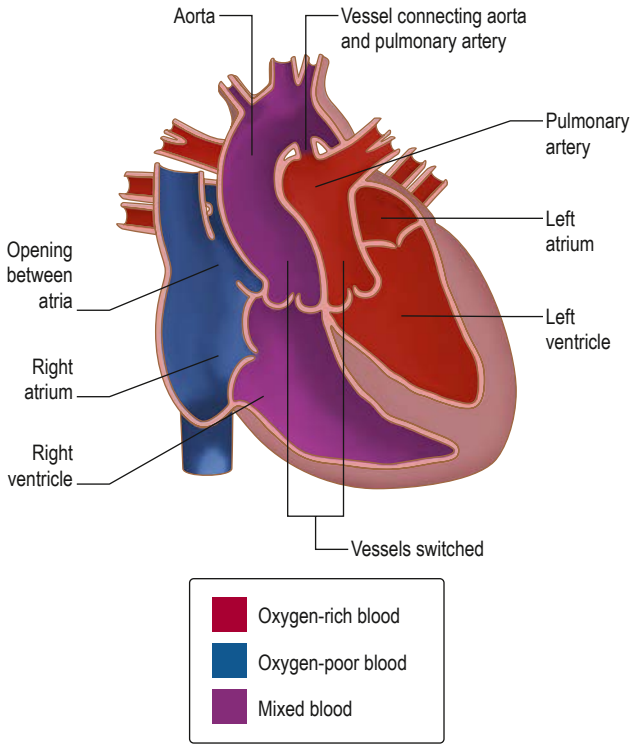

Fig. 17.96 **Transposition of the great arteries.**

Marfan's syndrome

Marfan's syndrome (MFS) is a multisystem connective tissue disorder with autosomal dominant inheritance pattern and a prevalence of 1:5000. One-quarter of cases are not inherited and are due to *de novo* mutations. MFS is caused by mutations in the *FBN1* gene on chromosome 15q21. The *FBN1* gene encodes the protein fibrillin-1, which is a component of structures called microfibrils that make up the extracellular matrix in elastic and non-elastic tissues.

Diagnosis

The diagnosis is currently made using the Modified Ghent Criteria (Box 17.45) and requires a complete medical and family history, examination, relevant investigations, and, increasingly, genetic analysis. The findings of aortic root aneurysm, lens dislocation (ectopia lentis), or a family history of MFS are major criteria in the diagnosis of MFS in these guidelines. The syndrome can affect the eyes, lungs, skeletal system, and cardiovascular system (Figs. 17.97 and 17.98).

Management

The management of patients with MFS requires multidisciplinary input from geneticists, cardiologists, cardiothoracic, vascular and orthopaedic surgeons, ophthalmologists, and physiotherapists, among others.

Box 17.45 Modified Ghent Criteria for Marfan's syndrome (MFS)

No family history of MFS

- Aortic root dilation Z-score ≥2 AND ectopia lentis = MFS
- Aortic root dilation Z-score ≥2 AND *FBN1* = MFS
- Aortic root dilation Z-score ≥2 AND systemic score ≥7 points* = MFS
- Ectopia lentis AND *FBN1* with known aortic root dilation = MFS

Family history of MFS

- Ectopia lentis = MFS
- Systemic score ≥7 points* = MFS
- Aortic root dilation Z-score ≥2 above 20 years old, ≥3 below 20 years old = MFS

*Systemic features	Score
Wrist AND thumb sign	3
Wrist OR thumb sign	1
Pectus carinatum (protrusion of chest wall)	2
Pectus excavatum (indentation of chest wall) or chest asymmetry	1
Hindfoot deformity	2
Pes planus (flat foot)	1
Spontaneous pneumothorax	2
Dural ectasia	2
Protrusio acetabuli	2

Reduced elbow extension	1
3/5 facial features (dolichocephaly, enophthalmos, down-slanting palpebral fissure, malar hypoplasia, retrognathia)	1
Skin striae	1
Severe myopia	1
Mitral valve prolapse	1
Reduced upper segment/lower segment (<0.85 whites, <0.78 blacks AND increased arm span/height >1.05).	1
	*Maximum total 20 points; score ≥7 indicates systemic involvement

Cardiovascular surveillance and management

The primary cause of death in MFS is cardiovascular. In the 1970s the mean age of death was 32 years, primarily from type A aortic dissection, but survival has significantly improved with better means of assessing for this condition and with prophylactic aortic root replacement for those with dilated ascending aortas. Patients with MFS are followed up with serial cardiovascular imaging, tailored to the specific cardiovascular findings of the individual. Yearly follow-up of aortic dimensions is recommended; however, patients with a cross-sectional diameter of more than 4.5 cm on the initial scan or a growth rate of more than 0.3 cm per year require more frequent (6-monthly) surveillance as they approach surgical thresholds. Echocardiography is readily available and useful for assessing the aortic sinuses, sinotubular junction, and part of the ascending aorta, as well as valvular and left ventricular function, which may be impaired in MFS. Cross-sectional imaging (CT or MRI) is necessary to assess the arch and descending aorta, which can also be involved. These modalities give more readily reproducible images to monitor interval change and may be preferred for this purpose in patients approaching the need for surgical intervention.

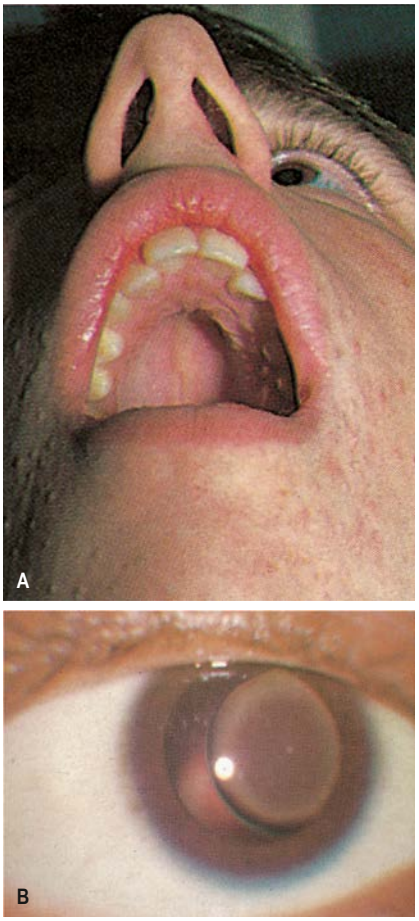

Fig. 17.97 Marfan's syndrome. **(A)** High-arched palate. **(B)** Eye lens dislocation. *(From Forbes CD, Jackson WF. Color Atlas and Text of Clinical Medicine, 3rd edn. St Louis: Mosby; 2003, p. 134, ©Elsevier.)*

Lifestyle

Contact sports and strenuous and isometric exertion should be avoided but moderate cardiovascular exercise is encouraged. Patients with Marfan's are excluded from joining the military.

Medical therapy

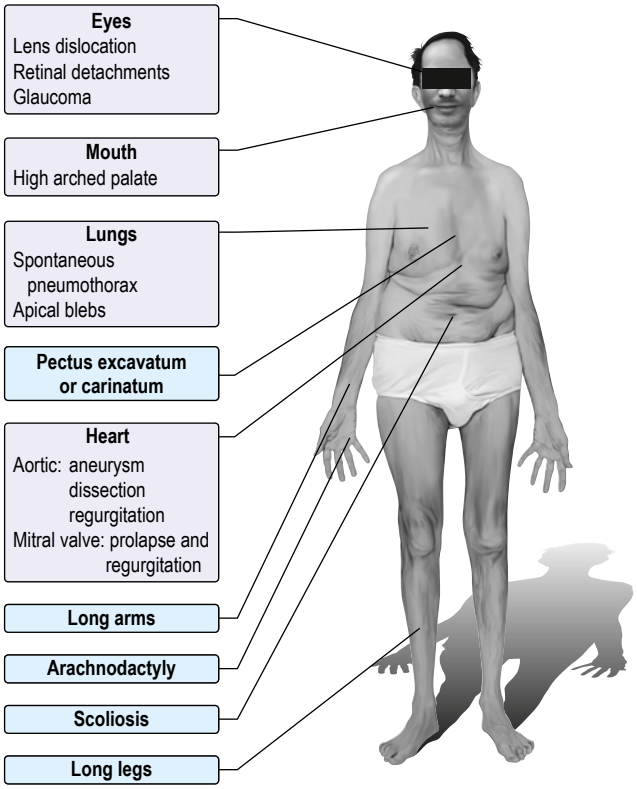
The current recommendation is to treat patients with MFS and aortic root dilatation with either a ***beta-blocker or angiotensin receptor blocker (ARB)***, or both if tolerated to reduce the rate of aortic dilatation.

Surgery

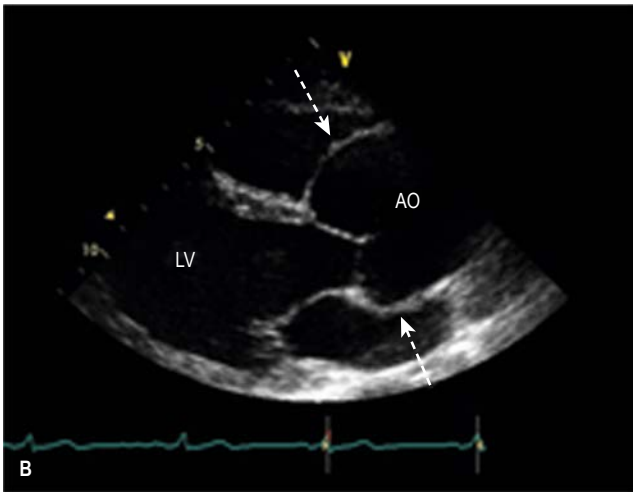
The current indication (European and American guidelines) for prophylactic aortic root replacement in patients with MFS is an aortic root measuring 5 cm or more (or ≥4.5 cm in those with a family history of dissection). This has very low surgical risk and prevents type A aortic dissection, thereby improving survival.

Pregnancy

All women with MFS should have preconceptual assessment and counselling. There is a 50% chance of their child being affected and there are options for pre-implantation genetic diagnosis (*in vitro* fertilization pregnancy where embryos can be assessed for the *FBN*



A



B

mutation prior to implantation) and prenatal diagnosis (amniocentesis and chorionic villus sampling). Women having MFS with or without aortic dilation are at increased risk of aortic dissection during pregnancy. This is estimated at 1% if the aortic root measures less than 4 cm and 10% if it is over 4 cm. Pregnancy should be discouraged in women with aortic dimensions of more than 4.5 cm and they should be offered prophylactic aortic root replacement prior to pregnancy. This threshold is lowered to 4.0 cm if there has been rapid aortic growth of ≥0.3 cm/year. Current recommendations are that echocardiography should be performed every 6 to 8 weeks throughout pregnancy and the postpartum period. Blood pressure should be regularly monitored, and hypertension treated aggressively. As ARBs are teratogenic, women planning pregnancy should be given beta-blockers.

PULMONARY HEART DISEASE

The normal values for mean pulmonary artery pressure (mPAP), mean capillary wedge pressure (mPCWP), and cardiac output are 12 ± 2 mmHg, 6 ± 2 mmHg, and 5 L/minute, respectively, with an upper limit of normal for mPAP of 20 mmHg. The fall in pressure across the lung circulation is known as the transpulmonary gradient and reflects the difference between mPAP and mPCWP. The normal transpulmonary gradient is 6 ± 2 mmHg.

The ***pulmonary vascular resistance*** (PVR) is calculated by the formula:

$$\frac{\text{mPAP} - \text{mPCWP}}{\text{CO}}$$

It is normally about 1.5 mmHg/L per minute (1.5 Wood units). Approximately 60% of the body's endothelial surface is in the lungs and the lungs normally offer a low resistance to blood flow. This is because the media of the pre-capillary pulmonary arterioles is thin, as compared with their more muscular systemic counterparts that must respond constantly to postural changes under the influence of gravity. The fact that lung circulation normally offers a low resistance to flow explains the preferential passage of blood through the lungs in specific forms of congenital heart disease, which may eventually lead to remodelling of the lung circulation and pulmonary hypertension.

Pulmonary hypertension

Pulmonary hypertension is defined as an mPAP of more than 25 mmHg at rest, as measured on right heart catheterization. The clinical classification of pulmonary hypertension is provided in **Box 17.46**.

Box 17.46 Clinical classification of pulmonary hypertension[a]

Group	Aetiological classification	Subtypes
1	Pulmonary arterial hypertension (PAH)	1.1—Idiopathic 1.2—Heritable 1.2.1—*BMPR2* 1.2.2—*ALK1*, *ENG*, *SMAD9*, *CAV1*, *KCNK3* 1.2.3—Unknown 1.3—Drugs and toxins 1.4—Associated with: 1.4.1—Connective tissue disease[b] 1.4.2—HIV infection 1.4.3—Portal hypertension 1.4.4—Congenital heart disease 1.4.5—Schistosomiasis
1′	Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary haemangiomatosis	
1″	Persistent pulmonary hypertension of the newborn (PPHN)	
2	Pulmonary hypertension due to left heart disease	2.1—Systolic dysfunction 2.2—Diastolic dysfunction 2.3—Valvular disease 2.4—Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3	Pulmonary hypertension due to lung diseases and/or hypoxia	3.1—Chronic obstructive pulmonary disease 3.2—Interstitial lung disease 3.3—Other pulmonary disease with mixed restrictive and obstructive pattern 3.4—Sleep-disordered breathing 3.5—Alveolar hypoventilation disorders 3.6—Chronic exposure to high altitude 3.7—Developmental abnormalities
4	Chronic thromboembolic pulmonary hypertension (CTEPH)	
5	Pulmonary hypertension with unclear and/or multifactorial mechanisms	5.1—Haematological disorders: chronic haemolytic anaemia, myeloproliferative disorders, splenectomy 5.2—Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis 5.3—Metabolic disorders: glycogen storage disease, Gaucher's disease, thyroid disorders 5.4—Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis, segmental pulmonary hypertension

Pathophysiology

The different groups are characterized by variable amounts of hypertrophy, proliferation, and fibrotic changes in distal pulmonary arteries (pulmonary arterial hypertension, PAH; pulmonary veno-occlusive disease, PVOD; pulmonary hypertension due to left heart disease; pulmonary hypertension due to lung disease and/or hypoxia). Pulmonary venous changes are seen in PVOD and pulmonary hypertension groups due to left heart disease, and the vascular bed may be destroyed in emphysematous or fibrotic areas seen in lung disease. In chronic thromboembolic pulmonary hypertension (CTEPH) organized thrombi are seen in the elastic pulmonary arteries. Patients with pulmonary hypertension with unclear and/or multifactorial mechanisms have variable pathological findings.

Patients with progressive pulmonary hypertension develop right ventricular hypertrophy, dilation, heart failure, and death.

Pulmonary artery hypertension

Epidemiology

A French registry of 674 patients with PAH identified 39.2% with idiopathic pulmonary artery hypertension (IPAH), 3.9% with familial (or heritable) disease, 9.5% caused by drugs and toxins (most prominently the now little used anorexigen fenfluramine), 15.3% with autoimmune rheumatic disease, 11.3% with congenital heart disease, 10.4% with portal hypertension, and 6.2% with HIV-associated disease. In familial or heritable PAH mutations in the bone morphogenetic protein receptor type 2 *(BMPR2)* gene are detected in over 70% of cases; other mutations are seen in patients with hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu syndrome).

Clinical features

Patients with PAH may present with symptoms of dyspnoea, fatigue, weakness, angina, syncope, or abdominal distension. Clinical signs of PAH and right heart hypertrophy include a left parasternal heave, a loud P2 heart sound, a soft pansystolic murmur from tricuspid regurgitation, or an early diastolic murmur from pulmonary regurgitation. Right heart failure leads to jugular venous distension, hepatomegaly, ascites, and peripheral oedema. Clinical signs of associated diseases, such as systemic sclerosis or chronic liver disease, should be sought.

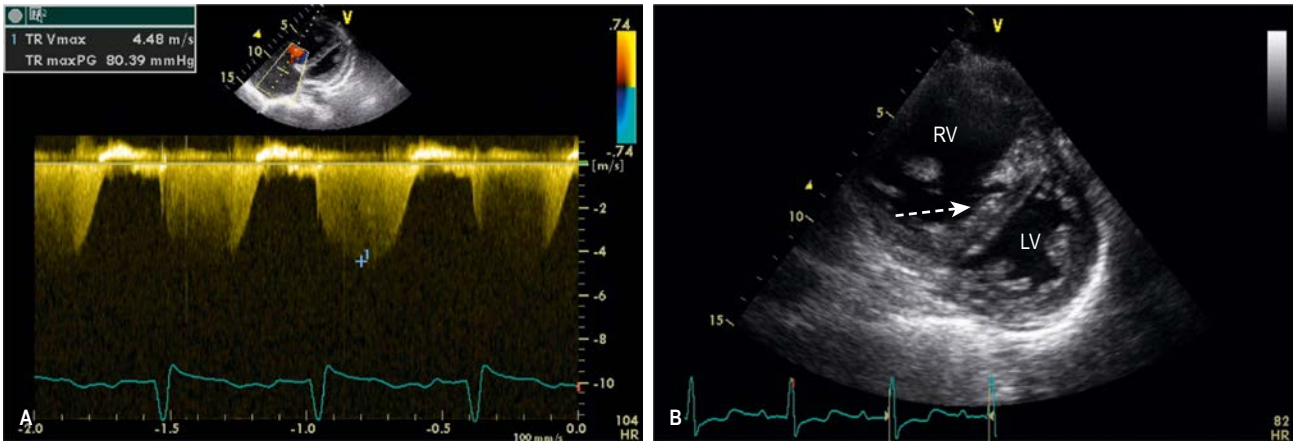

Fig. 17.99 Pulmonary hypertension. (A) Continuous wave Doppler echocardiography demonstrating markedly elevated tricuspid regurgitation velocity consistent with pulmonary hypertension. **(B)** Parasternal short-axis echocardiogram with a dilated right ventricle (RV) and septal flattening *(arrowed)* in a patient with pulmonary hypertension. *LV,* Left ventricle.

Investigations

- ***Routine blood tests*** include full blood count, renal and liver biochemistry, thyroid function tests, and serological assays for underlying autoimmune rheumatic diseases, HIV, and hepatitis.
- ***Chest X-ray*** shows enlargement of the pulmonary arteries and the major branches, with marked tapering (pruning) of peripheral arteries. The lung fields are usually lucent and there may be right atrial and right ventricular enlargement. There may be signs of chronic lung disease.
- ***ECG*** shows right ventricular hypertrophy and right atrial enlargement (P pulmonale).
- ***Echocardiography*** (Fig. 17.99) with tricuspid regurgitation can be used for determination of PAP using the simplified Bernoulli equation (PAP = 4 × (tricuspid regurgitation velocity)^2 + estimated right atrial pressure). Right atrial pressure can be assumed at 5 to 10 mmHg unless there is significant dilation of the inferior vena cava with reduced respiratory variation. mPAP = 0.61 × pulmonary artery systolic pressure +2 mmHg (although the Bernoulli equation may not be accurate in cases of severe tricuspid regurgitation).
- ***CMR*** may be useful in adult congenital heart disease and in assessing right ventricular function and volumes by serial assessment.
- ***Abdominal liver ultrasound*** is useful to exclude liver cirrhosis and portal hypertension.
- ***Right heart catheterization*** may be indicated as part of the clinical assessment to confirm the diagnosis (elevated PAP), determine the pulmonary wedge pressure (PWP), calculate the cardiac output, and assess PVR and reactivity. In PAH a vasodilator challenge (inhaled nitric oxide, intravenous adenosine, or epoprostenol) should be performed to identify patients who might benefit from these therapies. A responder is defined as a reduction in mean PAP of 10 mmHg or more to reach an absolute mPAP of 40 mmHg or less with increased or unchanged cardiac output. These vasodilator challenges are not recommended in patients with other types of pulmonary hypertension (types 2–5).

Management

- ***Physical activity.*** Patients should be encouraged to remain physically active but avoid exertion that precipitates severe dyspnoea, chest pain, or pre-syncope.
- ***Pregnancy.*** Patients with PAH have a very high mortality rate during pregnancy (30%–50%) and should be counselled against conception and contraceptive advice given.
- ***Travel.*** During plane travel, supplementary oxygen at 2 L/min may be appropriate for patients with reduced functional class and with resting hypoxia of less than 8 kPa.
- ***Vaccination.*** Vaccination should be given for influenza and pneumococcal pneumonia.
- ***Elective surgery.*** Epidural anaesthesia may be preferable to a general anaesthetic.
- ***Oral anticoagulation.*** There is evidence to support the use of oral anticoagulation in patients with IPAH, heritable PAH, and PAH due to anorexigens. The European target INR range is 2.0 to 3.0.
- ***Diuretics.*** These are used in patients with right heart failure and fluid overload.
- ***Digoxin.*** This may be helpful in patients with tachyarrhythmias.
- ***Calcium-channel blockers.*** These can be effective in high doses in selected patients with IPAH who demonstrate a response to a vasodilator challenge. Right heart catheterization should be repeated in 3 to 4 months to assess response to therapy.
- ***Prostanoids.*** Prostacyclin is a potent vasodilator that also inhibits platelet aggregation and cell proliferation. Synthetic prostacyclins are generally short-acting compounds requiring continuous intravenous or subcutaneous infusion or regular aerosol inhalation. They provide symptomatic relief and can improve exercise capacity; ***epoprostenol*** can improve survival in patients with both IPAH and associated pulmonary arterial hypertension. Oral ***selexipag*** has been approved by the US Food and Drug Administration for PAH treatment.
- ***Endothelin receptor antagonists.*** ET-1 is a potent vasoconstrictor and mitogen that binds to ET A and B receptors in the pulmonary vasculature. Both dual antagonists ***(bosentan)*** and selective A receptor antagonists ***(sitaxentan, ambrisentan)*** can improve symptoms, exercise capacity, and haemodynamics in patients with IPAH.
- ***Phosphodiesterase type 5 inhibitors.*** These produce vasodilation in the pulmonary vasculature and reduce cellular proliferation. ***Sildenafil*** and ***tadalafil*** have been demonstrated to provide symptomatic relief and improve exercise capacity in patients with IPAH.
- ***Balloon atrial septostomy.*** This technique may be considered palliative therapy in severe cases of pulmonary hypertension.

- ***Lung transplantation.*** This is used in patients with an adverse prognosis, although the 5-year survival following transplantation may be only 40% to 50%.

Other pulmonary hypertension groups

Left-sided heart disease (systolic and diastolic heart failure) and valvular heart disease are frequently associated with pulmonary hypertension, as is advanced chronic obstructive pulmonary disease (see Chapter 20, 'Chronic obstructive pulmonary disease' section), pulmonary fibrosis, and emphysema. Following acute pulmonary embolism, 0.5% to 2.0% of patients will develop CTEPH.

MYOCARDIAL AND ENDOCARDIAL DISEASE

Cardiac tumours

Primary cardiac tumours are rare and three-quarters of these are benign.

Atrial myxomas are the most common. Most are sporadic, but some are familial or part of a multisystem syndrome (Carney complex—hyperpigmented skin lesions with extracardiac tumours). Histologically, they are benign, polypoid, gelatinous structures. Most are solitary and occur in the left atrium (75%), attached by a pedicle to the atrial septum. The tumour may obstruct the mitral valve or may be a site of thrombi, which can embolize. The mean age of presentation is 50 years and there is a female predominance. Patients may be asymptomatic or present with dyspnoea, syncope, or a mild fever. Physical signs include a loud first heart sound, a tumour 'plop' (a loud third heart sound produced as the pedunculated tumour comes to an abrupt halt), a mid-diastolic murmur, and/or signs of embolization. Echocardiography, CT, and CMR are appropriate to confirm the diagnosis (Fig. 17.100) prior to cardiac surgery. Because of local recurrence, long-term surveillance is recommended.

Other benign cardiac tumours include lipoma, papillary fibroelastoma, fibroma, haemangioma, and rhabdomyoma.

Malignant primary cardiac tumours include angiosarcoma, undifferentiated sarcoma, rhabdomyosarcoma (children), osteosarcoma, and leiomyosarcoma. Primary cardiac lymphoma typically occurs in the right heart.

Secondary cardiac tumours from metastatic spread are 20 to 40 times more common than primary tumours. Direct invasion can occur with bronchogenic, breast, and oesophageal carcinoma. There may be haematogenous or lymphatic spread with lymphoma, leukaemia, transvenous renal cell carcinoma, hepatoma, and adrenal tumours. Pericardial effusions are common, and pericardiocentesis may be required for diagnosis or for cases with cardiac tamponade.

Myocardial disease

Myocardial disease that is not due to ischaemic, valvular, or hypertensive heart disease, or a known infiltrative, metabolic/toxic or neuromuscular disorder, may be caused by:

- an acute or chronic inflammatory pathology (myocarditis)
- idiopathic myocardial disease (cardiomyopathy).

Myocarditis

Acute inflammation of the myocardium has many causes (Box 17.47). In North America and Europe the most common causes of inflammation are viruses (enteroviruses, adenoviruses, human herpes virus-6, Epstein–Barr virus, cytomegalovirus, hepatitis C, and parvovirus B19). Chagas' disease, due to *Trypanosoma cruzi*, which is endemic in South America, is one of the most common causes of myocarditis worldwide. Additionally, toxins (including prescribed drugs), physical agents, hypersensitivity reactions, and autoimmune conditions may also cause myocardial inflammation.

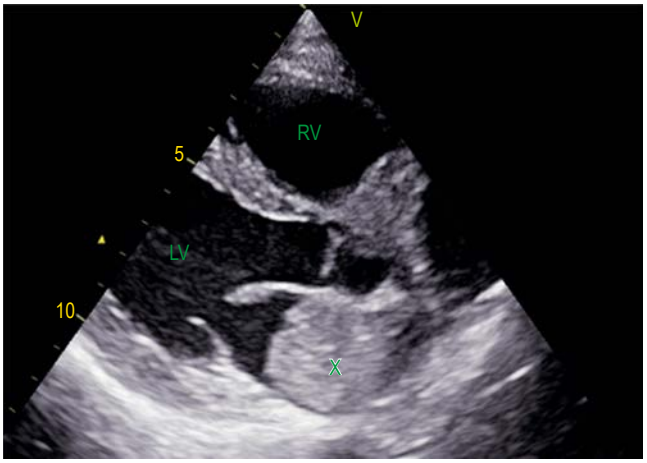

Fig. 17.100 Atrial myxoma shown by a two-dimensional echocardiogram (long-axis view). The myxoma (X) is an echo-dense mass obstructing the mitral valve orifice. It was removed surgically. *LV,* Left ventricle; *LA,* left atrium.

? Box 17.47 Causes of myocarditis

- Idiopathic
- Infective:
  - Viral: coxsackievirus, adenovirus, cytomegalovirus, echovirus, influenza, polio, hepatitis, HIV
  - Parasitic: *Trypanosoma cruzi*, *Toxoplasma gondii* (a cause of myocarditis in the newborn or immunocompromised)
  - Bacterial: streptococcus (most commonly, rheumatic carditis), diphtheria (toxin-mediated heart block common)
  - Spirochaetal: Lyme disease (heart block common), leptospirosis
  - Fungal
  - Rickettsial
- Toxic:
  - Drugs: those causing hypersensitivity reactions, e.g., methyldopa, penicillin, sulphonamides, anti-tuberculous, modafinil
  - Radiation: may cause myocarditis but pericarditis is more common
- Autoimmune:
  - An autoimmune form with autoactivated T cells and organ-specific antibodies may occur
  - Giant cell myocarditis
- Alcohol
- Hydrocarbons

Pathology

In the acute phase myocarditic hearts are flabby with focal haemorrhages; in chronic cases they are enlarged and hypertrophied. Histologically (Fig. 17.101), an inflammatory infiltrate is present—lymphocytes predominating with viral causes, polymorphonuclear cells with bacterial causes, and eosinophils with allergic and hypersensitivity causes.

Clinical features

Myocarditis typically presents in young adult patients. Presentation may vary from subclinical disease to mild fatigue, palpitations, chest pain, and dyspnoea through to fulminant congestive cardiac

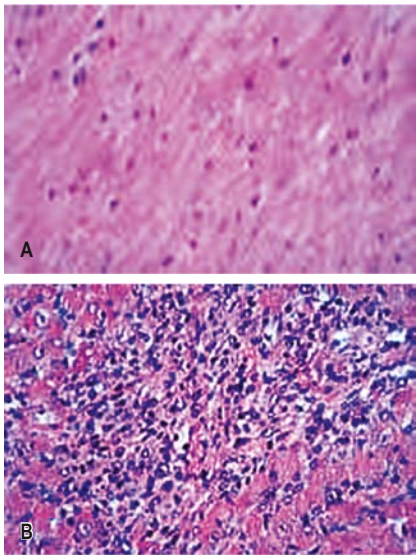

Fig. 17.101 Myocardial biopsies. (A) Normal myocardium. (B) Myocarditis, with increased interstitial inflammatory cells.

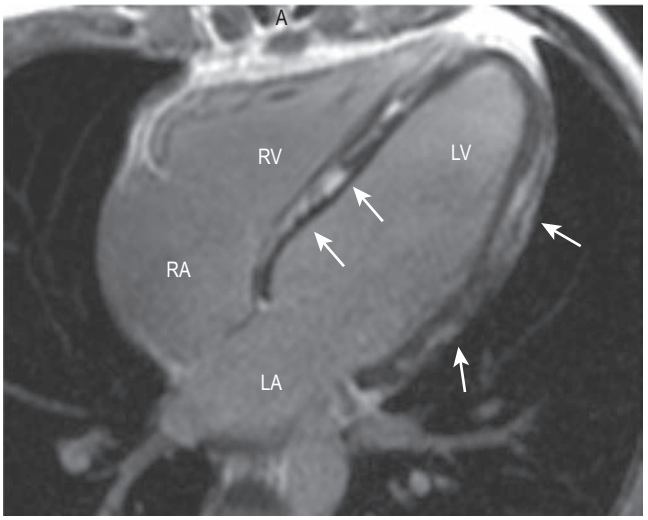

Fig. 17.102 Acute myocarditis. There is patchy mid-wall and epicardial myocardial enhancement *(arrowed)* with gadolinium. *A,* Anterior chest wall; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

failure. Physical examination may reveal soft heart sounds, a prominent third sound, and a tachycardia. A pericardial friction rub may be heard.

Investigations

- ***ECG*** may demonstrate diffuse ST- and T-wave abnormalities (concave ST elevation) and arrhythmias. AV block may be seen with Lyme disease, sarcoid, giant-cell myocarditis, and Chagas' disease (see later).
- ***Echocardiography*** is required and may reveal normal or reduced biventricular function with resting regional wall motion abnormalities.
- ***Blood tests*** include ESR and CRP, which are frequently elevated in the acute presentation. Cardiac troponin and creatine kinase levels will also be elevated. Viral serology is not usually helpful.
- ***CMR*** is recommended to confirm the diagnosis. Patients with acute myocarditis may demonstrate myocardial oedema on T2-weighted images and patchy myocardial enhancement with gadolinium (Fig. 17.102).
- ***Endomyocardial biopsy*** is considered the gold standard for the diagnosis of myocarditis, although its use is reserved for selected patients (fulminant presentation or clinical deterioration) as this is an invasive test performed in specialized units. It may be helpful in giant cell myocarditis, sarcoidosis, and other autoimmune conditions as diagnosis will enable specific treatment.
- ***Coronary angiography*** is frequently performed to exclude acute ischaemia as the cause of the patient's presentation.

Management

Myocarditis resolves within a few weeks in the majority of patients, although a small percentage of patients deteriorate and may require urgent transfer to a cardiac centre with access to ECMO and/or cardiac transplantation. Bed rest is recommended in the acute phase of the illness and athletic activities should be avoided for 6 months. Heart failure should be treated with conventional medical therapy (see 'Management of heart failure' section).

Giant cell myocarditis

This severe form of myocarditis is characterized by the presence of multinucleated giant cells within the myocardium. The cause is unknown but it may be associated with sarcoidosis, thymomas, and autoimmune disease. The disease has a rapidly progressive course and a poor prognosis. Immunosuppression is recommended.

Chagas' disease

Chagas' disease (see Chapter 42, 'South American trypanosomiasis [Chagas' disease]' section) is caused by the protozoon *T. cruzi* and is endemic in South America, where upwards of 20 million people are infected. Acutely, features of myocarditis are present with fever and congestive heart failure. Chronically, there is progression to a DCM with a propensity towards heart block and ventricular arrhythmias. Treatment is discussed in Chapter 42 ('South American trypanosomiasis [Chagas' disease]' section).

Cardiomyopathy

Cardiomyopathies are a group of diseases of the myocardium leading to structural and functional abnormalities of the heart in the absence of other causes such as CAD, hypertension, valvular disease, and congenital heart disease. The ESC provides a classification system according to a phenotype-based integrated aetiological diagnosis using morphological and functional differences of the myocardium (Fig. 17.103):

- HCM
- ACM
- DCM
- RCMs
- unclassified.

Hypertrophic cardiomyopathy

HCM includes a group of inherited conditions that produce hypertrophy of the left ventricular myocardium. Left ventricular wall thickness is 15 mm or more (or if 13–14 mm requires evaluation of other features such as family history or genetics) in the absence of abnormal loading conditions such as aortic stenosis or hypertension. It is the most common cause of sudden cardiac death in young people and affects 1 in 500 of the population. The majority of cases are familial autosomal dominant and are due to mutations in the genes encoding sarcomeric proteins. The most common causes of HCM

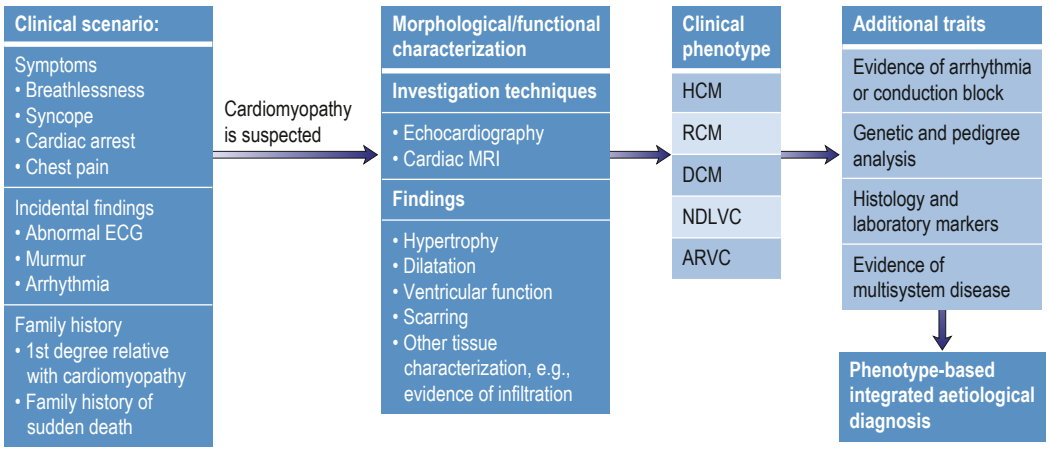

Fig. 17.103 Clinical diagnostic workflow of cardiomyopathy. *ARVC,* Arrhythmogenic right ventricular cardiomyopathy; *CMP,* cardiomyopathy; *CMR,* cardiac magnetic resonance; *DCM,* dilated cardiomyopathy; *ECG,* electrocardiogram; *HCM,* hypertrophic cardiomyopathy; *NDLVC,* non-dilated left ventricular cardiomyopathy; *RCM,* restrictive cardiomyopathy.

are mutations of the β-myosin heavy chain *MYH7* and myosin-binding protein C *MYBPC3*.

There are non-sarcomeric protein mutations in genes that control cardiac metabolism that result in glycogen storage diseases (Danon's, Pompe's, and Fabry's diseases) and cause cardiac hypertrophy that may be indistinguishable from inherited HCM on echocardiography.

Clinical features

Myocardial hypertrophy frequently involves the interventricular septum but can be in any distribution and histologically is characterized by disorganization ('disarray') of cardiac myocytes and myofibrils. Some 25% of patients have dynamic LVOT obstruction due to the combined effects of hypertrophy, systolic anterior motion of the anterior mitral valve leaflet, and rapid ventricular ejection. The salient clinical and morphological features of the disease vary according to the underlying genetic mutation. For example, marked hypertrophy is common with β-myosin heavy chain mutations, whereas mutations in troponin T may be associated with mild hypertrophy but a high risk of sudden death. The hypertrophy may not manifest before completion of the adolescent growth spurt, making the diagnosis difficult in children. HCM due to myosin-binding protein may not manifest until the sixth decade of life or later.

Symptoms

- Many cases are asymptomatic and are detected by family screening of an affected individual or by a routine ECG examination.
- Chest pain, dyspnoea, syncope or pre-syncope (typically with exertion), cardiac arrhythmias, and sudden death may occur.
- Sudden death can occur at any age but the highest rates (up to 6% per annum) occur in adolescents or young adults. Risk factors for sudden death are discussed later.
- Dyspnoea occurs due to impaired relaxation of the heart muscle or the LVOT obstruction that occurs in some patients. The systolic cavity remains small until the late stages of disease, when progressive dilation may occur. If a patient develops atrial fibrillation, there is often a rapid deterioration in clinical status due to the loss of atrial contraction and tachycardia, resulting in elevated left atrial pressure and acute pulmonary oedema.

Signs

- Double apical pulsation (forceful atrial contraction producing a fourth heart sound)
- Jerky carotid pulse because of rapid ejection and sudden obstruction to left ventricular outflow during systole
- Ejection systolic murmur due to left ventricular outflow obstruction late in systole; it can be increased by manoeuvres that decrease afterload, such as standing or Valsalva, and decreased by manoeuvres that increase afterload and venous return, such as squatting
- Pansystolic murmur due to mitral regurgitation (secondary to systolic anterior motion)
- Fourth heart sound (if not in atrial fibrillation).

Investigations

- ***ECG*** abnormalities in HCM include left ventricular hypertrophy (see Fig. 17.74), ST- and T-wave changes, and abnormal Q waves, especially in the inferolateral leads.
- ***Echocardiography*** is usually diagnostic. In classical HCM there is asymmetric left ventricular hypertrophy (involving the septum more than the posterior wall), systolic anterior motion of the mitral valve, and a vigorously contracting ventricle (Fig. 17.104). However, any pattern of hypertrophy may be seen, including concentric and apical hypertrophy.
- ***CMR*** can detect both hypertrophy and abnormal myocardial fibrosis (Fig. 17.105) and can differentiate between HCM and infiltrative cardiomyopathies.
- ***Genetic analysis***, where available, may confirm the diagnosis and provide prognostic information for the patient and relatives.

Management

The management of HCM includes treatment of symptoms and prevention of sudden cardiac death in the patient and relatives.

Risk factors for sudden death are:

- massive left ventricular hypertrophy (>30 mm on echocardiography)
- family history of sudden cardiac death (<50 years old)
- non-sustained ventricular tachycardia on 24-hour Holter monitoring
- prior unexplained syncope

- abnormal blood pressure response on exercise (flat or hypotensive response).

The presence of these cardiac risk factors is associated with an increased risk of sudden death, and patients with two or more should be assessed for ICD insertion. When the risk is less, amiodarone may be an appropriate alternative.

Patients with left ventricular outflow tract obstruction (LVOTO) should avoid dehydration and vasodilators, such as nitrates and phosphodiesterase type 5 inhibitors, as these may worsen obstruction or cause refractory hypotension. Treatment includes non-vasodilating beta-blockers (e.g., metoprolol) or, if not tolerated, verapamil or diltiazem. Disopyramide may be added if patients are still symptomatic. Mavacamten is a first-in-class cardiac myosin ATPase inhibitor and may be used as second-line therapy as it reduces LVOT gradient and improves exercise capacity in patients with HCM and symptomatic LVOTO.

The threshold for invasive treatment of significant LVOTO (usually considered ≥50 mmHg) involves careful evaluation and may include alcohol (non-surgical) ablation of the septum or surgical ventricular septal myectomy. Both appear to offer favourable results in reduction of outflow tract obstruction and subsequent improvement in exercise capacity. However, there is a risk of AV block and MI with alcohol ablation and iatrogenic VSD and AV block with surgery.

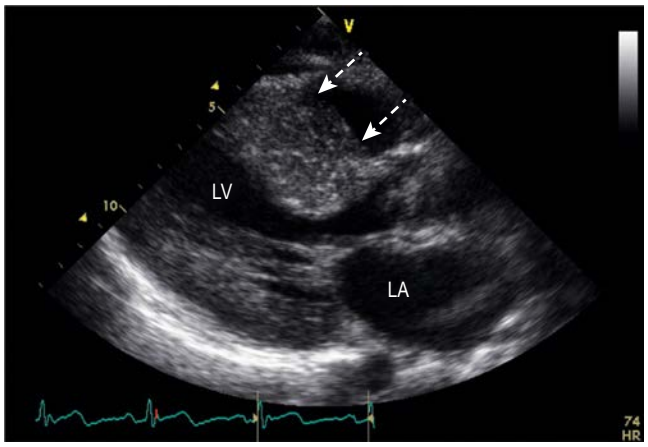

Fig. 17.104 Hypertrophic cardiomyopathy. A two-dimensional echocardiogram (short-axis view). The grossly thickened interventricular septum is shown, resulting in a small left ventricular cavity. This condition is associated with an abnormal anterior motion of the mitral valve during systole *(arrowed)*. *LA,* Left atrium; *LV,* left ventricle.

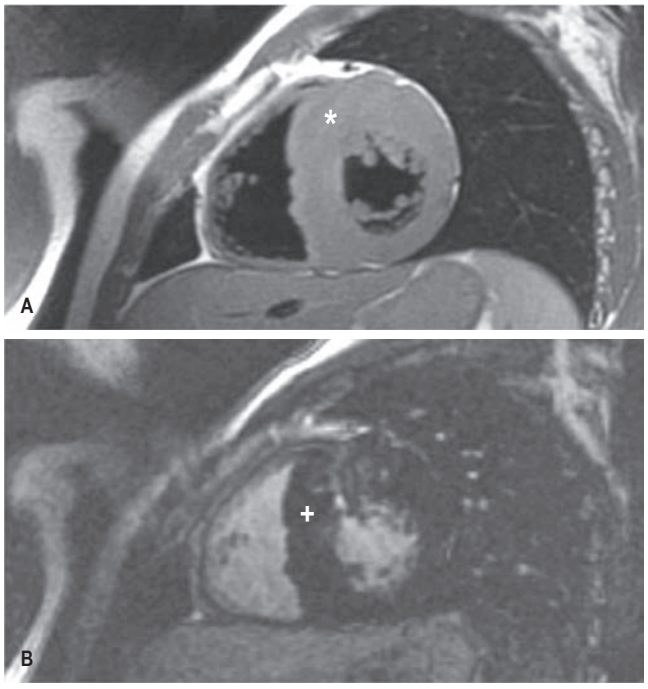

Fig. 17.105 Cardiac magnetic resonance imaging in a patient with hypertrophic cardiomyopathy. **(A)** Turbo spin-echo demonstrates marked thickening of the basal to mid-anterior wall and septum (*). **(B)** Inversion recovery image post gadolinium demonstrates regional fibrosis with enhancement (+).

Dilated cardiomyopathy

Dilated cardiomyopathy (DCM) has a prevalence of 7 to 12 in 10 000 and is characterized by dilation of the ventricular chambers and systolic dysfunction in the absence of abnormal loading conditions and CAD.

Familial DCM is predominantly autosomal dominant and can be associated with over 20 abnormal loci and genes (Fig. 17.106). Many of these are genes encoding cytoskeletal or associated myocyte proteins (dystrophin in X-linked cardiomyopathy; actin, desmin, troponin T, β-myosin heavy chain, sarcoglycans, vinculin, and lamin a/c in autosomal dominant DCM; Fig. 17.107). Many of these have prominent associated features, such as skeletal myopathy or

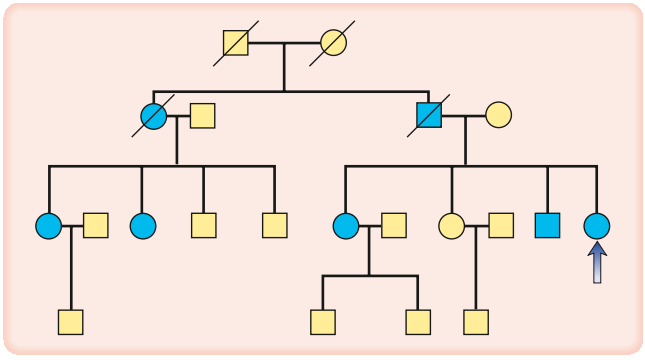

Fig. 17.106 Pedigree of a family with dilated cardiomyopathy. Blue symbols are affected family members. The *arrow* indicates the index case.

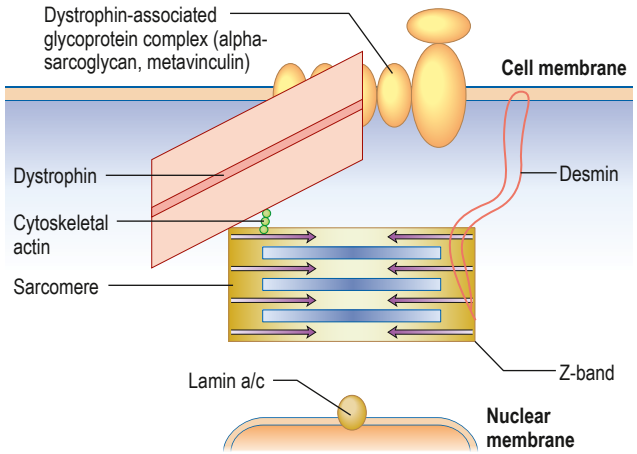

Fig. 17.107 Myocyte proteins implicated in dilated cardiomyopathy.

conduction system disease, and therefore differ from the majority of cases of DCM.

Sporadic DCM can be caused by multiple conditions:

- myocarditis: Coxsackievirus, adenoviruses, erythroviruses, HIV, bacteria, fungi, mycobacteria, parasitic (Chagas' disease)
- toxins: alcohol, chemotherapy, metals (cobalt, lead, mercury, arsenic)
- autoimmune disorders
- endocrine disorders
- neuromuscular disorders.

Clinical features

DCM can present with heart failure, cardiac arrhythmias, conduction defects, thromboembolism, or sudden death. Increasingly, evaluation of relatives of DCM patients is allowing identification of early asymptomatic disease, prior to the onset of these complications. Clinical evaluation should include a family history and construction of a pedigree where appropriate.

Investigations

- ***ECG*** may demonstrate diffuse non-specific ST-segment and T-wave changes. Sinus tachycardia, conduction abnormalities, and arrhythmias (i.e., atrial fibrillation, ventricular premature contractions, or ventricular tachycardia) are also seen.
- ***Echocardiogram*** reveals dilation of the left and/or right ventricle with reduced global function (Fig. 17.108).
- ***CMR*** may demonstrate other aetiologies of left ventricular dysfunction (e.g., previous MI) or show abnormal myocardial fibrosis (Fig. 17.109).
- ***Coronary angiography*** or CTCA should be performed to exclude CAD in all individuals at risk (generally, patients > 40 years, or younger if symptoms or risk factors are present).
- ***Biopsy*** is not normally indicated outside specialist care.
- ***Genetic testing:*** causative gene variants may be found in up to 40% and 10% to 15% of those with a presumed acquired cause such as peripartum, alcoholic, or chemotherapy-induced cardiomyopathy.

Management

Treatment is with conventional medical therapy for heart failure. Cardiac resynchronization therapy and/or ICDs may be indicated in those with an LVEF of 35% or less. ICDs may be considered in those with a high-risk gene even if LVEF is more than 35% (e.g., LMNA mutation encoding lamin A and C). Cardiac transplantation may be appropriate for certain patients.

Arrhythmogenic cardiomyopathy/ arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic cardiomyopathy (ACM) is an uncommon (1 in 1000–5000 population) inherited condition that predominantly affects the right ventricle with fatty or fibro-fatty replacement of myocytes, leading to segmental or global dilation (Fig. 17.110). Left ventricular involvement has been reported in up to 75% of cases, and some may have predominant LV disease. The fibro-fatty replacement leads to ventricular arrhythmia and risk of sudden death in its early stages and right ventricular or biventricular failure in its later stages.

Autosomal dominant ACM has been mapped to mutations in genes coding for desmosomal proteins. These are the cardiac ryanodine receptor RyR2 (also responsible for familial catecholaminergic polymorphic ventricular tachycardia, CPVT), desmoplakin, plakophilin-2, and mutations altering the regulatory sequences of the TGF-β gene.

There are two recessive forms: ***Naxos disease*** (associated with palmoplantar keratoderma and woolly hair), which is due to a

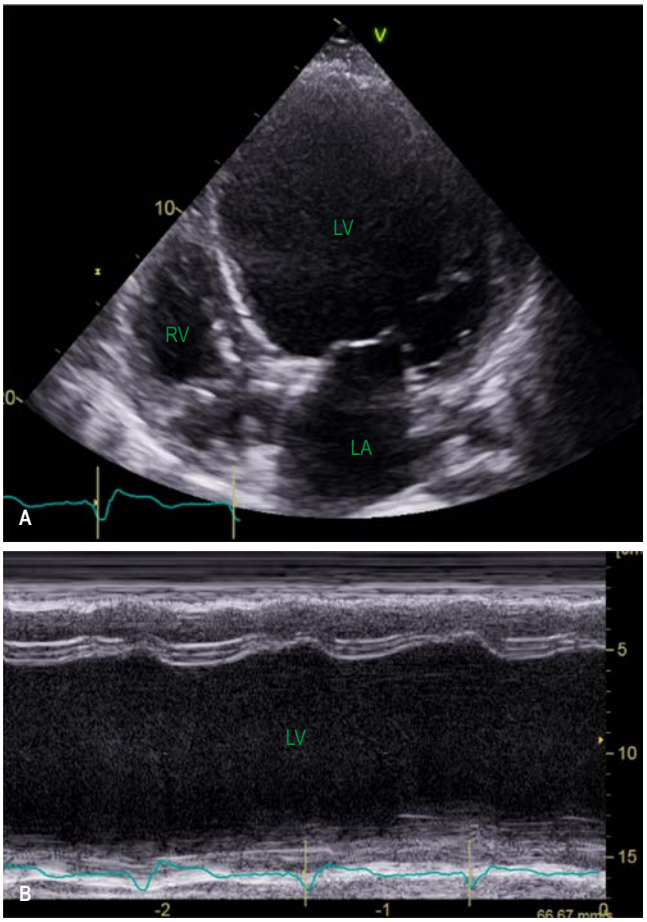

Fig. 17.108 Dilated cardiomyopathy. **(A)** Two-dimensional (apical four-chamber view) echocardiogram. The heart has a 'globular' appearance with all four chambers dilated. **(B)** M mode echocardiogram. The extremely impaired left ventricular function can be appreciated by comparing the systolic shortening fraction with that of Fig. 17.21. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium.

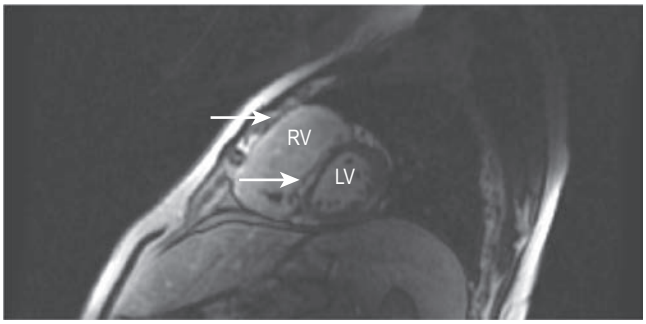

Fig. 17.112 Arrhythmogenic cardiomyopathy (ACM). Inversion recovery magnetic resonance image post gadolinium demonstrates marked hyper-enhancement *(arrowed)* in the right ventricular free wall and inferoseptum consistent with fibro-fatty replacement in right ventricle (RV) and left ventricle (LV).

mutation in junctional plakoglobin, and the rarer variant ***Carvajal's syndrome***, due to a mutation in desmoplakin.

Clinical features

Most patients are asymptomatic and men appear to be affected more. Symptomatic ventricular arrhythmia, syncope, or sudden death occurs. Occasionally, presentation is with symptoms and signs of right heart failure, although this is more common in the later stages of the disease. Some patients may be detected through family screening, although frequently, the morphological appearance of the right ventricle is normal, despite significant cardiac arrhythmias.

Investigations and diagnosis

- ***ECG*** is usually normal but may demonstrate T-wave inversion in the precordial leads related to the right ventricle (V_1–V_3). Small-amplitude potentials occurring at the end of the QRS complex (epsilon waves) may be present (Fig. 17.111), and incomplete or complete right bundle branch block is sometimes seen. Signal-averaged ECG may indicate the presence of late potentials and the delayed depolarization of individual muscle cells; 24-hour Holter monitoring may demonstrate frequent extrasystoles of right ventricular origin or runs of non-sustained ventricular tachycardia.
- ***Echocardiography*** is frequently normal but, with more advanced cases, may demonstrate right ventricular dilation and aneurysm formation; there may be left ventricular dilation.
- ***CMR*** can assess regional wall motions, size, and aneurysms of the right ventricle more accurately and in some cases can demonstrate fibro-fatty infiltration (Fig. 17.112).
- ***Genetic testing and family screening:*** the pattern of inheritance is autosomal dominant involving mutations of the desmosomal genes.

Clinical diagnosis is made using Task Force Criteria, which include:

- structural abnormalities of the right ventricle and right ventricular outflow tract (dilation and abnormal wall motion on echocardiography or MRI)
- fibro-fatty replacement of myocytes on tissue biopsy
- repolarization and conduction abnormalities on ECG or signal-averaged ECG
- ventricular tachycardia or frequent ventricular extrasystoles on Holter monitoring
- family history of ACM in a first- or second-degree relative
- premature sudden death (<35 years) due to ACM.

Management

Beta-blockers are first-line treatment for patients with non-life-threatening arrhythmias. Amiodarone is used for symptomatic arrhythmias when beta-blocker therapy fails. For refractory or life-threatening arrhythmias and those at highest risk of sudden cardiac death, catheter ablation and an ICD is required. Occasionally, cardiac transplantation is indicated for either intractable arrhythmia or cardiac failure.

Left ventricular non-compaction

Left ventricular non-compaction (LVNC) is associated with a sponge-like appearance of the left ventricle. The condition predominantly affects the apical portion of the left ventricle and may be associated with congenital heart abnormalities. LVNC is diagnosed by echocardiography, CMR, or left ventricular angiography. The natural history is unresolved but includes congestive cardiac failure, thromboembolism, cardiac arrhythmias, and sudden death. Familial and spontaneous cases have been described. It is important to differentiate LVNC from phenotypically similar conditions which may arise during athletic adaptation and pregnancy, which resolve with deconditioning and following pregnancy, respectively.

Restrictive cardiomyopathy

This is a rare condition with restrictive left and/or right ventricular pathophysiology in the setting of normal or reduced diastolic volumes of either one or both ventricles with normal or reduced systolic volumes and normal ventricular wall thickness.

The restrictive physiology produces symptoms and signs of heart failure. Conditions associated with this form of cardiomyopathy include amyloidosis (most common), sarcoidosis, glycogen storage disorders, Loeffler's endocarditis, and endomyocardial fibrosis; in the latter two conditions there is myocardial and endocardial fibrosis, associated with eosinophilia. The idiopathic form of RCM may be familial.

Clinical features

Patients with RCM may present with dyspnoea, fatigue, and embolic symptoms. On clinical examination there will be elevated JVP with diastolic collapse (Friedreich's sign) and elevation of venous pressure with inspiration (Kussmaul's sign), hepatic enlargement, ascites, and dependent oedema. Third and fourth heart sounds may be present.

Investigations

- ***ECG*** may demonstrate low-voltage QRS and ST-segment and T-wave abnormalities.
- ***Echocardiography*** shows symmetrical myocardial thickening and often a normal systolic EF but impaired ventricular filling. There is usually significant bi-atrial enlargement. In patients with amyloid the myocardium typically appears speckled with reduced longitudinal shortening with relative apical sparing (Fig. 17.113).
- ***CMR*** may show abnormal myocardial fibrosis in amyloidosis or sarcoidosis.
- ***Cardiac catheterization*** and haemodynamic studies may help distinguish between RCM and constrictive pericarditis, although volume loading may be required.
- ***Endomyocardial biopsy*** is often useful in this condition, in contrast to other cardiomyopathies, and may permit a specific diagnosis, such as amyloidosis, to be made.

Management

There is no specific treatment. Cardiac failure will require diuretics and embolic manifestations managed with anticoagulation. Cardiac transplantation is necessary in some severe cases, especially the idiopathic variety. Management of primary amyloidosis is discussed elsewhere but may include tafamidis, a transthyretin stabilizer. Liver transplantation may be effective in familial amyloidosis (due to production of mutant pre-albumin) and may lead to reversal of the cardiac abnormalities.

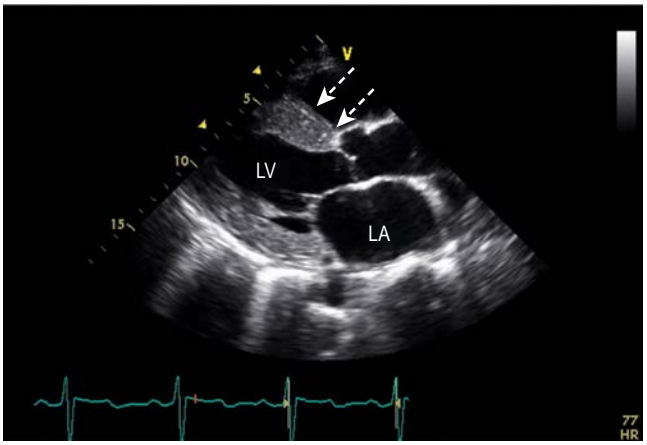

Fig. 17.113 Cardiac amyloidosis. Parasternal long-axis echocardiogram demonstrating left ventricular hypertrophy with reduced systolic function. The septum has a speckled appearance *(arrowed)*. *LA,* Left atrium; *LV,* left ventricle.

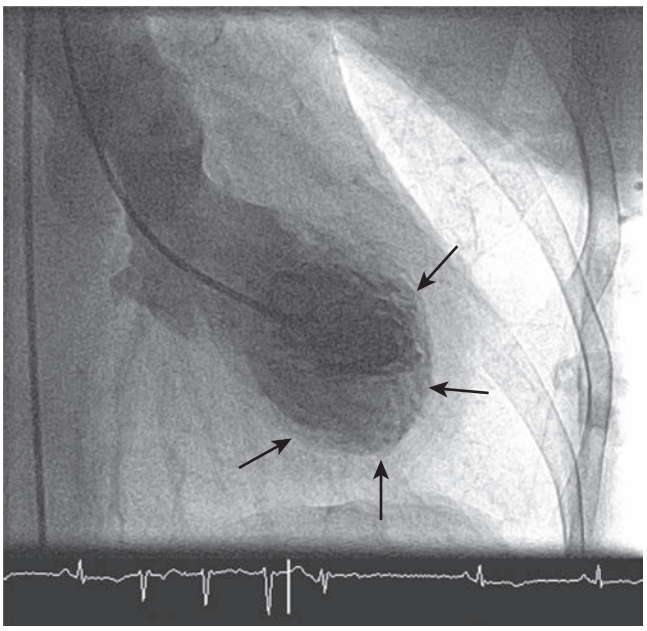

Fig. 17.114 Takotsubo cardiomyopathy. Left ventricular angiography in a patient admitted with chest pain following emotional stress demonstrates apical ballooning *(arrowed)* consistent with Takotsubo cardiomyopathy. Diagnostic coronary angiography showed normal coronary arteries.

Acquired cardiomyopathies

Takotsubo syndrome (stress cardiomyopathy)

Patients with this condition typically are postmenopausal women and present acutely with chest pain and breathlessness associated with ECG changes and elevated cardiac biomarkers consistent with acute MI. Diagnostic coronary angiography typically demonstrates unobstructed coronary arteries, with characteristic akinesia of the mid-apical segments of the left ventricle on ventriculography or echocardiography, and preserved basal function (Fig. 17.114). The pathophysiology is uncertain but disease may be due to transient catecholamine excess, coronary vasospasm, abnormalities of the coronary microcirculation, and hypertrophy of the basal septum. Severe cases may have cardiogenic shock and pulmonary oedema.

Patients with a significant left ventricular gradient may respond to cautious beta-blockade. Complete recovery of function is usual within 4 to 6 weeks, and therefore technically this is not classified as a cardiomyopathy. Recurrence is uncommon and may be reduced by long-term beta-blocker therapy.

Peripartum cardiomyopathy

This rare condition affects women in the last trimester of pregnancy or within 5 months of delivery. It presents as a DCM; is more common in obese, multiparous women over 30 years old and with Black ethnicity; and is associated with pre-eclampsia. Nearly half of patients will recover to normal function within 6 months, but in some it can cause progressive heart failure and sudden death. Genetic testing should be considered for an underlying cardiomyopathy, and counselling given regarding future pregnancies.

Arrhythmia-induced cardiomyopathy ('tachycardia cardiomyopathy')

Patients with prolonged periods of supraventricular arrhythmias (e.g., atrial fibrillation, atrial flutter, atrial tachycardia), and particularly with tachycardia and frequent ventricular ectopy (>15% of all heartbeats), are at risk of deterioration of left ventricular function. Patients present with heart failure symptoms and may have palpitations. Rate control with beta-blockers and conventional heart failure therapy is required, but cardioversion and ablation may be necessary to allow for recovery of cardiac function.

PERICARDIAL DISEASE

The pericardium acts as a protective covering for the heart. It consists of an outer fibrous pericardial sac and an inner serous pericardium; the latter is made up of the inner visceral epicardium that lines the heart and great vessels, and its reflection, the outer parietal pericardium that lines the fibrous sac. The normal amount of pericardial fluid is 20 to 49 mL, and this fluid lubricates the surface of the heart. Presentations of pericardial disease include:

- acute, incessant (usually 4–6 weeks up to 3 months) and chronic (>3 months) pericarditis
- pericardial effusion and cardiac tamponade
- constrictive pericarditis
- pericardial masses.

Acute pericarditis

This term refers to inflammation of the pericardium, which may account for 5% of accident and emergency presentations with chest pain. The condition is more common in young adults, particularly men. Acute pericarditis has numerous aetiologies (**Box 17.48**), although, in most cases, a cause is not identified (idiopathic).

Clinical features and investigations

There are four common clinical features of acute pericarditis:

- ***chest pain*** that may be pleuritic, exacerbated by movement, and relieved by sitting forwards
- ***pericardial friction rub***

? Box 17.48 Aetiology of pericarditis

Infectious pericarditis
- Viral (Coxsackievirus, echovirus, mumps, herpes, HIV)
- Bacterial (staphylococcal, streptococcal, pneumococcal and meningococcal infections, *Haemophilus influenzae*, mycoplasmosis, borreliosis, chlamydia)
- Tuberculous
- Fungal (histoplasmosis, coccidioidomycosis, candidiasis)

Post-myocardial infarction pericarditis
- Acute myocardial infarction (early)
- Dressler's syndrome (late)

Malignant pericarditis
- Primary tumours of the heart (mesothelioma)
- Metastatic pericarditis (breast and lung carcinoma, lymphoma, leukaemia, melanoma)

Uraemic pericarditis

Myxoedematous pericarditis

Chylopericardium

Autoimmune pericarditis
- Collagen-vascular (rheumatoid arthritis, rheumatic fever, systemic lupus erythematosus, scleroderma)
- Drug-induced (procainamide, hydralazine, isoniazid, doxorubicin, cyclophosphamides)

Post-radiation pericarditis

Post-surgical pericarditis
- Post-pericardiotomy syndrome

Post-traumatic pericarditis

Familial and idiopathic pericarditis

- ***ECG abnormalities*** with widespread concave-upwards (saddle-shaped) ST elevation (**Fig. 17.115**), reciprocal ST depression in leads AVR and V_1, and PR segment depression
- ***pericardial effusion***.

A clinical diagnosis of acute pericarditis can be made with two out of four of these features.

Inflammatory blood tests will be elevated ***(CRP, ESR, white cell count)*** and can be used to monitor disease resolution. Cardiac troponin and creatine kinase may be elevated in cases with myopericarditis. Chest X-ray may demonstrate cardiomegaly in patients with a large pericardial effusion.

Management and treatment

In 70% to 90% of cases, acute pericarditis is self-limiting. Most patients can be treated with aspirin 750 to 1000 mg three times daily or ibuprofen 600 to 800 mg three times daily for 1 to 2 weeks. Colchicine for 3 months is also recommended to improve response and importantly reduce recurrence. Corticosteroids should be reserved for patients with a known immune cause, as their use is associated with an increased rate of recurrence. High-risk patients (fever >38°C, subacute onset, large effusion, tamponade, lack of response to therapy) should be admitted for treatment. Activity should be restricted until the inflammatory markers are normalized, and competitive athletes should avoid exercise for at least 3 months.

Incessant or chronic pericarditis

About 20% of cases of acute pericarditis go on to develop idiopathic relapsing pericarditis, which may be incessant (recurring within 6 weeks) or chronic (lasting >3 months). The first-line treatment is non-steroidal anti-inflammatory drugs (NSAIDs) or aspirin with colchicine for up to 6 months. In resistant cases low-dose oral corticosteroids may be effective, particularly in autoimmune disease

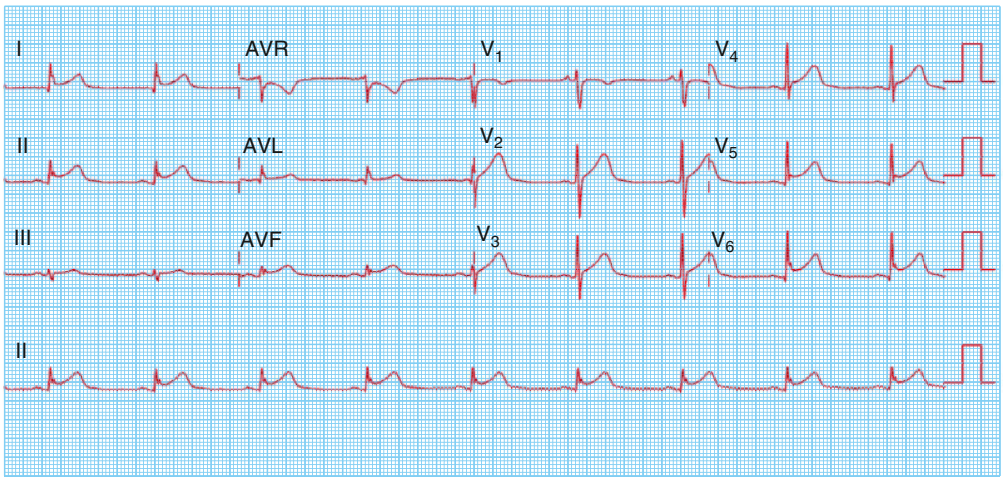

Fig. 17.115 Electrocardiogram associated with acute pericarditis. Note the diffuse, concave, raised ST segments seen in most leads.

and if an infectious cause has been excluded. CT or CMR may be helpful in demonstrating thickened (>4 mm) or inflamed pericardium.

Tuberculous pericarditis

This is uncommon (<5%) in the developed world but may account for over 50% of cases in low- and middle-income countries and over 90% in patients with HIV. Tuberculous pericarditis usually presents with chronic low-grade fever, particularly in the evening, associated with features of acute pericarditis, dyspnoea, malaise, night sweats, and weight loss. Pericardial aspiration is often required to make the diagnosis. Constrictive pericarditis is a frequent outcome. Treatment is as for pulmonary tuberculosis (see Chapter 20, 'Tuberculosis' section) with high-dose corticosteroids daily for 2 to 6 weeks.

Post-cardiac injury syndromes

This includes pericarditis following MI (Dressler's syndrome), cardiac surgery, or trauma. An autoimmune reaction is triggered by myocardial or pericardial damage, leading to pericarditis. Recurrences are common. Colchicine and anti-inflammatory agents are the treatment of choice.

Malignant pericarditis

Carcinoma of the bronchus, carcinoma of the breast, and Hodgkin's lymphoma are the most common causes of malignant pericarditis. Leukaemia and malignant melanoma are also associated with pericarditis. A substantial pericardial effusion is typical and is due to obstruction of lymphatic drainage from the heart. The effusion is often haemorrhagic. Radiation and therapy for thoracic tumours may cause radiation injury to the pericardium, resulting in serous or haemorrhagic pericardial effusion and pericardial fibrosis.

Pericardial effusion and cardiac tamponade

A pericardial effusion is a collection of fluid within the potential space of the serous pericardial sac (Fig. 17.116); it commonly accompanies an episode of acute pericarditis. When a large volume collects in this space, ventricular filling is compromised, leading to haemodynamic compromise. This is known as cardiac tamponade.

Clinical features

Symptoms of a pericardial effusion commonly reflect the underlying pericarditis. On examination:

- Heart sounds are soft and distant.
- Apex beat is commonly obscured.
- A friction rub may be evident due to pericarditis in the early stages, but this becomes quieter as fluid accumulates and pushes the layers of the pericardium apart.
- Rarely, the effusion may compress the base of the left lung, producing an area of dullness to percussion below the angle of the left scapula (Ewart's sign).
- As the effusion worsens, signs of cardiac tamponade may become evident:
  - raised JVP with sharp × descent
  - Kussmaul's sign (rise in JVP/increased neck vein distension during inspiration)
  - pulsus paradoxus (an exaggeration in the normal variation in pulse pressure seen with inspiration, such that there is a drop in systolic blood pressure of ≥10 mmHg)
  - reduced cardiac output.

Investigations

- ***ECG*** reveals low-voltage QRS complexes (<0.5 mV in limb leads) with sinus tachycardia and there may be electric alternans (alteration of QRS amplitude or axis between beats).
- ***Chest X-ray*** (see **Fig. 17.116A**) shows a large, globular heart with clear lung fields. Typically, the pulmonary veins are not distended.
- ***Echocardiography*** (see Fig. 17.116) is the most useful technique for demonstrating the effusion and looking for evidence of tamponade: late diastolic collapse of the right atrium, early diastolic collapse of the right ventricle, ventricular septum displacement into the left ventricle during inspiration, diastolic flow reversal in the hepatic veins during expiration, and dilated inferior vena cava with less than 50% reduction during inspiration.
- ***Cardiac CT or MRI*** is helpful if loculated pericardial effusions are suspected (post cardiac surgery).
- ***Pericardiocentesis*** is the removal of pericardial fluid with an aseptic technique under echocardiographic guidance (see **Fig. 17.32**). It is indicated to improve symptoms and also can aid with diagnosis, particularly when an infectious or malignant effusion is suspected.
- ***Pericardial biopsy*** may be needed if tuberculosis is suspected and pericardiocentesis is not diagnostic.

Other tests may be required to identify underlying causes: for example, blood cultures, autoantibody screen, and cross-sectional imaging usually with CT.

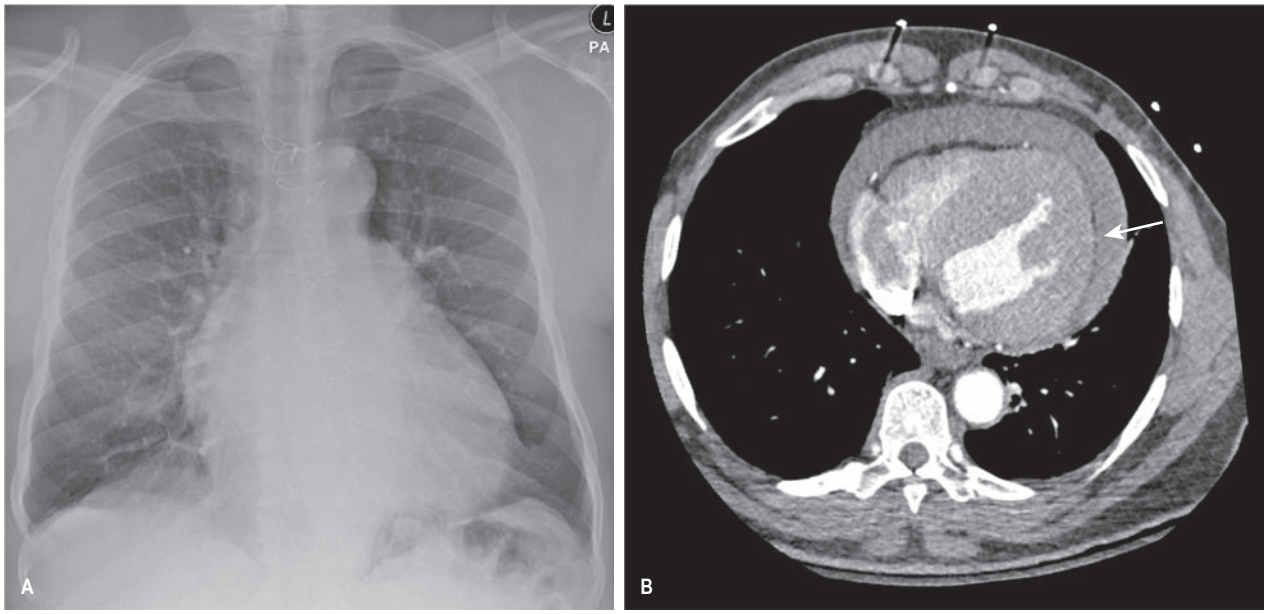

Fig. 17.116 Pericardial effusion. **(A)** Note the globular appearance to the cardiac silhouette on chest X-ray. **(B)** CT scan confirms the circumferential pericardial effusion *(arrowed)*. Note the absence of pericardial calcification that is a feature of chronic pericardial disease.

Management

An underlying cause should be sought and treated if possible. Most pericardial effusions resolve spontaneously. However, when the effusion collects rapidly, tamponade may result. Pericardiocentesis is then indicated to relieve the pressure; a drain may be left in place temporarily to allow sufficient release of fluid. Pericardial effusions may re-accumulate, most commonly due to malignancy (in the UK). This may require surgical creation of a pericardial window, or pericardiotomy, to allow the slow release of fluid into the surrounding tissues, usually under video-assisted thoracoscopy or open surgery.

Constrictive pericarditis

Certain causes of pericarditis, such as tuberculosis, haemopericardium, bacterial infection, and rheumatic heart disease, result in the pericardium becoming thick, fibrous, and calcified. This may also develop late after open heart surgery, and fibrosis also occurs with the use of dopamine agonists, such as cabergoline and pergolide. In many cases these pericardial changes do not cause any symptoms. If, however, the pericardium becomes so inelastic as to interfere with diastolic filling of the heart, constrictive pericarditis is said to have developed. As these changes are chronic, allowing the body time to compensate, this condition is not as immediately life-threatening as cardiac tamponade, in which the circulation is more acutely compromised.

Constrictive pericarditis should be distinguished from RCM. The two conditions are very similar in their presentation, but the former is fully treatable, whereas most cases of the latter are not. In the late stages of constrictive pericarditis the subepicardial layers of myocardium may undergo fibrosis, atrophy, and calcification.

Clinical features

The symptoms and signs of constrictive pericarditis occur due to:

- reduced ventricular filling (raised JVP with deep y descent, Kussmaul's sign, pulsus paradoxus)
- systemic venous congestion (ascites, dependent oedema, hepatomegaly and raised JVP)
- pulmonary venous congestion (dyspnoea, cough, orthopnoea, PND).

Less commonly, it may cause:

- reduced cardiac output (fatigue, hypotension, reflex tachycardia)
- rapid ventricular filling (a 'pericardial knock' is heard in early diastole at the lower left sternal border)
- atrial dilation (30% of cases have atrial fibrillation).

Investigations

- ***Chest X-ray*** shows a relatively small heart, disproportionate to the symptoms of heart failure. Pericardial calcification may be present in up to 50%. A lateral chest film may be useful for detecting calcification that is missed on a postero-anterior film. However, a calcified pericardium is not necessarily a constricted one.
- ***ECG*** reveals low-voltage QRS complexes with generalized non-specific ST- and T-wave changes.
- ***Echocardiography*** shows small ventricular cavities with normal wall thickness, moderate atrial enlargement, and a dilated inferior vena cava. A thickened, calcified pericardium may be seen. Doppler studies may be useful.
- ***CT and CMR*** are used to assess pericardial anatomy, thickness (≥4 mm), and inflammation (see Fig. 17.26).
- ***Endomyocardial biopsy*** may be helpful in distinguishing constrictive pericarditis from RCM in difficult cases.
- ***Cardiac catheterization*** will usually reveal equal end-diastolic pressures in the left and right ventricles, owing to pericardial constriction.

RCM is a close mimic of constrictive pericarditis, and all the above tests may help to distinguish the two conditions.

Management

The treatment for chronic constrictive pericarditis is complete resection of the pericardium. This is a risky procedure with a high

complication rate due to the presence of myocardial atrophy in many cases at the time of surgery. Thus early pericardiectomy is suggested in non-tuberculous cases, before severe constriction and myocardial atrophy have developed.

In cases of tuberculous constriction the presence of pericardial calcification implies chronic disease. Early pericardiectomy with anti-tuberculous drug cover is used in these cases. If there is no calcification, a course of anti-tuberculous therapy should be attempted first. If the patient's haemodynamic state remains static or deteriorates after 4 to 6 weeks of therapy, pericardiectomy is recommended.

PERIPHERAL VASCULAR DISEASE

Peripheral arterial disease

Peripheral vascular disease (PVD) is commonly caused by atherosclerosis and usually affects the aorto-iliac or infra-inguinal arteries. It is present in 7% of middle-aged men and 4.5% of middle-aged women and increases sharply with age. The mortality associated with coexisting cardiovascular and cerebrovascular disease means that only a proportion of patients with PVD progress to losing their leg.

Limb ischaemia

Limb ischaemia may be classified as chronic or acute.

Chronic lower limb ischaemia

Common risk factors are:

- smoking
- diabetes
- hypercholesterolaemia
- hypertension.

Other risk factors which may lead to premature atherosclerosis include autoimmune and chronic inflammatory conditions (e.g., SLE, rheumatoid arthritis), thrombophilia, and hyperhomocysteinaemia.

Clinical features

Symptoms

Peripheral arterial disease can be described using the Fontaine classification:

- Stage I: asymptomatic
- Stage II: intermittent claudication
- Stage III: rest pain/nocturnal pain
- Stage IV: necrosis/gangrene.

Patients with ***intermittent claudication*** complain of exertional discomfort, most commonly in the calf, which is relieved by rest. Patients with aorto-iliac disease may experience pain in the buttock, hip, or thigh and may notice erectile dysfunction. The 'claudication distance' may be reproducible.

Patients with ***rest pain*** experience severe, unremitting pain in the foot, which stops a patient from sleeping. It is partially relieved by dangling the foot over the edge of the bed or standing on a cold floor.

Patients with severe PVD or critical lower limb ischaemia may have ulceration or ***necrosis*** of the tissue ***(gangrene)***.

Signs

The lower limbs are cold with dry skin and lack of hair. Pulses may be diminished or absent. Ulceration may occur in association with dark discoloration of the toes or gangrene. The abdomen should be examined for a possible aortic aneurysm.

Differential diagnosis

Symptoms may be confused with those of:

- spinal canal claudication (when all pulses are present)
- osteoarthritis of the hip/knee (knee pain often at rest)
- peripheral neuropathy (associated with numbness and tingling)
- popliteal artery entrapment (young patients who may have normal pulses)
- venous claudication (bursting pain on walking with a previous history of a DVT)
- fibromuscular dysplasia
- Buerger's disease (young males, heavy smokers).

Investigations

An estimation of the anatomical level of disease may be possible with the examination of pulses. First-line non-invasive assessment of the severity of disease is by measurement of the ***ankle/brachial pressure index*** (ABPI). This is a measurement of the cuff pressure at which blood flow is detectable by Doppler in the posterior tibial or anterior tibial artery compared to the pressure in the brachial artery. Intermittent claudication is associated with an ABPI of 0.5 to 0.9, while values less than 0.5 are associated with critical limb ischaemia. The sensitivity of the test may be improved by a fall in ABPI after exercise. If the arteries are heavily calcified and incompressible, commonly where there is coexisting renal or diabetic disease, the ABPI will be falsely elevated. In these patients toe pressure values are more sensitive. Diagnostic imaging includes the following options:

- ***Duplex ultrasound (DUS)*** can provide an accurate anatomical map of the lower limbs with sensitivity of 87% and specificity of more than 95% to detect stenosis of greater than 50% compared to formal angiography.
- ***Contrast-enhanced MR angiography*** provides excellent imaging of both legs with a single contrast injection without exposure to ionizing radiation and is commonly used to assess the extent of disease prior to planned intervention. It can sometimes overestimate the degree of stenosis.
- ***CT angiography*** is an effective alternative to MR angiography, where MR is contraindicated, although extensive calcification may obscure stenoses. CT angiography requires ionizing radiation and iodinated contrast media.
- ***Digital subtraction angiography (DSA)*** provides an arterial map (Fig. 17.117) and may be required for below-the-knee arteries but needs peripheral arterial cannulation and exposes the individual to iodinated contrast. It should be reserved for use in patients immediately prior to intervention.

Management

Medical

All patients need aggressive risk factor management, as PVD also puts them at significant risk of ischaemic heart disease and cerebrovascular disease. Preventative strategies include antiplatelet treatment, lipid-lowering therapies, smoking cessation support, and optimal management of hypertension and diabetes. Regular review by a chiropodist may be needed.

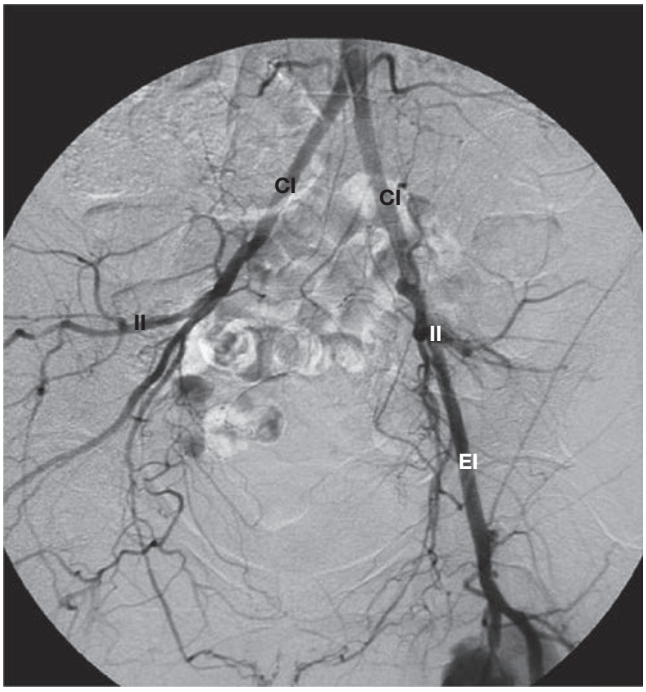

Fig. 17.117 Angiogram showing occlusion of the right external iliac artery. *CI,* Common iliac; *EI,* external iliac; *II,* internal iliac.

A supervised exercise programme should be offered to all patients with intermittent claudication, where they are encouraged to undergo aerobic exercise for at least 2 hours per week, up to the point of maximal pain.

Naftidrofuryl oxalate is a vasodilator agent that inhibits vascular and platelet 5-hydroxytryptamine$_2$ (5-HT$_2$) receptors and can reduce lactic acid levels. It may increase walking distance and improve quality of life and may be considered for a trial period of 3 to 6 months when patients are reluctant to undergo interventional treatment and supervised exercise has proved insufficient to control symptoms.

Surgical and radiological

Vascular intervention for stable claudication is not generally recommended, except when symptoms are severe or disabling. ***Percutaneous transluminal angioplasty*** is the first option and is carried out via a catheter inserted into the femoral artery. The long-term patency rates decrease as the angioplasty becomes more distal. Overall results of angioplasty appear to be similar to those achieved with a continued exercise programme. Arterial stents may be deployed in recurrent iliac disease, and DESs allowing long-term patency are also used. ***Bypass procedures*** may be performed using Dacron, polytetrafluoroethylene (PTFE), or autologous veins. Bypasses to distal vessels have poorer long-term patencies. Prosthetic grafts have equal patencies in above-knee bypasses but are inferior to veins in bypasses below the knee. In severe ischaemia with un-reconstructable arterial disease, an ***amputation*** may be necessary. An amputation commonly leads to loss of independence, with only 70% of below-knee and 30% of above-knee amputees achieving full mobility.

Acute lower limb ischaemia

Clinical features

Symptoms

Patients complain of the 'five Ps': ***pain***, the fact that the leg looks white ***(pallor)***, ***paraesthesia***, ***paralysis***, and the sensation that it is ***perishingly*** cold. The pain is unbearable and normally requires opioids for relief.

Signs

The limb is cold, with mottling or marbling of the skin. Pulses are diminished or absent. Sensation in and movement of the leg are reduced in severe ischaemia. Patients may develop a compartment syndrome with pain in the calf on compression.

Aetiology

Acute limb ischaemia (ALI) may occur because of embolic or thrombotic disease. ***Embolic disease*** is commonly due to cardiac thrombus and cardiac arrhythmias such as atrial fibrillation. Emboli may also occur secondary to aneurysm thrombus or thrombus on atherosclerotic plaques. Emboli from atrial myxomas are rare.

ALI is more often due to ***thrombotic disease***. Acute thrombus usually forms on a chronic atherosclerotic stenosis in a patient who has previously reported symptoms of claudication. Thrombus may also form in normal vessels in individuals who are hypercoagulable because of malignancy or thrombophilia defects. Prosthetic or venous grafts may also thrombose either *de novo* or secondary to a developing stenosis in the graft or the native vessels. Popliteal aneurysms may thrombose or embolize distally.

Acute upper limb ischaemia may be caused by similar processes or occur secondary to external compression with a cervical rib/band.

Investigations

Investigations are similar to those described for chronic lower limb disease and must be carried out urgently.

Management

Medical

Management is dependent on the degree of ischaemia. Patients showing improvement may be treatable with heparin, analgesia, and appropriate treatment of the underlying cause. Those with emboli following MI or atrial fibrillation need long-term anticoagulation. Wounds, ulceration, and infection require careful management.

Surgical and radiological

Patients with mild to moderate ischaemic symptoms who have an occluded graft may need graft thrombolysis. Intra-arterial thrombolysis may reveal an underlying stenosis within a graft or native vessel that could be treated with angioplasty.

Patients with severe ALI require emergency surgical or radiological attempts at revascularization. An embolus may benefit from its surgical removal (embolectomy). A bypass graft may be required after occlusion of a popliteal aneurysm or acute-on-chronic lower limb arterial disease. When an ischaemic limb is revascularized, the sudden improvement in blood flow can cause reperfusion injury, with release of toxic metabolites into the circulation. In muscle compartments the consequent oedema may lead to a 'compartment syndrome', which requires fasciotomies (release of the fascia to prevent muscle damage). An amputation may be warranted in un-reconstructable disease or severe ischaemia. In patients dying from other causes ALI may occur as a 'terminal event' and intervention may then be inappropriate.

Aneurysmal disease

Aneurysms are defined as a permanent dilation of the artery 50% greater than the normal diameter and may be classified as true or false. In true aneurysms the arterial wall forms the wall of the aneurysm. The arteries most frequently involved are the abdominal aorta, the iliac, popliteal and femoral arteries, and the thoracic aorta (in decreasing frequency). In false aneurysms (pseudoaneurysms) the surrounding tissues form the wall of the aneurysm. False aneurysms can occur following femoral artery puncture. A haematoma is formed because of inadequate compression of the entry site and continued bleeding into the surrounding compressed soft tissue forms the wall of this aneurysm.

Abdominal aortic aneurysm

Abdominal aortic aneurysms (AAAs) occur most commonly below the renal arteries (infra-renal). The incidence increases with age, with AAAs being present in 5% of the population over 60 years of age. They arise five times more frequently in men, and in 1 in 4 male children of an affected individual. Aneurysms may occur secondary to atherosclerosis, infection (syphilis, *Escherichia coli*, *Salmonella*), and trauma or may be genetic (Marfan's or Ehlers–Danlos syndrome).

Screening

In England and Wales approximately 6000 deaths occur each year from a ruptured aortic aneurysm. The mortality rate for elective surgery is 3.5% or lower, compared to 50% for an emergency open repair. As with all cardiovascular disease, there are fixed risk factors—age, male sex, strong family history—and modifiable risk factors—smoking, hypertension, hypercholesterolaemia.

The UK recommendation is that screening should be offered to men aged 65 to 74 years, who receive an abdominal ultrasound.

- ***Normal*** or ***less than 3 cm*** aortas do not require treatment or further scans.
- ***Small (3–4.4 cm)*** aortas require annual ultrasound surveillance and GP review to optimize lifestyle.
- ***Medium (4.5–5.4 cm)*** aortas require quarterly ultrasound surveillance and cardiovascular secondary prevention therapy.
- ***Large (≥5.5 cm)*** aortas are referred for assessment and possible elective repair.

Screening of female patients is not recommended, as the prevalence is much lower.

Clinical features

Symptoms

Most aneurysms are asymptomatic and are found on routine abdominal examination or plain X-ray or during investigations for other problems. Rapid expansion or rupture of an AAA may cause ***severe pain*** (epigastric pain radiating to the back). A ruptured AAA causes ***hypotension***, ***tachycardia***, ***profound anaemia***, and ***sudden death***. The symptoms of rupture may mimic renal colic, diverticulitis, and severe lower abdominal or testicular pain. Gradual erosion of the vertebral bodies may cause non-specific back pain. The aneurysm may embolize distally, causing ALI. Inflammatory aneurysms can obstruct adjacent structures, such as the ureter, duodenum, and vena cava. Rarely, aneurysms can present with severe haematemesis secondary to an aorto-duodenal fistula.

Signs

The aorta is retroperitoneal, and in overweight patients there may be no overt signs. An aneurysm is suspected if a pulsatile, expansile abdominal mass is felt. The presence of an AAA should alert a clinician to the possibility of popliteal aneurysms. Patients may present with 'trash feet', dusky discoloration of the digits secondary to emboli from the aortic thrombus.

Management

As with any operation, treatment of an asymptomatic aneurysm depends on the balance of operative risk and conservative management. The UK Small Aneurysm Trial showed that patients with infra-renal AAAs did best with an operation if the aneurysm was:

- 5.5 cm or more in diameter
- expanding at a rate of more than 1 cm/year
- symptomatic.

Medical

Aneurysmal disease needs careful control of hypertension, smoking cessation, and lipid-lowering medication. Patients with AAAs of less than 5.5 cm are followed up by regular ultrasound surveillance.

Surgical and endovascular intervention

Intervention to treat AAA can be performed by open aneurysm repair, hand-assisted or total laparoscopic repair, or endovascular stent insertion (via the femoral or iliac arteries). The Endovascular Aneurysm Repair (EVAR) studies (stent versus open surgical repair) and EVAR 2 (stent versus medical therapy in patients unsuitable for open repair) investigated the role of endovascular stents in patients with an AAA of 5.5 cm or more on CT. 3D-printed fenestrated grafts which are individualized to patients' anatomy may be employed. In EVAR the 30-day mortality rate was 1.7% with stenting versus 4.7% with surgery (p = 0.009), but the long-term mortality rate was similar in both groups at 4 years. In EVAR 2 the 30-day mortality rate with stenting was 9%. Long-term mortality rate was similar in both stent and medical therapy groups. Current UK guidance recommends surgical repair rather than EVAR for unruptured aneurysms in patients who are fit for open surgery, and EVAR or conservative (medical) management in patients at high surgical or anaesthetic risk. EVAR has a more prominent role in treating ruptured aneurysms, especially in older and frailer patients.

Prognosis

After repair, patients with an AAA should return to normal activity within a few months.

Thoraco-abdominal aneurysm

The ascending, arch, or descending thoracic aorta may become aneurysmal. Ascending thoraco-abdominal aneurysms (TAAs) occur most commonly in patients with MFS or hypertension. Descending or arch TAAs occur secondary to atherosclerosis and are now rarely due to syphilis.

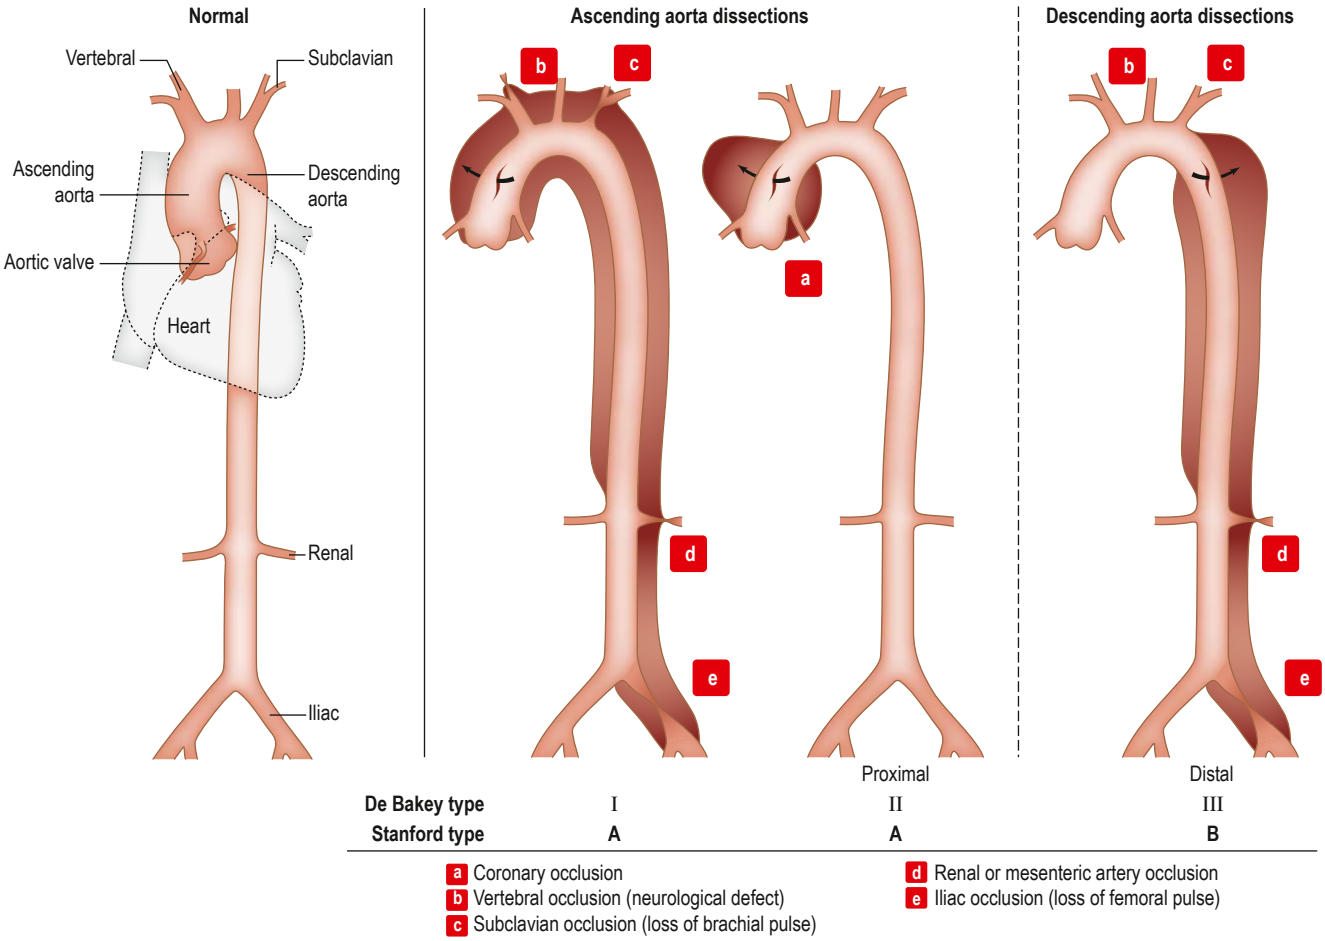

Fig. 17.118 **Classification of aortic aneurysms.**

Clinical features

Most aneurysms are asymptomatic and are found on routine chest X-ray or cardiological investigation. Rapid expansion may cause severe pain (chest pain radiating to the upper back) and rupture is associated with hypotension, tachycardia, and death. Chest symptoms from expansion may include stridor (compressed bronchial tree), haemoptysis (aortobronchial fistula), and hoarseness (compression of the recurrent laryngeal nerve). Aorto-oesophageal fistula is an uncommon cause of haematemesis.

Investigations

- ***CT or MRI scan*** is used for assessment of a TAA.
- ***Aortography*** may be helpful for assessing the position of the key branches in relation to the aneurysm.
- ***TOE*** can be useful for identifying an aortic dissection.

Management

If the aneurysm is bigger than 6 cm, then open repair or stenting may be appropriate, but these procedures can be technically difficult and carry a high risk of mortality and paraplegia. 3D-printed fenestrated aortic stents may be employed. EVAR is, at present, the procedure of choice for isolated descending thoracic aneurysms.

Acute aortic syndromes

Acute aortic syndromes include aortic dissection, intramural haematoma (IMH), and penetrating aortic ulcers. Aortic dissection usually begins with a tear in the intima. Blood penetrates the diseased medial layer and then cleaves the intimal laminal plain, leading to dissection. IMH is considered a precursor of dissection, in which there is rupture of the vasa vasorum in the aortic media with aortic wall infarction. IMH is typically in the descending thoracic aorta. Deep penetrating aortic plaques may lead to IMH, dissection, or ulceration/perforation. There is a predisposition to aortic dissection in patients with autoimmune rheumatic disorders and Marfan's and Ehlers–Danlos syndromes.

Aortic dissection can be classified according to the timing of diagnosis from the origin of symptoms: acute, less than 2 weeks; subacute, 2 to 8 weeks; and chronic, more than 8 weeks, with mortality and extension decreasing with time. It can also be classified anatomically:

- ***Type A*** involves the aortic arch and aortic valve proximal to the left subclavian artery origin. This category includes De Bakey type I (extends to the abdominal aorta) and De Bakey type II (localized to the ascending aorta).

- ***Type B*** involves the descending thoracic aorta distal to the left subclavian artery origin. This category includes De Bakey type III (Fig. 17.118).

Clinical features

Symptoms

Most patients present with a sudden onset of severe and central ***chest pain*** that often radiates to the back and down the arms, mimicking MI. The pain is often described as tearing in nature and may be migratory.

Signs

Patients may be shocked and may have neurological symptoms secondary to loss of blood supply to the spinal cord. They may develop aortic regurgitation, coronary ischaemia, and cardiac tamponade. Distal extension may produce acute kidney failure, acute lower limb ischaemia, or visceral ischaemia. Peripheral pulses may be absent.

Investigations

The mediastinum may be widened on chest X-ray; urgent CT scan, TOE, or MRI will confirm the diagnosis (see Fig. 17.98).

Management

At least 50% of patients are hypertensive and may require urgent antihypertensive medication to reduce blood pressure to below 120 mmHg; intravenous beta-blockers (labetalol, metoprolol) and vasodilators (GTN) are used. Type A dissections should undergo surgery (arch replacement) if the patient is fit enough, as medical management carries a high mortality (50% within 2 weeks). Type B dissections carry a better prognosis and have a survival rate of 89% at 1 month; initially, these patients should be managed medically unless they develop complications. Endovascular intervention with stents may be indicated in individuals with rapidly expanding dissections (>1 cm/year), critical diameter (>5.5 cm), refractory pain or malperfusion syndrome, blunt chest trauma, penetrating aortic ulcers, or IMH. Patients will require long-term follow-up with CT or MRI.

Other types of peripheral arterial disease

Raynaud's phenomenon or Raynaud's disease

Raynaud's phenomenon consists of spasm of the digital arteries, usually precipitated by cold and relieved by heat. If there is no underlying cause, it is known as Raynaud's disease. This affects 5% of the population, mostly women. The disorder is usually bilateral and fingers are affected more commonly than toes.

Clinical features

Vasoconstriction causes skin ***pallor*** followed by ***cyanosis*** due to sluggish blood flow, then redness secondary to hyperaemia. The duration of the attacks is variable but they can sometimes last for hours. Numbness, a burning sensation, and severe pain occur as the fingers warm up. In chronic, severe disease tissue, ***infarction*** and ***digital loss*** can occur.

Diagnosis

Primary Raynaud's disease needs to be differentiated from secondary treatable causes leading to Raynaud's phenomenon. These are the rheumatic autoimmune disorders, such as systemic sclerosis. It can be associated with atherosclerosis or occupations that involve the use of vibrating tools. Ergot-containing drugs and beta-blockers, as well as smoking, can aggravate symptoms.

Management

Patients should avoid cold provocation by wearing gloves and warm clothes and stop smoking. Vasodilators can be prescribed but are often unacceptable, as cerebral vasodilation causes severe headaches. Sympathectomy or prostacyclin infusion can be helpful in severe disease.

Takayasu's disease

This is rare, except in Japan. It is known as the pulseless disease or aortic arch syndrome. It is of unknown aetiology and occurs in females. There is a vasculitis involving the aortic arch, as well as other major arteries. A systemic illness is also present, with pain and tenderness over the affected arteries. Absent peripheral pulses and hypertension are common. Corticosteroids help the constitutional symptoms. Eventually, heart failure and strokes may occur, but most patients survive for at least 5 years. Treatment may involve a surgical bypass to improve perfusion of the affected areas.

Thromboangiitis obliterans (Buerger's disease)

This disease, involving the small vessels of the lower limbs, occurs in young men who smoke. Although sometimes clinically indistinguishable from atheromatous disease, pathologically there is inflammation of the arteries and sometimes veins, which may indicate a separate disease entity. Clinically, it presents with severe claudication and rest pain, leading to gangrene. A thrombophlebitis is sometimes present. Treatment is as for all peripheral vascular disease but patients must stop smoking.

Cardiovascular syphilis

This gives rise to:

- uncomplicated aortitis
- aortic aneurysms, usually in the ascending part
- aortic valvulitis with regurgitation
- stenosis of the coronary ostia.

The diagnosis is confirmed by serology. Treatment is with penicillin. Aneurysms and valvular disease are treated as necessary by the usual methods.

PERIPHERAL VENOUS DISEASE

Venous thromboembolic disease is covered in Chapter 40.

Varicose veins

Varicose veins are a common problem and sometimes give rise to pain. They may be treated by surgery, injection with ultrasound-guided foam sclerotherapy, or thermal ablation with endovenous lasers.

Superficial thrombophlebitis

This commonly affects the saphenous vein and is often associated with varicosities. Occasionally, the axillary vein is involved, usually as a result of trauma. There is local superficial inflammation in the vein wall, with secondary thrombosis.

The clinical picture is of a painful, tender, cord-like structure with associated redness and swelling.

The condition usually responds to symptomatic treatment with rest, elevation of the limb, and analgesics (e.g., NSAIDs). The Comparison of Arixtra in Lower Limb Superficial Vein Thrombosis with Placebo (CALISTO) trial demonstrated that a 45-day course of subcutaneous fondaparinux (2.5 mg daily), compared with placebo, significantly decreased the rate of thromboembolic events (pulmonary embolism and DVT) from 1.3% to 0.2%, and limited the extension of superficial vein thrombosis to the saphenofemoral junction from 3.4% to 0.3% with no increased risk of bleeding.

CORE SKILLS AND KNOWLEDGE

Hypertension is a major cardiovascular (CV) risk factor affecting one-third of the adult population. It should be managed as part of a comprehensive CV risk reduction strategy while also assessing for hypertensive end-organ damage and ruling out secondary causes. Treatment involves modifying lifestyle to improve diet and body weight and making use of a range of antihypertensive medications.

Most hypertension is managed in primary care. However, young patients with hypertension, or patients who have uncontrolled hypertension despite taking three or more antihypertensives, should be referred for expert evaluation. Doctors may subspecialize in the management of hypertension after completing training in clinical pharmacology, cardiology, renal medicine, or another medical specialty.

Key skills in hypertension include:

- Diagnosing appropriately, and placing this in the context of an individual's overall CV risk
- Screening for secondary causes of hypertension and seeking evidence of end-organ damage
- Understanding the evidence-based guidelines for treating hypertension and becoming familiar with the main classes of drug used.

Gaining experience in the practical management of hypertension is best done during primary care attachments, for instance, by observing patients undergoing annual blood pressure medication reviews with their general practitioner. Attending a specialist hypertension clinic in a secondary or tertiary care setting gives an interesting insight into secondary causes and more severe phenotypes of hypertension.

BACKGROUND

Elevated blood pressure (BP) is a leading risk factor for death worldwide, outstripping tobacco smoking, poor sanitation and infectious diseases. It is a leading risk factor for atrial fibrillation, stroke, myocardial infarction and end-stage kidney disease. It is such a powerful predictor of these CV events that modern drug therapies are licensed for CV protection simply based on evidence of sustained BP reduction.

Hypertension refers to the ***persistent elevation of BP in the systemic arterial circulation***. It is the most common chronic health condition for which patients receive medication from their primary care doctor and is associated with 1 in 10 of all primary care appointments. It affects one-third of adults and this number continues to rise in all populations. Annual drug costs related to hypertension are well in excess of £1 billion in the UK.

Hypertension is diagnosed against threshold levels of BP from the evidence gathered from large multicentre, multinational studies. However, given the continuous relationship between BP and CV disease (**Fig. 18.1**) and renal morbidity, there is a trend towards basing treatment on even lower thresholds, and towards using total ***CV risk*** (see Chapter 17) to guide decisions on whether lowering BP is of benefit in individual patients.

The majority of patients with hypertension are managed in primary care, with specialist hospital services usually reserved for evaluation of secondary causes, or for those patients with problematic BP phenotypes (see 'Phenotypes of hypertension' section) or medication intolerances. Despite the wide availability of diagnostics (i.e., BP monitors) and proven treatments (i.e., medications), reduction of BP in hypertensive patients to target levels is less than 50% in most populations and remains the focus of renewed efforts on an international, national, and local scale.

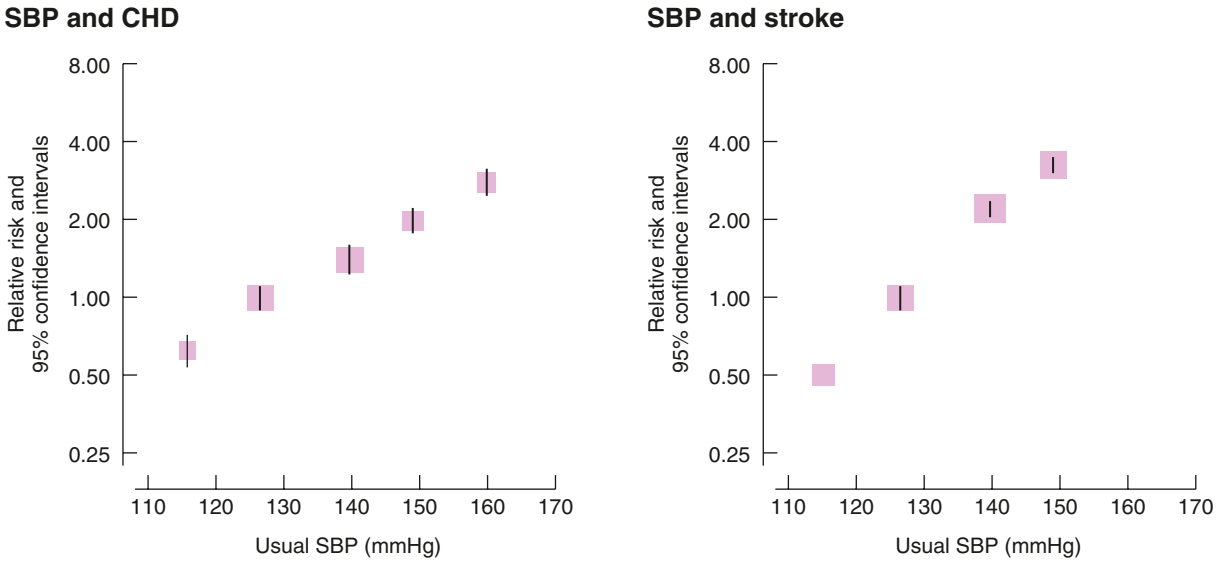

Fig. 18.1 The relationship between blood pressure (BP) and cardiovascular (CV) morbidity.
CHD, Coronary heart disease; *SBP,* systolic BP. (*Jackson et al.* Lancet *2005; 365: 434–441.*)

AETIOLOGY AND PATHOPHYSIOLOGY

Hypertension is a disease of ***ageing***. It is rare in children and adolescents, and a diagnosis in those under 30 years of age requires careful evaluation of possible underlying secondary causes (see 'Secondary hypertension' section). Due to age-related stiffening in large arteries (arteriosclerosis), BP tends to increase throughout middle and later life. Female sex hormones appear to protect against raised BP, as women have lower BP levels at all ages until menopause, when both prevalence of hypertension and achieved BP levels approximate to those of men. Hypertension is more common in certain ethnic groups (black African, African–Caribbean) and is also associated with urbanized and migrant populations, although an unequivocal explanation for these phenomena is not agreed.

Primary hypertension

Over 90% of patients have no singular identifiable cause of their elevated BP; this is called ***primary hypertension*** (now preferred to the historical term, 'essential hypertension', see later). Advances in genomic research have increased our understanding of polygenic effects on BP (see Chapter 5). We now know that several hundred genes are individually associated with prevalent BP levels but that each one contributes only small amounts (perhaps 0.5–1 mmHg). Combined, however, they may account for 60% of the BP level in any one person. As such, a family history of hypertension is common, though a family history of hypertension or strokes at unusually young ages should instigate careful evaluation for secondary causes. While there are a large number of distinct genetic influences on BP regulation, for the purposes of clinical assessment and management the main mechanisms affecting BP are ***vascular volume and tone***, and ***cardiac output*** (Fig. 18.2). The remaining effects on BP (up to 40%) are mediated by environmental (e.g., temperature, noise) and lifestyle stressors (e.g., diet).

Sudden development of severe hypertension or worsening of previously good control should alert healthcare professionals to the need for careful evaluation of ***adherence to treatment***, and for consideration of lifestyle and secondary causes of hypertension if adherence is confirmed. Adherence issues and causes of secondary hypertension should also be borne in mind in patients with ***resistant hypertension*** (usually defined as uncontrolled BP despite three separate, guideline-recommended antihypertensives).

Lifestyle-related issues

Diet

Relevant ***dietary*** information provided by patients is often inaccurate. Nevertheless, some clear dietary patterns are associated with raised BP:

- high salt intake
- low vegetable and fruit intake
- high saturated fat intake
- high simple carbohydrate intake
- excessive liquorice (inhibits an enzyme that normally prevents cortisol from activating the mineralocorticoid receptor).

Lack of exercise

Both CV and strength training forms of ***exercise*** are associated with lower BP values, along with other health benefits.

Drugs

Many patients with hypertension will have other co-morbidities that require additional pharmacological treatment, and consideration should therefore be given to the possible interference of these other drugs with BP control. Both over-the-counter medicines, such as non-steroidal anti-inflammatory drugs, and recreational drugs, such as alcohol and sympathomimetic stimulants, should be taken into account, as patients may not mention them when a history is being taken unless specific enquiry is made.

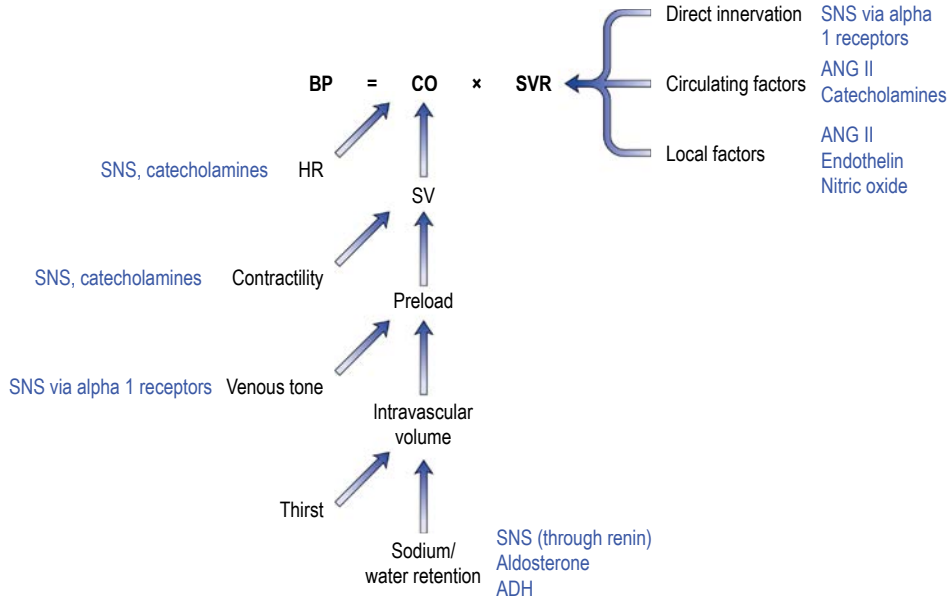

Fig. 18.2 The main mechanisms affecting BP. *ANGII,* Angiotensin II; *CO,* cardiac output; *HR,* heart rate; *SNS,* sympathetic nervous system; *SVR,* systemic vascular resistance.

Commonly implicated drugs that raise BP include:

- alcohol
- stimulant, recreational drugs
- oral contraceptive pill
- non-steroidal anti-inflammatory drugs
- corticosteroids
- calcineurin inhibitors
- vascular endothelial growth factor inhibitors
- some antidepressants (e.g., venlafaxine)
- mirabegron.

Secondary hypertension

Hypertension can have an identifiable singular cause, removal or reversal of which leads to normalization of BP. These are ***secondary causes*** of hypertension, and are broadly categorized into renal, vascular, endocrine, and neural problems (**Box 18.1**). Together, these are present in <10% of all hypertensive patients (though this proportion is higher in those under 30 years of age). The most common causes of secondary hypertension are largely thought to be ***primary hyperaldosteronism*** (increased salt/water retention), ***obstructive sleep apnoea*** and ***obesity*** (the last two causing sympathetic overdrive), though the precise proportions ascribed to these and other causes vary in different studies due to advances in evaluation and diagnostics.

Hypertension in pregnancy

Although it is not usually considered a secondary cause, ***pregnancy*** can be associated with elevated BP. The normal physiological response to pregnancy is an increase in circulating volume that is offset by significant vasodilation, leading to lower BP, particularly in the second trimester. However, in some pregnant women, defects in placental formation or vascularity lead to pregnancy-induced hypertension and/or ***pre-eclampsia*** (see Chapter 48). Hypertension associated with pregnancy often improves within a few months of the infant's delivery but women with hypertensive disorders of pregnancy are more likely to develop hypertension earlier in life than age-matched controls. The history should establish whether women of childbearing age are actively trying to become pregnant, as many of the first-line drugs are not recommended in this situation (see **Box 18.6**).

CLINICAL APPROACH TO THE PATIENT WITH HYPERTENSION

Hypertension is largely asymptomatic, though it is associated with increased prevalence of headaches, epistaxis and, less commonly, other neurological symptoms such as visual disturbance and dizziness. Furthermore, in the absence of a hypertensive emergency syndrome (see 'Hypertensive emergencies' section), symptoms related to raised BP are not an indication for treatment. Indeed, antihypertensive therapy is more likely to be the cause of adverse symptoms, such as postural intolerance. History and examination should seek out identifiable causes of elevated BP and asymptomatic organ damage.

There are four key considerations in the clinical assessment of patients with hypertension (**Fig. 18.3**) that can be determined through history, examination and investigations:

- What is the true BP level?
- Is there an identifiable cause for high BP?
- Does the BP level require lowering?
- Are there compelling reasons to use certain therapeutic approaches above others?

History

This should cover:

- symptoms of hypertension or secondary causes
- lifestyle issues: weight, alcohol excess, stimulant recreational drug use, tobacco smoking, exercise, stressors (work and personal)
- family history
- pregnancy history including episodes of pre-eclampsia
- adherence to antihypertensives.

Box 18.1 Drivers/secondary causes of hypertension

System	Causes	History	Examination	Investigations	Management
Lifestyle	Diet	Dietary history		24 h urinary sodium excretion (as a guide and to track improvement in salt intake)	Dietary advice
	Lack of exercise	<30 min/day moderate-intensity exercise			Exercise advice
Drugs	Alcohol	Alcohol history, features of alcohol dependence	May have signs of chronic liver disease	Only if indicated for underlying liver disease	Alcohol reduction <14 units/week
	BP-increasing medications	Medication history, including supplements, recreational and over-the-counter		Use of reference sources to identify BP-increasing medications	Cessation, switching where possible
	Poor adherence to antihypertensives	Validated adherence questionnaires Open, non-judgemental attitude		Urine or plasma qualitative drug monitoring	Shared decision-making, single-pill combinations
Metabolic	Obesity	Recent weight gain	Body mass index >30		Weight loss advice, bariatric surgery
Vascular	Coarctation of aorta		Unequal arm–arm or arm–leg pulses or BP Cardiac murmur or abdominal bruit	MR or CT angiography of whole aorta	Surgery, angioplasty or conservative
Renal	Renal artery stenosis	Sudden deterioration in renal function with ACE inhibitor/ARB Flash pulmonary oedema with normal cardiac function	Abdominal bruit	MR or CT renal angiogram	Balloon angioplasty ± stenting
	Chronic kidney disease	Often asymptomatic Childhood UTIs Features of vasculitis/GN	Often no physical signs Ballotable renal masses (PKD) Vasculitic rash	Urine dipstick and ACR eGFR Renal ultrasound Immunological tests (if GN likely) Renal biopsy (if GN likely)	Treatment of BP Treatment of underlying inflammatory renal disease
Endocrine	Primary hyperaldosteronism (Conn's syndrome)	Weakness, fatigue		Low K, raised aldosterone: renin MRI/CT adrenal ± adrenal vein sampling	Laparoscopic adrenalectomy if unilateral secretion
	Hypercortisolaemia (Cushing's syndrome)	Weight gain, fatigue	Centripetal weight distribution, hirsutism, pigmented striae	Low-dose dexamethasone suppression (cortisol should normally be low)	Laparoscopic adrenalectomy or pituitary surgery, depending on source
	Phaeochromocytoma	Palpitations, sweating, BP surges, dizziness, pallor, anxiety	Associated cutaneous neurofibromata (in neurofibromatosis-1)	Plasma metanephrines MIBG scan/MRI chest/abdomen/pelvis to localize	Surgery after sufficient alpha blockade
	Acromegaly	Sweating, skin tags, growth of soft tissues, visual disturbance	Large hands, feet, interdental separation, bitemporal hemianopia	Serum IGF-1	Pituitary surgery
	Thyroid (both hypo- and hyperthyroidism)	Weight gain, tiredness (hypothyroidism) Irritability, weight loss (hyperthyroidism)	Pretibial myxoedema, slow relaxing reflex (hypothyroidism) exophthalmos, acropachy (hyperthyroidism)	Serum TSH	Thyroxine replacement (hypothyroidism) or thyroid blockade/surgery (hyperthyroidism)

Box 18.1 Drivers/secondary causes of hypertension—cont'd

System	Causes	History	Examination	Investigations	Management
Respiratory	Obstructive sleep apnoea (Chapter 20)	Daytime somnolence (Epworth score), snoring, nocturnal sweating, morning headaches	Large neck, Mallampati score 3 or 4 (see Chapter 14)	Overnight oximetry (screening) Sleep study	Weight loss Mandibular advancement device CPAP
Neurological	Autonomic failure	Postural intolerance, thermoregulatory issues, parkinsonism	Variable BP Supine hypertension with normal or low BP sitting, standing	24 h BP: nocturnal hypertension Autonomic function testing	Symptom-based, nocturnal medication if supine hypertension
Obstetric	Pregnancy	Secondary amenorrhea Visual disturbance, oedema, headaches, seizures (for PET/eclampsia only)	Fundal palpation	Urine or serum β-hCG	Pregnancy-safe medicines Delivery of fetus

ACE, Angiotensin-converting enzyme; *ACR,* albumin creatinine ratio; *ARB,* angiotensin II receptor blocker; *BP,* blood pressure; *β-hCG,* beta-human chorionic gonadotrophin; *CPAP,* continuous positive airways pressure; *CT,* computed tomography; *eGFR,* estimated glomerular filtration rate; *GN,* glomerulonephritis; *IGF-1,* insulin-like growth factor 1; *MIBG,* meta-iodobenzylguanidine; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography; *PKD,* polycystic kidney disease; *TSH,* thyroid stimulating hormone; *UTI,* urinary tract infection.

Examination and investigations

These should include:

- 'out-of-office' BP level
- asymptomatic organ damage: eyes, kidneys, heart
- exclusion of secondary causes where relevant
- estimation of total CV risk.

Measurement of blood pressure

Due to the non-continuous, pulsatile blood flow maintained by the cardiac cycle, BP is represented by two numbers: systolic (peak arterial pressure during cardiac contraction) and diastolic (lowest arterial pressure during cardiac relaxation). It is presented as ***systolic pressure/diastolic pressure in mmHg*** (millimetres of mercury). BP is dynamic and has patterns of variability over seconds (related to breathing, sympathetic activation), minutes (exertion), hours (wake–sleep, circadian hormonal patterns), and the longer term (seasonal). Therefore, the measurement of BP and its use to determine the treatment of hypertension are inherently imprecise and a single measure may not reliably represent the usual (real) BP and its contribution to overall CV risk. As with any biological variable, the true usual BP is better approximated with multiple measurements at each assessment, and sometimes over several different assessment episodes, before decisions are made regarding changes in treatment.

BP can be measured in several different locations on the body, though readings are traditionally taken in the non-dominant arm. Initially, BP should be checked in both arms; if there is a significant difference (usually considered to be >10 mmHg), then the arm with the higher BP is used for subsequent measurements.

It is important to measure BP correctly. Methodological variation can falsely and enormously over- or underestimate BP. For static measurements (office/surgery, home), BP should be measured in the seated position after 5 minutes' uninterrupted rest, with the back supported and the legs uncrossed. The BP bladder should encircle at least 80% of the upper arm circumference and should be placed at the level of the heart; the arm should be supported (**Fig. 18.4**). More than one reading should be taken (in a row with minimal waiting between) during a measurement episode and the average of all the readings used to determine BP. If there is a significant reduction (>10 mmHg) between subsequent readings, further readings should be taken until the difference is <10 mmHg and the initial higher readings should be discarded before averaging at least the last two readings where there is <10 mmHg variation.

Although the unit of BP is still 'millimetres of mercury' (mmHg), mercuric sphygmomanometers are obsolete. Modern monitors are usually electronic, oscillometric devices that are automated and have been validated against mercuric devices or intra-arterial BP catheters.

One situation where auscultatory (i.e., using a cuff and stethoscope to listen over the brachial artery) methods are still preferred is in ***atrial fibrillation*** (see Chapter 17), where variations in pulse volume and rapid variation in BP due to variable left ventricular filling time lead to inaccuracies when oscillometric BP machines are used, especially when ventricular rates are uncontrolled. In particular, diastolic BP tends to be poorly estimated in this situation.

Office/clinic measurement

This refers to measurement of the BP by a healthcare professional in a healthcare setting, such as a primary care clinic or hospital outpatient department. This is the most established method of measurement and all clinical trials of antihypertensive drugs have used it to assess for inclusion and for titration towards target.

Issues with this approach include:

- a requirement for healthcare professionals and setting (expense, time)
- a requirement for multiple visits to obtain sufficient data for decision-making (expense, time)
- a 'white coat effect': for most people, BP measured by healthcare professionals is approximately 5/5 mmHg higher than at home, though there is inter-individual variation in the magnitude

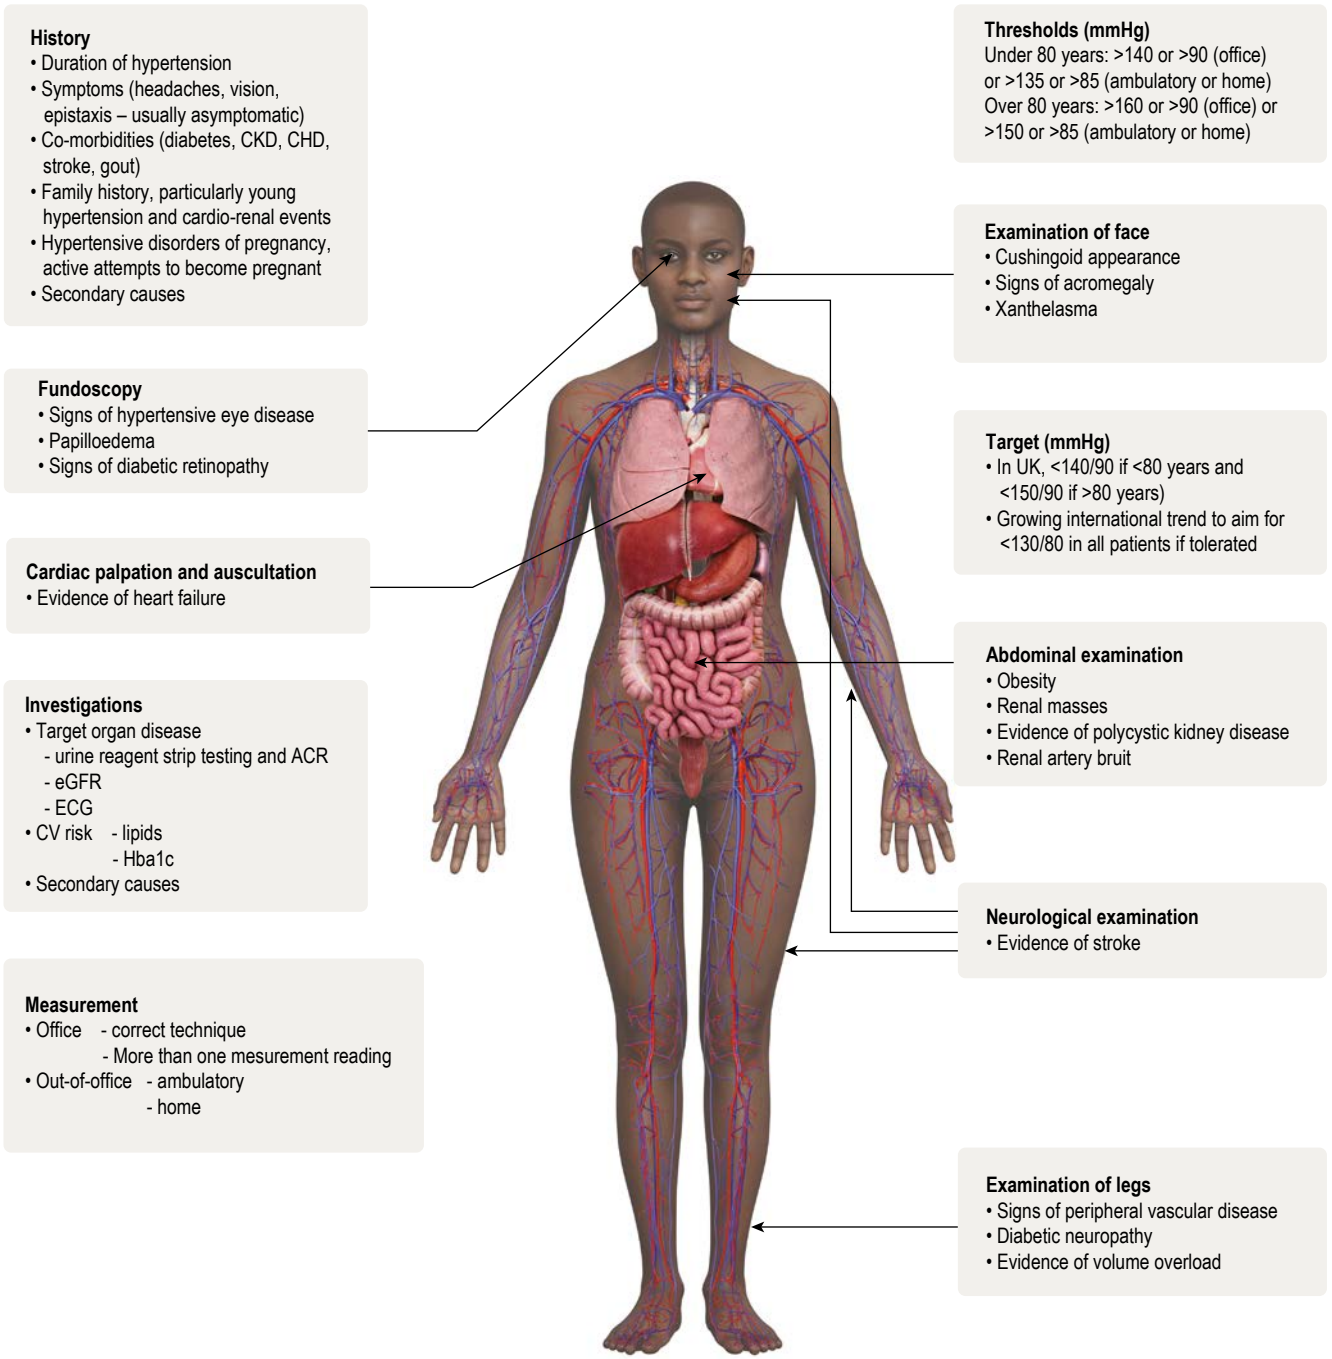

Fig. 18.3 Clinical assessment in hypertension. *ACR,* Albumin creatinine ratio; *CAD,* coronary artery disease; *CKD,* chronic kidney disease; *CV,* cardiovascular; *eGFR,* estimated glomerular filtration rate.

- home and ambulatory BP measurements are more predictive of CV events, as patients do not live in healthcare settings.

Although office BP is no longer recommended as the sole measure for diagnosis in many guidelines, it is still advocated as adjunctive for on-going monitoring and medication titration, as no CV outcome trials have used out-of-office readings to adjust treatment.

Home measurement

This is measurement of BP at home by the patients themselves, using the same type of machine as in the clinic. It is a type of 'out-of-office' BP measurement and is closely approximated to daytime ambulatory BP. It is particularly useful for:

- identification of different BP phenotypes
- engagement of patients in healthcare and shared decision-making
- long-term monitoring of BP between healthcare visits.

Current recommendations suggest that BP is measured on two or more occasions in sequence, in the morning prior to medicines and again in the evening for 4 to 7 days. The initial day's readings are discarded and the rest of the values are averaged to calculate home BP. This BP is highly predictive of CV events.

Issues with this approach include:

- a requirement for patients to obtain or be supplied with their own machine (expense)
- a requirement for training
- the lack of objective readings (i.e., the measurements are often patient-reported averages, rather than independent evaluations).

Ambulatory measurement

Ambulatory BP monitors are portable, oscillometric devices that measure BP discontinuously throughout a 24-hour period, most commonly every 20 to 30 minutes during waking hours and every 30 to 60 minutes during sleep.

The large number of readings that this provides gives an accurate estimate of true BP. The 24-hour mean of the sequence of daytime and nocturnal BP measurements is more predictive of CV events than both home and office BP measurements. Ambulatory BP monitoring is now recommended in the UK and some other high-income health economies instead of office BP for diagnosis, and is mostly recommended as a complementary strategy to office BP elsewhere.

Similar to home BP, ambulatory BP allows in a single measurement:

- improved diagnostic accuracy over office BP
- identification of different BP phenotypes.

Daytime ambulatory BP is 5 to 10/5 mmHg lower than office BP in the same patient. Issues with this approach include dislike of repeated BP measurement, especially at night.

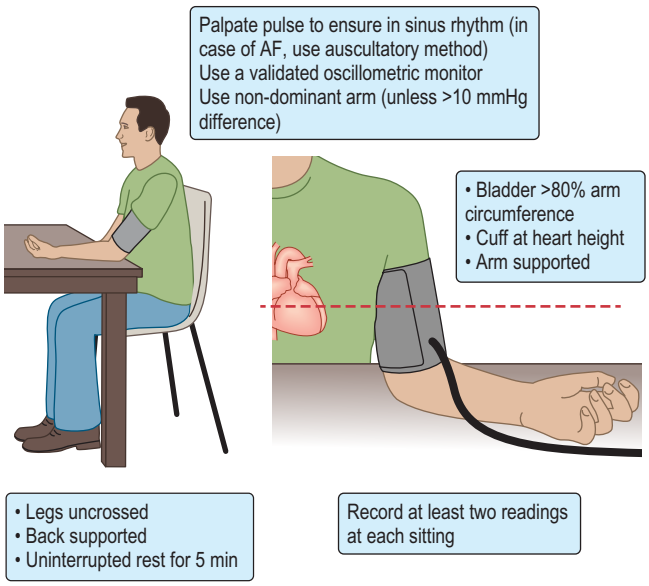

Fig. 18.4 The correct way to measure BP. *AF,* Atrial fibrillation.

Phenotypes of hypertension

The measurement techniques described can describe different phenotypes of hypertension (Box 18.2). Although both ***white coat hypertension*** and ***masked hypertension*** represent intermediate CV risk phenotypes, masked hypertension is treated using out-of-office values to guide treatment, while antihypertensives are not recommended for use in white coat hypertension, despite elevated CV risk, due to a current lack of evidence.

There are other common phenotypes of hypertension:

Isolated systolic hypertension

Due to age-related arterial stiffening, systolic BP continues to rise in patients above 50 years of age, with a corresponding reduction in diastolic BP. This widening ***pulse pressure*** (the difference between systolic and diastolic BP, usually <50 mmHg) is associated with increased vascular damage. Drug treatment in isolated systolic hypertension is the same as for combined hypertension (where both systolic and diastolic BP are elevated), though care is needed not to reduce diastolic BP below 60 mmHg, which theoretically could cause problems with coronary blood flow (which is dependent on diastolic pressure). Aortic valve incompetence can also cause an isolated systolic phenotype, though this is normally apparent on cardiac auscultation and/or echocardiography.

Orthostatic hypotension

This refers to a sustained fall in BP within 3 minutes of assuming an upright position of either more than 20 mmHg systolic or more than 10 mmHg diastolic BP. It is more common in older age (see Chapter 49), in conditions associated with ***autonomic neuropathies*** (such as diabetes mellitus and Parkinson's disease) and in those taking antihypertensive drugs. It is typically asymptomatic, although it can cause postural intolerance or instability, dizziness and falls. It should be actively screened for those with typical symptoms or risk factors. Most guidelines recommend using the standing BP as the true BP value for guiding treatment.

Variable blood pressure

Although BP is a highly dynamic variable, the degree of variability is exaggerated in some patients. This is often due to disorders of the autonomic nervous or endocrine system. Reliable assessment is achieved only through a combination of repeated short-term (ambulatory) and long-term (home) methodologies. Management of BP levels in such patients is often complex and best performed in specialist clinics.

? Box 18.2 Phenotypes of hypertension and corresponding BP measurements

Phenotype/method	Office BP	Out-of-office BP	Cardiovascular risk
Normal BP	Normal (<120/70)	Normal (<120/70)	Lowest
Elevated BP	Normal (<140/90)	Normal (<135/85)	Intermediate
White coat hypertension	High	Normal	Intermediate
Masked hypertension	Normal	High	Intermediate
Hypertension	High	High	Highest

BP, Blood pressure.

Hypertensive target organ damage

Hypertension can cause structural or functional changes in the heart, kidney and central nervous system that may be regarded as intermediate end-points with respect to reducing the absolute clinical end-points of myocardial infarction, heart failure, end-stage renal disease and strokes.

Eyes

Direct ophthalmoscopy (fundoscopy) of the dilated eye is recommended in most guidelines for evaluation of hypertensive vascular changes. The most commonly used grading classification is the Keith–Wagener–Barker system, comprising four distinct ophthalmic hypertensive phenotypes ***(retinopathy)***. More recent evaluation, however, has suggested combining the two milder phenotypes, leaving three grades to consider (**Fig. 18.5**):

- ***Mild:*** Generalized arteriolar narrowing, focal arteriolar narrowing, arteriovenous nicking (modest association with CV and cerebral events).
- ***Moderate:*** Haemorrhage (blot, dot or flame-shaped), microaneurysm, cotton-wool spot, hard exudate, or a combination of these signs (strong association with CV and cerebral events).
- ***Severe:*** Signs of moderate retinopathy plus papilloedema (swelling of optic head) (strong association with CV events, stroke and death).

Heart

The heart is a muscle and hypertrophy may occur in response to increased workload. Left ventricular remodelling is initially a compensatory phenomenon to reduce wall stress but eventually leads to a pathogenic increase in left ventricular mass.

Hypertensive left ventricular hypertrophy is usually asymptomatic but can be detected as a thrusting apex beat on precordial palpation. It is also sometimes detected on standard 12-lead electrocardiography (ECG), demonstrating various patterns of increased voltages in the chest leads and T-wave abnormalities (see Fig. 17.74). There are many different scoring systems for ECG criteria for diagnosing left ventricular hypertrophy; all are quite insensitive (20%–50%) but specificity is better (>90%), which means that if criteria are positive, true left ventricular hypertrophy is likely to be present.

Electrocardiograms are recommended in all hypertensive patients, as they are widely available and cheap, and do not require much in the way of additional training to interpret, especially as modern ECG machines have in-built reporting algorithms. However, cardiac imaging, using transthoracic echocardiography and cardiac magnetic resonance imaging, is more sensitive and specific for left ventricular hypertrophy than ECG (when compared to autopsy data), though access, cost and need for additional trained staff to conduct and report these tests limit their wide utility and acceptance in all hypertensive patients. These cardiac imaging modalities can estimate the actual mass of the left ventricle; this is indexed to height and weight, and has sex-specific normal values.

Kidney

Kidney disease is both a cause and a consequence of hypertension. Early hypertensive kidney damage may be detected through an increase in microalbuminuria on urine test strips or as an increased laboratory albumin : creatinine ratio, although in pure hypertensive nephropathy there may be little or only modest albuminuria. Estimates of glomerular filtration rate (GFR), based on serum creatinine and demographic criteria, are also obtained, especially as several antihypertensive medications are potentially nephrotoxic. However, there is usually an initial reduction in GFR associated with chronic BP-lowering from any cause, and this usually reflects intra-renal haemodynamic changes rather than intrinsic renal damage; it is therefore common practice to allow GFR to reduce by up to 10% on initiation of antihypertensive therapy. More regular follow-up is mandated to ensure that this does not indicate progressive renal decline.

Thresholds and targets in hypertension

Primary hypertension used to be termed ‘essential’ as, in the 19th century, raised BP was largely thought to be an appropriate physiological adaptation. However, with the advent of randomized clinical trials and modern therapeutics, there is now substantial evidence that lowering BP is beneficial, reducing both cardiorenal events and overall mortality.

The first Veterans Administration Cooperation study, commenced in 1964, randomized patients with a diastolic BP of 115 to 129 mmHg to active or placebo treatments. By modern standards, this would be considered to be severe hypertension. There were substantial differences between active and placebo-treated patients in a range of CV end-points, including mortality, and the trial was ended early because the degree of treatment benefit made it unethical to continue to give placebo.

Treatment threshold

Since around 1990, the threshold for diagnosis of hypertension has mostly been an office BP of more than 140 mmHg systolic or more than 90 mmHg diastolic (whichever is *worse*). Treatment has largely been reserved for those with ***grade 2 hypertension*** (**Box 18.3**), as there is a large evidence base for lowering BP with medications in these patients. For ***grade 1 hypertension***, it has been usual practice to persevere with lifestyle changes to lower BP and to recommend immediate treatment for those with an overall elevated CV risk (>1% per year, using validated CV risk equations), or evidence of organ injury due to hypertension (hypertensive target organ damage). Drug therapy is advocated, however, if BP fails to normalize after a 3-month period of best-tolerated lifestyle changes.

More recently, treating BP even in those not hypertensive but with elevated BP and at high CV risk has been proposed. For those at highest risk, either with existing CV disease or from coexisting risk factors, treatment initiation at lowers levels of BP than required for a hypertension diagnosis is associated with CV risk reduction.

Treatment target

For the most part, then, the target has been an office BP of less than 140/90 mmHg, with stricter targets for patients with diabetes and proteinuric chronic renal disease (<130/80 mmHg). However, recent trials such as SPRINT and meta-analysis of other trials have suggested that there is incremental benefit in targeting all patients to a BP 120–130/70–80 mmHg; this is reflected in most international guidelines, although not currently in those produced by the National Institute for Health and Care Excellence (NICE) in the UK.

Box 18.3 Thresholds for diagnosis of hypertension and related phenotypes

Description	Office BP (mmHg)		Daytime ambulatory or home BP (mmHg)	
	Systolic BP	Diastolic BP	Systolic BP	Diastolic BP
Normal BP	**<120**	**<70**	**120**	**70**
Elevated BP	120–139	70–89	120–135	70–85
Grade 1 hypertension	140–159	90–99	135–149	85–94
Grade 2 hypertension	160–179	100–109	150–169	95–104
Severe hypertension	>180	>110	>170	>105
Isolated systolic hypertension	>140	<90	>135	<85

BP, Blood pressure.

In older people (over 80 years), there is less evidence for treating mild hypertension, and most guidelines recommend treating only moderate (i.e., grade 2) hypertension. Some guidelines (e.g., NICE) suggest a lax target office BP of below 150/90 mmHg in patients diagnosed over 80 years of age. However, age is often used incorrectly as a surrogate for frailty, and although there is good reason to lower BP cautiously and judiciously in the frail elderly or in those at increased risk of falls or postural hypotension, there is a trend in updated international guidelines, to reduce BP to similar levels as for younger patients in biologically fit elderly patients, if tolerated.

There are additional considerations relating to these values. As mentioned, there has been a consistent shift to using out-of-office methods, preferably ambulatory, for diagnosis. In the hypertensive range, home and ambulatory BP is generally 5 to 10/5 mmHg lower than measurements taken contemporaneously in the office. At lower levels of BP, such as the 120/70 mmHg treatment target, there is less difference between measurements from different measurement techniques.

TREATMENT

Meta-analyses of large-scale randomized controlled trials have shown that a 10/5 mmHg reduction in BP is associated with a 15% reduction in all-cause mortality, 35% reduction in stroke, 40% reduction in heart failure and 20% reduction in myocardial infarction. Hypertension is treated to reduce these major CV and renal events. For this reason, treatment of hypertension without managing other modifiable CV risk factors (raised cholesterol, diabetes mellitus, tobacco smoking, obesity) is suboptimal. CV risk scores, such as QRISK3®, are useful for integrating all of these risk factors, to judge when there is benefit in treating hypertensive patients. Ten-year risk estimates are less useful than lifetime risk estimates in young patients, given the powerful role of age in all CV risk scores.

Population interventions

In view of the potential effects of lifestyle issues, together with those associated with obesity (see Chapter 37), population approaches are increasingly being taken to reduce BP, including public health education drives to:

- reduce salt intake such as regulatory approaches to reducing salt in processed foods
- reduce simple carbohydrate intake through 'sugar taxes'
- reduce alcohol intake through minimum unit pricing
- reduce body weight
- increase exercise.

Lifestyle changes

These are recommended for all hypertensive patients, irrespective of grade or duration of disease. The BP reductions accompanying such lifestyle changes are complementary and similar in magnitude (compared to half-standard monotherapy) to those achieved by antihypertensive medications (**Box 18.4**).

Bariatric surgery (see Chapter 37) is indicated for those with hypertension and a body mass index of more than 35 kg/m^2, but it is not commonly performed without the additional co-morbidity of type 2 diabetes. Recent data confirm the profound BP-lowering effect of such surgery, which may be due to additional gut hormonal changes postoperatively, in addition to expected weight loss.

Drug treatment

A single antihypertensive medication at standard dose reduces BP by about 9/5 mmHg in mild hypertension. Although patients with mild hypertension may achieve control with monotherapy, those with moderate or worse hypertension generally require several drugs in combination. Greater effects are obtained by combining medications from different classes, targeting different pathophysiological mechanisms. Three antihypertensives at half-standard dose reduce BP by 20/11 mmHg. Most ***adverse effects*** with antihypertensives, in keeping with most pharmaceuticals, are type A adverse reactions (see Chapter 7) and are thus dose-dependent. Keeping doses to a minimum but combining different classes minimizes the chances of adverse effects and maximizes the likelihood of effectively lowering BP to target levels.

Physician inertia in the face of elevated BP should be avoided—leaving BP higher than target BP for more than a few months is

Box 18.4 Impact of lifestyle changes on BP

Lifestyle change	Expected mean BP reduction
Regular cardiovascular exercise (30 min daily)	5 mmHg
Weight reduction if overweight (body mass index >25 kg/m^2)	1 mmHg/kg
Increased intake of fruits and vegetables, reduced intake of saturated fat	10 mmHg
Dietary salt reduction <6 g day	5 mmHg
Alcohol <2 units daily	3 mmHg

BP, Blood pressure.

associated with excess CV morbidity. Achieving control early with combination medications is preferred.

Adherence to treatment

Adherence is increasingly recognized as a key barrier to achieving BP control. Although there are different validated measures to assess this, such as the Morisky-8 Medication Adherence Scale (Box 18.5), along with prescription refill rate (whether patients request a resupply at the right time to have therapy every day), modern drug analytical techniques on plasma or urine have demonstrated that question-/refill-based assessment correlates poorly to objective evidence of measurable drug in biological matrices. From these newer techniques, it appears that up to two-thirds of patients in specialist care do not take some or any of their antihypertensive medications. There are no easy solutions to such covert non-adherence, but keeping an open, non-judgemental approach can facilitate the volunteering of this information and then shared-decision-making can determine how best to proceed and what patients want for their own health.

In view of this, and with evidence that suggests there is an elevated CV risk when there is failure to achieve timely BP control, guidelines have recently tended to abandon monotherapy and suggest starting with a combination of medicines to achieve BP controleffectively and rapidly, including initiating patients with single-pill combination therapies.

Choice of therapy

There are numerous classes of antihypertensive medication available and their key features are described in Box 18.6.

Most guidelines recommend initial therapy with two of the following three classes of drugs:

- angiotensin-converting enzyme inhibitors/angiotensin II receptor blockers (ARBs),
- calcium channel blockers
- thiazide-like diuretics.

Monotherapy should be initiated only in the mildest of stage I hypertension, as most patients require two or medications to get to guideline-based targets (Fig. 18.6).

Current UK NICE guidelines use age and ethnicity as surrogates for plasma renin activity. Hypertension in older patients and those of black African ancestries is associated with low renin status and so patients have reduced responsiveness to angiotensin-converting enzyme inhibitors and ARBs as monotherapy: hence calcium-channel blockers are recommended in these groups. Younger white patients are recommended to start

Box 18.5 Morisky medication adherence scale[a]

Please answer each question, based on your personal experience with your medications. Note that there is no right or wrong answer.

1. Do you sometimes forget to take your medications?	No	Yes
2. People sometimes miss taking their medications for reasons other than forgetting. Thinking over the past 2 weeks, were there any days when you did not take your medications?	No	Yes
3. Have you ever cut back or stopped taking your medications without telling your doctor because you felt worse when you took it?	No	Yes
4. When you travel or leave home, do you sometimes forget to bring along your medications?	No	Yes
5. Did you take your medications yesterday?	No	Yes
6. When you feel that your health condition is under control, do you sometimes stop taking your medications?	No	Yes
7. Taking medications every day is a real inconvenience for some people. Do you ever feel hassled about sticking to your treatment plan?	No	Yes
8. How often do you have difficulty remembering to take all your medications?	Never/rarely Once in a while Sometimes Usually All the time	1 0 0 0 0

[a]'No' answers to questions 1–4, 6 and 7, a 'Yes' answer to question 5 and 'Never/rarely' to question 8 score 1. A score of 8 suggests good adherence. Score of 7 or less suggests poor adherence and is associated with poorer BP control.
(Adapted from Morisky DE, Ang A, Krousel-Wood M et al. Predictive validity of a medication adherence measure in an outpatient setting. J Clin Hypertens *2008;10:348–354.)*

on an ACEI or ARB, which are largely thought to be interchangeable, except that ARBs are better tolerated, with less cough and angio-oedema.

There is clear evidence from the PATHWAY-2 study that spironolactone is the best fourth-line drug, in preference to beta- or alpha-blockers, though it is unlicensed for this indication in most countries and patients should be appropriately counselled.

Referral to specialist care

The majority of hypertensive patients are managed in primary care. Once a patient is on three or four drugs and remains uncontrolled ***(resistant hypertension)***, they should be referred for specialist assessment. Other reasons to mandate referral to specialist secondary care include:

- Suspected secondary causes:
  - Young age (<30–40 years)
  - Suggestive comorbidities (i.e., obstructive sleep apnoea, phaeochromocytoma)
  - Examination findings (i.e., abdominal bruit suggesting renal artery stenosis)
  - Sudden change in BP
- Target organ damage detected with normal BP values
- Intolerance of medicines preventing guideline-based treatment

Box 18.6 Main classes of antihypertensive agent and their key features

Class	Mechanism	Adverse effects	Compelling indication	Compelling contraindication	Monitoring	Example
Angiotensin-converting enzyme (ACE) inhibitor	Reduce angiotensin II vasoconstriction	Cough Angio-oedema Hyperkalaemia	CKD with proteinuria, diabetes, heart failure with reduced ejection fraction	Bilateral RAS Angio-oedema	eGFR, K	Ramipril 2.5–10 mg daily
Angiotensin II receptor blockers (ARB)	Reduce angiotensin II vasoconstriction	Hyperkalaemia	CKD with proteinuria, diabetes, heart failure with reduced ejection fraction	Bilateral RAS	eGFR, K	Losartan 25–100 mg daily
DHP CCB	Peripheral vasodilation	Constipation, headache, oedema	Nifedipine/amlodipine recommended for use in pregnancy			Amlodipine 5–10 mg daily
Non-DHP CCB	Peripheral vasodilation	Constipation, bradycardia		High grade atrioventricular block Bradycardia	Heart rate	Verapamil 120–480 mg daily
Thiazide-like diuretic	Vasodilation, salt/water loss	Hyponatraemia, hypokalaemia, hyperuricaemia, hyperglycaemia	Heart failure	Gout	Serum electrolytes, HbA_{1c}, urate	Indapamide 1.5–2.5 mg daily
Potassium-sparing diuretic	Salt/water loss	Hyponatraemia, hyperkalaemia, gynaecomastia	Primary hyperaldosteronism Resistant hypertension	eGFR <30 mL/min K >5.0 mmol/L	Serum electrolytes	Spironolactone 25–50 mg daily
Beta-blocker	Vasodilation through renin inhibition, sympatholysis	Bradycardia, sleep disturbance, bronchospasm	Heart failure with reduced ejection fraction Ischaemic heart disease Labetalol licensed in pregnancy	Asthma High-grade atrioventricular block Bradycardia	Heart rate	Bisoprolol 2.5–10 mg daily
Alpha-blocker	Venodilation	Postural hypotension, urine incontinence, oedema	Suspected phaeochromocytoma Benign prostatic hypertrophy	Urinary incontinence Postural hypotension Heart failure		Doxazosin 1–8 mg twice daily
Central	Sympatholysis	Depression, drowsiness, dry mouth	Methyldopa licensed in pregnancy	Mood disorders Heart failure with reduced ejection fraction	Rebound hypertension on cessation	Methyldopa 250–500 mg 3 times daily

ACE, Angiotensin-converting enzyme; *ARB*, angiotensin receptor blocker; *CKD*, chronic kidney disease; *DHP CCB*, dihydropyridine calcium-channel blocker; *eGFR*, estimated glomerular filtration rate; *K*, potassium; *RAS*, renin–angiotensin system.

- Symptomatic hypertension or hypotension
- Labile or highly variable BP
- Elevated BP when it is not clear whether a patient would benefit from BP-lowering
- Presentation with a hypertensive emergency.

Renal sympathetic denervation

Neural sympathetic signalling has a key role in vascular homeostasis, with effects mediated via afferent renal and aortic/carotid baroreceptor functions. Novel interventional approaches to alter this signalling are currently under evaluation to improve BP in both medicine-naive and treated hypertensive patients. The most advanced, in terms of regulatory pathways and evidence base, is renal sympathetic denervation. This group of procedures uses modern endovascular catheter-based approaches to the renal sympathetic nerves, which lie on the outside of the renal artery. Catheters can then deliver energy (radiofrequency, ultrasound) or neurotoxins (such as alcohol) across the renal artery wall to reach the sympathetic nerves and abrogate afferent signalling to the vasomotor centres, thus reducing total sympathetic drive and BP. Although the technological advancements are impressive and there is evidence of robust BP-lowering using modern out-of-office measurements, the magnitude of these effects is similar to that of antihypertensive monotherapy and thus most patients will still require drug therapy to control BP in the long term. Furthermore, these are new technologies: the long-term safety of the procedures is not clear, as regards the renal artery or otherwise, and there are no outcome studies investigating cardiac, renal, stroke or death end-points using any technology apart from drugs. Most guidelines recommend considering renal denervation an add-on option in expert centres only for patients uncontrolled BP despite maximally or best tolerated therapies once shared-decision-making process to understand the uncertainty of benefit or risk is discussed and agreed.

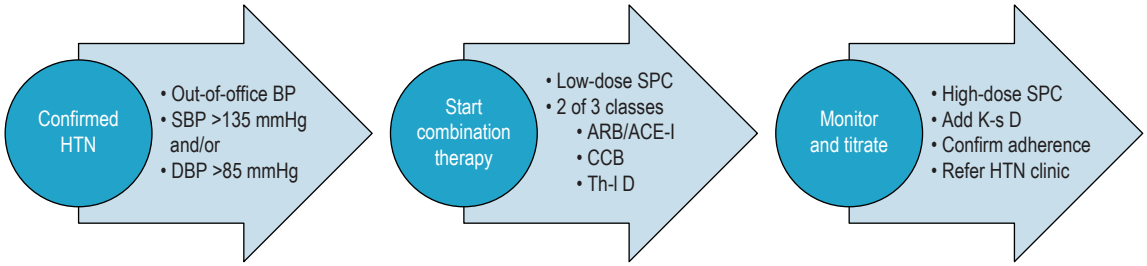

Fig 18.6 Summary of treatment recommendations. Elevated BP or hypertension should be confirmed with ambulatory or home BP (out-of-office monitoring) prior to initiation of therapy unless it is severe at presentation. Combination therapy, ideally in a single pill combination should be used in all patients unless there is clinical frailty or very mild elevated BP as most patients need 2 or more medications to control BP long term. BP should be monitored and medication adjusted proactively as leaving BP uncontrolled for more than a few months is associated with excess morbidity. Potassium sparing diuretics have the best evidence being added in as 4th line medication, though uncontrolled BP on 3 medications should prompt reviews for secondary causes and adherence and consideration of referral to a specialist clinic. *ACE-i,* Angiotensin converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *CCB,* calcium channel blocker; *DBP,* diastolic blood pressure; *HTN,* hypertension; *K-S D,* potassium sparing diuretic; *SBP,* systolic blood pressure; *SPC,* single pill combination; *th-l d,* thiazide like diuretic.

Management of cardiovascular risk

In keeping with the view that reduction in total CV risk is paramount, cholesterol-lowering therapy, most commonly with small doses of potent statins, is recommended in all patients with a total CV risk of more than 10% per year. This threshold may not be reached in younger patients due to the power of age in the risk calculators, and so a more long-term view of risk reduction should be taken in these patients. Although low-dose aspirin has been used in ***primary CV prevention*** for many decades, contemporary large-scale trials have not demonstrated a net benefit on mortality, even in patients with diabetes, with any gains from reduction in CV events offset by increases in bleeding events. Given these data, aspirin is no longer recommended in any patient group for primary prevention.

MANAGING BLOOD PRESSURE IN HOSPITAL

Blood pressure on the wards

Patients with hypertension are often admitted to hospital for other medical reasons. Various factors can contribute to acute elevations of BP, such as omission of regular antihypertensive medication, drug-induced hypertension, anxiety, pain, bladder distension, recreational drug withdrawal, and neurological injury. In the absence of a hypertensive emergency or other co-morbidity that requires acute BP management (e.g., to facilitate thrombolysis in acute stroke), uncontrolled BP does not require immediate management. However, as with most phenotypes, there is a threshold value that makes most healthcare professionals anxious about increased cerebral and CV risk, even in inpatients, and it is therefore common for BPs consistently above 180/110 mmHg to be treated, where there is no other clear precipitant. There is no role for short-acting drugs, such as sublingual glyceryl trinitrate or nifedipine, and titration of standard chronic therapies with on-going monitoring is preferred.

Hypertensive emergencies

Occasionally, hypertension is so severe with evidence of end-organ damage that urgent, specialist inpatient or closely-supervised outpatient care is required. The term ***hypertensive emergency*** is used to describe patients with significantly elevated BP (usually >180/120 mmHg) and signs or symptoms of acute target-organ damage (**Box 18.7**). The rate and magnitude of any increase in BP may be more important than the absolute level of BP in determining the severity of organ injury; this is key in obstetric medicine, where the usual BP in younger women may be verging on hypotensive (90–110/60–70 mmHg), and pre-eclampsia may develop with a BP over 140/90 mmHg.

In most hypertensive emergencies, intravenous antihypertensive medication therapy is indicated to cause rapid reduction of BP, as this is thought to minimize on-going organ damage and prevent or reduce the risk of morbidity and mortality. The exception to this is malignant hypertension with only eye changes and no other features (haemaotological, renal, etc.) where in specialist centres, treatment with oral therapy may be suitable with appropriate monitoring and follow up.

Box 18.7 Management of hypertensive emergencies

Presentation/syndrome	History	Examination	Investigation of choice	Target/timeframe	First line therapies	Notes
'Malignant' or 'accelerated' hypertension	Visual disturbance, headache	Moderate–severe retinopathy		25% MAP reduction within a few hours	i.v. labetalol, nicardipine (with retinopathy only, some consider oral treatment sufficient)	Often associated with acute kidney injury, due to fibrinoid small-artery necrosis
Hypertensive encephalopathy	Visual disturbance, headache, seizures, confusion, coma	Often features moderate–severe retinopathy	MRI brain: posterior fossa oedema (PRES)—see Chapter 28	Immediate MAP reduction by 25%	i.v. labetalol, nicardipine	
Acute aortic dissection	Tearing chest pain	Unequal arm pulses or BP Aortic valve incompetence	CT angiogram aorta, trans-oesophageal echo: dissection flap visible	Immediate SBP reduction to 100–120 mmHg *and* heart rate to 50–60 beats/min	i.v. labetalol Once rate control is adequate, vasodilators can be added (GTN, nicardipine)	Patients with Marfan's or proximal aorta syndromes more commonly proceed to early surgery
Acute pulmonary oedema	Shortness of breath	Bibasal crackles, elevated jugular venous pressure	Chest X-ray: interstitial oedema	Immediate SBP reduction to <140 mmHg	i.v. GTN, diamorphine	Loop diuretics are also vasodilating and lower BP
Acute coronary syndrome	Chest pain	Diaphoretic	ECG: ST/T-wave changes Serum troponin elevated	Immediate SBP reduction to <140 mmHg	i.v. GTN, labetalol	BP control should not delay procedural intervention
Pre-eclampsia	Oedema, visual disturbance, abdominal pain	Oedematous New proteinuria		Immediate SBP reduction to <160 and DBP to <105 mmHg	i.v. labetalol, nicardipine	i.v. magnesium used to prevent/treat eclamptic seizures

BP, Blood pressure; *CT,* computed tomography; *DBP,* diastolic blood pressure; *ECG,* electrocardiography; *GTN,* glyceryl trinitrate; *MAP,* mean arterial pressure; *MRI,* magnetic resonance imaging; *PRES,* posterior reversible encephalopathy syndrome; *SBP,* systolic blood pressure.

Blood pressure control in special populations

The management of hypertension in pregnancy is discussed in Chapter 48. The management of hypertension around surgical procedures is discussed in Chapter 14.

Disorders of HDL 516
Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia) 516
Other lipid disorders 517
Management of hyperlipidaemia 517
Non-pharmacological approaches 518
Lipid-lowering drugs 518

CORE SKILLS AND KNOWLEDGE

Lipid disorders are common and of great public health importance. All doctors need to be comfortable with managing such patients in the context of their overall cardiovascular disease risk.

Key skills in this area include:

- History taking to quantify cardiometabolic risk
- Recognition of physical signs of hyperlipidaemia
- Familiarisation with the different drugs for lowering lipids and their role in reducing cardiovascular disease risk.

Opportunities for learning in this specialty include observing clinics in specialist metabolic medicine centres and shadowing a dietician giving advice to patients on reducing cardiovascular disease risk.

BACKGROUND

Lipid disorders are common, with 95% of the Western population having raised cholesterol levels compared with undeveloped societies. Cholesterol contributes to up to half of the population's cardiovascular disease (CVD) risk worldwide. A single genetic disorder of cholesterol metabolism—familial hypercholesterolaemia (FH)—is one of the commonest autosomal dominant disorders globally. Other disorders are less common, but defects of the lipoprotein lipase (LPL) pathway constitute a medical emergency as they can present as gross hypertriglyceridaemia associated with pancreatitis.

APPROACH TO THE PATIENT

History

Significant factors relevant to lipid disorders include:

- Demographics, including ethnicity
- A cardiovascular risk factor history, including current and previous smoking, diabetes or pre-diabetes, family history of CVD prior to age 60 (to second generation if available), and family history of hyperlipidaemia
- A history of unexplained pancreatitis.

Examination

Examination of a patient with a lipid disorder includes:

- Noting signs of soft tissue lipid accumulation, such as tendon lumps (xanthomata), eyelid xanthelasma, and eruptive or planar xanthomata
- Measuring waist circumference and calculating body mass index (BMI)
- Measuring blood pressure.

Investigations

Patients with lipid disorders require a random or fasting lipid profile and (at their first clinic visit) exclusion of secondary causes of hyperlipidaemia such as nephrotic syndrome (by measuring urine protein).

PHYSIOLOGY

Lipids are essential as fuel sources, structural components of membranes, and the basis for paracrine mediators.

Lipid components can be synthesized from both fatty acids and carbohydrates, via acetyl-CoA derived from the tricarboxylic acid (Krebs) cycle pathway. Acetyl-CoA either can then be made into linear chain fatty acids (to be used or stored as metabolic fuel) or can be made into the ring structures of cholesterol, which is an essential component of cell membranes (e.g., in lipid rafts).

The cholesterol synthesis pathway is regulated by its end-product through its rate-limiting initial enzyme, hydroxy-methyl-glutaryl coenzyme A reductase (HMG-CoAR), which is inhibited by 'statins', explaining their importance in the control of lipid disorders.

Lipids are insoluble in water and are transported in the bloodstream as macromolecular complexes. These complexes comprise a core of hydrophobic triglyceride (TG), cholesterol, and cholesterol esters surrounded by a phospholipid coat. Proteins (called apolipoproteins) on the surface of these 'lipoprotein' particles act as

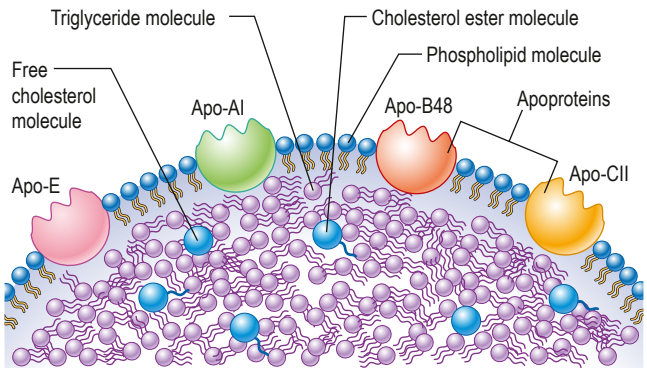

Fig. 19.1 A chylomicron particle (75–1200 nm) showing apoproteins lying in the surface membrane.

modulators of metabolism (e.g., enzyme cofactors) and ligands for receptors in the liver and the peripheral tissues. The structure of a chylomicron (one type of lipoprotein particle) is illustrated in Fig. 19.1.

Five principal types of lipoprotein particles are found in the blood: chylomicrons, the largest; very-low-density; intermediate-density; low-density; and high-density lipoproteins (VLDL, IDL, LDL, and HDL, respectively) (Fig. 19.2). They are structurally different and can be separated in the laboratory by their composition, density, and electrophoretic mobility. The larger particles give postprandial plasma its cloudy appearance (lipaemia). The major apolipoproteins and most receptors have been defined, but the functions of some remain unclear.

Plasma lipid levels are dependent on nutritional and environmental factors as well as genetic variants and contribute 55% of population-attributable risk for atherosclerotic CVD. Genetic disorders of lipid metabolism are relatively common and contribute to a highly increased risk of CVD in some individuals.

Chylomicrons

Chylomicrons (see Fig. 19.1) are synthesized in the small intestine postprandially in response to the presence of gut fats (TGs) and cholesterol. They are secreted into the intestinal lymphatic drainage and then pass along the thoracic duct into the bloodstream to be cleared eventually by the liver. They contain large quantities of TGs, some cholesterol, and cholesterol esters. They are the main mechanism for transporting dietary fat, cholesterol, and dietary-derived fat-soluble vitamins. Apolipoprotein C2 on the surface of chylomicrons binds to specific vascular surface (endothelial) receptors in adipose tissue, skeletal muscle, and the liver, where the endothelial enzyme LPL hydrolyzes TGs into fatty acids for local uptake. The chylomicron remnant particle, containing most of the cholesterol, is taken up by the liver by a specific receptor and also by the apo E/B-100 receptor.

Very-low-density lipoprotein particles

VLDL particles are synthesized continuously in the liver. They transport the body's endogenously synthesized TG and cholesterol. Apolipoprotein B-100 is the signature protein component of VLDL and its metabolic derivatives and is present at one per particle. VLDL particles become denser and turn into IDL as TGs are removed and apo C1-3 and E are incorporated from HDL particles.

Intermediate-density lipoprotein particles

IDL particles contain apo B-100 and apo C1-3 and apo E molecules on the particle surface. Most IDL particles bind to liver LDL (apo-E/B-100) receptors through the apo E molecule and are catabolized. Further TG removal leads to a denser remnant called LDL particles.

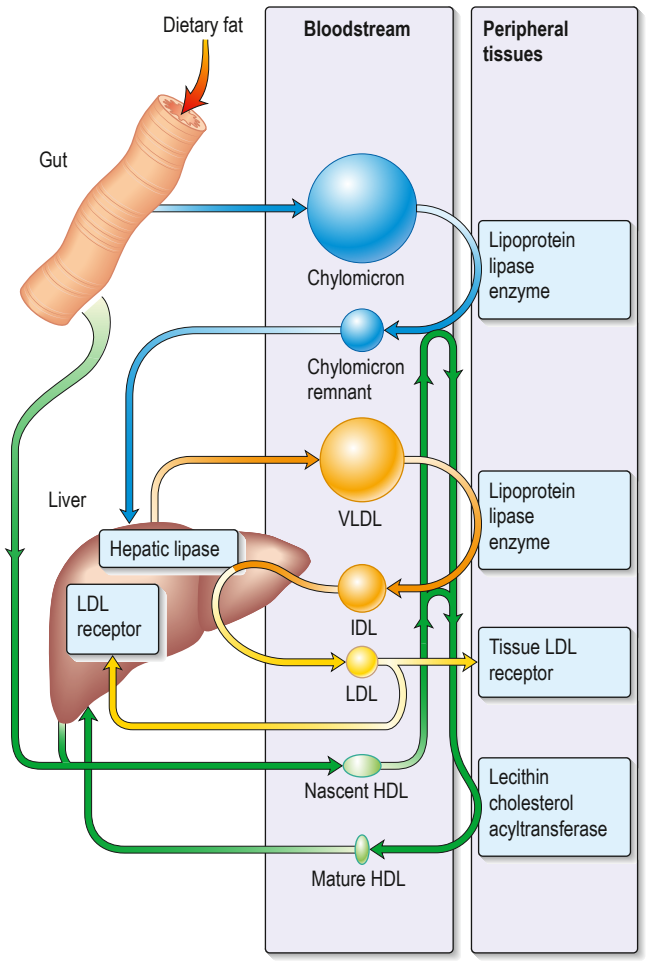

Fig. 19.2 The sites of origin of the major lipoprotein particles, showing their interaction and fate. *HDL,* High-density lipoprotein; *IDL,* intermediate-density lipoprotein; *LDL,* low-density lipoprotein; *VLDL,* very-low-density lipoprotein.

Low-density lipoprotein particles

LDL particles are the main carrier of cholesterol in fasting plasma and deliver it both to the liver and to peripheral cells. The surface of the LDL particle contains one apo B-100 molecule and varying quantities of apo C-3 and apo-E. Apolipoprotein B-100 is the principal ligand for the LDL (apo-E/B-100) receptor (LDLR). The LDLR binds LDL particles and forms coated pits on the surface of the hepatocyte, which invaginate and fuse with lysosomes and proteasomes. These destroy the LDL particle, releasing its components (Fig. 19.3). This process is, in part, regulated by a serine protease, proprotein convertase subtilisin/kexin type 9 (PCSK9). PCSK9 binds to LDL–LDLR complexes, increasing the rate of clearance of the complexes. If no PCSK9 is bound, then the LDLR can be recycled to the cell surface. The number of hepatic LDLR regulates the circulating LDL particle number and LDL cholesterol. Molecules that inhibit PCSK9 have been licensed in the UK for the control of dyslipidaemia, which cannot be controlled with statins and diet alone.

LDL particles are closely linked to CVD risk. They can deposit lipid into the walls of the peripheral vasculature through binding to elastin and other hyaline components, causing macrophage entry and atherosclerosis.

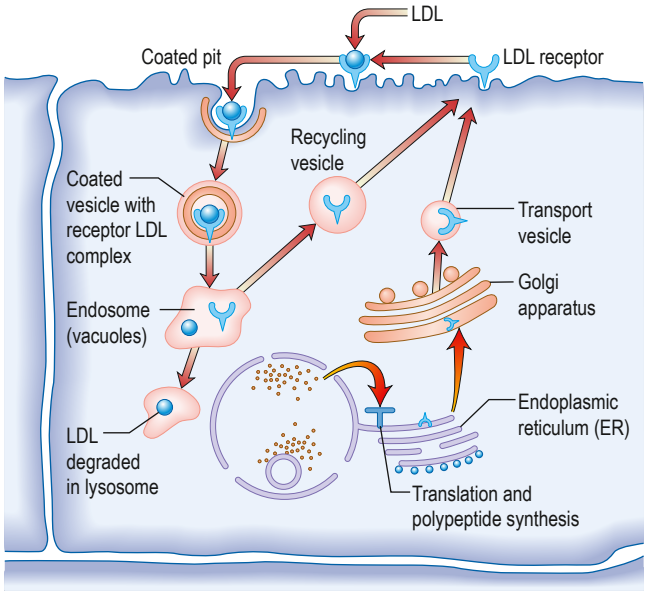

Fig. 19.3 Receptor-mediated endocytosis. Low-density lipoprotein (LDL) receptors are formed in the endoplasmic reticulum and transported via the Golgi apparatus to the surface of a hepatocyte. LDLs bind to these receptors and are internalized and taken up by the endosome. The receptor is recycled back to the surface, while the LDL is broken down by the lysosomes, freeing the cholesterol needed for membrane synthesis.

Lipoprotein(a)

Lipoprotein(a) (Lp(a)) is a subgroup of LDL particles associated with high rates of CVD. Lp(a) is derived from apo B-100 containing particles by addition and covalent binding of apo(a) at the liver cell surface. The apo(a) binds to apo B-100 in such a way as to impede clearance of the Lp(a) through the LDLR. High levels of Lp(a) are genetically co-dominantly inherited. Most Caucasians have little Lp(a), unlike West African populations. Lp(a) is 'sticky', binding avidly to arterial glycans and acting to promote atherosclerosis. Patients with high levels of Lp(a) show increased rates of CVD even if they have only moderate levels of LDL-C. The use of niacin, PCSK9 inhibitors, and other novel agents have all been tried or are being trialled to reduce CVD risk in patients with high Lp(a) concentrations.

High-density lipoprotein particles

Nascent HDL particles are produced in both the liver and the intestine. They are initially disc shaped and contain their signature protein apoprotein A1 (4 molecules), other apolipoprotein components, and some phospholipid. HDL particles take up cholesterol from cells through the ATP-binding cassette transporter-A1 (ABC-A1). A concentration gradient for export is maintained by esterifying this cholesterol through the action of lecithin-cholesterol acyltransferase (LCAT). The particles acquire further cholesterol through ABC-G1 and also phospholipids, apo C1-3, and apo-E by transfer from chylomicrons and VLDL particles.

The HDL particle transports excess cholesterol from the periphery and may transfer it to other particles, such as VLDL (through the action of cholesterol ester transfer protein, CETP), or may deliver cholesterol directly to the liver (reverse cholesterol transport) or to steroid-synthetic tissues (ovaries, testes, adrenal cortex). HDL particles are taken up by the liver scavenger receptor B1 (SRB1).

In contrast to apo B-100 particles such as LDL, the apo A1 core of HDL is recycled and re-secreted. HDL can be modified, and its handling changed by serum amyloid A substituting for apoA1 molecules, changing it to a more pro-atherogenic form. Highly depleted or modified HDL particles are eventually cleared by the kidney through megalin and cubilin receptors. Cholesterol in the liver can be oxidized to bile acids, which are secreted into the bile to promote cholesterol and TG uptake in the gut. Excess bile salts are resorbed in the terminal ileum and recirculate in the enterohepatic circulation (see Chapter 24). HDL particles also have multiple other actions including reducing inflammation, being anti-parasitic, modulating clotting factor activity, affecting bone marrow function, and promoting endothelial health.

Measurement of serum lipids

In a fasting serum lipid profile, the majority of the total cholesterol (TC) concentration is present in LDL particles, with about 20% to 30% in HDL particles. The TG concentration largely reflects VLDL particles, as chylomicrons are normally completely cleared by 8 to 12 hours of fasting. In non-fasting samples, the total TG concentration will be raised, due to the presence of TG-rich chylomicrons. The laboratory will usually supply the non-HDL cholesterol (difference between total and HDL cholesterol) concentration as this is the strongest index of CVD risk. In patients with TGs below 4.5 mmol/L, and ideally fasting, the laboratory typically calculates the LDL cholesterol (LDL-C) concentration using the Friedewald formula: LDL-C = TC – HDL-C – (TG/2.2) (in mmol/L). A newer formula to calculate LDL-C, which is less affected by fasting and accurate with TG below 8 mmol/L has recently been defined: LDL-C = (TC/0.948) – (HDL-C/0.971) – ((TG/3.74) + (TG × (TC-HDLC)/24.16) – (TG × TG/79.36)) – 0.244. Some laboratories measure concentrations of LDL-C directly, as well as those of Lp(a), apo B-100, and apo A1.

Plasma lipids and cardiovascular risk

Population studies have repeatedly demonstrated a strong association between total, non-HDL cholesterol (a surrogate for apo B-100-containing particles), and LDL-C with CVD risk; the strongest association is with coronary heart disease. Risk of CVD also rises progressively with TC: HDL-C ratio (**Fig. 19.4**). Higher HDL-C concentrations (up to 1.8 mmol/L), conversely, protect against CVD. There is a weak additional risk associated with TG-rich VLDL or IDL particles and CVD risk possibly driven by the cholesterol content of remnant particles. Chylomicrons do not confer an excess CVD risk but do raise the total plasma TG concentrations. Raised TG levels (>5 mmol/L), and especially those associated with continuing plasma persistence of chylomicrons, are exponentially associated with an increased risk of pancreatitis.

Screening

CVD secondary to atherosclerosis is common. Most patients with hyperlipidaemia are asymptomatic and have no clinical signs. Screening practices for CVD vary between countries ranging from opportunistic measurements to systematic programmes targeting individuals aged greater than 40 years. Opportunistic measurement of lipids is justified for:

- a family history of coronary heart disease (especially below 60 years of age);
- a family history of lipid disorders;
- the presence of physical signs, for example, xanthoma or xanthelasma at any age, or corneal arcus before the age of 40 years;
- diabetes mellitus;
- hypertension;
- obesity;
- acute pancreatitis; and

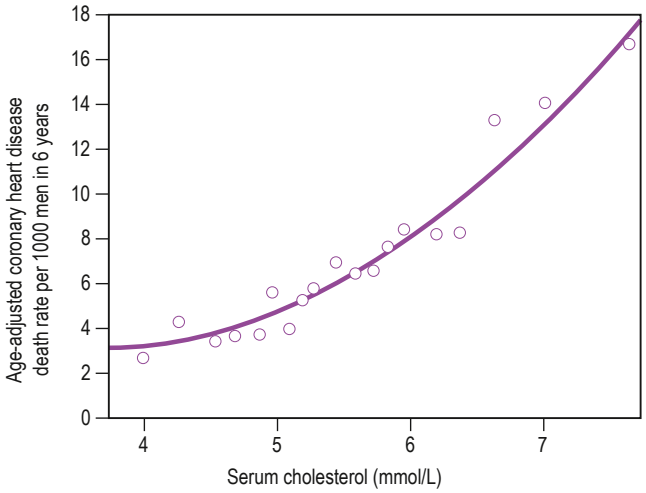

Fig. 19.4 The Multiple Risk Factor Intervention Trial.
Relationship between levels of serum cholesterol and risks of fatal coronary artery disease in a longitudinal study of more than 361 000 men screened for entry into the trial. *(Data from Stamler J, Wentworth D, Neaton JD. Is relationship between serum cholesterol and risk of death from coronary heart disease continuous and graded? Findings in 356222 primary screenees of the Multiple Risk Factor Intervention Trial [MRFIT].* JAMA *1986; 256:2823.)*

- patients undergoing renal replacement therapy.

Where one family member is known to have a monogenic disorder, such as FH, direct relatives, siblings, and children should have their plasma lipid concentrations measured.

Acute severe illnesses, such as myocardial infarction, reduce plasma lipid concentrations for up to 3 months. Lipid profiles should be measured either within 48 hours of an acute myocardial infarction (before derangement has had time to occur) or 3 months later. Cholesterol and HDL-C concentrations do not change significantly after a meal, so screening is performed using random blood samples for TC, TG, and HDL-C. Patients with moderate hypertriglyceridaemia should have a repeat fasting profile performed.

HYPERLIPIDAEMIA

Hyperlipidaemia results from genetic predispositions interacting with the environment, including nutritional factors.

Secondary hyperlipidaemia

Glucose and liver metabolism influence lipid levels. A clinical history, examination, and simple investigations need to be performed to detect the causes of secondary hyperlipidaemia (**Box 19.1**), which may need specific treatment in their own right. Hypothyroidism, untreated diabetes, renal disease (especially nephrotic syndrome), and abnormal liver function can all raise plasma lipid level.

Atherogenic dyslipidaemia is found in two-thirds of patients with metabolism-associated steatotic liver disease (MASLD, see Chapter 23), the most common chronic liver disease in the Western world. MASLD-associated dyslipidaemia is driven mainly by increased insulin resistance and is commonly characterized by excess TG-rich particles (VLDL), increased LDL-C, and low HDL-C. TG-rich apolipoprotein causes activation of the interleukin-1 (IL-1) family with subsequent induction of the inflammatory response through IL-6 and CRP pathway, promoting vascular inflammation, which plays a central role in the development of CVD. CVD is the most common cause of death among MASLD patients.

? Box 19.1 Causes of secondary hyperlipidaemia

- Hypothyroidism
- Diabetes mellitus (when poorly controlled)
- Obesity
- Chronic kidney disease
- Nephrotic syndrome
- Dysglobulinaemia
- Hepatic dysfunction and cholestasis
- Alcohol
- Anorexia nervosa
- Drugs:
  - Oral contraceptives in susceptible individuals
  - Retinoids, thiazide diuretics, corticosteroids, beta-blockers, sirolimus (and other immunosuppressive agents), anti-retroviral drugs

Primary hyperlipidaemia

Primary lipid disorders can be grouped as follows:

- Disorders of VLDL and chylomicrons—hypertriglyceridaemia
- Disorders of LDL—hypercholesterolaemia alone
- Disorders of HDL (rare)
- Combined hyperlipidaemia

Disorders of VLDL and chylomicrons: moderate and severe hypertriglyceridaemia

Most cases are caused by multiple gene variants acting together to produce a modest excess of circulating concentration of VLDL particles, with such cases being termed polygenic hypertriglyceridaemia.

Lipoprotein lipase pathway deficiencies

These are rare orphan diseases that produce greatly elevated TG concentrations (>20 mmol/L) owing to the persistence of chylomicrons (not VLDL particles), because their TG content cannot be properly metabolized. This may occur if the enzyme LPL is defective (95% of cases) or otherwise unable to function. Patients with homozygous or dual deficiency present in childhood with pancreatitis and hepatosplenomegaly, lipaemia retinalis (yellow lipid particles visible in retinal arteries), and sometimes eruptive xanthomas. Heterozygotes can present as adults with gross hypertriglyceridaemia often associated with pancreatitis. The presence of chylomicrons floating like cream on top of fasting lipaemic plasma suggests this diagnosis. The aetiology can be implied by measurement of the TG:apo B-100 ratio or ultracentrifugation, but the diagnosis is confirmed by DNA sequencing. Management is by strict reduction of dietary fat and use of lipid-lowering agents such as inhibitors of apo C3 (e.g., volanesorsen) and, in the case of heterozygotes, drugs such as fibrates to reduce TG levels.

Disorders of LDL: hypercholesterolaemia alone

Heterozygous familial hypercholesterolaemia

Heterozygous familial hypercholesterolaemia (HeFH) is an autosomal dominant monogenic disorder present in 1 in 350 of the population. Mutations affect the LDLR receptor (90%; more than 1500 mutations described), the apo B-100 LDLR ligand domain (5%; 1 principal mutation), and proteins such as PCSK9 that control LDLR expression (2%). The defect results in a reduction

Box 19.2 Genetic defects underlying some lipoprotein disorders

Disorder	Affected gene	Chromosome	Frequency and inheritance
Common disorders			
Heterozygous familial hypercholesterolaemia	*LDLR* (inactivating)	19	1:350 Autosomal dominant
Familial defective apolipoprotein B	*Apo B-100* (exon 26 mostly)	2	1:5000 Autosomal dominant
'Familial hypercholesterolaemia phenocopies'	*PCSK9* (activating) *apoE deletion Leu167*	1 19	1:30 000 Autosomal dominant
Autosomal recessive familial hypercholesterolaemia (ARFH)	*LDLRAP-1*	1	1:200 000 Autosomal recessive
Hypobetalipoproteinaemia	*Apo B-100* (various exons), MTP	2 4	1:10 000 Autosomal recessive
Familial combined hyperlipidaemia	Complex	Multiple	1:250 Complex
Familial hypertriglyceridaemia	Mostly polygenic	Multiple	1:1000 Complex
Some rarer disorders			
'Homozygous' familial hypercholesterolaemia	*LDLR>PCSK9*, *Apo-B* (exon 26)	19	1:350 000 Autosomal dominant
Familial chylomicronaemia syndrome (Lipoprotein lipase pathway deficiencies)	*LPL*, *>apoC2*, *apoA5*, *LMF-1, GPIHBP-1*	8, 19,11, 16, 8	1:1 000 000 (homozygous) Autosomal recessive
Tangier disease	*ABC-A1*	9	Very rare Autosomal recessive
Lecithin-cholesterol acyltransferase deficiency	*LCAT*	16	Very rare Autosomal recessive
Apolipoprotein A1 deficiency	*Apo-A1*	1	Very rare Autosomal dominant

in LDLR function, causing accumulation of LDL particles and LDL-C in plasma (**Box 19.2**). There is extensive phenotypic variation, but more severe cases have a 50% CVD mortality rate by age 65 with an approximate four- to nine-fold increase in CVD risk. Even individuals with FH and average levels of LDL-C show a three-fold increase in lifetime CVD risk. Genetic founder effects increase the prevalence in some groups (e.g., Afrikaner South Africans, Lebanese, French-Canadians). Pathognomic signs of FH include cholesterol deposition in extensor tendons such as the Achilles or those of the fingers. Diagnosis is easier if pathognomonic clinical features are present, but these only occur in 10%. Patients often have no physical signs, in which case the diagnosis is made on the presence of very high plasma cholesterol or LDL-C concentrations that are unresponsive to dietary modification and are usually associated with a family history of early CVD before age 60. Lipid deposition in the skin around the eyes (xanthelasma) may be present in some patients but is not diagnostic of FH and is more typical of high triglyceride-low HDL disorders. The diagnosis of FH is confirmed by DNA sequencing. Given its autosomal dominant inheritance, mutation screening is simple to apply, and children of affected individuals have a 50% chance of inheriting the defect.

Homozygous familial hypercholesterolaemia

Homozygous familial hypercholesterolaemia (HoFH) is an ultra-orphan disorder (affecting 1 in 250 000). Affected children have minimal LDLR function in the liver. They have a hugely elevated LDL-C (greater than 13 mmol/L) and massive deposition of lipid in arterial walls, the proximal aorta, and the skin on extensor surfaces (tuberose xanthomata). Most die from ischaemic heart disease by age 35 if untreated. They have a limited response to drugs such as statins, but PCSK9 inhibitors have been used with some success, especially in patients with point mutations. Other options include inhibitors of microsomal transfer protein (e.g., lomitapide) or newer agents such as angiopoietin-like peptide 3 (ANGPTL3) inhibitors (e.g., evinacumab). Repeated fortnightly lipid-specific plasma extraction (apheresis) can be used to remove LDL-C in patients with null mutations. LDLR function can be restored by partial lobe liver transplantation, which normalizes LDL-C levels and causes regression of xanthomata. Some orphan drug therapies are licensed for use in HoFH (**Box 19.3**).

Mutations in the apoB and PCSK9 genes

Mutations in the terminal part of *apoB* affect binding to the LDLR and cause familial defective apolipoprotein B (FDB), another relatively common single-gene disorder resembling FH. The clinical picture resembles classical HeFH but is often milder, with lower LDL-C levels as some LDLR functions are preserved. Patients with FDB form the commonest non-LDLR form of FH, with a prevalence of 1 in 10 000 or up to 10% of FH cases in some areas (e.g., Ireland, Switzerland). Activating mutations in *PCSK9* cause down-regulation of LDLR. This causes a phenocopy of FH and *PCSK9* mutations, which account for 1% of FH cases. In contrast, inactivating mutations in *PCSK9* are associated with enhanced LDLR function and lower cholesterol levels. A specific mutation in apolipoprotein E deleting leucine 167 also gives a phenocopy of FH and may account for 1% of cases. A very small proportion of FH is autosomally recessively inherited and caused by mutations in the low-density lipoprotein receptor adaptor protein 1 (LDLRAP-1). Most cases of autosomal recessive FH have been found in Sardinia. The different subtypes of FH can be distinguished clearly only by genetic tests. The approach to treatment is the same for all.

Box 19.3 Drugs used in the treatment of hyperlipidaemia

Drug/examples[a]	Mechanism of action	Contraindications	Adverse effects	Expected therapeutic effect	Safety
Statins					
Pravastatin Atorvastatin Rosuvastatin (Simvastatin) (Fluvastatin) (Pitavastatin) (Lovastatin)	Inhibit the rate-limiting step in cholesterol synthesis (HMG-CoA reductase)	Active liver disease, pregnancy, breastfeeding	Constant aches/muscle stiffness, myopathy, rhabdomyolysis, derangement of liver biochemistry Gastrointestinal upset Some statins have CYP3A4 interactions (e.g., simvastatin)	Reduce LDL cholesterol (LDL-C) by 20%–60% Have modest lowering effect on triglycerides Little effect on HDL cholesterol (HDL-C) Atorvastatin and rosuvastatin are the most potent	Atorvastatin and rosuvastatin have good long-term safety and extensive outcomes evidence Avoid if possible in women of childbearing age
Cholesterol absorption inhibitors					
Ezetimibe	Inhibits gut absorption of cholesterol from food and bile; inhibits activity of NPC1L1, a lipid transporter found in the duodenum	Breastfeeding	Occasional abdominal discomfort, skin rash	Reduce LDL-C by 20% Reduce triglyceride concentrations by <10% Minimal effect on HDL-C	Mostly act in gut, and recirculate in enterohepatic circulation Some safety and some outcome evidence
Acid-citrate lyase inhibitors					
Bempedoic acid	Inhibits the step in liver cholesterol synthesis before HMG-CoA reductase	Active liver disease, pregnancy, breastfeeding	Gout, diarrhoea, nausea, muscle spasms, anaemia Interaction with simvastatin and pravastatin	Reduce LDL-C by 20% Reduce triglyceride concentrations by 10% Minimal effect on HDL-C	Low rate of muscle adverse effects Increased occurrence of gout
Bile acid sequestrants					
Colesevelam (Colestyramine) (Colestipol)	Bind bile acids in the gut, preventing enterohepatic circulation; the liver makes more bile acids from cholesterol, depleting the cholesterol pool	Biliary obstruction	Gastrointestinal side-effects are very common, e.g., constipation, diarrhoea, bloating, flatulence; may reduce fat-soluble vitamin and drug absorption Other drugs bind to resins and should be taken 1 hour before or 4 hours afterwards	Reduce LDL-C by 15%–25% Increase triglyceride concentration by 5%–15% Have little or no effect on HDL-C	Not systemically absorbed Safety profile is good Appear safe in women of childbearing age Fat-soluble vitamin supplements may be required in children, and pregnant and breastfeeding women
Fibric acid derivatives					
Bezafibrate Fenofibrate (Ciprofibrate) (Gemfibrozil)	Activate peroxisome proliferator-activated nuclear receptors (esp. PPAR-α), producing protean effects on lipid metabolism	Severe hepatic or renal impairment, gall bladder disease, pregnancy	Reversible myositis, nausea, predisposition to gallstones, non-specific malaise, impotence Reversibly increase creatinine by 15% Drug interactions (e.g., statins), an issue with gemfibrozil	Reduce LDL-C by 0%–15% Reduce triglycerides by 25%–70% depending on baseline Increase HDL-C by 10%–30% depending on baseline	No knowledge of effect on developing fetus; however, avoid in women of childbearing age Long-term safety good and moderate beneficial CVD outcomes effects

Box 19.3 Drugs used in the treatment of hyperlipidaemia—cont'd

Drug/examples[a]	Mechanism of action	Contraindications	Adverse effects	Expected therapeutic effect	Safety
Nicotinic acid/niacin (NA) derivatives					
Modified-release niacin (Acipimox)	Unclear: probably inhibit lipid synthesis in the liver by effect on DGAT-2	Pregnancy, breastfeeding	Value limited by frequent side-effects: painful prostaglandin D2- and E2-induced flushing, nausea, malaise, itching, abnormal liver biochemistry Glucose intolerance, hyperuricaemia, dyspepsia; hyperpigmentation may occur	Reduce LDL-C by 15%–20% Reduce triglycerides by 20%–40% Increase HDL-C by 10%–20%	Medium-term safety good but marred by adverse effects Some monotherapy outcomes evidence Modified-release preparations better but still need high-dose aspirin to reduce flushing
Fatty acid compounds					
Omega-3 fatty acids (mixed) Omega-3 fatty acid ethyl esters (e.g., icosapent ethyl)	Reduce hepatic VLDL secretion and inflammation via FFAR-4	Avoid with anticoagulants since bleeding time is prolonged	Occasional nausea and belching	Reduce triglycerides in severe hypertriglyceridaemia No effect on other lipids	Long-term safety is good. High-dose CVD outcomes evidence
MTP inhibitors					
Lomitapide	Inhibits MTP, which is necessary for VLDL assembly and secretion in the liver	Unclear	Abnormal liver biochemistry	Lowers LDL-C by 50% Orphan drug licensed only for homozygous familial hypercholesterolaemia	Long-term safety data very limited
Proprotein convertase subtilisin kexin-9 (PCSK9) inhibitors					
Antibodies: Alirocumab Evolocumab Small interfering RNA: Inclisiran	Inhibit the action of PCSK9 to upregulate liver LDL receptor expression	Needle phobia (injectable agents)	Myalgia (flu-like illness), injection site reactions	Reduce LDL-C by 45%–60% Have modest lowering effect on triglycerides Little effect on HDL-C	Good safety and CVD outcomes evidence

[a]Drugs now rarely used in brackets.

CVD, Cardiovascular disease; *HMG-CoA,* hydroxymethylglutaryl coenzyme A; *LDL,* low-density lipoprotein; *MTP,* microsomal triglyceride transfer protein; *VLDL,* very-low-density lipoprotein.

Polygenic hypercholesterolaemia

This is a term used to lump together the large group of patients without evidence of monogenic cholesterol disorders above but with cholesterol in the upper part of the normal distribution. Panels for diagnosis of polygenic variants have been devised and include genes known to significantly affect cholesterol levels and CVD disease risk such as LDLR, apoA5, apo(a), apo-E, and PCSK9.

Disorders of HDL

Genetic disorders of HDL metabolism are rare and recessively inherited. They include those causing low HDL-C levels including mutations in apo-A1, ABC-A1, and LCAT. Apo-A1 mutations cause low HDL-C, which are associated with amyloid deposition and either atherosclerosis or protection from atherosclerosis, depending on the exact site affected. Very high HDL-C levels are caused by mutations in CETP or endothelial lipase, which affect the metabolism of HDL particles.

Tangier disease

Macrophages are involved in the uptake of excess cholesterol in arterial walls and donate this to HDL particles. If a defect occurs in cholesterol transport, for example, the ABC-A1 transporter, then they accumulate cholesterol (see **Box 19.2**). In Tangier disease, cholesterol accumulates in reticuloendothelial tissue and arteries, causing enlarged, orange-coloured tonsils and hepatosplenomegaly, corneal opacities, and polyneuropathy, as well as CVD.

Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)

The most common patient group with abnormalities of serum lipid concentrations have a polygenic combined hyperlipidaemia. Patients have an increased CVD risk due to high non–HDL-C concentrations, abundant pro-atherogenic TG-rich particles, high LDL-C, and reduction of HDL-C concentrations by hypertriglyceridaemia (low LPL, excess CETP activity).

Familial combined hyperlipidaemia

Familial combined hyperlipidaemia (FCHL) is relatively common, affecting 1 in 200 of the general population. Its lipid phenotype includes hypertriglyceridaemia, hypercholesterolaemia, or both, associated with premature CVD. The genetic basis for the disorder is not clear, though current studies suggest that the primary defect lies in excess adipose tissue fatty acid release. It is diagnosed by finding raised cholesterol and TG concentrations in association with a typical family history. There are no typical physical signs.

Remnant hyperlipidaemia

This is a rare (1 in 5000) cause of combined hyperlipidaemia. It is due to the accumulation of IDL remnant particles and is associated with an extremely high risk of CVD. It may be suspected in a patient with almost equal cholesterol and TG concentrations and by finding lipid deposition in the dermis visible at palmar creases (planar xanthomata, which is diagnostic) and in the skin over the knees and elbows (tuberose xanthomata) (**Fig. 19.5**). Remnant hyperlipidaemia is commonly associated with inheritance of apo-E variant alleles (e.g., homozygosity for apoprotein E2 that has reduced LDLR binding), together with aggravating factor such as another primary hyperlipidaemia. The diagnosis can be confirmed using the TG:apoB-100 ratio, by genotyping apo-E for two specific single nucleotide polymorphisms (cysteine 158 to arginine [apoE2]; cysteine 112 to arginine [apoE4]) or by ultracentrifugation.

Other lipid disorders

Hypolipidaemia

Low lipid levels can be found in severe protein–energy malnutrition. However, some patients with severe anorexia may manifest high cholesterol levels secondary to protein-based gluconeogenesis in the liver. Low lipid levels are also seen occasionally with severe malabsorption and in intestinal lymphangiectasia.

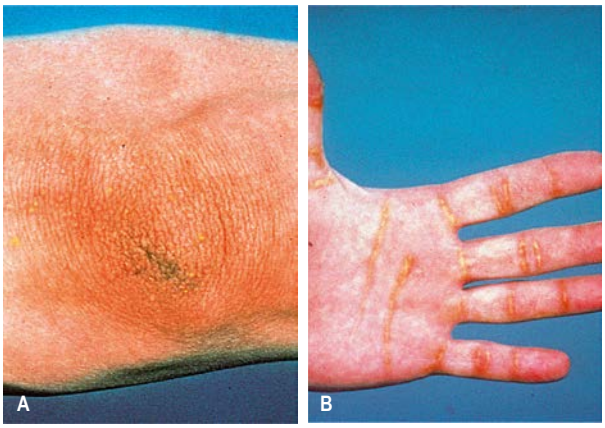

Fig. 19.5 Remnant hyperlipidaemia. **(A)** Tuberous xanthomas behind the elbow. **(B)** Lipid deposits in the hand creases.

Hypobetalipoproteinaemia (see **Box 19.2**) is a benign familial condition with cholesterol levels in the range of 1 to 3.5 mmol/L. Rare causes include mutations in apo-B, PCSK9, and apoC3.

Abetalipoproteinaemia

This is described in Chapter 36.

MANAGEMENT OF HYPERLIPIDAEMIA

Management of patients with abnormal lipid concentrations may require a combination of dietary and non-pharmacological interventions alongside lipid-lowering drugs. Sometimes, lipid abnormalities are so severe that treatment is indicated to prevent life-threatening complications such as pancreatitis in severe hypertriglyceridaemia; sometimes, lipid-lowering may be indicated in patients with only modestly elevated lipid concentrations as part of wider efforts to reduce cardiovascular risk.

The main indications for lipid-lowering are listed below:

Familial hypercholesterolaemia

Individuals with severe elevations of serum cholesterol often require treatment with dietary measures and more than one cholesterol-lowering drug from their teenage years to prevent early development of CVD. Ezetimibe is often added to a statin therapy (**Boxes 19.3** and **19.4**) and PCSK9 inhibitors are used in severe refractory cases.

Hypertriglyceridaemia

A serum TG concentration below 2.0 mmol/L is normal. In the range of 2.0 to 6.0 mmol/L, no specific intervention will be needed unless there are coincident CVD risk factors and, in particular, a strong family history of early CVD or an increased calculated CVD risk. Patients should be told they have a minor lipid problem and offered advice on lifestyle improvement including weight reduction if obese. The commonest causes are associated with MASLD (moderately raised transaminases, raised gamma-glutamyl transferase [GGT], and high TG:HDL-C ratio) or pre-diabetes. Patients with uncontrolled diabetes tend to have raised lipid levels, especially TGs. Some individuals have livers that respond to even moderate degrees of alcohol intake by increased production of VLDL, so a trial of abstinence is advised. Other drugs, including high-dose thiazides, oestrogens, and glucocorticoids, can have similar effects in susceptible patients.

If the TG concentration remains above 6.0 mmol/L despite lifestyle measures, drug therapy is warranted (see **Boxes 19.3** and **19.4**).

Box 19.4 Drug therapy for hyperlipidaemia

Hypertriglyceridaemia (predominantly)	Combined hyperlipidaemia	Hypercholesterolaemia (predominantly)
First-line agents		
Fibrate	Statin	Statin: moderate dose high intensity drug (atorvastatin or rosuvastatin) in primary prevention. Highest tolerated dose in secondary prevention (established CVD)
Additional/alternative agents		
Fish oil capsules including derivatives, e.g., icosapent ethyl (Niacin derivatives)	Fibrate may be required in addition to lower triglycerides adequately (monitor carefully for muscle aches, creatine kinase rise or worsening liver function). Avoid gemfibrozil in combination therapy Ezetimibe (to lower cholesterol further) (Niacin derivative to lower cholesterol and triglycerides further)	Ezetimibe and/or bempedoic acid if statin not tolerated or greater LDL-C lowering needed PCSK9 inhibitor (Cholesterol-binding resin)

LDL-C, Low-density lipoprotein cholesterol.

The severe hypertriglyceridaemia associated with disorders of the LPL pathway may require restriction of dietary fat to 10% to 20% of total energy intake, the use of orphan disease drugs, and the use of special preparations of medium-chain TGs in cooking in place of oil or fat as these are not absorbed via chylomicrons.

Management of combined hyperlipidaemia

Hypertriglyceridaemia increases CVD risk for any cholesterol concentration. Therapy is with diet in the first instance and then with drugs if required. Statins are first-line in patients with TGs less than 8 mmol/L, while fibrates are used first-line for higher levels. Combination therapy is often required (see **Box 19.4**).

Secondary prevention of cardiovascular disease

Statin treatment with high-dose, high-potency agents is warranted for any patient with known macrovascular disease (coronary artery disease, transient ischaemic attack or stroke, peripheral arterial disease), irrespective of the total or LDL-C level. The treatment target is TC below 4.0 mmol/L and LDL-C below 2 mmol/L (ideally <1.5 mmol/L), or alternatively, the maximum tolerated statin dose can be used. If a statin is not tolerated, combinations of other agents are tried (**Box 19.4**).

Primary prevention of cardiovascular disease in people with type 2 diabetes

Lipid-lowering therapy with a moderate dose statin, or alternatives as given previously, is used routinely in asymptomatic individuals with type 2 diabetes alone aged over 40 years, unless the LDL-C is particularly low (<1.8 mmol/L). Calculated CVD risk usually exceeds 10% per decade in these individuals. Good glycaemic control is essential.

Primary prevention of cardiovascular disease in people without diabetes

Lipid-lowering with a moderate dose statin in the first instance is offered to people after an unsuccessful trial of lifestyle intervention whose calculated CVD risk exceeds 10% over the next decade. Cardiovascular risk (below) may be calculated using various scoring systems based on large population studies.

Risk prediction tables

CVD risk is typically multifactorial. An isolated high level of a risk factor may not justify treatment unless levels are extreme (e.g., 95th centile). Epidemiological studies consistently identify age, gender, smoking, presence of type 2 diabetes, hypertension, and the ratio of TC:HDL cholesterol as primary risk factors for CVD. Ancillary risk factors such as family history of premature CVD may add to predictive efficiency in some cases.

CVD risk calculators rely on population studies to predict risk in individuals. This is always an approximate process. The commonest tools calculate either CVD mortality or events based on 10-year, 30-year, or lifetime absolute risk horizons. They are unreliable in populations aged less than 40 years or greater than 75 years, as CVD risk is driven principally by age. Relative risk compared to age and gender-matched controls may be informative outside the core age range.

Generally, drug therapy to lower serum lipids (typically using a statin) is considered mandatory if the cardiovascular risk is 20% or above and may be recommended if the risk is 10% or above. Discussion should be had with patients whose risk is above 5% despite lifestyle intervention. In young individuals, treatment decisions are often based on excess relative risk driven by family history, while in older patients, co-morbidities and life expectancy are significant factors to consider. In some countries imaging techniques such as coronary artery calcium scores are used to refine CVD risk predictions in borderline cases.

Non-pharmacological approaches

Lipid-lowering diet

The main elements of a lipid-lowering diet are similar to those for people with diabetes or hypertension. Additional specific measures are to:

- reduce alcohol consumption, since this may worsen primary lipid disorders at doses that would not affect normal individuals; and
- include foods capable of binding cholesterol such as bran or soya protein.

Undeveloped societies typically have a TC of 3.5 to 4.0 mmol/L with LDL-C of 1.5 to 2.0 mmol/L. A vegan diet can reduce cholesterol and LDL-C by 2 mmol/L and a vegetarian diet by 1 mmol/L compared to the usual Western diet. Several 'nutraceutical' or alternative health products are available that can reduce LDL-cholesterol levels. Plant stanols are analogues of cholesterol that bind to gut cholesterol transporters and reduce the absorption of cholesterol. Products containing sitostanol or sitosterol reduce cholesterol by approximately 0.35 to 0.5 mmol/L, but with a wide inter-individual variation. Red yeast rice is a Chinese medicine that contains a homologue of a statin (monacolin A) capable of reducing LDL-C by 5% to 20%.

Exercise, weight loss, and smoking

Regular exercise, weight loss, and stopping smoking all reduce CVD risk, irrespective of lipid levels. In patients with MASLD, weight loss of 5% will result in at least 10% reduction in serum TG concentration.

Lipid-lowering drugs

See **Box 19.3** for the classes of drugs used to treat hyperlipidaemia and **Box 19.4** for principles of use.

Statins

Statins block HMG-CoA reductase, the rate-limiting step in cholesterol synthesis, leading to compensating effects that increase the expression of LDLRs and hence a reduction in plasma cholesterol concentrations of 20% to 50%. Statins reduce CVD events by 21% per 1 mmol/L reduction in LDL-C. Statins are the first-line treatment for dyslipidaemia in primary and secondary prevention of CVD. In general, their adverse effects are uncommon and reversible; however, the rate of discontinuation of statins ranges between 25% and 50% following the initiation of the treatment. The main cause for the non-adherence is statin intolerance.

Statin intolerance

Statin intolerance can be defined as any adverse effect deemed unacceptable by the patient and/or some laboratory abnormalities (e.g., deranged liver function or elevated creatine kinase [CK]) that are attributed to statins and which improve on discontinuation of the treatment and reappear on re-introduction. Importantly, the nocebo effect (development of adverse effects independent of the active treatment due to negative perceptions or beliefs about the treatment) should be excluded before statin intolerance is confirmed. The nocebo effect is influenced by healthcare beliefs, professional interaction, mainstream media, and social models.

Statin-associated muscle symptoms (SAMSs) are the main reported side-effects, with deranged biomarkers representing the minority of statin-intolerant cases. SAMSs commonly present as generalized muscular aches (myalgia) and occasionally as myositis if CK is elevated; rarely this extends to rhabdomyolysis in severe cases (CK > 5000 IU/L). Pharmacogenetics effects exist for some statins due to variants in the *SLCO1B1* transporter, which increase gut uptake of the statin, resulting in higher levels in plasma of free statin acids and increased toxicity.

Strategies to reduce statin intolerance include having a patient-centred approach and personalized treatment, as well as managing any reversible risk factors that increase the frequency of statin intolerance.

Gut-acting cholesterol-lowering drugs

Ezetimibe is a gut-acting drug binding to the Niemann–Pick C1-like protein 1 (NPC1L1) duodenal cholesterol transporter. This molecule is also the binding site for campesterol and beta-sitosterol. Ezetimibe reduces plasma cholesterol by 20% and has been shown to reduce CVD events when added to statin therapy. It is generally very well tolerated.

Bile acid sequestrants (e.g., colesevelam) are drugs that bind bile acids, preventing micelle formation and thus reducing gut cholesterol uptake. They reduce cholesterol by 15% to 20% and have some CVD outcome evidence from previous trials with monotherapy, but data is lacking on CVD outcomes in the era of statins. They are commonly associated with excess gastrointestinal side-effects and are now rarely used outside the context of liver disorders associated with raised cholesterol with concurrent itch secondary to bile acids.

Acid-citrate lyase inhibitors

Bempedoic acid is a liver-acting drug that inhibits acid-citrate lyase, the step before HMG-CoA reductase. It reduces plasma LDL-C by 20% to 30% and has been shown to reduce CVD events in patients intolerant to statin therapy in line with its effects in reducing LDL-C. It is often co-prescribed with ezetimibe. Little data exists on triple therapy of bempedoic acid with ezetimibe and statins.

PCSK9 inhibitors

PCSK9 is involved in downregulating LDLR expression. Antibodies to PCSK9 (e.g., alirocumab) and small interfering RNA (siRNA) drugs targeting PCSK9 mRNA (e.g., inclisiran) reduce LDL-C by 40% to 60%. Antibodies to PCSK9 have been shown to reduce CVD events, and trials are underway with siRNAs and small molecule PCSK9 inhibitors. These drugs are used as third-line agents in FH, in severe progressing CVD, or for patients intolerant to multiple statins.

Fibrates

Fibrates are gene regulators affecting the peroxisomal-proliferator-activating receptors-alpha subtype (PPAR-α). They reduce TGs by increasing the synthesis of LPL, reducing the synthesis of apoC3 to promote clearance of TG-rich particles (e.g., VLDL), and can increase apo-A1. They have a moderate effect in reducing CVD events, with best evidence in monotherapy. They do not seem to add to the benefits of reducing LDL-C in patients on statins.

Niacin

Niacin (and its related derivative acipimox) are old lipid-lowering drugs. The mechanism of action of niacin is unclear but involves effects in inhibiting diacylglycerol O-acyltransferase 2 (DGAT-2) in the liver to reduce TG and cholesterol transfer to nascent VLDL particles, thus reducing LDL-C. It also inhibits the liver beta-chain adenosine triphosphate synthase receptor to raise plasma apoA1 and HDL-C levels. Its adverse effects include prostaglandin D2 and prostaglandin E mediated flushing and hyperglycaemia. Though effective in reducing CVD events in monotherapy studies, niacin was ineffective when added to statins in recent trials.

Omega-3 fatty acids

These preparations (often termed fish oils) include the essential fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). They bind to specific free fatty acid receptors (FFAR-4) to affect lipid and inflammation pathways. They exert dose-proportional effects in reducing TGs by 20% to 50%. Their effects in the prevention of CVD are controversial, with conflicting results. Low doses in low-risk patients seem to do little, but high doses of EPA derivatives (e.g., icosapent ethyl) in high-risk patients reduce CVD events when added to statins and are independent of any effect on lipid profiles.

Lipoprotein(a) inhibitors

Epidemiological evidence, cohort, and apheresis studies support a role for reducing Lp(a) levels. Previously, both niacin and recently PCSK9 inhibitors have been shown to reduce Lp(a) levels by 25% to 30%, but subgroup analyses have been unable to clearly differentiate their effects on LDL-C as opposed to reducing Lp(a). Newer antisense therapies are capable of reducing Lp(a) by 70% to 80% and are now in clinical trials in patients with CVD and Lp(a) levels exceeding 150 nmol/L.

Apolipoprotein C3 inhibitors

The clearance of TG-rich particles is promoted by apoE and inhibited by apoC3. Antisense inhibitors of apoC3 have been developed and shown to reduce TGs by 70% to 80% in patients with familial hyperchylomicronaemia syndrome (FCS). This results in a 30% to 50% reduction in pancreatitis events. Volanesorsen, the first in the class, is licensed for the management of FCS but has adverse effects including reducing platelet counts. Newer derivatives (e.g., siRNA) seem to avoid this adverse effect. Studies are being considered to address whether reducing apoC3, and hence residual TGs in statin-treated patients will result in further CVD event reduction as non-HDL-C is a stronger predictor of CVD events than LDL-C levels.

Apheresis

Though drug therapies are the mainstay of lipid management, physical removal of apoB-containing lipoprotein particles (including Lp(a)) is possible by plasmapheresis or, more specifically, by lipid apheresis. This invasive recurrent therapy is used in the management of patients with homozygous FH not responding adequately to drug therapies and in individuals showing rapid progression of atherosclerosis despite reasonable lipid profiles who have high Lp(a) levels or evidence of concurrent inflammation. Plasmapheresis is also used in the management of chylomicronaemia syndromes especially in the later stages of pregnancy to reduce the risk of pancreatitis.

Box 19.5 Classes of drugs in clinical trials for the potential treatment of hyperlipidaemia

Drug class	Mechanism of action
Proprotein convertase subtilisin/kexin type-9 (PCSK9) inhibitors For example: inclisiran; MK-0616	Small interfering RNA drug that promotes PCSK9 mRNA destruction and lowers LDL-C by 50%; 3- to 6-monthly dosing. Phase 3 clinical trial on CVD outcomes (ORION-4) in progress. Small molecule PCSK9 inhibitor: MK-0616 in early-phase trials.
Anti-lipoprotein(a) antisense therapy For example: Apo(a)Lrx	Inhibits formation of lipoprotein(a) in the liver. Reduces Lp(a) by 80%. Phase 3 clinical trials in progress
Apolipoprotein C3 inhibitors For example: volanesorsen; siRNA apoC3	Inhibits the action of apoC3, thus increasing clearance of triglyceride-rich particles. Already used in the management of familial chylomicronaemia syndrome. In development for use in patients with CVD and residual hypertriglyceridaemia.
DNA targeted therapy V-101 PCSK9 base editing AAV8.hLDLR	Introducing a functional gene copy to restore the function of the mutated gene, e.g., LDLR gene or inactivating PCSK9 to compensate for reduced LDLR function in HeFH CRISPR/Cas9 system work as gene editors by cutting part of the gene and altering the function of the transcript to either repair it or inactivate a gene to compensate for the original defect

HDL, High-density lipoprotein; *LDL,* low-density lipoprotein; *Lp(a),* lipoprotein(a); *RNA,* ribonucleic acid.

Novel therapeutics

New classes of lipid-lowering drugs in development are listed in **Box 19.5**. Some of these are developments of existing classes such as oral small-molecule PCSK9 inhibitors to reduce LDL-C or anti–apo C3 drugs with improved hepatic clearance and reduced dosing or formulated through small interfering ribonucleic acid (siRNA) technology to reduce TGs. Novel therapeutic approaches include targeting Lp(a) with siRNA to reduce CVD risk in individuals who have inherited high levels or antagonists to angiopoietin-like peptide 3 (ANGPTL3) to reduce TGs. Gene therapy approaches have included a previous unsuccessful attempt to introduce LDLR into hepatocytes using lentiviruses to treat homozygous FH. An adeno-associated viral (AAV) vector to introduce functional LPL and ameliorate FCS (alipogene tiparvovec) was successful in transiently reducing TGs and in reducing pancreatitis but was withdrawn for commercial reasons. A gene therapy for heterozygous FH caused by LDLR mutations by inactivating PCSK9 using siRNA technology (Verve-101) is in early trials.

CORE SKILLS AND KNOWLEDGE

Respiratory medicine is an exciting and varied specialty caring for patients with a range of acute and chronic conditions (Box 20.1). One-third of visits to primary care are due to respiratory symptoms, and respiratory conditions are the reason for one-quarter of medical admissions to hospital.

Respiratory physicians provide a large amount of inpatient care for acute problems such as pneumonia, exacerbations of chronic obstructive pulmonary disease, and other chronic respiratory conditions. General respiratory outpatient care undertakes the initial investigation and diagnosis of patients with respiratory symptoms, with specialist clinics providing long-term follow-up of individual conditions. Care is shared with community teams and nurse specialists to promote health and quality of life through education, self-management, and admission-avoidance strategies. Practical procedures performed by respiratory physicians include bronchoscopy, endobronchial ultrasound scanning, and pleural interventions.

Key skills in respiratory medicine include:

- Managing respiratory emergencies: type 1 and type 2 respiratory failure, pleural effusion, pneumothorax, and large-volume haemoptysis
- Interpreting examination findings and respiratory investigations: chest radiographs, arterial blood gas analysis, and spirometry
- Understanding treatments for respiratory conditions: inhaled and nebulized medications, home oxygen therapy, and non-invasive ventilation.

Respiratory medicine can be learned through attending general and specialty respiratory clinics (e.g., lung cancer, tuberculosis, or sleep clinics), observing specialist investigations such as lung function measurement or bronchoscopy, attending clinics and home visits with specialist nurses, and interpreting arterial blood gases to manage oxygen delivery or assisted ventilation systems.

CLINICAL SKILLS

History

The following are relevant in respiratory disease:

- ***Respiratory symptoms:*** cough, sputum production, breathlessness, chest pain, haemoptysis, wheeze. Specify acuity of onset, change over time, change in symptoms with location/work.
- ***Systemic symptoms:*** weight loss, malaise, night sweats.
- ***Occupational exposure:*** previous occupations, with a specific focus on exposure to asbestos, to organic materials such as hay, mushrooms, or cotton, or to animals. Establish any relationship of symptoms to work.

- ***Smoking:*** duration of smoking, number of cigarettes smoked per day, cessation attempts including nicotine replacement and e-cigarettes.
- ***Illicit drug use:*** especially smoked cannabis.
- ***Family history:*** emphysema, bronchiectasis, or cystic fibrosis.
- ***Childhood history:*** preterm delivery, childhood infections such as whooping cough or measles.
- ***Travel history:*** including risk factors for tuberculosis.

Examination

General
- Posture (lying flat or sitting forward)
- Colour (cyanosed)
- Pain on breathing (pleuritic)?
- Fever
- Cachexia
- Anemia

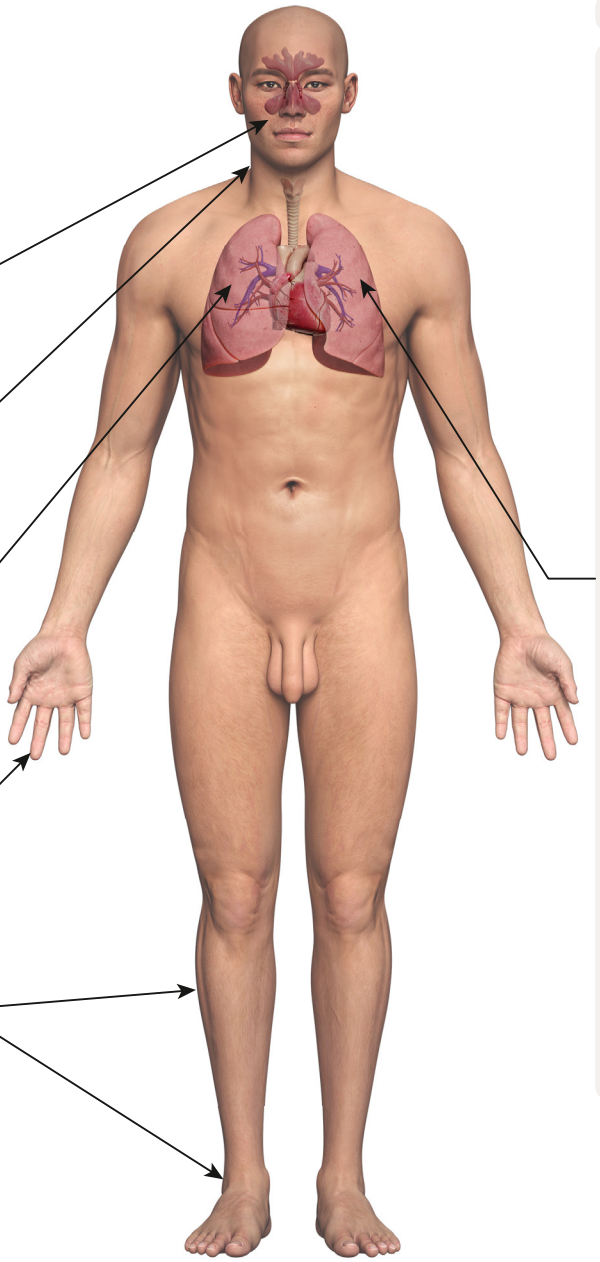
Face
- Horner's syndrome
- Pursed lips
- Beak-like nose
- Central cyanosis

Neck
- Jugular venous pressure (raised, distended)
- Lymphadenopathy

Sputum
- Volume (↑↑ bronchiectasis)
- Mucopurulent (infection)
- Blood-stained (cancer, pulmonary embolism, tuberculosis, bronchiectasis)

Hands
- Clubbing
- Tar staining
- Peripheral cyanosis
- CO_2 retention flap
- Bounding pulse

Peripheries
- Deep vein thrombosis
- Oedema



Chest

Inspection
- Colour
- Breathlessness
- Deformity
- Scars
- Symmetry of movement
- Abdominal paradox
- Hyperinflation
- Prominent veins
- Intercostal indrawing
- Scoliosis
- Respiratory rate
- Use of accessory muscles

Palpation
- Tracheal position
- Cricosternal distance
- Supraclavicular fossa nodes
- Apex beat
- Tenderness
- Liver
  - Position (low lying)
  - Enlargement

Percussion
- Dull
- 'Stony dull' (fluid)
- Hyper-resonant

Auscultation
- Normal = vesicular
- Bronchial breathing
- Wheeze
  - Monophonic (single large airway obstruction)
  - Polyphonic (narrowing of small airways)
- Crackles
  - Coarse
  - Fine, late inspiratory
- Pleural rub
- Vocal resonance

Box 20.1 Core content in respiratory medicine

The 'top 10' respiratory conditions
- Acute and chronic cough
- Airflow obstruction: asthma, chronic obstructive pulmonary disease (COPD), obstructive sleep apnoea
- Pneumonia
- Pulmonary tuberculosis
- Pneumothorax
- Pleural effusion
- Lung cancer
- Bronchiectasis
- Interstitial lung disease

The 'top 10' concepts in respiratory medicine
- Smoking cessation
- Atopy
- The 'treatment ladder' approach to asthma and COPD
- Self-management of chronic conditions
- Admission avoidance
- Home oxygen therapy
- Respiratory failure
- Diagnosis and staging of lung cancer
- Multidisciplinary cancer care
- Management of chest drains

The 'top 10' respiratory medications
- Oxygen
- β_2 agonists
- Antimuscarinics
- Oral and inhaled corticosteroids
- Combination inhalers
- Antihistamines
- Leukotriene receptor antagonists
- Mucolytics
- Monoclonal antibodies
- Antifibrotics

FUNCTION OF THE RESPIRATORY SYSTEM

The principal functions of the respiratory system are to extract oxygen from the external environment and to dispose of carbon dioxide. This requires the lungs to function as efficient bellows, bringing fresh air to the alveoli, and expelling used air at an appropriate rate. Gas exchange is achieved by exposing thin-walled capillaries to alveolar gas and matching ventilation to blood flow through the pulmonary capillary bed. The excretion of carbon dioxide by the lungs is part of acid–base homeostasis.

The lungs expose a large surface area of body tissue to the external environment to achieve gas exchange, hence they can be damaged by dusts, gases, and infective agents. Host defence is therefore a key priority achieved by a combination of structural and immunological mechanisms. The pulmonary circulation acts as a reservoir that can allow response to increased oxygen demands in exercise. The lungs act as a filtration system for small pulmonary emboli. The pulmonary circulation also plays a role in innate immunity, for example, in de-priming neutrophils. Finally, the lungs have a role in speech, as the passage of air through the vocal cords is necessary for phonation.

Anatomy

Nose, pharynx, and larynx

See Chapter 21.

Trachea, bronchi, and bronchioles

The trachea is 10–12 cm in length. It lies slightly to the right of the midline and divides at the carina into right and left main bronchi. The carina lies under the junction of the manubrium sterni and the second right costal cartilage. The right main bronchus is more vertical than the left and inhaled material is therefore more likely to end up in the right lung.

The right main bronchus divides into the upper lobe bronchus and the intermediate bronchus, which further subdivides into the middle and lower lobe bronchi. On the left, the main bronchus divides into upper and lower lobe bronchi only. Each lobar bronchus further divides into segmental and subsegmental bronchi. There are about 25 divisions in all between trachea and alveoli.

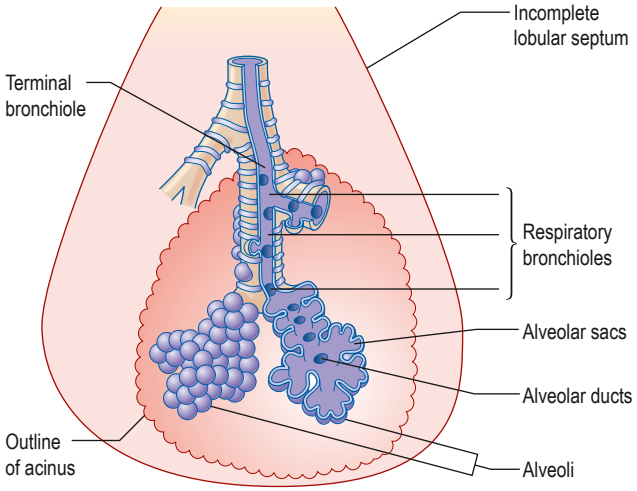


Fig. 20.1 Branches of a terminal bronchiole ending in the alveolar sacs.

The first seven divisions are bronchi that have:
- walls consisting of cartilage and smooth muscle
- an epithelial lining with cilia and goblet cells
- submucosal mucus-secreting glands
- endocrine cells.

The next 16–18 divisions are bronchioles that have:
- no cartilage and a muscular layer that progressively becomes thinner
- a single layer of ciliated cells but very few goblet cells
- granulated Clara cells that produce a surfactant-like substance.

The ciliated epithelium is a key defence mechanism. Each cell bears approximately 200 cilia beating at 1000 beats/min in organized waves of contraction. Mucus, which contains macrophages, cell debris, inhaled particles, and bacteria, is moved by the cilia towards the larynx at about 1.5 cm/min (the 'mucociliary escalator'; see later).

The bronchioles divide within the acinus into smaller respiratory bronchioles that have alveoli arising from the surface (Fig. 20.1). Each respiratory bronchiole supplies approximately 200 alveoli via alveolar ducts. The term 'small airways' refers to bronchioles of less than 2 mm; the average lung contains about 30 000 of these.

Alveoli

There are approximately 300 million alveoli in each lung. Their total surface area is 40–80 m^2. The epithelial lining consists mainly of ***type I pneumocytes*** (Fig. 20.2). These cells have an extremely thin layer of cytoplasm, which only offers a thin barrier to gas exchange. Type I cells are connected to each other by tight junctions that limit the movements of fluid in and out of the alveoli. Alveoli are not completely airtight; holes in the alveolar wall allow communication between alveoli of adjoining lobules (pores of Kohn). ***Type II pneumocytes*** are slightly more numerous than type I but cover less of the epithelial lining. They are found generally in the borders of the alveolus and contain distinctive lamellar vacuoles, which are the source of surfactant. Type I pneumocytes are derived from type II cells. Large alveolar macrophages are present within the alveoli and assist in defence of the lung.

Lungs

The lungs are separated into lobes by invaginations of the pleura, which are often incomplete. The right lung has three lobes, whereas

the left lung has two. The positions of the oblique fissures and the right horizontal fissure are shown in Fig. 20.3. The upper lobe lies mainly in front of the lower lobe and therefore physical signs on the right side in the front of the chest are due to lesions of the upper lobe or the middle lobe.

Pleura

The pleura is a layer of connective tissue covered by a simple squamous epithelium. The visceral pleura covers the surface of the lung, lines the interlobar fissures, and is continuous at the hilum with the parietal pleura, which lines the inside of the hemithorax. At the hilum, the visceral pleura continues alongside the branching bronchial tree for some distance before reflecting back to join the parietal pleura. In health, the pleurae are in apposition, apart from a small quantity of lubricating fluid.

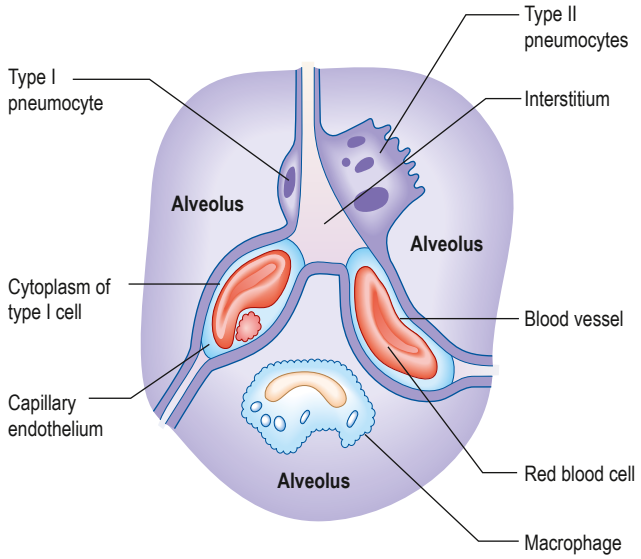

Fig. 20.2 The structure of alveoli, showing the pneumocytes and capillaries.

Diaphragm

The diaphragm is covered by parietal pleura above and peritoneum below. The diaphragmatic muscle fibres arise from the lower ribs and insert into the central tendon. Motor and sensory nerve fibres go separately to each half of the diaphragm via the phrenic nerves. Fifty percent of muscle fibres are of the slow-twitch type with low glycolytic capacity, and are relatively resistant to fatigue.

Pulmonary vasculature and lymphatics

The lung has a dual blood supply made up of deoxygenated blood cells from the right ventricle via the pulmonary artery into which oxygen from the alveoli diffuse, and oxygenated blood via the bronchial artery circulation. The pulmonary artery divides to accompany the bronchi. The arterioles accompanying the respiratory bronchioles are thin-walled and contain little smooth muscle. The pulmonary venules drain laterally to the periphery of the lobules, pass centrally in the interlobular and intersegmental septa, and eventually join to form the four main pulmonary veins. The bronchial circulation arises from the descending aorta. These bronchial arteries supply tissues down to the level of the respiratory bronchiole. The bronchial veins drain into the pulmonary veins, forming a physiological shunt.

Lymphatic channels lie in the interstitial space between the alveolar cells and the capillary endothelium of the pulmonary arterioles.

The tracheobronchial lymph nodes are arranged in five main groups: pulmonary, bronchopulmonary, subcarinal, superior tracheobronchial, and paratracheal. For practical purposes, these form a continuous network of nodes from the lung substance up to the trachea.

Nerve supply to the lung

The innervation of the lung remains incompletely understood. Parasympathetic and sympathetic fibres from the vagus and sympathetic chain, respectively, accompany the pulmonary arteries and the airways. Airway smooth muscle is innervated by vagal afferents, postganglionic muscarinic vagal efferents, and vagally derived non-adrenergic non-cholinergic (NANC) fibres that use a range of neurotransmitters. Three muscarinic receptor subtypes have been identified: M_1 receptors on parasympathetic ganglia, a smaller number of M_2 receptors on muscarinic nerve terminals, and M_3 receptors on airway smooth muscle. The parietal pleura is innervated

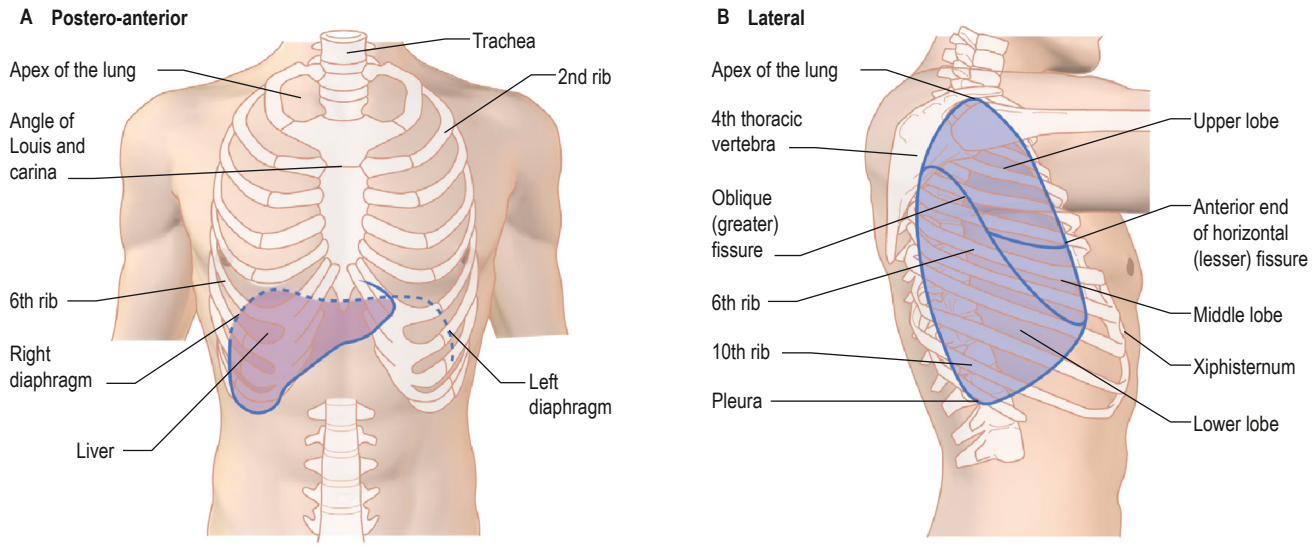

Fig. 20.3 Surface anatomy of the chest. (A) Anterior. (B) Lateral.

from intercostal and phrenic nerves, but the visceral pleura has no innervation.

Physiology

Nose

The major functions of nasal breathing are:

- to heat and moisten the air
- to remove particulate matter.

Nasal secretions contain immunoglobulin A (IgA) antibodies, lysozyme, and interferons. In addition, the cilia of the nasal epithelium move the mucous gel layer rapidly back to the oropharynx, where it is swallowed. Bacteria have little chance of settling in the nose. Mucociliary protection is less effective against viral infections because viruses bind to receptors on epithelial cells. The majority of rhinoviruses bind to an adhesion molecule, intercellular adhesion molecule 1 (ICAM-1), which is shared by neutrophils and eosinophils. Many noxious gases, such as sulphur dioxide, are almost completely removed by nasal breathing.

Breathing

Lung ventilation consists of:

- the mechanical process of inspiration and expiration
- the control of respiration appropriate for metabolic needs.

Mechanical process

The lungs have an inherent elastic property that causes them to tend to collapse away from the thoracic wall, generating a negative pressure within the pleural space. The strength of this retractive force relates to the volume of the lung: at higher lung volumes, the lung is stretched more, and a greater negative intrapleural pressure is generated. ***Lung compliance*** is a measure of the relationship between this retractive force and lung volume. At the end of a quiet expiration, the retractive force exerted by the lungs is balanced by the tendency of the thoracic wall to spring outwards. At this point, respiratory muscles are resting. The volume of air remaining in the lung after a quiet expiration is called the ***functional residual capacity*** (***FRC***, see Fig. 20.13).

Inspiration from FRC is an active process: a negative intrapleural pressure is created by descent of the diaphragm and movement of the ribs upwards and outwards through contraction of the intercostal muscles. During tidal breathing in healthy individuals, inspiration is almost entirely due to contraction of the diaphragm. More vigorous inspiration requires the use of accessory muscles of ventilation: sternomastoid and scalene. Respiratory muscles are similar to other skeletal muscles but less prone to fatigue. However, inspiratory muscle fatigue contributes to respiratory failure in patients with severe chronic airflow limitation and in primary neurological and muscle disorders. At rest or during low-level exercise, expiration is passive and results from the natural tendency of the lung to collapse. Forced expiration involves activation of accessory muscles, chiefly those of the abdominal wall, which help to push up the diaphragm.

Control of respiration

Coordinated respiratory movements result from rhythmical discharges arising in an anatomically ill-defined group of interconnected neurons in the reticular substance of the brainstem, known as the respiratory centre. Motor discharges from the respiratory centre travel via the phrenic and intercostal nerves to the respiratory musculature. Ventilation is controlled by a combination of neurogenic and chemical factors (Fig. 20.4). In healthy individuals, the main driver for respiration is the arterial pH, which is closely related to the partial pressure of carbon dioxide in arterial blood. Oxygen concentrations in arterial blood are usually above the level that triggers respiratory drive. Typical reference values are shown in Box 20.2.

Breathlessness on physical exertion is normal and is not a symptom unless the level of exertion is very light, such as walking slowly. Surveys of healthy Western populations reveal that over 20% of the general population report breathlessness on relatively minor exertion. Although breathlessness is a very common symptom, the sensory and neural mechanisms underlying it remain obscure. The sensation of breathlessness is derived from at least three sources:

- ***changes in lung volume:*** sensed by receptors in thoracic wall muscles signalling changes in length
- ***tension developed by contracting muscles:*** sensed by Golgi tendon organs
- ***central perception of effort***

Airways of the lungs

From the trachea to the periphery, the airways decrease in size and increase in number. Overall, the cross-sectional area available for airflow increases as the total number of airways increases. The airflow rate is greatest in the trachea and slows progressively towards the periphery since the velocity of airflow depends on the cross-sectional area. In the terminal airways, gas flow occurs solely by diffusion. The resistance to airflow is very low (0.1–0.2 kPa/L in a normal tracheobronchial tree), steadily increasing from the small to the large airways.

Airways expand as lung volume increases. At full inspiration (***total lung capacity***, TLC) they are 30%–40% larger in calibre than at full expiration (***residual volume***, RV). In chronic obstructive pulmonary disease (COPD) the small airways are narrowed but this can be partially compensated by breathing closer to TLC.

Control of airway tone

Bronchomotor tone is maintained by vagal efferent nerves and can be reduced by atropine and β-adrenoceptor agonists. Adrenoceptors on the surface of bronchial muscles respond to circulating catecholamines; there is no direct sympathetic innervation. Airway tone shows a circadian rhythm, which is greatest at 4 am and lowest in mid-afternoon. Tone can be increased transiently by inhaled stimuli acting on epithelial nerve endings, which trigger reflex bronchoconstriction via the vagus. Stimuli include cigarette smoke, solvents, inert dust, and cold air. Airway responsiveness to these stimuli increases following respiratory tract infections, even in healthy subjects. In asthma, the airways are very irritable: as the circadian rhythm remains the same, asthmatic symptoms are usually worse in early morning.

Airflow

Movement of air through the airways results from a difference between atmospheric pressure and pressure in the alveoli; alveolar pressure is negative in inspiration and positive in expiration. During quiet breathing, the pleural pressure is negative throughout the breathing cycle. With vigorous expiratory efforts (e.g., cough) the pleural pressure becomes positive (up to 10 kPa). This compresses the central airways, but the smaller airways do not close off because the driving pressure for expiratory flow (alveolar pressure) is also increased.

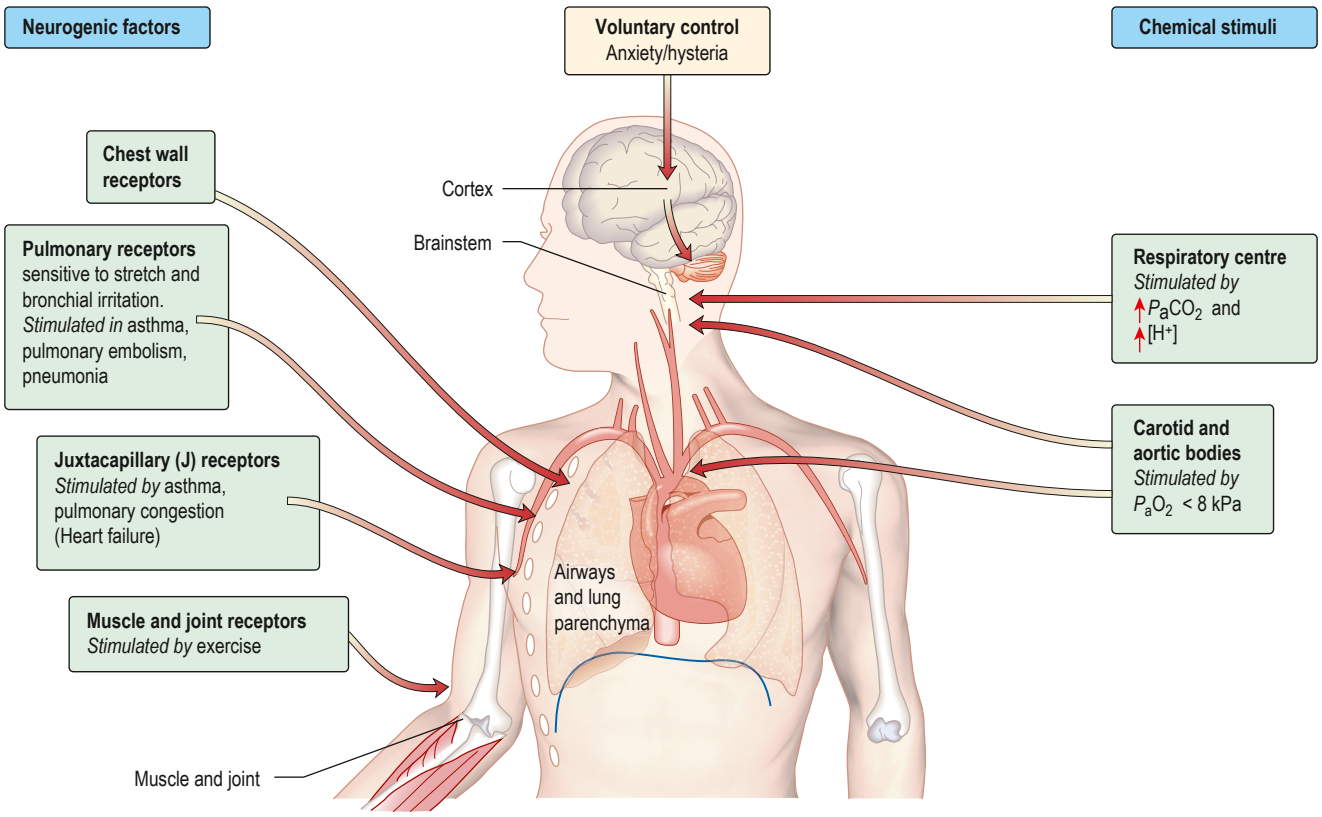

Fig. 20.4 Chemical and neurogenic factors in the control of ventilation. The strongest stimulant to ventilation is a rise in P_aCO_2, which increases $[H^+]$ in cerebrospinal fluid. Sensitivity to this may be lost in chronic obstructive pulmonary disease, when hypoxaemia becomes the chief stimulus to respiratory drive; oxygen treatment may therefore reduce respiratory drive and lead to a further rise in P_aCO_2. An increase in $[H^+]$ due to metabolic acidosis, as in diabetic ketoacidosis, will increase ventilation with a fall in P_aCO_2, causing deep sighing (Kussmaul) respiration. The respiratory centre is depressed by severe hypoxaemia and sedatives (e.g., opiates).

Box 20.2 Normal values for respiratory physiology

In a typical, non-pregnant adult at rest:

- Pulmonary blood flow: 5 L/min carrying 11 mmol/min (250 mL/min) of O_2 to tissues
- Ventilation: 6 L/min removing 9 mmol/min (200 mL/min) of CO_2 from the body
- Pressure of oxygen in arterial blood (P_aO_2): 11–13 kPa
- Pressure of carbon dioxide in arterial blood (P_aCO_2): 4.8–6.0 kPa

Flow–volume loops

The relationship between maximal flow rates and lung volume is demonstrated by the maximal flow–volume (MFV) loop (Fig. 20.5A). In subjects with healthy lungs, maximal flow rates are rarely achieved, even during vigorous exercise. However, in patients with severe COPD, limitation of expiratory flow occurs even during tidal breathing at rest (Fig. 20.5B). To increase ventilation, these patients breathe at higher lung volumes and allow more time for expiration, both of which reduce the tendency for airway collapse. To compensate, they increase flow rates during inspiration, where there is relatively less flow limitation.

The volume that can be forced in from the RV in 1 second (FIV_1) will always be greater than that which can be forced out from TLC in 1 second (FEV_1). Thus, the ratio of FEV_1 to FIV_1 is less than 1. The only exception to this is when there is significant obstruction to the airways outside the thorax, such as tracheal tumour or retrosternal goitre. Expiratory airway narrowing is prevented by tracheal resistance, and expiratory airflow is more effort-dependent. During forced inspiration, this same resistance causes negative intraluminal pressure and tracheal compression by surrounding atmospheric pressure. Inspiratory flow thus becomes less effort-dependent, and the ratio of FEV_1 to FIV_1 is greater than 1. This phenomenon, and the characteristic flow–volume loop, are diagnostic of extrathoracic airways obstruction (Fig. 20.5C).

Ventilation and perfusion relationships

For optimum gas exchange there is a match between (V) and perfusion of the alveoli (Q). In reality there is variation in the $\left(\dot{V}/\dot{Q}\right)$ ratio in both normal and diseased lungs (Fig. 20.6). In the normal lung, ventilation, and perfusion are greater at the bases than at the apices but the gradient for perfusion is steeper, so the net effect is that ventilation exceeds perfusion towards the apices while perfusion exceeds ventilation at the bases. Other causes of mismatch include direct shunting of deoxygenated blood through the lung without passing through alveoli (e.g., the bronchial circulation) and areas of lung deadspace that receive no blood (e.g., bullae, areas of underperfusion during acceleration and deceleration in aircraft and high-performance cars). Increased physiological shunt results in arterial hypoxaemia since it is not possible to compensate for blood being under-oxygenated by increasing ventilation of well-perfused areas. Increased physiological deadspace increases the work of breathing but has less impact on gas exchange in the normal lung as perfused alveoli remain well-ventilated. In lung disease, this compensation

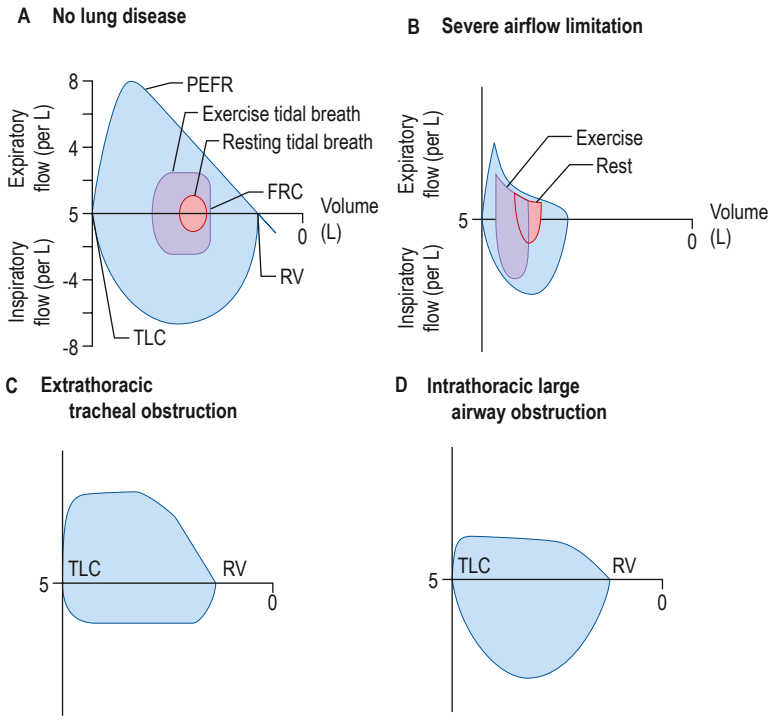

Fig. 20.5 Flow–volume loops. Maximal flow–volume loops, showing the relationship between maximal flow rates on expiration and inspiration. Flow–volume loops during tidal breathing at rest (starting from the functional residual capacity, FRC) and during exercise are also shown **(A)** ***Normal subject***. The highest flow rates are achieved when forced expiration begins at total lung capacity (TLC) and represents the peak expiratory flow rate (PEFR). As air is blown out of the lung, the flow rate decreases until no more air can be forced out, a point known as the residual volume (RV). Because inspiratory airflow is dependent only on effort, the shape of the maximal inspiratory flow–volume loop is different, and inspiratory flow remains at a high rate throughout the manoeuvre. **(B) Severe airflow limitation**. The ventilatory demands of exercise cannot be met, greatly reducing effort tolerance. **(C–D) Flow–volume loops in large airway (tracheal) obstruction**, showing plateauing of maximal expiratory flow. **Extrathoracic tracheal obstruction (C)** has proportionally greater reduction of maximal inspiratory flow rate. In **intrathoracic large airway obstruction (D)** the expiratory plateau is more pronounced.

may not occur, leading to increased alveolar and arterial PCO_2 (P_ACO_2 and P_aCO_2, respectively) and hypoxaemia, which cannot be compensated for by increasing ventilation.

Hypoxaemia occurs more readily than hypercapnia because of the different ways in which oxygen and carbon dioxide are carried in the blood. Carbon dioxide is carried in three forms (in bicarbonate, carbamino compounds, and as simple solution) and the volume carried is proportional to the partial pressure of CO_2. Oxygen is carried in chemical combination with haemoglobin in the red blood cells, with a non-linear relationship between the volume carried and the partial pressure. Alveolar hyperventilation reduces the alveolar PCO_2 and diffusion leads to a proportional fall in the carbon dioxide content of the blood. However, as haemoglobin is already saturated with oxygen, increasing the alveolar PO_2 through hyperventilation will not increase blood oxygen content. This means that hypoxaemia due to physiological shunting cannot be compensated for by hyperventilation.

In individuals who have mild degrees of mismatch, the P_aO_2 and P_aCO_2 will still be normal at rest. Increasing the requirements for gas exchange by exercise will widen the mismatch and the P_aO_2 will fall. Mismatch is by far the most common cause of arterial hypoxaemia.

Alveolar stability

Pulmonary alveoli are polygonal spaces within a sponge-like matrix. Surface tension acting at the curved internal surface tends to cause the alveoli to decrease in size. The surface tension within the alveoli would make the lungs extremely difficult to distend, if not for the presence of surfactant, which reduces surface tension so that alveoli remain stable.

Defence mechanisms of the respiratory tract

Pulmonary disease often results from a failure of normal lung host defence mechanisms (Fig. 20.7). These can be divided into physical, physiological, humoral, and cellular mechanisms.

Physical and physiological mechanisms include

- **Humidification:** prevents dehydration of the epithelium.
- **Particle removal:** >90% of particles of >10 μm in diameter are removed in the nostril or nasopharynx. This includes most pollen grains (typically >20 μm). Particles between 5 and 10 μm become impacted at the carina. Particles capable of reaching the deep lung are those in the 1–5 μm range as they remain airborne.
- **Particle expulsion:** facilitated by coughing, sneezing, or gagging.
- **Respiratory tract secretions:** the mucus of the respiratory tract is gelatinous, consisting of water and highly glycosylated proteins (mucins). The mucus forms a thick gel that is relatively impermeable to water and floats on a liquid or sol layer found around the cilia of the epithelial cells (see Fig. 20.7). The gel layer is secreted from goblet cells and mucus glands as distinct

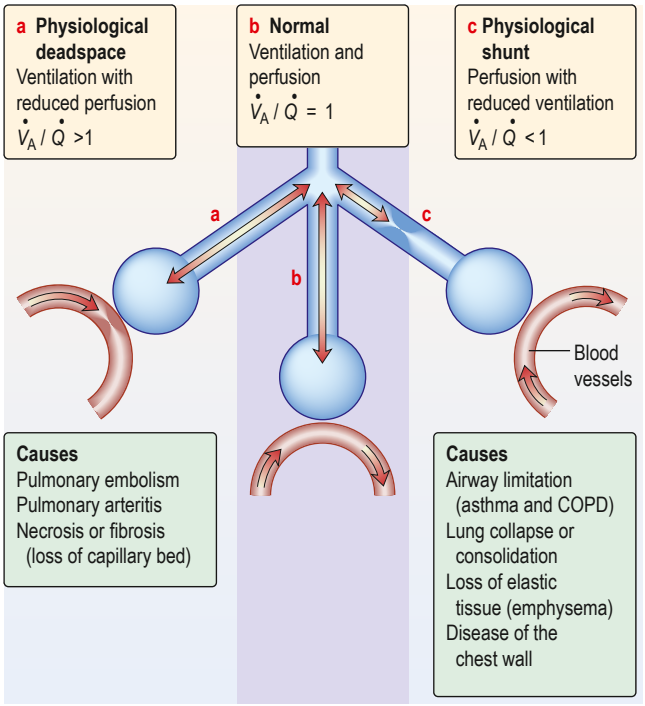

Fig. 20.6 Relationships between ventilation and perfusion: the alveolar–capillary interface. The *centre* **(b)** shows ***normal ventilation*** and perfusion. On the left **(a)** there is a ***block in perfusion (physiological deadspace)***, while on the right **(c)** there is ***reduced ventilation (physiological shunting)***.

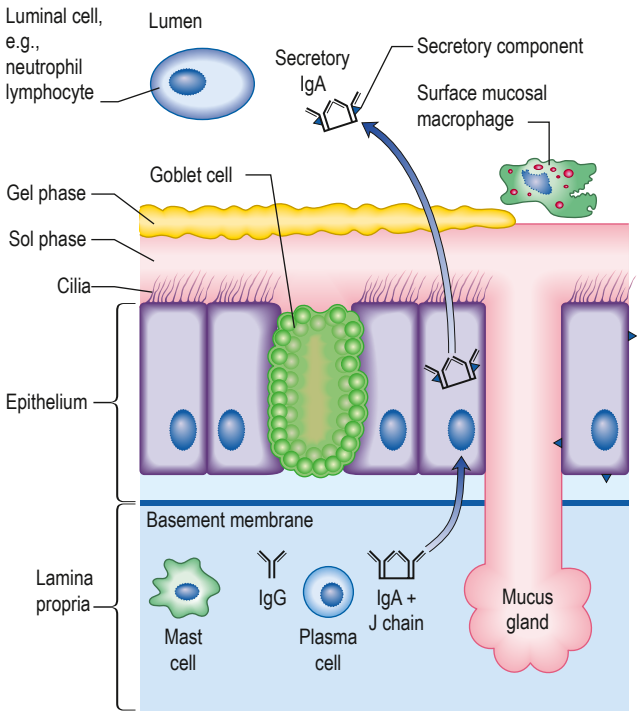

Fig. 20.7 Defence mechanisms present at the epithelial surface.

globules that coalesce increasingly in the central airways to form a continuous mucus blanket. In addition to the mucins, the gel contains various antimicrobial molecules (lysozyme, defensins), specific antibodies (IgA), and cytokines, which are secreted by cells in airways and incorporated into the mucus gel. Bacteria, viruses, and other particles become trapped in the mucus and are either inactivated or simply expelled before they can do any damage. Under normal conditions the tips of the cilia engage with the undersurface of the gel phase and by coordinated movement push the mucus blanket upwards and outwards to the pharynx, where it is either swallowed or coughed up. A major long-term effect of cigarette smoking is reduced mucociliary transport contributing to recurrent infection and prolonged contact with carcinogens. Air pollutants, local and general anaesthetics, and products of bacterial and viral infection also reduce mucociliary clearance. Congenital defects in mucociliary transport (cystic fibrosis [CF] and immotile cilia syndrome) lead to recurrent infections and bronchiectasis.

The respiratory microbiome

There is resident bacterial flora in the lung that is similar to that of the mouth. The composition of the respiratory microbiome is determined by three factors:

- ***microbial immigration:*** by inhalation or microaspiration from the gastrointestinal tract
- ***local growth conditions:*** for bacteria, e.g., temperature, pH, nutrients, concentration and activation of local inflammatory cells, epithelial cell interactions
- ***microbial elimination:*** the mucociliary escalator, coughing, innate, and adaptive humoral mechanisms.

These factors change in acute and chronic lung conditions when there is an increase in pathological bacteria. This respiratory tract dysbiosis causes dysregulation of local immune responses (e.g., prolonged inflammation), which favours growth of bacteria. The composition of the bacterial microbiome in different conditions might favour exacerbation of disease.

Humoral and cellular mechanisms

Non-specific soluble factors

- ***Alpha-antitrypsin*** (α_1-antiprotease) in lung secretions is derived from plasma. It inhibits chymotrypsin and trypsin, and neutralizes proteases including neutrophil elastase.
- ***Antioxidant defences*** include enzymes such as superoxide dismutase and low-molecular-weight antioxidant molecules (ascorbate, urate) in the epithelial lining fluid.
- ***Lysozyme*** is a bactericidal enzyme found in granulocytes.
- ***Lactoferrin*** is synthesized from epithelial cells and neutrophil granulocytes and has bactericidal properties.
- ***Interferons*** are produced by most cells in response to viral infection and are potent modulators of lymphocyte function.
- ***Complement*** in secretions is derived from plasma. In association with antibodies, it plays a major role in cytotoxicity.
- ***Surfactant protein A*** (SPA) is one of four species of surfactant protein that opsonize bacteria or particles, enhancing phagocytosis by macrophages.
- ***Defensins*** are bactericidal peptides present in the azurophil granules of neutrophils.
- ***Dimeric secretory IgA*** targets specific antigens.

Innate and adaptive immunity

These mechanisms act as a defence against microbes, inorganic substances such as asbestos, particulate matter such as dust, and other antigens. They aid opsonization so that macrophages can better ingest foreign material.

With infection, neutrophils migrate out of pulmonary capillaries into the air spaces and phagocytose and kill microbes with

antimicrobial proteins (lactoferrin), degradative enzymes (elastase), and oxidant radicals. In addition, neutrophil extracellular traps ensnare and kill extracellular bacteria. Neutrophils also generate a variety of mediators, such as tumour necrosis factor-alpha (TNF-α), interleukin 1 (IL-1), and chemokines that attract additional inflammatory cells as part of adaptive immunity.

Microbes are detected by host cells by pattern recognition receptors such as toll-like receptors. These act via nuclear factor-kappa B (NF-κB) transcription factors in the epithelial cells to produce adhesion molecules, chemokines, and colony-stimulating factors to initiate inflammation. Inflammation is necessary for innate immunity and host defence but can lead to lung damage; there is a fine line between defence and injury.

CLINICAL APPROACH TO THE PATIENT WITH RESPIRATORY DISEASE

Clinical features of respiratory disease

Nasal symptoms

Nasal symptoms are extremely common; 'runny nose' (rhinorrhoea), nasal blockage, and sneezing can be caused by allergic rhinitis (see Chapter 21) and by viral infection. Nasal secretions are usually thin and runny in allergic rhinitis, but thicker and discoloured in viral infections. Nose bleeds and blood-stained nasal discharge are common and rarely indicate serious pathology, unless associated with nasal obstruction and/or pain (see Chapter 21). Nasal polyps typically present with nasal blockage and loss of smell.

Cough

Cough is the most common symptom of lower respiratory tract disease. It is caused by mechanical or chemical stimulation of cough receptors in the epithelium of the pharynx, larynx, trachea, bronchi, and diaphragm. Impulses travel via an afferent pathway to the cough centre in the medulla, with efferent signalling to the expiratory musculature. Smokers often have a morning cough with little sputum. A productive cough is a key feature of chronic bronchitis. Dry coughing, particularly at night, can be a symptom of asthma or acid reflux. Cough also occurs in asthma after mild exertion or forced expiration. Cough can have no definable pathology; psychological causes are postulated with limited evidence.

A worsening cough is the most common presenting symptom of lung cancer. The normal explosive character of the cough is lost when a vocal cord is paralyzed, usually due to cancer infiltrating the left recurrent laryngeal nerve. Cough can be accompanied by stridor in whooping cough or in laryngeal or tracheal obstruction.

Sputum

Approximately 100 mL of mucus is produced daily in a healthy, non-smoking individual. This flows up the airways, through the larynx, and is then swallowed. Excess mucus is expectorated as sputum. Cigarette smoking is the most common cause of excess mucus production.

Mucoid sputum is clear and white but can contain black specks from inhalation of carbon. Yellow or green sputum is due to the presence of cellular material, including bronchial epithelial cells, neutrophils, or eosinophil granulocytes. Yellow sputum is not necessarily due to infection, since granulocytes in the sputum, as seen in asthma, give the same appearance as neutrophils. The production of large quantities of yellow or green sputum is characteristic of bronchiectasis.

Haemoptysis

Haemoptysis (blood-stained sputum) varies from small streaks of blood to massive haemorrhage. The most common cause of mild haemoptysis is infection (**Box 20.3**), particularly in exacerbations of COPD, but this should not be assumed without investigation. Other common causes are pulmonary infarction (e.g., secondary to pulmonary embolism), bronchial carcinoma, and tuberculosis. Pink, frothy sputum is seen in pulmonary oedema, while in bronchiectasis the blood is often mixed in purulent sputum. Massive haemoptysis (>200 mL of blood in 24 h) is usually due to bronchiectasis or tuberculosis, but can be seen in later stages of lung cancer.

Although a diagnosis can often be made from a chest radiograph (e.g., bronchiectasis, tuberculosis), a normal film does not exclude serious disease. However, if the chest radiograph is normal, CT scanning and bronchoscopy are diagnostic in only about 5% of patients with haemoptysis.

Breathlessness

Dyspnoea (breathlessness) is a sense of awareness of increased respiratory effort that is unpleasant and recognized by the patient as inappropriate. Patients often experience tightness in the chest, which must be differentiated from angina. (**Box 20.4**). The degree of breathlessness should be assessed in relation to lifestyle. For example, a moderate degree of breathlessness will be disabling if the patient has to climb many flights of stairs to reach home. Breathlessness can be graded using the Medical Research Council grading of dyspnoea (**Box 20.5**).

Tachypnoea and ***hyperpnoea*** are, respectively, an increased rate of breathing and an increased level of ventilation. These may be appropriate responses (e.g., during exercise).

Hyperventilation is inappropriate over-breathing. This may occur at rest or on exertion, and results in a lowering of alveolar and arterial PCO_2.

Orthopnoea is breathlessness on lying down. While it is classically linked to heart failure, the weight of abdominal contents

? Box 20.3 Causes of haemoptysis

- Malignant and benign lung tumours, including lung metastases
- Pulmonary infection, including bacterial pneumonia, tuberculosis, lung abscess, and fungal infection
- Bronchiectasis, including cystic fibrosis
- Pulmonary emboli
- Congestive heart failure
- Pulmonary fibrosis
- Pulmonary vasculitis, e.g., Goodpasture's syndrome, microscopic polyangiitis
- Severe pulmonary hypertension
- Arteriovenous malformation
- Chest trauma and foreign body
- Endometriosis
- Anticoagulation, coagulopathy (look for underlying pathology)
- Drugs, e.g., cocaine, thrombolytics

Box 20.4 Causes of breathlessness

Acute
- Airways obstruction
- Anaphylaxis
- Asthma
- Pneumothorax
- Pulmonary embolus
- Myocardial infarction
- Pulmonary oedema
- Arrhythmia
- Anxiety

Subacute
- Pneumonia
- Exacerbation of COPD
- Angina
- Cardiac tamponade
- Metabolic acidosis
- Pain
- Pontine haemorrhage

Chronic
- COPD
- Pleural effusion
- Malignancy
- Chronic pulmonary emboli
- Restrictive lung disease
- Congestive cardiac failure
- Valvular dysfunction
- Cardiomyopathy
- Anaemia
- Neuromuscular disorders
- Deconditioning
- Breathing pattern disorder with no underlying pathology

Box 20.5 Medical Research Council grading of dyspnoea (breathlessness scale)

1. Not troubled by breathlessness except on strenuous exercise
2. Short of breath when hurrying or walking up a slight hill
3. Walks slower than contemporaries on the level because of breathlessness, or has to stop for breath when walking at own pace
4. Stops for breath after about 100 m or after a few minutes on the level
5. Too breathless to leave the house, or breathless when dressing or undressing

pushing the diaphragm up into the thorax may contribute; thus patients with diaphragm paralysis may present with symptoms of orthopnoea. Such patients may also become breathless on bending over.

Paroxysmal nocturnal dyspnoea describes acute episodes of breathlessness at night, typically due to heart failure.

Wheezing

Wheezing is a common symptom resulting from airflow limitation due to any cause. It is not diagnostic of asthma; other causes include vocal cord dysfunction, bronchiolitis, and COPD. Conversely, wheeze may be absent in early-stage asthma.

Chest pain

Common chest pain reported in respiratory disease is a localized, sharp pain termed 'pleuritic'. It is made worse by deep breathing or coughing. Localized anterior chest wall pain with tenderness of a costochondral junction is caused by costochondritis. Shoulder tip pain suggests irritation of the diaphragmatic pleura, and subdiaphragmatic pathology should be considered for example, liver abscess. Central chest pain radiating to the neck and arms is likely to be cardiac. Retrosternal soreness occurs in tracheitis. Malignant invasion of the chest wall causes a constant, severe, dull pain.

Examination of the respiratory system

Examination of the nose and throat are detailed in Chapter 21.

Inspection

Observe the patient as they enter the room or move around the bed. Are they breathless at rest/exertion? Do they have a cough

Box 20.6 Signs to look for in the hands

- Clubbing
- Pallor
- Warm, well-perfused palms (CO_2 retention)
- Cyanosis
- Flap
- Tremor
- Tobacco staining
- Bruising and/or thin skin
- Pulse: rate and character

or wheeze? Assess mental alertness, cyanosis, use of accessory muscles, and chest wall shape, deformity, scars, and movement on both sides. Kyphosis and scoliosis of the spine can cause asymmetry of the chest. CO_2 intoxication causes coarse tremor or flap of the outstretched hands. Prominent veins on the chest may imply obstruction of the superior vena cava. The patient's face may reveal signs of anaemia, or there may be a Horner's syndrome due to a Pancoast tumour.

Respiratory rate and rhythm may be altered; the normal respiratory rate is 14–16 breaths per minute. Tachypnoea is an increased respiratory rate. Apnoea is the absence of breathing; some patients have episodes of apnoea during sleep.

Hands should be inspected for evidence of tobacco staining on the fingers, clubbing, or a fine tremor (Box 20.6).

Cyanosis is a dusky discoloration of the skin and mucous membranes, due to the presence of more than 50 g/L of desaturated haemoglobin. When it has a central cause, cyanosis is visible on the tongue (especially the underside) and lips. Patients with central cyanosis will also be cyanosed peripherally. Peripheral cyanosis without central cyanosis is caused by a reduced peripheral circulation and is noted on the fingernails and skin of the extremities, with associated coolness of the skin.

Finger clubbing is present when the normal angle between the base of the nail and the nail fold is lost (Fig. 20.8). The base of the nail is fluctuant owing to increased vascularity, and there is an increased curvature of the nail in all directions, with expansion of the end of the digit (Box 20.7). Clubbing is not a feature of uncomplicated COPD.

Palpation and percussion

The position of the trachea and apex beat should be checked. The supraclavicular fossa, cervical chains, and axilla are examined for enlarged lymph nodes. The distance between the sternal notch and the cricoid cartilage (3–4 finger-breadths in full expiration) is reduced in patients with severe airflow limitation reflecting hyperinflated lungs. Chest expansion should be checked; a tape measure may be used if precise or serial measurements are needed, such as in ***ankylosing spondylitis***. Local discomfort over the sternochondral joints suggests costochondritis. In rib fractures, compression of the chest laterally and anteroposteriorly produces localized pain. On percussion, liver dullness is usually detected anteriorly at the level of the sixth right-sided rib. Liver and cardiac dullness disappear when the lungs are over-inflated.

Auscultation

The patient is asked to take deep breaths through the mouth. Inspiration should be longer than expiration. Normal breath sounds are caused by turbulent flow in the larynx and sound harsher anteriorly over the upper lobes (particularly on the right). Healthy lungs filter out most of the high-frequency component,

and the resulting sounds are termed vesicular. If the lung is consolidated or collapsed, the high-frequency hissing components of breath are not attenuated and can be heard as 'bronchial breathing'. Similar sounds may be heard over areas of localized fibrosis or bronchiectasis. Bronchial breathing is accompanied by whispering pectoriloquy (whispered, high-pitched sounds heard distinctly through a stethoscope).

Fig. 20.8 Clubbing deformity. The finger on the right is clubbed compared with the normal-shaped finger on the left. *(From Hochberg MC, Gravallese EM, Silman AJ et al.* Rheumatology, *7th edn. Elsevier Inc.; 2019; Fig. 213.2.)*

? Box 20.7 Some causes of finger clubbing

Respiratory
- Bronchial carcinoma, including hypertrophic pulmonary osteoarthropathy
- Chronic suppurative lung disease:
  - Bronchiectasis
  - Lung abscess
  - Empyema
- Idiopathic lung fibrosis
- Pleural and mediastinal tumours (e.g., mesothelioma)
- Cryptogenic organizing pneumonia

Cardiovascular
- Cyanotic heart disease
- Subacute infective endocarditis
- Atrial myxoma

Miscellaneous
- Congenital
- Cirrhosis
- Inflammatory bowel disease
- Thyroid acropachy

Added sounds

Wheeze. Wheeze results from vibrations in the collapsible part of the airways when the large and medium-sized bronchi become constricted. It is usually heard during expiration and is commonly, but not invariably, present in asthma and COPD. In acute severe asthma, wheeze may not be heard, as airflow may be insufficient to generate the sound. Wheezes may be monophonic (single large airway obstruction) or polyphonic (narrowing of many small airways). An end-inspiratory wheeze or 'squeak' may be heard in obliterative bronchiolitis.

Crackles. Brief crackling sounds are probably produced by opening of previously closed bronchioles; early inspiratory crackles are associated with diffuse airflow limitation, while late inspiratory crackles are characteristically heard in pulmonary oedema, lung fibrosis, and bronchiectasis.

Pleural rub. A creaking or groaning sound (said to sound like a foot crunching through fresh snow), which is usually well localized. It indicates inflammation and roughening of pleural surfaces, which no longer glide silently over one another, and is heard in lung infection and consolidation.

Vocal resonance. Healthy lung attenuates high-frequency notes, as compared to the lower-pitched components of speech. Low-frequency sounds such as 'ninety-nine' are well transmitted across healthy lung (vocal resonance/fremitus). Tactile vocal fremitus is the palpation of sound vibration, usually by placing the edge of the hand on the chest wall. Consolidated lung transmits sound more easily than air, thereby resulting in increased vocal resonance/fremitus, whereas pleural fluid severely dampens or obliterates the vibrations altogether. Consolidated lung also transmits high frequencies, so that spoken word has a bleating quality and whispered (high-pitched) speech can be clearly heard over consolidated areas compared to healthy lung (whispered pectoriloquy).

Stridor: see Chapter 21.

Respiratory examination findings in different diseases are detailed in **Box 20.8**.

i Box 20.8 Physical signs of respiratory disease

Pathological process	Mediastinal displacement	Percussion note	Breath sounds	Vocal resonance	Added sounds
Consolidation (i.e., lobar pneumonia)	None	Dull	Bronchial	Increased	Fine crackles
Collapse					
Major bronchus	Towards lesion	Dull	Diminished or absent	Reduced or absent	None
Peripheral bronchus	Towards lesion	Dull	Bronchial	Decreased	Fine crackles
Fibrosis					
Localized	Towards lesion	Dull	Bronchial	Increased	Coarse crackles
Diffuse (e.g., idiopathic lung fibrosis)	None	Normal	Vesicular	Increased	Fine crackles
Pleural effusion (>500 mL)	Away from lesion (in massive effusion)	Stony dull	Vesicular reduced or absent	Reduced or absent	None
Large pneumothorax	Away from lesion	Normal or hyperresonant	Reduced or absent	Reduced or absent	None
Asthma	None	Normal	Vesicular Prolonged expiration	Normal	Expiratory polyphonic wheeze
Chronic obstructive pulmonary disease	None	Normal	Vesicular Prolonged expiration	Normal	Expiratory polyphonic wheeze and coarse crackles
Bronchiectasis	None	Normal	Vesicular	Normal	Coarse crackles

Additional bedside tests

Review measured oxygen saturations and the concentration of additional oxygen received. Inspect any sputum pots. Many patients with respiratory disease have airflow limitation, so airflow should be routinely measured using a peak flow meter or spirometer, which is a more useful assessment of airflow limitation than any physical sign.

Investigation of respiratory disease

Imaging

Imaging is essential in the investigation of most chest symptoms. Some diseases, such as tuberculosis or lung cancer, may be undetectable on clinical examination but may be obvious on a chest radiograph. Conversely, asthma or chronic bronchitis may be associated with a normal chest radiograph. Try to obtain previous images for comparison.

Plain radiograph imaging of the chest is addressed in Chapter 8.

Computed tomography

Computed tomography (CT) provides excellent images of the lungs and mediastinal structures (Fig. 20.9). It is essential in staging bronchial carcinoma by demonstrating tumour size, nodal involvement, metastases, and invasion of mediastinum, pleura, or chest wall. CT-guided needle biopsy allows samples to be obtained from peripheral masses. Staging scans should assess liver and adrenals, which are common sites for metastatic disease. Mediastinal structures are shown more clearly after injecting intravenous contrast medium.

High-resolution CT (HRCT) samples lung parenchyma with 1–2 mm thickness scans at 10–20 mm intervals and is used to assess diffuse inflammatory and infective parenchymal processes. HRCT scanning does not require intravenous contrast. It is valuable in:

- evaluation of diffuse disease of the lung parenchyma, including sarcoidosis, hypersensitivity pneumonitis (HP), occupational lung disease, and any other form of interstitial pulmonary fibrosis
- diagnosis of bronchiectasis, having a sensitivity and specificity of >90%
- distinction of emphysema from both diffuse parenchymal lung disease and pulmonary vascular disease as a cause of a low gas transfer factor with otherwise normal lung function
- suspected opportunistic lung infection in immunocompromised patients
- diagnosis of lymphangitis carcinomatosa.

Multidetector CT scanners can produce detailed images in two or three dimensions in any plane. This allows spaced, contiguous, and/or overlapping HRCT images to be reconstructed. Pulmonary nodules and airway disease can be easily defined.

CT pulmonary angiography (CTPA) is used to investigate for pulmonary embolism and enables visualization of the pulmonary arteries. Contrast is injected and images are taken in timed fashion while the contrast agent is in the pulmonary circulation.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) with electrocardiography (ECG) gating allows accurate imaging of the heart and aortic aneurysms. MRI has been used in staging lung cancer and assessing tumour invasion in the mediastinum, chest wall, and at the lung apex because it produces good images in the sagittal and coronal planes. Vascular structures can be clearly differentiated, as flowing blood produces a signal void on MRI.

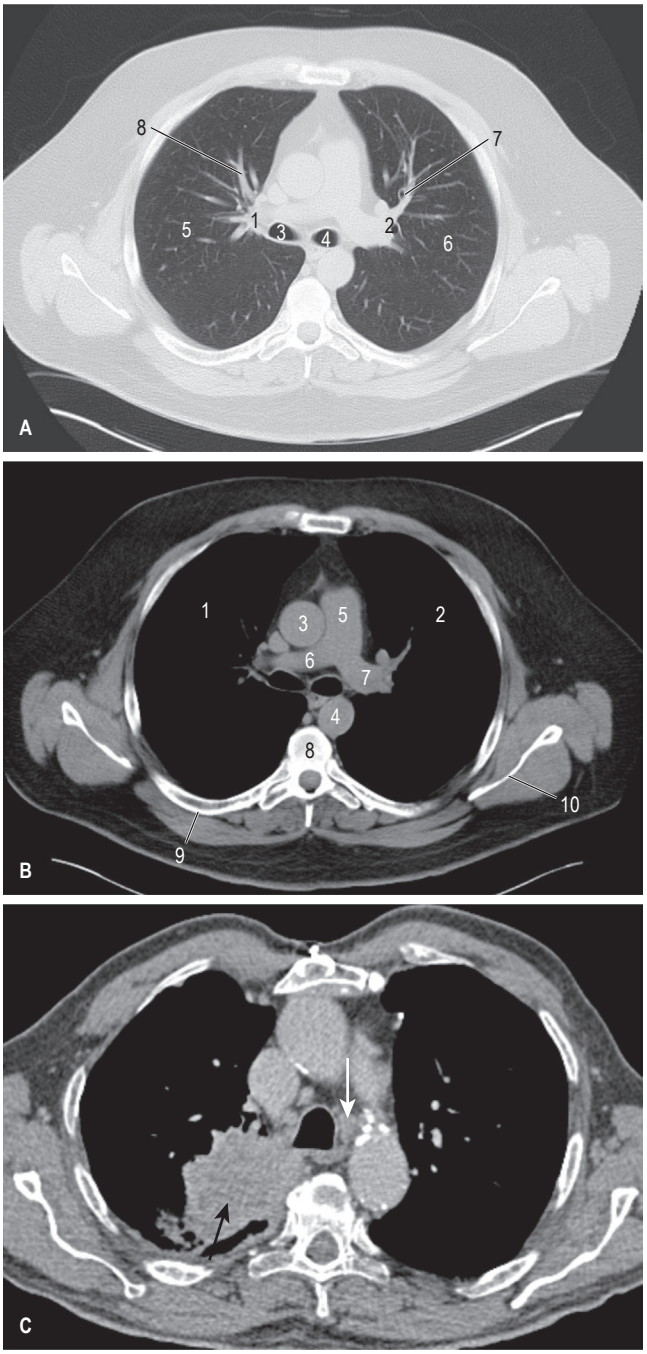

Fig. 20.9 Computed tomography scans of the lung. **(A)** Axial CT image of the thorax on lung settings. (1) Right hilum; (2) left hilum; (3) right main bronchus; (4) left main bronchus; (5) right lung; (6) left lung; (7) bronchus; (8) blood vessel. **(B)** Axial CT image of the thorax on soft tissue settings. (1) Right lung; (2) left lung; (3) ascending aorta; (4) descending aorta; (5) pulmonary trunk; (6) right pulmonary artery; (7) left pulmonary artery; (8) vertebra; (9) rib; (10) scapula. **(C)** CT chest demonstrates a right upper lobe carcinoma that is invading the mediastinum *(black arrow)* and prominent mediastinal lymph nodes *(white arrow)*.

Positron emission tomography–computed tomography

PET-CT combines a CT scan and positron emission tomography. Positron-emitting isotopes such as ^{18}fluorodeoxyglucose (^{18}FDG) are used as contrast and are taken up rapidly by metabolically

active tissue such as lung cancers. PET imaging is used for lung cancer staging prior to curative treatment such as surgery or radiotherapy. FDG-PET can also be useful in determining an appropriate site for a biopsy and can assist with differentiating benign from malignant tumours. Inflammatory lesions may also be FDG-avid.

Scintigraphic imaging

Isotopic ventilation/perfusion (V/Q) lung scans were widely used for the detection of pulmonary emboli but are now performed less often, owing to the widespread use of CTPA. They may be used in pregnancy, where plain chest radiography is normal and other diagnoses are considered unlikely, to reduce radiation exposure to the maternal breast.

Single photon emission computed tomography (SPECT) is increasingly used. It is a three-dimensional nuclear medicine imaging technique that combines information from scintigraphy with that of CT. This offers better detail, contrast, and spatial information than isolated planar nuclear imaging.

Ultrasound

Two-dimensional transthoracic ultrasound is a technique used for assessing a pleural effusion. Ultrasound confirms the presence of pleural fluid and provides details about the nature of the effusion, such as whether it is a simple pleural effusion (single collection), heavily loculated with adhesions or organized (more gelatinous). Ultrasound assists in determining the best site for aspiration and it is recommended that any invasive pleural procedure, such as pleural aspiration and intercostal chest drain placement, is performed with ultrasound screening. Ultrasound-guided biopsy is used for lung masses that abut the pleura or pleural masses, if appropriate. It is also used in bronchoscopy (endobronchial ultrasound, EBUS) to stage and sample mediastinal lymph nodes (see 'Fibreoptic bronchoscopy' section).

Respiratory function tests

Airflow limitation can be assessed by a variety of tests that have good intra-subject repeatability (**Box 20.9**). Results must be compared with predicted values for healthy subjects, as reference intervals vary with sex, age, height, and ethnicity. Even then, there remains considerable variation between healthy individuals of the same size and age; the standard deviation for PEFR is approximately 50 L/min, and for FEV_1 approximately 0.4 L. Repeated measurements of lung function are useful for assessing disease progression.

Spirometry

The patient takes maximum inspiration followed by a forced expiration (for as long as possible) into the spirometer. The spirometer measures the 1-second forced expiratory volume (FEV_1) and the total volume of exhaled gas (forced vital capacity, FVC). Both FEV_1 and FVC are related to height, age, sex, and ethnicity. These measures differentiate between an obstructive and a restrictive pattern of respiratory compromise (**Fig. 20.10**; **Box 20.10**).

In chronic airflow limitation (particularly COPD and asthma), the TLC is usually increased, yet there is nearly always some reduction in the FVC. This is because collapse of small airways causes obstruction to airflow before the normal RV is reached. Trapping of air within the lung is a characteristic feature of these diseases.

Peak expiratory flow rate

Peak expiratory flow rate (PEFR) is a simple, cheap, and reproducible test. Subjects take a full inspiration to TLC and then blow out forcefully into the peak flow meter (**Fig. 20.11**). The best of three attempts is recorded. PEFR is mainly dependent on flow in larger airways and may be falsely reassuring in moderate airflow limitation. PEFR is mainly used to diagnose and monitor asthma, including response to treatment. Regular measurements of peak flow rates on

Box 20.9 Respiratory function and exercise tests

Test	Use	Advantages	Disadvantages
PEFR	Monitoring changes in airflow limitation in asthma	Portable Can be used at the bedside	Effort-dependent Poor measure of chronic airflow limitation
FEV, FVC, FEV_1/FVC	Assessment of airflow limitation (the best single test)	Reproducible Relatively effort-independent	Bulky equipment but smaller portable machines available
Flow–volume curves	Assessment of flow at lower lung volumes Detection of intra- and extrathoracic large-airway obstruction (e.g., tracheal stenosis, tumour)	Flow–volume curve patterns for different diseases	Sophisticated equipment needed for full test but expiratory loop possible with compact spirometry
Airways resistance	Assessment of airflow limitation	Sensitive	Technique difficult to perform
Lung volumes	Differentiation between restrictive and obstructive lung disease	Effort-independent, complements FEV_1	Sophisticated equipment needed
Gas transfer	Assessment and monitoring of extent of interstitial lung disease and emphysema	Non-invasive	Sophisticated equipment needed
Blood gases	Assessment of respiratory failure	Can detect early lung disease when measured during exercise	Invasive
Pulse oximetry	Postoperative, sleep studies and respiratory failure	Continuous monitoring Non-invasive	Measures saturation only
Exercise test (6-min walk)	Practical assessment for disability and effects of therapy	No equipment required	Time-consuming Learning effect At least two walks required
Cardiorespiratory assessment	Early detection of lung/heart disease Fitness assessment	Differentiates breathlessness due to lung or heart disease	Sophisticated equipment needed

waking, during the afternoon, and before going to bed demonstrate the wide diurnal variations in airflow limitation that characterize asthma and allow objective assessment of response to treatment (Fig. 20.12).

Plethysmography

Measurement of airways resistance in a body box is more sensitive than PEFR but the equipment is expensive and necessary manoeuvres are exhausting for many patients with chronic airflow limitation.

Flow–volume loops

Plotting flow rates against expired volume (flow–volume loops, see Fig. 20.5) shows the site of airflow limitation within the lung. At the start of expiration from TLC, maximum resistance is from large airways, which affects flow rate for the first 25% of the curve. Obstruction of large airways includes tracheal narrowing for example, due to tumour or retrosternal goitre. As air is exhaled, lung volume reduces and flow rate becomes dependent on resistance of smaller airways. In COPD, which mainly affects the smaller airways, expiratory flow rates at 50% or 25% of the vital capacity are disproportionately reduced when compared with flow rates at larger lung volumes.

Lung volumes

The subdivisions of lung volume are shown in Fig. 20.13. Tidal volume and vital capacity can be measured using a simple spirometer but alternative techniques are needed to measure TLC and RV. TLC is measured by inhaling air containing a known concentration of helium and measuring its dilution in the exhaled air. TLC measurements using this technique are inaccurate if there are large cystic spaces in the lung because helium cannot diffuse into them. Under these circumstances the thoracic gas volume can be measured more accurately using body plethysmograph (see earlier). RV can be calculated by subtracting the vital capacity from the TLC. The

difference between measurements made by these two methods shows the extent of non-communicating air space within the lungs.

Gas transfer

In normal lungs, transfer factor reflects how efficiently oxygen diffuses from alveolar air into blood, and depends on the thickness of the alveolar–capillary membrane. In lung disease, this diffusing capacity (D_{CO}) is also affected by ventilation and perfusion. Carbon monoxide is used as a surrogate marker to measure this, as it has similar diffusion to oxygen. A low concentration of carbon monoxide is inhaled, and rate of absorption is calculated. To control for differences in lung volume, the uptake of carbon monoxide is expressed relative to lung volume as a transfer coefficient (K_{CO}). Gas transfer is reduced in patients with severe emphysema and fibrosis but also in heart failure and anaemia. Although relatively non-specific, gas transfer is particularly useful in the detection and monitoring of diseases affecting the lung parenchyma (e.g., idiopathic pulmonary fibrosis [IPF], sarcoidosis, and asbestosis). The K_{CO} is raised in pulmonary haemorrhage.

Peripheral oxygen saturation (S_pO_2) can be continuously measured using an oximeter with either ear or finger probe. Pulse oximetry has become an essential part of routine monitoring of patients in hospital and clinics. It is also useful in exercise testing and reduces the need to measure arterial blood gases.

Measurement of blood gases

Measurement of the partial pressures of oxygen and carbon dioxide in arterial blood is essential in managing respiratory failure, when repeated measurements guide therapy (see **Boxes 20.2**, **11.11**, and **20.18**).

Fractional exhaled nitric oxide (FeNO)

Nitric oxide (NO) is produced by the bronchial epithelium and increases in eosinophilic asthma and other forms of airway inflammation. A portable device can be used to measure the concentration of exhaled nitric oxide and guide therapy in asthma.

Six-minute walk test

In this validated test, the distance walked in metres in 6 minutes is recorded. Oxygen saturations and heart rate are also measured.

Cardiopulmonary exercise testing

This provides a functional assessment of cardiopulmonary reserve and provides information about cardiorespiratory and metabolic muscle function. It is usually performed on a treadmill or a cycle ergometer. Oxygen consumption, carbon dioxide production, and ventilation can be calculated. Indications include the investigation of unexplained breathlessness, establishing prognosis in respiratory illnesses, and predicting risk in perioperative assessment.

Nocturnal polygraphy

This multichannel sleep study records heart rate, oxygen saturations, nasal flow, body position, and thoracic and abdominal wall movement. It is useful in the investigation of sleep-disordered breathing.

Haematological and biochemical tests

It is useful to measure:

- ***haemoglobin:*** detects anaemia or polycythaemia
- ***packed cell volume:*** secondary polycythaemia occurs with chronic hypoxia
- ***routine biochemistry:*** abnormalities may be detected in lung cancer and infection
- ***D-dimer:*** a negative test may be helpful when there is low clinical suspicion of pulmonary embolism.

Other blood investigations sometimes required include α_1-antitrypsin concentration, *Aspergillus* antibodies, viral and mycoplasma serology, autoantibody profiles, immunoglobulin concentrations, and specific IgE measurements.

Sputum

Sputum should be inspected for colour:

- Yellowish green indicates inflammation (infection or allergy).
- Blood suggests bronchiectasis, lung cancer, or pulmonary infarction.

Gram stain and culture are rarely helpful in upper respiratory tract infections or in acute or chronic bronchitis. Conversely, they are of value in:

- pneumonia
- tuberculosis (a specific request for acid-fast bacilli [AFB] is required)
- bronchiectasis
- cystic fibrosis.

Sputum cytology

This may be an adjunct in the management of asthma, and is used in research studies. Advantages are speed, cost, and its non-invasive nature. A reliable cytologist is needed. Sputum can be induced by inhalation of nebulized hypertonic saline (5%), although better samples can be obtained by bronchoscopy and bronchial washings.

Pleural aspiration

Diagnostic aspiration may be necessary to determine the aetiology of a pleural effusion, especially if unilateral. This is usually done under ultrasound guidance. A needle is inserted under local anaesthesia through an intercostal space towards the top of the fluid area identified on ultrasound. Fluid is withdrawn and the presence of any blood is noted. Samples are sent for cytology and biochemical analysis (protein estimation, lactate dehydrogenase [LDH], and bacteriological examination, including culture and Ziehl–Neelsen/auramine staining for tuberculosis). Therapeutic aspiration of a large pleural effusion to help relieve breathlessness.

Pleural biopsy

A pleural biopsy may be necessary for a unilateral exudative pleural effusion or suspicious pleural thickening. Pleural biopsies may be obtained using CT or ultrasound guidance. An alternative technique is video-assisted thoracoscopy (VATS). A scope is introduced into the pleural space, allowing direct visualization and biopsy of the parietal pleura. A pleural effusion can be drained during this procedure.

Intercostal drain placement

An intercostal chest drain is an indwelling drain placed in the pleural space using ultrasound guidance (see Box 11.7). Occasionally, a ***long-term pleural drain*** may be needed for recurrent malignant effusions.

Fibreoptic bronchoscopy

This endoscopic procedure performed using local anaesthesia and sedation, allows direct visualization of the endobronchial tree down to the subsegmental level (Fig. 20.14).

Indications for bronchoscopy (Box 20.11) are:

- ***Visualization and biopsy of an endobronchial lesion*** i.e., suspected of malignancy.
- ***Collapsed lung or lobe*** to determine the nature of the obstruction. Causes include aspirated foreign body or mucus plug (removed during the bronchoscopy by suction, forceps, or a dormier basket) and endobronchial tumours (which can be biopsied). Airway patency may be restored by cryotherapy, laser therapy, or stenting.
- ***Microbiological sampling*** in the context of unresolved infection or suspected tuberculosis. Distal lesions may be sampled by washing or blind brushing.
- ***Cytological assessment*** of bronchoalveolar lavage samples may be helpful to diagnose malignancy. Differential cell counts may be useful in differentiating parenchymal lung disease.
- ***Diagnosis of diffuse inflammatory processes*** by bronchoalveolar lavage and transbronchial biopsy. Diagnostic yield is best in sarcoidosis, lymphangitis carcinomatosa, and HP. (Other fibrotic lung diseases may require open or thoracoscopic lung biopsy.)

Endobronchial ultrasound (EBUS) A dedicated scope is used with an ultrasound probe at the distal end, which allows detailed visualization of the mediastinal nodes, under local anaesthesia and sedation. The lymph nodes can be aspirated for cytological and microbiological examination. EBUS is performed when CT imaging shows enlarged mediastinal lymph nodes, for which the differential diagnosis includes sarcoid, tuberculosis, lung cancer, lymphoma, and metastatic disease.

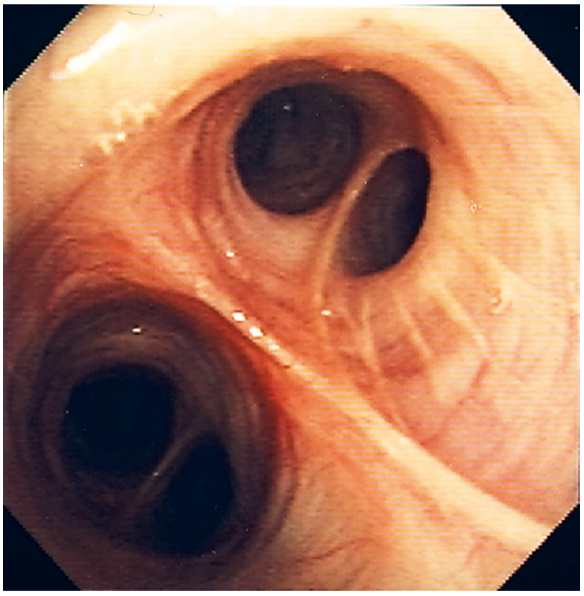

Fig. 20.14 Normal endobronchial appearances seen at fibreoptic bronchoscopy.

Box 20.11 Fibreoptic bronchoscopy

Indications

- Lesions requiring biopsy seen on chest radiograph
- Haemoptysis
- Stridor
- Positive sputum cytology for malignant cells with no chest radiograph abnormality
- Collection of bronchial secretions for bacteriology, especially tuberculosis
- Recurrent laryngeal nerve paralysis of unknown aetiology
- Infiltrative lung disease (to obtain a transbronchial biopsy)
- Investigation of collapsed lobes or segments and aspiration of mucus plugs

Disadvantages

- Sedation required
- Minor and transient cardiac dysrhythmias in up to 40% of patients on passage of the bronchoscope through the larynx. Monitoring is required
- Oxygen supplementation required in patients with P_aO_2 <8 kPa
- Risk of pneumothorax
- Massive bleeding may occur after biopsy, e.g., vascular lesions or carcinoid tumours. Rigid bronchoscopy may be required to allow adequate access for haemostasis

Navigational bronchoscopy is an advanced bronchoscopy technique which enables the operator to reach peripheral pulmonary lesions not accessible by traditional bronchoscopy. It utilizes a traditional bronchoscope, electromagnetic navigation, and software with preloaded CT images which enable guided targeting of small peripheral lesions. It is an alternative to a CT-guided lung biopsy and may be preferable in selected cases.

Mediastinoscopy

This surgical procedure is performed under general anaesthesia. A rigid scope is passed from just above the sternum into the anterior

mediastinum. Mediastinoscopy is used in the diagnosis and staging of nodal disease. Use has declined due to availability of EBUS.

Video-assisted thoracoscopic lung biopsy

VATS lung biopsy has largely replaced open thoracotomy when lung biopsy is required.

Skin-prick tests

Allergen solutions are placed on the skin (usually the volar surface of the forearm) and the epidermis is broken using a 1 mm tipped lancet. A separate lancet should be used for each allergen. Positive and negative controls are also tested. Weal development reveals sensitivity with diameter measured after 10 minutes. A weal of at least 3 mm diameter is regarded as positive, provided the control test is negative. History informs interpretation. Skin tests are not affected by bronchodilators or corticosteroids, but antihistamines should be discontinued at least 48 hours before testing.

Bronchial provocation testing

Airway hyper-responsiveness (AHR) is a characteristic feature of asthma and can be demonstrated by asking patients to inhale gradually increasing concentrations of histamine or methacholine. This induces transient airflow limitation in susceptible individuals (approximately 20% of the population). Severity is graded according to the provocation dose (PD) or concentration (PC) of the agonist that produces a 20% fall in FEV_1. Patients with asthma respond to very low doses of methacholine. AHR can also be assessed by exercise testing or inhalation of cold/dry air, mannitol, or hypertonic saline.

DISEASES OF THE UPPER RESPIRATORY TRACT

Rhinitis

Rhinitis is defined clinically as sneezing attacks, nasal discharge, or blockage occurring for more than an hour on most days.

Viral rhinitis

The common cold (acute coryza) is a highly infectious illness (see Chapter 21) caused by several respiratory viruses including rhinoviruses (most common), coronaviruses, and adenoviruses. Infectivity from personal contact (nasal mucus on hands) or droplets is high in early infection. There are at least 100 different antigenic strains of rhinovirus, making it difficult for the immune system to confer ongoing protection. The incubation period varies from 12 hours to 5 days. Clinical features are tiredness, pyrexia, malaise, and sore nose and pharynx. Sneezing and profuse, watery nasal discharge are followed by thick mucopurulent secretions that may persist for up to a week. Secondary bacterial infection occurs in a minority of cases.

Other forms of rhinitis

Rhinitis can be subdivided by the frequency with which symptoms occur:

1. for a limited period of the year (seasonal or intermittent rhinitis)
2. throughout the whole year (perennial or persistent rhinitis).

Seasonal rhinitis (intermittent)

This is the most common allergic disorder. It is often called 'hay-fever', but as this implies that only grass pollen is responsible, it is better described as seasonal (or intermittent) allergic rhinitis. Common seasonal allergens include tree and grass pollens and mould spores. Since the pollination patterns vary from country to country, seasonal rhinoconjunctivitis and accompanying wheeze may occur at different times of year in different regions. Worldwide prevalence varies from 2%–20%. Prevalence is maximal in the second decade, and up to 30% of UK teenagers and young adults are affected.

Nasal irritation, sneezing, and watery rhinorrhoea occur, but many also suffer from itching of the eyes and soft palate. Itching of the ears can occur due to the common innervation of the pharyngeal mucosa and the ear. Approximately 20% have associated seasonal wheeze.

Perennial rhinitis (persistent)

In about 50% symptoms of sneezing and watery rhinorrhoea predominate, while the other 50% complain mostly of nasal blockage. The patient may lose sense of smell and taste, but rarely has eye or throat symptoms. Sinusitis occurs in about 50% of cases, due to mucosal swelling that obstructs drainage from the sinuses. Perennial rhinitis is most frequent in the second and third decades, decreasing with age; there are a number of common subtypes:

Perennial allergic rhinitis

The most common cause is allergy to the faecal particles of the house-dust mite, *Dermatophagoides pteronyssinus* or *D. farinae* (Fig. 20.15). Mites live off desquamated human skin scales and the highest concentrations (4000 mites/g of surface dust) are found in human bedding. The next most common allergens are proteins derived from the skin or urine or saliva spread over the surface of domestic pets (especially cats). Allergy to urinary proteins from small mammals is a major cause of morbidity among laboratory workers. Industrial dust, vapours, and fumes cause occupationally related perennial rhinitis more often than asthma. The presence of perennial rhinitis makes the nose more reactive to non-specific stimuli, such as cigarette smoke, washing powders, household detergents, strong perfumes, and traffic fumes. Although patients often think they are allergic to these stimuli, these are irritant responses and do not involve antibodies.

Perennial non-allergic rhinitis with eosinophilia

No extrinsic allergic cause can be identified, either by history or skin testing, but eosinophilic granulocytes are present in nasal secretions. Most of these patients are intolerant of aspirin/non-steroidal anti-inflammatory drugs (NSAIDs).

Vasomotor rhinitis

Rhinitis occurs without demonstrable allergy or nasal eosinophilia. Watery secretions and nasal congestion are triggered by, for example, cold air, smoke, perfume, or newsprint, possibly because of an imbalance of the autonomic nerves controlling the erectile tissue (sinusoids) in the nasal mucosa.

Investigations and diagnosis

Allergic factors causing rhinitis can usually be identified from the history. Skin-prick testing supports the history. A positive test does not mean that an allergen is the cause of respiratory disease, but it is likely to be relevant if there is a compatible clinical history.

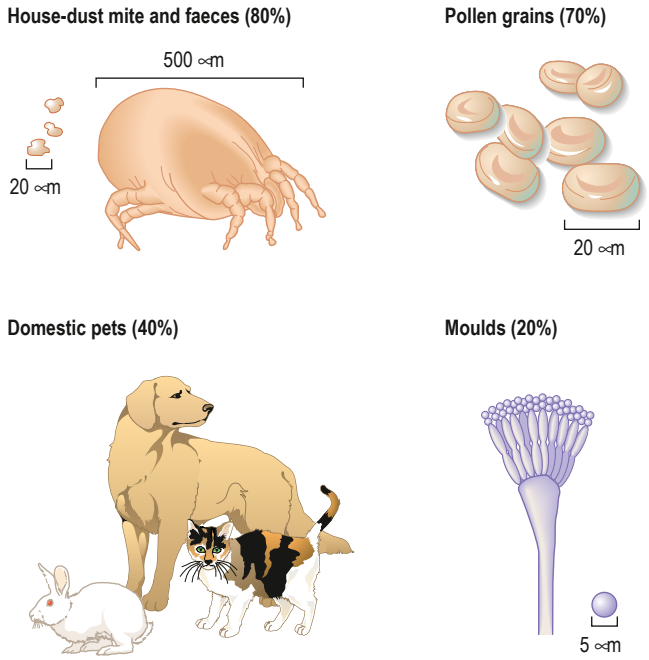

Fig. 20.15 Common allergens causing allergic rhinitis and asthma. These include the house-dust mite, faeces of house-dust mites, pollen grains, domestic pets, and moulds. Percentages indicate the proportion of positive skin-prick tests to these allergens in patients with allergic rhinitis.

Allergen-specific IgE antibodies can be measured in blood but such tests are much more expensive than skin tests and should be used only in patients who cannot be skin-tested for some reason (e.g., dermatographism, eczema, inability to stop antihistamines).

Management

Allergen avoidance

Removal of a household pet or total enclosure of industrial processes releasing sensitizing agents can lead to cure of rhinitis and, indeed, asthma. However, pollen avoidance is impossible. Contact may be diminished by wearing sunglasses, driving with car windows shut, avoiding countryside walks (particularly in late afternoon, when pollen grain number at ground level is highest), and keeping bedroom windows shut at night, those these measures are rarely sufficient in themselves to control symptoms. Exposure to pollen is generally lower in coastal regions, where sea breezes carry pollen grains inland. Exposure to mite allergen can be reduced by enclosing bedding in fabric specifically designed to prevent its passage, while allowing water vapour through. This is comfortable and reduces symptoms. Acaricides (substances toxic to mites) are less effective and not recommended. Increased room ventilation and reduced soft furnishings help to reduce the mite load.

H_1 antihistamines

Antihistamines remain the most common therapy for rhinitis. In the UK, most can be purchased without prescription. They are particularly effective against sneezing and itching of the eyes and palate, but are less effective against rhinorrhoea, and have little influence on nasal blockage. First-generation antihistamines (chlorphenamine, hydroxyzine) cause sedation and loss of concentration in all patients and are no longer used. Second-generation drugs include loratadine (10 mg once daily), desloratadine (5 mg daily), cetirizine (10 mg daily), and fexofenadine (120 mg daily) are at least as potent and do not cause sedation.

Decongestants

Drugs with sympathomimetic activity (α-adrenergic agents) are widely used to treat nasal obstruction. They may be taken orally or, more commonly, as nasal drops or sprays (e.g., ephedrine nasal drops). Xylometazoline and oxymetazoline are widely used because they have a prolonged action and tachyphylaxis does not develop. Secondary nasal hyperaemia can occur some hours later as a rebound effect and *rhinitis medicamentosa* can develop if patients take increasing quantities of decongestant to try and treat this phenomenon. Although local decongestants are an effective treatment for vasomotor rhinitis, patients must be warned about rebound nasal obstruction and should use the drugs carefully. Ideally, preparations should be prescribed for only a limited period to open the nasal airways and allow better access for other local therapy, such as topical corticosteroids.

Anti-inflammatory drugs

Sodium cromoglicate and nedocromil sodium act by blocking an intracellular chloride channel and influence mast cell and eosinophil activation and nerve function. Topical sodium preparations can be very effective in allergic conjunctivitis but are of limited value in allergic rhinitis.

Corticosteroids

The most effective treatment for rhinitis is a topical corticosteroid preparation (e.g., beclometasone, fluticasone propionate, fluticasone furoate). Topical steroids should be started before the beginning of seasonal symptoms. The combination of a topical corticosteroid with a non-sedating antihistamine taken regularly is particularly effective. Patients should be carefully instructed in nasal steroid device use to achieve optimal drug deposition. In selected cases an α-adrenergic agonist may help to decongest the nose prior to taking the topical corticosteroid. Nasal steroids can cause epistaxis but the amount used is insufficient to cause systemic steroid side-effects.

If other therapy has failed, a short course of corticosteroids could be considered with oral prednisolone 0.5 mg/kg for 5 to 10 days in adults. Nasal polyps may respond to oral corticosteroids and their recurrence may then be prevented by continuous use of topical corticosteroids.

Leukotriene antagonists

If there is no response to antihistamines or topical steroids, a leukotriene antagonist (e.g., montelukast 10 mg daily in the evening) may be helpful, especially in patients with a history of NSAID sensitivity or concomitant asthma.

Immunotherapy

This is used for patients with seasonal allergic rhinitis who have not responded to standard drugs (see Chapter 21).

Nasal polyps

These are round, smooth, soft, semitranslucent, pale or yellow, glistening structures attached to the sinus mucosa by a relatively narrow stalk or pedicle, occurring in patients with allergic or vasomotor rhinitis. The mechanism(s) of their formation is not known. They contain mast cells, eosinophils, and mononuclear cells in large numbers and cause nasal obstruction, loss of smell and taste, and mouth breathing. Sneezing is rare since the mucosa of the polyp is largely denervated.

Pharyngitis

The most common viruses causing pharyngitis are adenoviruses. Endemic adenovirus infection causes sore throat, in which the oropharynx and soft palate are reddened, and tonsils are inflamed and

swollen. Within 1–2 days tonsillar lymph nodes enlarge. Over several decades the proportion of sore throats due to bacterial infections, such as haemolytic streptococcus, has fallen. Pharyngitis is usually self-limiting and requires symptomatic treatment, with no role for antibiotics. Persistent and severe tonsillitis may be managed with phenoxymethypenicillin 500 mg four times daily, cefalexin 500 mg three times daily, or clarithromycin 500 mg bd. Amoxicillin and ampicillin should be avoided if there is a possibility of infectious mononucleosis (see Chapter 42), due to drug rash development.

Acute laryngotracheobronchitis

Acute laryngitis is an occasional but striking complication of upper respiratory tract infections, particularly those caused by parainfluenza viruses and measles. The condition is most severe in children under the age of 3 years. Inflammatory oedema extends to the vocal cords and the epiglottis, causing narrowing of the airway, with associated ***tracheitis*** or ***tracheobronchitis***. The voice becomes hoarse, and there is a barking cough (croup) and audible stridor. Progressive airways obstruction may occur, with recession of the soft tissue of the neck and abdomen during inspiration and, in severe cases, central cyanosis. Steam inhalations are not helpful. Nebulized adrenaline (epinephrine) gives short-term relief. Oral or intramuscular corticosteroids (e.g., dexamethasone) should be given, with oxygen and fluids if clinically indicated. Endotracheal intubation and tracheostomy are rarely required.

Acute epiglottitis

Haemophilus influenzae type b (Hib) can cause life-threatening infection of the epiglottis, usually in children under 5 years of age. High fever occurs and severe airflow obstruction may develop rapidly. This is a life-threatening emergency and requires urgent endotracheal intubation and intravenous antibiotics (e.g., ceftriaxone, chloramphenicol). The epiglottis, which is red and swollen, should not be inspected until facilities to maintain the airways are available.

Other manifestations of Hib infection are meningitis, septic arthritis, and osteomyelitis. A highly effective vaccine is routinely offered in the UK to infants, given at 2, 3, and 4 months with a booster at about 12 months of age. Vaccination has reduced death rates from Hib infections virtually to zero.

Influenza

The influenza virus belongs to the orthomyxovirus group and exists in two main forms, A and B. Influenza B is associated with localized outbreaks of mild disease, whereas influenza A causes worldwide pandemics (see Chapter 42).

Clinical features

The incubation period of influenza is usually 1–3 days. The illness starts abruptly with a fever, shivering, and myalgia. This is associated headache, sore throat, and a dry cough that can persist for several weeks. Diarrhoea occurs in 70% of cases of H5N1 ('bird flu').

Complications

Secondary bacterial infection is common, particularly with *Streptococcus pneumoniae* and *H. influenzae*. Secondary pneumonia caused by *Staphylococcus aureus* is rarer but more severe, with mortality of up to 20%. Post-infectious encephalomyelitis is rare. Influenza infection can be followed by a prolonged period of debility and depression.

Diagnosis and management

Laboratory diagnosis is not usually necessary in the community, but definitive diagnosis can be established via nasopharyngeal swabs. Testing is undertaken for hospital inpatients to facilitate appropriate infection control.

Management is supportive and includes rest and paracetamol; antibiotics should be considered if secondary infection is suspected, particularly in vulnerable patients such as those with chronic bronchitis or cardiac or kidney disease. Neuraminidase inhibitors, such as oseltamivir and zanamivir, are recommended in high-risk individuals, and, if possible, should be given within 48 hours of first symptoms. Inpatients should have respiratory isolation measures in place to avoid cross-infection.

Prophylaxis

Protection by influenza vaccines is effective in about 70% of people and lasts for about a year. New vaccines are prepared annually according to predicted viral antigenicity. Routine vaccination is recommended in the UK for those aged 65 years or more, and for younger people at risk of severe disease including those with heart, lung, and kidney disease, diabetes, and any who are immunosuppressed. Front-line healthcare workers are also offered vaccination annually. Egg-free vaccines are available for those with allergy to egg proteins.

Inhalation of foreign bodies

Children inhale foreign bodies more commonly than adults. Risk factors for inhalation include excess alcohol and general anaesthesia (loose teeth or dentures). When the foreign body is large, it may impact the trachea. The person chokes and then becomes silent; death ensues unless the material is quickly removed. Guidelines for the management of choking should rapidly be followed (**Box 20.12**). More often, impaction occurs in the right main bronchus and produces choking and persistent monophonic wheeze. It may lead to a suppurative pneumonia and/or lung abscess.

Cough

Cough is one of the most common respiratory symptoms. Acute cough lasts less than 3 weeks, chronic cough persists for more than 8 weeks, with the term subacute cough used between 3 and 8 weeks.

Acute cough

Acute cough is often associated with upper respiratory tract infection, particularly in the winter months (**Box 20.13**). Any patient with worrying symptoms or signs including haemoptysis, breathlessness, fever, weight loss, night sweats, chest pain, or foreign body inhalation, should have an urgent chest radiograph to exclude

Box 20.12 Sequence of steps for managing adult foreign body airway obstruction

Suspect: suddenly unable to talk, particularly if eating
Cough: encourage to cough
Back blows: if cough becomes ineffective, give up to five back blows:
- Lean the person forwards
- Apply blows between the shoulder blades using the heel of one hand

Abdominal thrusts: if back blows are ineffective, give up to 5 abdominal thrusts
- Stand behind the person and put both your arms around their upper abdomen
- Lean the person forwards
- Clench your fist and place it between umbilicus and ribcage
- Grab your fist with the other hand and pull upwards

Alternate: if choking not relieved after 5 abdominal thrusts, continue alternating 5 back blows with 5 abdominal thrusts until it is relieved, or the person becomes unresponsive.
CPR: if the person becomes unresponsive, start CPR

CPR, Cardiopulmonary resuscitation.
Reproduced with the kind permission of Resuscitation Council UK.

Box 20.13 Causes of cough

Cause	Example
Respiratory disease	Viral or bacterial infection, bronchospasm, chronic obstructive pulmonary disease, non-asthmatic eosinophilic asthma, bronchiolitis, malignancy, parenchymal disease (e.g., interstitial lung disease, bronchiectasis, cystic fibrosis, sarcoidosis), pleural disease, aspiration
Upper airways disease	Postnasal drip, sinusitis, inhaled foreign body, tonsillar enlargement
Cardiovascular disease	Heart failure, mitral stenosis
Gastro-oesophageal disease	Gastro-oesophageal reflux disease, also associated with laryngopharyngeal reflux
Neurological disease	Aspiration
Drugs and irritants	Angiotensin-converting enzyme (ACE) inhibitors, cigarette smoke

malignancy, pneumonia, and tuberculosis. Most acute cough is self-limiting, and antibiotics are not indicated.

Chronic cough

All patients with a chronic cough should have a chest radiograph and those with abnormalities should be investigated. If the chest radiograph is normal, then the most likely diagnoses are undiagnosed asthma, postnasal drip, gastro-oesophageal reflux disease, recent upper respiratory tract infection, or smoking. Spirometry should be performed, and reversible airways obstruction treated as asthma. It is important to identify treatable traits that may cause cough. An individual may have more than one treatable trait. If spirometry is normal, patients should have a trial of treatment for the most likely cause based on their history:

Potential treatable traits:

- **angiotensin-converting enzyme (ACE) inhibitor:** convert to angiotensin receptor antagonist
- ***nocturnal cough or wheeze:*** trial of oral or inhaled steroids
- ***acid reflux:*** trial of a proton pump inhibitor
- ***postnasal drip:*** trial of topical nasal steroids
- ***smoking:*** referral to the local smoking cessation service
- ***obstructive sleep apnoea:*** assessment and weight loss, consider CPAP therapy
- ***cough hypersensitivity:*** cough control, speech, and language therapy, low dose opiates or gabapentin
- ***anxiety and depression:*** reassurance, psychological intervention as necessary.

If a chronic cough does not settle after empirical treatment and the aetiology remains unclear, further investigations might include CT chest, bronchoscopy, bronchial provocation testing, oesophageal manometry, and sinus imaging. Referral to a specialist cough clinic may be available.

OBSTRUCTIVE RESPIRATORY DISEASE

Asthma

Asthma is a common chronic condition, the cause of which is incompletely understood. Symptoms include wheeze, chest tightness, cough, and shortness of breath, often worse at night. Asthma commonly starts in childhood between the ages of 3 and 5 years and may either worsen or improve during adolescence. Classically, asthma has three characteristics:

- ***airflow limitation:*** usually reversible spontaneously or with treatment
- ***airway hyper-responsiveness:*** to a wide range of stimuli
- ***bronchial inflammation:*** T-lymphocytes, mast cells, eosinophils with plasma exudation, oedema, smooth muscle hypertrophy, matrix deposition, mucus plugging, epithelial damage.

In chronic asthma, inflammation leads to irreversible airflow limitation as a result of large and small airway wall remodelling and mucus impaction.

Prevalence

In many countries, the prevalence of asthma has increased since the mid-1980s, particularly in children and young adults, with up to 15% of the population affected. Asthma is more common in high-income countries, with some of the highest prevalence in the UK, New Zealand, and Australia, and lower rates in East Asia, Africa, and Eastern Europe. Long-term follow-up in low- and middle-income countries suggests that asthma prevalence may increase with adoption of a 'Westernized' lifestyle though the environmental factors accounting for this remain unknown. Studies of occupational asthma suggest that a large proportion of the workforce (15%–20%) may become asthmatic if exposed to potent sensitizers. Worldwide, over 300 million people have asthma and the disease kills approximately 1000 people per day.

Classification

Asthma is a complex disorder with symptoms caused by several different mechanisms. Asthma can be classified according to trigger factors, age of onset, inflammatory subtypes, or response to therapy, with considerable overlap.

Childhood-onset asthma is commonly a wheezing illness with inhaled allergic triggers. Up to 90% of children and 70% of adults with persistent asthma have positive skin-prick tests to common inhalant allergens such as dust mite, animal danders, pollens, and fungi. Childhood-onset asthma is often accompanied by eczema.

Adult-onset asthma is often triggered by respiratory infections. Nevertheless, many patients show positive allergen skin tests and, on close questioning, some of these will give a history of childhood respiratory symptoms suggesting allergic asthma. Non-atopic individuals may develop asthma in middle age from extrinsic causes, such as sensitization to occupational agents like toluene diisocyanate, intolerance to NSAIDs, or prescription of β-adrenoceptor-blocking agents that block the protective effect of endogenous catecholamines. Extrinsic causes must be considered in all asthma and avoided if possible.

Asthma can also be classified as eosinophilic or non-eosinophilic. Eosinophilic airway inflammation is often present in asthma particularly in patients with more severe symptoms.

Aetiology

The major factors involved in the development of asthma and stimuli that can precipitate attacks are shown in **Fig. 20.16**.

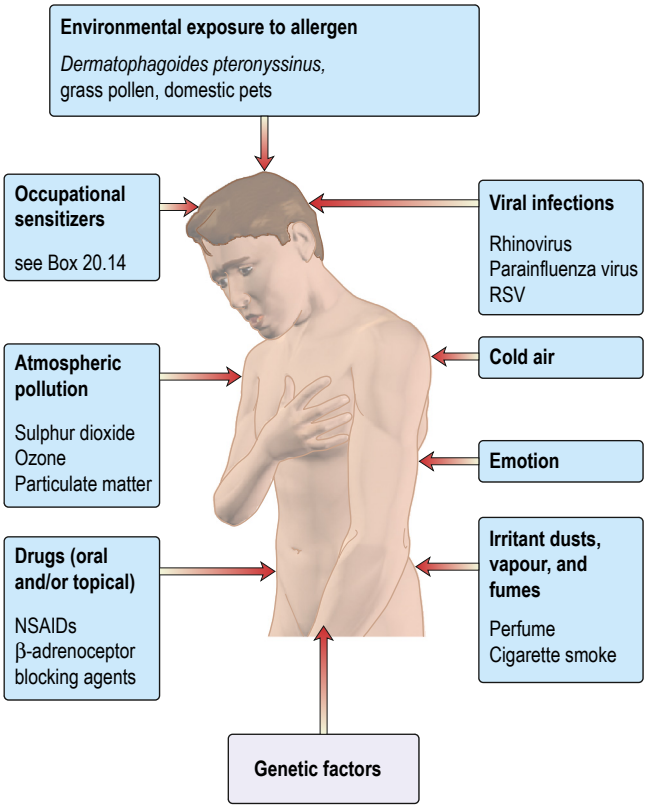

Fig. 20.16 Causes and triggers of asthma. *NSAIDs,* Non-steroidal anti-inflammatory drugs; *RSV,* respiratory syncytial virus.

Atopy and allergy

The term 'atopy' describes a group of disorders, including asthma and hayfever, that run in families, have positive skin-prick tests to common inhalant allergens, and have circulating allergen-specific antibodies. Allergen-specific IgE is present in 30%–40% of the UK population, and elevated serum IgE concentrations are linked to airway hyper-responsiveness and the prevalence of asthma. Serum total IgE concentrations are affected by genetic and environmental factors.

Genetic factors: There is no single gene for asthma. Several genes appear to influence asthma development, in combination with environmental factors, including genes involved cytokine and IgE synthesis.

Environmental factors: Early childhood exposure to allergens and maternal smoking influence IgE production. Intestinal bacteria and childhood infections are hypothesized to shape the immune system in early life. Growing up in a relatively 'clean' environment may predispose to an IgE response to allergens ('hygiene hypothesis'). Conversely, growing up in a 'dirtier' environment may prevent the immune system from developing allergic responses, with early-life exposure to inhaled and ingested products of microorganisms reducing subsequent risk of allergy and asthma.

The allergens involved in allergic asthma are similar to those in rhinitis, although pollens are less implicated in asthma. Most patients with allergic asthma are sensitized to house-dust mite allergens. Allergens from furry pets (especially cats) are increasingly common. Cockroach allergy has been implicated in asthma in inner-city children in the USA. Fungal spores from *Aspergillus fumigatus* cause a range of lung disorders, including asthma.

? Box 20.14 Occupational asthma

Cause	Source/occupation
Low molecular weight (non–IgE-related)	
Isocyanates	Polyurethane varnishes Industrial coatings Spray painting
Colophony fumes	Soldering/welders Electronics industry
Wood dust	
Drugs	
Bleaches and dyes	
Complex metal salts, e.g., nickel, platinum, chromium	
High molecular weight (IgE-related)	
Allergens from animals and insects	Farmers, workers in poultry and seafood processing industry; laboratory workers
Antibiotics	Nurses, health industry
Latex	Health workers
Proteolytic enzymes	Manufacture (but not use) of 'biological' washing powders
Complex salts of platinum	Metal refining
Acid anhydrides and polyamine hardening agents	Industrial coatings

Occupational sensitizers

Over 250 materials encountered in the workplace can cause occupational asthma, which accounts for up to 15% of all asthma (**Box 20.14**). Patients in insurable employment are eligible for statutory compensation, provided they apply within 10 years of leaving the occupation in which the asthma developed.

Asthma can be due to:

- low-molecular-weight compounds, e.g., reactive chemicals such as isocyanates and acid anhydrides that bond chemically to epithelial cells to activate them, as well as providing haptens recognized by T cells
- high-molecular-weight compounds, e.g., flour, organic dusts, and other large protein molecules involving specific IgE antibodies.

The proportion of employees developing occupational asthma depends primarily on the level of exposure. Enclosure of industrial processes and appropriate ventilation reduce risk. Atopic individuals develop occupational asthma more rapidly when exposed to agents triggering development of specific IgE antibody. Non-atopic individuals can also develop asthma when exposed to such agents, but after a longer period of exposure. Smoking increases the risk of developing some forms of occupational asthma.

Non-specific factors

Due to their AHR (airway hyper-responsiveness), patients with asthma will respond to a wide variety of non-specific direct and indirect stimuli, as well as reacting to specific allergens.

Cold air and exercise

Most asthmatics wheeze after prolonged exercise or inhalation of cold, dry air. Typically, the attack does not occur while exercising but afterwards. Exercise-induced wheeze is driven by release of histamine, prostaglandins (PGs), and leukotrienes (LTs) from mast cells, as well as stimulation of neural reflexes.

Atmospheric pollution and irritant dusts, vapours, and fumes

Many patients with asthma experience worsening of symptoms on exposure to tobacco smoke, car exhaust fumes, solvents, strong perfumes, or high concentrations of airborne dust. Major epidemics have been recorded when large amounts of allergens are released into the air, and asthma exacerbations increase during summer and winter air pollution episodes associated with climatic temperature inversions: in the presence of high concentrations of ozone, particulates, and NO_2 in the summer and particulates, NO_2 and SO_2 in the winter.

Diet

Increased intake of fresh fruit and vegetables has been shown to be protective, possibly owing to antioxidants or other protective molecules such as flavonoids. Genetic variation in antioxidant enzymes is associated with more severe asthma.

Emotion

Emotional factors influence both acute and chronic asthma. Patients at high risk of life-threatening attacks are understandably anxious, but there is no evidence patients with asthma have more psychological pathology than peers without asthma.

Drugs

NSAIDs, particularly aspirin, indomethacin, and ibuprofen, are implicated in triggering asthma in approximately 5% of patients. NSAID intolerance is especially prevalent in those with nasal polyps and asthma, and is often associated with rhinitis and flushing on drug exposure.

Beta-blockers. Parasympathetic innervation of the airways leads to bronchoconstriction. There is no direct sympathetic innervation of bronchial smooth muscle, so antagonism of parasympathetically induced bronchoconstriction is critically dependent on circulating adrenaline (epinephrine) acting through β_2-receptors on the surface of smooth muscle cells. Inhibition by non-selective β-adrenoceptor-blocking drugs (e.g., propranolol, carvedilol) leads to bronchoconstriction and airflow limitation in asthmatic subjects. Selective β_1-adrenergic-blocking drugs (e.g., atenolol, bisoprolol) may also induce attacks of asthma.

Clinical features

The principal symptoms of asthma are wheezing attacks and episodic shortness of breath. Symptoms are usually worst during the night. Cough is a frequent symptom that sometimes predominates, especially in children, in whom nocturnal cough can be a presenting feature. Attacks vary greatly in frequency and duration and may be precipitated by a wide range of triggers (see **Fig. 20.16**). Asthma is a major cause of impaired quality of life and has an impact on work and recreation, affecting both physical activities and emotions.

Investigations

There is no single satisfactory diagnostic test for all patients with asthma.

Lung function tests

PEFR measurements on waking, before bed, and prior to and after taking a bronchodilator are useful in demonstrating the variable airflow limitation that characterizes asthma (see **Figs 20.11 and 20.12**). Diurnal variation in PEFR is a good measure of asthma activity and aids longer-term assessment of the disease and response to treatment.

Spirometry is useful, especially in assessing reversibility. Asthma can be diagnosed by demonstrating a greater than 15% improvement in FEV_1 or PEFR following inhalation of a bronchodilator. Carbon monoxide (CO) transfer is normal in asthma.

Interpretation of results

In asthma there is evidence of airflow obstruction (FEV_1:FVC ratio <75%) AND evidence of variation. Variation means that lung function tests can range from normal to severely obstructed in a single individual.

Evidence of variation may include

- Post-bronchodilator improvement of FEV_1 >12% or 200 mL compared to pre-bronchodilator values (measure spirometry pre and post 200–400 mcg inhaled salbutamol). An increase of >15% or 400 mL provides greater assurance.
- Average diurnal variation in peak flow of >10% (measured twice daily over a 2-week period)
- Significant increase in lung function after 4 weeks of anti-inflammatory treatment—improvement of FEV_1 >12% or 200 mL compared to pre-bronchodilator values
- Positive bronchial challenge test: drop in FEV_1 >20% with standard doses of inhaled methacholine or >15% with mannitol
- Variation of FEV_1 of >12% or >200 mL between visits (in absence of infection).

Fractional exhaled nitric oxide (FeNO)

This test is a measure of airway inflammation and corticosteroid response. The trend in the values can help to determine a response to, or failure of, treatment. FeNO is measured in parts per billion (ppb). FeNO <25 ppb is considered normal in a treatment naïve patient, or controlled inflammation in a patient on steroid treatment. FeNO 25–50 ppb is intermediate. FeNO >50 ppb is high and indicative of airways inflammation.

Blood and sputum tests

Patients with asthma sometimes have increased numbers of eosinophils in peripheral blood (>0.4 × 10^9/L) but sputum eosinophilia is a more specific diagnostic finding.

Chest radiograph

There are no diagnostic features of asthma on chest radiography, although overinflation is characteristic during an acute episode or in chronic severe disease. A chest radiograph excludes a pneumothorax, which can occur as a complication of asthma, and in detection the pulmonary infiltrates associated with allergic bronchopulmonary aspergillosis.

Skin tests

Skin-prick tests should be performed in all asthma to help identify allergic trigger factors. Allergen-specific IgE can be measured in serum if skin-prick test facilities are not available, the patient is taking antihistamines, or no suitable allergen extracts are available.

Allergen provocation tests

Allergen inhalation challenge is a useful research tool. It is required when investigating patients with suspected occupational asthma but not in ordinary asthma.

Management

The ***aims of treatment*** are to:

- abolish symptoms
- restore normal or best possible lung function
- reduce the risk of severe attacks
- enable normal growth in children
- minimize absence from school or employment.

This involves:

- patient and family education about asthma
- patient participation in treatment
- avoidance of identified triggers where possible
- the lowest effective doses of convenient medications to minimize short-term and long-term side-effects.

Many people with asthma join self-help groups to improve understanding of disease and to foster self-confidence and fitness.

Control of extrinsic factors

Where specific allergen triggers are identified, these should be avoided if possible. Sublingual allergen immunotherapy (SLIT) with house-dust mites reduces the number of asthma attacks in children and is now being developed for management of asthma in adults. Active and passive smoking should be avoided, as should beta-blockers in both tablet and eye-drop form. Individuals intolerant to aspirin should avoid NSAIDs, although they may tolerate cyclo-oxygenase-2 (COX-2) inhibitors. About one-third of individuals sensitized to occupational agents may be cured if they permanently avoid exposure.

Drug treatment

The mainstay of asthma therapy is use of inhaled therapeutic agents, delivered as aerosols or powders directly into the lungs (**Box 20.15**). The advantages of this method are drug delivery direct to the airways avoiding first-pass metabolism in the liver; thus lower doses are necessary and systemic side-effects are minimized. To help those who cannot coordinate aerosol activation and inhalation, breath-activated and dry powder devices have been developed. Patients vary in ability to use such devices. Care should be taken in device selection and education.

Box 20.15 Inhaled therapy for asthma

Patients should be taught how to use inhalers and their technique should be checked regularly.

Use of a metered-dose inhaler

1. The canister is shaken.
2. The patient exhales to functional residual capacity (not residual volume), i.e., normal expiration.
3. The aerosol nozzle is placed to the open mouth.
4. The patient simultaneously inhales rapidly and activates the aerosol.
5. Inhalation is completed.
6. The breath is held for 10 sec if possible.

Even with good technique, only 15% of the contents is inhaled; 85% is deposited on the wall of the pharynx and ultimately swallowed.

Spacers

- Plastic cones/spheres inserted between the patient's mouth and the inhaler, or in-built extension to inhaler.
- Designed to reduce particle velocity so less drug is deposited in the mouth.
- Diminish the need for coordination between aerosol activation and inhalation.
- They are useful in all who find inhaler technique difficult, e.g., children, elderly.
- Reduced risk of oral candidiasis.

Several national and international guidelines have been published on the treatment of asthma (**Fig. 20.17**) based on three principles:

- Asthma should be self-managed with an agreed, individualized, documented treatment plan including monitoring using PEFR.
- Asthma is an inflammatory disease, so anti-inflammatory (controller) therapy should be started, even in mild cases.
- Short-acting inhaled bronchodilators (e.g., salbutamol and terbutaline) should be used only to relieve breakthrough symptoms. Increased use of bronchodilator treatment to relieve increasing symptoms is an indication of deteriorating disease.

A list of drugs used in asthma is shown in **Box 20.16**. These are used in a stepwise fashion, as indicated in **Fig. 20.17**.

Beta$_2$-adrenoceptor agonists

Beta$_2$-adrenoceptor agonists are selective for the respiratory tract and do not stimulate the β_1 adrenoceptors of the myocardium. These drugs relax bronchial smooth muscle and are effective in relieving symptoms, but do not affect underlying airways inflammation.

- ***Short-acting β agonists (SABAs):*** salbutamol 100 μg (albuterol in the USA) or terbutaline 250 μg. SABAs without inhaled corticosteroids are no longer recommended in the management of asthma.
- ***Long-acting β_2-adrenoceptor agonists (LABAs):*** salmeterol or formoterol are effective by inhalation for up to 12 hours and are given once or twice daily. They are used in combination with an inhaled corticosteroid as fixed-dose combinations (e.g., salmeterol/fluticasone and formoterol/budesonide) in the same inhaler.

SABA treatment should no longer be used alone, even for management of mild symptoms. The Global Initiative for Asthma 2023 recommends that the first step in management of chronic asthma is a combination inhaled corticosteroid-formoterol inhaler as needed, or inhaled corticosteroids whenever a SABA is taken as needed.

Inhaled corticosteroids

Inhaled corticosteroids (ICS) are now recommended for all patients with asthma. Beclometasone dipropionate (BDP) is the most widely used inhaled steroid and is available in doses of 50, 100, 200, and 250 μg per puff. Other inhaled steroids include budesonide, fluticasone propionate, fluticasone furoate, mometasone furoate, and triamcinolone. Side-effects of inhaled steroids include oral thrush and hoarseness; patients should be instructed to rinse their mouths after use. Subcapsular cataract formation is rare but can occur in the elderly. Osteoporosis is less likely than with oral steroids but can occur with high-dose inhaled corticosteroids (beclometasone or budesonide >800 μg daily). In children, inhaled corticosteroid doses above 400 μg daily retard short-term growth, although final heights are not affected. Inhaled corticosteroid use should be stepped down to the minimum effective dose once asthma is under control.

Oral corticosteroids and steroid-sparing agents

Oral corticosteroids are needed for acute exacerbations. Acute exacerbations of asthma in adults should be treated with 40 to 50 mg prednisolone for 5 to 7 days. The benefit of short-term treatment with prednisolone 30 mg daily as measured by PEFR is shown in **Fig. 20.12**. Steroids are rarely used longer term, and only when other drug regimens do not control symptoms. The dose should be kept as low as possible to minimize side-effects. Steroid-sparing agents should be considered to allow discontinuation of oral steroid use. These include monoclonal antibodies, low-dose methotrexate, and ciclosporin.

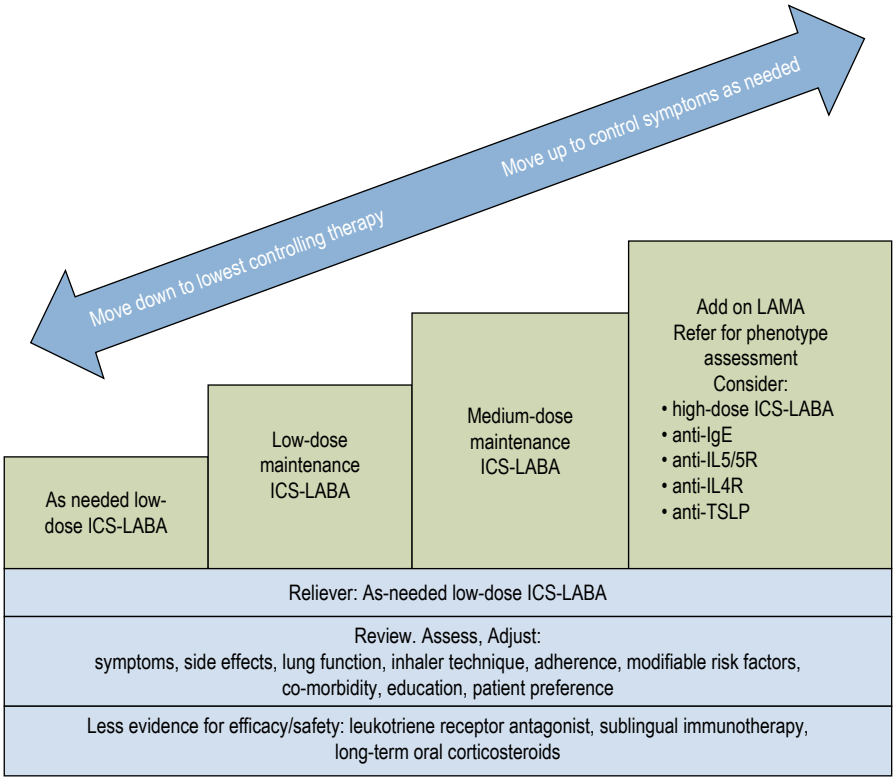

Fig. 20.17 Summary of asthma management in adults. *ICS,* Inhaled corticosteroid; *LABA,* long-acting β agonist; *LTRA,* leukotriene receptor antagonist; *MART,* maintenance and reliever therapy. *(Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention, 2023. Updated July 2023. Available from www.ginasthma.org.)*

Box 20.16 Drugs used in asthma

Short-acting relievers
- Inhaled β_2 agonists (e.g., salbutamol [albuterol in the USA], terbutaline)

Long-acting relievers/disease controllers
- Inhaled long-acting β_2 agonists (e.g., salmeterol, formoterol)
- Inhaled corticosteroids (e.g., beclometasone, budesonide, fluticasone)
- Compound inhaled long-acting β_2 agonists and corticosteroids (e.g., salmeterol and fluticasone)
- Sodium cromoglicate
- Leukotriene modifiers (e.g., montelukast, zafirlukast, zileuton)

Other agents with bronchodilator activity
- Inhaled antimuscarinic agents (e.g., ipratropium, oxitropium, aclidinium)
- Theophylline preparations

Other
- Oral corticosteroids (e.g., prednisolone 40 mg daily)

Steroid-sparing agents
- Anti-IgE monoclonal antibody: omalizumab
- Anti-interleukin monoclonal antibody: mepolizumab, benralizumab, dupilumab, reslizumab
- Ciclosporin
- Methotrexate
- Intravenous immunoglobulin

Leukotriene receptor antagonists

Therapy targets the cysteinyl LT1 receptor. Montelukast, pranlukast, and zafirlukast are given orally. They are effective in some patients with asthma, though prediction of effectiveness is difficult: a 4-week trial of leukotriene receptor antagonist (LTRA) therapy is recommended before a decision is made to continue or stop. LTRAs should be tried if disease is not controlled on low to medium doses of inhaled steroids; action is additive to that of LABAs. LTRAs are particularly useful in patients with aspirin-intolerant asthma. These drugs are also helpful in asthma combined with rhinitis, and in young children with asthma and/or virus-associated wheezing

Antimuscarinic bronchodilators

Muscarinic receptors are found in the respiratory tract: large airways contain mainly M_3 receptors, and the peripheral lung tissue contains M_3 and M_1 receptors. Nebulized short-acting ipratropium is used in acute severe exacerbations of asthma (**Box 11.21** in Acute medicine chapter). There is no benefit to long-term use of inhaled, short-acting antimuscarinic agents. Longer-acting, inhaled antimuscarinics (tiotropium, aclidinium) are considered in the latest guidelines at Step 4 if symptoms are not controlled despite medium to high dose ICS-LABA.

Anti-inflammatory drugs

Sodium cromoglicate and nedocromil sodium prevent activation of inflammatory cells, but are no longer recommended in the treatment of asthma due to their low efficacy.

Monoclonal antibodies

Omalizumab, a recombinant humanized monoclonal antibody directed against IgE, chelates free IgE and downregulates number and activity of mast cells and basophils. It is given subcutaneously every 2–4 weeks, depending on total serum IgE concentration and body weight. It is cost-effective in patients with frequent exacerbations requiring oral corticosteroids. Mepolizumab, reslizumab and

benralizumab target interleukin-5 (IL-5) or its receptor. Dupilumab (targets interleukin-4 and interleukin-13 signalling) and tezepelumab (targets thymic stromal lymphopoietin [TSLP], reducing a broad spectrum of biomarkers and cytokines) are other alternatives. They are effective in eosinophilic asthma and are cost-effective in patients with recurrent exacerbations despite high-dose inhaled corticosteroids.

Antibiotics

There is little evidence that antibiotics are helpful in managing patients with acute asthma. During acute exacerbations, yellow or green sputum containing eosinophils and bronchial epithelial cells may be coughed up. This is usually due to viral rather than bacterial infection and antibiotics are not required. There is mixed evidence in severe asthma for long-term treatment with the macrolide antibiotic azithromycin, which has both anti-inflammatory and antibacterial actions.

Bronchial thermoplasty

Bronchial thermoplasty is an approach for patients who still have symptoms despite optimization of treatment and referral to a specialist asthma centre. This bronchoscopic procedure uses radiofrequency radiation to heat the bronchial wall and reduce the mass of airway smooth muscle, decreasing bronchoconstriction. Long-term risks and benefits are under evaluation. With the advent of biologic therapies this procedure is not performed often.

Asthma attacks

Exacerbations of asthma are most associated with reduced adherence to treatment, respiratory virus infection, or exposure to an allergen or triggering drug. Whenever possible, patients should have a personalized documented plan to implement in anticipation, or at the start, of an exacerbation, which includes early use of a short course of oral corticosteroids. If the PEFR is >150 L/min, patients may improve dramatically with nebulized therapy and may not require hospital admission. Regular treatment should be increased, to include treatment with prednisolone 40 to 50 mg for 5 to 7 days, followed by inhaled corticosteroids. Short courses of oral prednisolone can be stopped without tailing down the dose.

The diagnosis and management of acute severe asthma is detailed in the Acute medicine chapter (see Chapter 11).

Further reading

Global Initiative for Asthma. *Global Strategy for Asthma Management and Prevention*, 2023. Updated July 2023. Available from www.ginasthma.org.

Acute bronchitis

Acute bronchitis is an acute inflammation of the bronchi, usually due to viral infection. It is most commonly a mild self-limiting condition with symptoms lasting a few days, which does not cause long-term complications. Asthma in contrast is a relapsing and remitting condition due to genetic and environmental factors.

Acute bronchitis illness begins with an irritating, non-productive cough, together with discomfort behind the sternum. There may be associated chest tightness, wheezing, and shortness of breath. The cough becomes productive, with yellow or green sputum. Wheeze with occasional crackles can be heard on auscultation. There is a mild fever and a neutrophil leucocytosis. In otherwise healthy adults, the disease improves spontaneously in 4–8 days without serious illness.

Acute bronchitis in those without underlying lung disease is most commonly viral. In most cases, antibiotics are not indicated. Secondary bacterial infection with *S. pneumoniae* or *H. influenzae* is more likely in cigarette smokers and those with COPD.

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is characterized by airflow limitation that is not fully reversible. Airflow limitation is usually progressive. It is associated with and abnormal inflammatory response of the lungs to noxious particles or gases, with destruction of lung parenchyma. COPD is an overarching diagnosis that includes a number of clinical syndromes: emphysema, small airways disease, and chronic bronchitis. There is hyperinflation of the lungs, ventilation/perfusion mismatch, increased work of breathing, and breathlessness. Association with co-morbidities (ischaemic heart disease, hypertension, diabetes, heart failure, cancer), means that it may be part of a generalized, systemic, inflammatory process.

Epidemiology and aetiology

COPD is caused by long-term exposure to toxic particles and gases. In high-income countries, cigarette smoking accounts for over 90% of cases. Only 10%–20% of smokers develop COPD, suggesting underlying individual susceptibility. In low-income countries, inhalation of smoke from biomass heating fuels and cooking in poorly ventilated areas may contribute. The effects of urbanization, air pollution, deprivation, and occupation are difficult to separate from smoking. Animal studies suggest that diet could be a risk factor for COPD but there are limited human data.

The economic burden of COPD is considerable. In the UK, COPD causes approximately 20 million lost working days annually, accounting for about 7% of sick-leave days. Nevertheless, the number of admissions to UK hospitals due to COPD has been falling since the mid-1980s.

Pathophysiology

Airways inflammation and structural changes within the airways and the lung parenchyma are evident. Increased mucus-producing goblet cells in the bronchial mucosa lead to chronic bronchitis (**Figs. 20.18 and 20.19**) and development of airflow limitation. Acute and chronic inflammation is seen on endobronchial biopsies with a predominance of neutrophils, CD8-predominant lymphocytes, and macrophages. Chronic inflammation results in scarring and fibrosis of small airways. Inflammatory destruction of the alveolar walls results in emphysema. The clinical phenotype of the disease differs depending on the predominance of small airways disease, emphysema, or chronic bronchitis.

Emphysema

Emphysema is defined as abnormal and permanent enlargement of air spaces distal to the terminal bronchiole, accompanied by destruction of their walls. It is classified according to distribution:

- ***Centri-acinar emphysema*.** Distension and damage of lung tissue are concentrated around the respiratory bronchioles, while more distal alveolar ducts and alveoli tend to be well preserved. This form of emphysema is extremely common.
- ***Pan-acinar emphysema*.** Distension and destruction affect the whole acinus, and in severe cases the lung is just a collection of bullae. Severe airflow limitation and mismatch occur. This is

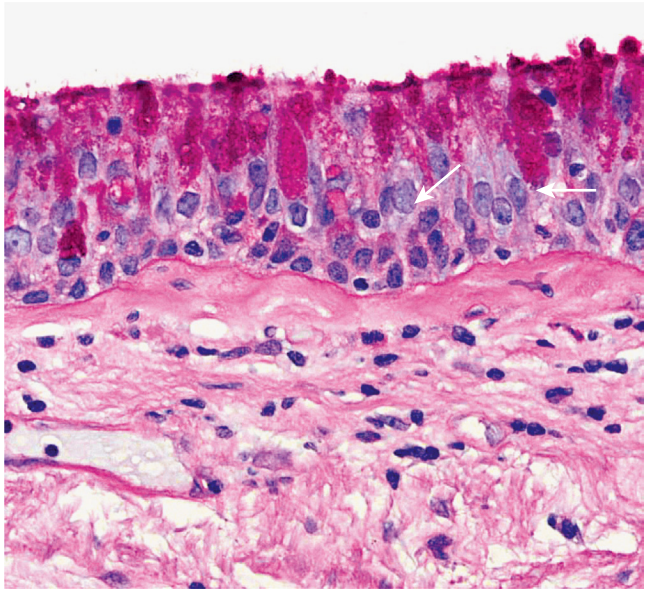

Fig. 20.18 Chronic obstructive pulmonary disease (COPD). Section of bronchial mucosa stained for mucus glands by periodic acid–Schiff (PAS) showing an increase in mucus-secreting goblet cells *(arrowed)*. (*Courtesy of Dr J Wilson and Dr S Wilson, University of Southampton.*)

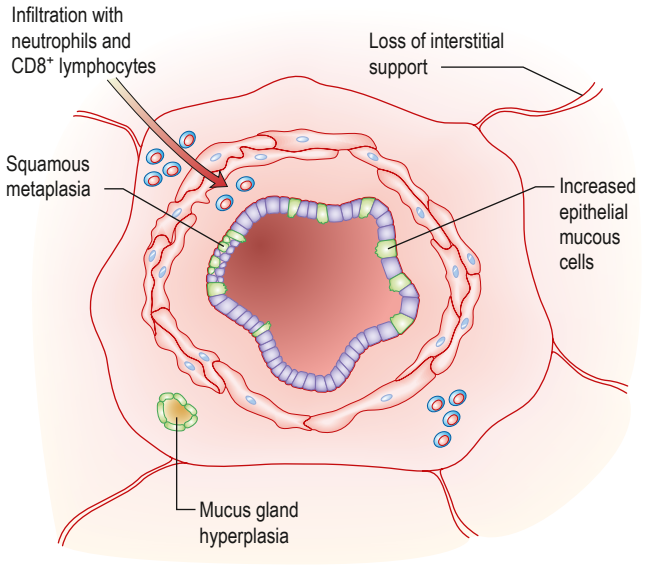

Fig. 20.19 Pathological changes in the airways in chronic obstructive pulmonary disease.

less common than the centri-acinar disease. α_1-antitrypsin deficiency causes pan-acinar disease (see later).

- ***Irregular emphysema*.** There is scarring and damage that affect the lung parenchyma patchily, independent of acinar structure.

Emphysema leads to expiratory airflow limitation and air trapping. The loss of lung elastic recoil results in an increase in TLC. Premature closure of airways limits expiratory flow while the loss of alveoli decreases gas transfer.

The historical ***Fletcher and Peto studies*** (Fig. 20.20) showed a FEV_1 loss of 50 mL per year in patients with COPD compared with 20 mL per year in healthy people. More recent data shows a 40 mL loss per year in only 38% of patients studied. Biomarkers to predict rate of lung function decline have not yet been identified.

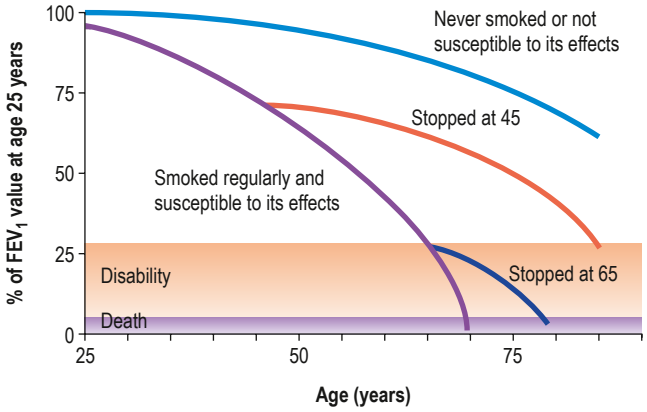

Fig. 20.20 Influence of smoking on airflow limitation. FEV_1, Forced expiratory volume in 1 sec. *(From Fletcher CM, Peto R. The natural history of chronic airflow obstruction*. Bri Med J *1977; 1:1645.)*

Chronic bronchitis

This clinical syndrome of COPD is defined as a daily productive cough for 3 months per year for 2 consecutive years.

Pathogenesis

Cigarette smoking

Bronchoalveolar lavage and airway biopsies in smokers show an increased number of neutrophil granulocytes. These granulocytes release elastases and proteases; an imbalance between protease and antiprotease activity is a factor in development of emphysema. Mucous gland hypertrophy in larger airways is thought to be a direct response to persistent irritation from inhalation of cigarette smoke. An adverse effect on surfactant favours over-distension of the lungs.

Infections

Respiratory infections are a common precipitant of acute exacerbations of COPD. It is less clear whether infection contributes to disease progression. Prompt use of antibiotics and routine vaccination against influenza, SARS-CoV-2, and pneumococci are appropriate.

Alpha$_1$-antitrypsin deficiency

Alpha$_1$-antitrypsin is a proteinase inhibitor produced in the liver and secreted into blood with diffusion into the lung. It inhibits proteolytic enzymes such as neutrophil elastase, which can destroy alveolar wall connective tissue. In α_1-antitrypsin deficiency, accumulation in the liver leads to low concentrations in the lung. More than 75 alleles of the α_1-antitrypsin gene have been described. The three main phenotypes are MM (normal), MZ (heterozygous deficiency), and ZZ (homozygous deficiency). Hereditary deficiency of α_1-antitrypsin accounts for about 2% of emphysema in the UK.

Clinical features

Symptoms

Characteristic symptoms are productive cough with white or clear sputum, wheeze, and breathlessness. Individuals are prone to lower respiratory tract infections. Systemic effects include hypertension, osteoporosis, depression, weight loss, reduced muscle mass and weakness, and right heart failure.

Signs

In mild COPD there may be no signs or quiet wheeze throughout the chest. In severe disease the patient is tachypnoeic, with

prolonged expiration and accessory muscle use. Intercostal indrawing on inspiration and pursing of the lips on expiration is seen. The cricosternal distance is reduced. Chest expansion is reduced. Lungs are hyperinflated with loss of the normal cardiac and liver dullness.

Patients who maintain a respiratory response to CO_2 are usually breathless and rarely cyanosed. Heart failure and oedema are also rare, except as terminal events. In contrast, patients whose respiratory drive is insensitive to CO_2 are often oedematous and cyanosed, but not particularly breathless. Hypercapnia leads to peripheral vasodilation, a bounding pulse, and a coarse flapping tremor of the outstretched hands. Severe hypercapnia causes confusion and progressive drowsiness. Papilloedema may be present but it is specific or sensitive for diagnosis. Patients in later-stage disease develop respiratory failure, pulmonary hypertension, and cor pulmonale.

Degree of breathlessness may be recorded using the Medical Research Council (MRC) dyspnoea score, while the COPD Assessment Test (CAT) is a patient-scored symptom tool that measures the disease's impact on individual health and wellbeing (**Box 20.17**).

Diagnosis

Diagnosis is usually clinical, based on history of breathlessness and sputum production in a chronic smoker. In the absence of cigarette smoking, asthma, and α_1-antitrypsin deficiency should be considered. No specific clinical feature is diagnostic. Lung hyperinflation also occurs in other diseases such as asthma and centri-acinar emphysema may be present without signs of over inflation. A 'barrel-shaped' but this can also occur in osteoporosis.

Investigations

- ***Lung function tests*** show evidence of airflow limitation (see **Fig. 20.10**). Post-bronchodilator FEV_1:FVC ratio is reduced to less than 0.7 (in contrast to asthma) and the PEFR is low. Airflow limitation is not fully reversible (change in FEV_1 <15%). Lung volumes may be normal or increased. Carbon monoxide gas transfer factor is low when significant emphysema is present. The severity of COPD is classified by the degree of airflow limitation (see **Box 11.39** in Acute medicine chapter).
- ***Chest radiograph*** is often normal, even in advanced disease. Possible features include over-inflation of the lungs with low, flattened diaphragms, and sometimes the presence of large bullae. Blood vessels may be 'pruned', with large proximal vessels and relatively little blood visible in peripheral lung fields.
- ***CT*** may be useful to confirm emphysema if there is diagnostic uncertainty. It may also be helpful to determine the distribution of emphysema and to look for coexistent pathology such as bronchiectasis.
- **A nuclear perfusion scan** may be useful in determining suitability for lung volume reduction surgery or endobronchial valve placement.
- ***Haemoglobin concentration and packed cell volume*** can be increased because of persistent hypoxaemia (see secondary polycythaemia, Chapter 38).
- ***Blood eosinophil count*** >300 cells per microlitre is associated with a greater risk of exacerbations and identifies benefit from inhaled corticosteroid therapy.
- ***Blood gases*** for evidence of respiratory failure.
- ***Sputum examination.*** Many acute episodes have a viral trigger. *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* can also cause infective exacerbation.
- ***ECG*** is often normal. Pulmonary hypertension secondary to COPD leads to a tall P-wave (P pulmonale), right bundle branch block, and right ventricular hypertrophy.
- ***Echocardiography*** is indicated to assess cardiac function where there is disproportionate dyspnoea.
- ***α_1-Antitrypsin*** concentrations and genotype are measured in premature disease and life-long non-smokers.
- ***Bone densitometry*** is considered in those at risk of osteoporosis, e.g., frequent courses of oral corticosteroids.

Box 20.17 COPD Assessment Test (CAT)

The score ranges from 0–40. The higher the score, the greater the impact on the patient:

<10 low impact, 10–20 medium impact, 20–30 high impact, >30 very high impact. The CAT score helps to identify what symptoms may need to be treated and may guide the treatment plan.

(From Jones PW, Harding G, Berry P et al. Development and first validation of the COPD Assessment Test. Eur Respir J *2009; 34:648–654.)*

Management

See **Fig. 20.21** for management strategies.

Smoking cessation

The single most useful treatment is smoking cessation. Even in advanced disease, this may slow down the rate of deterioration and prolong time before disability and death (see **Fig. 20.20**). Smoke from burning biomass fuels in poorly ventilated homes should be reduced whenever possible.

Drug therapy

This is used both for short-term management of exacerbations and long-term relief of symptoms.

Bronchodilators

Inhaled bronchodilator therapy helps manage symptoms. When choosing the device, it is important to check inhaler technique to ensure appropriate delivery. Pressurized metered dose inhalers contribute to greenhouse gas emissions and should be avoided if an appropriate alternative can be used. If using a dry powder inhaler, it is important to assess peak inspiratory flow to ensure the necessary inspiratory flow to achieve effective drug delivery.

- ***β-Adrenoceptor agonists:*** Many patients with mild COPD feel less breathless after inhaling a β-adrenergic agonist such as salbutamol (200 μg every 4–6 h). In more severe airway limitation (moderate and severe COPD) a long-acting β_2 agonist (LABA) should be used.
- ***Antimuscarinic drug:*** Regular use of a long-acting antimuscarinic agent (LAMA) such as inhaled tiotropium improves lung function, symptoms of dyspnoea, and quality of life. Use of a LAMA does not prevent decline in FEV_1.
- ***Combination inhalers:*** LABA/LAMA inhalers are available and may aid adherence.
- ***Theophyllines:*** Long-acting preparations of theophylline are of little benefit in COPD.

Phosphodiesterase type 4 inhibitors

Roflumilast is a phosphodiesterase inhibitor with anti-inflammatory properties. It is used as an adjunct to bronchodilators for

maintenance treatment in those patients with an FEV_1 of less than 50% and chronic bronchitis.

Corticosteroids

Inhaled corticosteroids (ICS) are recommended in patients with frequent exacerbations or a FEV_1 of less than 50% predicted. Demonstration of a blood eosinophilia may identify patients more likely to have a beneficial response. High-dose inhaled steroids are not advised, as use is linked to increased rates of pneumonia. Triple therapy combination inhalers which include LABA/LAMA/ICS are available. Oral corticosteroids are only prescribed in the context of an acute exacerbation.

Antibiotics

Prompt antibiotic treatment shortens bacterial exacerbations and use may prevent hospital admission and further lung damage. Patients can be given antibiotics to keep at home, starting them as soon as sputum turns yellow or green. In patients who experience frequent exacerbations, long-term treatment with macrolide antibiotics such as azithromycin has been shown to reduce exacerbations and improve quality of life.

Mucolytic agents

These reduce sputum viscosity. Meta-analysis data shows that mucolytics such as carbocysteine are useful in preventing exacerbations in those who experience them frequently.

Biologic therapy

Currently, biologic therapies are not licensed for the treatment of COPD. Promising results in Phase III trials suggest they may emerge as a treatment option in the future.

Oxygen therapy

Two controlled trials (predominantly in males) showed improved survival with continuous administration of oxygen at 2 L/min via nasal prongs to achieve an oxygen saturation of more than 90% for large proportions of the day and night. Survival curves from these two studies are shown in Fig. 20.22. Only 30% of those not receiving long-term oxygen therapy survived for more than 5 years. A fall in pulmonary artery pressure was achieved if oxygen was given for 15

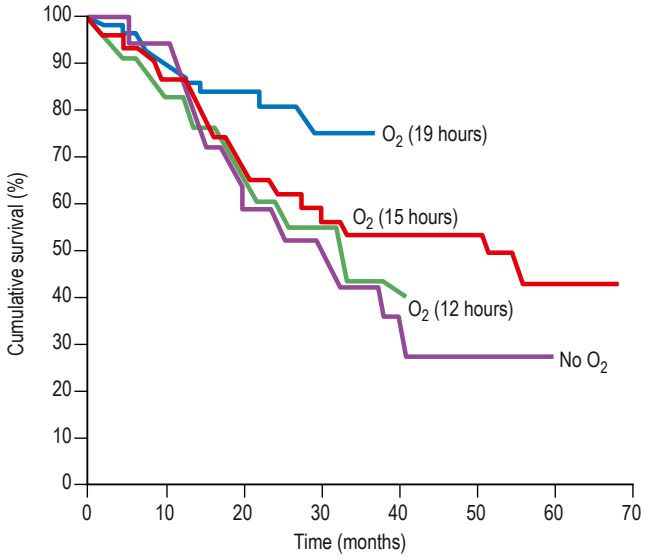

Fig. 20.22 Cumulative survival curves for patients with COPD receiving domiciliary oxygen. Oxygen doses are in hours per day.

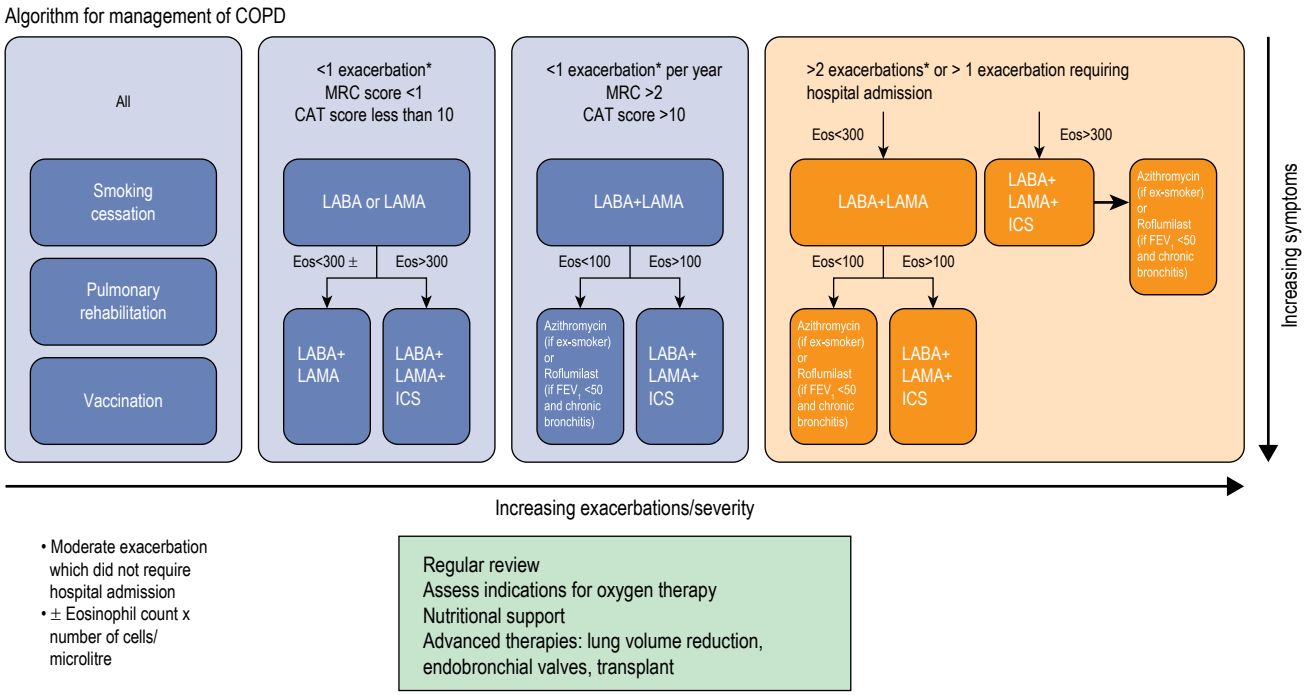

Fig. 20.21 Algorithm for the treatment of chronic obstructive pulmonary disease. The various components of management based on dyspnoea scores, exacerbation frequency, and eosinophil counts. (*Adapted from Pharmacological treatment of stable COPD, in Global Initiative for Chronic Obstructive Lung Disease (GOLD). Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease report 2023.*)

hours daily, but substantial improvement in mortality was achieved only by administration of oxygen for 19 hours daily. Domiciliary oxygen is best provided via an oxygen concentrator. Long-term continuous domiciliary oxygen therapy is available for patients with:

- P_aO_2 of <7.3 kPa (55 mmHg) when breathing air. Measurements should be taken on two occasions at least 3 weeks apart after appropriate bronchodilator therapy (Box 20.18)
- P_aO_2 of <8 kPa with secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema, or evidence of pulmonary hypertension
- carboxyhaemoglobin of <3% (i.e., patients who have stopped smoking).

Pulmonary rehabilitation

Pulmonary rehabilitation courses are an essential part of management in COPD. Randomized control trials have shown benefits in improving symptoms of fatigue and dyspnoea, as well as exercise tolerance.

Additional measures

- ***Vaccines*.** Patients with COPD should be offered a single dose of the polyvalent pneumococcal polysaccharide vaccine and annual influenza vaccinations. SARS-CoV-2 vaccination is offered in line with national programmes.
- ***Nutrition*.** Additional metabolic requirements due to systemic inflammation and increased work of breathing should be assessed.
- ***α_1-antitrypsin replacement*.** Weekly or monthly infusions of α_1-antitrypsin are recommended for patients with serum concentrations <310 mg/L and abnormal lung function. Whether this modifies long-term progression has not been determined.
- ***Heart failure*.** This should be treated according to best practice (see Chapter 17). Systematic reviews and population studies that have assessed the use of beta-blockers in COPD suggest a reduction in mortality. Cardioselective beta-blockers have not been shown to affect lung function tests. Beta-blockers should be prescribed in line with cardiovascular risk factors with observation for breathlessness.
- ***Secondary polycythaemia*.** Venesection if packed cell volume >55%.
- ***Sensation of breathlessness*.** Breathing techniques and fan therapy may be helpful. Short-acting sedation such as sublingual lorazepam or opiates may be a helpful palliative measure for intractable dyspnoea.
- ***Air travel*.** Commercial aircraft are pressurized to the equivalent of 2000–2400 m altitude. In those without lung disease, this causes P_aO_2 to fall from 13.5–10 kPa and a 3% drop in oxygen saturation. Patients with moderate COPD may desaturate significantly. Air travel can be simulated by breathing 15% oxygen at sea level and if saturation drops below 85% within 15 min, supplemental oxygen is required for air travel.
- ***Surgery*.** Some patients have large emphysematous bullae that reduce lung capacity. Bullectomy theoretically enables adjacent areas of collapsed lung to re-expand, improving lung function. Lung volume reduction surgery in carefully selected patients with severe COPD (FEV_1 <1 L) has shown improved ventilation and a reduced sensation of breathlessness but no mortality benefit. A controlled trial in severe emphysema found no disease improvement and increased mortality. ***Single lung transplantation*** (see 'Lung and heart–lung transplantation' section) is considered in end-stage emphysema.
- ***Endobronchial valves*.** These occlude the airways of hyperinflated emphysematous lungs, effectively achieving lung volume reduction. Studies have shown an improvement in quality of life and exercise tolerance in selected patients.
- ***Palliative care*.** Specialist palliative care input can aid in the management of breathlessness and advanced care planning.

Acute exacerbation of COPD

The diagnosis and management of an acute exacerbation of COPD is addressed in Chapter 11 ('Exacerbation of chronic obstructive pulmonary disease [COPD]' section).

Prognosis of COPD

Poor prognostic factors include increasing age and worsening airflow limitation (decreasing FEV_1). The BODE (***B***ody mass index, degree of airflow ***O***bstruction, ***D***yspnoea, and ***E***xercise capacity) predictive index is shown in Box 20.19. A patient with a BODE index of 0–2 has a 4-year mortality rate of 10%, compared with 80% in someone with a BODE index of 7–10. This scoring tool may be useful in timing of referral for consideration of lung transplantation.

Box 20.18 Guidelines for home oxygen use in adults

- Chronic obstructive pulmonary disease with P_aO_2 <7.3 kPa when breathing air during a period of clinical stability
- Chronic obstructive pulmonary disease with P_aO_2 7.3–8 kPa in the presence of secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema, or evidence of pulmonary hypertension
- Severe chronic asthma with P_aCO_2 <7.3 kPa or persistent disabling breathlessness
- Diffuse lung disease with P_aO_2 <8 kPa or P_aO_2 >8 kPa with disabling dyspnoea
- Cystic fibrosis with P_aO_2 <7.3 kPa or P_aO_2 7.3–8 kPa in the presence of secondary polycythaemia, nocturnal hypoxaemia, pulmonary hypertension, or peripheral oedema
- Pulmonary hypertension without parenchymal lung involvement with P_aO_2 <8 kPa
- Obstructive sleep apnoea despite continuous positive airways pressure therapy, after specialist assessment
- Pulmonary malignancy or other terminal disease with disabling dyspnoea
- Heart failure with a daytime P_aO_2 <7.3 kPa on air or with nocturnal hypoxaemia

(*British Thoracic Society guidelines, June 2015*)

Obstructive sleep apnoea

Obstructive sleep apnoea (OSA) is a form of sleep-disordered breathing characterized by upper airway collapse, resulting in obstructive apnoeas and hypopnoeas with desaturation. Prevalence is 3%–5% of the population, most common in overweight,

Box 20.19 BODE index: B = *B*ody mass index, O = degree of airflow *O*bstruction, D = *D*yspnoea, E = *E*xercise capacity

Variable	Points on BODE index			
	0	1	2	3
FEV_1 (% of predicted)	≥65	50–64	36–49	≤35
Distance walked in 6 min (m)	≥350	250–349	150–249	≤149
MMRC dyspnoea scale[a]	0–1	2	3	4
Body mass index	>21	≤21		

[a]Scores on the modified Medical Research Council (MMRC) dyspnoea scale range from 0 to 4, a score of 4 indicating that the patient is breathless when dressing.

Box 20.20 Symptoms in obstructive sleep apnoea (OSA)

Symptom	% of patients with OSA
Loud snoring	95
Daytime sleepiness	90
Unrefreshed sleep	40
Restless sleep	40
Morning headache	30
Nocturnal choking	30
Reduced libido	20
Morning 'drunkenness'	5
Ankle swelling	5

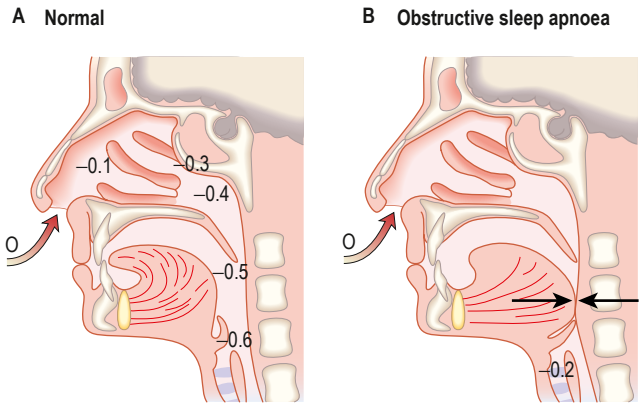

Fig. 20.23 Section through head, showing pressure changes in normal subjects and patients with obstructive sleep apnoea (OSA). **(A)** There is a pressure drop during inspiration as air is sucked through the turbinates. Changes are shown in kPa. **(B)** In OSA this is sufficient to collapse the pharynx *(arrowed on right)*, obstructing inspiration.

middle-aged males. Prevalence increases with age, menopause, obesity, and endocrine conditions such as acromegaly and hypothyroidism. OSA prevalence is predicted to rise with increasing obesity in the population. OSA can occur in children, particularly those with enlarged tonsils or trisomy 21. Major symptoms of OSA and their frequency are listed in Box 20.20.

Pathophysiology

During sleep, activity of respiratory muscles is reduced, especially during rapid eye movement (REM) sleep when the diaphragm is virtually the only active muscle. Apnoeas occur when the oropharyngeal airway closes in inspiration during sleep. This is prevented during waking by upper airway muscles (genioglossus and palatal muscles), but these become hypotonic during sleep (Fig. 20.23). Partial narrowing results in snoring, critical narrowing causes hypopnoea, and complete occlusion causes apnoea. Apnoea leads to hypoxia and increasingly strenuous respiratory efforts to overcome resistance. The combination of central hypoxic stimulation and the effort to overcome obstruction wakes the patient from sleep. These awakenings are so brief that patients may be unaware of them but may be woken hundreds of times per night, leading to sleep deprivation, daytime sleepiness, and impaired intellectual performance.

Correctable factors occur in about one-third of cases and include:

- ***encroachment on pharynx:*** obesity, acromegaly, enlarged tonsils
- ***nasal obstruction:*** nasal deformities, rhinitis, polyps, adenoids
- ***respiratory depressants:*** alcohol, sedatives, strong analgesia.

Box 20.21 Epworth sleepiness scale

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

Situation	Chance of dozing
Sitting and reading	_____
Watching TV	_____
Sitting and inactive in a public place (theatre or meeting)	_____
As a passenger in a car for an hour without a break	_____
Lying down to rest in the afternoon when circumstances permit	_____
Sitting and talking to someone	_____
Sitting quietly after lunch (without alcohol)	_____
In a car, while stopped for a few minutes in the traffic	_____
TOTAL	_____

Normal <9

Excessive daytime somnolence >9. Causes include obstructive sleep apnoea, environmental disruption, anxiety/depression, epilepsy, Parkinson's disease, narcolepsy, restless leg syndrome, periodic limb movement disorder, and sedating medication.

Box 20.22 STOP BANG tool

Question	Answer
S*noring*—do you snore?	Yes/No
T*iredness*—do you often feel tired, fatigued, or sleepy?	Yes/No
O*bserved apnoeas*	Yes/No
P*ressure*—do you have high blood pressure or are you on treatment for it?	Yes/No
B*ody mass index* >35	Yes/No
A*ge* >50 years	Yes/No
N*eck size* (≥male 43 cm, female ≥41 cm)	Yes/No
G*ender/sex*—male	Yes/No

Score: 0–2 = low risk, 3–4 = possible risk, 5–8 = high risk.

Diagnosis

A collateral history of a snore–silence–snore cycle may be given. Patients experience poor concentration and wake feeling unrefreshed. The Epworth Sleepiness Scale (Box 20.21) measures daytime sleepiness. The STOP BANG tool (Box 20.22) is a useful screening tool for OSA, facilitating appropriate referral for further investigation and may help discriminate OSA from simple snoring.

Investigations

If the diagnosis is suspected, investigation for sleep-disordered breathing is necessary. Many of these investigations can be

performed at home including overnight pulse oximetry and heart rate monitoring. Oximetry will demonstrate desaturations in a cyclical manner, which give a typical sawtooth appearance. The oximetry desaturation index (ODI) measures the number of desaturations per hour. Overnight oximetry will not differentiate central and obstructive apnoeas. Multichannel sleep studies (nocturnal polygraphy) measure body posture and movements, breathing rate, and electroencephalography alongside pulse oximetry. Polysomnography yields the ***apnoea–hypopnea index (AHI),*** the number of episodes of apnoea or hypopnea per hour, which determines severity:

- AHI <5: normal
- AHI 5–15: mild OSA
- AHI 15–30: moderate OSA
- AHI >30: severe OSA.

Management

Management consists of correction of treatable factors, including weight loss and alcohol reduction. Patients who have associated daytime somnolence should be offered continuous positive airway pressure (CPAP) during sleep. CPAP splints the upper airway such that it cannot occlude. It improves symptoms, quality of life, daytime alertness, and survival. In the event that an individual is unable to tolerate CPAP therapy, second-line treatment options considered on a case-by-case basis include custom-made mandibular advancement splints, ENT surgery, and hypoglossal nerve stimulation.

Chronic ventilatory failure

Chronic ventilatory failure is type II respiratory failure due to failure of alveolar ventilation leading to hypercapnia. This can be the sequela of several conditions (**Box 20.23**). Symptoms of hypercapnia include morning headaches, daytime somnolence, confusion, memory impairment, and unsteadiness.

Domiciliary non-invasive ventilation can be considered if a patient has persistent hypercapnia. Patients typically use a portable ventilator overnight, which provides positive pressure support at different levels during inspiration and expiration. Home mechanical ventilation improves survival in patients with COPD and persistent type II respiratory failure following an acute admission. There are no randomized trials of non-invasive ventilation in kyphoscoliosis; however, survival is improved with use. In patients with neuromuscular disorders, home non-invasive ventilation improves quality of life and prolongs survival.

? Box 20.23 Causes of chronic ventilatory failure

Airflow obstruction
- Chronic obstructive pulmonary disease

Restrictive lung disease
- Obstructive sleep apnoea/obesity hypoventilation syndrome
- Idiopathic pulmonary fibrosis
- Kyphoscoliosis
- Thoracoplasty

Neuromuscular disease
- Post-polio syndrome
- Diaphragm palsy
- Motor neuron disease
- Myotonic dystrophy

Central causes
- Brain injury
- Multiple system atrophy

SMOKING

Prevalence

There are an estimated 1.3 billion tobacco smokers worldwide. Cigarette smoking is declining in the Western world but remains a leading cause of preventable death and remains prevalent in low- and middle-income countries. The World Health Organization (WHO) predicts that tobacco is directly responsible for the death of 8 million people each year. Information from the World Health Organization in 2020 reported that 36.7% of males and 7.8% of females worldwide used tobacco. The UK annual population survey of 2021 showed that 13.3% of adults smoke.

Toxic effects

Cigarette smoke contains polycyclic aromatic hydrocarbons and nitrosamines, which are potent carcinogens. Smokers have an increase in neutrophils and macrophages in the airways. These inflammatory cells release proteases that can destroy elastin and lead to lung damage. Pulmonary epithelial permeability increases, even in symptomless cigarette smokers, and correlates with the concentration of carboxyhaemoglobin in blood. This altered permeability may allow carcinogens easier access into the blood stream.

Dangers

Cigarette smoking is addictive and harmful to health (**Box 20.24**). Smoking 20 cigarettes daily for 20 years increases the lifetime

i Box 20.24 Dangers of cigarette smoking

General
- Cancer: lung, oesophagus, larynx, tongue, bladder
- Chronic obstructive pulmonary disease (COPD)
- Ischaemic heart disease
- Peripheral vascular disease
- Abnormal spermatozoa
- Cognitive impairment

Maternal smoking
- Fetal growth restriction
- Preterm delivery
- Childhood asthma

Passive smoking
- Asthma, pneumonia, and bronchitis in children of smoking parents
- Increased symptoms in asthma and COPD
- Cancer

risk of lung cancer by about ten times compared to a life-long non-smoker. Smoking and asbestos exposure are synergistic risk factors; the amount of asbestos exposure and smoking increase the risk of lung cancer risk considerably. Environmental tobacco smoke ('passive smoking') increases frequency and severity of asthma in children and may also increase incidence. It is also associated with a small but definite increase in lung cancer. Worldwide, second-hand smoke is estimated to cause premature death in 1.3 million people per annum. Surveys completed by the Global Youth Tobacco Survey in 142 countries over the period 2010–2018 showed a worldwide prevalence of second-hand smoke exposure (in adolescents) in any place was 62.9%. By 2022, 74 countries benefited from comprehensive smoke-free policies, which represents 38% of countries worldwide. Partial bans are in place in 35% countries, with no smoke-free legislation in 27%.

Smoking cessation

Smoking cessation has a huge effect on healthcare. National campaigns, bans on cigarette advertising, a substantial increase in the cost of cigarettes, and smoking bans in workplaces and public spaces contribute on a population level. Meanwhile, active encouragement to stop smoking is a useful approach for individuals: ask about smoking status, advise to quit, and refer to a smoking cessation programme for behavioural support. WHO reports state that 74 countries have comprehensive national smoke-free law which protects a quarter of the world's population.

Recommended approaches to smoking cessation include the '5A' approach:

1. Ask about smoking status at every healthcare visit
2. Advise: provide personalized clear advice
3. Assess willingness to quit
4. Assist in quitting
5. Arrange follow-up/support.

Pharmacological therapies have been shown to facilitate smoking cessation. Nicotine replacement therapies including gum, lozenges, inhalator, nasal spray, and patches have been shown to improve cessation over placebo. Varenicline is an oral partial agonist of the $\alpha_4\beta_2$ subtype of the nicotinic acetylcholine receptor. It stimulates the nicotine receptor, reducing withdrawal symptoms and craving for cigarettes. A 12-week course doubles the chances of smoking cessation. Therapy should be changed after 3 months if abstinence is not achieved.

The role of e-cigarettes remains unclear, and their long-term effects are unknown. Bupropion and nortriptyline have been shown to improve sustained quit rates and can be used as part of a smoking cessation intervention programme.

RESPIRATORY INFECTION

Pneumonia

The presentation, management, and complications of pneumonia are detailed in Chapter 11 ('Pneumonia' section).

COVID-19 pneumonitis

SARS-CoV-2 is a novel coronavirus which emerged in 2019 leading to COVID-19 disease. The virus mutated rapidly and produced several variants. It primarily causes respiratory symptoms in adults. In some, it causes coryzal-like symptoms with high temperature, myalgia, cough, and runny nose. In the early waves of the pandemic, the virus classically caused loss of smell (anosmia) and loss of taste (ageusia) which could last for months after general recovery. The initial variants showed a predisposition to develop a rapidly progressive pneumonitis. Certain groups of patients were much more susceptible to progressing to pneumonitis and respiratory failure: older age, people from minority ethnic backgrounds, patients with diabetes, hypertension, and kidney disease, those living with obesity, and those with immunodeficiency of any cause.

Symptoms and signs of severe COVID-19 pneumonitis are cough, progressive shortness of breath, and severe hypoxia in a conscious and talking patient; the clinical state can rapidly change to unconsciousness and death from acute and rapid respiratory failure. Chest radiograph appearances showed widespread confluent shadows throughout the lung fields which clear completely on recovery. COVID-19 pneumonitis is more likely to be associated with thromboembolic disease and, when slow to recover, a superadded bacterial infection should be considered. Patients can be left with residual pulmonary fibrosis, which appears to be more common in those needing mechanical ventilation. Treatment for respiratory failure is predominantly supportive. The Recovery trial demonstrated that in those that required oxygen therapy, treatment with dexamethasone for 10 days reduced 28-day mortality. The Recovery RS trial found that CPAP therapy reduced the need for invasive ventilation in those with respiratory failure. Additional management strategies included appropriate thromboprophylaxis, and judicious fluid balance. In selected patients, additional treatment options such as antiviral or IL-6 inhibitors may be appropriate.

Respiratory symptoms associated with long COVID are unresolved breathlessness and chronic cough in the presence of otherwise normal imaging and respiratory function tests. Cough can be helped by low-dose steroid inhalers and gradually settles. Patients with breathlessness should be encouraged to build up from a gentle exercise regimen and respiratory physiotherapy is the main stay of treatment if no other cause is found.

Pneumocystis jirovecii pneumonia

Pneumocystis pneumonia is one of the most common opportunistic infections encountered in clinical practice. It affects patients on immunosuppressant therapy, including prolonged corticosteroids, monoclonal antibodies, methotrexate, anti-rejection medication after a solid organ or haemopoietic stem cell transplantation; and those infected with HIV. Individuals with CD4 counts of less than

200/mm^3 are at particular risk. *Pneumocystis jirovecii* is found in the air, and pneumonia arises from re-infection rather than reactivation of persisting organisms acquired in childhood.

Pneumocystis pneumonia is associated with a high fever, breathlessness, and dry cough. Rapid desaturation on exercise or exertion is characteristic. The typical radiographic appearance is diffuse bilateral alveolar and interstitial shadowing beginning in the perihilar regions and spreading out in a butterfly pattern. Other chest radiograph appearances include localized infiltration, nodules, cavitation, or pneumothorax. Empirical treatment is justified in sick, high-risk patients. Whenever possible, diagnosis should be confirmed by indirect immunofluorescence on induced sputum or PCR of bronchoalveolar lavage fluid. Increasingly measurement of serum beta-D-glucan (BDG) may assist in the diagnosis of PCP. BDG is raised in mycological infections as it is present in the cell wall of pathological fungi. First-line treatment of *Pneumocystis* pneumonia is with high-dose co-trimoxazole, with adjunctive corticosteroids in patients with HIV infection.

Tuberculosis

Tuberculosis (TB) is one of the world's most common infectious diseases. It is caused by the bacterium *Mycobacterium tuberculosis*. It is estimated that one-third of the world's population is infected with tuberculosis, with most cases (around 65%) in Africa and Asia. There is a growing incidence of multidrug-resistant and extremely drug-resistant strains, which, together with HIV co-infection, places a huge health burden on resource-poor nations, with a high mortality from the two coexistent diseases. TB was responsible for 1.5 million deaths worldwide in 2020 and 20% of these were in HIV co-infected individuals. There are several factors affecting prevalence and risk of TB (**Box 20.25**).

Pathogenesis

M. tuberculosis is an aerobic, intracellular pathogen. Due to their relative impermeability to acid-based dyes in the laboratory, these organisms are often termed 'acid-fast bacilli'. TB is an airborne infection spread by coughing via respiratory droplets. Only a small number of bacteria need to be inhaled for infection to develop, but not all those who are infected develop active disease. On initial contact with infection, less than 5% of patients develop active disease. This increases to 10% within the first year of exposure.

Primary tuberculosis

'Primary TB' describes the first infection with TB. When the bacteria reach the alveolar macrophages, they are ingested and the subsequent inflammatory reaction results in tissue necrosis and formation of a granuloma. These granulomatous lesions consist of a central area of necrotic material called caseation, surrounded by epithelioid cells and Langhans giant cells. Subsequently, the caseated areas heal and many calcify. Some of these calcified nodules contain bacteria, which are contained by the immune system (and the hypoxic acidic environment created within the granuloma) and are capable of lying dormant for many years. This is the primary focus or the 'Ghon focus' of the disease. On a chest radiograph, the Ghon focus can be evident as a small, calcified nodule.

Box 20.25 Risk factors for tuberculosis in high-income countries

Contact with high-risk groups
- Origination from a high-incidence country (defined as >40/100 000)
- Frequent travel to high-incidence areas

Immune deficiency
- HIV infection
- Corticosteroids or immunosuppressant therapy
- Chemotherapeutic drugs
- Nutritional deficiency
- Diabetes mellitus
- Chronic kidney disease
- Malnutrition

Lifestyle factors
- Drug/alcohol misuse
- Homelessness/hostels/overcrowding
- Prison inmates

Genetic susceptibility
- Twin studies of gene polymorphisms

Box 20.26 Factors implicated in the reactivation of latent tuberculosis

- HIV co-infection
- Immunosuppressant therapy: corticosteroids, chemotherapy, monoclonal antibody treatment
- Diabetes mellitus
- Kidney failure requiring renal replacement
- Malnutrition
- Old age

Reactivation tuberculosis

In most people infected by *Mycobacterium* spp., the immune system contains the infection, and the patient develops cell-mediated immune memory of the bacteria. This is termed 'latent TB'. Most active TB cases are due to reactivation of latent infection, where the initial contact usually occurred many years earlier. Most patients are young and previously healthy but may have one or more risk factors for development of active disease (**Box 20.26**). In patients with HIV infection, newly acquired TB is common. The majority of active TB occurs in the lung, but extrapulmonary infection occurs with spread to the lymph nodes, particularly cervical and intrathoracic chains where it causes active disease in 20%–25% in the UK, and also via the bloodstream to more distant sites including brain, bones, and skin.

Clinical features and diagnosis

Cardinal symptoms of TB are cough, haemoptysis, and systemic features including fevers, night sweats, and weight loss. With infection in extrapulmonary sites, respiratory symptoms are often absent, and systemic symptoms may be neglected by both patients and healthcare practitioners.

In all cases of suspected TB, it is essential, depending on the site of disease, to obtain sputum, biopsy samples, or fluid for microscopy, smear, and culture, for information on sensitivity. Tissue samples should also be sent for histopathological examination.

Pulmonary TB

Patients are frequently symptomatic with a productive cough and, occasionally haemoptysis, along with systemic symptoms. Where

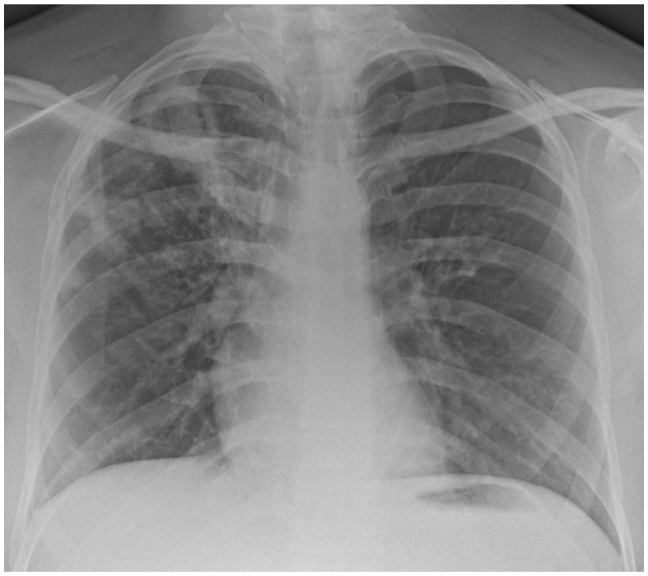

Fig. 20.24 Chest radiograph demonstrating patchy right mid and upper lobe consolidation and a cavity at the right apex in a patient with tuberculosis.

there is laryngeal involvement, a hoarse voice and a severe cough are found. If disease involves the pleura, pleuritic pain is frequent.

The chest radiograph (Fig. 20.24) can show consolidation with or without cavitation, pleural effusion, or thickening or widening of the mediastinum caused by hilar or paratracheal adenopathy.

Serial sputum samples should be collected on at least three occasions (ideally, first thing in the morning). If the patient is unable to produce sputum, induced sputum or bronchoscopy may be needed to obtain samples.

Patients whose sputum is smear-positive for TB are considered infectious and should be isolated when in hospital. Those who are smear-negative but subsequently culture-positive are less infectious and generally do not need to be isolated, although care should be taken when contacts include immunocompromised individuals.

Lymph node TB

The lymph nodes are the second most commonly affected organs. Extrathoracic nodes are more commonly involved than intrathoracic or mediastinal nodes. Usually, presentation is with firm, non-tender enlargement of a cervical or supraclavicular node. The node becomes necrotic centrally and can liquefy and be fluctuant if peripheral. The overlying skin is frequently indurated and there can be sinus tract formation with purulent discharge. Characteristically there is no erythema ('cold abscess'). Nodes are typically enlarged for several months prior to diagnosis. On CT imaging, the central area appears necrotic (Box 20.27). Samples should be obtained via either ultrasound-guided fine needle aspiration (FNA), core biopsy, or node excision. All samples must be sent for AFB, smear and culture, with cytology to help exclude malignancy. EBUS can be used to biopsy intrathoracic nodes.

Miliary TB

Miliary disease occurs through haematogenous spread of the bacilli to multiple sites, including the central nervous system (CNS) in 20% of cases. It often presents with systemic symptoms. The chest radiograph demonstrates multiple nodules, which appear like millet seeds, hence the term 'miliary'. Other findings are liver and splenic microabscesses with deranged liver enzymes, cholestasis, and gastrointestinal symptoms. All patients should have brain imaging to look for evidence of cerebral disease, which can present as an asymptomatic brain tuberculoma.

Microbiological diagnosis

Once samples have been taken, the rapid identification of the presence of mycobacterium by stains is essential and should be performed within 24 hours. Culture allows determination of antibiotic sensitivity.

Stains

Auramine–rhodamine staining is more sensitive and therefore more widely used than Ziehl–Neelsen staining. It requires fluorescence microscopy and highlights bacilli as yellow–orange on a green background.

Culture

The majority of high-income countries uses liquid/broth culture of mycobacteria in addition to solid media (Lowenstein–Jensen slopes or Middlebrook agar), as time to culture is shorter (1–3 weeks) for liquid culture compared to solid culture (3–8 weeks). Using liquid culture in the presence of antimycobacterial drugs (usually first-line therapy) establishes the sensitivity.

Nucleic acid amplification

Nucleic acid amplification testing (NAAT) is increasingly used for rapid identification of MTb complex and is useful in differentiating between *M. tuberculosis complex* and non-tuberculous mycobacteria (NTM), as well as identifying TB in smear-negative sputum specimens. It works by using the polymerase chain reaction (PCR) to replicate and then identify mycobacterium DNA. PCR is useful only at the initial stage of diagnosis, as it frequently remains positive despite treatment, due to detection of dead organisms. Culture and staining are still necessary.

Identification of mycobacterial DNA is useful in facilitating rapid treatment including identification of drug resistance. Genetic mutations conferring rifampicin resistance are highly predictive of drug resistance. The development of a highly specific probe designed to detect this mutation thereby allows efficient identification of resistant disease and commencement of appropriate therapy sooner than waiting for culture results. Commercial kits, such as GeneXpert, reliably perform molecular testing in the field and take less than 2 hours. They are now widely used in low- and middle-income countries to detect mutations associated with rifampicin resistance.

Whole-genome sequencing (WGS) can identify different strains of mycobacterium and also detect drug resistance. This is starting to replace routine culture and phenotypic testing.

Management

All patients should have routine blood tests, a viral hepatitis screen, and be offered testing for HIV before treatment. Patients with active viral hepatitis have an increased risk of fatal drug-induced hepatitis and need careful monitoring and counselling. Those with fully sensitive TB require 6 months of treatment; extended to 12 months for CNS infection. Isoniazid, rifampicin, pyrazinamide, and ethambutol are the first-line TB drugs, known as quadruple therapy. In CNS and pericardial disease, corticosteroids are used as an adjunct at treatment initiation to reduce long-term complications. Box 20.28 summarizes standard recommended regimens. Enhanced case management, together with ***directly observed therapy (DOT)***, is recommended where there are concerns about adherence (Box 20.29).

Box 20.27 TB infection: radiological findings and diagnostic investigations

Radiology	Investigations
Pulmonary, pleural and laryngeal TB	
Chest radiograph of suspected pulmonary TB	Smear and culture of: • Sputum: ≥2 samples increases diagnostic yield • Induced sputum: e.g., inhaled hypertonic saline, diagnostic yield comparable to bronchoscopy • Bronchoalveolar lavage: if cough unproductive and induced sputum not possible • Aspiration of pleural fluid and pleural biopsy • Gastric aspirates: useful in paediatric disease • Laryngeal disease: naso/endoscopic examination and biopsy
Miliary TB	
Chest radiograph with miliary pulmonary changes	Blood cultures for AFB Bronchoalveolar lavage fluid: usually smear-negative but culture-positive MRI head and lumbar puncture in all cases, unless contraindicated, to assess for central nervous system involvement (affects treatment duration) Sampling of other involved organs as indicated
Central nervous system TB	
 MRI head with lesion in right cerebellum	Neurology/neurosurgery MDT discussion Lumbar puncture if no contraindication: • CSF protein very high (usually >2–3 g/L) • CSF glucose <½ blood glucose • CSF lymphocytosis Biopsy if concerns about diagnosis

(Continued)

Box 20.27 TB infection: radiological findings and diagnostic investigations—cont'd

Radiology	Investigations
Lymph node TB	
 CT thorax with left anterior mediastinal nodes with necrotic centre	Fine needle aspiration/biopsy of lymph node: culture, smear, and histopathological examination. Mediastinal nodal sampling: EBUS, transbronchial needle aspiration, mediastinoscopy/mediastinotomy

CSF, Cerebrospinal fluid; *EBUS,* endobronchial ultrasound; *MDT,* multidisciplinary team.

Box 20.28 Usual treatment and duration in fully sensitive tuberculosis

Site of disease	Duration of therapy	Drug choice
Pulmonary[a] **Extrapulmonary** (excluding CNS) **Miliary** (excluding CNS)	6 months	2 months HRZE then 4 months HR[a]
CNS TB	12 months	2 months HRZE then 10 months HR Plus corticosteroids, e.g., dexamethasone 0.3–0.4 mg/kg/day weaned over 8–12 weeks
Latent TB	3 or 6 months	3 months RH OR 6 months H

[a]For pulmonary TB: 3 times weekly dosing for 4 months HR, is acceptable.
CNS, Central nervous system; *E,* ethambutol; *H,* isoniazid; *R,* rifampicin; *Z,* pyrazinamide.

Box 20.29 Criteria for implementation of directly observed therapy (DOT) for tuberculosis

- Adherence factors
  - History of non-adherence to TB or other therapies
  - Previous TB treatment
  - Mental illness impacting adherence
- Multidrug-resistant TB
- Street-, shelter-, or hostel-dwelling homelessness
- Prison history
- Substance misuse

The most common side-effects of quadruple TB therapy are nausea, vomiting, rash, and itching. An antiemetic or antihistamine can be prescribed to alleviate these symptoms, although in some cases treatment may need to be interrupted. If liver function tests become deranged and there is concern about a drug-induced hepatitis, it is often necessary to stop all four drugs and re-introduce one at a time. Drugs should be stopped only if the serum bilirubin becomes elevated or if transaminases are more than three times greater than the upper reference limit.

Isoniazid can cause a polyneuropathy due to B_6 deficiency, as isoniazid interacts with pyridoxal phosphate. Vitamin B_6 (pyridoxine 10–25 mg daily) should be prescribed concomitantly to prevent this. Occasionally, isoniazid gives rise to allergic reactions, such as a skin rash and fever. Hepatitis occurs in less than 1% of cases but may lead to liver failure, transplantation, or death if the drug is continued.

Rifampicin induces liver enzymes, which may be transiently elevated in the serum of many patients. Concomitant drug treatment metabolized by the same enzymes may therefore be less effective and a careful review of other medications is required, particularly antidepressants, anticoagulants, and antiepileptics. Oral and subdermal contraception may be less effective, so alternative birth-control methods should be used (e.g., depot-medroxyprogesterone acetate, intrauterine device). Rifampicin stains body secretions red/pink and patients should be warned of change in colour of urine, tears (affecting contact lenses), and sweat. Thrombocytopenia has been reported.

Pyrazinamide has common side-effects including itch, rash, and arthralgia. Renal excretion of urate is reduced and hyperuricaemic gout may develop. Hepatic toxicity is rare.

Ethambutol can cause a dose-related optic retrobulbar neuritis that presents with colour blindness for green, reduction in visual acuity, and a central scotoma. Patients should have visual acuity and colour vision checked prior to treatment using Snellen and Ishihara charts. This condition usually reverses provided the drug is stopped when symptoms develop; patients should therefore be warned of its effects. An urgent ophthalmology opinion should be sought if optic symptoms develop.

Drug resistance

Mono- or multidrug resistance arises due to incomplete or incorrect drug treatment and can be spread from person to person. Isoniazid monoresistance exists in approximately 10% of TB cases in the UK. A risk assessment for drug resistance should be routine (**Box 20.30**). The incidence of multidrug resistance in TB (resistance to both rifampicin and isoniazid, termed MDR-TB) is relatively low in high-income countries (around 1%). Extensively drug-resistant disease (XDR-TB) is

Box 20.30 Factors associated with an increased risk of drug-resistant tuberculosis

- History of prior drug treatment of TB (particularly if unsupervised/self-administered)
- Co-infection with advanced HIV
- Infection acquired in a region with high rates of drug resistance
- Contact with a known case of resistant TB
- Failure to respond to empirical TB therapy despite documented adherence
- Exposure to multiple courses of fluoroquinolone antibiotics for presumed community-acquired pneumonia
- Healthcare workers exposed to cases of resistant TB

defined as high-level resistance to rifampicin, isoniazid, any fluoroquinolone, and one additional WHO Group A drug (drugs effective in MDR-TB including levofloxacin or moxifloxacin, bedaquiline, and linezolid).

TB in special situations

Mycobacterium bovis infection

Mycobacterium bovis infection occurs in humans who have consumed unpasteurized milk, farmers working with infected cows, and abattoir workers. TB due to *M. bovis* does not differ from ordinary TB in the chest but extrapulmonary sites of infection, such as lymph nodes, are more frequently involved. Immunosuppression is also a risk factor. The tuberculin test is positive. Treatment is with isoniazid, rifampicin, and ethambutol; pyrazinamide resistance is common.

HIV co-infection

Increased TB prevalence over recent decades has occurred in association with HIV co-infection, especially in sub-Saharan Africa, the Indian subcontinent, and parts of Eastern Europe and Russia. The incidence of HIV infection in TB worldwide is around 10% and TB is responsible for about one-quarter of acquired immunodeficiency syndrome (AIDS)-related deaths. Alongside the increased morbidity and mortality of co-infection, there are specific issues relating to the treatment of TB with HIV co-infection including drug interactions, intolerability, and increased treatment toxicity, drug resistance, and immune reconstitution reactions. TB/HIV infection should be managed by experts in TB (respiratory or infectious disease physicians) alongside HIV specialists.

Latent TB infection

Latent TB infection (LTBI) is diagnosed by demonstrating immune memory to mycobacterial proteins. Two tests are available:

1. ***Tuberculin skin test ('Mantoux test').*** A positive result is indicated by a delayed hypersensitivity reaction (raised, indurated lesion) 48–72 h after intradermal injection of purified protein derivative (PPD). False-negative (anergic) results are common in patients with immunosuppression due to HIV infection ($CD4^+$ <200/mm^3), those taking immunosuppressant medications (chemotherapy, anti-TNF therapy, steroids), those at the extremes of age, and those with active disease. False-positives occur due to cross-reactivity with NTM and bacille Calmette–Guérin (BCG) vaccination.
2. ***Interferon-gamma release assays (IGRAs)*** detect T-cell secretion of IFN-γ following exposure to *M. tuberculosis*–specific antigens (ESAT-6, CFP-10). Where a person has been previously infected or is currently infected with TB, activated T cells within their extracted whole blood secrete quantifiable levels of IFN-γ in response to re-exposure to TB-specific antigens. The test does not differentiate between active and latent infection. However, it is highly specific compared to tuberculin skin testing, with similar or better sensitivity, and requires only a single patient visit.

In certain groups with LTBI, ***chemoprophylaxis*** is offered to reduce the risk of active infection, depending on whether a high-burden or low-burden country:

- household and close workplace contacts of patients with pulmonary and laryngeal TB
- health workers
- recent new migrant entrants from high-risk countries
- patients who are immunocompromised
- those about to commence treatment with biologic agents (such as infliximab)
- those due to have stem cell or solid organ transplants.

LTBI ***treatment*** is either with isoniazid and rifampicin for 3 months or with isoniazid monotherapy for 6 months.

BCG vaccination

BCG is a live attenuated vaccine derived from *M. bovis* that has lost its virulence. Though it is no longer offered routinely to all due to the lack of cost efficacy, it is recommended to some high-risk populations. In the UK, it is offered to neonates and children living in high-prevalence areas in the UK or immigrating from high-prevalence areas, and to close contacts of those with infectious TB.

Non-tuberculous mycobacterial infection

Non-tuberculous mycobacteria (NTM) occur in soil and water, and are not usually pathogenic due to lack of virulence. However, where there is a breach of normal host defence mechanisms, certain strains have the potential to become pathogenic (**Box 20.31**). Factors associated with an increased risk of pulmonary NTM infection include structural lung disease such as COPD, bronchiectasis and CF, and immunosuppression. Treatment is indicated if there is a compatible clinical context, or isolation of the organism from an invasive sample or more than one sputum sample obtained at different times.

PLEURAL DISEASE

Pleural effusion

A pleural effusion is an excessive accumulation of fluid in the pleural space. It can be detected on chest radiography when 300 mL or more of fluid is present, and clinically when there is 500 mL or more. Chest radiograph appearances (**Fig. 20.25**) range from obliteration of the costophrenic angle to dense homogeneous shadows occupying part or all of the hemithorax. Fluid below the lung (a subpulmonary effusion) can simulate a raised hemidiaphragm. Fluid in a lung fissure may resemble an intrapulmonary mass. The physical signs are described in **Box 20.8**.

Diagnosis

Pleural aspiration (see Box 11.7) is usually done under ultrasound guidance. Fluid may be a transudate or an exudate.

Transudates

Transudates can be bilateral but are often larger on the right. A pleural transudate is defined by pleural protein content of less than 30 g/L (provided serum protein concentration is normal), LDH less than 200 IU/L, and fluid to serum LDH ratio less than 0.6. If the serum protein is less than 30 g/L, then Lights criteria (see **Box 20.32**) should be used to determine if the sample is a transudate or an exudate.

Causes include:

- heart failure
- hypoproteinaemia (e.g., nephrotic syndrome)
- constrictive pericarditis
- hypothyroidism
- ovarian tumours producing right-sided pleural effusion (Meigs' syndrome).

Box 20.31 Some non-tuberculous mycobacteria strains implicated in disease

Strain	Site of disease
M. avium intracellulare complex (MAC)	Pulmonary
	Disseminated (usually in immunosuppression/HIV)
	Hypersensitivity pulmonary disease ('hot-tub lung')
	Lymphadenitis in children
M. kansasii	Pulmonary
	Disseminated disease (in immunosuppression/HIV)
M. abscessus	Skin, soft tissue, and bone disease
	Pulmonary
M. chelonae	Skin, bone, and soft tissue
	Pulmonary: similar to *M. abscessus*
M. fortuitum	Pulmonary: similar to *M. abscessus*
M. gordonae	Rarely pathogenic: can be significant in immunocompromised host
M. xenopi	Pulmonary: fibrocavitary disease in chronic obstructive pulmonary disease
	Contaminated surgical instruments causing bone/soft tissue infection
M. malmoense	Pulmonary
	Lymph node
M. marinum	Soft tissue, skin, and bone
M. szulgai	Pulmonary: similar to *M. tuberculosis*
M. chimaera	Pulmonary, prosthetic valve, bone, disseminated—linked to contaminated heater coolers used in heart bypass surgery

Exudates

The protein content of exudates is over 30 g/L and the LDH is more than 200 IU/L. Causes include:

- bacterial pneumonia (common)
- carcinoma of the bronchus—fluid may be blood-stained (common)
- pulmonary infarction
- TB
- autoimmune connective tissue diseases
- mesothelioma
- post-myocardial infarction syndrome (rare)
- acute pancreatitis (high amylase content) (rare)
- sarcoidosis (very rare)
- yellow-nail syndrome (effusion due to lymphoedema, very rare)
- familial Mediterranean fever (very rare).

Pleural biopsy may be necessary if diagnosis is not established by simple aspiration and clinical features.

Box 20.32 Light's criteria to diagnose an exudative effusion

- Pleural fluid protein: serum protein >0.5
- Pleural fluid LDH: serum LDH >0.6
- Pleural fluid LDH >2/3 upper limit of normal for serum (105–333 IU/L)

(Adapted from Light RW, Macgregor MI, Luchsinger PC et al. Pleural effusions: the diagnostic separation of transudates and exudates. Ann Intern Med *1972; 77:507–513).*

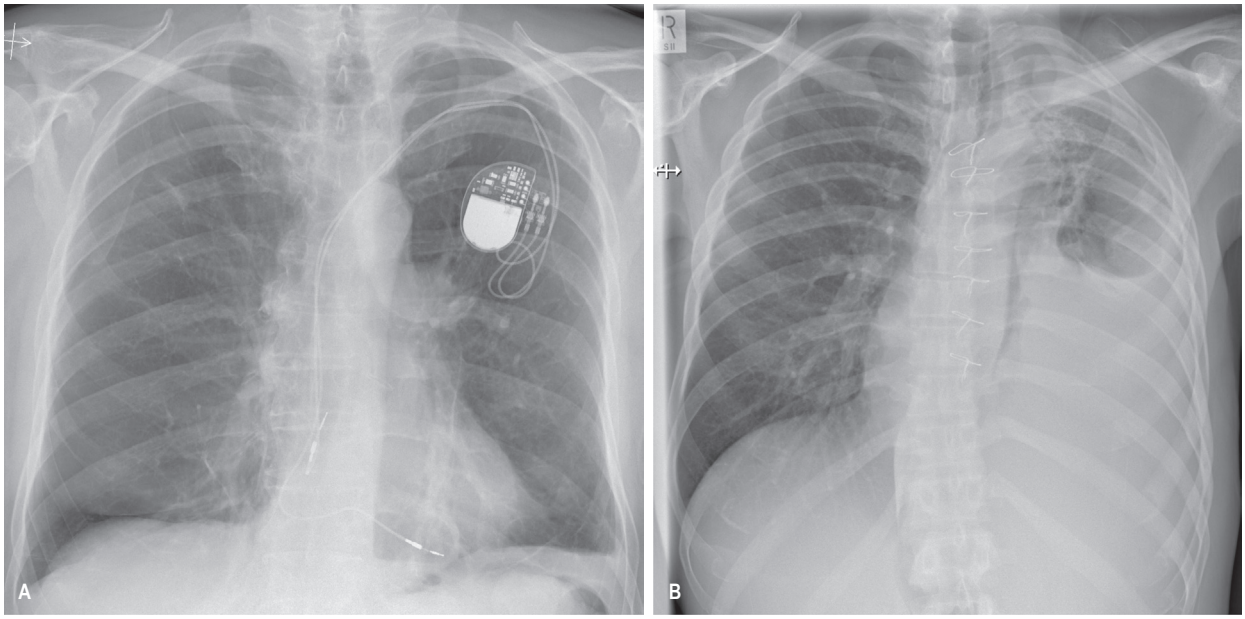

Fig. 20.25 Chest radiograph demonstrating pleural effusion. **(A)** Blunting of the left costophrenic angle due to a small left pleural effusion. There is a dual-lead pacemaker *in situ*. **(B)** Large left-sided pleural effusion.

Management

Treatment is of underlying condition.

Empyema

The presence of pus in the pleural space can be a complication of pneumonia. It requires urgent drainage.

Malignant pleural effusion

Malignant pleural effusions that reaccumulate and are symptomatic can be aspirated to dryness followed by the instillation of a sclerosing agent such as talc. Effusions should be drained slowly since rapid shift of the mediastinum causes pain and occasionally shock. For longer-term relief, indwelling pleural catheters (IPC) are being increasingly utilized for recurrent malignant pleural effusions in the community and can be managed by patients, their relatives, and/or community nursing teams.

Chylothorax

This is caused by accumulation of lymph in the pleural space, usually resulting from leakage from the thoracic duct following trauma or infiltration by carcinoma.

TUMOURS OF THE RESPIRATORY TRACT

Malignant tumours

Bronchial carcinoma

Bronchial carcinoma is the most common malignant tumour worldwide, causing around 1.76 million deaths annually. It is the third most common cancer in the UK, and the most common cause of cancer-related death. Cigarette smoking (including passive smoke exposure) accounts for 72% of lung cancer cases. There remains a higher incidence of bronchial carcinoma in urban compared with rural areas, even when allowance is made for cigarette smoking. Other aetiological factors include:

- ***Environmental:*** radon exposure, asbestos, polycyclic aromatic hydrocarbons, ionizing radiation, occupational exposure to arsenic, chromium, nickel, petroleum products, and oils.
- ***Host factors:*** pre-existing lung disease, e.g., pulmonary fibrosis, HIV infection, genetic factors.

Pathophysiology

Historically, lung cancers have been divided into small-cell and non–small-cell carcinoma, based on histological appearance of the cells within the tumour. This distinction is helpful with respect to prognosis and determining best treatment. Non–small-cell carcinoma is further divided into a number of cell types (adenocarcinoma, squamous cell carcinoma, and large-cell carcinoma; **Box 20.33**). A number of molecular characteristics have been described in the subtypes of cancer, which confer potential prognostic benefit and may result in the ability to deliver a more personalized therapy with targeted agents. The most common of these are activating mutations within epidermal growth factor receptor *(EGFR)*, most commonly encountered in non-smokers, females, and those of Asian origin; and the presence of anaplastic lymphoma kinase *(ALK)* fusion oncogene, more commonly found in non- or ex-smokers and younger patients.

Box 20.33 Lung cancer cell types and clinical features

Cell type	% of lung cancers in the UK	Features
Non–small-cell carcinoma		
Squamous cell carcinoma	25–30	Arises from epithelial cells, associated with production of keratin
		Occasionally cavitates with central necrosis
		Causes obstructing lesions of bronchus with post-obstructive infection
		Local spread common, metastasizes relatively late
Adenocarcinoma	40%	Increasing incidence since 2005 possibly linked to low-tar cigarettes
		Originates from mucus-secreting glandular cells
		Most common cell type in non-smokers
		Often causes peripheral lesions on chest radiograph/CT
		Subtypes include bronchoalveolar cell carcinoma (associated with copious mucus secretion, multifocal disease)
		Metastases common: pleura, lymph nodes, brain, bones, adrenal glands
Large-cell carcinoma	10–15	Often poorly differentiated
		Metastasizes relatively early
Small-cell carcinoma	15–20	Arises from neuroendocrine cells (APUD cells)
		Often secretes polypeptide hormones
		Often arises centrally and metastasizes early

Clinical features

The presentation and clinical course vary between the different cell types (see **Box 20.33**). Symptoms and signs may be different, depending on the extent and site of disease. Common presenting features can be divided into those caused by direct/local tumour effects, metastatic spread, and non-metastatic extrapulmonary features.

Local effects

- ***Cough.*** The most common symptom in lung cancer. Due to evidence that cough is neglected by both patients and healthcare professionals, campaigns in the UK have highlighted the '3-week cough' as a symptom that merits a chest radiograph.
- ***Breathlessness.*** Central tumours occlude large airways, resulting in collapse and breathlessness on exertion. Many patients with lung cancer have coexistent COPD, which is also a cause of breathlessness. Patients may develop a pleural effusion due to metastatic involvement of the pleura.

- ***Haemoptysis.*** Fresh or old blood is coughed up because of tumour bleeding into an airway.
- ***Chest pain.*** Peripheral tumours invade the well-innervated chest wall or pleura, resulting in sharp pleuritic pain. Large-volume mediastinal nodal disease can present with a characteristic dull central chest ache.
- ***Wheeze.*** A monophonic wheeze is due to partial airway obstruction by tumour.
- ***Hoarse voice.*** Mediastinal nodal disease or direct tumour invasion of the mediastinum results in compression of the left recurrent laryngeal nerve.
- ***Nerve compression.*** Pancoast tumours in the apex of the lung invade the brachial plexus, causing C8/T1 palsy with small muscle weakness and wasting in the hand, and weakness and pain radiating down the arm. An associated Horner's syndrome also occurs due to compression of the sympathetic chain causing miosis, ptosis, and anhidrosis.
- ***Recurrent infections.*** Tumour causing partial obstruction of an airway result in post-obstructive pneumonia.
- ***Direct invasion of the phrenic nerve.*** Bronchial carcinoma invading the phrenic nerve causes paralysis of the ipsilateral hemidiaphragm. Involvement of the oesophagus produces progressive dysphagia. Involvement of the pericardium leads to pericardial effusion and malignant dysrhythmias.
- Superior vena caval obstruction. See Chapter 11.
- ***Tracheal tumours.*** These cause progressive dyspnoea and stridor. Flow–volume curves show reduced inspiratory flow (see Fig. 20.5C).

Metastatic effects

Bronchial carcinoma commonly spreads to mediastinal, cervical, axillary, and intra-abdominal nodes. In addition, the liver, adrenal glands, bones, brain, and skin are frequent sites for metastases:

- ***Liver.*** Common symptoms are anorexia, nausea, and weight loss. Right upper quadrant pain radiating across the abdomen due to liver capsular pain.
- ***Bone.*** Bone pain and pathological fractures occur. If the spine is involved, there is a risk of spinal cord compression (see Chapter 11), which requires urgent treatment.
- ***Adrenal glands.*** Metastases to the adrenals do not usually result in adrenal insufficiency and are generally asymptomatic.
- ***Brain.*** Metastases present as space-occupying lesions with mass effect and signs of raised intracranial pressure. Carcinomatous meningitis with cranial nerve defects, headache, and confusion is less common.
- ***Malignant pleural effusion.*** This presents with breathlessness and is commonly associated with pleuritic pain.

Non-metastatic extrapulmonary manifestations

Haematological manifestations of lung cancer including normocytic anaemia and thrombocytosis are common. Finger clubbing and hypertrophic pulmonary osteoarthropathy (HPOA) occur. Approximately 10% of small-cell tumours produce ectopic hormones, giving rise to paraneoplastic syndromes (Box 41.10).

Investigations

Investigations are indicated to:

- stage the extent of disease
- make a tissue diagnosis (to differentiate small-cell from non–small-cell lung cancer and detail molecular characteristics for targeted biologic agents and immunotherapy)
- assess fitness to undergo treatment.

Staging and diagnosis

Chest radiograph

Plain chest radiographs may show obvious evidence of lung cancer or non-specific appearances (Box 20.34). In some cases, the initial film appears normal, either because the lesion is small or because disease is confined to central structures.

Computed tomography

CT indicates the extent of disease. Imaging should include liver and adrenal glands, which are common sites for metastases. The International Association for the Study of Lung Cancer (IASLC) has devised the most widely used staging definitions, based on CT imaging of tumour size (T), nodal involvement (N), and metastases (M), along with prognostic data (Box 20.35). Using CT criteria, lymph nodes <1 cm in diameter are not classed enlarged, yet they can contain malignant cells. With increasing node size, the positive predictive value of CT in detecting malignancy grows, though not all enlarged nodes are malignant. PET-CT and biopsy may be indicated. If cerebral metastases are suspected, CT imaging of the brain should be performed. Bone metastases that lie within the staging field of view may be seen.

Other imaging modalities

MRI is not useful for the diagnosis of primary lung tumours other than Pancoast tumours with nerve invasion or the assessment of chest wall involvement prior to surgery. MRI spine is required if there is clinical suspicion of spinal cord compression. MRI brain may also be required to assess cerebral metastases.

Bone is a common site for metastatic deposits. Bone scan of sites of bone pain not included in other imaging may be helpful to demonstrate bony deposits.

Obtaining histology and cytology

Investigations for this purpose are listed in Box 20.36.

Other investigations

These include a full blood count for the detection of anaemia, and biochemistry to assess for liver involvement, hypercalcaemia, and hyponatraemia. Investigations for non-metastatic extrapulmonary manifestations of cancer may be indicated (Box 20.37)

Assessing fitness for treatment

The Eastern Cooperative Oncology Group (ECOG) performance status should be recorded for all patients with malignancy (Box 20.38). Depending on the treatment proposed and co-morbidity, assessment of fitness may include lung function testing with transfer capacity, cardiopulmonary exercise testing, stress echo, or other assessment of coronary perfusion.

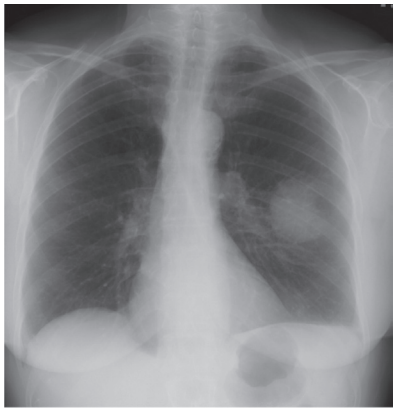
Management

The management of lung malignancy is detailed in Chapter 41.

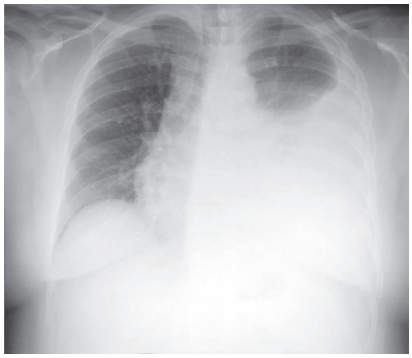
Mesothelioma

Mesothelioma is a malignant tumour arising from the parietal or visceral mesothelial lining of the lung. These tumours are almost always related to asbestos exposure and typically develops from pre-existing pleural plaque disease. The number of cases of mesothelioma has increased progressively since the mid-1980s, now causing 2500 deaths per year in the UK. The most common presentation of mesothelioma is a pleural effusion. Persistent chest wall pain should raise the index of suspicion even if the initial pleural

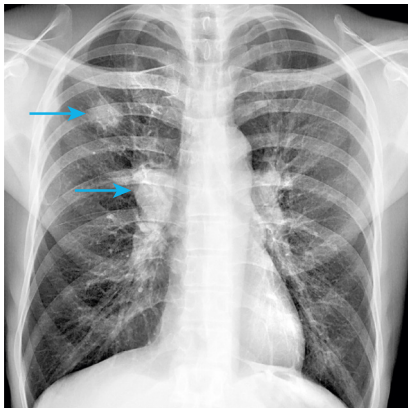
Box 20.34 Lung cancer presentations on chest X-ray



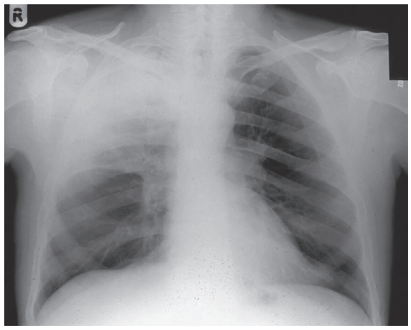
Mass lesion
Visible if >1 cm in diameter. Spiculated, cavitating, or smooth-edged. Often an incidental finding, usually asymptomatic if small. Chest radiograph is almost always abnormal if symptomatic mass lesion.



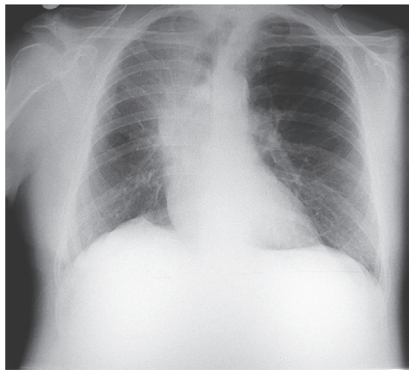
Pleural effusion
Usually unilateral. Can obscure an underlying mass or pleural tumour. Differential includes mesothelioma and metastatic disease.



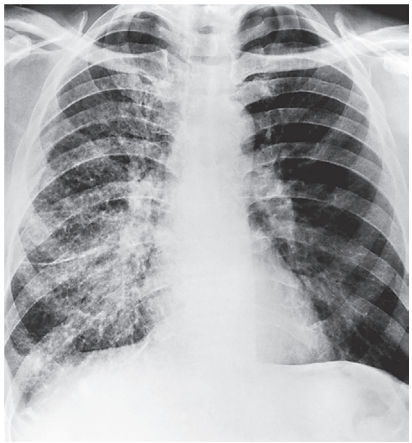
Mediastinal widening or hilar adenopathy
Splayed carina, hilar enlargement, paratracheal shadowing



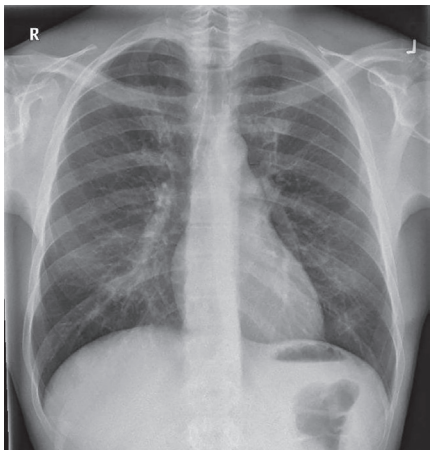
Slow-resolving consolidation
Tumour causes partial obstruction of a bronchus, resulting in retention of secretions, bacterial overgrowth, and infection. Radiograph changes persist due to tumour in right upper lobe.



Collapse
Endoluminal tumour causes complete collapse of a lung and associated mediastinal shift, or collapse of a lobe/segment with volume loss on the affected side: raised hemidiaphragm/deviated trachea.



Reticular shadowing
Carcinoma spreads through the lymphatic channels of the lung to give rise to lymphangitis carcinomatosa. In bronchial carcinoma this is usually unilateral and associated with striking dyspnoea. Bilateral lymphangitis should prompt investigation for a primary site other than lung, such as breast, stomach, or bowel.



Normal
A normal film does not rule out an underlying tumour. A minority of tumours are confined to the central airways and mediastinum without obvious change on plain chest radiograph. Normal chest radiograph should not discourage further investigation in symptomatic smokers over 40 years.

Box 20.35 TNM staging system for lung cancer

Notation	Description		
T—primary tumour			
TX	Primary tumour cannot be assessed, or tumour proven by the presence of malignant cells in sputum or bronchial washings, but not visualized by imaging or bronchoscopy		
T0	No evidence of primary tumour		
Tis	Carcinoma *in situ*[a]		
T1	Tumour 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus); subtypes mi, a, b, and c exist according to the tumour size.		
T2	Tumour more than 3 cm but not more than 5 cm; or tumour with any of the following features[b]: • Involves main bronchus, regardless of distance to the carina but without involvement of the carina • Invades visceral pleura • Associated with atelectasis or obstructive pneumonitis that extends to the hilar region involving either part of or the entire lung		
T2a	Tumour more than 3 cm but not more than 4 cm in greatest dimension		
T2b	Tumour more than 4 cm but not more than 5 cm in greatest dimension		
T3	Tumour more than 5 cm but not more than 7 cm in greatest dimension or one that directly invades any of the following: parietal pleura, chest wall (including superior sulcus tumours), phrenic nerve, parietal pericardium; or tumour nodule(s) in the same lobe as the primary		
T4	Tumour more than 7 cm or of any size that invades any of the following: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, oesophagus, vertebral body, carina; separate tumour nodule(s) in a different ipsilateral lobe to the primary		
N—regional lymph nodes			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension		
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)		
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)		
M—distant metastasis			
M0	No distant metastasis		
M1	Distant metastasis		
M1a	Separate tumour nodule(s) in a contralateral lobe; tumour with pleural nodules or malignant pleural or pericardial effusion[c]		
M1b	Single extrathoracic metastasis in a single organ[d]		
M1c	Multiple extrathoracic metastasis in a single or multiple organs		
Resultant stage groupings			
Occult carcinoma	TX	N0	M0
Stage 0	Tis	N0	M0
Stage IA[e]	T1	N0	M0
Stage IB	T2a	N0	M0
Stage IIA	T2b	N0	M0
Stage IIB	T1, T2a, b	N1	M0
	T3	N0	M0
Stage IIIA	T1, T2a, b	N2	M0
	T3	N1	M0
	T4	N0, N1	M0
Stage IIIB	T1, T2a, b	N3	M0
	T3, T4	N2	M0
Stage IIIC	T3, T4	N3	M0
Stage IV	Any T	Any N	M1
Stage IVA	Any T	Any N	M1a, M1b
Stage IVB	Any T	Any N	M1c

[a]Tis includes adenocarcinoma *in situ* and squamous carcinoma *in situ*.
[b]T2 tumours with these features are classified T2a if 4 cm or less or if size cannot be determined, and T2b if greater than 4 cm but not larger than 5 cm.
[c]Most pleural (pericardial) effusions with lung cancer are due to tumour. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumour, and the fluid is non-bloody and is not an exudate. Where these elements and clinical judgement dictate that the effusion is not related to the tumour, the effusion should be excluded as a staging descriptor.
[d]This excludes involvement of a single non-regional node.
[e]Stage IA is split into three subclasses 1, 2, and 3 according to tumour size.
(Based on data from Goldstraw P, Crowley J, Chansky K et al.; International Association for the Study of Lung Cancer International Staging Committee; Participating Institutions. The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (8th) edition of the TNM classification of malignant tumours. J Thorac Oncol *2016; 2:706–714.)*

Box 20.36 Investigations to obtain histology and cytology

- Fibreoptic bronchoscopy (**Fig. 20.26**)
- Endobronchial ultrasound (**Fig. 20.27**)
- CT/ultrasound-guided biopsy of lung lesions
- Ultrasound-guided biopsy of lymph nodes, liver metastases, or skin lesions
- Ultrasound-guided pleural aspiration
- Medical or video-assisted thoracoscopy
- Mediastinoscopy

Box 20.37 Non-metastatic extrapulmonary manifestations of bronchial carcinoma

Metabolic
- Loss of weight
- Lassitude
- Anorexia

Endocrine (10%) (usually small-cell carcinoma)
- Ectopic adrenocorticotrophin syndrome
- Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
- Hypercalcaemia (usually squamous cell carcinoma)
- Rarer: hypoglycaemia, thyrotoxicosis, gynaecomastia

Neurological (2%–16%)
- Encephalopathy—including subacute cerebellar degeneration
- Myelopathies—motor neuron disease
- Neuropathies—peripheral sensorimotor neuropathy
- Muscular disorders—polymyopathy, myasthenic syndrome (Eaton–Lambert syndrome)

Vascular and haematological
- Venous thromboembolic disease
- Thrombophlebitis migrans
- Non-bacterial thrombotic endocarditis
- Microcytic and normocytic anaemia
- Disseminated intravascular coagulopathy
- Thrombotic thrombocytopenic purpura
- Haemolytic anaemia

Skeletal
- Clubbing (30%)
- Hypertrophic osteoarthropathy (± gynaecomastia) (3%)

Cutaneous (rare)
- Dermatomyositis
- Acanthosis nigricans
- Herpes zoster

Box 20.38 Eastern Cooperative Oncology Group (ECOG) Performance Status

Grade	Description
0	Fully active, able to carry out all pre-disease performance without restriction
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work
2	Ambulatory and capable of all self-care but unable to carry out work activities. Up and about more than 50% of waking hours
3	Capable of limited self-care only. Confined to bed or chair for more than 50% of waking hours
4	Disabled, cannot carry out any self-care, confined to bed or chair

fluid or biopsy samples are non-diagnostic. CT/ultrasound-guided biopsy or VATS pleural biopsy is often needed to obtain sufficient tissue for diagnosis. Clinical trials of chemotherapy, sometimes combined with surgery, are under way but the outlook for most patients remains very limited.

Screening for lung cancer

A large trial carried out in the USA demonstrated a 20% mortality benefit from low-dose helical CT screening for lung cancer in high-risk populations of smokers and ex-smokers aged 55–74. A similar trial has been undertaken in the Netherlands and the UK. Targeted lung screening is therefore being implemented in the UK. The programme invites 'at risk' individuals for low-dose CT scanning.

Secondary tumours

Metastases in the lung are very common. They are usually detected on chest radiography or CT in patients already diagnosed as having cancer, but can be the first presentation. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix, or ovary. Single pulmonary metastases can be removed surgically but exclusion of additional metastases usually on CT or CT-PET scanning is essential before surgery.

Cancer (particularly stomach, pancreas, and breast) can involve mediastinal glands and spread along the lymphatics of both lungs, leading to progressive and severe breathlessness (lymphangitis carcinomatosis). This may be seen on a chest X-ray as bilateral lymphadenopathy with streaky basal shadowing fanning out over both lung fields.

Solitary pulmonary nodules

A solitary pulmonary nodule is defined as a discrete lesion of less than 3 cm in diameter. The differential diagnoses for a solitary pulmonary nodule are:

- primary bronchial carcinoma
- pulmonary metastases
- inflammatory lesions, e.g., rounded pneumonia or abscess
- granuloma
- benign tumour of the lung, e.g., hamartoma
- rheumatoid nodules
- hydatid cyst.

With the increased use of CT scanning for other conditions, there has been greater incidental detection of asymptomatic, small, sub-centimetre nodules. The majority of these are benign; however, radiological follow-up should be arranged at intervals in line with recommended guidelines, determined by the size of the nodule in millimetres and the risk of malignancy. Scoring tools such as the Brock score are useful in assessing the risk of malignancy based on nodule characteristics and size.

Bronchial carcinoid tumours

These rare tumours arising from neuroendocrine cells in the bronchial epithelium and account for approximately 1% of all bronchial tumours. Many of these are asymptomatic. Some patients will present with symptoms related to obstruction, recurrent infection, or haemoptysis. They are typically slow-growing and low-grade although aggressive, atypical tumours can occur. Surgery is usually the treatment of choice, with long-term surveillance. As foregut derivatives, bronchial carcinoids can produce adrenocorticotrophic hormone (ACTH) leading to clinical Cushing's syndrome in a minority. They do not usually produce 5-hydroxytryptamine seen in midgut or hindgut carcinoid tumours.

Benign tumours

Pulmonary hamartoma

This is the most common benign tumour of the lung and is usually seen on chest radiography as a well-defined round lesion 1–2 cm

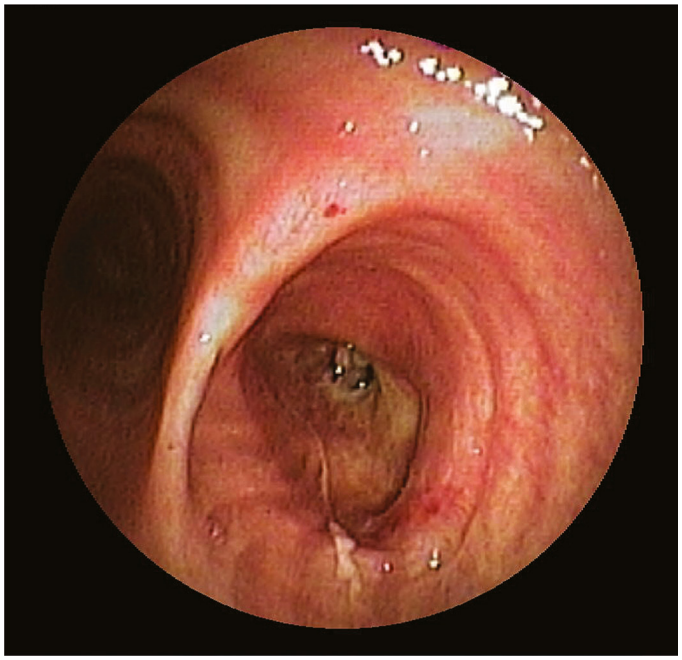


Fig. 20.26 Rigid bronchoscopy. A large obstructing tumour mass is well visualized. Similar endobronchial appearance can be seen at fibreoptic bronchoscopy. (*Optimal processing of diagnostic lung specimens. Practical Pulmonary Pathology: A Diagnostic Approach, Fourth Edition. pii:B9780323795470000126/f003-018-9780323795470.*)

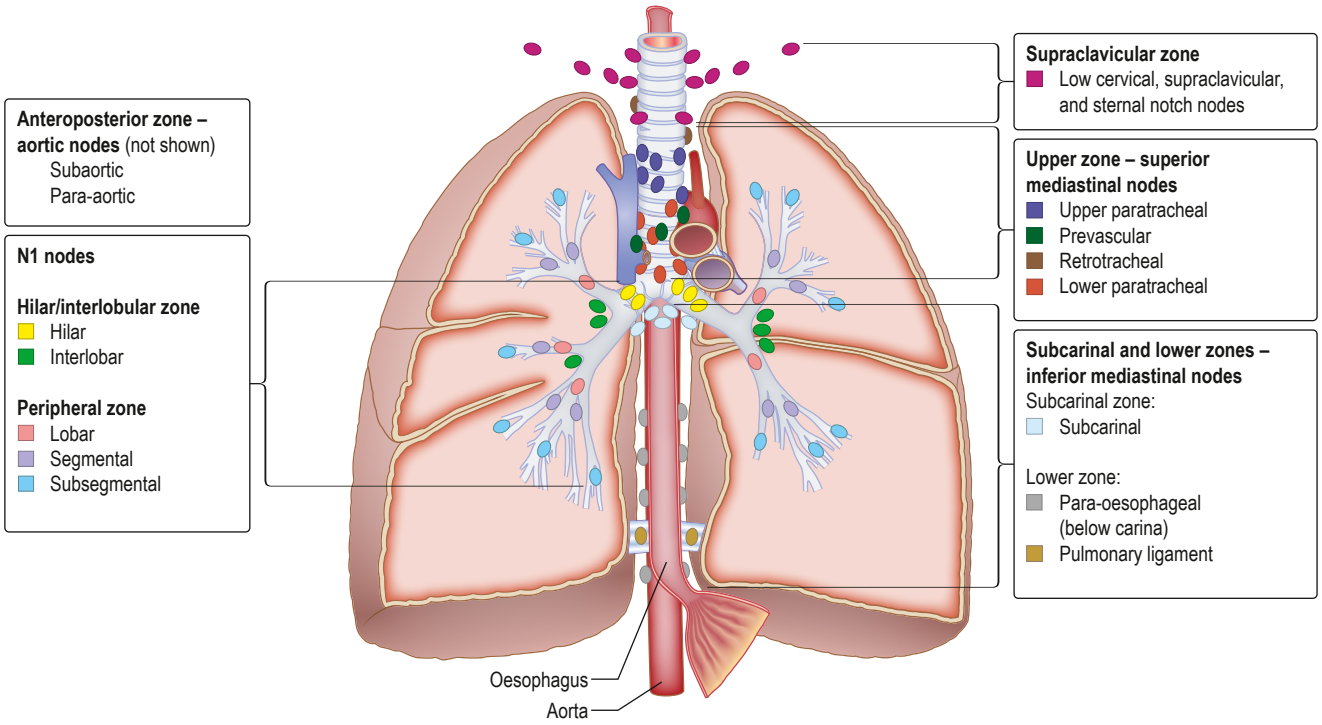

Fig. 20.27 Lymph nodes commonly involved in lung cancer. Histopathology and molecular analysis help determine staging and optimum treatment.

in diameter in the periphery of the lung. Growth is extremely slow, but the tumour can reach several centimetres in diameter. Rarely, it arises from a major bronchus and causes obstruction.

Bronchial adenoma

This diverse group of benign tumours arises from mucus glands and ducts of the windpipe.

Cylindroma, chondroma, and lipoma

These extremely rare tumours grow in the bronchus or trachea, causing obstruction.

Tracheal tumours

Benign tumours include squamous papilloma, leiomyoma, and haemangiomas.

BRONCHIECTASIS

Bronchiectasis describes abnormal and permanently dilated airways. The disease is characterized by a cycle of neutrophilic inflammation, recurrent infection, and airway damage which further impairs mucociliary clearance.

Bronchiectasis is associated with a number of diseases but is a cause found in only around 50% of cases. Little is known about the epidemiology and there is a wide variation in reported incidence. Bronchiectasis related to CF is generally considered a separate entity.

Aetiology

The causes of bronchiectasis are listed in **Box 20.39**. Globally, TB is the leading cause. Bronchiectasis associated with other lung diseases, particularly COPD, is increasingly recognized.

Clinical features

These are shown in **Box 20.40**.

Investigations

The aims of investigation are to confirm the diagnosis, rule out an underlying cause, look for reversible factors, and exclude/prevent complications.

- ***CT scan*** is the investigation of choice. Characteristically, non-tapering 'tram track' airways and an increased bronchoarterial ratio termed the 'signet ring' sign are seen (**Fig. 20.28**).
- ***Chest radiograph*** is often normal but tram track airways, ring shadows, and cysts may be seen.
- ***Sputum examination*** is useful for targeted antibiotic treatment, as well as exclusion of non-tuberculous mycobacterial disease. Extended microbiological culture is often required and needs to be specifically requested.
- ***Immune assessment*** includes immunoglobulin concentrations and response to Hib, tetanus, and pneumococcal vaccines. More detailed immunological assessment by an immunologist may be necessary.
- ***Sweat test and CF genetic assessment*** should be carried out in all patients under 40 years and any patient in where there is a clinical suspicion.
- ***Nasal nitric oxide*** is a useful test for screening for primary ciliary dyskinesia (PCD), in which it is very low. Further ciliary investigation in a specialist centre may be required.
- ***Total IgE and* Aspergillus*-specific IgE or* Aspergillus *skin-prick testing*** should be done to exclude allergic bronchopulmonary aspergillosis.

Management

Therapy can be divided into airway clearance, anti-inflammatories, and treatment of infection and complications.

? Box 20.39 Causes of bronchiectasis

Congenital
- Deficiency of bronchial wall elements
- Pulmonary sequestration

Mechanical bronchial obstruction

Intrinsic
- Foreign body
- Inspissated mucus
- Post-tuberculous stenosis
- Tumour

Extrinsic
- Lymph node
- Tumour

Postinfective bronchial damage
- Bacterial and viral pneumonia, including pertussis, measles, and aspiration pneumonia

Granuloma
- Tuberculosis
- Sarcoidosis

Diffuse diseases of the lung parenchyma
- Idiopathic pulmonary fibrosis

Pathological immunological response
- Allergic bronchopulmonary aspergillosis
- Post-lung transplant
- Graft-versus-host disease

Immune deficiency

Primary
- Panhypogammaglobulinaemia
- Selective immunoglobulin deficiencies (IgA and IgG_2)

Secondary
- Human immunodeficiency virus
- Immunosuppressive medication

Mucociliary clearance defects

Genetic
- Primary ciliary dyskinesia (Kartagener's syndrome with dextrocardia and situs inversus)
- Cystic fibrosis

Acquired
- Young's syndrome—azoospermia, sinusitis

i Box 20.40 Symptoms and signs in bronchiectasis

- ***Cough:*** usually persistent
- ***Sputum production:*** large amounts and purulent
- ***Breathlessness:*** as disease progresses
- ***Haemoptysis:*** usually a sign of infection; streaking is common, massive haemoptysis is a rare medical emergency
- ***Infection:*** usually characterized by increased sputum volume and increased purulence
- ***Pleuritic chest pain:*** can be a feature of infection
- ***Coarse crackles:*** heard on auscultation but examination can be normal
- ***Clubbing:*** especially in cystic fibrosis

Airway clearance

Daily airway clearance therapies are advised. Active cycle breathing techniques, autogenic/self-drainage and postural drainage are used. Several devices are available to assist, including Flutter or Acapella, providing positive expiratory pressure with or without airway oscillation. Nebulized hypertonic saline is approved as a mucoactive agent.

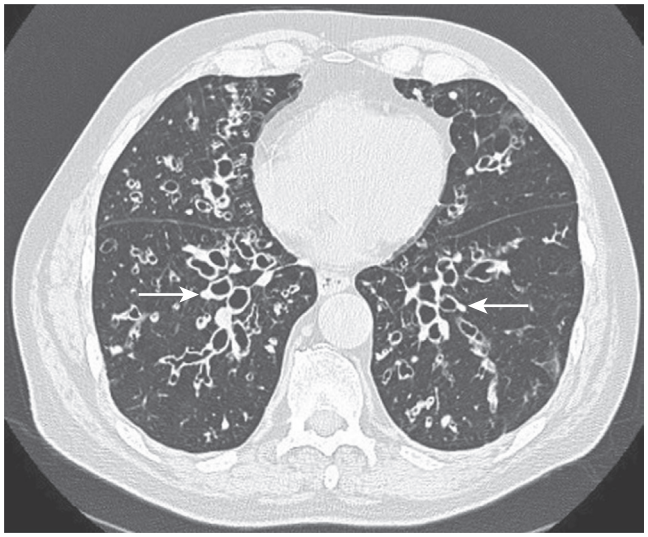

Fig. 20.28 CT scan showing bronchiectasis. Note the dilated bronchi with thickened wall, which are larger than adjacent arteries, giving a signet ring appearance *(white arrows)*.

Anti-inflammatories

Long-term azithromycin has an immunomodulatory effect and has been demonstrated to reduce exacerbation frequency. Inhaled corticosteroids are beneficial to some patients.

Treatment of infection

Treatment of exacerbations usually lasts 2 weeks and is initially based on previously obtained microbiological information. High-dose ciprofloxacin (750 mg twice daily) is a useful oral drug for treatment of *Pseudomonas*, though dual therapy is often required due to multiresistant pathogens. *H. influenzae* infection is common and usually responds to amoxicillin, co-amoxiclav, or doxycycline. Multiresistant species may need intravenous cephalosporin treatment. Experience in CF has promoted the use of aggressive antibiotic strategies in bronchiectasis, with eradication therapy and chronic suppressive nebulized therapy with colistimethate or an aminoglycoside for *P. aeruginosa*. Rotating oral antibiotic regimens and long-term quinolones should be avoided.

Treatment of complications

- Pulmonary rehabilitation should be offered to patients with a reduced exercise capacity and breathlessness.
- Massive haemoptysis is a life-threatening medical emergency. Treatment is resuscitation with airway protection until bronchial artery embolization can be performed. If this is not successful or available, surgery may be required.
- Treatment of *Aspergillus* lung disease and NTM is covered in 'Diseases caused by *Aspergillus fumigatus*' section.
- Respiratory failure should be treated with oxygen and non-invasive ventilation. Suitable patients should be referred for transplantation.
- Surgery may be considered for localized disease.

Prognosis

Prognosis is variable, depending on disease severity. A low FEV_1 and infection with *P. aeruginosa* are associated with poorer outcomes.

Box 20.41 CFTR abnormalities in CF

Class	CFTR effect	Mutation example
I	Protein synthesis defect. No functional CFTR	G542X, R553X
II	Folding/trafficking defect. Does not reach apical membrane	F508del
III	Gating defect	G551D
IV	Conductance impairment due to narrow channel	R117H
V	Splicing defect	3849+10kbC>T
VI	Reduced stability	4326delTC

CYSTIC FIBROSIS

Cystic fibrosis (CF) is an autosomal recessive condition. In the UK, the birth prevalence is 1 in 2500 and the carrier rate is 1 in 25. Rates are lower in non-Caucasian populations. Survival has improved dramatically. The current expected median survival is now over 50 years of age and is likely to continue to improve with new developments in treatments. CF is a multisystem disease, although respiratory problems are usually the most prominent. A cycle of mucus stasis, inflammation, and infection leads to progressive respiratory failure. Most individuals with CF have pancreatic insufficiency.

Pathogenesis

The CF gene is located on the long arm of chromosome 7 at position 31.2. Mutations lead to abnormalities in the production of the cystic fibrosis transmembrane conductance regulator (CFTR) protein. This protein is expressed in the apical membrane of epithelial cells and acts as a chloride channel. Over 1000 mutations have been identified, most of them rare. The F508del mutation is the most common, accounting for around 70% of cases. Mutations have been divided into different classes, depending on their effect on CFTR (Box 20.41). This classification is used therapeutically, with new CF treatments aimed at improving CFTR function. Ivacaftor was the first drug available for CF that improves CFTR function.

In the lungs, CFTR dysfunction leads to dehydrated airway surface liquid, mucus stasis, airway inflammation, and recurrent infection. This process originates in the small airways, leading to progressive airway obstruction and bronchiectasis (Fig. 20.29).

Clinical features and complications

CF is a multisystem disease but in 90% of cases morbidity and mortality are related to respiratory disease. Pancreatic insufficiency occurs in the majority of patients and CF-related diabetes is becoming increasingly common as survival improves, occurring in up to 50% of older adults with CF. Liver disease occurs in around 20%, leading to cirrhosis in around 2%. Clinical manifestations and complications are summarized in Box 20.42.

Diagnosis

Most new CF diagnoses are currently made at newborn screening. The test involves measuring immunoreactive trypsinogen at the time of the neonatal heel-prick test. If the concentration is raised, formal testing is performed. Aside from neonatal screening, diagnosis for children and adults is based on a combination of:

- Common clinical features (see Box 20.42).
- CFTR functional testing. The ***sweat test (pilocarpine iontophoresis)*** measures chloride concentration. The normal range is <30

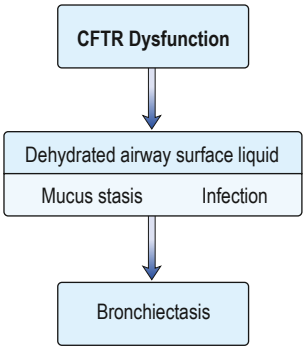

Fig. 20.29 **Cystic fibrosis: pathogenesis of lung disease.**

Box 20.42 Clinical features and complications of cystic fibrosis

Respiratory
- Recurrent respiratory infection
- Chronic daily cough and sputum production
- Breathlessness
- Nasal polyps
- Haemoptysis (sometimes massive)
- Pneumothorax
- Respiratory failure
- Cor pulmonale
- Recurrent sinusitis

Gastrointestinal
- Failure to thrive in infancy, low body mass index in adults
- Meconium ileus in infancy
- Distal intestinal obstruction syndrome
- Steatorrhoea secondary to pancreatic insufficiency
- Cystic fibrosis-related liver disease and cirrhosis
- Increased risk of gastrointestinal malignancy

Other
- Cystic fibrosis-related diabetes
- Male and female infertility
- Osteoporosis
- Arthropathy

mmol/L, with concentrations of 30–60 mmol/L found in milder 'atypical' phenotypes. Where there is diagnostic difficulty, nasal potential difference can be measured.
- Confirmatory genetic testing.

Management

Patients with CF should be managed in a specialist centre by a multidisciplinary team of healthcare professionals. They should have a clinical review at least every 3 months and a detailed annual review. Lung function (FEV_1) and body mass index (BMI) should be recorded at every appointment, as they have prognostic importance.

Treatment of pulmonary disease

The aim of chronic pulmonary therapies is to slow the decline in FEV_1 and reduce daily symptoms and exacerbation frequency.
- ***Airway clearance techniques*** are a vital part of CF treatment, taught to patients and their caregivers by specialist respiratory physiotherapists. Techniques include percussion, vibration, deep breathing, and forced coughing. There is no consensus on the best technique and patient choice is an important factor.
- ***Nebulized therapy:***
  - Recombinant human DNase (rhDNase) works by lysing bacterial DNA and reducing sputum viscosity. Routine treatment is advised from early childhood (regardless of disease status) due to evidence of improvement in lung disease and possible survival benefit.
  - Hypertonic saline works as an osmotic agent to draw water to the cell surface and reduce sputum viscosity.
  - Inhaled mannitol increases mucociliary clearance.
- ***Anti-inflammatory treatment*** with long-term azithromycin is widely used in CF and has an immunomodulatory effect.

Treatment of respiratory infection

Respiratory infection is dangerous for patients with CF. Clinics are microbiologically cohorted, patients are managed in single rooms, and no patient social events are organized. *P. aeruginosa* infection is common and associated with accelerated decline in lung function. Eradication is aim of treatment. A combination of oral, nebulized, and intravenous antibiotics can be given, together with long-term nebulized suppression therapy. Other organisms, such as *Burkholderia cepacia*, methicillin-resistant *S. aureus* (MRSA), and *Stenotrophomonas maltophilia*, have been associated with worsening respiratory outcomes and so eradication regimens for these bacteria are also used. Non-tuberculous mycobacterial disease, in particular *M. abscessus*, can be associated with rapid decline and active infection may preclude transplantation. In exacerbations, intravenous antibiotic therapy is based on previous infection history; *in vitro* sensitivities are less useful. Many patients have a permanently implanted venous access device for delivery of intravenous therapy.

CFTR modulators

CFTR modulators (Kaftrio, Kalydeco, and Symdeko) are licensed in the UK. Ninety percent of patients are eligible for this highly effective combination therapy which is already changing outcomes and life expectancy.

Advanced disease

Respiratory failure is treated with oxygen and NIV. Patients are referred for consideration of lung transplantation when FEV_1 falls to around 30% predicted. In end-stage disease, palliative care is an essential. This can be challenging when patients are on an active waiting list for a lung transplant.

Non-respiratory complications

Pancreatic enzymes and vitamin supplements are used to treat patients with pancreatic insufficiency. Close attention is paid to diet and calorie supplementation. Overnight gastric feeding may be required to maintain BMI in some patients.

CF-related diabetes is screened for at annual review. It is distinct from type 1 and type 2 diabetes. It commonly requires treatment with insulin. Osteoporosis is screened for and treated. Fertility treatment is available for males with CF who are infertile. Females with CF should be offered pre-pregnancy counselling, and have close maternal and fetal surveillance in pregnancy, usually delivering in a maternal medicine centre.

INTERSTITIAL LUNG DISEASES

This heterogeneous group of conditions is also referred to as ***diffuse parenchymal lung diseases*** and accounts for about 15% of respiratory clinical practice. They are characterized by varying degrees of inflammation and fibrosis, initially affecting the interstitium of the lung and typically presenting with exertional dyspnoea, with or without cough. A classification is shown in Fig. 20.30.

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder; it commonly affects young adults and typically presents with bilateral hilar lymphadenopathy, pulmonary infiltration, and skin or eye lesions.

Epidemiology and aetiology

Sarcoidosis is a disease of unknown aetiology, often detected on routine chest radiography. It is most common in Northern Europe (annual incidence 5–40/100 000) and uncommon in Japan (incidence 1–2/100 000). It occurs more frequently in Afro-Caribbean patients, who are also more likely to develop extrapulmonary and chronic disease. There is a female preponderance with a peak incidence in the third and fourth decades. There is no relation to any histocompatibility antigen, but first-degree relatives (particularly Caucasians) have an increased risk of developing sarcoidosis.

Immunopathology

- Typical sarcoid granulomas consist of focal accumulations of epithelioid cells, macrophages, and lymphocytes, mainly T cells.
- Depressed cell-mediated reactivity to tuberculin; the Mantoux test is usually negative. Circulating T lymphocytes are low but B cells are slightly increased, with overall lymphopenia.
- Bronchoalveolar lavage shows an increase in the overall cell number; a lymphocytosis (particularly $CD4^+$ T-helper cells) is common.
- Transbronchial biopsies show infiltration of the alveolar walls and interstitial spaces with leucocytes, mainly T cells, prior to granuloma formation.

Clinical features

Sarcoidosis can affect any organ (Box 20.43) but has a predilection for the lungs (up to 90%). Presentation may be with respiratory symptoms, but it is not unusual for the diagnosis to be made incidentally on chest radiography. Common extrathoracic manifestations include eye, skin, or lymph node involvement. Constitutional upset with fatigue is frequent and often refractory.

Löfgren's syndrome is the typical combination of bilateral hilar lymphadenopathy, erythema nodosum, arthralgia, and fever. It usually resolves spontaneously without the need for treatment.

In less classic presentations, HRCT may suggest sarcoidosis, but tissue biopsy of an affected organ is required for definitive diagnosis (non-caseating granuloma). Skin biopsy is relatively non-invasive, and careful examination for infiltration of scars and tattoos amenable to sampling should be undertaken.

Pulmonary manifestations

Cough, exertional breathlessness, and vague chest discomfort are common presentations. The chest is often clear to auscultation, although wheeze may be evident if there is significant endobronchial

disease. There are four radiological stages of lung involvement, which help inform prognosis:

- ***Stage 1.*** Bilateral hilar lymphadenopathy (BHL) alone: 55%–90% spontaneous remission.
- ***Stage 2.*** Pulmonary infiltrates with BHL: 40%–70% spontaneous remission.
- ***Stage 3.*** Pulmonary infiltrates without BHL: 10%–20% spontaneous remission.
- ***Stage 4.*** Pulmonary fibrosis: once established, tends to be irreversible

Patients may present with any stage of disease and do not necessarily progress through the stages sequentially. Moreover, the extent of disease on chest radiography does not correlate with impairment on pulmonary function testing.

Box 20.43 Clinical presentations of sarcoidosis

Constitutional
- Fever
- Weight loss
- Fatigue

Reticuloendothelial
- Splenomegaly
- Lymphadenopathy

Respiratory
- Stage 1–4 pulmonary involvement
- Cough
- Dyspnoea
- Wheeze

Hepatic
- Deranged liver function
- Hepatomegaly

Renal
- Interstitial nephritis and chronic kidney disease

Ocular
- Anterior uveitis
- Keratoconjunctivitis sicca

Hypercalcaemia/ hypercalciuria
- Nephrocalcinosis
- Calculi
- Tubulointerstitial nephritis

Cutaneous
- Erythema nodosum
- Lupus pernio

Neurological
- Cognitive dysfunction
- Headache
- Cranial nerve palsies
- Mononeuritis multiplex
- Peripheral neuropathy
- Seizures

Cardiac
- Arrhythmias
- Heart block
- Cardiomyopathy
- Sudden death

Bilateral hilar lymphadenopathy

Symmetrical BHL is a characteristic feature of sarcoidosis and is usually asymptomatic. Occasionally, it is associated with a dull ache in the chest, malaise, and a mild fever. The differential diagnosis of BHL includes:

- ***Lymphoma:*** rarely affects the hilar lymph nodes in isolation.
- ***Pulmonary TB:*** asymmetrical enlargement is usual.
- ***Carcinoma of the bronchus with lymph node spread:*** rarely symmetrical.

Pulmonary infiltration

Although the lung fields may appear normal on plain chest radiography, the lung parenchyma is frequently involved as shown by CT scanning (Fig. 20.31), transbronchial biopsy, and bronchoalveolar lavage. Symptoms may be minimal (or even absent) despite marked radiographic abnormalities. Progressive disease leads to irreversible fibrosis in up to 20% of cases. The principal differential diagnoses are TB, pneumoconiosis, IPF, and HP.

Extrapulmonary manifestations

Sarcoidosis can affect any organ. Cutaneous sarcoidosis and ocular sarcoidosis are the most common extrapulmonary presentations, but cardiac, CNS, and renal involvement are the most important clinically.

Skin

Occur in 10%–30% of cases. Sarcoidosis is the most common cause of erythema nodosum (see Chapter 45, 'Erythema nodosum' section). Lupus pernio (indurated erythematous or violaceous papules or plaques, Fig. 20.32) may be seen over the face and ears.

Eye

Anterior, or less commonly posterior, uveitis presents with misting of vision, a painful, red eye, or progressive loss of vision in 5% of patients. Asymptomatic uveitis may be found in up to 25% of patients, and ophthalmological assessment should be considered in all patients with a new diagnosis. Keratoconjunctivitis sicca and lacrimal gland enlargement also occur.

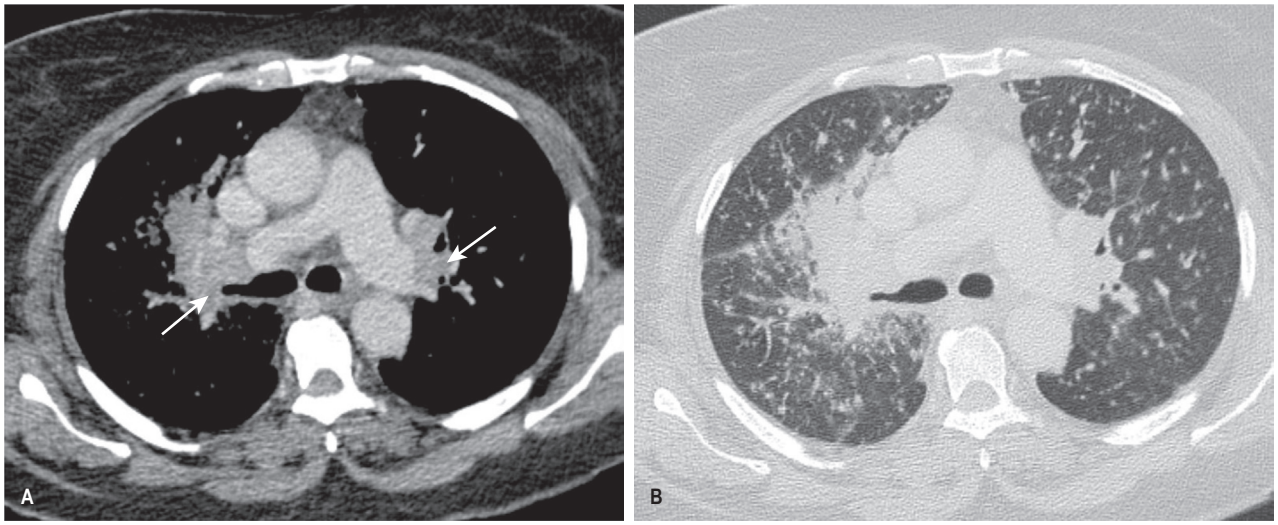

Fig. 20.31 CT chest showing sarcoidosis. **(A)** Soft tissue settings demonstrate bilateral hilar lymphadenopathy *(arrowed)*. **(B)** Lung settings demonstrate multiple small nodules and reticulation in both lungs.

Fig. 20.32 **The lupus pernio form of sarcoidosis.**

Metabolic manifestations

Hypercalcaemia and hypercalciuria can lead to the development of renal calculi, nephrocalcinosis, chronic kidney disease, and kidney failure.

Central nervous system

CNS involvement is rare (2%) but can lead to severe neurological disease (see Chapter 28).

Bone and joint involvement

Arthralgia without erythema nodosum is seen in 5% of cases. Bone cysts with associated swelling, particularly affecting the digits, may be seen on plain radiographs.

Hepatosplenomegaly

Mild derangement of liver function tests is common, and granulomas are seen in most biopsy specimens, although these findings are rarely of clinical consequence. Progression to portal hypertension or liver failure is uncommon.

Renal involvement

Sarcoidosis classically causes a granulomatous tubulointerstitial nephritis, although kidney damage secondary to hypercalcaemia and stone formation may also be seen.

Cardiac involvement

Ventricular dysrhythmias, conduction defects, and cardiomyopathy with congestive cardiac failure are rare (3%). Severity ranges from benign rhythm disturbance to sudden cardiac death. All patients with sarcoidosis should have an ECG and echo at presentation.

Investigations

- ***Imaging*.** Chest radiography is the initial modality for staging, followed by HRCT for assessment of parenchymal involvement. This may show nodules of up to 10 mm diameter that form a characteristic 'beading' appearance along airways, vessels, and fissures. Nodules may aggregate into larger nodules or masses of up to 3 cm. There may be increased reticulation due to septal thickening, with honeycombing in severe cases fibrotic.
- ***Full blood count*.** Mild, normochromic, normocytic anaemia with raised ESR.
- ***Biochemistry*.** Kidney involvement is occasionally found and biopsy may be indicated. Hypercalcaemia occurs in 10%–20% and hypercalciuria in 30%–50%. Activated macrophages in lung and lymph nodes are able to hydroxylate vitamin D directly (independent of parathyroid hormone levels), leading to increased intestinal absorption of dietary calcium. Urinary calcium excretion should be performed at presentation.
- ***Serum ACE concentration*.** This is elevated in over 75% of patients with untreated sarcoidosis. Raised (but lower) concentrations are also seen in patients with lymphoma, pulmonary TB, asbestosis, and silicosis limiting specificity. The utility of serum ACE in monitoring disease activity and response to treatment is contentious.
- ***Cardiac tests*.** ECG and echocardiogram should be performed at presentation. If these raise concern about underlying cardiac sarcoidosis, then further investigation is with cardiac MRI.
- ***EBUS and bronchoscopy*.** Both EBUS and bronchoscopy can be used for diagnosis. EBUS has been shown to give a higher diagnostic yield. Transbronchial biopsy of the lung parenchyma is positive in up to 80% of cases of stage 2 and 3 disease. Bronchoalveolar lavage typically shows a lymphocytosis with raised CD4:CD8 ratio.
- ***Lung function tests*.** These show a restrictive lung defect with reduced gas transfer in patients with parenchymal infiltration or fibrosis. However, an obstructive defect may be seen in endobronchial disease, and a mixed pattern is also possible. Lung function is usually normal in patients with isolated hilar adenopathy or extrapulmonary disease.

Prognosis and management

The disease course is unpredictable and varies from spontaneous remission to progression and death in a small number (1%–5%). Even if remission occurs, relapses are common. Worse outcomes are seen in patients of Afro-Caribbean and Asian ethnicities, and those presenting with extrathoracic disease. Systemic treatment is indicated for hypercalcaemia and extrathoracic major organ involvement, particularly neurological, cardiac, and renal, and in ocular disease resistant to topical therapy. Treatment of pulmonary sarcoidosis is less clear-cut as spontaneous resolution is frequently seen, typically within the first 6 months. Moreover, although corticosteroids improve radiographic appearances, this is not consistently reflected in improved lung function. Treatment is therefore reserved for patients with troublesome symptoms, deteriorating lung function, or radiological evidence of disease progression. First-line treatment is with prednisolone (or equivalent) 0.5 mg/kg for 4–6 weeks, gradually tapering to a maintenance dose for at least 12 months. Alternative immunosuppressants, including methotrexate, azathioprine, and hydroxychloroquine, have been used in place of, or in addition to, prednisolone. Relapses are common on withdrawal of therapy. Lung transplantation should be considered for suitable patients with stage IV disease and respiratory failure.

Idiopathic interstitial pneumonias

The terminology used to describe the idiopathic interstitial pneumonias can be confusing, but distinction must be made between subgroups due to significant differences in prognosis and treatment. Clinical patterns usually link to particular histological subtypes; classification is shown in **Box 20.44**.

Idiopathic pulmonary fibrosis

Idiopathic pulmonary fibrosis (IPF) is the most common of the idiopathic interstitial pneumonias. It is a progressive and ultimately fatal disease of unknown cause. There is significant worldwide variation in reported prevalence, but incidence appears to be increasing. The onset is usually in the seventh decade, and is rare below the age of 50. Males are twice as likely to be affected.

Box 20.44 Classification of idiopathic interstitial pneumonias

Clinical diagnosis	Pathological pattern
Idiopathic pulmonary fibrosis (IPF)	Usual interstitial pneumonia (UIP)
Desquamative interstitial pneumonia (DIP)	Desquamative interstitial pneumonia (DIP)
Respiratory bronchiolitis interstitial lung disease (RBILD)	Respiratory bronchiolitis interstitial lung disease (RBILD)
Acute interstitial pneumonia (AIP)	Diffuse alveolar damage (DAD)
Non-specific interstitial pneumonia (NSIP)	Non-specific interstitial pneumonia (NSIP)
Cryptogenic organizing pneumonia (COP)	Organizing pneumonia (OP)

(From ATS/ERS. An official American Thoracic Society/European Respiratory Society statement: update of the international multidisciplinary classification of the idiopathic interstitial pneumonias. Am J Respir Crit Care Med *2013; 188:733–748.)*

Pathology

Usual interstitial pneumonia (UIP) is the histological finding in IPF. The key feature is a heterogenous appearance with areas of normal lung punctuated by areas of marked fibrosis, honeycombing mainly in subpleural areas, and fibroblastic foci (dense proliferations of fibroblasts and myofibroblasts). The terms IPF and UIP are often used interchangeably but they are *not* synonymous, as UIP is also the primary histological finding in several other diffuse parenchymal lung diseases (e.g., pulmonary autoimmune rheumatic disease).

Pathogenesis

It is thought that repetitive injury to the alveolar epithelium, caused by currently unidentified environmental stimuli, leads to the activation of several pathways responsible for repair of the damaged tissue. However, in IPF, the wound healing mechanisms become uncontrolled, leading to over-production of fibroblasts and deposition of increased extracellular matrix in the interstitium with little inflammation. The structural integrity of the lung parenchyma is therefore disrupted: there is loss of elasticity and the ability to perform gas exchange is impaired, leading to progressive respiratory failure.

Clinical features

Patients typically present with insidious onset of progressive dyspnoea that may be accompanied by cough, with or without sputum production. Bi-basal end-inspiratory crackles are found on examination and therefore it is not uncommon for patients to be mistakenly treated for heart failure or recurrent chest infections before diagnosis of IPF is made. Finger clubbing is seen in 25%–50% of cases.

Progressive respiratory failure may be complicated by pulmonary hypertension. Stepwise deterioration can occur due to pneumothorax, pulmonary embolism, or intercurrent infection, but acute exacerbations with no identifiable cause are well recognized and are associated with increased mortality.

Investigations

- ***Respiratory function tests*** usually show a restrictive pattern (FEV_1/FVC ratio >70%), with reduced lung volumes and gas transfer. However, spirometry may be normal in early disease and lung volumes can be preserved in the presence of coexisting emphysema.

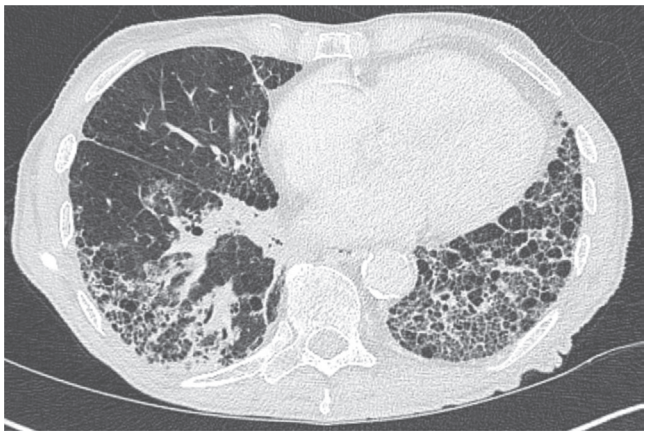

Fig. 20.33 CT demonstrating idiopathic pulmonary fibrosis.
There is subpleural reticulation and honeycombing of both lungs.

- ***Blood tests.*** There is no specific serological test for IPF. Antinuclear antibodies (ANA) and rheumatoid factor (RF) are performed to exclude autoimmune connective tissue disease.
- ***Chest radiograph*** shows small-volume lungs with increased reticular shadowing at the bases. It may be normal in early disease.
- ***CT*** is the imaging modality of choice. A confident diagnosis of IPF may be made in patients with:
  - ***Basal distribution:*** abnormalities are more pronounced at lung bases
  - ***Subpleural reticulation:*** reticulation most evident in lung peripheries
  - ***Traction bronchiectasis:*** the fibrotic process distorts normal lung architecture, pulling the airways open and causing bronchiectasis
  - ***Honeycombing:*** basal layers of small, cystic airspaces with irregularly thickened walls composed of fibrous tissue (Fig. 20.33).
- ***Bronchoalveolar lavage*** is performed to exclude malignancy and infection. A differential cell count may support other diagnoses: lymphocytosis is suggestive of HP or sarcoidosis, and eosinophilia occurs in eosinophilic pneumonia.
- ***Histological confirmation*** is necessary in some patients. Surgical lung biopsy, usually via VATS, is the most reliable method for obtaining diagnostic histological samples; transbronchial biopsy can be undertaken bronchoscopically but only obtains small samples. Cryobiopsies are undertaken in some centres.

Differential diagnosis

The main differential diagnoses for the UIP pattern of fibrosis are vasculitis, HP, connective tissue disease, and asbestos exposure. Differentials for the chest radiograph appearance include interstitial pulmonary oedema, infection, and lymphangitis carcinomatosa.

Prognosis and management

The median survival time for patients with IPF is 2–5 years. Serial lung function testing is used to monitor disease progression and a 10% decline in FVC or 15% decline in gas transfer (TLCO) in the first 6–12 months confers a worse prognosis. Periods of stability may be interspersed with spells of more accelerated decline but failure to recover back to baseline following these episodes is common. Mortality is increased following acute exacerbations.

Pirfenidone and nintedanib, two licensed antifibrotic agents, have been shown to slow the rate of FVC decline. The most common

Box 20.45 Other idiopathic interstitial pneumonias (IIPs)

IIP	Presentation	HRCT	Pathology	Treatment[a]
Desquamative interstitial pneumonia (DIP)	Middle-aged smokers Males 2:1 females Dyspnoea and cough over weeks to months	Widespread ground-glass opacification	Alveolar spaces filled with pigmented macrophages (due to tobacco smoke)	Smoking cessation—may remit spontaneously Corticosteroids in severe or progressive disease ± additional immunosuppressants Response generally good
Respiratory bronchiolitis interstitial lung disease (RBILD)	Current or ex-smokers Similar to DIP	Centrilobular nodules Ground-glass opacification	Pigmented macrophages in lumen of respiratory bronchioles	Smoking cessation No clear benefit to corticosteroids Outcome more favourable than in DIP
Acute interstitial pneumonia (AIP)	Dyspnoea and progressive respiratory failure over days to weeks Often preceded by viral prodrome	Ground-glass opacification Traction bronchiectasis Consolidation Septal thickening	Diffuse alveolar damage (DAD)	Pulsed i.v. methylprednisolone for 3 days followed by maintenance oral corticosteroids Additional immunosuppressants may be required Mortality 50%–80%
Non-specific interstitial pneumonia (NSIP)	Similar to IPF but more indolent course May be associated with connective tissue disease	Similar to IPF but increased ground-glass opacification, minimal honeycombing	Uniform inflammatory infiltrate with or without fibrosis (fibrotic vs cellular NSIP)	Smoking cessation Corticosteroids ± additional immunosuppressants e.g., azathioprine, cyclophosphamide Prognosis better with cellular form Outcome more favourable than in IPF
Cryptogenic organizing pneumonia (COP)	Influenza-like symptoms, dyspnoea, cough over weeks to months Secondary OP may be related to connective tissue, autoimmune disease, or drugs	Bilateral flitting/migratory peripheral consolidation Variable ground-glass opacification	Buds of connective tissue (Masson bodies) in alveoli and alveolar ducts	Usually rapidly responsive to corticosteroids but relapses common

[a]Nintedanib is recommended as an additional therapy in all fibrotic interstitial lung disease with a progressive phenotype (symptoms, lung function, or radiology), despite adequate treatment of underlying cause.
HIV, Human immunodeficiency virus; *HRCT,* high-resolution computed tomography; *IPF,* idiopathic pulmonary fibrosis.

side-effects are a reversible photosensitive rash and gastrointestinal disturbance. Gastro-oesophageal reflux disease should be treated if symptomatic. Immunosuppression is avoided in IPF and steroids are not recommended.

Even with treatment, IPF is a life-limiting disease and transplant assessment should be undertaken in accordance with local guidelines. All patients should have their need for supportive care evaluated with respect to oxygen therapy, pulmonary rehabilitation, and palliative care input.

Other idiopathic interstitial pneumonias

These are described in **Box 20.45**.

Hypersensitivity pneumonitis

Hypersensitivity pneumonitis (HP) is an allergic reaction affecting the small airways and alveoli in response to an inhaled antigen or occasionally following ingestion of a causative drug. See **Box 20.46**. One of the most common causes worldwide is farmer's lung, which affects up to 9% of farmers in humid climates. Cigarette smokers have a lower risk of developing HP due to decreased antibody reaction to antigen, but once established, smoking may lead to a more chronic or severe disease course.

Pathogenesis

Histological features include chronic inflammatory infiltrates and poorly defined interstitial granulomas, together with interstitial fibrosis and honeycomb change in chronic disease. The allergic response to the inhaled antigen involves both cellular immunity and deposition of immune complexes, causing foci of inflammation through activation of complement via the classical pathway.

Clinical features

HP can be categorized according to the time course of symptoms, determined by duration and intensity of exposure. Symptoms include weight loss, malaise, dyspnoea, and cough. Auscultation reveals inspiratory squeaks due to bronchiolitis, and bilateral fine crackles. Wheeze is uncommon.

- ***Acute:*** Symptom onset 4–6 h following exposure. Fever is common and patients may be mistakenly diagnosed with infection. Resolution occurs 24–48 h after inciting antigen removal.
- ***Subacute:*** Usually occurs with intermittent or lower-level exposure. Improvement is seen in weeks to months following antigen removal.
- ***Chronic:*** Insidious onset of respiratory and constitutional symptoms is typical, with no history of preceding acute symptoms.

Box 20.46 Some causes of hypersensitivity pneumonitis

Disease	Situation	Antigens
Farmer's lung	Forking mouldy hay/vegetable material	Thermophilic actinomycetes, e.g., *Micropolyspora faeni* Fungi, e.g., *Aspergillus umbrosus*
Bird fancier's lung	Handling pigeons, cleaning lofts or budgerigar cages	Proteins present in the 'bloom' on the feathers and in excreta
Maltworker's lung	Turning germinating barley	*Aspergillus clavatus*
Humidifier fever	Contaminated humidifying systems in air conditioners or factories (especially printing works)	Possible variety of bacterium or amoeba (e.g., *Naegleria gruberi*) Thermophilic actinomycetes
Mushroom worker's lung	Turning mushroom compost	Thermophilic actinomycetes
Cheese washer's lung	Mouldy cheese	*Penicillium casei* *Aspergillus clavatus*
Winemaker's lung	Mould on grapes	Botrytis

Finger clubbing may be present. Progression to irreversible fibrosis is associated with increased mortality.

Investigations

A high index of suspicion and detailed exposure history are required. Identification of a culprit antigen in the context of typical clinical and radiological findings often makes lung biopsy unnecessary.

- ***Chest radiograph*** may be normal in acute and subacute disease. When present, abnormalities include diffuse small nodules and increased reticular shadowing.
- ***CT*** shows nodules with ground-glass opacity and evidence of air trapping. Increased reticulation and honeycomb change are seen in advanced disease. Abnormalities are most marked in mid or upper zones.
- ***Lung function tests*** are not diagnostic. A restrictive ventilatory defect with decreased carbon monoxide gas transfer is seen in chronic disease.
- ***Precipitating antibodies*** are present in the serum. One-quarter of pigeon fanciers have precipitating IgG antibodies against pigeon protein and droppings in their serum, but only a small proportion have lung disease. Precipitating antibodies are therefore evidence of exposure, not disease.
- ***Bronchoalveolar lavage*** shows a lymphocytosis. A low CD4:CD8 ratio can help differentiate HP from sarcoidosis.
- ***Lung biopsy*** demonstrates a lymphocyte-rich infiltrate with varying degrees of fibrosis, depending on chronicity.

Differential diagnosis

Although HP due to inhalation of the spores of *Micropolyspora faeni* is common among farmers (farmer's lung), it is probably more usual for these individuals to suffer from asthma related to inhalation of antigens from the variety of mites that infest stored grain and other vegetable material, such as *Lepidoglyphus domesticus, L. destructor,* and *Acarus siro*.

Management

Avoidance of exposure to the inciting antigen (if known) is key and may require change in work practice. Pigeon fancier's lung is more difficult to control, as affected individuals remain strongly attached to their hobby. Prednisolone should be initiated in patients whose symptoms persist despite withdrawal from the causative antigen, and in severe disease. Immunosuppressants such as azathioprine and mycophenolate (MMF) may be used as second-line steroid-sparing agents. Established fibrosis will not resolve and, in some patients, the disease may progress inexorably to respiratory failure despite intensive therapy. Farmer's lung is a recognized occupational disease in the UK and sufferers are entitled to compensation, depending on the degree of disability.

Rare interstitial lung diseases

Langerhans cell histiocytosis

This rare disease is characterized histologically by proliferation of Langerhans cells. There is a wide variation in clinical presentation, from isolated lytic bone lesions to multisystem disease involving skin, lymph nodes, and major organs (more common in young children). Pulmonary involvement occurs in 10% of cases and is strongly associated with cigarette smoking. Recurrent spontaneous pneumothorax is seen in up to 25% and is a common mode of presentation. CT shows characteristic interstitial thickening, nodules, cysts, and honeycombing with mid- and upper-zone predominance. This may be sufficient for diagnosis in a young smoker (typical age 20–40 years). Smoking cessation is essential. Various treatment strategies including corticosteroids, chemotherapy agents, and the purine analogue cladribine, have been used with variable success. Lung transplantation may be considered in advanced disease. Outcome varies from spontaneous remission to progressive end-stage fibrosis. Overall, 5-year survival is 75%.

Pulmonary lymphangioleiomyomatosis

Pulmonary lymphangioleiomyomatosis (LAM) is a rare disorder of premenopausal females, causing hamartomatous smooth muscle infiltration of the lungs. Extrapulmonary involvement, especially with renal angiomyolipomas (hamartomas), is common. Some 15% of patients with pulmonary LAM have tuberous sclerosis. Presentation is with dyspnoea, chylous pleural effusions, and pneumothorax. CT shows diffuse thin-walled cysts scattered throughout the lungs. Treatment with hormonal manipulation or oophorectomy has shown a variable response. Sirolimus (rapamycin) can be effective but lung transplantation may be necessary.

Pulmonary alveolar proteinosis

In this rare disease, lipoproteinaceous material accumulates within the alveoli. It can be congenital but most cases are acquired and appear to have an autoimmune basis, with antibodies directed against cytokine granulocyte-macrophage colony-stimulating factor (GM-CSF). The disease mostly affects males and presents with progressive exertional dyspnoea and cough. Inspiratory crackles are present in 50%. Diagnosis is made by bronchoalveolar lavage,

which reveals a milky appearance and many large, foamy macrophages but few other inflammatory cells. Initial therapy is with whole-lung lavage.

Small-vessel vasculitides

The vasculitides are a group of autoimmune diseases that cause inflammation of blood vessels. The small-vessel vasculitides associated with ***anti-neutrophil cytoplasmic antibody (ANCA)*** include granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA, formerly called Churg–Strauss syndrome). Staining for ANCA shows either a diffuse pattern (c-ANCA) with antibodies directed against proteinase 3 (PR3), or a perinuclear pattern (p-ANCA) with antibodies to myeloperoxidase (MPO). The respiratory tract and kidneys are frequently involved and the ESR is often markedly elevated (>100 mm/h).

Granulomatosis with polyangiitis

GPA typically affects older adults and is more common in Caucasians. c-ANCA is usually positive with elevated PR3 antibodies. The ears and upper respiratory tract are frequently affected with bloody nasal discharge, crusting and destruction, sinusitis, and otitis media. Evidence of glomerulonephritis should be sought on urinalysis (see Chapter 26). Respiratory symptoms include cough, dyspnoea, and pleuritic chest pain. Diffuse alveolar haemorrhage occurs in up to 45% and haemoptysis can be life-threatening. Thoracic imaging characteristically shows multiple nodules that often cavitate, areas of consolidation, and ground-glass opacification (which may be due to pulmonary haemorrhage). Diagnosis should be confirmed with biopsy of the active site but it is sometimes necessary to initiate empirical treatment in acutely unwell patients. Biopsy has highest yield from kidneys, if renal involvement, or nasal sinuses if sinus involvement. Lung biopsy has lower yield. Initial immunosuppressant therapy is with a combination of glucocorticoids, cyclophosphamide, rituximab, or mycophenolate.

Microscopic polyangiitis

MPA is primarily associated with p-ANCA positivity. Presentation and treatment are similar to those of granulomatosis with polyangiitis. It is diagnosed on tissue biopsy, where the absence of granuloma formation differentiates it from GPA.

Eosinophilic granulomatosis with polyangiitis

EGPA classically presents in early adulthood with allergic rhinitis, asthma that is often difficult to control, and peripheral blood eosinophilia (>10%). ANCA is positive in up to 60% (usually p-ANCA). Systemic vasculitis subsequently develops, sometimes many years later. Involvement of skin (tender subcutaneous nodules, petechiae, or purpuric lesions), peripheral nerves (mononeuritis multiplex), heart, kidneys, and gastrointestinal tract may occur. Chest radiography shows migratory patchy opacities that may be accompanied by nodules and pleural effusions. EGPA generally responds well to corticosteroids, although additional immunosuppressants are required for severe or refractory disease. Occasionally, EGPA is 'unmasked' when oral steroids are withdrawn in patients being treated for asthma.

Anti-glomerular basement membrane disease (Goodpasture's syndrome)

Anti-glomerular basement membrane (anti-GBM) disease is characterized by the triad of pulmonary haemorrhage, glomerulonephritis, and the presence of circulating antibodies directed against an antigen intrinsic to the basement membrane of both kidney and lung. Respiratory symptoms may precede the onset of glomerulonephritis by weeks or months. Chest radiography shows transient patchy shadows due to intrapulmonary haemorrhage. Haemoptysis can vary from negligible to life-threatening. Carbon monoxide gas transfer is increased due to the presence of haemoglobin in the alveoli. The extent of renal recovery depends on early detection and treatment. Treatment is with plasmapheresis to remove circulating antibodies and immunosuppression (prednisolone and cyclophosphamide) to prevent further antibody production.

Diffuse alveolar haemorrhage

Bleeding into the alveolar spaces is associated with certain drugs, infections, and autoimmune rheumatic diseases including vasculitis, but can also occur without an identifiable precipitating cause. Haemoptysis may be minimal (or even absent), despite significant blood loss into the lungs. It is one of the relatively few causes of raised carbon monoxide gas transfer (K_{CO}). Gas exchange is impaired due to the presence of blood in the alveoli and patients may present with severe respiratory failure requiring intensive care support. Treatment is directed at the underlying cause, if known.

Pulmonary manifestations of autoimmune diseases

Rheumatoid lung disease

The lungs can be affected by rheumatoid arthritis (RA) (Fig. 20.34), and also by some of the drugs used in its treatment.

- ***Pleural effusions*** are often unilateral and tend to be chronic. Low glucose content is typical but not specific.
- ***Pulmonary fibrosis*** in RA has similar clinical features to the idiopathic form of the disease but often follows a more chronic course. In patients taking methotrexate, it is often impossible to determine whether fibrosis is due to the drug or the underlying disease so methotrexate is substituted for an alternative agent.
- ***Rheumatoid nodules*** appearing on chest radiography may be single or multiple, ranging in size from a few millimetres to a few

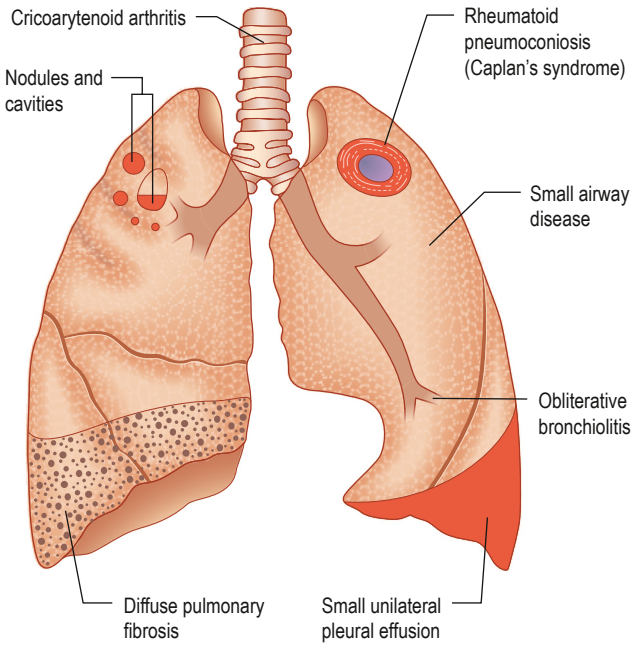

Fig. 20.34 **Respiratory manifestations of rheumatoid disease.**

centimetres, with frequent cavitation. They usually produce no symptoms but can give rise to a pneumothorax or pleural effusion.

- ***Obliterative bronchiolitis*** causing concentric narrowing of the bronchioles is a rare disorder characterized by progressive breathlessness and irreversible airflow limitation. Response to immunosuppressive therapy is generally poor. Macrolide antibiotics may have a role.
- ***Cricoarytenoid joint involvement*** in RA gives rise to dyspnoea, stridor, and hoarseness. Occasionally, severe obstruction necessitates tracheostomy.
- ***Caplan's syndrome*** is due to occupational dust inhalation in patients with RA. It occurs particularly in coal worker's pneumoconiosis but can be caused by exposure to other dusts, such as silica and asbestos. Typically, the chest radiograph shows rounded nodules 0.5–5.0 cm in diameter but progressive fibrosis can sometimes occur. These lesions may precede the development of arthritis. Rheumatoid factor is positive in the majority of patients.
- ***Drugs*** used in the treatment of RA can cause pulmonary disease:
  - pneumonitis with methotrexate, gold, and NSAIDs
  - fibrosis with methotrexate
  - bronchospasm with NSAIDs
  - infections with corticosteroids and other immunosuppressants
  - reactivation of TB with anti-TNF therapy.

Systemic lupus erythematosus

The most common respiratory manifestation is pleurisy, occurring in up to two-thirds of cases, with or without an effusion, which is usually small and bilateral. Pneumonia also occurs, either because of infection or because of the disease process itself. In contrast to RA, diffuse pulmonary fibrosis is uncommon.

Systemic sclerosis

Some degree of lung involvement is present in most cases of systemic sclerosis, and pulmonary complications are the leading cause of death. Interstitial fibrosis and pulmonary arterial hypertension are the most common pathologies. Serial lung function testing can aid early detection. Other complications include bronchiectasis and aspiration pneumonitis secondary to oesophageal dysfunction.

Pulmonary infiltration with eosinophilia

This is a group of allergic respiratory conditions. Common types and characteristics are shown in **Box 20.47**. They range from simple pulmonary eosinophilia to the often-fatal hypereosinophilic syndrome. ***Simple pulmonary eosinophilia*** is a relatively mild illness, with a slight fever and cough, and usually lasts for less than 2 weeks. If symptoms become more prolonged and there is an eosinophilia in the blood, it is then called ***chronic pulmonary eosinophilia***. In both conditions, the chest radiograph shows either localized or diffuse opacities. The simple form is probably due to a transient allergic reaction in the alveoli. Many allergens have been implicated including *Ascaris lumbricoides*, *Ancylostoma*, *Trichuris*, *Trichinella*, *Taenia*, and *Strongyloides*. Drugs such as aspirin, penicillin, nitrofurantoin, and sulphonamides have also been implicated. Often, however, no allergen is identified. The disease is self-limiting and no treatment is required, apart from withdrawing the identified cause. In the more chronic form, all unnecessary treatment should be withdrawn and corticosteroid therapy may be indicated, with resolution over weeks.

Asthmatic bronchopulmonary eosinophilia is characterized by the presence of asthma, transient fleeting shadows on the chest X-ray, and blood or sputum eosinophilia. By far the most common cause worldwide is allergy to *A. fumigatus* (see later), although *Candida albicans* and other mycoses may be the inciting allergen in a small number of patients. In many, no allergen can be identified. Whether these cases are intrinsic or driven by an unidentified extrinsic factor is uncertain. ***Tropical pulmonary eosinophilia*** is the term reserved for an allergic reaction to microfilaria from *Wuchereria bancrofti*.

Hypereosinophilic syndrome is characterized by eosinophilic infiltration in various organs, sometimes associated with an eosinophilic arteritis. The heart muscle is particularly involved, but pulmonary involvement in the form of a pleural effusion or interstitial lung disease occurs in about 40% of cases.

Diseases caused by *Aspergillus fumigatus*

The various types of lung disease caused by *A. fumigatus* are illustrated in **Fig. 20.35**.

Spores (diameter 5 mm) are readily inhaled and are present in the atmosphere throughout the year. *Aspergillus* can be grown from sputum in up to 15% of patients with chronic lung disease, in whom it does not produce active fungal disease. They are a cause of extrinsic asthma in atopic individuals.

Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)

This rare disease is caused by a hypersensitivity reaction when the bronchi are colonized by *Aspergillus*. It can complicate asthma and CF. Proximal bronchiectasis occurs.

Episodes of eosinophilic pneumonia present with wheeze, cough, fever, and malaise, associated with expectoration of firm sputum plugs containing fungal mycelium. Occasionally, large mucus plugs obliterate the bronchial lumen, causing collapse of the lung. Left untreated, repeated episodes of eosinophilic pneumonia can result in progressive pulmonary fibrosis that usually affects the upper zones.

The peripheral blood eosinophil count is usually raised and total levels of IgE are usually extremely high, at more than 1000 ng/mL (both specific to *Aspergillus* and non-specific). Sputum may show eosinophils and mycelia. Treatment is with 0.5 mg/kg of prednisolone daily for 2 weeks followed by a tapering regimen, which causes rapid clearing of pulmonary infiltrates. Antifungal agents should be

Box 20.47 Common types and characteristics of pulmonary infiltration with eosinophilia

Disease	Symptoms	Blood eosinophils (%)	Multisystem involvement	Duration	Outcome
Simple pulmonary eosinophilia	Mild	10	None	<1 month	Good
Prolonged pulmonary eosinophilia	Mild/moderate	>20	None	>1 month	Good
Asthmatic bronchopulmonary eosinophilia	Moderate/severe	5–20	None	Years	Fair
Tropical pulmonary eosinophilia	Moderate/severe	>20	None	Years	Fair
Hypereosinophilic syndrome	Severe	>20	Always	Months/years	Poor

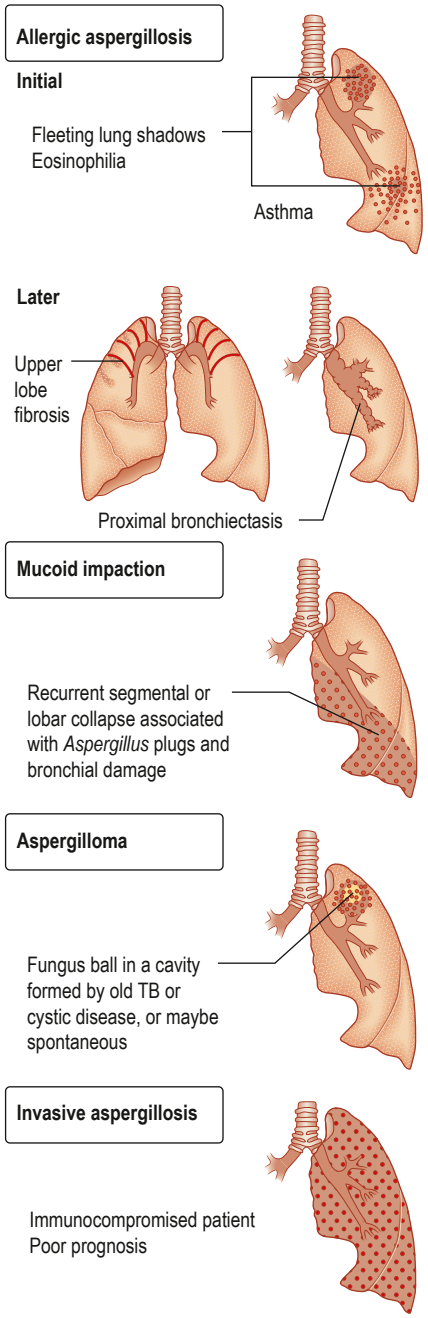

Fig. 20.35 **Diseases caused by *Aspergillus fumigatus*.**

used in patients on high doses of steroids. The asthma component responds to inhaled corticosteroids, although these do not influence the occurrence of pulmonary infiltrates.

Aspergilloma and invasive aspergillosis

Aspergilloma is the growth of *A. fumigatus* within previously damaged lung tissue, where it forms a ball of mycelium within lung cavities. Typically, the chest radiograph shows a round lesion with an air 'halo' above it. The aspergilloma itself causes little trouble, though occasionally haemoptysis may occur, requiring resection of the area of damaged lung containing the aspergilloma. Treatment is with oral antifungal agents, although invasive aspergillosis is a recognized complication of immunosuppression and often requires intravenous antifungal therapy.

Box 20.48 Some drug-induced respiratory reactions

Bronchospasm
- Penicillins, cephalosporins
- Sulphonamides
- Aspirin/NSAIDs
- Monoclonal antibodies, e.g., infliximab
- Iodine-containing contrast media
- β-Adrenoceptor-blocking drugs (e.g., propranolol)
- Non-depolarizing muscle relaxants
- Intravenous thiamine
- Adenosine

Interstitial lung disease and/or fibrosis
- Amiodarone
- Anakinra (IL-1 receptor antagonist)
- Nitrofurantoin
- Paraquat (weedkiller)
- Continuous oxygen
- Cytotoxic agents: particularly busulfan, CCNU, bleomycin, methotrexate

Pulmonary eosinophilia
- Antibiotics:
  - Penicillin
  - Tetracycline
  - Sulphonamides, e.g., sulfasalazine
- NSAIDs
- Cytotoxic agents

Acute lung injury
- Paraquat

Pulmonary hypertension
- Fenfluramine, dexfenfluramine, phentermine

SLE-like syndrome including pulmonary infiltrates, effusions, and fibrosis
- Hydralazine
- Procainamide
- Isoniazid
- Phenytoin
- Anti-TNF agents, particularly etanercept and infliximab

Drug- and radiation-induced respiratory reactions

Drugs affecting the respiratory system are shown in **Box 20.48**, together with the types of reaction they produce. Pulmonary infiltrates with fibrosis may result from a number of cytotoxic drugs used in cancer treatment. The most common causative drug is bleomycin, which causes dose-related pulmonary damage. The most sensitive test is a decrease in carbon monoxide gas transfer, and therefore gas transfer should be measured repeatedly during treatment with the drug. The use of corticosteroids may help resolution.

Irradiation of the lung during radiotherapy can cause radiation pneumonitis. Patients experience breathlessness and a dry cough. Radiation pneumonitis results in a restrictive lung defect. Corticosteroids should be given in the acute stage.

LUNG AND HEART–LUNG TRANSPLANTATION

Indications and donor selection

The main diseases treated by transplantation are:

- pulmonary fibrosis
- primary pulmonary hypertension
- cystic fibrosis
- bronchiectasis
- emphysema (particularly α_1-antitrypsin inhibitor deficiency)
- Eisenmenger's syndrome.

Patients selected for transplantation are usually under 60 years, have an untreated life expectancy of less than 18 months, with no underlying cancer and no serious systemic disease. Organs are taken from donors under 40 years, with good cardiac and lung function, and chest measurements slightly smaller than those of the recipient. Matching for ABO blood group is essential but Rhesus blood group compatibility is not necessary. Since donor material is limited, single-lung transplantation is preferred to double-lung or heart–lung transplantation. It can be successfully undertaken in pulmonary fibrosis, pulmonary hypertension, and emphysema. Bilateral lung transplantation is needed in infective conditions to prevent spillover of bacteria from the diseased lung to a single transplanted lung. Eisenmenger's syndrome requires heart–lung transplantation.

Immunosuppression is with ciclosporin (the inhaled formulation has shown benefit), tacrolimus, azathioprine, mycophenolate mofetil, and prednisolone.

Complications and their treatment

- ***Early post-transplant pulmonary oedema*** requires diuresis and ventilatory support.
- ***Infections*** are common, particularly within the first 3 months, and need prompt treatment:
  - bacterial pneumonia: antibiotics
  - cytomegalovirus infection: ganciclovir or valganciclovir (prophylaxis given in the early post-transplantation period)
  - herpes simplex virus: aciclovir
  - *Pneumocystis jirovecii:* co-trimoxazole (prophylaxis given in the early post-transplantation period).
- ***Rejection:***
  - Early (first few weeks): high-dose intravenous corticosteroids.
  - Late (after 3 months): often produces the histological pattern of obliterative bronchiolitis. High-dose intravenous corticosteroids are sometimes effective.
- ***Post-transplant lymphoproliferative disease*** refers to a range of lymphomas seen in recipients of solid organ transplants; they may respond to rituximab, an anti–B-cell monoclonal antibody, or other forms of chemotherapy.

Prognosis

Several studies show a major improvement in quality of life after transplantation. One-year survival rates are around 80%, with mortality rate thereafter of about 10%/year. Death is mainly due to obliterative bronchiolitis. Overall survival varies with the original diagnosis but median survival is approximately 4 years.

OCCUPATIONAL LUNG DISEASE

Exposure to dusts, gases, vapours, and fumes at work can cause several different types of lung disease:

- ***acute bronchitis*** and ***pulmonary oedema*** from irritants such as sulphur dioxide, chlorine, ammonia, or oxides of nitrogen
- ***pulmonary fibrosis*** caused by mineral dust
- ***occupational asthma*** (see **Box 20.14**) is now the most common industrial lung disease in high-income countries
- ***hypersensitivity pneumonitis*** (see **Box 20.46**)
- ***bronchial carcinoma*** due to industrial agents, e.g., asbestos, polycyclic hydrocarbons, and radon in mines.

Box 20.49 Taking an occupational history

- Proceed chronologically. Most people cannot randomly remember, for example, what they might have been doing 20 years ago, or indeed, if asked in isolation, when they worked in a particular job. But if you start at the beginning of their life and work forward they find it much easier to remember (try it on yourself, starting with school).
- Start by asking the patient how old they were when they left school, and what job or further education they went to; then ask them to continue through their life to the present day.
- Particularly for those who went on to further education, ask about holiday jobs (you might be surprised at their responses) and if they travelled overseas with their employment, especially if they were in the armed forces.
- Do not assume that all 80 year olds are retired or that all young patients are in employment.

The degree of fibrosis that follows inhalation of mineral dust varies. While iron (siderosis), barium (baritosis), and tin (stannosis) lead to dramatic, dense, nodular shadowing on chest radiography, their effect on lung function and symptoms is minimal. In contrast, exposure to silica or asbestos leads to extensive fibrosis and disability. Coal dust has an intermediate fibrogenic effect and historically accounted for 90% of all compensated industrial lung disease in the UK.

Box 20.49 outlines how to take an occupational history in lung disease.

Coal-worker's pneumoconiosis

Caused by coal dust particles approximately 2–5 μm in diameter and retained in the small airways and alveoli. Incidence is related to total dust exposure, which is highest at the coal face, particularly if ventilation and dust suppression are poor. Improved ventilation and working conditions reduce disease risk.

Two very different syndromes result from the inhalation of coal.

Simple pneumoconiosis

Due to deposition of coal dust in the lung, which produces fine micronodular shadowing on the chest radiographs. It is graded on the chest radiograph appearance according to standard categories set by the International Labour Office:

- ***Category 1:*** small round opacities definitely present but few in number
- ***Category 2:*** numerous small round opacities but normal lung markings still visible
- ***Category 3:*** very numerous small round opacities and normal lung markings partly or totally obscured.

There is considerable dispute about the effects of simple pneumoconiosis on respiratory function and symptoms. In many cases, symptoms may be due to COPD related to coexisting cigarette smoking. Changes to UK workers' compensation legislation mean that coal miners who develop COPD are compensated for disability regardless of chest radiograph appearance.

Simple pneumoconiosis can progress to the development of progressive massive fibrosis (see next section). The latter virtually never occurs on a background of category 1 simple pneumoconiosis but does arise in about 7% of category 2 disease and 30% of category 3 disease. Miners with category 1 pneumoconiosis are

unlikely to receive compensation unless they also have evidence of COPD. Those with more extensive radiographic changes are compensated solely on the basis of chest radiograph appearances.

Progressive massive fibrosis

In progressive massive fibrosis (PMF), patients develop round, fibrotic masses several centimetres in diameter, almost invariably situated in the upper lobes, sometimes with necrotic central cavities. Rheumatoid factor and antinuclear antibodies are both often present in the serum. Pathologically, there is apical destruction and disruption of the lung, resulting in emphysema and airway damage. Lung function tests show a mixed restrictive and obstructive defect with loss of lung volume, irreversible airflow limitation, and reduced gas transfer.

PMF leads to considerable effort dyspnoea, usually with a cough. Sputum may be black. The disease can progress (or even develop) after exposure to coal dust has ceased and may lead to respiratory failure.

Silicosis

Silicosis is caused by inhalation of silica (silicon dioxide). While uncommon, it may still be encountered in stonemasons, sandblasters, pottery and ceramic workers, and foundry workers involved in fettling (removing sand from metal castings made in sand-filled moulds). The dust is highly fibrogenic; a coal miner can remain healthy with 30 g of coal dust in the lungs but 3 g of silica is sufficient to kill. Silica seems particularly toxic to alveolar macrophages and readily initiates fibrogenesis. The chest radiograph appearances and clinical features of silicosis are similar to those of PMF but distinctive thin streaks of calcification may be seen around the hilar lymph nodes ('eggshell' calcification).

Diseases caused by asbestos

Asbestos is a mixture of silicates of iron, magnesium, nickel, cadmium, and aluminium, and has the unique property of occurring naturally as a fibre. It is remarkably resistant to heat, acid, and alkali, and has been widely used for roofing, insulation, and fireproofing. Several different types of asbestos are recognized: about 90% is chrysotile, 6% crocidolite, and 4% amosite.

Chrysotile (white asbestos) is the softest asbestos fibre. Each fibre is often as long as 2 cm but only a few microns thick. It is less fibrogenic than crocidolite.

Crocidolite (blue asbestos) is particularly resistant to chemical destruction and exists in straight fibres up to 50 cm in length and 1–2 μm in width. Crocidolite is the type of asbestos most likely to produce asbestosis and mesothelioma.

Amosite (brown asbestos) was used in cement and pipe insulation and has sharp, needle-like fibres. Exposure carries a higher risk of cancer compared to chrysotile asbestos.

Exposure to asbestos occurred particularly in shipbuilding yards and in power stations, but it was used so widely that low levels of exposure were very common. There is a considerable time lag between exposure and development of disease, particularly mesothelioma (20–40 years). Regulations in the UK prohibit the use of crocidolite and severely restrict the use of chrysotile. Careful dust control measures are enforced, which should eventually abolish the problem.

Risk of primary lung cancer (usually adenocarcinoma) is increased in people exposed to asbestos, even non-smokers. This risk is about five- to sevenfold greater in those who have parenchymal asbestosis and about 1.5-fold in those with pleural plaques without parenchymal fibrosis. A synergistic relationship exists between asbestosis and cigarette smoking for the risk of bronchial carcinoma, depending on the amount smoked and degree of asbestos exposure.

Diseases caused by asbestos are summarized in **Box 20.50**. Bilateral diffuse pleural thickening, asbestosis, mesothelioma, and asbestos-related carcinoma of the bronchus are all eligible for industrial injury benefits in the UK.

Asbestosis

Asbestosis is defined as fibrosis of the lungs caused by asbestos dust, which may or may not be associated with fibrosis of the parietal or visceral layers of the pleura. It is a progressive disease characterized by breathlessness, accompanied by finger clubbing and bilateral basal end-inspiratory crackles. Minor degrees of fibrosis that are not seen on chest radiography are often revealed on CT scan. No treatment is known to alter progress, though corticosteroids are often prescribed.

Byssinosis

This disease is caused by cotton dust. It occurs worldwide but is declining where the number of people employed in cotton mills is falling. Typically, symptoms start on the first day back at work after a break (Monday sickness), with improvement as the week progresses. Tightness in the chest, cough, and breathlessness occur within the first hour in dusty areas of the mill. The exact nature of the disease and its aetiology remain disputed. Pure cotton does not cause the disease, and cotton dust has some effect on airflow limitation in all those exposed. Individuals with asthma are particularly affected by exposure to cotton dust. The most likely aetiology is constriction of the airways of the lung caused by endotoxins from bacteria present in raw cotton. There are no changes on chest radiographs.

Berylliosis

Beryllium–copper alloy has a high tensile strength and is resistant to metal fatigue, high temperature, and corrosion. It is used in the aerospace industry, atomic reactors, and many electrical devices. When beryllium is inhaled, it can cause a systemic illness with a clinical picture similar to that of sarcoidosis. Clinically, there is progressive dyspnoea with pulmonary fibrosis. Strict controls have made this disease a rarity.

MISCELLANEOUS RESPIRATORY DISORDERS

Lung cysts

These can be congenital, bronchogenic, or the result of a sequestrated pulmonary segment (dysplastic lung tissue with no communication with the rest of the tracheobronchial tree). Lung cysts therefore have a wide differential diagnosis, informed by clinical presentation. Causes include:

- hydatid disease: fluid-filled cysts
- lung abscesses: thin-walled cysts, found particularly in staphylococcal pneumonia
- tuberculosis: cavitation

Box 20.50 Effects of asbestos on the lung

Effect	Exposure	Chest radiograph	Lung function	Symptoms	Outcome
Asbestos bodies	Light	Normal	Normal	None	Evidence of asbestos exposure only
Pleural plaques	Light	Pleural thickening (parietal pleura) and calcification (also in diaphragmatic pleura)	Mild restrictive ventilatory defect	Rare, occasional mild effort dyspnoea	No other sequelae
Effusion	First two decades following exposure	Effusion	Restrictive	Pleuritic pain, dyspnoea	Often recurrent
Bilateral diffuse pleural thickening	Light/moderate	Thickening of both parietal and visceral pleura >5 mm and extending over more than ¼ of chest wall	Restrictive ventilatory defect	Effort dyspnoea	May progress in absence of further exposure
Mesothelioma	Light: interval of 20–40 years from exposure to disease	Pleural effusion, usually unilateral	Restrictive ventilatory defect	Pleuritic pain, increasing dyspnoea	Median survival 2 years
Asbestosis	Heavy: interval of 5–10 years from exposure to disease	Diffuse bilateral streaky shadows, honeycomb lung	Severe restrictive ventilatory defect and reduced gas transfer	Progressive dyspnoea	Poor, progression in some cases after exposure
Asbestos-related carcinoma of the bronchus	The features of asbestosis, bilateral diffuse pleural thickening, or bilateral pleural plaques plus those of bronchial carcinoma				Fatal

- septic pulmonary infarction
- primary bronchogenic carcinoma or cavitating metastatic neoplasms
- paragonimiasis caused by the lung fluke *Paragonimus westermani*
- systemic conditions associated with pulmonary cysts, e.g., Birt–Hogg–Dubé syndrome.

Trauma

Trauma to the thoracic wall can cause penetrating wounds and lead to pneumothorax or haemothorax.

Rib fractures are caused by trauma or coughing (particularly in the elderly), and can occur in osteoporosis. Pathological rib fractures are due to metastatic spread (most often bronchus, breast, kidney, prostate, or thyroid cancer). Ribs can also become involved in mesothelioma. Fractures may not be readily visible on a postero-anterior chest radiograph and so lateral radiograph and oblique views may be necessary. Pain prevents adequate chest expansion and coughing, and this can lead to pneumonia. Treatment is with adequate oral analgesia, or by local infiltration or an intercostal nerve block. Two fractures in one rib can lead to a flail segment with paradoxical movement: that is, part of the chest wall moves inwards during inspiration. This can produce inefficient ventilation and may require intermittent positive-pressure ventilation, especially if several ribs are similarly affected.

Rupture of the trachea or a major bronchus can occur during deceleration injuries, leading to pneumothorax, surgical emphysema, pneumomediastinum, and haemoptysis. Surgical emphysema is caused by air leaking into the subcutaneous connective tissue; this can also arise after insertion of an intercostal drainage tube. A pneumomediastinum occurs when air leaks from the lung inside the parietal pleura and extends along the bronchial walls.

Rupture of the oesophagus (see Chapter 22, 'Oesophageal rupture' section) leads to mediastinitis, usually with mixed bacterial infection. This is a serious complication of external injury, endoscopic procedures, bougienage, carcinoma, or necrotic tuberculous lymph nodes and requires broad-spectrum antibiotics.

Lung contusion causes widespread fluffy shadows on the chest radiography due to intrapulmonary haemorrhage. It may give rise to acute respiratory distress syndrome.

Kyphoscoliosis

Kyphoscoliosis may be congenital, due to disease of the vertebrae such as TB or osteomalacia, or due to neuromuscular disease such as Friedreich's ataxia or poliomyelitis. The respiratory effects of severe kyphoscoliosis are often more pronounced than might be expected and respiratory failure and death often occur in the fourth or fifth decade. The abnormality should be corrected at an early stage if possible. Positive airway pressure ventilation delivered through a tightly fitting nasal mask is the treatment of choice for respiratory failure.

Ankylosing spondylitis

Limitation of chest wall movement is often well compensated by diaphragmatic movement and so the respiratory effects of this disease are relatively mild. It is occasionally associated with upper lobe fibrosis.

Pectus excavatum and pectus carinatum

Pectus excavatum causes few problems other than the aesthetic of a deep vertical furrow in the chest, which can be corrected surgically. The heart is seen to lie well to the left on chest radiography.

Pectus carinatum (pigeon chest) is often the result of rickets. No treatment is required.

Pleurisy

Pleurisy is pain arising from any disease of the pleura. Localized inflammation produces sharp localized pain, which is worse on deep inspiration, coughing, and occasionally on twisting and bending movements. Common causes are pneumonia, pulmonary infarct, and carcinoma. Rarer causes include rheumatoid arthritis and systemic lupus erythematosus.

Epidemic myalgia (Bornholm disease) is caused by infection with Coxsackie B virus. It is common in young adults in late summer and autumn. It is characterized by upper respiratory tract illness followed by pleuritic pain in the chest and upper abdomen with tender muscles. The chest radiograph remains normal and spontaneous resolution occurs within a week.

DISORDERS OF THE DIAPHRAGM

Diaphragmatic fatigue

The diaphragm can become fatigued if the force of contraction during inspiration exceeds 40% of the force it can develop in a maximal static effort. When this occurs acutely, in patients with exacerbations of COPD or CF, or in those with quadriplegia, positive-pressure ventilation is required. Breathing against resistance for 30 minutes a day increases strength and endurance.

Unilateral diaphragmatic paralysis

This is common and symptomless. The affected diaphragm is usually elevated and moves paradoxically on inspiration. It can be diagnosed by ultrasound when a sniff causes the paralyzed diaphragm to rise and the unaffected diaphragm to descend. Causes include:

- surgery
- carcinoma of the bronchus with involvement of the phrenic nerve
- neurological disease, including poliomyelitis and herpes zoster
- trauma to the cervical spine, birth injury, or subclavian vein puncture
- infection, such as TB, syphilis, or pneumonia.

Bilateral diaphragmatic weakness or paralysis

This causes breathlessness in the supine position and may lead to sleep apnoea, with daytime headaches and somnolence. Tidal volume is decreased and respiratory rate is increased. Vital capacity is substantially reduced when lying down, and sniffing causes a paradoxical inward movement of the abdominal wall, best seen in the supine position. Causes include viral infections, multiple sclerosis, motor neuron disease, poliomyelitis, Guillain–Barré syndrome, quadriplegia after trauma, and rare myopathies. Treatment is either diaphragmatic pacing or night-time assisted ventilation.

Complete eventration of the diaphragm

This is a congenital condition (invariably left-sided) in which muscle is replaced by fibrous tissue. It presents as marked elevation of the left hemidiaphragm, sometimes associated with gastrointestinal symptoms. Partial eventration, usually on the right, causes a hump (often anteriorly) on the diaphragmatic shadow on chest radiography.

Diaphragmatic hernia

These are most commonly through the oesophageal hiatus but occasionally occur anteriorly through the foramen of Morgagni, posterolaterally through the foramen of Bochdalek, or at any site following traumatic tear.

Hiccups

Hiccups are due to involuntary diaphragmatic contractions with closure of the glottis and are extremely common. Occasionally, patients present with persistent hiccups. This can be as a result of diaphragmatic irritation (e.g., subphrenic abscess) or may have a metabolic cause (e.g., uraemia). The underlying cause should be treated, if known. Gabapentin or pregabalin may be tried.

Further reading

McCool ED, Tzelepis GE. Dysfunction of the diaphragm. *N Engl J Med* 2012; 366:932–942.

MEDIASTINAL LESIONS

The mediastinum is defined as the region between the pleural sacs. It is additionally divided as shown in Fig. 20.36. Tumours affecting the mediastinum are rare. Masses are detected accurately on CT or MRI (Fig. 20.37), and can be localized to the anterior, middle, or posterior mediastinum. The position and characteristics of the lesion will help to determine the underlying aetiology.

Retrosternal or intrathoracic thyroid

The most common mediastinal mass is a retrosternal or intrathoracic thyroid, which is nearly always an extension of the thyroid present in the neck. Enlargement of the thyroid by a colloid goitre or malignant disease, or, rarely, in thyrotoxicosis, can cause displacement of the trachea and oesophagus to the opposite side. Symptoms of compression develop insidiously before producing

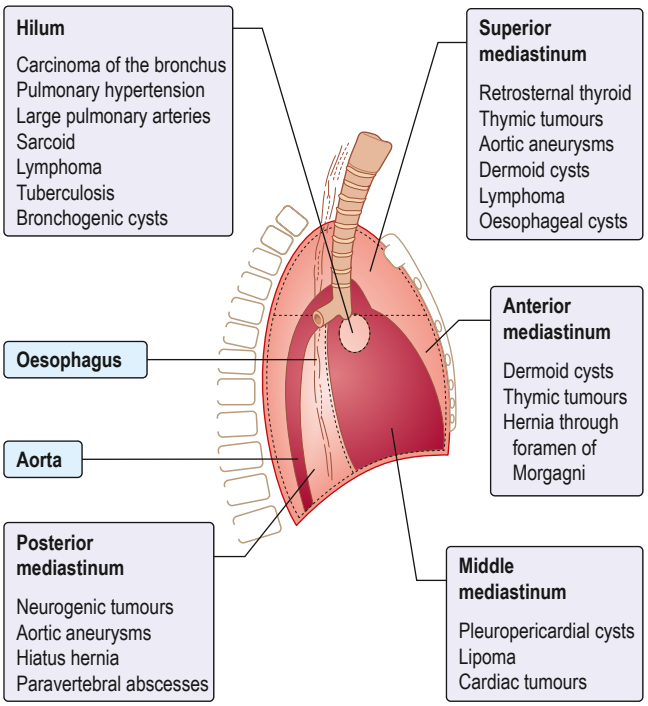

Fig. 20.36 **Subdivisions of the mediastinum and mass lesions.**

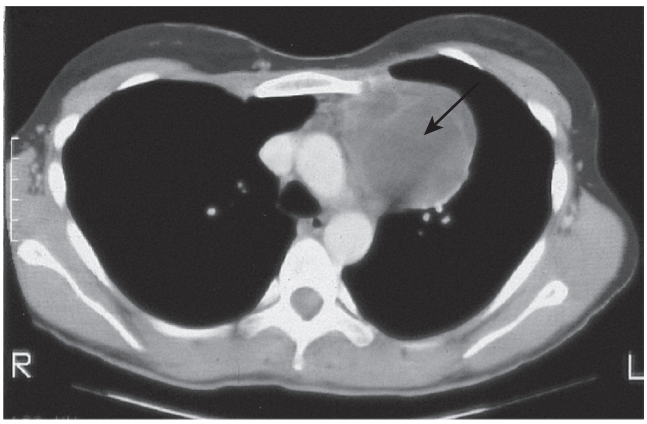

Fig. 20.37 **CT scan of a dermoid cyst *(arrowed)* in the mediastinum.**

dyspnoea. Flow–volume loops are useful to assess physiological impact. Very occasionally, an intrathoracic thyroid may cause dysphagia or hoarseness and vocal cord paralysis due to stretching of the recurrent laryngeal nerve. The treatment is surgical removal.

Thymic tumours (thymomas)

The thymus is large in childhood and occupies the superior and anterior mediastinum. It involutes with age but may be enlarged by cysts, which are rarely symptomatic, or by tumours that compress the trachea, or rarely, the oesophagus. Surgery is the treatment of choice. Approximately half of patients presenting with a thymic tumour have myasthenia gravis. Good's syndrome, a combined defect of humoral and cellular immunity, is seen in 10% of thymomas.

Middle mediastinum pathology

- ***Bronchogenic cyst***, a benign embryological remnant.
- ***Mediastinal lymphadenopathy*** due to a number of conditions including metastatic lesions, primary lung cancer, sarcoid, and infection such as tuberculosis. Both Hodgkin and non-Hodgkin lymphoma commonly present with enlargement of middle mediastinal nodes (see Chapter 39).
- ***Pericardial cysts***, which may be up to 10 cm in diameter, are filled with clear fluid. Up to 70% are situated anteriorly in the cardiophrenic angle on the right side. Infection is rare and malignant change does not occur. The diagnosis may be made on MRI, with needle aspiration in diagnostic uncertainty. No treatment is required but patients should be followed up, as an increase in cyst size suggests an alternative pathology and surgical excision is then advised.
- ***Vascular abnormalities*** include aortic aneurysm and aortic dissection.
- ***Tracheal tumours*.**

Posterior mediastinum pathology

- ***Embryological remnants*** include neurogenic and neuroenteric cysts.
- ***Oesophageal abnormalities***, e.g., oesophageal tumour, hiatus hernia

CORE SKILLS AND KNOWLEDGE

Ear, nose, and throat (ENT) is a broad specialty that, in addition to covering diseases of the ears, nose, and throat, is also concerned with diseases of the trachea and skull base. It is responsible for head and neck cancer, facial plastic surgery, sleep-disordered breathing, and congenital head and neck anomalies.

One in every five primary care consultations relates to ENT conditions, and while only 3% of emergency department visits are related to ENT diagnoses, they are often life-threatening (e.g., acute airway obstruction, major upper airway haemorrhage). Common emergency presentations include epistaxis, upper airway compromise (e.g., due to infection, malignancy), ingested or inhaled foreign bodies, and penetrating neck injuries.

Surgical treatments for ENT conditions often involve technological aids such as endoscopes, microscopes, powered instruments, lasers, and more recently robotics. Technology is also used in treatment (e.g., cochlear and brainstem auditory implants). The head and neck are complicated anatomical regions with multiple vital structures near each other. While being mindful of this complicated anatomy, surgery varies from the fine (e.g., stapedotomy) to expansive (e.g., laryngopharyngectomy). Nearly three-quarters of the operative load is now performed as day case surgery, reducing inpatient burden.

Multidisciplinary working is important with many conditions managed in collaboration with other specialists including oncologists and plastic surgeons for head and neck cancers, endocrinologists for thyroid disease, neurosurgeons for skull base disease, and respiratory physicians for tracheal disease, sleep-disordered breathing, and allergy. Collaboration with allied health professionals includes speech and language therapists for speech and swallowing, electrophysiologists for voice assessment, audiologists for hearing and balance, teachers of the deaf for those with cochlear implants, and psychologists for body dysmorphic disorders.

Key skills in ENT include:

- Developing a diagnostic approach for core symptoms
- Identifying and managing ENT emergencies including life-threatening airway obstruction and large-volume epistaxis
- Understanding symptoms of ENT malignancy, which should prompt urgent referral
- Interpretation of imaging including CT radiographs of the head and neck and endoscopic images of the ear, nose, or larynx.

CLINICAL SKILLS

When a patient presents with a location-specific symptom, it is wise to ask about other symptoms specific to that site. Common symptoms depend on the anatomical location of the lesion (Fig. 21.1). The nose communicates with the ear through the Eustachian tube and with the throat through the nasopharynx, so symptoms can cross from one location to another (e.g., patients with chronic rhinosinusitis often experience pressure in their ears). In addition, dual innervation by multiple branches of the same nerve can lead to referred symptoms, for example, ear pain with throat or dental infection.

The nature, character, and chronological features of symptoms should be systematically explored. Concomitant medical problems, medication use, and occupational and environmental factors can be the cause of ENT disorders and impact treatment, so a detailed history is essential. It is important to be aware of the red flag symptoms related to the ENT (Box 21.1).

Box 21.1 Red flags for head and neck cancer by anatomical site

Red flag symptoms for malignancy by anatomical site

Ear
Otalgia—particularly severe and night pain
Bloody ear discharge
Facial nerve palsy
Visible mass or growth in or around ear
Neck lumps
Risk factors—smoking, sun exposure, immunosuppression

Nose
Unilateral symptoms
Pain—especially severe and persistent
Blood-stained rhinorrhea
Unilateral glue ear
Neck lumps
Numbness/paraesthesia of the cheek
Proptosis or cheek swelling
Visible mass in nose
Epiphora (watery eye)
Risk factors—smoking, alcohol, occupational exposure to metal including nickel, leather and woodworkers

Throat
Otalgia—especially if unilateral and persistent
Neck lump
Stridor and dyspnoea
Hoarseness
Odynophagia
Dysphagia
Non-healing painless ulcer or tonsillar asymmetry
Risk factors—smoking, alcohol, or human papilloma virus exposure

THE EAR

Anatomy

The ear is divided into three parts: outer, middle, and inner (Fig. 21.2).

The ***outer ear*** has a skin-lined tube 2.5 cm long leading to the tympanic membrane (ear drum). The outer third is cartilaginous and contains hair and sebaceous and ceruminous glands; the inner two-thirds are bony. The outer ear is self-cleaning as the skin is migratory, so there are no indications to clean with cotton buds. Wax should only be seen in the outer third.

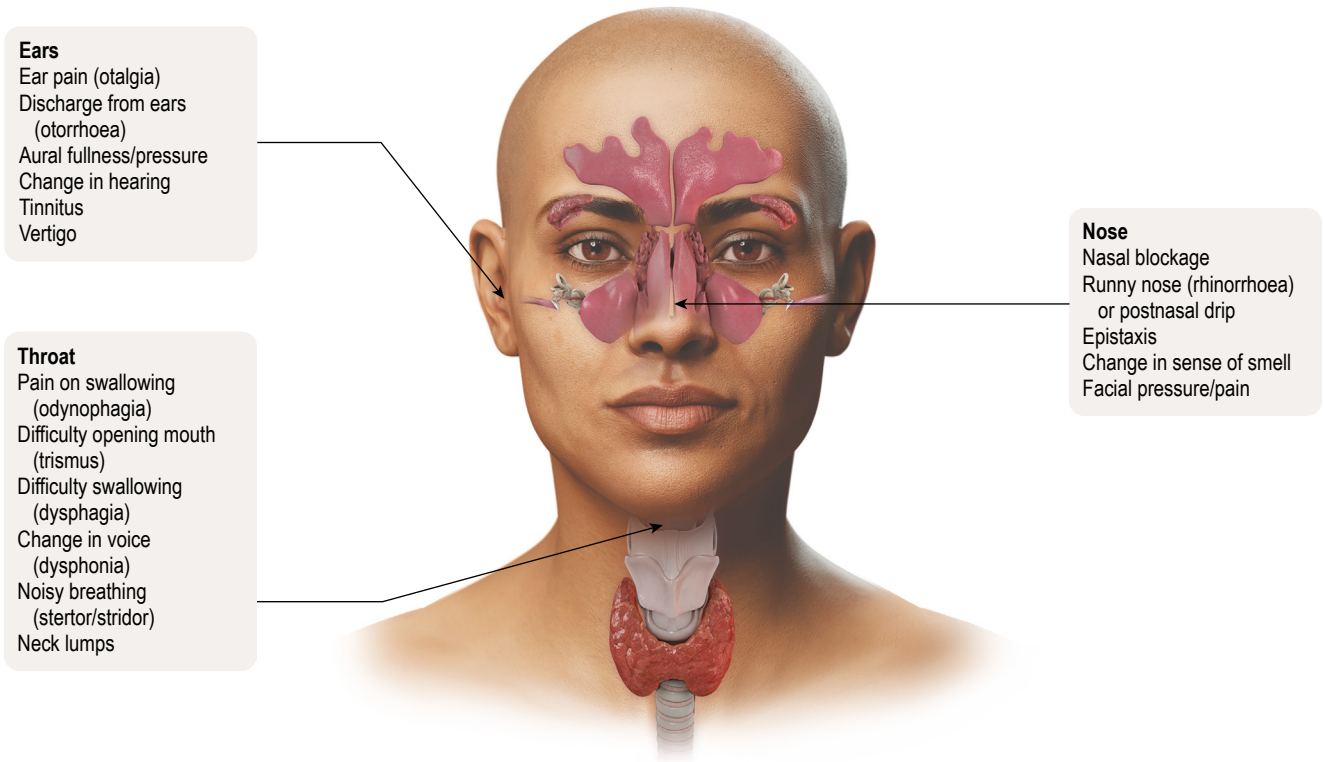

Fig. 21.1 Symptoms of ear, nose, and throat disorders.

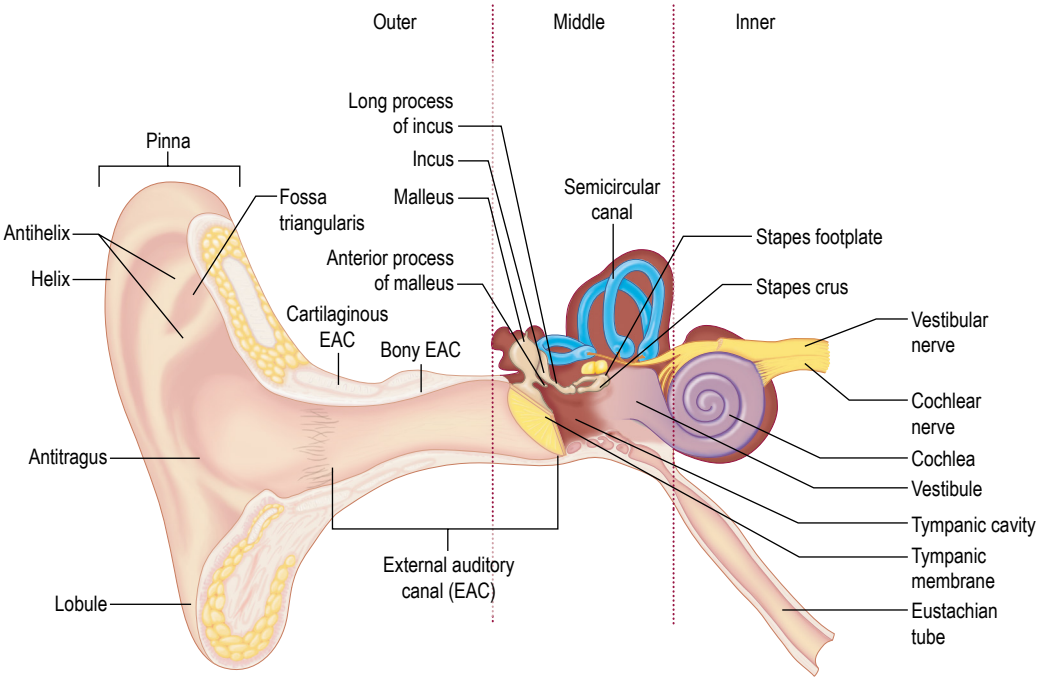

Fig. 21.2 The anatomy of the ear. The ear is anatomically divided into outer, middle, and inner ear, as indicated at the top. The outer ear consists of the pinna and external auditory meatus and funnels sound energy to the middle ear, selectively amplifying sounds in the 2 to 4 kHz range by 15 decibels (dB, speech sounds). When sound energy passes from air in the outer ear to fluid in the inner ear, it loses 30 dB due to energy that is reflected at the interface of the two mediums. The middle ear acts as a transformer, increasing the pressure of the acoustic wave to account for the energy lost at this air–fluid interface. As the acoustic wave moves across the tunnel of the inner ear, passing from the oval window to the round window, it causes maximal vibration of the basilar membrane in a location that is specific to its resonant frequency. This vibration causes the hair cell to open its ion gates and an action potential to be propagated along a fibre of the cochlear nerve. The location of the nerve fibre and the strength of its action potential allow the central nervous system to construct meaning from the sound we hear.

The ***middle ear*** is an air-containing cavity derived from the branchial clefts. It communicates with the mastoid air cells superiorly and connects to the nasopharynx medially via the Eustachian tube. The Eustachian tube ventilates the middle ear and maintains equal air pressure across the tympanic membrane. It is normally closed but opens via the action of the palatal muscles to allow air entry when swallowing or yawning. A defect in this mechanism, for example, cleft palate, will prevent air from entering the middle ear cleft, which may then fill with fluid (otitis media with effusion). Lying within the middle ear cavity are three ossicles, namely malleus, incus, and stapes, which transmit sound from the tympanic membrane (Fig. 21.3) to the inner ear. On the medial wall of the cavity is the horizontal segment of the facial nerve, which can be damaged during surgery or by direct extension of infection in the middle ear.

The ***inner ear*** contains the cochlea for hearing and the vestibule and semicircular canals for balance. There is a semicircular canal arranged in each body plane, and these canals are stimulated by rotatory movement. The facial, cochlear, and vestibular nerves emerge from the inner ear and run through the internal acoustic meatus to the brainstem.

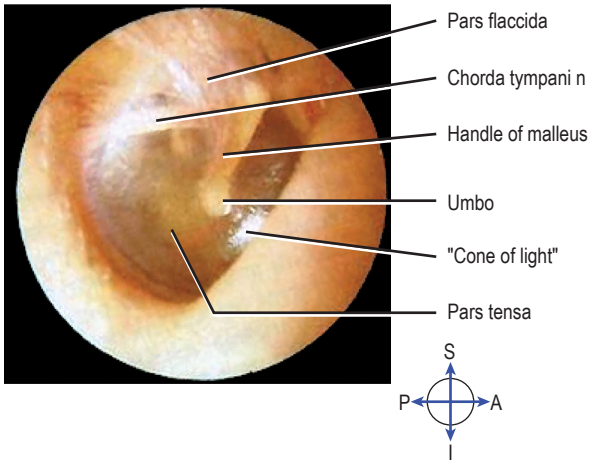

Fig. 21.3 An otoendoscopic view of a normal right tympanic membrane. *(From The Anatomical Basis of Dentistry, Fifth Edition. pii:B9780323824057000060/f06-118-9780323824057.)*

Physiology of hearing

The ossicles, in the middle ear, transmit sound waves from the tympanic membrane to the cochlea. The ossicles amplify sound by approximately 1.5 times using a lever system, while the large surface area of the tympanic membrane compared to the oval window is responsible for amplification by a factor of 20. Together, these amplification mechanisms compensate for the loss of sound waves moving from the air-filled middle ear to the fluid-filled cochlea. Hair cells in the basilar membrane of the cochlea detect vibrations and transduce these into nerve impulses, which pass to the cochlear nucleus and then to the superior olivary nuclei of the pons; thus

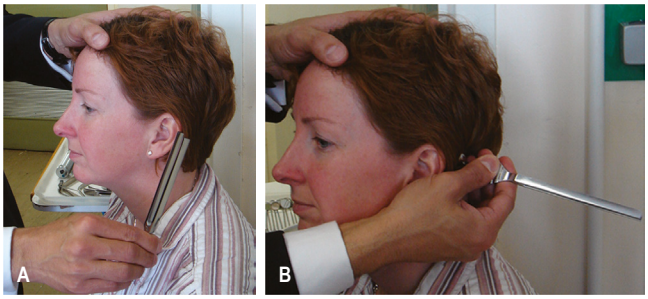

Fig. 21.4 Rinne test. Comparing conduction of sound. **(A)** Air conduction. **(B)** Bone conduction.

lesions medial to the cochlear nucleus do not cause unilateral hearing loss. If the ossicles are diseased, sound can reach the cochlea by vibration of the temporal bone (bone conduction).

CLINICAL APPROACH TO THE PATIENT WITH A DISORDER OF THE EAR

Examination

The pinna and post-auricular region should be examined for erythema, scars, and swelling. An otoscope is used to examine the external ear canal while the pinna is retracted backwards and upwards. Check for wax, discharge, and foreign bodies. The tympanic membrane should always be visualized, with a light reflex seen anteroinferiorly. Previous repeated infections may cause a thickened, whitish drum due to chronic inflammation leading to calcium deposition (tympanosclerosis). Fluid in the middle ear may show as dullness of the drum, a yellow or orange appearance of fluid behind the drum, or air bubbles. Perforations can be described as marginal if they involve the annulus (thickened peripheral rim of the tympanic membrane). Retraction pockets may occur in the pars tensa or pars flaccida of the tympanic membrane (Fig. 21.3), indicating longstanding middle ear disease (chronic otitis media), which may lead to perforations or ossicular erosion with resulting hearing loss, recurrent infections, and cholesteatoma formation.

Investigations

Tuning fork tests and interpretation

Rinne test

1. Rinne test positive (normal): A tuning fork (512 Hz) is heard louder if held next to the ear (air conduction) than if placed on the mastoid bone (bone conduction).
2. Rinne test negative (abnormal): The tuning fork is perceived as louder when placed on the mastoid (bone conduction) due to a defect in the conducting mechanism of the external or middle ear (Fig. 21.4).

Weber test

A tuning fork placed on the forehead or vertex of a patient with normal hearing (or symmetrical hearing loss) is perceived centrally by the patient. A patient with unilateral conductive hearing loss will hear the sound loudest in the affected ear, whereas a patient with unilateral sensorineural hearing loss will report the sound to be loudest in the unaffected ear (Fig. 21.5).

Fig. 21.5 Weber test.

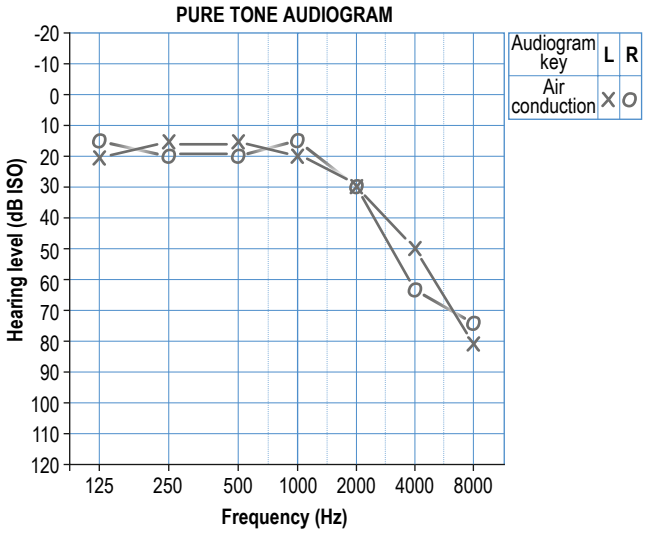

Fig. 21.6 Audiogram showing presbycusis (high-frequency loss).

Pure-tone audiometry

The patient is asked to respond when they hear sounds presented as pure tones at varying intensities and frequencies. Sounds are presented to each ear (air conduction) and each mastoid (bone conduction) in turn. An audiogram is produced by the lowest sound intensity reliably perceptible (Fig. 21.6).

Dix-Hallpike test

The patient sits on a couch with their head turned towards one ear. The head is supported by the examiner while the patient lies down so that their head is just below horizontal. This is then repeated with the patient's head turned towards the other ear. Upbeat tortional nystagmus following a latent interval of a few seconds is noted when the head is turned towards the affected ear (Fig. 21.7).

COMMON DISORDERS OF THE EAR

Common disorders of the ear are outlined in Box 21.2.

The painful ear (otalgia)

Otitis externa

When natural barriers to infection are overcome, the skin of the ear canal can become infected. Discharge and itch are initial presenting

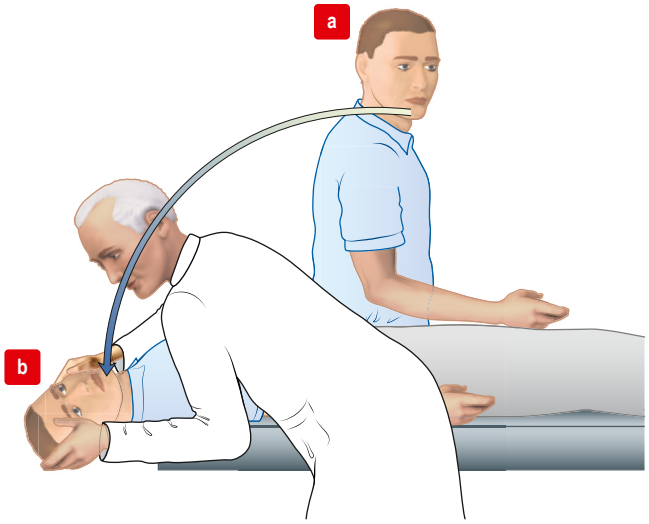

Fig. 21.7 Dix–Hallpike test. The patient sits on a couch with their head turned towards one ear. The head is supported by the examiner while the patient lies down, so their head is just below horizontal. This is then repeated with the patient's head turned towards the other ear. Geotropic (beating towards the ground) rotational nystagmus following a latent interval of a few seconds is noted when the head is turned towards the affected ear.

symptoms, followed by pain and reduction in hearing as the ear canal closes off due to swelling of the ear canal skin. Infection can spread to the pinna, causing cellulitis. Although the causative organism is most commonly bacterial (pseudomonal species > staphylococcal species), it can also be fungal. There may be swelling of the pre-auricular or post-auricular lymph nodes that can be mistaken for mastoiditis.

Examination often reveals debris in the canal, which needs to be removed by gentle mopping or preferably by suction viewed directly under a microscope. The tympanic membrane is normal, when visible. In severe cases, the canal is swollen and view of the tympanic membrane is impossible. Any foreign body should be removed by trained personnel.

Treatment includes ear plugs to prevent water ingress into the ear canal during showering or swimming. Mild infections may respond to topical ear drops containing acetic acid. These alter ear canal pH, which inhibits bacterial and fungal growth. More severe infection requires either topical antibiotic (e.g., ciprofloxacin) or combination of topical antibiotic and steroid (e.g., hydrocortisone acetate 1% and gentamicin 0.3%) if the ear canal is swollen. If symptoms do not resolve within 5 to 7 days, microsuction may be necessary.

Acute otitis media

Acute otitis media is a common infection of the middle ear seeded from the upper respiratory tract through the Eustachian tube. It

Box 21.2 Common diagnoses of the ear

Symptom	Diagnosis	Key clinical features
Otalgia	Acute otitis media	Pain, fever, hearing loss. *Complications: facial nerve palsy, mastoiditis, abscess*
	Otitis externa	Itching, discharge. *Complication: osteomyelitis*
	Temporal bone malignancy	Growth, severe pain, lymphadenopathy. *Complication: facial nerve palsy*
	Referred pain	Normal ear examination
Otorrhea	Acute otitis media	Pain, fever, hearing loss. *Complications: facial nerve palsy, mastoiditis, abscess*
	Chronic otitis media	Hearing loss, often painless. *Complication: osteomyelitis*
	Otitis externa	Itching, discharge. *Complication: osteomyelitis*
Conductive hearing loss	Acute otitis media	Pain, fever, hearing loss. *Complications: facial nerve palsy, mastoiditis, abscess*
	Chronic otitis media	Hearing loss, often painless. *Complication: osteomyelitis*
	Otitis media with effusion ('glue ear')	Usually in children, nasal obstruction. *Complication: speech delay*
	Otosclerosis	Normal tympanic membrane, family history
	Trauma	History of trauma
Sensorineural hearing loss	Sudden sensorineural hearing loss	Sudden onset
	Presbyacusis	Gradual loss in older adults
	Meniere's disease	Episodic vertigo, aural fullness, tinnitus, fluctuating loss
	Medication	Ototoxic medications e.g., cisplatin, loop diuretic, aminoglycoside
	Trauma	History of trauma
Peripheral vertigo	BPPV	Sort lived, positional, fatigable
	Vestibular neuronitis	Onset hours to days, preceding viral infection
	Meniere's disease	Episodic vertigo, aural fullness, tinnitus, fluctuating hearing loss
Central vertigo	Vestibular migraine	Episodic, history of migraine, photophobia/phonophobia
	Posterior circulation stroke	Neurological signs of stroke
	Multiple sclerosis	Presents with vertigo in 7%–10%, other neurological signs
Non-pulsatile tinnitus	Due to any cause of hearing loss	Early sign of hair cell damage which leads to hearing loss
	Eustachian tube dysfunction	Tinnitus related to respiration, autophony, may resolve on lying down
	Temporomandibular disorder	Treatment of TMD improves symptoms
Pulsatile tinnitus	Vascular disorders	Other vascular disease/risk
	Myoclonic spasm	Other neurological or ontological disease
	Middle ear disease	Features of e.g., otitis media

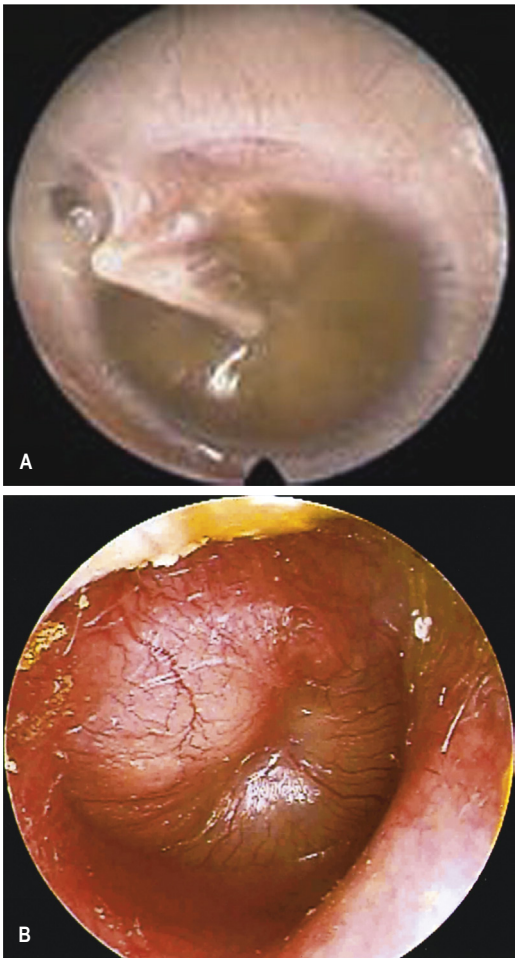

Fig. 21.8 Otitis media with effusion and acute otitis media. **(A)** The tympanic membrane is retracted and the middle ear filled with yellow serous fluid. **(B)** Acute otitis media. Note the red bulging tympanic membrane with pus in the middle ear. *([A] From Woodbury et al., 2011; [B] From Kliegman et al., 2016.)*

may also occur on a background of glue ear (otitis media with effusion) where the stagnant middle ear fluid gets secondarily infected (Fig. 21.8A). Common pathogens are those that also cause upper respiratory tract infections: respiratory syncytial virus, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Acute otitis media most commonly affects children under 10 years. Infection causes inflammation of the middle ear mucosa and inflammatory exudate in the middle ear space. It can lead to tympanic membrane perforation and discharge. Rare complications include mastoiditis as inflammatory fluid escapes from the middle ear into the mastoid, and meningitis due to spread through the tegmen into the intracranial cavity. Examination shows a healthy ear canal but an erythematous and bulging tympanic membrane (Fig. 21.8B). Initial treatment is with non-steroidal anti-inflammatory drugs. If symptoms do not improve within 72 hours or the patient becomes systemically unwell, they should be reassessed for antibiotics. Initial treatment with antibiotics is advised in children less than 3 months old, those less than 6 months old with temperature greater than 39°C, systemic infection, complications such as mastoiditis, or risk of complications (e.g., immunosuppression). Patients presenting with otorrhea and children under 2 with bilateral symptoms are also likely to benefit from antibiotic use. Oral amoxicillin (clarithromycin in penicillin allergy) can be used in uncomplicated cases. If symptoms recur or do not resolve, a beta-lactamase inhibitor (e.g., co-amoxiclav) may be required to cover beta-lactamase-producing bacteria (e.g., *H. influenzae*). When antibiotics are indicated, treatment should be systemic rather than topical, as any perforation may heal quickly limiting access of topical therapy to the middle ear. Topical ear drops containing anaesthetic or analgesics for pain may be used (providing there is no ear drum perforation).

Chronic otitis media is a longer-term inflammatory disorder of the middle ear of two main types:

- Mucosal: tympanic membrane perforation
- Squamous: tympanic membrane retraction or cholesteatoma

Active mucosal disease is characterized by infection. In inactive mucosal disease the perforation is dry and uninfected. Squamous disease is inactive if there is a retraction only and active when there if uncontrolled growth of squamous keratinized epithelium (cholesteatoma).

All patients with a perforation of the tympanic membrane are managed with water precautions, as water entry into the middle ear through a perforated tympanic membrane leads to infection. If otorrhea is present, topical antibiotics are used with or without adjunctive aural toilet (manual cleaning of the ear). Topical antibiotics are likely more effective than oral antibiotics due to limited systemic drug penetration through the relatively avascular mucosa of the middle ear and mastoid. Retraction pockets may be monitored to check whether they are stable or progressing and whether they may require surgery. Surgery for retraction pockets may be performed in order to prevent hearing loss if the retraction is draped onto, and at risk of eroding the ossicular chain or to prevent further retraction, infections, and cholesteatoma formation. Cholesteatoma requires surgical removal to create a dry ear, repair the tympanic membrane, eradicate infection, and prevent complications and recurrence (see below).

Referred otalgia

Pain may be referred from:

- the teeth and temporomandibular joint via the auriculotemporal nerve, a branch of the mandibular nerve;
- the cervical spine from C1 to C3;
- the tonsil and tongue base via the glossopharyngeal (Jacobson's) nerve;
- the larynx and pharynx via the vagus (Arnold's) nerve; and
- Ramsay Hunt syndrome, causing vesicles along the distribution of the facial nerve.

The innervation of the pinna is from the auriculotemporal branch of the trigeminal and first two cervical nerves (Fig. 21.9). Therefore dental pain, temporomandibular joint dysfunction, and upper cervical osteoarthritis can all present as otalgia. The ear canal is innervated by the above-mentioned nerves, in addition to facial and vagus nerves (see Fig. 21.9). Hence Ramsay Hunt syndrome (varicella reactivation along the sensory division of the facial nerve) causes otalgia in association with ear canal vesicles, and laryngeal and pharyngeal cancers occasionally present with otalgia due to referred pain along the vagus nerve. The middle ear is innervated by the glossopharyngeal nerve and therefore infections of the pharynx are associated with otalgia.

The discharging ear (otorrhoea)

Discharge from the ear is usually due to infection of the outer or middle ear. The most common cause is otitis externa, followed by otitis media with a perforated tympanic membrane (see above).

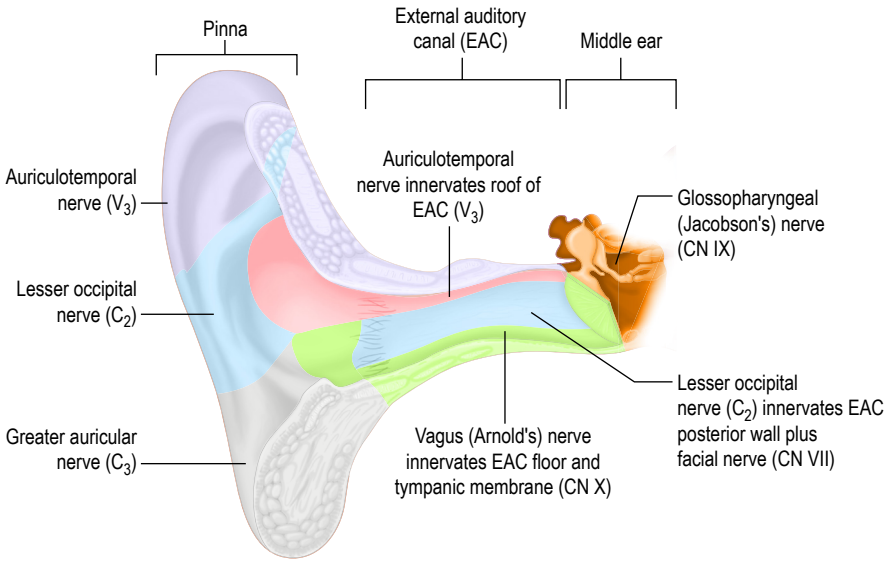

Fig. 21.9 Sensory innervation of the ear. Due to the sophisticated embryology of ear structures, the sensory innervation is complicated. Therefore otalgia can be referred from many sites, and knowledge of aural sensory innervation is a good guide for a comprehensive examination of idiopathic ear pain. The auriculotemporal nerve (a branch of the mandibular division of the trigeminal nerve) supplies innervation to the superolateral pinna and roof of the external auditory canal (EAC). Pathology related to the upper teeth, temporomandibular joint, and parotid gland can cause referred otalgia through this nerve. The lesser occipital nerve (a branch from the second cervical nerve) supplies most of the medial surface of the pinna and the posterior wall of the EAC. Cervical osteoarthritis can cause referred otalgia through this nerve. The greater auricular nerve (a branch from the third cervical nerve) supplies the inferior portion of the pinna, including the lobule. Cervical osteoarthritis can cause referred otalgia through this nerve. Arnold's nerve (a branch of the vagus cranial nerve) supplies the EAC floor and lateral surface of the tympanic membrane. Tumours of the larynx and pharynx can cause referred otalgia through this nerve. Jacobson's nerve (a branch of the glossopharyngeal nerve) supplies innervation to the mucosa of the middle ear, including the medial surface of the tympanic membrane. Tonsillitis and pharyngitis can cause referred otalgia through this nerve. *CN,* Cranial nerve.

Cholesteatoma

Although cholesteatoma is a rare cause of otorrhoea, it has significant implications if missed and should be considered in non-resolving or recurrent otorrhoea. Cholesteatoma is a subtype of chronic otitis media (active squamous disease) defined as keratinizing squamous epithelium within the middle ear cleft. It can present with foul-smelling otorrhoea (which is usually painless) as the keratinizing squamous epithelium acts as a nidus for infection. Examination shows a defect in the tympanic membrane, most commonly in the superior portion of the drum (attic), full of white, cheesy material or a brown attic crust (Fig. 21.10). Mastoid surgery is required to remove this sac of squamous debris, as it can erode local structures including the ossicles or facial nerve, and extend intracranially, leading to meningitis or an intracranial abscess.

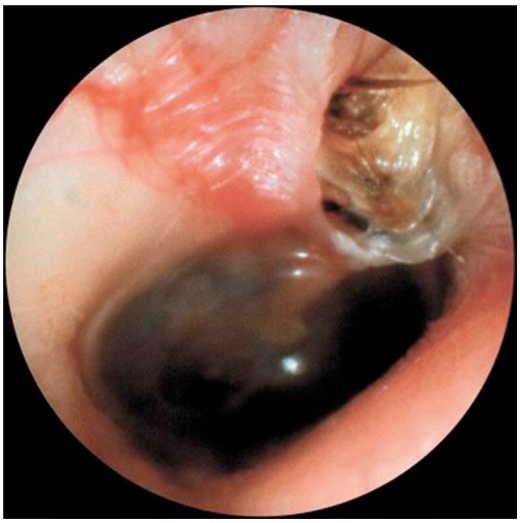

Fig. 21.10 Cholesteatoma of the pars flaccida (attic) of the tympanic membrane. *(From Self-Assessment in Otolaryngology.)*

Hearing loss

Deafness can be conductive or sensorineural, and these can be differentiated at the bedside by the Rinne and the Weber tests (Box 21.3) or with pure-tone audiometry (see investigations above).

Conductive hearing loss has many causes (Box 21.4), but occlusive wax is the most common.

Conductive hearing loss

Otitis media with effusion ('glue ear')

This is common in children when Eustachian tube dysfunction leads to poorly ventilated middle ears. The vacuum created by poor ventilation leads to a non-inflammatory effusion, which resolves in most cases but can persist or recur, causing hearing loss that impacts speech and language development. It can therefore present as hearing loss or speech/educational delay. Otalgia is not a usual feature.

Examination shows a dull tympanic membrane with loss of light reflex (Fig. 21.8A). Occasionally fluid air bubbles are visible in the

Box 21.3 Testing hearing loss

Type	Defect	Rinne test	Weber test
Conductive	Outer or middle ear	Negative. Bone conduction louder than air conduction	Sound heard louder on the affected side
Sensorineural	Inner ear or more centrally	Positive. Air conduction louder than bone conduction	Sound heard louder on unaffected side

Drugs (e.g., aminoglycoside, furosemide)

Labyrinthitis

middle ear. Children frequently have adenoidal hypertrophy and nasal blockage.

If symptoms are persistent and impact hearing, treatment options include insertion of a grommet (tympanostomy tube) through the tympanic membrane or provision of a hearing aid. If otorrhea occurs in the presence of a grommet, combined topical antibiotic-glucocorticoid ear drops are more effective than oral antibiotics. Adenoidectomy may be required if there is complete nasal blockage or recurrent upper respiratory tract infection. Grommets are extruded from the tympanic membrane as it heals (over 6 months to 2 years). In most children, the middle third of the face grows between 7 and 14 years of age and Eustachian tube dysfunction is less common after this, although in some patients it persists to adulthood.

Otosclerosis

This is usually a hereditary disorder, in which new bony deposits occur within the stapes footplate and the cochlea. Characteristically seen in the second and third decades, it is more common in females and can worsen during pregnancy. The hearing loss may be mixed, and management includes a hearing aid or replacement of the fixed stapes with a prosthesis (stapedectomy). The choice of treatment is individualized: surgery has very good success rates in the hands of a regular stapedectomist but confers a small risk of complete hearing loss. Hearing aids, while safe, require adherence for benefit.

Sensorineural hearing loss

Presbycusis

This is the most common cause of hearing loss. It is a degenerative disorder of the cochlea, typically in older age. It can occur due to loss of outer hair cells (sensory), loss of ganglion cells (neural), or strial atrophy (metabolic), or aetiology can be mixed. Environmental noise toxicity is a major factor. Onset is gradual, and higher frequencies are most often affected (**Fig. 21.6**). Speech has two components: low frequencies (vowels) and high frequencies (consonants). When high-frequency consonants are lost, speech loses intelligibility, and increasing low-frequency volume leads to the characteristic response, 'Do not shout. I am not deaf'. Management is with a high-frequency-specific hearing aid. Patients with severe to profound hearing loss, in whom adequate amplification by conventional hearing aids is not possible, may be candidates for cochlear implants and referral to a cochlear implant centre is required.

Noise trauma

Cochlear damage due to noise trauma (e.g., shooting without ear protectors, industrial noise) characteristically leads to high-frequency loss. Similar to other types of sensorineural hearing loss, management is with a conventional hearing aid.

Vestibular schwannoma

This is a slow-growing, benign tumour of the vestibular nerve that can present with progressive sensorineural hearing loss. Imaging (e.g., magnetic resonance imaging [MRI]) is required in any patient with unilateral or sudden-onset sensorineural hearing loss. Treatment is determined according to the size and growth rate of the tumour and includes surveillance with repeat MRI imaging, stereotactic radiosurgery (for growing tumours below 2.5 cm), and surgery. Unilateral hearing loss caused by this pathology may be managed with a contralateral routing of sound hearing aid, or a bone-anchored hearing aid that utilizes conduction to direct sound to the cochlear of the unaffected ear.

Vertigo

See also Chapter 11. There are many causes of dizziness, many of which are not related to the ear and vestibular system. Determining aetiology requires a detailed history. Conditions causing dizziness rather than true rotatory vertigo include:

- Postural hypotension. Ask about pre-syncopal symptoms on standing, antihypertensive medication, and history of cardiovascular disease/diabetes.
- Peripheral neuropathy, for example, secondary to diabetes or chemotherapy.
- Joint pathology, e.g., knee arthritis affecting proprioception which affects proprioception.
- Persistent postural perceptual dizziness. This is a chronic, long-lasting form of dizziness without true rotatory vertigo, worsened

by sitting upright, standing, walking, and visually complex stimuli. It is associated with anxiety and depression.

Clues as to peripheral or vestibular origin include the presence of true rotatory vertigo, or concurrent symptoms of ear disease: otalgia, otorrhoea, tinnitus, or hearing loss. Central causes of vertigo are associated with other neurological symptoms (ataxia, weakness, numbness, hoarseness) or signs (facial palsy or nystagmus [direction changing or vertical types]).

Vertigo can be classified according to the duration of vertigo:

- Seconds (<1 min): benign paroxysmal positional vertigo (BPPV)
- Minutes to hours: Ménière's disease or vestibular migraine
- Hours to days: labyrinthine or central pathology, for example, vestibular neuronitis, labyrinthitis, posterior fossa mass, cerebellar haemorrhage, multiple sclerosis

Vertigo may also be divided into peripheral and central causes.

Peripheral causes of vertigo

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo is thought to occur when otoconia (tiny crystals of calcium carbonate) are dislodged from the utricle into the semicircular canals, commonly the posterior canal. Positional vertigo is precipitated by head movements, usually to a particular position, and often occurs when turning in bed or upon sitting up. The onset is typically sudden and distressing. The vertigo lasts seconds (<1 min), and the phenomenon becomes less severe on repeated movements (fatigue). There is no serious underlying cause, but it sometimes follows vestibular neuronitis (see later), head injury, or ear infection. Diagnosis is made based on history and by the Dix–Hallpike manoeuvre (**Fig. 21.7**). A positive Dix–Hallpike test, defined as geotropic nystagmus, which habituates on repeated testing, confirms BPPV. The differential diagnosis of a cerebellar mass can be distinguished by positional nystagmus (and vertigo) that is immediately apparent, with no latent interval, and does not fatigue, and urgent neuroimaging should be used to confirm this. BPPV, on the other hand, is treated in over 90% of cases by the Epley manoeuvre. This involves gentle but specific manipulation and rotation of the patient's head to shift loose otoliths from the semicircular canals into the utricle.

Ménière's disease

This is a rare condition. It is a clinical diagnosis characterized by episodic, rotatory vertigo lasting 30 minutes to a few hours, recurring over months or years. Classically, it is associated with a low-frequency sensorineural hearing loss, a feeling of fullness in the affected ear, loss of balance, tinnitus, and vomiting. It occurs due to a build-up of endolymphatic fluid in the inner ear, the aetiology of which is unknown. MRI imaging (with delayed contrast administration) can confirm endolymphatic hydrops, though this finding is not specific to Ménière's disease.

Treatment is with vestibular sedatives, such as cinnarizine, in the acute phase. Preventative measures include a low-salt diet and avoidance of caffeine, alcohol, and any identified triggers (e.g., nicotine, stress). Betahistine is commonly used despite a paucity of evidence that it is beneficial. The diagnosis of Ménière's should be made by ENT specialists and requires audiometric documentation of a low-frequency hearing loss. If symptoms are poorly controlled, intratympanic steroids or vestibulo-ablative intra-tympanic gentamicin can be considered. Gentamicin is more vestibulotoxic than ototoxic. It destroys the vestibular epithelium, giving the patient severe vertigo for around 2 weeks until able to compensate for the lack of vestibular input on that side. Occasional mild vertigo when the balance system is challenged is often preferable to the unpredictable, severe, and disabling vertigo of Ménière's disease. However, there is a risk of sensorineural hearing loss and complete vestibular failure if Ménière's recurs on the previously unaffected side. Surgical options include endolymphatic sac clipping to relieve endolymphatic hydrops, vestibular nerve section, or labyrinthectomy, although these are rarely performed.

Vestibular neuritis and labyrinthitis

This is due to a virus or postviral inflammation affecting the vestibular portion of the 8th cranial nerve (CN). It causes a rapid onset of vertigo, nausea, and vomiting. Examination shows spontaneous nystagmus that is unidirectional, horizontal, and not direction changing. The fast phase beats away from the side of the lesion. The patient will have a positive head thrust test and be unable to maintain visual fixation, resulting in a catch-up saccade. They may have some gait instability but will still be able to ambulate and will have no neurological symptoms. The Head Impulse, Nystagmus, Test of Skew examination (**Box 21.5**) is a useful way of distinguishing a central or peripheral cause of acute vertigo syndrome and determining who needs urgent neuroimaging. If hearing is simultaneously affected, the condition is termed labyrinthitis.

An acute vertigo syndrome where a central lesion has been excluded either clinically or on imaging is managed with steroids and vestibular sedatives in the acute phase. A patient with a deficit of vestibular function due to viral labyrinthitis or neuronitis should be able to cease vestibular sedatives within 2 weeks; long-term use can give parkinsonian side-effects, delay central compensation, and thus prolong vertigo. Vestibular rehabilitation by a physiotherapist or audiological scientist can speed up compensation, although most patients will be able to compensate themselves with time.

Central causes of vertigo

Posterior circulation stroke

Acute-onset, sustained vertigo may be a presentation of lesions in the cerebellum and brainstem including posterior circulation stroke or posterior fossa mass. Direction changing or vertical nystagmus and other neurological symptoms and signs are usually present. The Head Impulse, Nystagmus, Test of Skew examination can be used to determine whether an acute vertigo episode is central and therefore whether urgent neuroimaging is required (**Box 21.5**).

Box 21.5 The Head Impulse, Nystagmus, and Test of Skew examination[a]

	Peripheral vertigo	Central vertigo
Head Impulse Test	Abnormal, corrective saccade occurs	Normal, no corrective saccade
Nystagmus	None or unidirectional	Direction changing Vertical Torsional
Test of Skew	No vertical skew	Vertical skew present

[a]This test is performed on patients with acute vertigo syndrome to distinguish a peripheral from central vertigo. Acute central vertigo requires urgent neuroimaging. (See also: https://www.youtube.com/watch?v=1q-VTKPweuk).

Vestibular migraine

Vestibular migraine is a subtype of migraine that involves a combination of headache symptoms (severe, throbbing, usually unilateral headache, nausea/vomiting, sensitivity to light/smell/noise) in addition to vestibular symptoms including vertigo (which can last from 5 mins to 72 hours), unsteadiness, and sensitivity to motion. The migraine headaches and vertigo symptoms do not have to occur together. Tinnitus and aural fullness may also be present. Triggers and treatments are the same as for other migraine headaches (see Chapter 28).

Tinnitus

This is a sensation of a sound when there is no auditory stimulus. It can occur without hearing loss and results from heightened awareness of neural activity in the auditory pathways. It is usually benign. It is rarely due to vascular malformations (e.g., aneurysms) or vascular tumours (tinnitus may be pulsatile and commonly unilateral in these cases). It is a difficult symptom to treat. A tinnitus masker (a mechanically produced, continuous, soft sound) can help, or hearing aids can be used if there is associated audiological deficit. Cognitive behavioural therapy through audiological services may be helpful.

THE NOSE

Anatomy and physiology

The function of the nose is to facilitate smell and respiration:

- Smell is a sensation conveyed by the olfactory epithelium in the roof of the nose via the olfactory (1st cranial) nerve.
- The nose filters, moistens, and warms inspired air and, in doing so, assists normal respiration.

The external portion of the nose consists of two nasal bones attached to the facial skeleton and upper and lower lateral cartilages. The internal nose is divided by a midline septum that comprises both cartilage and bone, separating the external nostril from the posterior choanae. The posterior choanae are in continuity with the nasopharynx posteriorly. The paranasal sinuses open into the lateral wall of the nose and form a system of aerated chambers within the facial skeleton (Fig. 21.11). The blood supply of the nose is derived from the internal and external carotid arteries. The internal carotid artery supplies the upper nose via the anterior and posterior ethmoidal arteries. The external carotid artery supplies the posterior and inferior portions of the nose via the superior labial, greater palatine, and sphenopalatine arteries. On the anterior nasal septum there is an area of confluence of these vessels (Little's area; Fig. 21.12A), and nasal packing can be used to provide direct compression to these vessels and help to arrest nasal bleeding Fig. 21.12B).

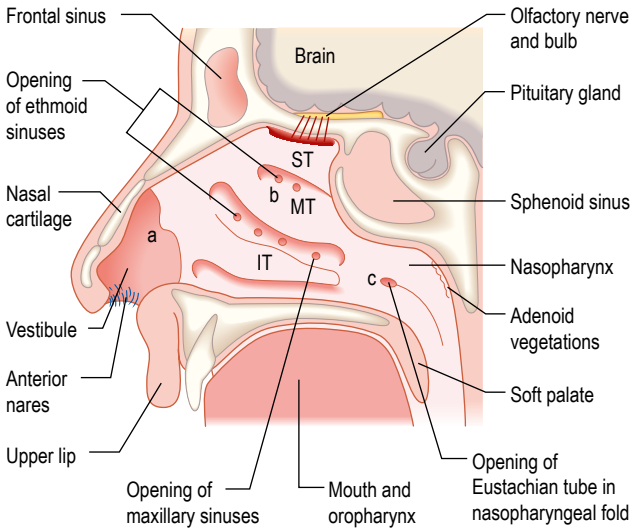

Fig. 21.11 The nose and paranasal sinus ostia. The paranasal sinuses all drain into distinct areas of the nasal cavity.

CLINICAL APPROACH TO THE PATIENT WITH A DISORDER OF THE NOSE

Examination

Inspection of the nose includes an assessment of facial proportions and symmetry. Nasal airflow is assessed by fogging on a cold spatula. A Thudicum speculum is used to examine the anterior nares for evidence of septal deviation and for prominent vessels in Little's area. The posterior nasal cavity and nasopharynx are examined using a rigid or flexible endoscope. Assessment of olfaction can be performed using 'Sniffin' sticks' or the University of Pennsylvania Smell Identification Test.

COMMON DISORDERS OF THE NOSE

Common disorders of the nose are outlined in Box 21.6.

Nasal obstruction

Nasal obstruction can significantly affect quality of life. Causes include:

- ***Allergic rhinitis.*** This is most commonly triggered by allergens, leading to erythema of the nasal mucosa and hypertrophy of inferior turbinates. Symptoms may be seasonal (e.g., grass pollen) or perennial (e.g., house dust mite). If an allergen is identified in the history and confirmed (e.g., via skin prick or radioallergosorbent [RAST] testing), then allergen avoidance is the mainstay of treatment. Oral antihistamines, topical steroids, or a combination nasal preparation may be tried. If rhinitis is severe, referral to an allergy clinic for immunotherapy may be warranted. Short-term benefit may be gained in severe nasal blockage by surgically reducing the inferior turbinate.
- ***Non-allergic rhinitis.*** Vasomotor rhinitis is the most common form, occurring in response to temperature changes, strong odours, or spicy food. Treatment is with an anticholinergic nasal spray (e.g., ipratropium bromide).

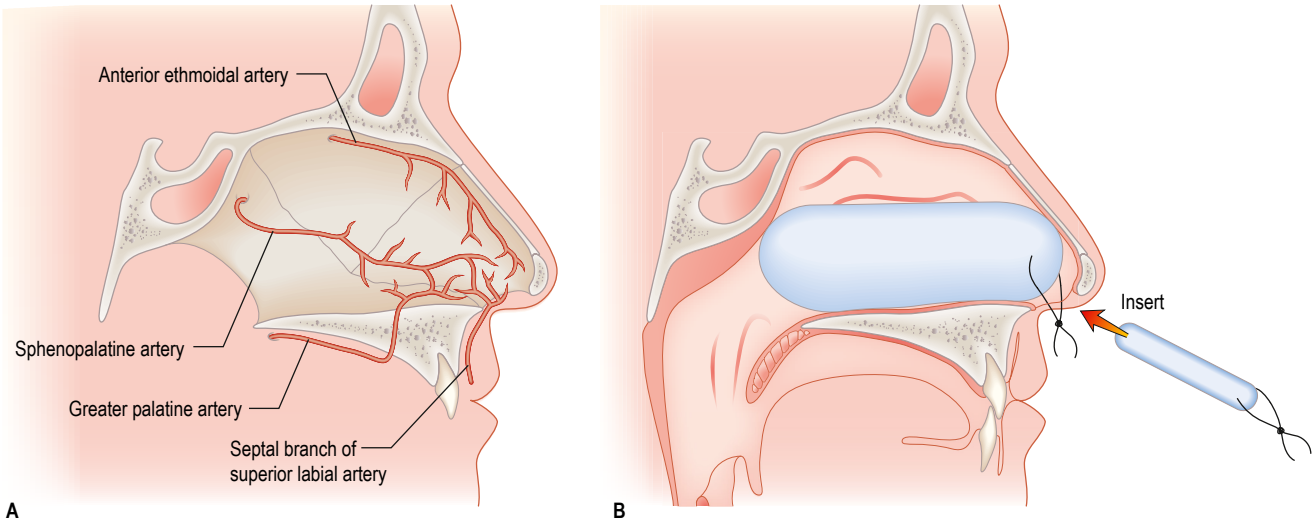

Fig. 21.12 **(A and B) Little's area and nasal packing.** **(A)** Blood supply of Little's area on the septum of the nose. **(B)** Nasal pack.

Box 21.6 Common diagnoses of the nose

Symptom	Diagnosis	Key clinical features
Obstruction	Rhinitis	Allergic symptoms
	Septal deviation	Congenital or traumatic, unilateral blockage
	Rhinosinusitis	Rhinorrhoea, facial pain, altered smell. *Complications: periorbital cellulitis, visual loss*
	Foreign body	Offensive discharge, may be bloody, aspiration risk
	Malignancy	Unilateral symptoms, red flag symptoms (see Box 21.1)
Rhinorrhoea	Rhinitis	Allergic symptoms
	Rhinosinusitis	Rhinorrhoea, facial pain, altered smell. *Complications: periorbital cellulitis, visual loss*
Anosmia	Rhinosinusitis	Rhinorrhoea, facial pain, altered smell. *Complications: periorbital cellulitis, visual loss*
	Neurological disease	Other features of neurological disease, e.g., Parkinson's, Alzheimer's
	Medication/drugs	e.g., beta-blockers, ACE-inhibitors, cocaine, smoking
	Head injury	Occurs following trauma
	Viral infection	e.g., SARS-CoV-2
	Malignancy	Unilateral, mass on endoscopy, associated epistaxis
Epistaxis	Local irritation	e.g., digital trauma, nasal oxygen, nasal corticosteroids
	Nose/face trauma	History of injury
	Foreign body	Offensive discharge, may be bloody, aspiration risk
	Juvenile nasal angiofibroma	Adolescent males, avoid biopsy due to bleeding risk
	Bleeding disorders	Other bleeding, easy bruising
	Medication	e.g., antiplatelets, anticoagulants
	Hereditary haemorrhagic telangiectasia	Telangiectasia around nose and mouth, haemoptysis, melaena

- ***Septal deviation.*** The septum may be deviated to one side of the nose, either congenitally or due to trauma, causing unilateral obstruction. Surgical correction can be undertaken.
- ***Foreign bodies.*** These are usually seen in children presenting with unilateral nasal discharge which may be offensive. Clinical examination of the nose with a light source often reveals the foreign body, which requires removal.
- ***Sinonasal tumours.*** These may be benign (e.g., inverted papilloma, see Fig. 21.13) or malignant (e.g., squamous cell carcinomas, adenocarcinomas, adenoid cystic carcinoma, olfactory neuroblastomas, lymphoma, melanoma, sinonasal undifferentiated carcinoma). Inverted papillomas are associated with squamous cell carcinoma in 5% of cases. Malignancy should be considered in the context of unusual, unilateral symptoms including nasal obstruction, epistaxis, pain, epiphora, paraesthesia of the cheek, unilateral serous otitis media, or proptosis of the orbit (Box 21.1). A unilateral polyp may be seen on examination and confirmed on imaging.
- ***Rhinosinusitis*** (see below).

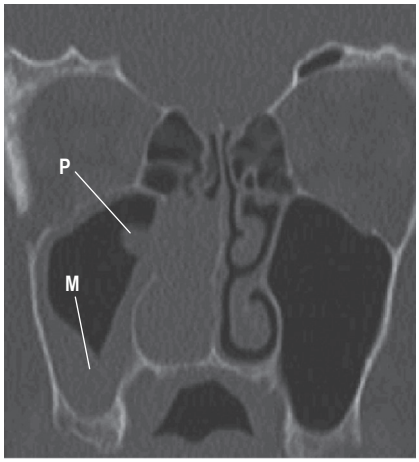

Fig. 21.13 CT of the sinuses. An inverted papilloma (P) can be seen obstructing the right nostril, and there is mucosal thickening (M) of the right maxillary sinus.

Box 21.7 Types of rhinosinusitis

Type	Duration of symptoms
Acute	Less than 12 weeks
Recurrent acute	>4 episodes of acute sinusitis per year with symptom-free intervals
Chronic	>12 weeks

Rhinorrhoea (runny nose)

Rhinosinusitis

Rhinosinusitis is inflammation of the nose and paranasal sinuses characterized by two or more symptoms, one of which should be nasal obstruction/congestion or nasal discharge, with or without change in smell, facial pain, or pressure. In addition, there must be either endoscopic signs of nasal polyps, mucopurulent discharge, or CT changes. Symptoms may be acute (<12 weeks) or chronic (≥12 weeks) (Box 21.7). Rhinosinusitis symptoms can be confused with a variety of other conditions, including migraine, trigeminal neuralgia, and temporal arteritis.

Acute rhinosinusitis is commonly associated with upper respiratory tract infection and can occur in asthma. Symptoms include frontal headache, purulent rhinorrhoea, facial pain with tenderness, and fever. Treatment includes saline spray and short courses of nasal decongestants (e.g., xylometazoline). Topical or short courses of oral corticosteroids are used to reduce mucosal swelling and can lead to symptom improvement. Signs of a superimposed bacterial infection (mainly *S. pneumoniae* and *H. influenzae*) in which antibiotic treatment is indicated include double sickening (getting worse after an initial period of recovery), fever (>38°C), unilateral symptoms, severe pain, and raised inflammatory markers.

Chronic rhinosinusitis (CRS) is classified as primary when disease originates in the nose and sinuses rather than secondary to other systemic disease, for example, cystic fibrosis. Causes of primary CRS can be determined initially by their distribution: localized to a single sinus, for example, maxillary, or diffuse and affecting all paranasal sinuses. Inflammatory subtypes are type 2 and non–type 2. Type 2 inflammation occurs due to immune system activation comparable to that of atopic dermatitis and asthma and is associated with nasal polyp formation. Non–type 2 inflammation is caused by recurrent acute bacterial infection, for example, following upper respiratory tract infection, which leads to tissue remodelling, bacterial colonization, and chronic symptoms (Box 21.8). Treatment is with daily intranasal saline irrigations and intranasal steroids. If symptoms persist or recur, nasoendoscopy can confirm the diagnosis. Endoscopic sinus surgery may be necessary to improve access to the sinuses for delivery of topical steroid therapy. CT imaging of the paranasal sinuses is undertaken prior to sinus surgery to define bony landmarks and anatomy. Patients with severe type 2 inflammatory disease (requiring multiple endoscopic sinus surgery procedures and oral steroids courses) may benefit from immune-modulating treatments including monoclonal antibodies targeting inflammatory cytokines involved in these pathways.

Periorbital cellulitis is an acute complication of acute or chronic rhinosinusitis. An urgent ENT opinion is indicated due to the potential for complications including visual loss, cavernous sinus thrombosis, or intracranial abscess, which can develop rapidly.

Fungal rhinosinusitis can be acute or chronic, invasive or non-invasive. Allergic fungal sinusitis is a chronic, non-invasive fungal sinusitis, associated with atopy, and treated similarly to other forms of chronic sinusitis with nasal steroids. Functional endoscopic sinus surgery is used as an adjunct to open the sinuses ostia, remove fungal disease, and provide access for topical therapies to the sinonasal mucosa. Acute, invasive fungal rhinosinusitis is an aggressive, life-threatening disease that occurs in immunosuppressed patients requiring aggressive surgical debridement and intravenous antifungal treatment. Prognosis is poor.

Fokkens WJ et al. Executive summary of EPOS 2020 including integrated care pathways. *Rhinology* 2020; 58(2):82–111.

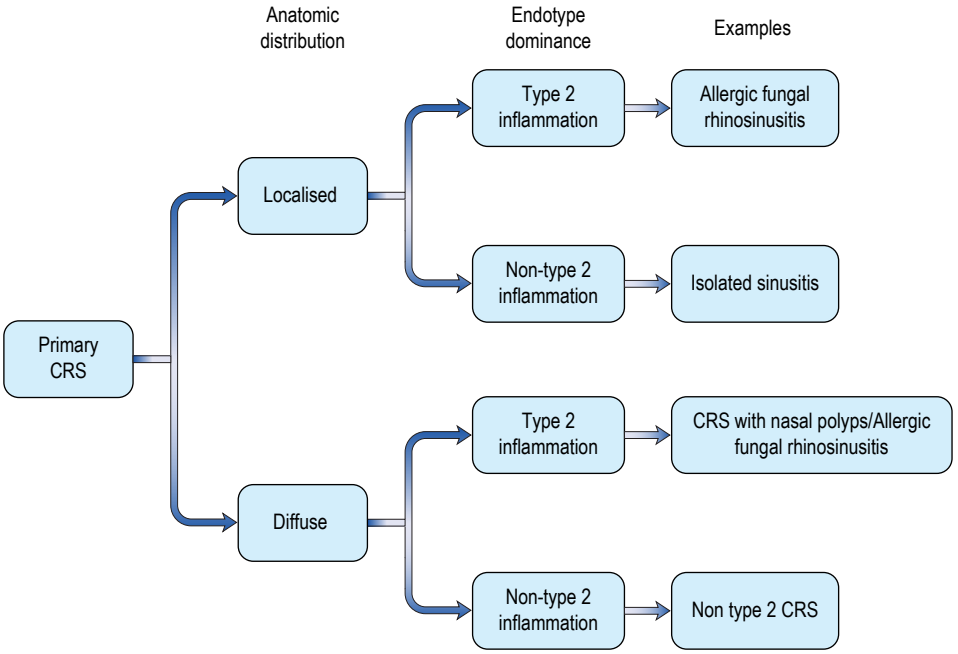
Anosmia

Anosmia is a complete loss of the sense of smell, and hyposmia is a decreased sense of smell. Olfaction is mainly transmitted by the CN I, although irritant and unpleasant nasal sensations are also stimulated by CNs V, IX, and X. A conductive deficit of smell occurs if odorant molecules do not reach the olfactory epithelium high in the nose. Sensorineural loss of smell results from affected neural transmission. Some conditions predispose to a mixed (conductive and sensorineural) loss of smell. The most common cause of a loss of smell is nasal obstruction due to upper respiratory infection or nasal polyps. In many, anosmia is idiopathic, but this is a diagnosis of exclusion, and assessment to exclude an intranasal tumour or intracranial mass should be undertaken, initially with nasendoscopy, followed by MRI in the absence of obvious nasal pathology. Other causes include sinonasal disease, infection, older age, drugs (beta-blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors, tobacco, cocaine), and head injury/trauma. It can be difficult to predict the speed and extent of recovery.

Epistaxis

Nose bleeds vary in severity from minor to life-threatening. Common causes of epistaxis include nose picking, nasal foreign body, mucosal irritation from nasal oxygen cannula or intranasal steroids, and nose/facial trauma.

Box 21.8 Classification of primary chronic rhinosinusitis



(From European position paper on Rhinosinusitis and nasal polyps guidelines, 2020.)

Box 21.9 Aetiology of epistaxis

Local
Idiopathic
Trauma: foreign body, nose-picking, nasal fractures
Iatrogenic: surgery, intranasal steroids
Neoplasm: nasal, paranasal sinus, nasopharyngeal tumours, e.g., juvenile angiofibroma, squamous cell carcinoma

General
Coagulopathy: anticoagulants/antiplatelet agents, coagulation disorders
Severe hypertension
Hereditary haemorrhagic telangiectasia

Little's area is a frequent site of nasal haemorrhage (Fig. 21.12A). Immediate first aid measures include external digital compression of the anterior lower cartilaginous portion of the external nose, ice pack, and leaning forward. The patient should try to avoid swallowing blood running posteriorly as this causes nausea. If profuse bleeding continues, resuscitation in the form of intravenous access and volume/blood product replacement should be administered. Topical adrenaline and intranasal cautery with silver nitrate or bipolar cautery can be used when the bleeding vessel can be identified. If bleeding persists but the vessel cannot be directly identified, a combination of tranexamic acid, absorbable haemostatic agents, or non-absorbable intranasal packing can help to control bleeding. If the above treatments fail, then surgical ligation of the sphenopalatine artery can be undertaken endoscopically, or interventional arterial embolization can be performed. In addition to direct control of epistaxis, the underlying cause should be sought and treated (Box 21.9).

Trauma

People with a fractured nose present with epistaxis, bruising of the eyes, and nasal bridge swelling. It can be difficult to assess whether bones are deviated, particularly if there is significant swelling. The patient should be examined for a head injury and the nose checked for septal haematoma (Fig. 21.14). This is painful, can cause nasal obstruction, is fluctuant to touch on the nasal septum, and requires urgent drainage to prevent destruction of the septal cartilage (which may otherwise result in a saddle nose deformity). Reduction of the fracture should be undertaken in the first 2 to 3 weeks after injury and can be achieved by manipulation. If the fracture sets after this time, rhinoplasty may have to be undertaken at a later stage.

Fig. 21.14 Septal haematoma.

Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia is a genetic condition where arteriovenous malformations (AVM) occur on the nasal mucosa, as well as in the liver, GI tract, and brain. Epistaxis is a common presenting feature. Treatment includes saline spray, moisturizing creams to avoid drying of the nasal mucosa, and avoidance of mucosal trauma. Potassium titanyl phosphate (KTP) laser treatment is used to treat the mucosal AVM in the nose in order to reduce the frequency of epistaxis.

Juvenile nasal angiofibroma

Juvenile nasal angiofibroma is a rare vascular nasal tumour that presents predominantly in adolescent males and can cause severe

epistaxis. Although benign, they can invade local structures and be challenging to completely excise. The diagnosis is confirmed on CT or MRI imaging. Biopsy should be avoided due to the risk of life-threatening bleeding.

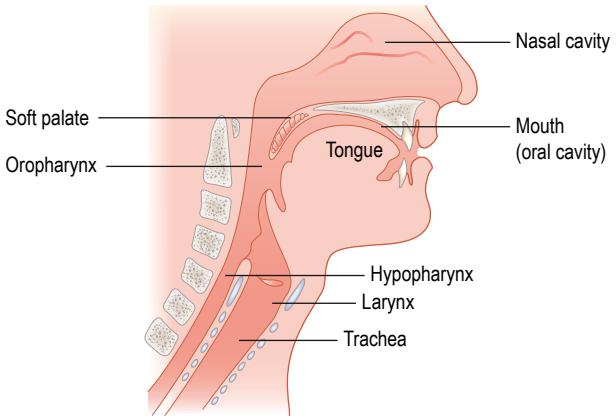


Fig. 21.15 **Normal anatomy of the throat.**

THE THROAT

Anatomy and physiology

The throat extends from the lips to the tonsils and consists of the oral cavity, pharynx, and larynx (Fig. 21.15). The pharynx is innervated from the pharyngeal plexus and is divided into three areas:

- Nasopharynx: posterior nasal openings to soft palate
- Oropharynx: soft palate to tip of epiglottis
- Hypopharynx: tip of the epiglottis to just below the level of cricoid cartilage

Lying within the hypopharynx is the larynx. This consists of cartilaginous, ligamentous, and muscular tissue with the primary function of protecting the distal airway. Two vocal cords abduct (open) during inspiration and adduct (close) to protect the airway and produce the voice (phonation). The main nerve supply of the vocal cords comes from recurrent laryngeal nerves which arise in the neck as branches of the vagus nerve. **The course of the recurrent laryngeal nerve is longer on the left than on the right** (Fig. 21.16). In phonation, normal vocal cords vibrate between 90 (male) and 180 (female) times per second, giving the voice its

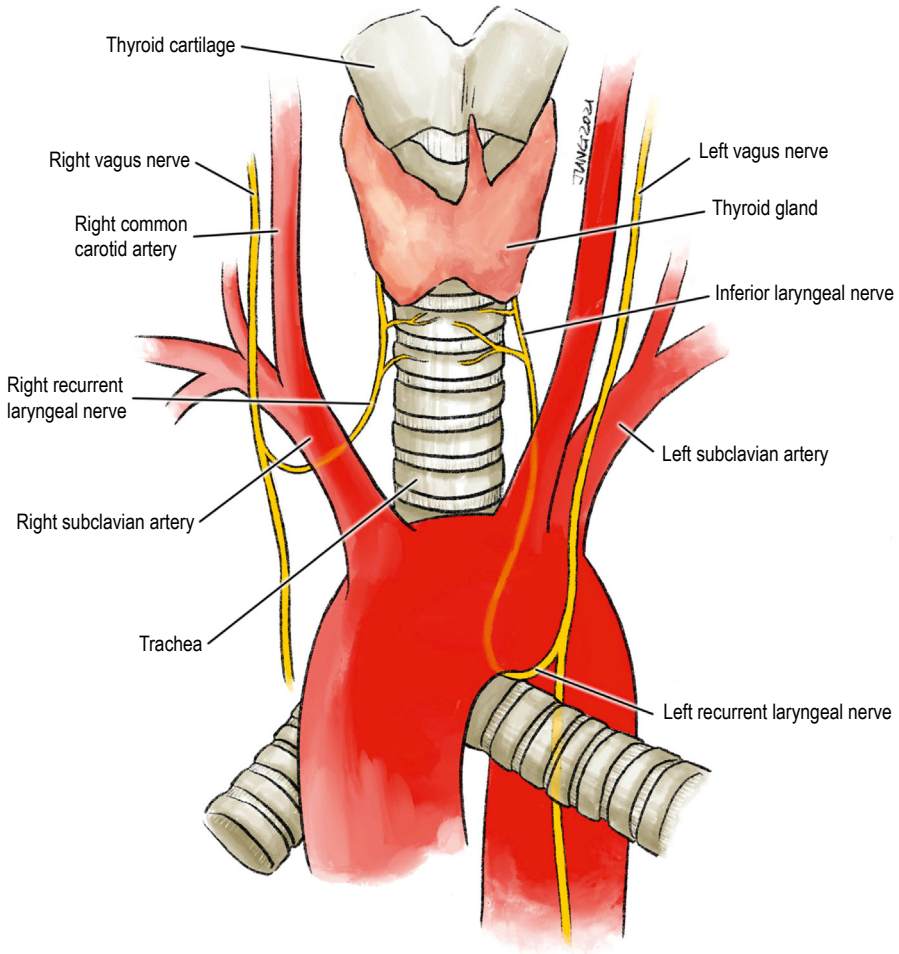

Fig. 21.16 **Anatomy of the recurrent laryngeal nerves differs on the right and left sides of the neck.** The course of the left recurrent laryngeal nerve is longer, passing down around the aortic arch before ascending in the tracheo-oesophageal groove to the larynx, meaning left vocal cord paralysis is more common than right. A patient with a paralysed vocal cord must have a CT of the neck and chest (from skull base to diaphragm) to identify pathology along the course of the vagus or recurrent laryngeal nerves.

pitch or frequency. A healthy voice requires full closure of the vocal cords with a smooth, regular pattern of vibration. Any pathology that prevents full closure results in air escaping during phonation and a 'breathy' voice.

CLINICAL APPROACH TO THE PATIENT WITH A DISORDER OF THE THROAT

Examination

Good illumination is essential. Inspect teeth, gums, tongue, floor of mouth, and oral cavity. The tonsils, soft palate, and uvula are easily visualized. A gag reflex should be present. The remainder of the pharynx and larynx can be inspected with a flexible laryngopharyngoscope. The neck should be examined for lymph nodes and other masses.

COMMON DISORDERS OF THE THROAT

Common disorders of the throat are outlined in **Box 21.10**.

Odonophagia (pain on swallowing)

Tonsillitis/pharyngitis

Most infections are of viral origin and self-limiting, settling with time and analgesia. If pyrexia, dysphagia, or lymphadenopathy is present, then bacterial infection is more likely, with β-haemolytic streptococcus being the most common organism. Infectious mononucleosis caused by Epstein–Barr virus (see Chapter 42) can present as tonsillitis with a confluent white tonsillar exudate and associated petechial rash on the soft palate and lymphadenopathy. The fever pain score is a tool used in primary care to predict the likelihood of bacterial throat infection and guide antibiotic use (**Box 21.11**). Oropharyngeal candidiasis is uncommon and warrants exclusion of immunosuppression including diabetes mellitus and HIV.

Indications for a tonsillectomy are shown in **Box 21.12**. Current surgical techniques include cold steel, diathermy dissection, and coblation (which uses an ultrasonic dissecting probe under general anaesthesia). There are strong advocates for each technique, and much depends on the individual surgeon's preference. Most tonsillectomy is performed as a day-case procedure, as most reactionary bleeding occurs in the first 8 postoperative hours.

Box 21.10 Common diagnoses of the throat

Symptom	Diagnosis	Key clinical features
Odynophagia	Tonsilitis/pharyngitis	Fever, pain on swallowing, pus on tonsils, lymphadenopathy
	Quinsy	Fever, pain on swallowing, trismus, swelling above tonsil, uvula deviation
	Parapharyngeal abscess	Fever, pain on swallowing, pain with neck movement, breathlessness. *Complications: airway compromise, mediastinitis*
	Malignancy	Pain (persistent, unilateral), mass, lymphadenopathy
Dysphagia	Foreign body	Sudden onset, pain, drooling, airway compromise
	Pharyngeal pouch	Dysphagia to solids, regurgitation, halitosis, compressible neck mass, aspiration pneumonia
	Globus pharyngeus	Worse with saliva, better with eating and drinking, normal endoscopy
	Malignancy	Progressive dysphagia, pain (unilateral), lymphadenopathy, smoking, airway compromise
Hoarseness	Vocal cord nodules	Professional voice user (e.g., teacher, singer), smoking, reflux
	Vocal cord polyps	Can follow episode of haemorrhage e.g., screaming, coughing
	Recurrent respiratory papillomatosis	Usually in children after HPV acquired at the time of delivery, airway compromise
	Reinke's oedema	Husky voice, smoking
	Vocal cord palsy	Breathy voice, aspiration pneumonia
	Laryngeal cancer	Stridor in advanced disease
Stridor	Malignancy	Hoarseness, dysphagia, odynophagia, smoking, alcohol
	Recurrent respiratory papillomatosis	Usually in children after HPV acquired at the time of delivery, airway compromise
	Supraglottitis	Odynophagia, fever, stridor. Normal oropharynx despite severe symptoms
	Parapharyngeal abscess	Fever, pain on swallowing, pain with neck movement, breathlessness. *Complications: airway compromise, mediastinitis*
	Foreign body	Sudden onset, usually in a child
	Anaphylaxis	Tongue/upper airway swelling over minutes to hours
	Angioedema	Swelling of lips, tongue, posterior pharynx, and larynx
	Trauma	Following traumatic injury
	Smoke inhalation	History of inhalation, soot around mouth. Consider early intubation

Box 21.11 Fever pain score for tonsillitis

Clinical feature		Score 1 if present
Fever during last 24 hours		
Purulence (pus) on tonsils		
Presentation within 3 days of symptoms		
Tonsils severely inflamed		
No cough or coryza		
Fever pain score		**Total (max 5)**
Fever pain score	**Likelihood of streptococcus**	**Antibiotics**
0–1	13%–18% (similar to asymptomatic carrier rate)	Not recommended
2–3	34%–40%	Delayed 24–48 hours
4–5	62%–65%	Recommended

Box 21.12 Indications for tonsillectomy

Suspected malignancy (e.g., asymmetrical tonsils, or for diagnostic workup in the case of an unknown primary)
Obstructive sleep apnoea due to tonsillar hypertrophy
Recurrent tonsillitis: three episodes per year for more than 3 years, five episodes per year for 2 years, or seven episodes in 1 year (Paradise criteria)
Quinsy
Specific conditions where tonsillitis may contribute to disease activity, e.g., periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis syndrome.

Quinsy (peritonsillar abscess)

Quinsy is a collection of pus outside the capsule of the tonsil, usually located adjacent to its superior pole. Trismus is a key feature and can make examination difficult. The area around the tonsil is hyperaemic and can push the uvula across the midline. Awake transoral needle aspiration of the abscess by an ENT surgeon is required. If untreated, infection can spread through the superior constrictor muscles of the pharynx, forming a parapharyngeal abscess. From there, pus may spread rapidly via deep fascial planes of the neck and chest, with the potential airway compromise, mediastinitis, and sepsis to occur.

Oropharyngeal squamous cell carcinoma

Unilateral throat pain with an ulcerated or asymmetrically enlarged tonsil is concerning for malignancy and urgent biopsy is required. Human papilloma virus (HPV) infection accounts for 50% to 70% of oropharyngeal malignancy. HPV-related tumours have distinct tumour characteristics and slightly more favourable outcomes compared to HPV-negative oropharyngeal squamous cell carcinomas (which are associated with the traditional risk factors of smoking and alcohol excess).

Dysphagia

See also Chapter 22. Dysphagia can occur because of disease anywhere between the throat and stomach. The pharyngeal pouch and foreign body in the pharynx are managed by ENT specialists. Aetiologies arising further down the oesophagus are managed by gastroenterology.

Pharyngeal pouch

A pharyngeal pouch is a herniation of mucosa through the fibres of the inferior pharyngeal constrictor muscle (cricopharyngeus)

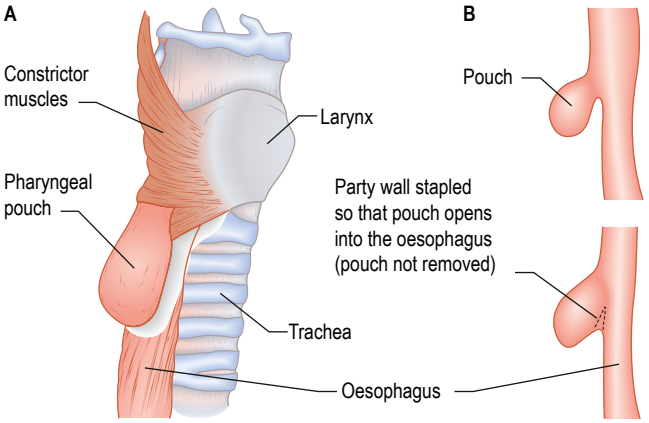

Fig. 21.17 (A and B) Pharyngeal pouch. **(A)** Position of pharyngeal pouch. **(B)** Stapling of the party wall between oesophagus and pouch.

(Fig. 21.17A). An area of weakness known as Killian's dehiscence allows a pulsion diverticulum to form. Patients present with neck swelling following a failed swallow attempt. They can occasionally compress the swelling, which pushes food particles back into the oesophagus. A gurgling sound may be heard in the neck following a swallow as liquid and food collect in the pouch. Occasionally, patients present with recurrent pneumonia following aspiration of food into the trachea. Diagnosis is made on barium swallow imaging (Fig. 21.18), and treatment is surgical, either via an external approach through the neck or, more commonly, via endoscopy with stapling of the party wall (see Fig. 21.17B).

Foreign body

Foreign bodies in the pharynx can be classified as one of four main types: soft food bolus, coins, button batteries (smooth with a halo/double ring/narrow rim on plain radiograph imaging, Fig. 21.19A and B), and bones. Soft food boluses can be managed conservatively with muscle relaxants for 24 hours. Impacted coins should be removed at the earliest opportunity. Button batteries and sharp objects require emergency removal to avoid perforation of the muscle wall. If the patient perceives the foreign body to be on one side and located above the manubrium, then the foreign body is usually found above the cricopharyngeus and can be located with flexible laryngopharyngoscopic examination; common areas are the tonsillar fossae, base of tongue, posterior pharyngeal wall, and valleculae. Lateral and anterior-posterior radiographs can identify and locate a foreign body not visible on examination, as these frequently lodge at the level of the cricopharyngeus. A coin or sharp foreign body that has passed this junction will often pass into the stomach and no further treatment may be required as it will exit naturally. While not all fish bones are radio-opaque, soft tissue changes resulting from the impacted foreign body may be seen. CT imaging may provide additional information or reassurance where the history is equivocal. Direct laryngopharyngooesophagoscopy is the best diagnostic tool.

Globus pharyngeus

This is an intermittent sensation of a lump in the throat, without true dysphagia. The sensation is perceived in the midline at the level of the cricoid cartilage, is worse when swallowing saliva, and is better or disappears when ingesting food/liquid. Examination including flexible laryngopharyngoscopy is normal. Patients with features or risk factors for head and neck cancers should undergo panendoscopy. Treatment is with explanation

and reassurance. Gastric acid suppression therapy can be tried if symptoms persist.

Malignancy of upper aerodigestive tract

Dysphagia may be caused by a malignancy of the upper aerodigestive tract, usually in the presence of red flag features, including odonophagia, hoarseness, dyspnoea, neck lymphadenopathy, and weight loss. Risk factors include tobacco and alcohol excess. Visualization of the upper aerodigestive tract with a flexible laryngopharyngoscope may reveal an irregular mass or an area of salivary pooling. MRI imaging of the head and neck and cross-sectional chest imaging are required prior to biopsy. Ultrasound localization and fine needle aspiration of neck lymphadenopathy may be performed in a one-stop diagnostic clinic and provide a same-day diagnosis. Investigation and management are undertaken with multidisciplinary discussion and consensus.

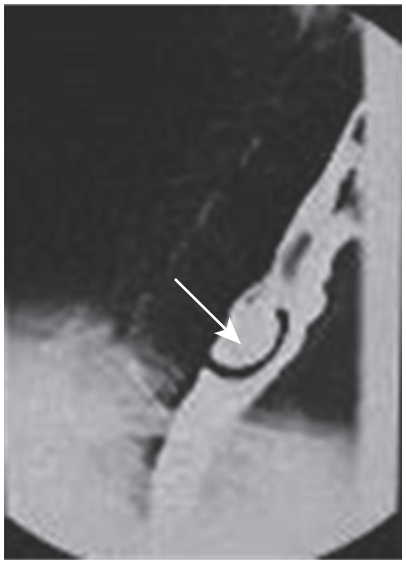

Fig. 21.18 **Pharyngeal pouch shown on barium swallow.**

Hoarseness (dysphonia)

There are three essential components for voice production: an air source (lungs), a vibratory source (vocal cords), and a resonating chamber (pharynx, nasal and oral cavities). Although chest and nasal disorders can affect voice, the majority of hoarseness is due to vocal cord pathology.

Nodules/polyps

Nodules (usually bilateral, more common in females) and polyps (usually unilateral, more common in men) (Fig. 21.20A) occur secondary to chronic vocal fold irritation: smoking, laryngopharyngeal reflux, and muscle tension dysphonia. The presence of lesions on the free edge of the vocal cord prevents full closure and results in hoarseness. They are commonly found in professionals who rely on their voice for their livelihood such as teachers, singers, and lawyers. They are usually related to the technique of voice production and can be cured with speech therapy. If surgery is needed, great care must be taken to remain in the superficial layers of the vocal cord to prevent deep scarring, which leaves the voice permanently hoarse.

Reinke's oedema

This is a collection of tissue fluid in the subepithelial layer of the vocal cord (Fig. 21.20B). The vocal cord has poor lymphatic drainage, predisposing it to oedema. Reinke's oedema is associated with irritation of the vocal cords by smoking, voice abuse, laryngopharyngeal reflux, and, rarely, hypothyroidism. Treatment is to remove the irritant cause in most cases, but surgery to incise the cords and reduce the oedema may also allow the voice to return to normal pitch.

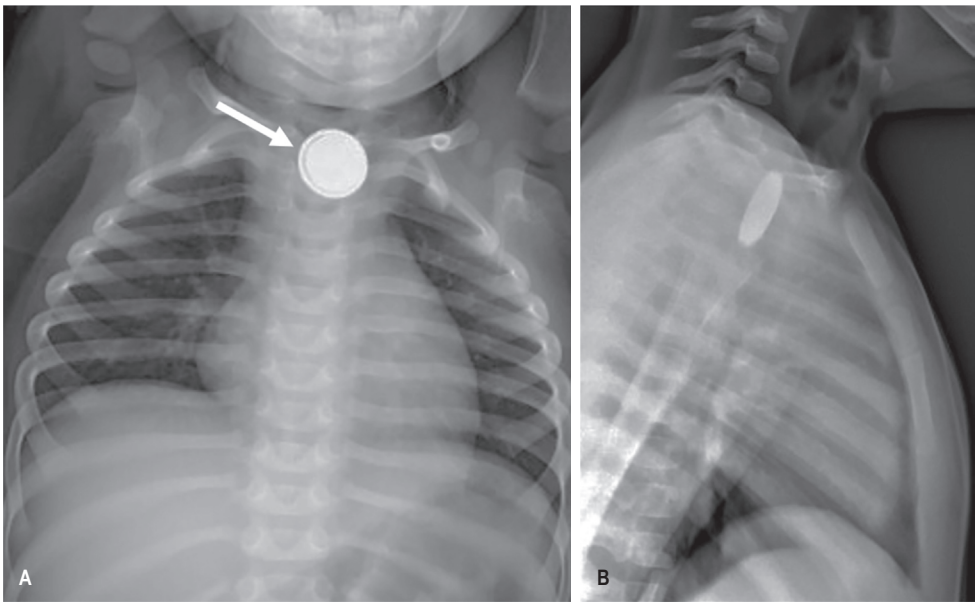

Fig. 21.19 **Button battery.** **(A)** Frontal chest radiograph in a 1-year-old shows a rounded metallic density foreign body projected over the upper oesophagus. A sub-peripheral lucency producing a 'double-ring' appearance *(arrow)* is seen to be suggestive of a button battery. **(B)** Lateral radiograph in this patient shows the battery in profile as would be expected for a foreign body in the oesophagus.

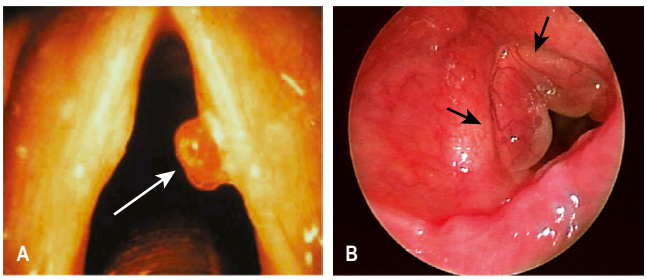

Fig. 21.20 (A and B) Disorders of the vocal cords. (A) Vocal cord polyp. (B) Reinke's oedema of the vocal cords.

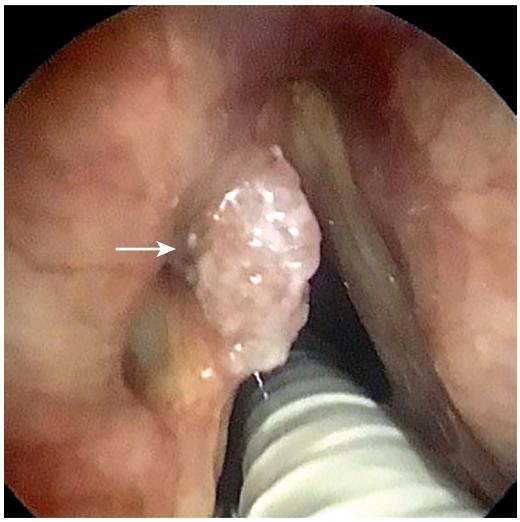

Fig. 21.21 Laryngeal carcinoma of the right vocal cord.

Laryngeal or bronchial carcinoma

Hoarseness in a person who smokes should be considered a sign of malignancy until proven otherwise. Any patient with a hoarse voice for over 6 weeks should be referred urgently for examination of the vocal cords using flexible nasopharyngolaryngoscopy. The voice may be deep, harsh, and breathy, indicating a mass on the vocal cord (Fig. 21.21), or it can be weak, suggesting a paralysed left vocal cord secondary to mediastinal disease, such as bronchial carcinoma. A patient with a paralysed vocal cord must have a CT of the neck and chest to identify pathology along the course of the vagus or recurrent laryngeal nerve (Fig. 21.16). If there is airway compromise, immediate surgical debulking of the laryngeal mass or tracheostomy to prevent life-threatening airway obstruction may be indicated.

Early squamous cell carcinoma of the larynx has a good prognosis due to limited lymphatic drainage of the vocal cords, with 5-year disease-free survival for stages I and II disease of 90% and 80%, respectively. Treatment is with a single modality of treatment, either transoral laser resection or radiotherapy. Larger tumours that spread to surrounding lymph nodes may require dual modality treatment (e.g., surgery with postoperative radiotherapy or chemoradiotherapy). Non–organ-preserving surgery (laryngectomy and neck dissection of affected lymph nodes) is reserved for large tumours that have invaded through the laryngeal cartilage, where safe swallow is already impaired, or where chemoradiotherapy has failed to cure disease. Patients with a paralysed vocal cord (e.g., from a bronchial carcinoma) can have vocal cord medialization surgery to improve their voice and help with laryngeal competence. This can be done under local or general anaesthesia.

Box 21.13 Indications for tracheostomy

Emergency

Upper airway obstruction in patients who have failed an endotracheal tube or in patients where an endotracheal tube cannot be placed, e.g., large obstructing tumour

In patients with select fractures or trauma to the oropharynx, face, or neck including penetrating laryngeal trauma

Elective

Patients who require or are likely to require long-term mechanical ventilation and have difficulty weaning off the ventilator

Patients with poor airway protection who need ventilation or secretion control (e.g., neuromuscular disorders, recurrent aspiration)

Severe obstructive sleep apnoea, vocal cord paralysis, and subglottic stenosis who have failed other therapies

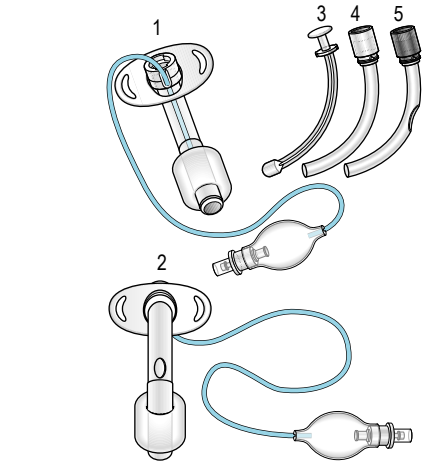

Fig. 21.22 Different types of adult tracheostomy tubes.

Stridor

Stridor, or noisy breathing, can be divided into the following types:

- ***Inspiratory:*** obstruction is at the level of the vocal cords or above.
- ***Mixed*** (inspiratory and expiratory): obstruction is in the subglottis or extrathoracic trachea.
- ***Expiratory:*** obstruction is in the intrathoracic trachea or distal airways.

All patients with stridor are at risk of asphyxiation and should be investigated. Volume of stridor is not a marker of severity if it is causing less laryngeal airflow. Stridor with significant respiratory distress may be an indication for intubation or a tracheostomy (Box 21.13). Types of tracheostomy tubes (Fig. 21.22) include:

- ***Cuffed or uncuffed.*** A high-volume, low-pressure cuff is used to prevent aspiration and to allow positive-pressure ventilation.
- ***Fenestrated or unfenestrated.*** A fenestrated cuff has a small hole on the greater curvature of the tube (both outer and inner), allowing air to escape upwards to the vocal cords; the patient can therefore speak. This tube is often used with a valve that allows air to enter from the stoma but closes on expiration, directing air through the fenestration.

Most adult long-term tracheostomy tubes have an inner and an outer tube, while paediatric tubes are usually single lumen to maximize internal diameter for ventilation. In adult tracheotomy

tubes the inner tube fits inside the outer tube and projects beyond its lower end. A major problem with a tracheostomy tube is the crusting of its distal end with dried secretions, and this arrangement allows the inner tube to be removed, cleaned, and replaced as frequently as required without disrupting the outer tube. In children with a single lumen tube frequent suctioning and humification are required to prevent tube obstruction with dried secretions. Decannulation (removal of a tracheostomy tube) requires laryngeal competence; assessment by ENT and speech therapists is needed. A tracheostomy tube can impair swallowing due to compression of the oesophagus (particularly cuffed tubes) and prevention of the larynx from rising during normal swallowing.

Stertor (snoring)

Snoring is caused by high-pressure airflow, resulting in vibration of soft tissue above the level of the larynx. It is a common symptom (50% of 50-year-old males). Obstruction to airflow can occur in three sites: nose, palate, and/or hypopharynx. There is a strong association between snoring and sleep-disordered breathing, including obstructive sleep apnoea. The Epworth Sleepiness Scale is a subjective measure of a patient's sleepiness and can prompt further investigation (see **Box 20.21**). Most patients will benefit from lifestyle changes, including weight loss and avoiding alcohol. Continuous positive airway pressure is used for obstructive sleep apnoea, which affects quality of life or daytime activities (see Chapter 20). Patients unable to tolerate standard continuous positive airway pressure can try changing from a nasal to orofacial mask, heated humification, or the use of a mandibular advancement splint if good dentition. Sleep nasendoscopy assesses a sedated, snoring patient using a flexible nasendoscope to identify the location of reduced airway tone and collapse. Nasal pathology such as polyps or enlarged tonsils can be removed surgically with good results.

CORE SKILLS AND KNOWLEDGE

Gastrointestinal disease is common throughout the world. The WHO estimates that diarrhoeal illnesses alone caused 1.4 million deaths in 2016. Gastrointestinal disease accounts for approximately 10% of primary care appointments, and colorectal cancer is the third commonest cancer globally.

Gastroenterologists care for patients in inpatient settings (e.g., for those with acute flares of inflammatory bowel disease or gastrointestinal bleeding), outpatient clinics (for long-term management of chronic gastrointestinal conditions, or diagnosis of newly presenting patients), and they provide diagnostic, therapeutic, and screening endoscopy services. Gastroenterology research is a fertile area with many exciting new therapies and technologies appearing in recent years, and gastroenterologists may also be active in medical education or hospital management.

Key skills in gastroenterology include:

- Managing and investigating acute and chronic gastrointestinal bleeding
- Understanding different treatment strategies for inflammatory bowel disease, including the role for biological agents and surgical treatment
- Developing an understanding of functional gastrointestinal disease and how to help patients suffering with problems such as irritable bowel syndrome.

There are many opportunities to gain the knowledge and skills to successfully manage patients with gastrointestinal diseases, including reviewing patients on general gastroenterology wards, attending general and specialist outpatient clinics, observing endoscopic procedures, and attending multidisciplinary team (MDT) meetings. MDTs commonly exist for upper and lower gastrointestinal cancers and inflammatory bowel disease, and allow the discussion of patients by gastroenterologists, radiologists, histopathologists, surgeons, oncologists, and nurse specialists.

CLINICAL SKILLS

Box 22.1 History-taking in gastroenterology

Symptoms of upper gastrointestinal disease

- **Dysphagia**—distinguish between a likely ***neurological cause*** (often high in mouth or pharynx, worse with swallowing liquids, often speech involvement), and a likely ***anatomical cause*** (lower down in chest or upper abdomen, worse with larger and more solid food boluses).
- **Dyspepsia**—often a non-specific symptom, but establish the relationship with food ingestion posture—symptoms of reflux disease are worsened by both.
- **Early satiety**—may be a symptom of stomach cancer
- **Nausea and vomiting**—these may be mediated by central causes, but a close relationship with food (e.g., projectile vomiting after eating) suggests a pyloric stricture.
- **Haematemesis**—vomiting of fresh red blood should be treated as a medical emergency. Vomiting of altered blood (sometimes described as 'coffee grounds') is more difficult to evaluate, but should still be taken seriously. Haematemesis after a prolonged bout of vomiting may suggest a Mallory–Weiss tear.
- **Melaena**—this describes the passage of thick, black, 'tarry' altered blood from the rectum and indicates upper gastrointestinal bleeding—a medical emergency.

Symptoms of lower gastrointestinal disease

- **Change in bowel habit**—while constipation is often a symptom of inadequate diet or physical exercise, unexplained loosening of stool, particularly if persistent, may be a symptom of colonic diseases, including cancer and colitis.
- **Rectal bleeding**—fresh blood dripping after passing stool, or present on wiping, suggests anorectal disease including haemorrhoids. Blood mixed with stool may indicate colitis or colonic malignancy.
- **Tenesmus**—a feeling of incomplete rectal emptying after defecation suggests anorectal pathology such as a tumour.

'Red flag' symptoms suggestive of malignancy

- Progressive weight loss.
- Anorexia.
- Symptoms of anaemia from chronic blood loss.

Past medical history

- Gastrointestinal disease.
- Autoimmune disease.
- Abdominal surgery.

Drug history

- All prescription drugs.
- Non-steroidal anti-inflammatories, over-the-counter drugs, and herbal remedies.
- Recent courses of antibiotics.

Social history

- Smoking.
- Alcohol consumption.

History and examination

Gastrointestinal disease can present with a variety of different symptoms and signs and an experienced clinician needs to be able to elicit these in a focused manner, and also ask about relevant risk factors (**Boxes 22.1 and 22.2**). The figure opposite illustrates signs of common gastrointestinal diseases to be found on examination.

Visualizing the bowel

The different types of endoscopy are discussed fully in the 'Endoscopy' section. **Box 22.3** illustrates the ability of different techniques of endoscopy (including contrast techniques in ERCP) to visualize different parts of the gastrointestinal and biliary tract. Most are readily available in the majority of units, although capsule endoscopy and balloon enteroscopy remain more specialist procedures. All except capsule endoscopy allow biopsies to be taken and a range of therapeutic procedures to be performed.

Box 22.2 Core knowledge in gastroenterology

The 'top ten' presentations

- Acute upper GI bleed
- Dysphagia
- Dyspepsia
- Abdominal pain
- Malabsorption
- Diarrhoea
- Iron-deficiency anaemia
- Rectal bleeding
- Constipation
- Tenesmus

The 'top ten' conditions

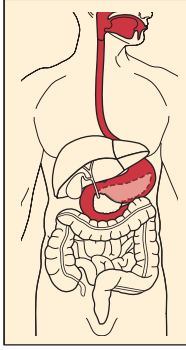
- Functional bowel disorders
- Peptic ulcer disease
- Gastro-oesophageal reflux disease
- Oesophageal cancer
- Gastric cancer
- Coeliac disease
- Inflammatory bowel disease
- Infectious diarrhoea
- Colorectal cancer
- Diverticulosis

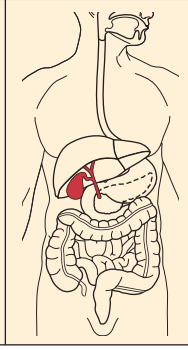
The 'top ten' medications

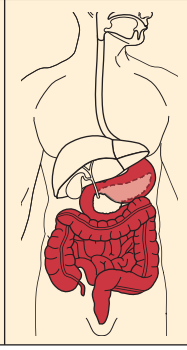
- Proton pump inhibitors and H_2 receptor antagonists
- *Helicobacter pylori* eradication regimens
- Antiemetics
- 5-aminosalicylic acids
- Oral and intravenous steroids
- Azathioprine and methotrexate
- Anti-tumour necrosis factor antibodies
- Oral iron preparations
- Antispasmodics
- Antibiotics for infectious diarrhoea, and when to use them

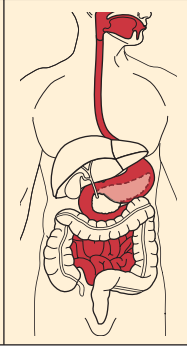
Box 22.3 Endoscopy techniques

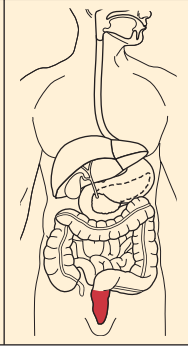
Oesophagogastroduodenoscopy (OGD)	Endoscopic retrograde cholangiopancreatography (ERCP)	Capsule endoscopy	Balloon enteroscopy	Proctoscopy	Flexible sigmoidoscopy	Colonoscopy
						

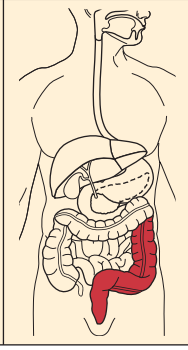


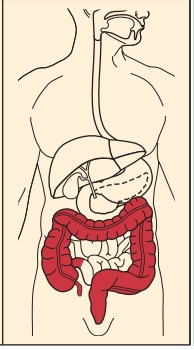


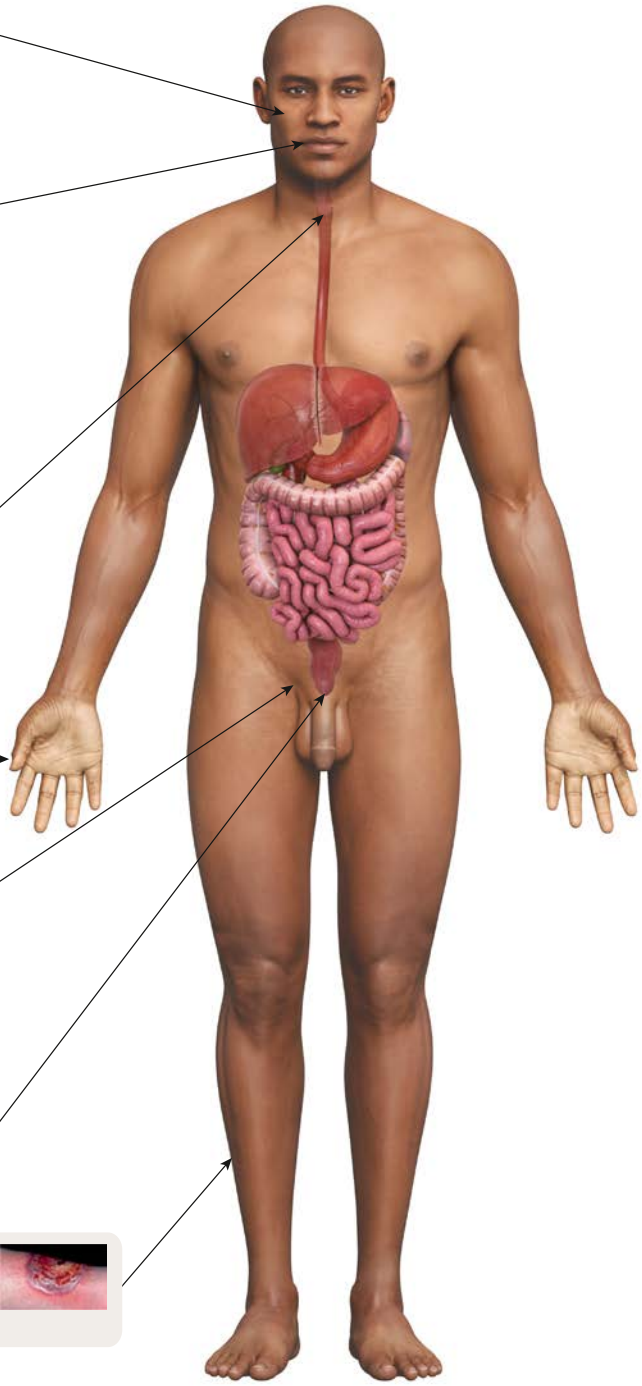












Face
Conjunctival pallor

Mouth

Angular stomatitis (malnutrition)
Oral ulcers (Crohn's)
Glossitis (inflammation of the tongue) can be due to iron-deficiency anaemia, B12 deficiency or malabsorption

Neck
Cervical and clavicular lymphadenopathy
Virchow's node (enlarged left supraclavicular lymph node) which is a sentinel lymph node for gastric cancer

Hands
Koilonychia (spoon-shaped nails, associated with iron-deficiency anaemia)
Clubbing

Hernial orifices
Signs of incarcerated hernia if intestinal obstruction is suspected

Digital examination of the rectum
Haemorrhoids
Anorectal cancer
Empty rectum (intestinal obstruction)
Full rectum (constipation)
Blood on finger (malignancy or colitis)

Legs

Pyoderma gangrenosum or erythema nodosum (both seen in inflammatory bowel disease)

General features
Cachexia
Jaundice
Pallor

Observation chart
Tachycardia or shock (in acute bleeding)

Abdomen
Inspection
- scars
- abdominal distension

Abdomen
Soft touch palpation
- abdominal tenderness
- masses

Abdomen
Deeper palpation
- masses
- hepatomegaly
- splenomegaly

Abdomen
Percussion
- shifting dullness (ascites)
- suprapubic dullness (distended bladder)
- hepatomegaly
- splenomegaly

Abdomen
Auscultation
- generally not of great value
- absent bowel sounds in peritonism
- high pitched or 'tinkling' in intestinal obstruction

BACKGROUND

The gastrointestinal tract has many functions, such as digestion, absorption, and excretion, as well as the synthesis of hormones, growth factors, and cytokines. In addition, a complex enteric nervous system (ENS) controls its function and communicates with the central and peripheral nervous systems. Finally, as the gastrointestinal tract is the part of the body containing the largest source of foreign antigens, it has very well-developed arms of both the innate and the acquired immune systems. The intestinal microbiota exerts a range of beneficial functions aiding nutrition, absorption, and the development of a mature immune system. Disruption of the composition and diversity of the microbiota is associated with the development of gastrointestinal and systemic disease.

ANATOMY AND PHYSIOLOGY OF THE GASTROINTESTINAL TRACT

Mouth, oropharynx, and oesophagus

The oral cavity extends from the lips to the pharynx and contains the tongue, teeth, and gums. Its primary functions are mastication, swallowing, and speech. The ***pharynx*** consists of the nasal, oral, and laryngeal sections. The latter is the part of the throat that connects to the oesophagus.

The ***oesophagus*** is a muscular tube approximately 20 cm long that connects the pharynx to the stomach just below the diaphragm. Its only function is to transport food from the mouth to the stomach. In the upper portion of the oesophagus, both the outer longitudinal layer and inner circular muscle layers are striated. In the lower two-thirds of the oesophagus, including the thoracic and abdominal parts containing the lower oesophageal sphincter (LOS), both layers are composed of smooth muscle.

The oesophagus is lined by stratified squamous epithelium, which extends distally to the squamocolumnar junction where the oesophagus joins the stomach, recognized endoscopically by a zigzag ('Z') line, just above the most proximal gastric folds.

The oesophagus is separated from the pharynx by the ***upper oesophageal sphincter*** (UOS), which is normally closed due to tonic activity of the nerves supplying the cricopharyngeus. The ***lower oesophageal sphincter*** consists of a 2- to 4-cm zone in the distal end of the oesophagus that has a high resting tone and, assisted by the diaphragmatic sphincter, is largely responsible for the prevention of gastric reflux.

Swallowing

During swallowing, the bolus of food is voluntarily moved from the mouth to the pharynx. This process is mediated by a complex reflex involving a swallowing centre in the dorsal motor nucleus of the vagus in the brainstem. Once activated, the swallowing centre neurons send pre-programmed discharges of inhibition followed by excitation to the motor nuclei of the cranial nerves. This results in initial relaxation, followed by distally progressive activation of neurons to the oesophageal smooth muscle and LOS. Pharyngeal and oesophageal peristalsis mediated by this swallowing reflex causes ***primary peristalsis***. ***Secondary peristalsis*** arises as a result of stimulation by a food bolus in the lumen, mediated by a local intra-oesophageal reflex. ***Tertiary contractions*** indicate pathological non-propulsive contractions resulting from aberrant activation of local reflexes within the myenteric plexus.

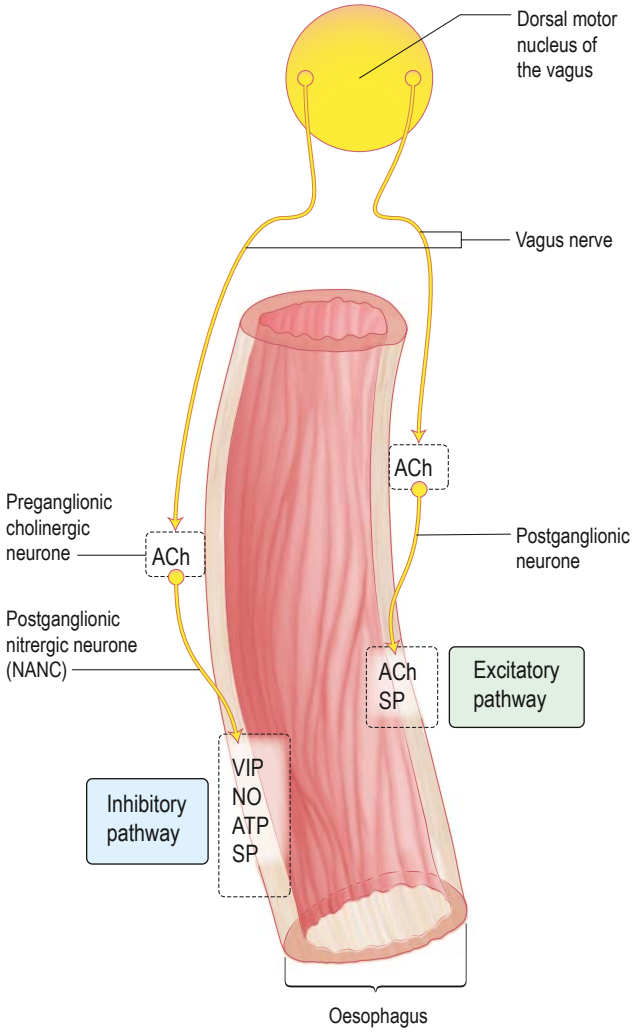


Fig. 22.1 Innervation of the oesophagus. The excitatory pathway consists of vagal preganglionic neurons releasing acetylcholine (ACh), connecting to postganglionic neurons that release ACh and substance P (SP). The inhibitory pathway consists of vagal preganglionic neurons releasing ACh, connecting to postganglionic neurons that release nitric oxide (NO), vasoactive intestinal peptide (VIP), adenosine triphosphate (ATP), and SP.

The smooth muscle of the thoracic oesophagus and LOS is supplied by vagal autonomic motor nerves consisting of extrinsic preganglionic fibres and intramural postganglionic neurons in the myenteric plexus (Fig. 22.1). There are parallel excitatory and inhibitory pathways.

Stomach and duodenum

The stomach occupies a small area immediately distal to the oesophagus (the cardia), the upper region (the fundus, under the left diaphragm), the mid-region or body, and the antrum, which extends to the pylorus (see Fig. 22.13). It serves as a reservoir where food can be retained and broken up before being actively expelled into the proximal small intestine.

The smooth muscle of the wall of the stomach has three layers: outer longitudinal, inner circular, and innermost oblique layers. There are two sphincters: the gastro-oesophageal sphincter and the pyloric sphincter. The latter is largely made up of a thickening of the

circular muscle layer and controls the exit of gastric contents into the duodenum.

The duodenum has outer longitudinal and inner circular smooth muscle layers. It is C-shaped and the pancreas sits in the concavity. It terminates at the duodenojejunal flexure, where it joins the jejunum.

- The ***mucosal lining*** of the stomach can stretch in size with feeding. The greater curvature of the undistended stomach has thick folds or rugae. The mucosa of the upper two-thirds of the stomach contains ***parietal cells***, which secrete hydrochloric acid, and ***chief cells***, which secrete pepsinogen (which initiates proteolysis). There is often a colour change at the junction between the body and the antrum of the stomach, which can be seen macroscopically and confirmed by measuring surface pH.
- The ***antral mucosa*** secretes bicarbonate and contains mucus-secreting cells and ***G cells***, which secrete gastrin, stimulating acid production. There are two major forms of gastrin, G17 and G34, depending on the number of amino-acid residues. G17 is the major form found in the antrum. Somatostatin, a suppressant of acid secretion, is also produced by specialized antral cells ***(D cells)***.
- ***Mucus-secreting cells*** are present throughout the stomach and secrete mucus and bicarbonate. The mucus is made of glycoproteins called mucins.
- The ***'mucosal barrier'***, made up of the plasma membranes of mucosal cells and the mucus layer, protects the gastric epithelium from damage by acid and, for example, alcohol, aspirin, non-steroidal anti-inflammatory drugs (NSAIDs), and bile salts. Prostaglandins stimulate secretion of mucus, and their synthesis is inhibited by aspirin and NSAIDs, which inhibit cyclo-oxygenase (see 'NSAIDs, Helicobacter and ulcers' section).
- The ***duodenal mucosa*** has villi like the rest of the small bowel, and also contains Brunner's glands, which secrete alkaline mucus. This, along with the pancreatic and biliary secretions, helps to neutralize the acid secretion from the stomach when it reaches the duodenum.

Physiology

Acid secretion is central to the functionality of the stomach; factors controlling acid secretion are shown in Fig. 22.2. Acid is not essential for digestion but does prevent some food-borne infections. It is under neural and hormonal control, and both stimulate acid secretion through the direct action of histamine on the parietal cell. Acetylcholine and gastrin also release histamine via the enterochromaffin cells. Somatostatin inhibits both histamine and gastrin release, and therefore acid secretion.

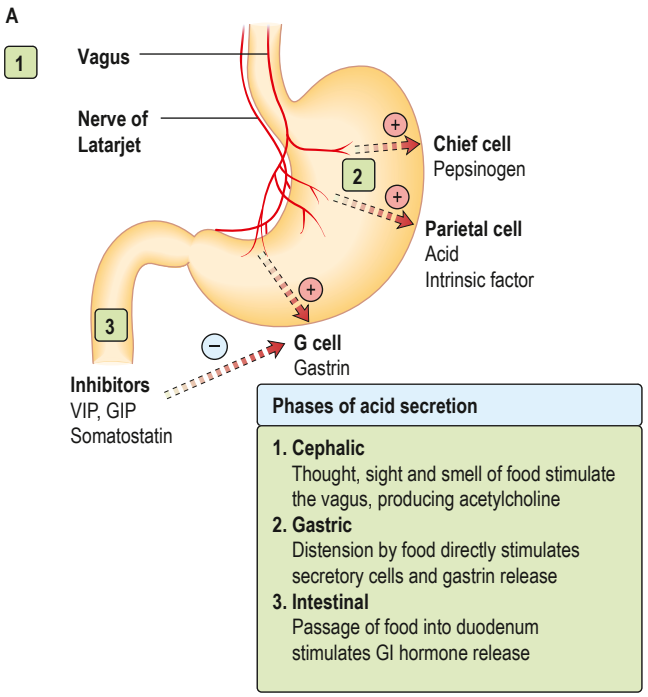
Other major gastric functions are:

- reservoir for food
- emulsification of fat and mixing of gastric contents
- secretion of intrinsic factor
- absorption (of only minimal importance).

Gastric emptying depends on many factors. There are osmoreceptors in the duodenal mucosa, which control gastric emptying by local reflexes and the release of gut hormones. In particular, intraduodenal fat delays gastric emptying by negative feedback through duodenal receptors.

Small intestine anatomy

The small intestine extends from the duodenum to the ileocaecal valve. It is 3 to 6 m in length, and 300 m^2 in surface area. The upper



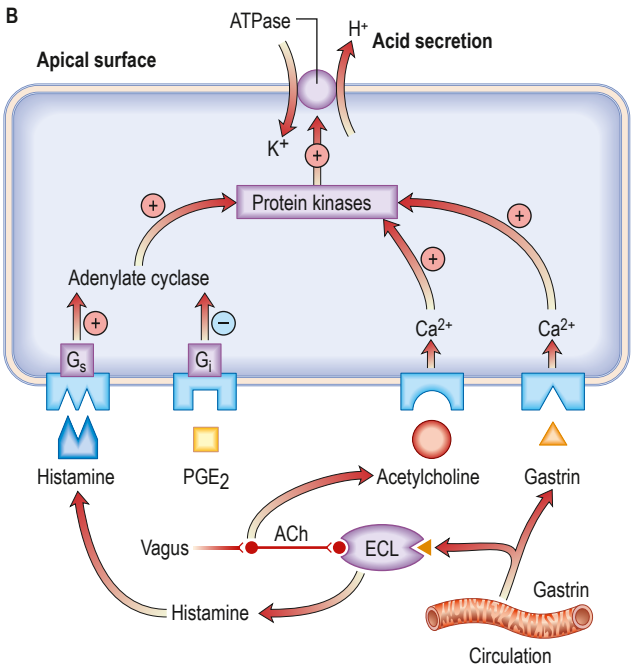


Fig. 22.2 Pathophysiology of acid secretion. **(A)** Control of acid secretion. **(B)** Mechanisms involved in acid secretion. Histamine stimulates the G_s protein via the H_2 receptors and acts via cyclic adenosine monophosphate (cAMP). Prostaglandin E_2 (PGE_2) activates the G_i protein and *inhibits* acid secretion. Acetylcholine (ACh) acts via the vagus M_3 receptors. ACh also acts via the enterochromaffin cell (ECL). Gastrin acts via the cholecystokinin B (CCKBB)–gastrin receptor, increasing the intracellular free calcium, and also via the ECL cell, stimulating histamine. *GIP,* Gastric inhibitory polypeptide; *Gs and Gi,* stimulating and inhibiting G-proteins; *VIP,* vasoactive intestinal polypeptide.

40% is the duodenum and jejunum; the remainder is the ileum. Its surface area is enormously increased by circumferential mucosal folds that bear multiple finger-like projections called villi. On the villi, the surface area is further increased by microvilli on the luminal side of the epithelial cells (enterocytes) (Fig. 22.3).

Each villus consists of a core that contains blood vessels, lacteals (lymphatics), and cells (e.g., plasma cells and lymphocytes). The lamina propria contains plasma cells, lymphocytes, macrophages, eosinophils, and mast cells. The crypts of Lieberkühn are the spaces between the bases of the villi.

Enterocytes are formed at the bottom of the crypts and migrate towards the tops of the villi, where they are shed. This process takes 3 to 4 days. On its luminal side, the enterocyte is covered by microvilli and a gelatinous layer called the glycocalyx. Scattered between the epithelial cells are mucin-secreting goblet cells and occasional intraepithelial lymphocytes and Paneth cells. Most of the blood supply to the small intestine is via branches of the superior mesenteric artery. The terminal branches are end arteries; there are no local anastomotic connections.

Enteric nervous system

The enteric nervous system (ENS) controls the functioning of the small bowel; it is an independent system that coordinates absorption, secretion, blood flow, and motility. It is estimated to contain 10^8 neurons (as many as the spinal cord), organized in two major ganglionated plexuses: the *myenteric plexus* between the muscular layers of the intestinal wall, and the *submucosal plexuses* associated with the mucosa. The ENS communicates with the central nervous system (CNS) via autonomic afferent and efferent pathways but can operate autonomously.

Coordination of small intestinal function involves a complex and only partly understood interplay between many neuroactive mediators and their receptors, ion channels, gastrointestinal hormones, nitric oxide, and other transmitters. Acetylcholine, adrenaline (epinephrine), adenosine triphosphate (ATP), vasoactive intestinal peptide (VIP), and other hormones and opioids have been shown to have actions in the small bowel but the exact role of each is not yet clear.

Gut motility

The contractile patterns of the small intestinal muscular layers are primarily determined by the ENS. The CNS and gut hormones also have a modulatory role in motility. The interstitial cells of Cajal, which lie within the smooth muscle, appear to govern rhythmic contractions.

During fasting, a distally migrating sequence of motor events, termed the migrating motor complex (MMC), occurs in a cyclical fashion. The MMC consists of:

- a period of motor quiescence *(phase I)*
- a period of irregular contractile activity *(phase II)*
- a short (5–10-min) burst of regular phasic contractions *(phase III).*

Each MMC cycle lasts for approximately 90 minutes. In the duodenum, phase III is associated with increased gastric, pancreatic, and biliary secretions. The role of the MMC is unclear, but the strong phase III contractions propel secretions, residual food, and desquamated cells towards the colon. It is named the 'intestinal housekeeper'.

After a meal, the MMC pattern is disrupted and replaced by irregular contractions. This seemingly chaotic pattern lasts typically for 2 to 5 hours after feeding, depending on the size and nutrient content of the meal. The irregular contractions of the fed pattern have a mixing function, moving intraluminal contents to and fro and aiding the digestive process.

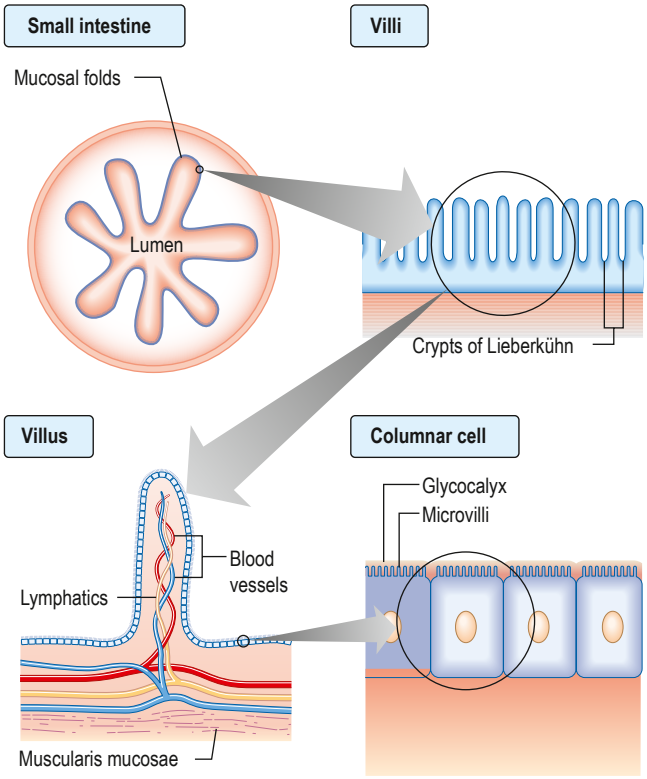

Fig. 22.3 Structure of the small intestine.

Neuroendocrine peptide production

The hormone-producing cells of the gut are scattered diffusely throughout its length and also occur in the pancreas.

Gut hormones play a part in the regulation and integration of the functions of the small bowel and other metabolic activities, including appetite. Their actions are complex and interactive, both with each other and with the ENS (Box 22.4).

Small intestine physiology

In the small bowel, digestion and absorption of nutrients and ions take place, as does the regulation of fluid absorption and secretion. The epithelial cells of the small bowel form a physical barrier that is selectively permeable to ions, small molecules, and macromolecules. Digestive enzymes, such as proteases and disaccharidases, are produced by intestinal cells and expressed on the surface of microvilli; others, such as lipases produced by the pancreas, are associated with the glycocalyx. Some nutrients are absorbed most actively in specific parts of the small intestine: iron and folate in the duodenum and jejunum, and vitamin B_{12} and bile salts in the terminal ileum, where they have specific receptors.

General principles of absorption

Simple diffusion

This process is non-specific, requires no carrier molecule or energy, and takes place if there is a concentration gradient from the intestinal lumen (high concentration) to the bloodstream (low concentration). Vitamin B_{12} can be absorbed from the jejunum by this means.

Facilitated diffusion

Absorption takes place down a concentration gradient but a membrane carrier protein is involved, conferring specificity on the process. Fructose transport is an example.

Box 22.4 Gut regulatory peptides

Peptide	Localization	Main actions
Gastrin/cholecystokinin family		
Cholecystokinin (CCK): multiple forms from CCK8 (8 amino acids) to CCK83; 8, 33 and 58 are predominant Terminal 5 amino acids same as gastrin	Duodenum and jejunum (I cells) Enteric nerves CNS	Causes gall bladder contraction and sphincter of Oddi relaxation. Trophic effects on duodenum and pancreas. Pancreatic secretion (minor role) Role in satiety—acting on CNS
Gastrin	G cells in gastric antrum and duodenum	Stimulates acid secretion. Trophic to mucosa
Secretin-glucagon family		
Secretin	Duodenum and jejunum (S cells)	Stimulates pancreatic bicarbonate secretion
Glucagon	Alpha cells of pancreas	Opposes insulin in blood glucose control
Vasoactive intestinal polypeptide (VIP)	Enteric nerves	Intestinal secretion of water and electrolytes. Neurotransmitter. Splanchnic vasodilation, stimulates insulin release
Glucose-dependent insulinotropic peptide (GIP)	Duodenum (K cells) Gastric antrum Ileum	Release by intraduodenal glucose causes greater insulin release by islets than i.v. glucose (incretin effect)
Glucagon-like peptide-1 (GLP-1)	Ileum and colon (L cells)	Incretin. Stimulates insulin synthesis. Trophic to islet cells. Inhibits glucagon secretion and gastric emptying Stimulates growth of enterocytes
Glicentin	L cells, A cells	Stimulates insulin secretion and gut growth, inhibits gastric secretion
Growth hormone-releasing factor (GHRF)	Small intestine	Unclear
Pancreatic polypeptide family		
Pancreatic polypeptide (PP)	Pancreas (PP cells)	Inhibits pancreatic and biliary secretion
Peptide YY (PYY)	Ileum and colon (L cells)	Inhibits pancreatic exocrine secretion. Slows gastric and small bowel transit ('ileal brake'). Reduces food intake and appetite
Neuropeptide Y (NPY)	Enteric nerves	Stimulates feeding. Regulates intestinal blood flow
Other		
Motilin	Whole gut	Increases gastric emptying and small bowel contraction
Ghrelin	Stomach	Stimulates appetite, increases gastric emptying
Obestatin	Stomach and small intestine	Opposes ghrelin
Oxyntomodulin	Colon	Inhibits appetite
Gastrin releasing-polypeptide (bombesin)	Whole gut and pancreas	Stimulates pancreatic exocrine secretion and gastric acid secretion
Somatostatin	Stomach and pancreas (D cells) Small and large intestine	Inhibits secretion and action of most hormones
Substance P	Enteric nerves	Enhances gastric acid secretion, smooth muscle contraction
Neurotensin	Ileum	Affects gut motility. Increases jejunal and ileal fluid secretion
Insulin	Pancreatic β cells	Increases glucose utilization
Chromogranins	Neuroendocrine cells	Precursor for other regulatory peptides that inhibit neuroendocrine secretion

Active transport

Absorption occurs via a specific carrier protein, powered by cellular energy, allowing a substance to be transported against a concentration gradient. Many carrier proteins are powered by ion gradients across the enterocyte wall. For example, glucose crosses the enterocyte microvillous membrane from the lumen into the cell against a concentration gradient by using a ***co-transporter*** carrier molecule. This is the sodium/glucose co-transporter, SGLT1 (Fig. 22.4). The process is powered by the energy derived from the flow of Na^+ ions from a high concentration outside the cell to a low concentration inside. The sodium gradient across the cell wall is maintained by a separate ATP-consuming Na^+/K^+ exchanger in the basolateral membrane. Glucose leaves the cell on the serosal side by facilitated diffusion via a sodium-independent carrier (GLUT-2) in the basolateral membrane.

Another active transport mechanism operates for Na^+ absorption in the ileum using an Na^+/H^+ ***exchange*** mechanism, powered by the outwardly directed gradient of H^+ across the cell membrane.

Absorption of nutrients in the small intestine

Carbohydrate

Dietary carbohydrate consists mainly of starch, with some sucrose and a small amount of lactose. Starch is a polysaccharide made up of numerous glucose units. In order to have a nutrient value,

starch must be digested into smaller oligo-, di- and finally monosaccharides, which may then be absorbed. Polysaccharide hydrolysis begins in the mouth and is catalyzed by salivary amylase, though the majority takes place under the action of pancreatic amylase in the upper intestine. The breakdown products of starch digestion are maltose and maltotriose, together with sucrose and lactose. These are further hydrolyzed on the microvillous membrane by specific oligo- and disaccharidases to form glucose, galactose, and fructose. These monosaccharides are then able to be transported across the enterocytes into the blood (see **Fig. 22.4**).

Protein

Dietary protein is digested by pancreatic proteolytic enzymes to amino acids and peptides prior to absorption. These enzymes are secreted by the pancreas as pro-enzymes and transformed to active forms in the lumen. Protein in the duodenal lumen stimulates the enzymatic conversion of trypsinogen to trypsin, and this, in turn, activates the other pro-enzymes, chymotrypsin, and elastase.

These enzymes break down protein into oligopeptides. Some di- and tripeptides are absorbed intact by carrier-mediated processes, while the remainder are broken down into free amino acids by peptidases on the microvillous membranes of the enterocytes, prior to absorption into the cell by a variety of amino acid and peptide carrier systems.

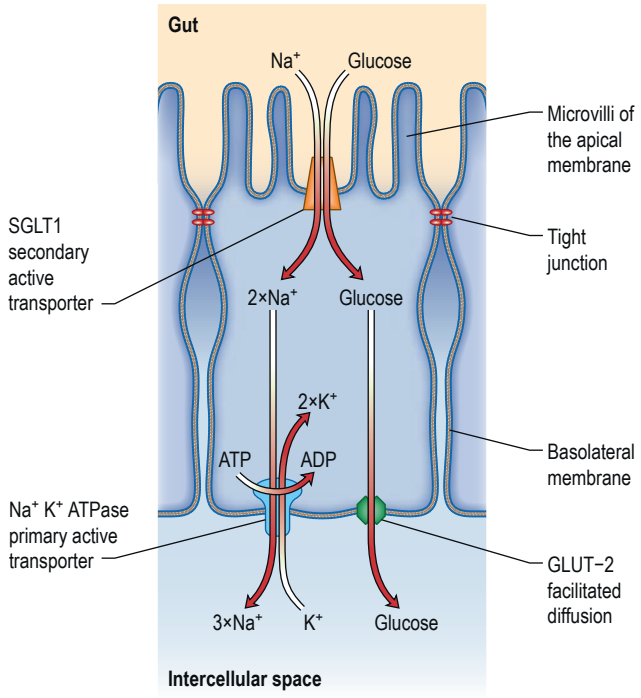

Fig. 22.4 Transcellular uptake of glucose across the intestinal epithelia. Glucose is co-transported across the apical membrane with sodium ions by the sodium-dependent glucose transporter (SGLT). This is secondary active transport, as the sodium is travelling down its electrochemical gradient. The sodium gradient is maintained by the primary active transport of sodium across the basolateral membrane by the Na^+/K^+ ATPase (thus intracellular Na^+ is kept low). Transcellular transport of glucose is achieved by facilitated diffusion across the basolateral membrane as glucose is moved down its concentration gradient by GLUT-2.

Fat

Dietary fat consists mainly of triglycerides with some cholesterol and fat-soluble vitamins. Fat is emulsified by mechanical action in the stomach. Bile containing the amphipathic detergents, bile acids, and phospholipids enters the duodenum following gall bladder contraction. These substances act to solubilize fat and promote hydrolysis of triglycerides in the duodenum by pancreatic lipase to yield fatty acids and monoglycerides. Bile acids, phospholipids, and the products of fat digestion cluster together with their hydrophilic ends on the outside to form aggregations called mixed micelles. Trapped in the centre of the micelles are the hydrophobic monoglycerides, fatty acids, and cholesterol. At the cell membrane, the lipid contents of the micelles are absorbed, while the bile salts remain in the lumen. Inside the cell, the monoglycerides and fatty acids are re-esterified to triglycerides. The triglycerides and other fat-soluble molecules (e.g., cholesterol, phospholipids) are then incorporated into chylomicrons to be transported into the lymph.

Any unabsorbed lipids that reach the ileum delay gastric emptying via peptide YY, which is secreted by the ileum (called the ***'ileal brake'***). This delay allows more time for absorption of lipids in the small intestine.

Medium-chain triglycerides (MCTs, fatty acids of chain length 6–12) are transported via the portal vein with a small amount of long-chain fatty acid. Patients with pancreatic exocrine or bile salt insufficiency can therefore supplement their fat absorption with MCTs.

Bile salts are not absorbed in the jejunum, so the intraluminal concentration in the upper gut is high. They pass down the intestine to be absorbed in the terminal ileum and are transported back to the liver. This enterohepatic circulation prevents excess loss of bile salts (see Chapter 23).

The pathophysiology of fat absorption is shown in **Fig. 22.5**. Interference with absorption can occur at all stages, as indicated, giving rise to steatorrhoea (>17 mmol or 6 g of faecal fat per day).

Water and electrolytes

Large amounts of water and electrolytes, partly dietary but mainly from intestinal secretions, are absorbed, coupled with absorption of monosaccharides, amino acids, and bicarbonate in the upper jejunum. Water and electrolytes are also absorbed paracellularly (between the enterocytes) down electrochemical and osmotic gradients. Additional water and electrolytes are absorbed in the ileum and colon, where active sodium transport is not coupled to solute absorption. Secretion of fluid and electrolytes occurs together to maintain the normal functioning of the gut. Secretory diarrhoea (see 'Secretory diarrhoea' section) can occur because of defects in intestinal secretory mechanisms.

Water-soluble vitamins, essential metals, and trace elements

These are all absorbed in the small intestine. Vitamin B_{12} (see Chapter 38) and bile salts are absorbed by specific transport mechanisms in the terminal ileum; malabsorption of both these substances often occurs following ileal resection.

Calcium

Calcium absorption is discussed in Chapter 33.

Iron

Iron absorption is discussed in Chapter 38.

Response of the small bowel to antigens and pathogens

The small bowel has a number of mechanisms to prevent colonization and invasion by pathogens while simultaneously preventing

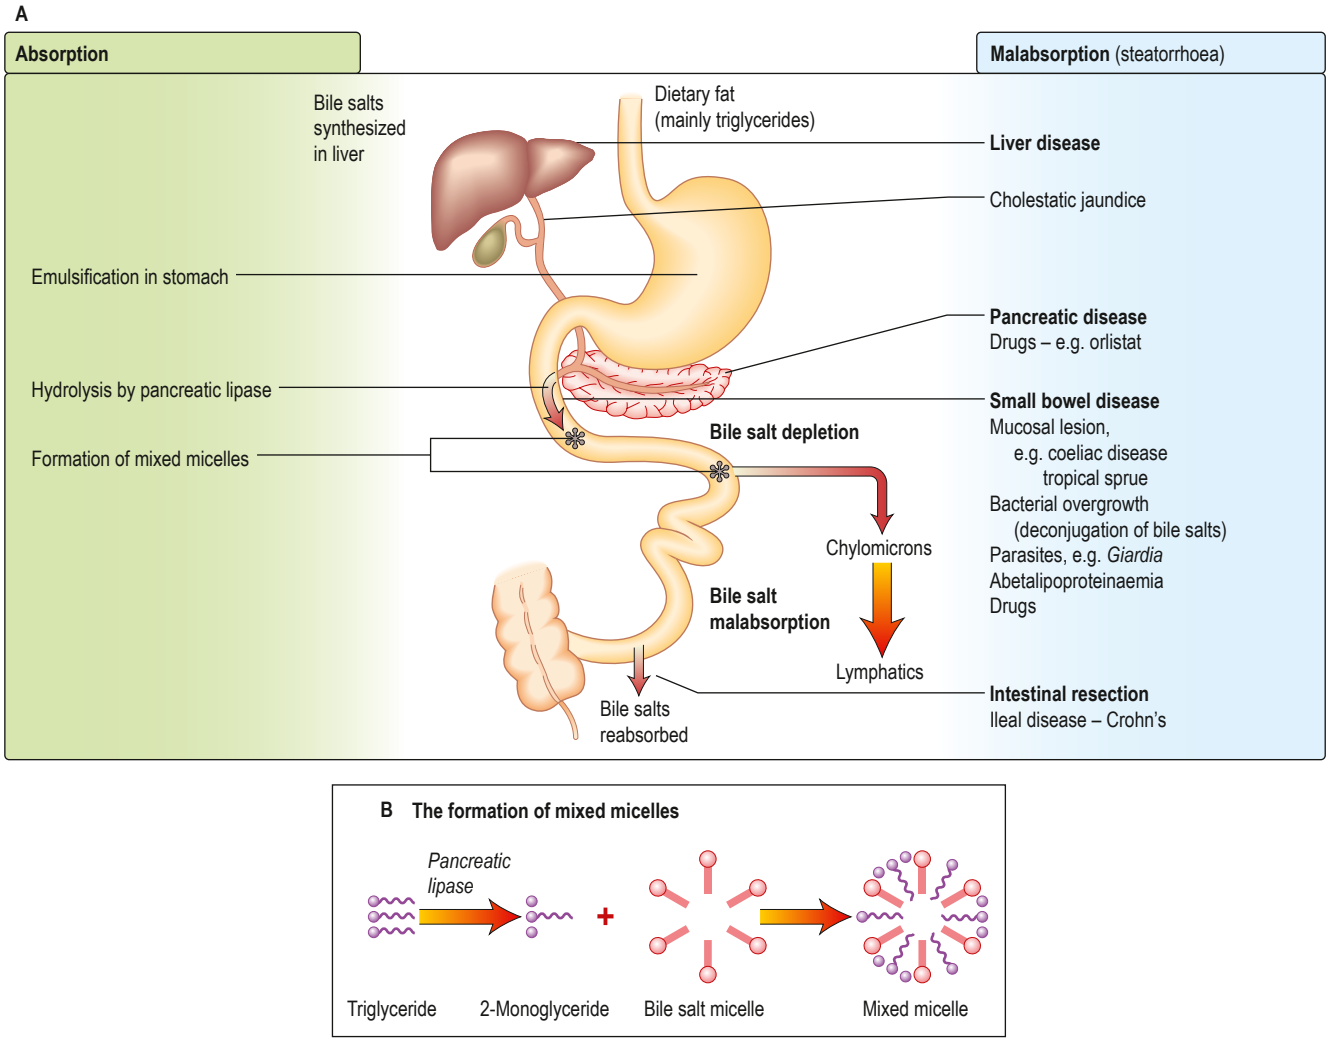

Fig. 22.5 Fat absorption in the small intestine. **(A)** The pathophysiology of fat absorption. Diseases impairing fat absorption, that may therefore cause steatorrhoea, are shown on the right of the diagram. **(B)** The formation of mixed micelles.

inappropriate responses to foreign antigens or the indigenous bacterial population. At the same time, commensal bacteria maintain the integrity of the small bowel and play a major role in host physiology.

Mechanisms

Physical defence

- The mucus layer.
- Continuous shedding of surface epithelial cells.
- The physical movement of the luminal contents.
- Colonization resistance—the ability of the indigenous microbiota to outcompete pathogens for a survival niche in the gut.

Innate chemical defence

- ***Enzymes*** such as lysozyme and phospholipase A_2, secreted by Paneth cells at the base of the crypts, help ensure an infection-free environment in the gut, even in the presence of commensal bacteria.
- ***Antimicrobial peptides*** are secreted from enterocytes and Paneth cells in response to pathogenic bacteria. These include ***defensins***, which are 15 to 20 amino-acid peptides with potent activity against a broad range of pathogens, including Gram-positive and Gram-negative bacteria, fungi, and viruses.
- ***Trefoil peptides*** are a family of small proteins secreted by goblet cells. They consist of a three-loop structure with intra-chain disulphide bonds, which makes the molecules highly resistant to digestion. Their actions include stabilization of mucus, promotion of cell migration to injured areas, and promotion of repair. Three trefoil factors (TFFs) are found in humans (TFF1, TFF2, and TFF3), all of which have been implicated in the response to gastrointestinal injury in experimental models. Their molecular mode of action is not yet known.

Innate immunological defence

- ***Humoral defence.*** IgA is the principal mucosal antibody. It mediates mucosal immunity by agglutinating and neutralizing pathogens in the lumen and preventing colonization of the epithelial surface (Fig. 22.6). IgA is secreted from immunocytes in the lamina propria as dimers joined by a protein called the 'joining chain' (J-chain); in this form, it is known as polymeric IgA (pIgA). This pIgA is internalized by endocytosis at the basolateral membrane of enterocytes. It crosses the cell as a complex of pIgA/pIgAR and is secreted on to the mucosal surface.

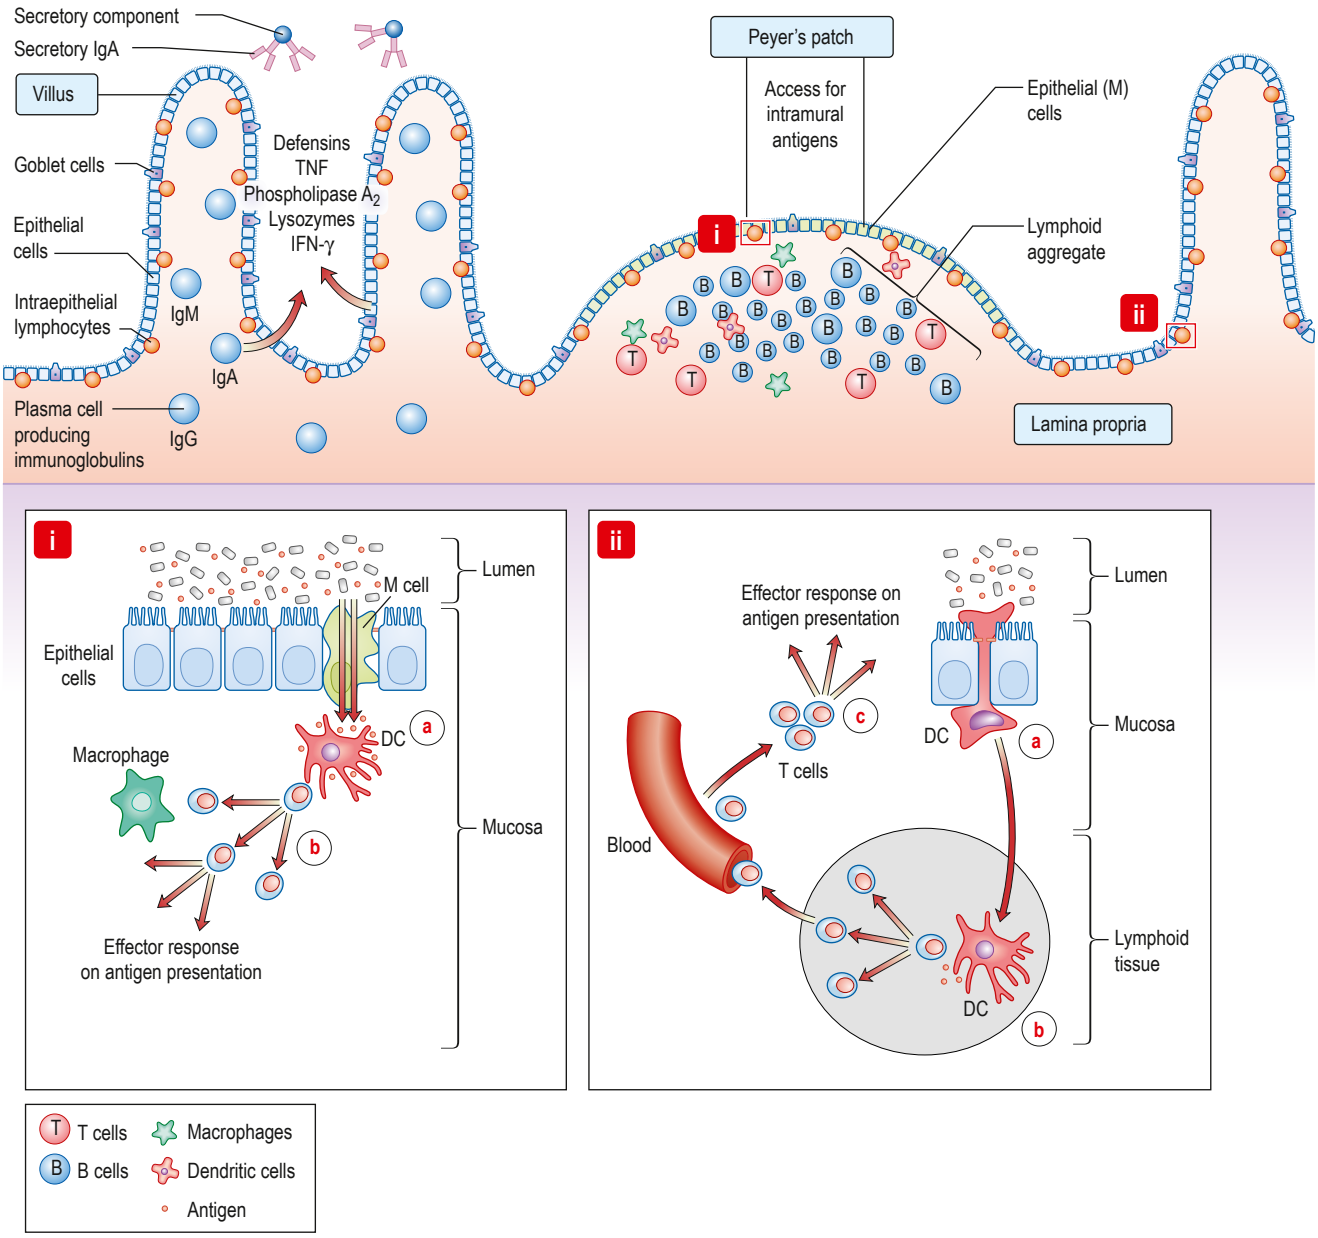

Fig. 22.6 Small intestinal mucosa with a Peyer's patch, showing the gut-associated lymphoid tissue (GALT). Inset i: **(A)** Specialized 'M' cells within a lymphoid follicle pass antigen to underlying antigen-presenting cells (APCs), such as dendritic cells (DCs). **(B)** DCs present antigen to T cells, resulting in activation and effector responses. Inset ii: **(A)** DCs pass dendrites through epithelial tight junctions to sample luminal antigen. **(B)** DCs traffic to the mesenteric lymph node and present antigen to naïve T cells, which differentiate into effector or regulatory subtypes and are imprinted with a gut-homing integrin. **(C)** On subsequent antigen presentation, activated T cells home to lamina propria and exert a regulatory or inflammatory effect, depending on their phenotype. *IFN-γ,* Interferon-gamma; *Ig,* immunoglobulin; *TNF,* tumour necrosis factor.

- ***B-cell sensitization.*** Antigens from the lumen of the bowel are transported by M cells and dendritic cells in the follicle-associated epithelium (FAE). This covers Peyer's patches in the 'dome' region that contain abundant virgin B cells, helper T cells, and antigen-presenting cells. Activated B cells then produce IgA locally and are programmed to home back to the lamina propria. They travel through mesenteric lymph nodes and then via the thoracic duct to the blood and back to the small bowel and other mucosal surfaces (such as the airways), where they undergo terminal differentiation into plasma cells. Homing back to the gut is facilitated by the α4β7-integrin on gut-derived lymphocytes binding to MAdCAM-1, uniquely expressed on blood vessels in the gut.
- ***Cellular defence.*** T lymphocytes also provide host defence and initiate, activate, and regulate adaptive immune responses. ***Intestinal T lymphocytes*** occur principally in three major compartments:
  - *Organized gut-associated lymphoid tissue (GALT)*, such as Peyer's patches, where mucosal T-cell responses are generated, and after which cells leave the organized lymphoid tissue and home back to the mucosa.

- *The lamina propria*, containing mostly CD4 cells.
- The *surface epithelium*, where these lymphocytes are known as intraepithelial lymphocytes (IELs) and are mostly CD8 cells. T cells are sensitized to antigen in the Peyer's patch lymphoid tissue in a similar fashion to B cells, and pass through mesenteric lymph nodes into the thoracic duct and into the circulation, homing back to the small bowel to end up in the lamina propria or the epithelium. It is probable that IELs are cytotoxic cells, capable of killing virally or bacterially infected epithelial cells. CD4 cells in the lamina propria of healthy individuals are highly activated cells, probably protecting against low-grade infections, since loss of these cells, as in HIV infection, leads to colonization of the gut by protozoa such as cryptosporidia.

The gut microbiome

The relationship between the hundred thousand billion microbes in the human gut and the host is only beginning to be appreciated. New molecular sequencing techniques have allowed the identification and classification of the gut microbiota. The use of metabonomics has aided the assessment of its functional output. There is increasing evidence that a reduction in the diversity of the gut microbiota is associated with a range of conditions, including inflammatory bowel disease (IBD) and metabolic syndrome. Germ-free mice have essentially no mucosal immune system, showing that the abundant and activated immune system seen in healthy individuals is driven by the flora, without adverse effects. Bacteria also release chemical signals, such as lipopolysaccharide (LPS) and lipoteichoic acid, which are recognized by Toll-like receptors (TLRs) (see Chapter 6) present on a variety of intestinal cells, priming repair processes and enhancing the ability of the epithelium to respond to injury.

Oral tolerance

The immune system must guard against pathogens and toxins while avoiding an excessive response to the multiplicity of food antigens and commensal bacteria. The mechanisms by which tolerance occurs are multiple, including maintenance of barrier function to prevent excess antigen uptake, active inhibition via regulatory T cells, and promotion of tolerogenic rather than immunogenic T-cell responses by dendritic cells. All of these are likely to play a role in diseases such as coeliac disease, caused by an excessive T-cell response to gluten, or Crohn's disease, where tolerance to the indigenous bacterial population is defective.

Colon and rectal anatomy

The large intestine starts at the caecum, on the posterior medial wall of which is the appendix.

The ***colon*** is made up of ascending, transverse, descending, and sigmoid parts, which join the rectum at the rectosigmoid junction (Fig. 22.7). The muscle wall consists of an inner circular layer and an outer longitudinal layer. The outer layer is incomplete, coming together to form the taeniae coli, which produce the haustral pattern seen in the normal colon.

The mucosa of the colon is lined with epithelial cells and goblet cells. There are crypts but no villi, so that the surface is flat. A variety of cells, mainly lymphocytes and macrophages, are found in the lamina propria.

The blood supply to the colon is from the superior and inferior mesenteric vessels. The colon is innervated mainly by the ENS with input from the parasympathetic and sympathetic pathways. Spinal afferent neurons from the dorsal root ganglia innervate the entire colon.

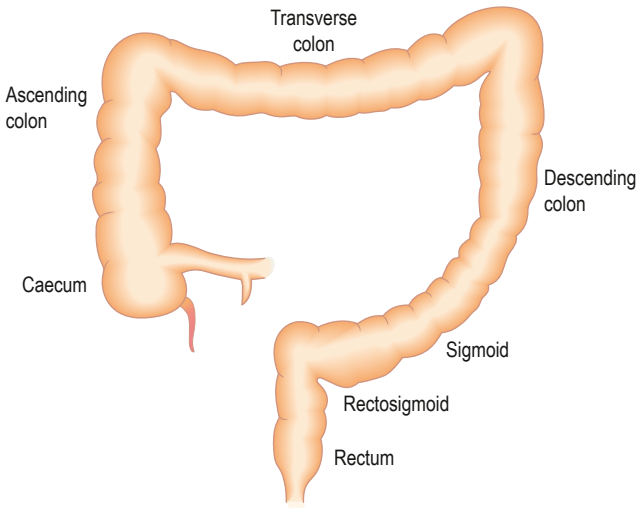

Fig. 22.7 Structure of the large intestine.

Box 22.5 Input and output of water and electrolytes in the gastrointestinal tract over 24 hours

	Water (mL)	Sodium (mmol)	Potassium (mmol)
Input			
Diet	1500	150	80
Gastrointestinal secretions	7500	1000	40
Totals	9000	1150	120
Output			
Faeces	150	5	12
Ileostomy (adapted)	500–1000	60–120	4

The ***rectum*** is about 12 cm long. Its interior is divided by three crescentic circular muscles that produce shelf-like folds. These are the rectal valves, which can be seen at sigmoidoscopy. The anal canal has an internal and an external sphincter.

Physiology of the colon

The main roles of the colon are the absorption of water and electrolytes (Box 22.5) and the propulsion of contents from the caecum to the anorectal region. Approximately 1.5 to 2 L of fluid pass the ileocaecal valve each day. Absorption is stimulated by short-chain fatty acids, which are produced predominantly in the right colon by the anaerobic metabolism of dietary fibre by bacterial polysaccharidase enzyme systems. Colonic contents are mixed, aiding absorption by non-propagative segmenting muscular contractions. High-amplitude propagative colonic contractions cause propulsion. Peristalsis is induced by the release of serotonin (5-HT) from neuroendocrine cells in response to luminal distension. Serotonin activates the HT_4 receptors, which, in turn, results in the activation of sensory (calcitonin gene-related peptide, CGRP) neurons. Normal colonic transit time is 24 to 48 hours with normal stool weights of up to 250 g/day.

Physiology of defecation

The role of the rectum and anus in defecation is complex. The rectum is normally empty. Stool is propelled into the rectum by propagated colonic contractions. A sensation of fullness, a desire to

defecate, and urgency to defecate are experienced with increasing volumes of rectal content (threshold 100 mL). The sensations are associated with rectal contraction and a relaxation of the internal anal sphincter, both of which serve to push the stool down into the proximal anal canal. This increases the defecatory urge, which can only be suppressed by vigorous contraction of the external sphincter and puborectalis. If conditions are appropriate for defecation, the subject sits or squats, contracts the diaphragm and abdominal muscles, and relaxes the pelvic floor muscles, including puborectalis, and the anal sphincter muscles, with the result that stool is expelled.

CLINICAL FEATURES OF GASTROINTESTINAL DISEASE

Dysphagia

Dysphagia refers to a difficulty in swallowing. There are a multitude of different causes (see **Box 22.6**) and can be a difficulty with swallowing liquids, solids, or both. It can be intermittent or progressive depending on the cause.

As described in the previous section, swallowing is a complex process that involves physical structures from the mouth down through the pharynx into the oesophagus and finally into the stomach. There is neurological involvement from the brainstem, and cranial and peripheral nerves. Dysfunction or disruption to any of these structures or processes can result in dysphagia. Broadly, dysphagia can be categorized into oropharyngeal or oesophageal.

Patients often describe a sensation of food getting stuck and the commonest place for this sensation to occur is the GOJ. Sometimes dysphagia can be associated with pain on swallowing—odynophagia—but this is not always the case. In the event that a patient's swallowing is impaired to the extent that they cannot maintain sufficient calorie intake, then they may experience sustained weight loss as well.

Investigation usually involves upper GI endoscopy if an oesophageal cause is suspected. If this does not identify a cause, then further investigations may include imaging, such as a CT or a barium swallow, or functional investigations such as oesophageal manometry. Treatment depends on the underlying cause.

Dyspepsia

'Indigestion' is common: 80% of the population will suffer from this symptom at some time. Dyspepsia is an inexact term used to describe a number of upper abdominal symptoms such as heartburn, acidity, pain or discomfort, nausea, wind, fullness, or belching. Patients who use the term 'indigestion' may also be describing lower gastrointestinal symptoms such as constipation or the presence of undigested vegetable material in the stool, so obtaining a precise history is necessary.

Features of dyspepsia that are suggestive of serious diseases such as cancer are known as ***'alarm' symptoms***. They include:

- dysphagia
- weight loss
- vomiting
- anorexia
- haematemesis or melaena.

Patients aged 55 years or over who demonstrate any of these features have a higher possibility of significant gastrointestinal pathology and should be investigated on an urgent basis. However, most patients with dyspepsia can be managed in primary care without need for referral to a gastroenterologist. In the UK, the National Institute of Clinical Excellence (NICE) has published a guideline algorithm for managing a patient with dyspepsia (https://www.nice.org.uk/guidance/cg184). A significant number of patients with these symptoms will have functional dyspepsia (see 'Functional dyspepsia' section).

? Box 22.6 Differential Diagnosis

Oesophageal	• Oesophagitis • Benign reflux stricture • Candidiasis • Eosinophilic oesophagitis • Oesophageal carcinoma • Schatzki ring • Pharyngeal pouch
Neuromuscular	• Achalasia • Scleroderma • Diffuse oesophageal spasm • Myasthenia gravis • Bulbar/pseudobulbar palsy • Myotonic dystrophy • Stroke
Extrinsic compression	• Retrosternal goitre • Mediastinal mass

Abdominal pain

Abdominal pain is an extremely common symptom and will be experienced by almost everyone in the population at some point or other during their lives. It can be acute or chronic, mild through to severe, and continuous or intermittent. Pain in the abdomen can be due to a wide range of causes, many of them not related to the gastrointestinal tract, for example, biliary and pancreatic problems, gynaecological problems, urinary tract problems including kidney stones, surgical issues including herniae, vascular problems such as abdominal aortic aneurysm. Abdominal pain is also one of the main presenting features of an acute abdomen (see 'The acute abdomen/Pain' section).

Gastrointestinal causes of abdominal pain can include gastro-oesophageal reflux (see 'Gastro-oesophageal reflux disease' section), dyspepsia (see earlier), acute infection, IBD, irritable bowel syndrome (IBS), and colorectal cancer. The key to diagnosis is to take a thorough history in order to establish:

- The location of the pain—is this constant or does it shift or radiate? Does it fit with referred pain (i.e., umbilical pain of appendicitis) or is it more generalized?
- The timeframe of the pain—acute versus chronic, intermittent versus continuous.
- Severity at its best and worst—a score out of 10 can be helpful.
- Nature of the pain—reflux is often a burning pain in the epigastrium, infectious diarrhoea, or colitis usually gives a crampy lower abdominal pain. However, pain can sometimes be difficult to characterize and patients can describe pain that fits multiple causes.
- Precipitants—for example, food (can suggest reflux, IBS, biliary issues), movement (acute abdomen, musculoskeletal problems), constipation.
- Relieving factors—analgesia (remember that chronic opioid use can lead to and worsen abdominal pain), defaecation (the crampy nature of colitis pain may be temporarily relieved by passing stool).
- Any associated symptoms—for example, nausea, vomiting, diarrhoea, fever can help narrow down or exclude a diagnosis.

Box 22.7 Commonly used antiemetic drugs

Antiemetic class	Drugs	When to use	Side-effects
Antihistamines	Cyclizine Promethazine	Motion sickness Vestibular nausea	i.v. cyclizine can be addictive
Dopamine-R antagonists	Prochlorperazine Chlorpromazine (phenothiazines)	Post-chemotherapy	Extra-pyramidal reactions—avoid in Parkinson's
	Haloperidol	Palliative	QT prolongation
	Metoclopramide	Gastroenteritis Migraine Postoperative	Increased gastric emptying Tardive dyskinesia with prolonged use
Serotonin receptor antagonists (5-HT_3)	Ondansetron	Chemotherapy-induced (1st-line)	Constipation Headache Dizziness
Glucocorticoids	Dexamethasone	Chemotherapy-induced (in combo with 5-HT_3 RA)	Steroid side-effect profile

This is an amended version of the SOCRATES mnemonic which can be a helpful tool to structure a history around.

Investigation and treatment will depend on the suspected differential diagnosis that is gained from the history.

Nausea and vomiting

Nausea is the sensation of being about to vomit, which can occur with or without vomiting. It can be more unpleasant and disabling for patients than vomiting alone. There are two central areas that are responsible for triggering nausea and vomiting. The nucleus tractus solitarius in the medulla, which acts as a central pattern generator for vomiting, and the area postrema in the floor of the fourth ventricle. This contains the 'chemoreceptor trigger zone' (CTZ), which has five different receptors:

- 5-HT receptors
- histamine H1 receptors
- muscarinic receptors
- dopamine D2 receptors
- substance P (neurokinin-1-neuropeptide).

Substances such as opioids, hormones, ketoacids, and urea can all stimulate the CTZ directly as they are carried in the bloodstream.

Nausea and vomiting can be caused by a huge number of varied conditions, physiological states (e.g., pregnancy), infections, medications, and toxins (see Box 11.38). The choice of antiemetic depends on the cause of the vomiting and the side-effect profile of the antiemetic (**Box 22.7**).

Diarrhoea

The word 'diarrhoea' comes from the Greek meaning 'to flow through'. It is a very common manifestation of GI disease with many causes (**Box 22.8**; see also Box 11.39 for common causes in the acute medical unit). There are many definitions but commonly it is accepted as being more than three loose stools in 24 hours.

Pathophysiology

Osmotic diarrhoea

The gut mucosa acts as a semipermeable membrane and fluid enters the bowel if there are large quantities of non-absorbed hypertonic substances in the lumen. This occurs because the patient:

- has ingested a non-absorbable substance (e.g., a purgative, such as magnesium sulphate or magnesium-containing antacid)
- has generalized malabsorption, so that high concentrations of solute (e.g., glucose) remain in the lumen
- has a specific absorptive defect (e.g., disaccharidase deficiency or glucose-galactose malabsorption).

Box 22.8 Causes of diarrhoea

Non-infective causes

- Inflammatory bowel disease
- Radiation proctitis or colitis
- Behçet's disease
- Diverticular disease
- Ischaemic colitis
- Gastrointestinal lymphoma
- Carcinoma of the colon (change in bowel habit)
- Malabsorption
- Gut resection
- Bile acid malabsorption
- Drugs—many, including:
  - Laxatives
  - Metformin
  - Anticancer drugs
  - Statins
  - Proton pump inhibitors
- Faecal impaction with overflow
- Irritable bowel syndrome and functional diarrhoea
- Endocrine causes:
  - Zollinger–Ellison syndrome
  - VIPoma
  - Somatostatinoma
  - Glucagonoma
  - Carcinoid syndrome
  - Thyrotoxicosis
  - Medullary carcinoma of thyroid
  - Diabetic autonomic neuropathy
- Factitious diarrhoea:
  - Purgative abuse
  - Dilutional diarrhoea

Infective causes

- Bacterial, for example,
  - *Campylobacter jejuni*
  - *Salmonella* spp.
  - *Shigella*
  - *Escherichia coli* (see Chapter 42)
  - *Staphylococcal enterocolitis*
  - *Bacillus cereus*
  - *Clostridium perfringens, C. botulinum, C. difficile*
  - Gastrointestinal tuberculosis
- Viral, for example,
  - Rotavirus
- Fungal, for example,
  - Histoplasmosis
- Parasitic, for example,
  - Amoebic dysentery *(Entamoeba histolytica)*
  - Schistosomiasis
  - *Giardia intestinalis*

The volume of diarrhoea produced by these mechanisms is reduced by the absorption of fluid by the ileum and colon. The diarrhoea stops when the patient stops eating or the malabsorptive substance is discontinued.

Secretory diarrhoea

In this disorder, there is both active intestinal secretion of fluid and electrolytes, and decreased absorption. The mechanism of intestinal secretion is shown in **Fig. 22.8A**.

Common causes of secretory diarrhoea are:

- enterotoxins (e.g., cholera, *E. coli* thermolabile or thermostable toxin, *Clostridium difficile* toxin)
- hormones (e.g., VIP in Verner–Morrison syndrome; see Chapter 24)
- bile salts (in the colon) following ileal resection

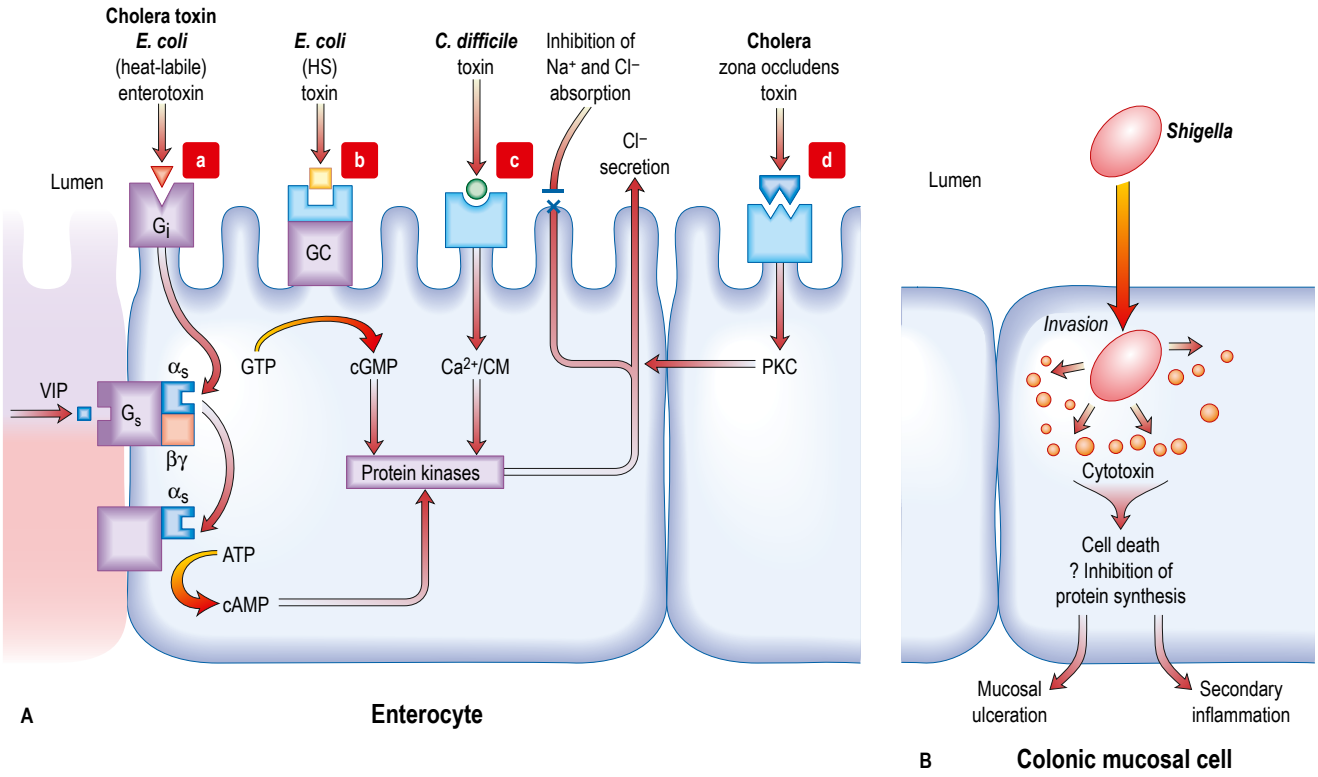

Fig. 22.8 Mechanisms of diarrhoea. (A) Small intestinal secretion of water and electrolytes. (a) *Cholera toxin* binds to its receptor (monosialoganglioside G_i) via fimbria (toxin co-regulated pili) on its β-subunit. This activates the α_s subunit (of the G_s protein), which in turn dissociates and activates cyclic AMP (cAMP). The increase in cAMP activates intermediates (e.g., protein kinase and Ca^{2+}), which then act on the apical membrane, causing Cl^- secretion (with water) and inhibition of Na^+ and Cl^- absorption. *Heat-labile E. coli enterotoxin* shares a receptor with cholera toxin. (b) *Heat-stable (HS) E. coli toxin* binds to its own receptor and activates guanylate cyclase (cGMP), producing the same effect on secretion. (c) *Clostridium difficile* activates the protein kinases via Ca^{2+}/calmodulin (Ca^{2+}/CM). (d) *Zona occludens toxin* is the product of the *ZOT* gene, which loosens tight junctions and is required for function of the cholera toxin. It has enterotoxic activity, producing secretion. Cholera and *E. coli* cause these effects without invasion of the cell. **(B)** Colonic mucosal cell. This demonstrates one of the mechanisms by which an invasive pathogen (e.g., *Shigella*) acts. Following penetration, the pathogens generate cytotoxins, which lead to mucosal ulceration and cell death. *ATP,* Adenosine triphosphate; *G,* G protein consisting of subunits α, β, γ; *GC,* guanyl cyclase; *GMP,* guanosine monophosphate; *GTP,* guanosine triphosphate; *i,* inhibitory; *PKC,* protein kinase C; *s,* stimulatory; *VIP,* vasoactive intestinal polypeptide.

- fatty acids (in the colon) following ileal resection
- some laxatives (e.g., docusate sodium).

Inflammatory diarrhoea (mucosal destruction)

Diarrhoea occurs because of damage to the intestinal mucosal cell so that there is a loss of fluid and blood (Fig. 22.8B). In addition, there is defective absorption of fluid and electrolytes. Causes are usually infective (e.g., dysentery due to *Shigella*) or inflammatory (IBD).

Abnormal motility

Diabetic, post-vagotomy, and hyperthyroid diarrhoea are all due to abnormal motility of the upper gut. Symptoms may be exacerbated by small bowel bacterial overgrowth.

Acute diarrhoea

Acute diarrhoea is defined as lasting less than 14 days. The cause is usually infectious, most commonly viral in children but sometimes bacterial (usually more severe cases). Common infectious causes include:

- Viral infection, for example, norovirus or rotavirus
- *E. coli* food poisoning (causes a secretory diarrhoea)
- Food poisoning from *Salmonella*, *Campylobacter*, or *Staphylococcus* bacteria
- *C. difficile* infection (usually due to recent course of antibiotics)
- Contaminated food or water ('traveller's diarrhoea'), often *Giardia* or *Entamoeba histolytica.*

Clinical features associated with acute diarrhoea include fever, abdominal pain, and vomiting. Stools are usually loose and watery but can also be bloody. If the diarrhoea is severe then dehydration can occur, especially in very young or elderly patients.

The key investigation is to send a stool sample to try to isolate an organism. ***Stool microscopy, culture, and sensitivities (MCS)*** should be sent in all patients. Samples for ***C. difficile toxin*** should be sent in at-risk patients (elderly, nursing home residents, recent antibiotic use). Stool for ova, cysts, and parasites (OCP) should be sent in the following cases:

- persistent diarrhoea (>14 days <30 days)
- men who have sex with men
- immunocompromised patients
- recent travel abroad

- if suspecting giardiasis/amoebiasis/cryptosporidium.

Management of acute diarrhoea focuses on volume repletion, usually with oral rehydration solutions that contain water, salt, and sugar. In severe cases of dehydration, patients may need to be admitted to hospital for intravenous fluid resuscitation. Antibiotics are not usually empirically given unless it is a particularly severe case or complications develop (**Box 22.9** lists common antibiotic regimens). Antimotility agents (e.g., codeine phosphate or loperamide) should be avoided if possible.

Indications for antibiotic treatment include:

- severe/prolonged symptoms (>5 days)
- systemic signs of infection
- extremes of age
- immunocompromise
- presence of complications
- bloody or mucoid stools.

Chronic diarrhoea

This is defined as diarrhoea present for longer than 30 days. The causes are listed in **Box 22.10**.

A thorough history is important including the onset, timeframe, and severity of symptoms. Important points to address are any associated features such as bloody stools, abdominal pain, weight loss, steatorrhoea, recent changes in medication, food/other triggers, and a full past medical history. A full examination is needed.

Initial investigations should include:

- full blood count, serum creatinine and electrolytes, thyroid function
- coeliac screen (tissue transglutaminase [tTG] or endomysial [EMA] antibodies)
- faecal calprotectin (see 'Stool tests' section for more information)
- stool MCS, *C. difficile* toxin.

If the above do not reveal a cause then patients should undergo a flexible sigmoidoscopy (FS). In the following circumstances, however, patients should undergo a full colonoscopy:

- iron deficiency anaemia
- abnormal faecal calprotectin with a suspicion of IBD
- older patients where screening for polyps and colorectal cancer would be advantageous.

Further investigations include bowel imaging (CT abdomen, MRI small bowel, pancreatic CT), video capsule endoscopy, SeHCAT scan, and lactose hydrogen breath tests; the choice will depend on the individual patient's symptoms. Management of chronic diarrhoea involves treating the underlying cause and this will be discussed in more detail later. See **Box 22.11** for a summary of take-home messages for the patient.

Box 22.9 Common antibiotic regimens for acute diarrhoea

Infection	Antibiotic
Empirical therapy	Ciprofloxacin p.o. 500 mg twice daily for 5 days
Salmonella/Shigella	Ciprofloxacin p.o. 500 mg twice daily for 5 days
Campylobacter	Clarithromycin p.o. 500 mg twice daily for 5 days
Clostridium difficile	Metronidazole p.o. 400 mg three times daily for 10–14 days OR Vancomycin p.o. 125–250 mg four times daily for 10–14 days

Box 22.10 Causes of chronic diarrhoea

Common causes

- Irritable bowel syndrome
- Microscopic colitis
- Inflammatory bowel disease
- Colonic cancer
- Medications
- Diet
- Bile acid diarrhoea
- Pancreatic insufficiency
- Coeliac disease
- Overflow diarrhoea

Infrequent causes

- Radiation enteritis
- Lymphoma
- Diabetes
- Faecal incontinence
- Small bowel overgrowth
- Hyperthyroidism
- Small bowel resection
- Mesenteric ischaemia
- Chronic pancreatitis

Rare causes

- VIPoma
- Carcinoid
- Gastrinoma
- Whipple's disease
- Amyloidosis
- Tropical sprue
- Addison's disease

Constipation

'Constipation' is a very common symptom, particularly in women and the elderly. A consensus definition used in research (the Rome IV criteria) defines constipation as having two or more of the following for at least 3 months:

- infrequent passage of stools (<3/week)
- straining >25% of time
- passage of hard stools (Bristol stool chart form 1–2) in >25% defecations
- incomplete evacuation and sensation of anorectal blockage in >25% defecations
- manual manoeuvres to facilitate >25% defecations (digital evacuation, support of the pelvic floor).

Other symptoms include abdominal bloating and/or discomfort (undistinguishable from irritable bowel syndrome), as well as local and perianal pain. The causes of constipation are shown in **Box 22.12**.

Diagnosis

This relies on the history. When there has been a recent change in bowel habit in association with other significant symptoms (e.g., rectal bleeding), a colonoscopy or CT pneumocolon is indicated. By these means, gastrointestinal causes, such as colorectal cancer and narrowed segments due to diverticular disease, can be excluded.

Constipation can be classified into three broad categories but there is much overlap:

- normal transit through the colon (59%)
- defecatory disorders (25%)
- slow transit (13%).

Defecatory disorders with slow transit can occur together (3%).

Normal-transit constipation

In normal-transit constipation, stool traverses the colon at a normal rate, the stool frequency is normal, and yet patients believe they are constipated. This is likely to be due to perceived difficulties of evacuation or the passage of hard stools. Patients may complain of abdominal pain or bloating. Normal-transit constipation can be distinguished from slow-transit constipation by undertaking marker studies of colonic transit. Capsules containing 20 radio-opaque shapes are swallowed on days 1, 2, and 3 and an abdominal X-ray is obtained 120 hours after ingestion of the first capsule. Each capsule contains shapes of different configuration and the presence of

Box 22.11 Take-home messages for patients presenting with diarrhoea

	Acute diarrhoea	Chronic diarrhoea
Length	<14 days	>30 days
Common causes	Unknown Viral illness Bacterial if severe	Irritable bowel syndrome, inflammatory bowel disease, medications, overflow diarrhoea, diet, coeliac
Key investigations	Stool MCS OCP if risk factors	Coeliac screen Faecal calprotectin Flexible sigmoidoscopy Imaging
Management	Volume repletion Antibiotics only if severe/complications	Treat cause

MCS, Microscopy culture and sensitivities; *OCP,* ova, cysts, and parasites.

Box 22.12 Causes of constipation

General
- Inadequate fibre intake
- Immobility

Metabolic/endocrine
- Diabetes mellitus
- Hypercalcaemia
- Hypothyroidism
- Porphyria

Functional
- Irritable bowel syndrome
- Idiopathic slow transit

Drugs
- Opiates
- Antimuscarinics
- Calcium-channel blockers, for example, verapamil
- Antidepressants, for example, tricyclics
- Iron

Neurological
- Spinal cord lesions
- Parkinson's disease

Psychological
- Depression
- Anorexia nervosa
- Repressed urge to defecate

Gastrointestinal disease
- Intestinal obstruction and pseudo-obstruction
- Colonic disease, for example, carcinoma, diverticular disease
- Aganglionosis, for example, Hirschsprung's disease, Chagas' disease
- Painful anal conditions, for example, anal fissure

Defecatory disorders
- Rectal prolapse, mucosal prolapse intussusception, and solitary rectal ulcer syndrome
- Large rectocele
- Pelvic floor dyssynergia/anismus
- Megarectum

Fig. 22.9 Slow-transit constipation. Frontal abdominal X-ray taken on day 6 after ingestion of capsules, each containing 20 radio-opaque shapes, which were administered daily on days 1, 2, and 3. All the markers are retained, confirming the diagnosis of severe slow-transit constipation.

more than 4 shapes from the first capsule, 6 from the second and 12 from the third denotes moderate to severe slow transit (Fig. 22.9).

Defecatory disorders

A 'paradoxical' contraction, rather than the normal relaxation of puborectalis and the external anal sphincter and associated muscles during straining, may prevent evacuation (pelvic floor dyssynergia, anismus). These are mainly due to dysfunction of the anal sphincter and pelvic floor. An anterior rectocele is a common problem where there is a weakness of the rectovaginal septum, resulting in protuberance of the anterior wall of the rectum with trapping of stool if the diameter is more than 3 cm. In some patients, the mucosa of the anterior rectal wall prolapses downwards during straining (see 'Rectal prolapse, intussusception, and solitary rectal ulcer syndrome' section), impeding the passage of stool, while in others there may be a higher mucosal intussusception.

In some patients, the rectum can become unduly sensitive to the presence of small volumes of stool, resulting in the urge to pass frequent amounts of small-volume stool and the sensation of incomplete evacuation.

The defecatory disorders can often be characterized by performing evacuation proctography and tests of anorectal physiology.

Slow-transit constipation

Slow-transit constipation occurs predominantly in young women who have infrequent bowel movements (usually less than once a week). The condition often starts at puberty and the symptoms include an infrequent urge to defecate, bloating, abdominal pain, and discomfort. Some patients with severe slow-transit constipation have delayed emptying of the proximal colon and others a failure of 'meal-stimulated' colonic motility. Histopathological abnormalities have been demonstrated in the colons of some patients with severe slow-transit constipation, and some patients have coexisting disorders of small intestinal motility, consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (see 'Acute colonic pseudo-obstruction' section).

Management

Any underlying cause should be treated. In patients with normal and slow-transit constipation, the main focus should be directed towards increasing the fibre content of the diet in conjunction with increasing fluid intake.

The use of laxatives should be restricted to cases where symptoms impact on the patient's quality of life. The types of laxatives available are listed in **Box 22.13**. *Osmotic laxatives* act by increasing the colonic inflow of fluid and electrolytes; this acts not only to soften the stool but also to stimulate colonic contractility. The *polyethylene glycols (macrogols)* have the advantage over the synthetic disaccharide lactulose in that they are not fermented anaerobically in the colon to gas that can distend the colon and cause pain. The osmotic laxatives are preferred to the stimulatory laxatives, which act by stimulating colonic contractility and by causing intestinal secretion. *Prucalopride* is a high-affinity 5-HT_4 agonist that increases colonic transit and is an effective therapy for refractory constipation.

Linaclotide, a minimally absorbed peptide agonist of guanylate cyclase-C receptor, works by activating the cystic fibrosis transmembrane conductance regulator to stimulate chloride secretion and increase gastrointestinal fluid secretion. Significant benefits over placebo have been shown in clinical trials. *Lubiprostone* is an orally active agonist for type 2 chloride channels and therefore also increases gastrointestinal fluid secretion.

Box 22.13 Laxatives and enemas

Bulk-forming laxatives
- Dietary fibre
- Wheat bran
- Methylcellulose
- Mucilaginous gums—sterculia
- Mucilaginous seeds and seed coats, for example, ispaghula husk

Stimulant laxatives
(Stimulate motility and intestinal secretion)
- Phenolphthalein
- Bisacodyl
- Anthraquinones—senna and dantron (only for the terminally ill)
- Docusate sodium
- Methylnaltrexone (for opioid-induced constipation)
- Lubiprostone
- Prucalopride
- Linaclotide
- Sodium picosulfate

Osmotic laxatives
- Magnesium sulphate
- Lactulose
- Macrogols

Suppositories
- Bisacodyl
- Glycerol

Enemas
- Arachis oil
- Docusate sodium
- Hypertonic phosphate
- Sodium citrate

Patients with defecatory disorders should be referred to a specialist centre, as surgery may be indicated: for example, for anterior rectocele or internal anal mucosal intussusception. Anterior mucosal prolapse can be treated by injection, and those with pelvic floor dyssynergia (anismus) can benefit from biofeedback therapy.

INVESTIGATION OF GASTROINTESTINAL DISEASE

Routine haematology and biochemistry, followed by endoscopy and radiology, are the principal investigations.

Blood tests

All patients undergoing investigation for gastrointestinal disease should have routine blood tests. These include a full blood count, serum creatinine and electrolytes, liver function tests, and clotting. This basic screen checks for anaemia, elevated/depleted white cell or platelet counts, electrolyte disturbances, and clotting abnormalities, which can be present in several gastrointestinal diseases.

Stool tests

Stool tests are vital investigation for GI disease. Stool should always be sent for microscopy, culture, and sensitivities (MCS) in order to exclude infection in patients presenting with diarrhoea. For patients who have travelled abroad recently it can be useful to also look for stool ova, cysts, and parasites to check for infections such as giardiasis, amoebiasis, or tapeworm. **Faecal calprotectin** is a protein found in stool during intestinal inflammation (e.g., IBD or infection). It is commonly used in outpatients both diagnostically (it is 93% sensitive and 96% specific for IBD in adults) and for monitoring disease activity. Below 100 μg/g is within normal limits and a level higher than 200 μg/g is suggestive of IBD or an infective colitis. It should not be used in older patients where malignancy is suspected.

Endoscopy

Video endoscopes relay colour images to a high-definition television monitor. The tip of the endoscope can be angulated in all directions, and channels in the instrument are used for air insufflation, water injection, suction, and the passage of accessories such as biopsy forceps or brushes for obtaining tissue, snares for polypectomy and needles for injection therapies.

- ***Oesophagogastroduodenoscopy*** (***OGD***, 'gastroscopy') is the investigation of choice for upper gastrointestinal disorders with the possibility of therapy and mucosal biopsy. Findings include reflux oesophagitis, gastritis, ulcers, and cancer. Therapeutic OGD is used to treat upper gastrointestinal haemorrhage and both benign and malignant obstruction. The mortality for diagnostic endoscopy is 0.001% with significant complications in 1:10000, usually when performed as an emergency (e.g., gastrointestinal haemorrhage).
- ***Colonoscopy*** allows good visualization of the whole colon and terminal ileum. Biopsies can be obtained and polyps removed. Benign strictures can be dilated and malignant strictures stented. Cancer, polyps, and diverticular disease are the most common significant findings. Perforation occurs in 1:1000 examinations but this is higher (up to 2%) after polypectomy and endoscopic mucosal resection (**Box 22.14**).
- ***Proctoscopy*** (**Box 22.15**) is performed in all patients with a history of bright red rectal bleeding to look for anorectal pathology such

Box 22.14 Gastroscopy and colonoscopy

- Explain the procedure to the patient, including benefits and risks.
- Discuss the need for sedation.
- Obtain written informed consent.

Gastroscopy

- The patient should be fasted for at least 4 h.
- Give oxygen and monitor oxygen saturation with an oximeter.
- Give lidocaine throat spray or sedation (midazolam ± opiate if required).
- Pass the gastroscope to the duodenum under direct vision.
- Examine during insertion and withdrawal.
- Gastroscopy takes 5–15 min, depending on the indication and findings.
- Withhold fluid and food until local anaesthetic/sedation wears off.
- Complications are rare but beware of over-sedation, perforation, and aspiration.
- The patient must be accompanied home if sedation has been given.

Colonoscopy

- Stop oral iron a week before the procedure.
- Restrict the diet to low-residue foods for 48 h; clear fluids only for 24 h.
- Use a local bowel-cleansing regime, usually starting 24 h beforehand (e.g., two sachets of sodium picosulfate with magnesium citrate and 2–4 bisacodyl tablets, or macrogols 2–4 L, or local alternative; more if constipated).
- Give oxygen and monitor O_2 levels.
- Give sedation (midazolam ± opiate) if required by the patient.
- Pass the colonoscope to the caecum or ileum under direct vision.
- Examine in detail during withdrawal.
- Colonoscopy takes 15–30 min, depending on the colon anatomy, indication, and findings.
- Withhold fluid and food until sedation wears off.
- Observe the patient for at least an hour after sedation has been given.
- Complications are rare but beware of over-sedation, perforation, and aspiration.
- The patient must be accompanied home if sedation has been given.

For patients on antiplatelet therapy and anticoagulants (including antithrombotic agents), see Veitch AM, Vanbiervliet G, Gershlick AH et al. Endoscopy in patients on antiplatelet or anticoagulant therapy including direct oral anticoagulants. British Society of Gastroenterology (BSG) and European Society of Gastrointestinal Endoscopy (ESGE) guidelines. Gut *2016; 65:374–389.*

Box 22.15 Proctoscopy

- The proctoscope is passed into the anus and the obturator is removed.
- The patient strains down as the proctoscope is removed.
- Haemorrhoids are seen as purplish veins in the left lateral, right posterior, or right anterior position.
- Fissures may also be seen, but pain often prevents the procedure from being performed.

as haemorrhoids; a rigid sigmoidoscope is too narrow and long to enable adequate examination of the anal canal.

- ***Sigmoidoscopy***, either flexible or rigid, is part of the routine hospital examination in cases of diarrhoea and in patients with lower abdominal symptoms such as a change in bowel habit or rectal bleeding. ***Rigid sigmoidoscopy*** can visualize the distal 20 to 25 cm of large bowel, whereas ***flexible sigmoidoscopy*** can reach up to the splenic flexure (60 cm), and is typically performed in the endoscopy unit after evacuation of the distal colon using an enema or suppository.
- ***Balloon enteroscopy***, either double- or single-balloon, can examine the small bowel from the duodenum to the ileum, adopting both cranial and caudal approaches, and using specialized enteroscopes in expert centres.
- ***Capsule endoscopy*** is used for the evaluation of obscure gastrointestinal bleeding (after negative gastroscopy and colonoscopy) and for the detection of small bowel tumours and occult IBD. It should be avoided if strictures are suspected.
- ***pH studies, impedance monitoring, and manometry*** are all discussed in more detail in the upper gastrointestinal disease section.

Imaging

Plain X-rays

Plain X-rays of the chest and abdomen are chiefly used in the investigation of an acute abdomen. Interpretation depends on analysis of gas shadows inside and outside the bowel. Plain films are particularly useful where obstruction or perforation is suspected, to exclude toxic megacolon in colitis, and to assess faecal loading in constipation. Calcification may be seen with gall bladder stones and in chronic pancreatitis, though computed tomography is more sensitive for both.

Ultrasound

Ultrasonography involves no radiation and is the first-line investigation for abdominal distension: for example, in ascites, a mass or suspected inflammatory conditions. It can show dilated, fluid-filled loops of bowel in obstruction, and thickening of the bowel wall. It can be used to guide biopsies or percutaneous drainage. In an acute abdomen, ultrasound can diagnose cholecystitis, appendicitis, enlarged mesenteric glands, and other inflammatory conditions.

Computed tomography

Computed tomography (CT) involves a significant dose of radiation (approximately 10 millisieverts). Modern multislice fast scanners and techniques, involving intraluminal and intravenous contrast, enhance diagnostic capability. Intraluminal contrast may be positive (Gastrografin or Omnipaque) or negative (usually water). The bowel wall and mesentery are well seen after intravenous contrast, especially with negative intraluminal contrast. Clinically unsuspected diseases of other abdominal organs are quite often also revealed (Fig. 22.10A).

CT is widely used as a first-line investigation for the acute abdomen. It is sensitive for small volumes of gas from a perforated viscus, as well as leakage of contrast from the gut lumen. Inflammatory conditions, such as abscesses, appendicitis, diverticulitis, Crohn's disease and its complications, are well demonstrated. In high-grade bowel obstruction, CT is usually diagnostic of both the presence and the cause of the obstruction.

CT is widely used in cancer staging and as guidance for biopsy of tumour or lymph nodes.

CT pneumocolon/CT colonography (virtual colonoscopy) after CO_2 insufflation into a previously cleansed colon provides an alternative to colonoscopy for diagnosis of colonic mass lesions (see Fig. 22.10B). It is being evaluated as a screening test for colon pathology with sensitivities of over 90% for polyps larger than 10 mm.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) uses no radiation and is particularly useful in the evaluation of rectal cancers and of abscesses and fistulae in the perianal region. It is also useful in small bowel disease (MR enteroclysis) and in hepatobiliary and pancreatic disease.

Positron emission tomography

Positron emission tomography (PET) relies on detection of the metabolism of fluorodeoxyglucose. It is used for staging oesophageal, gastric, and colorectal cancer and in detecting metastatic and recurrent disease. PET/CT adds additional anatomical information.

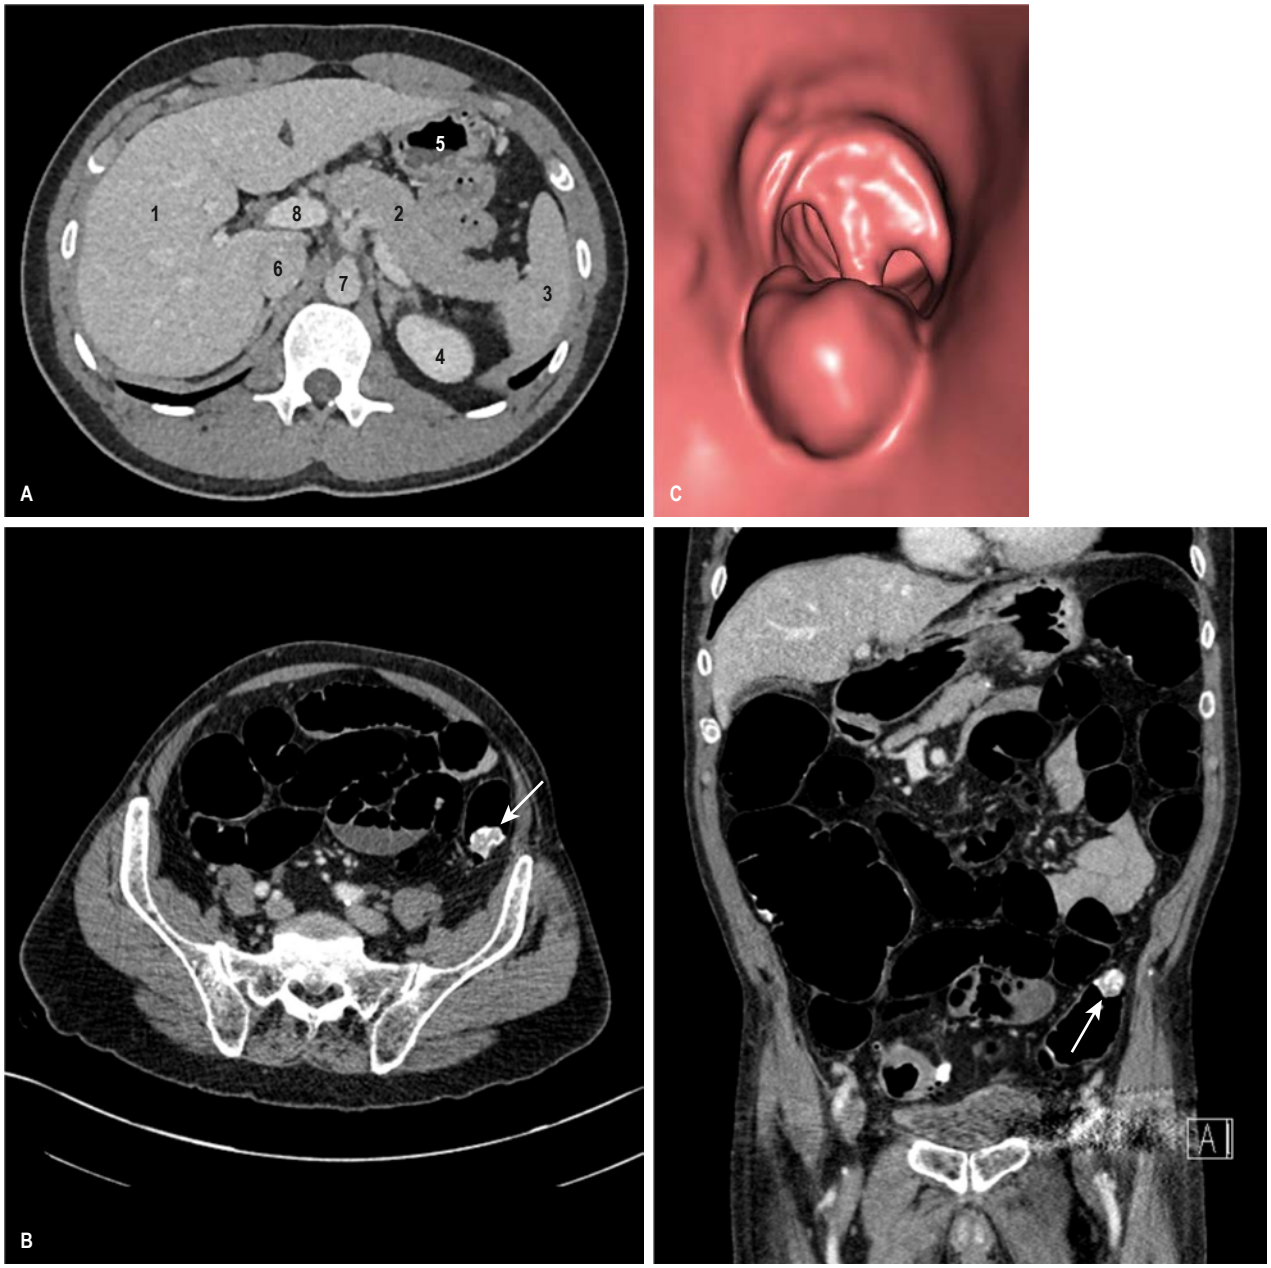

Fig. 22.10 Computed tomography in gastrointestinal disease. (A) Annotated axial CT image of the abdomen. (1) Liver; (2) pancreas; (3) spleen; (4) left kidney; (5) stomach; (6) inferior vena cava; (7) aorta; (8) portal vein. **(B)** Axial and coronal CT colonography images demonstrate a stalked polyp in the distal descending colon *(arrows)*. **(C)** 3D view of the polyp demonstrated in (B).

Contrast studies

These include barium swallow examination, double-contrast barium meal, and small bowel follow-through or meal. ***Absorbable water-soluble (Gastrografin or Omnipaque) contrast agents*** should be used in preference to barium when perforation is suspected anywhere in the gut. These are useful examinations for the upper GI tract and small bowel but do rely on good technique. They are gradually being superseded by other modalities of imaging, particularly MRI.

Radioisotopes

Radionuclides are used to a varying degree, depending on availability and expertise. Some of the more common indications are measuring the rate of gastric emptying, demonstration of a Meckel's diverticulum, evaluation of neuroendocrine tumours, assessment of bile salt malabsorption (SeHCAT scan), or detection of bacterial overgrowth. These will be explored in more detail in the relevant sections.

FUNCTIONAL GASTROINTESTINAL DISORDERS

There is a large group of gastrointestinal disorders that are termed 'functional' because symptoms occur in the absence of any demonstrable abnormalities in the digestion and absorption of nutrients,

fluid, and electrolytes, and no structural abnormality can be identified in the gastrointestinal tract, although there may be discernible abnormalities in neuromuscular function, such as dysmotility and visceral hypersensitivity, which are not routinely investigated.

Pathophysiology and brain–gut interactions

People with functional gastrointestinal disorders (FGIDs) are characterized by having a greater gastrointestinal motility response to life events than normal subjects. There is, however, a poor association between measured gastrointestinal motility changes and symptoms in many of the FGIDs. Patients with FGID have been shown to have abnormalities in visceral sensation and to have a lower pain threshold when tested with balloon distension (visceral hyperalgesia). Visceral hypersensitivity possibly relates to:

- altered receptor sensitivity at the viscus itself
- increased excitability of the spinal cord dorsal horn neurons
- altered central modulation of sensations.

A systematic review of published studies suggests that 10% of patients who experience an acute infective gastroenteritis develop a degree of FGID. It is not clear whether this is caused by post-infectious bile salt malabsorption, alterations in the mucosal immune system, or the use of antibiotics to treat the index infection.

The brain–gut axis describes a combination of intestinal motor, sensory, and activities (Fig. 22.11). Thus, extrinsic (e.g., vision, smell) and intrinsic (e.g., emotion, thought) information can affect gastrointestinal sensation because of the neural connections from higher centres. Conversely, viscerotropic events can affect central pain perception, mood, and behaviour.

Psychological stress can exacerbate gastrointestinal symptoms, and psychological disturbances are more common in patients with FGIDs. These disturbances alter attitude to illness, promote healthcare seeking, and often lead to a poor clinical outcome. They have psychosocial consequences with poor quality of life at home and work. Early in life, genetic and environmental influences (e.g., family attitudes towards bowel training, verbal or sexual abuse, exposure to an infection) may affect psychosocial development (susceptibility to life stress, psychological state, coping skills, development of social support) or the development of gut dysfunction (abnormal motility or visceral hypersensitivity). Therefore, FGID should be regarded as a dysregulation of brain–gut function and is often referred to as disorder of gut–brain interaction (DGBI).

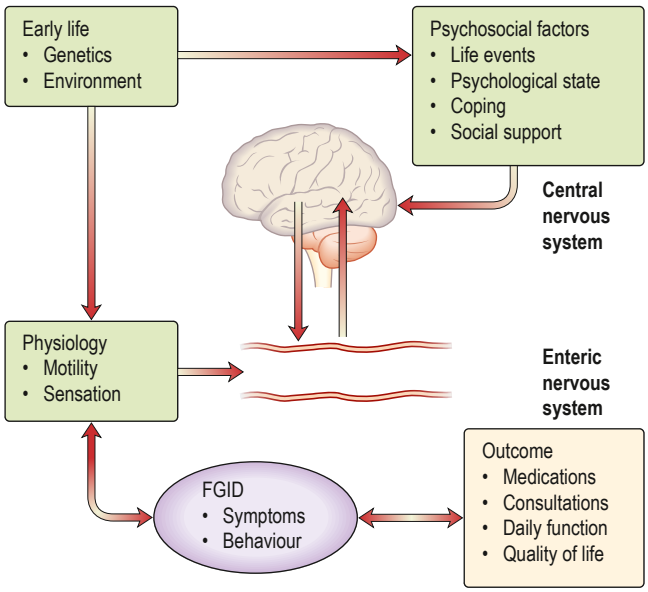

Fig. 22.11 A biopsychosocial conceptualization of the pathogenesis and clinical expression of functional gastrointestinal disorders (FGIDs). Genetic, environmental, and psychological factors may interact to cause dysregulation of brain–gut function. *(Modified from Drossman DA. The functional gastrointestinal disorders and the Rome III process.* Gastroenterology *2006; 130:1377–1390, with permission from Elsevier.)*

MOUTH

Recurrent aphthous ulceration

Idiopathic aphthous ulceration is common and affects up to 25% of the population. Recurrent painful round or ovoid mouth ulcers are seen with inflammatory halos. They are more common in females and non-smokers, usually appear first in childhood, and tend to reduce in number and frequency before the age of 40. Other family members may be affected. There is no sign of systemic disease.

- ***Minor aphthous ulcers*** are the most common; they are less than 10 mm diameter, have a grey/white centre with a thin erythematous halo, and heal within 14 days without scarring. They rarely affect the dorsum of the tongue or hard palate.
- ***Major aphthous ulcers*** (>10 mm diameter) often persist for weeks or months and heal with scarring.

The cause is not known. Deficiencies of iron, folic acid, or vitamin B_{12} (with or without gastrointestinal disorders) are sometimes found but are not causally linked. Secondary causes, such as Crohn's disease, should be excluded (Box 22.16).

There are no specific effective therapies. Sufferers should avoid oral trauma, and acidic foods or drinks that cause pain. Topical (1% triamcinolone) or systemic corticosteroids may lessen the duration and severity of the attacks. Chlorhexidine gluconate or tetracycline mouthwash, dapsone, colchicine, thalidomide, and azathioprine have all been used with variable effect.

? Box 22.16 Causes of mouth ulcers

- Idiopathic aphthous ulceration (most common)
- Gastrointestinal disease:
  - Inflammatory bowel disease
  - Coeliac disease
- Infection:
  - Viral—herpes simplex virus (HSV), human immunodeficiency virus (HIV), Coxsackie
  - Fungal—candidiasis
  - Bacterial—syphilis, tuberculosis
- Systemic disease:
  - Reactive arthritis (see Chapter 32)
  - Behçet's syndrome
  - Systemic lupus erythematosus
- Trauma:
  - For example, dentures
- Neoplasia:
  - For example, squamous cell carcinoma
- Drugs:
  - In erythema multiforme major, toxic epidermal necrolysis
  - Chemotherapy, antimalarials
- Skin disease:
  - Pemphigoid
  - Pemphigus
  - Lichen planus

Neoplasia (squamous cell carcinoma)

Malignant tumours of the mouth account for 1% of all malignant tumours in the UK. The majority develop on the floor of the mouth or lateral borders of the tongue. Early lesions may be painless, but advanced tumours are easily recognizable as hard, indurated ulcers with raised and rolled edges. Aetiological agents include tobacco, heavy alcohol consumption, and the areca nut. Human papillomavirus 16 causes some oral cancers. Pre-malignant lesions include leucoplakia (single adherent white patch), lichen planus, submucous fibrosis, and erythroplakia (a red patch).

Management

Treatment is by surgical excision, which may require extensive neck dissection to remove involved lymph nodes and/or radiotherapy. Ablative treatment with photodynamic therapy is being pioneered for early lesions.

Pigmented neoplastic lesions

These include melanotic naevi on the hard palate and buccal mucosa. These are rarer in the mouth than on the skin. Malignant melanomas are rare, but more common in males, and occur mainly on the upper jaw. The 5-year survival is only 5%.

Non-neoplastic lesions

Oral white patches

Transient white patches either are due to *Candida* infection or are very occasionally found in systemic lupus erythematosus. Local causes include mechanical, irritative, or chemical trauma from drugs (e.g., ill-fitting dentures or aspirin). Oral candidiasis in adults is seen following therapy with broad-spectrum antibiotics or inhaled steroids, and in people with diabetes, patients who are seriously ill or those who are immunocompromised.

Persistent white patches can be due to ***leucoplakia***, which is associated with alcohol and (particularly) smoking; it is pre-malignant. A biopsy should always be taken; histology shows alteration in the keratinization and dysplasia of the epithelium. Treatment is unsatisfactory. Isotretinoin possibly reduces disease progression. ***Oral lichen planus*** presents as white striae, which can rarely extend into the oesophagus.

Oral pigmented lesions

Racial pigmentation is scattered and symmetrically distributed. Amalgam tattoo is the most common form of localized oral pigmentation and consists of blue–black macules involving the gingivae; it results from dental amalgam sequestering into the tissues. Diseases causing pigmentation include Peutz–Jeghers syndrome and Addison's disease. Heavy metals (e.g., lead, bismuth, and mercury) and drugs (e.g., phenothiazines and antimalarials) all cause pigmentation of the gums.

Tongue

The tongue may be affected by inflammatory or malignant processes, with similar lesions to those described above.

Glossitis

Glossitis is a red, smooth, sore tongue associated with vitamin B_{12}, folate, iron, riboflavin, and nicotinic acid deficiency. It is also seen in infections due to *Candida*.

Geographic tongue

A geographic tongue is an idiopathic condition occurring in 1% to 2% of the population and may be familial. There are erythematous areas surrounded by well-defined, slightly raised irregular margins (Fig. 22.12). The lesions are usually painless and the patient should be reassured.

Gums

The gums (gingivae) are the mucous membranes covering the alveolar processes of the mandible and the maxilla. Diseases of the gum are shown in Box 22.17.

Teeth

Dental caries occur as a result of bacterial damage to tooth structures leading to tooth decay and 'cavities'. The main cause in humans is *Streptococcus mutans*, which is cariogenic only in the presence of dietary sugar. Dental caries can progress to pulpitis and pulp necrosis, and spreading infection can cause dentoalveolar abscesses. If there is soft tissue swelling, antibiotics (e.g., amoxicillin or metronidazole) should be prescribed prior to dental intervention.

Erosion of the teeth can result from exposure to acid (e.g., in bulimia nervosa) or, very occasionally, from severe gastro-oesophageal reflux disease.

SALIVARY GLANDS

Diseases of the salivary glands are shown in Box 22.18.

PHARYNX AND OESOPHAGUS

Gastro-oesophageal reflux disease

Epidemiology and pathophysiology

Gastro-oesophageal reflux disease (GORD) is common with a prevalence of 10% to 20% in the developed world. It is more common in the Western world than in Asia. There are a number of lifestyle risk factors as well as possible genetic factors, and the cardinal clinical feature is heartburn. Psychosocial factors are often determinants of symptom severity, with heartburn increased during times of stress. Factors associated with GORD are shown in Box 22.19.

Fig. 22.12 Geographic tongue. A florid example, demonstrating well-delineated areas of erythema partially surrounded by white serpiginous borders. *(Courtesy, Carl M. Allen, MD, and Charles Camisa, MD. From* Dermatology Essentials, *Second Edition.)*

Box 22.17 Gum diseases

	Cause	Management
Chronic gingivitis	Bacterial plaque	Plaque removal
Acute (necrotizing) ulcerative gingivitis (Vincent's angina)	Spirochaete and fusiform bacteria (poor hygiene and smoking)	Oral metronidazole 400 mg 3 times a day for 3 days Chlorhexidine mouthwash
Desquamative gingivitis (smooth red atrophic gingivae)	Lichen planus or mucous membrane pemphigoid	Confirmation with biopsy
Gingival swelling	Inflammation (e.g., pregnancy, scurvy), infiltrations (leukaemia), or fibrous hyperplasia (e.g., drug-induced—phenytoin, ciclosporin, nifedipine)	

Box 22.18 Diseases of the salivary glands

- Dry mouth (xerostomia):
  - Sjögren's syndrome
  - Drugs (e.g., antimuscarinic, anti-parkinsonian, lithium, tricyclics, monoamine oxidase inhibitors (MAOIs))
  - Radiotherapy
  - Psychogenic
  - Dehydration
- Acute sialadenitis:
  - Viral (e.g., mumps)
  - Bacterial (e.g., *Staphylococcus*, *Streptococcus*)
- Salivary duct obstruction:
  - Calculus
- Sarcoidosis (see Chapter 20)
- IgG4 disease (see Chapter 6)
- Neoplasms (3% of all tumours worldwide):
  - Pleomorphic adenoma (15% become malignant and can cause VII lower motor neuron signs)

Box 22.19 Factors associated with gastro-oesophageal reflux

- Pregnancy or obesity
- Fat, chocolate, coffee, or alcohol ingestion
- Large meals
- Cigarette smoking
- Drugs—antimuscarinic, calcium-channel blockers, nitrates
- Systemic sclerosis
- Treatment for achalasia
- Hiatus hernia

The underlying cause of GORD is reflux of gastric acid, pepsin, bile, and duodenal contents back into the oesophagus. This can be influenced by many factors that overcome the innate defence mechanisms, primarily the LOS. Between swallows, the muscles of the oesophagus are relaxed, except for those of the two sphincters. The LOS in the distal oesophagus remains closed because of the unique property of the muscle, and relaxes when swallowing is initiated (see 'Swallowing' section). ***Transient lower (o)esophageal sphincter relaxations*** (TLESRs) are part of normal physiology, but occur more frequently in patients with GORD, allowing gastric acid to flow back into the oesophagus (Fig. 22.13). Increased abdominal pressure (pregnancy) and low LOS pressure also predispose to GORD.

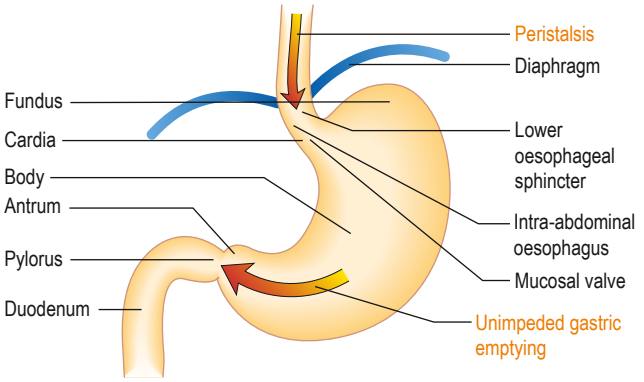

Fig. 22.13 The main anti-reflux mechanisms. These are shown on the right.

Box 22.20 Hiatus hernia

Sliding hiatus hernia

The oesophageal–gastric junction and part of the stomach 'slide' through the hiatus so that it lies above the diaphragm.

- Present in 30% of people over 50 years
- Produces no symptoms—any symptoms are due to reflux

Rolling or para-oesophageal hernia

Part of the fundus of the stomach prolapses through the hiatus alongside the oesophagus.

- The lower oesophageal sphincter remains below the diaphragm and remains competent
- Occasionally, severe pain occurs due to volvulus or strangulation

Other anti-reflux mechanisms involve the intra-abdominal segment of the oesophagus, which acts as a flap valve. In addition, the mucosal rosette, formed by folds of the gastric mucosa, and the crural diaphragm at the LOS, which contracts and acts like a pinchcock, prevent acid reflux. A hiatus hernia can impair this mechanism (Box 22.20). Normally, the oesophagus is also 'cleared' rapidly of refluxate by secondary peristalsis, gravity, and salivary bicarbonate.

The clinical features of reflux occur when the anti-reflux mechanisms fail, allowing acidic gastric contents to make prolonged contact with the lower oesophageal mucosa. The sphincter relaxes transiently, independently of a swallow, after meals, and this is the cause of almost all reflux in normal subjects and in about two-thirds of GORD patients.

The role of the ***acid pocket*** in GORD has gained more credence in the last 10 years. Food and fluid generally increase the gastric pH, but the acid pocket is an area of unbuffered gastric acid that accumulates postprandially in the proximal stomach. It serves as a reservoir for acid reflux, particularly in individuals with a hiatus hernia where the distal oesophagus is supradiaphragmatic, especially on lying flat. This can be specifically targeted with an antacid–alginate combination.

Clinical features

Heartburn is the major feature. This is a burning chest pain that is aggravated by bending, stooping, and lying down, all of which promote acid exposure. The patient typically complains of pain on eating spicy food or drinking hot liquids or alcohol.

Box 22.21 Classic features of the pain of gastro-oesophageal reflux and cardiac ischaemia

Reflux pain: burning, worse on bending, stooping, or lying down
- Seldom radiates to the arms
- Worse with spicy food, hot drinks, or alcohol
- Relieved by antacids

Cardiac ischaemic pain
- Gripping or crushing
- Radiates to neck or left arm
- Worse with exercise
- Accompanied by dyspnoea

The correlation between heartburn and oesophagitis is poor. Some patients have mild oesophagitis but severe heartburn, while others have severe oesophagitis in the absence of symptoms, and can present with haematemesis or iron deficiency anaemia from chronic blood loss.

Differentiation of cardiac and oesophageal pain can be difficult; 20% of cases seen in emergency departments have GORD (Box 22.21). A trial of antacid therapy is often useful, resolving reflux-induced pain, before progressing to 24-hour pH studies only if symptoms persist.

Regurgitation of food and acid into the mouth occurs, particularly on bending or lying flat. This can lead to excess salivation in the mouth, commonly known as water-brash. Aspiration pneumonia is unusual without an accompanying obstruction, but cough and asthma can occur and respond slowly (1–4 months) to a proton pump inhibitor (PPI).

Laryngopharyngeal reflux disease (LPRD) is the transport of gastric contents into the larynx and pharynx, usually, although not exclusively, in the context of GORD. Heartburn may be one of the associated symptoms but cough, hoarse voice, postnasal drip, and asthma are more frequently seen, but are not common.

Diagnosis and investigations

The ***clinical*** diagnosis can usually be made without investigation. Unless there are alarm symptoms, especially dysphagia (see 'Dysphagia' section), patients under the age of 45 years can safely be treated initially without investigations. If investigation is required, there are two aims:

- ***Assess oesophagitis and hiatal hernia by endoscopy.*** If there is oesophagitis (Fig. 22.14) or Barrett's oesophagus (see 'Barrett's oesophagus' section), reflux is confirmed.
- ***Intraluminal monitoring*** (Fig. 22.15). Intraluminal pH monitoring or impedance combined with manometry is helpful if there is no response to PPIs and should always be performed to confirm reflux before surgery. Ambulatory 24-hour pH monitoring consists of passing a nasogastric tube with a pH probe at its tip which is placed at the level of the LOS. This allows measurements of acid exposure and is worn for 24 hours. Some centres now offer a wireless probe (known as a Bravo capsule) that is clipped to the lower oesophagus without the need for an NG tube. This then gradually detaches and is passed in the stool. A composite score of the various parameters measured is then calculated, with a score higher than 14.72 indicating reflux. This is known as a DeMeester score. There should also be a good correlation between reflux (pH < 4.0) and symptoms. Impedance testing is when a catheter is used to measure the resistance to flow of 'alternating current' in the contents of the oesophagus. It can also be helpful to assess oesophageal dysmotility as a potential cause of the symptoms, leading to impaired oesophageal clearance.

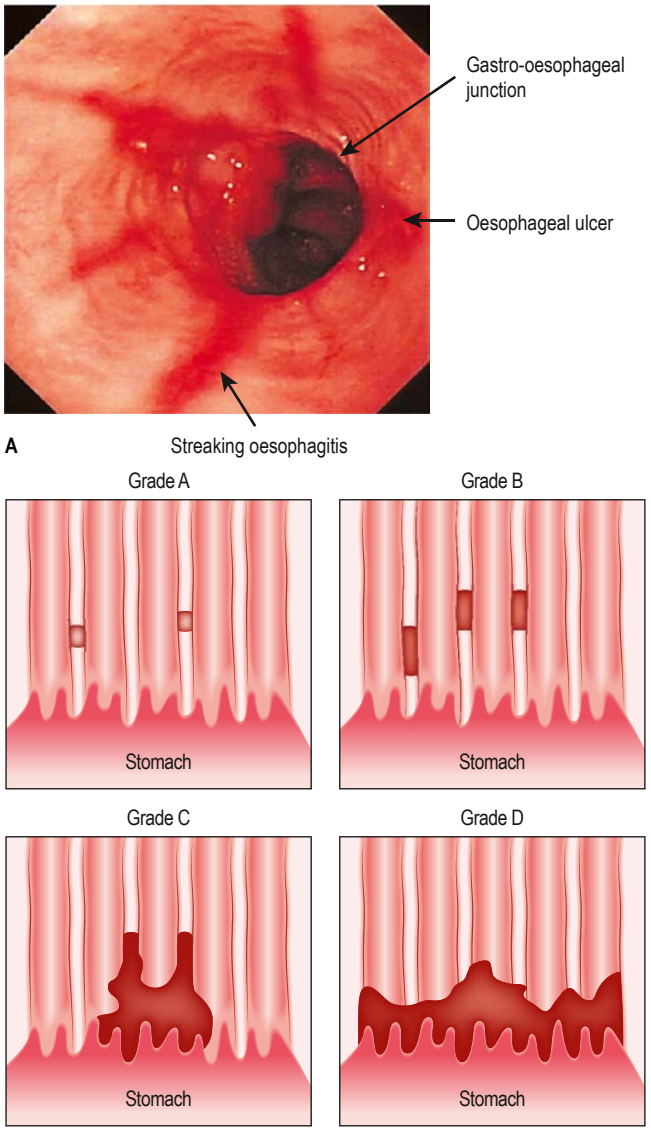

Fig. 22.14 Oesophagitis. (A) Oesophagitis seen on endoscopy. (B) Los Angeles classification of oesophagitis. **Grade A** = mucosal breaks confined to the mucosal folds, each no longer than 5 mm. **Grade B** = at least one mucosal break longer than 5 mm confined to the mucosal fold but not continuous between two folds. **Grade C** = mucosal breaks that are continuous between the tops of mucosal folds but not circumferential. **Grade D** = extensive mucosal breaks engaging at least 75% of the oesophageal circumference.

Management

Approximately half of patients with reflux symptoms in primary care can be treated successfully with simple antacids, loss of weight, and raising the head of the bed at night. Precipitating factors should be avoided, with dietary measures, reduction in alcohol and caffeine consumption, and cessation of smoking. These measures are simple to say but difficult to carry out, though they are useful in mild disease in compliant patients.

Drugs

Alginate-containing antacids

Alginate-containing antacids (10 mL three times daily) are the most frequently used 'over-the-counter' agents for GORD. They form a

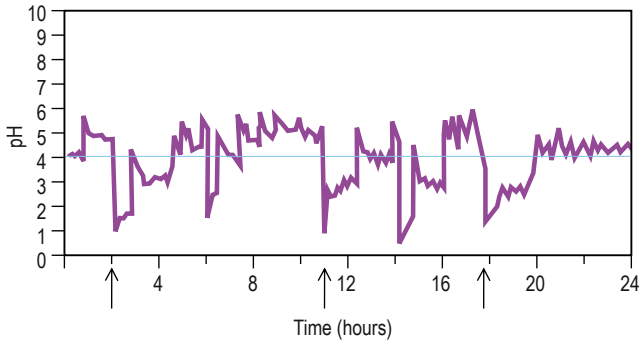

Fig. 22.15 Twenty-four-hour intraluminal pH monitoring. Five reflux episodes (pH < 4) occurred but only three produced symptoms *(arrowed)*.

gel or 'foam raft' with gastric contents to reduce reflux. Magnesium-containing antacids tend to cause diarrhoea while aluminium-containing compounds may cause constipation.

Proton pump inhibitors

Proton pump inhibitors (PPIs; omeprazole, rabeprazole, lansoprazole, pantoprazole, esomeprazole) inhibit gastric hydrogen/potassium-adenosine triphosphatase. PPIs reduce gastric acid secretion by up to 90% and are the drugs of choice for all but mild cases. Most patients with GORD will respond well, with approximately 60% symptom-free after 4 weeks of a once-daily PPI. Patients with severe symptoms may need twice-daily PPIs and prolonged treatment, often for years. Once oesophageal sensitivity has normalized, a lower dose, for example, omeprazole 20 mg, may be sufficient for maintenance. Long-term PPI prescription is not uncommon, and although some recent data have suggested side-effects such as osteoporosis, and an increase in gastrointestinal infections such as *C. difficile*, these are uncommon and tend to occur in at-risk patients.

Patients who do not respond to a PPI and have continuing symptoms with a normal endoscopy are described as having ***non-erosive reflux disease (NERD)*** (Fig. 22.16). These patients are usually female and often the symptoms are functional, although a small group have a 'hypersensitive' oesophagus, giving discomfort with only slight changes in pH. Isomers of some of the original PPIs (e.g., dexlansoprazole) have the benefit of more effective gastric acid inhibition over a longer time period, as their metabolism of the active metabolite is slower.

H_2-receptor antagonists

H_2-receptor antagonists (e.g., cimetidine, ranitidine, famotidine, and nizatidine) are frequently used for acid suppression if antacids fail, as they can easily be obtained. They can be used in conjunction with PPIs for patients with more severe GORD.

Dopamine antagonist prokinetic agents

The dopamine antagonist prokinetic agents metoclopramide and domperidone are occasionally helpful, as they enhance peristalsis and speed gastric emptying, but there are few data to substantiate this. The role of domperidone has been limited still further following reports of serious cardiac side-effects.

Endoluminal gastroplication

In this endoscopic procedure, multiple plications or pleats are made below the gastro-oesophageal junction. Randomized controlled trials have shown benefit with reduction in heartburn, acid reflux episodes and PPI usage, but not sustained improvements in the oesophageal pH measurements.

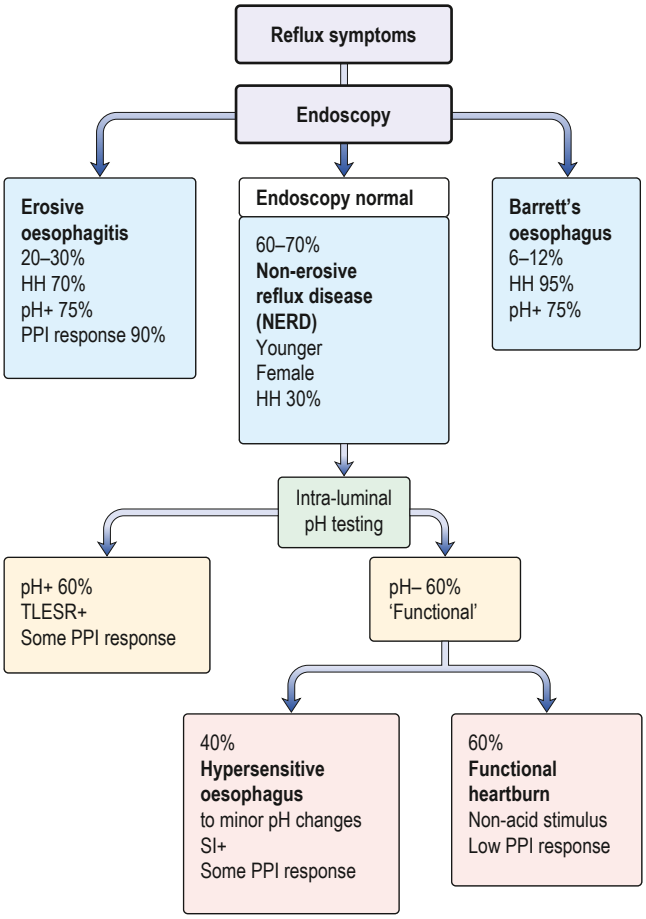

Fig. 22.16 Outcome of patients with reflux symptoms. *HH,* Hiatus hernia; *pH⁺,* meets standard criteria for excessive acid reflux on intraluminal testing; *pH⁻,* does not meet standard criteria for excessive acid reflux; *PPI,* proton pump inhibitor; *SI+,* symptom index (proportion of pH drops resulting in symptoms, >0.5 is significant); *TLESR,* transient lower (o)esophageal sphincter relaxation.

Surgery

Surgery should never be performed for a hiatus hernia alone. The best predictors of a good surgical result are typical reflux symptoms with documented acid reflux, which correlates with symptoms and response to a PPI. With such highly selected cases in experienced hands, the laparoscopic Nissen fundoplication has a satisfaction rate of over 90% at 5 years, and available 10-year data show satisfaction rates remain high at 88%. Current surgical techniques return the oesophagogastric junction to the abdominal cavity, mobilize the gastric fundus, close the diaphragmatic crura snugly, and involve a short, tension-free fundoplication.

The ***Linx reflux management system*** consists of a row of magnets that increase LOS closure pressure, allowing food passage during swallowing; it is inserted laparoscopically. Improvement in quality of life with no PPI therapy has been shown but further studies are necessary. Patients cannot have an MRI study with the device *in situ*.

Indications for operation are not clear-cut but include intolerance to medication, the desire for freedom from medication, the expense of therapy, and concern about long-term side-effects.

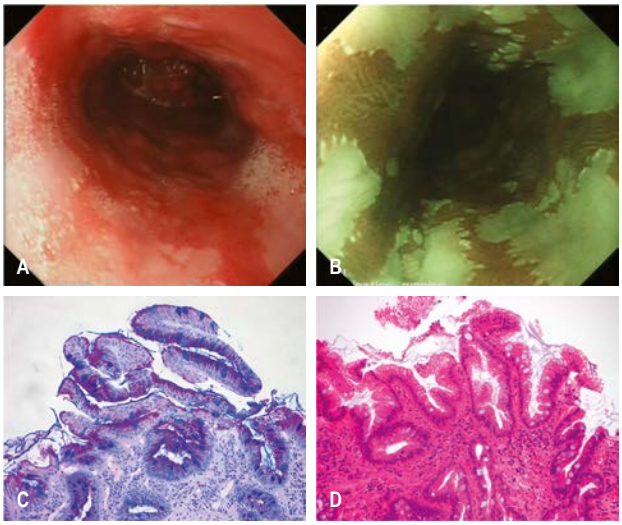

Fig. 22.17 Barrett's oesophagus. **(A)** Endoscopic picture of Barrett's oesophagus. **(B)** Endoscopic narrow-band imaging of Barrett's mucosa. **(C)** Alcian blue staining of Barrett's mucosa highlighting the blue-staining goblet cells. **(D)** Haematoxylin and eosin staining of Barrett's columnar mucosa.

The most common cause of mechanical fundoplication failure is recurrent hiatus hernia.

Patients with oesophageal dysmotility unrelated to acid reflux, those with no response to PPIs and those with underlying functional bowel disease should rarely have surgery.

Complications of gastro-oesophageal reflux disease

Peptic stricture

Since the advent of PPIs, peptic strictures have become far less common. They usually occur in patients over the age of 60 and present with intermittent dysphagia for solids, which worsens gradually over a long period. Mild cases may respond to PPIs alone. More severe cases need endoscopic dilation and long-term PPI therapy. Surgery is required if medical treatment fails.

Barrett's oesophagus

Barrett's oesophagus (Fig. 22.17) is a condition in which part of the normal oesophageal squamous epithelium is replaced by metaplastic columnar mucosa to form a segment of 'columnar-lined oesophagus' (CLO). It is a complication of GORD and there is almost always a hiatus hernia present.

Diagnosis and classification

The diagnosis is made if endoscopy shows proximal displacement of the squamocolumnar mucosal junction and biopsy demonstrates columnar lining above the proximal gastric folds (>1 cm); intestinal metaplasia is no longer a requirement of the British Society of Gastroenterology definition but is central to the American College of Gastroenterology guidelines. Barrett's oesophagus may be seen as a continual circumferential sheet, as finger-like projections extending upwards from the squamocolumnar junction or as islands of columnar mucosa interspersed with areas of squamous mucosa. The Prague classification (Fig. 22.18) is used for recording the endoscopic distribution, stating both the length of circumferential CLO (C measurement) and the maximum length (M measurement), the distance from the top of the gastric folds to the most proximal tongue of the columnar mucosa.

Central obesity increases the risk of Barrett's by 4.3 times. Long-segment (>3 cm) and short-segment (<3 cm) Barrett's is found, respectively, in 5% and 15% of patients undergoing endoscopy for reflux symptoms. Barrett's is also often found incidentally in endoscoped patients without reflux symptoms. It is most common in middle-aged obese males. The major concern is that approximately 0.12% to 0.5% of Barrett's patients develop oesophageal adenocarcinoma per year; the majority, probably, through a gradual transformation from intestinal metaplasia to low-grade then high-grade dysplasia, before invasive adenocarcinoma. Early studies suggested that Barrett's increases the chance of developing oesophageal adenocarcinoma 30- to 50-fold but recent studies have shown the risk to be much lower and closer to a 1% lifetime risk in the typical patient.

Screening for Barrett's oesophagus is not routinely recommended because of the poor correlation between symptoms and the presence of Barrett's. Once detected however, ongoing surveillance is carried out at regular intervals. The interval between endoscopies is determined by the length of the CLO and the degree of cellular disturbance within it (Fig. 22.19).

Surveillance involves inspection of the oesophageal mucosa with a high-definition gastroscope, and the taking of targeted biopsies of any focally abnormal tissue in addition to random biopsies from all four quadrants (every 1–2 cm) of the CLO. High-grade dysplasia (HGD) is usually associated with endoscopically visible nodules or ulceration, optimally visualized with a high-definition endoscope. Chromo-endoscopy (the topical application of stains or pigments via the endoscope), narrow band and autofluorescence imaging may aid the diagnosis of dysplasia and carcinoma. Endoscopic technology has improved the detection of pre-malignant lesions, enabling their removal by either endoscopic mucosal resection (EMR) or endoscopic submucosal dissection, therefore preventing surgical oesophagectomy.

If ***low-grade dysplasia*** is found on endoscopic surveillance, a repeat endoscopy with quadrantic biopsies every 1 cm is usually performed within 6 months, while on high-dose proton pump inhibition. Recent guidelines now suggest that if low-grade dysplasia persists then these patients should be offered endoscopic ablation therapy or 6-monthly surveillance.

If ***high-grade dysplasia*** is found, it is usually in the context of an endoscopically visible lesion, which, if nodular, is removed by endoscopic mucosal resection for more accurate histological staging. If high-grade dysplasia is detected in the absence of any endoscopically visible lesion, high-dose proton pump inhibition is started and repeat biopsies taken within 3 months. Endoscopic ultrasound is frequently used to stage this patient group more accurately, in order to exclude cancer and associated significant lymphadenopathy.

Radiofrequency ablation (RFA) has superseded photodynamic therapy as the technique of choice for endoscopic treatment of dysplasia within Barrett's segments following removal of any nodular lesions, returning the oesophagus to squamous lining. The benefit of RFA in low-grade dysplasia is currently under evaluation.

Motility disorders

Achalasia

Achalasia is characterized by oesophageal aperistalsis and impaired relaxation of the LOS. The lower oesophageal pressure is elevated in more than half of patients.

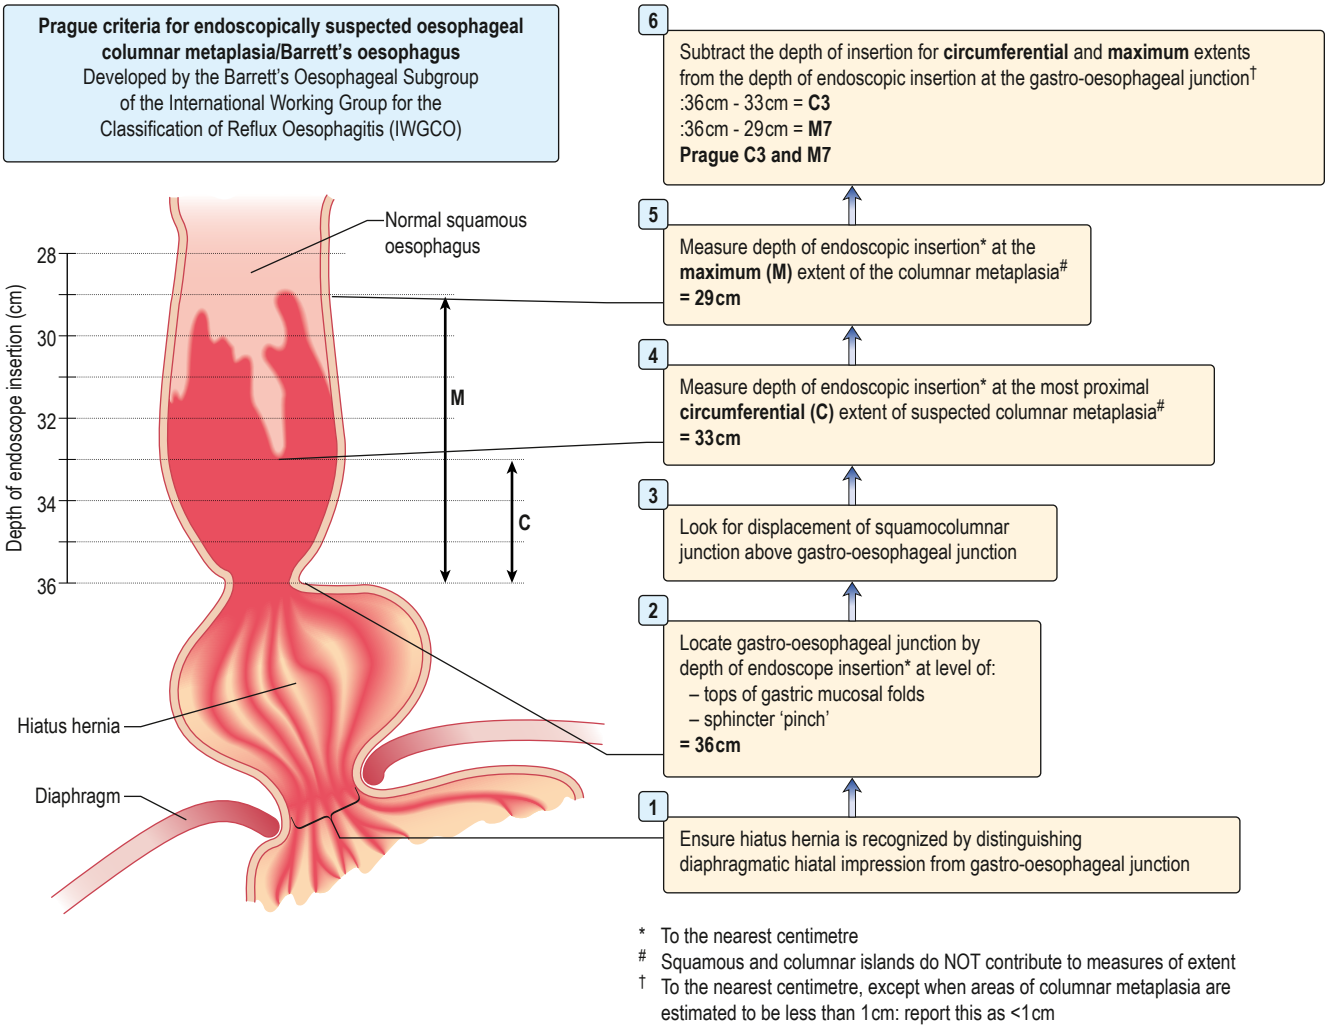

Fig. 22.18 The Prague criteria for endoscopically suspected oesophageal columnar metaplasia/Barrett's oesophagus.

Clinical features

The incidence of achalasia is 1:100000 and is equal in males and females. It occurs at all ages but is rare in childhood. Patients usually have a long history of intermittent dysphagia, characteristically for both liquids and solids from the onset. Regurgitation of food from the dilated oesophagus occurs, particularly at night, and aspiration pneumonia is a complication. Spontaneous chest pain occurs and is said to be due to oesophageal 'spasm'; it may be misdiagnosed as cardiac pain. Dysphagia may be mild and accepted by the patient as normal; weight loss is usually minimal.

Pathogenesis

The aetiology of achalasia is unknown, with autoimmune, viral, and neurodegenerative aetiologies all being postulated. A similar clinical picture is seen in chronic Chagas' disease (American trypanosomiasis; see Chapter 42), where there is damage to the neural plexus of the gut.

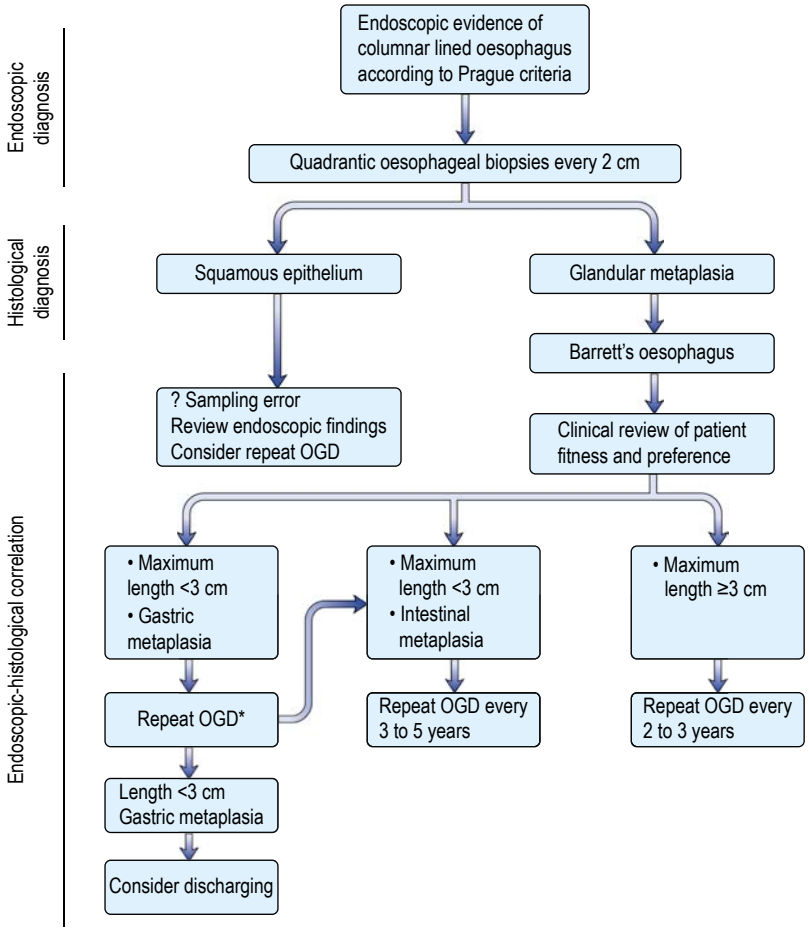
Histopathology shows inflammation of the myenteric plexus of the oesophagus with reduction of ganglion cell numbers. Cholinergic innervation appears to be preserved. Reduction in nitric oxide synthase-containing neurons has been shown by immunohistochemical staining. Pharmacological studies in patients with achalasia support the selective loss of ***inhibitory***, nitrergic neurons.

Differential diagnosis

The differential diagnosis of achalasia worldwide includes genetic syndromes, infectious diseases, neoplasms, and chronic inflammatory conditions.

Investigations

- ***Chest X-ray*** shows a dilated oesophagus, sometimes with a fluid level seen behind the heart. The fundal gas shadow is absent.
- ***Barium swallow*** shows lack of peristalsis and often synchronous contractions in the body of the oesophagus, sometimes with dilation. The lower end shows a 'bird's beak' due to failure of the sphincter to relax (Fig. 22.20).
- ***Oesophagogastroduodenoscopy*** is performed to exclude a carcinoma at the lower end of the oesophagus, as this can produce a similar X-ray appearance. When there is marked dilation, a 24-h liquid-only diet and a washout, prior to endoscopy, are useful to remove food debris. In true achalasia, the endoscope passes through the LOS with little resistance.



* Interval depends on the degree of clinical confidence about diagnosis (accuracy of endoscopic report and number of biopsies)

Fig. 22.19 British Society of Gastroenterology (BSG) Guidelines for surveillance.

- ***CT scan*** excludes distal oesophageal cancer.
- ***Manometry*** shows aperistalsis of the oesophagus and failure of relaxation of the LOS (Fig. 22.21).

There are three different subtypes (I, II, and III) based on findings of the high-resolution manometry. Type I is sometimes referred to as classic achalasia and is characterized by minimal oesophageal contractility. Type II features intermittent periods of oesophageal contraction and type III shows spastic or premature contractions of the distal oesophagus. All three types feature impaired relaxation of the LOS.

Management

All current forms of treatment for achalasia are ***palliative***. Drug therapy rarely produces satisfactory or durable relief; nitrates or sildenafil can be tried initially.

Endoscopic and surgical therapies are equally effective. Endoscopic dilation of the LOS, using a pneumatic balloon under X-ray control, weakens the sphincter and is initially successful in 80% of cases. About 50% of patients require a second or third dilation in the first 5 years. There is a low but significant risk of perforation. Intrasphincteric injection of botulinum toxin A produces satisfactory initial results but the effects wear off within months. Further injections can be given. It is safer and simpler than dilation, so may be valuable in patients at risk of death if a perforation occurs. Neither pneumatic dilation nor botulinum toxin works as well in younger patients.

Surgical division of the LOS, Heller's operation, usually performed laparoscopically, is the surgical treatment of choice. Per oral endoscopic myotomy (POEM) is a relatively novel technique, which is a division of the LOS using a gastroscope. This can be very effective method of treatment in all subtypes of achalasia.

Reflux oesophagitis complicates all procedures and aperistalsis of the oesophagus remains.

Complications

There is a slight increase in the incidence of squamous carcinoma of the oesophagus in both treated and untreated cases (7% after 25 years).

Systemic sclerosis

The oesophagus is involved in almost all patients with this disease. Diminished peristalsis and oesophageal clearance, detected manometrically (see Fig. 22.21) or by barium swallow, is due to replacement of the smooth muscle by fibrous tissue. LOS pressure is decreased, allowing reflux with consequent mucosal damage. Strictures may develop. Initially, there are no symptoms, but dysphagia and heartburn occur as the oesophagus becomes more severely involved. Similar motility abnormalities may be found in other autoimmune

rheumatic disorders, particularly if Raynaud's phenomenon is present. Treatment is as for reflux disease (see 'Gastro-oesophageal reflux disease/Management' section) and benign stricture.

Diffuse oesophageal spasm

This is a severe form of oesophageal dysmotility that can sometimes produce retrosternal chest pain and dysphagia. It can accompany GORD. Swallowing is accompanied by bizarre and marked contractions of the oesophagus without normal peristalsis (see **Fig. 22.21**). On barium swallow, the appearance may be that of a 'corkscrew' oesophagus. However, asymptomatic oesophageal 'dysmotility' is not infrequent, particularly in patients over the age of 60 years.

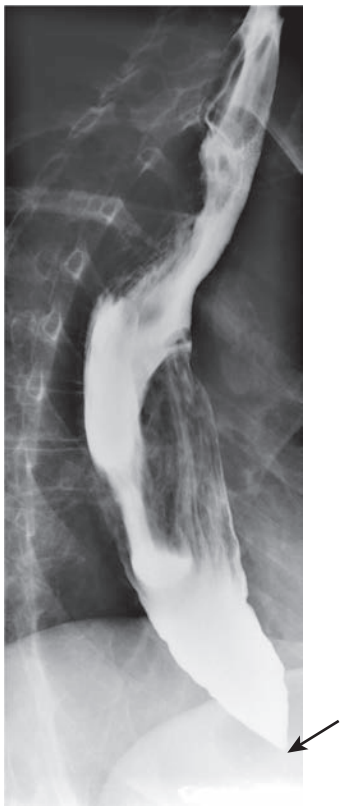


Fig. 22.20 Barium swallow demonstrating achalasia. The oesophagus is dilated and tapers inferiorly with a 'bird-beak' *(arrow)* appearance at the gastro-oesophageal junction.

A variant of diffuse oesophageal spasm is the 'nutcracker' oesophagus, which is characterized by very high-amplitude peristalsis (pressures >200 mmHg) within the oesophagus. Chest pain is more common than dysphagia.

Management

True oesophageal spasm producing severe symptoms is uncommon and treatment is often difficult. PPIs may be successful if reflux is a factor. Antispasmodics, nitrates, calcium-channel blockers, and γ-aminobutyric acid (GABA) receptor agonists (e.g., baclofen) are used. Occasionally, balloon dilation or even longitudinal oesophageal myotomy is necessary.

Miscellaneous motility disorders

Abnormalities of motility that occasionally produce dysphagia are found in the elderly, and in diabetes mellitus, myotonic dystrophy, oculopharyngeal muscular dystrophy, and myasthenia gravis, as well as neurological disorders involving the brainstem.

Other oesophageal disorders

Oesophageal diverticulum

Diverticula occur:

- immediately ***above*** the UOS (pharyngeal pouch—Zenker's diverticulum; see Chapter 21)
- near the ***middle*** of the oesophagus (traction diverticulum due to inflammation, or associated with diffuse oesophageal spasm or mediastinal fibrosis)
- just above the ***lower*** oesophageal sphincter (epiphrenic diverticulum—associated with achalasia).

Usually detected incidentally on a barium swallow performed for other reasons, these are often asymptomatic. Dysphagia and regurgitation can occur with a pharyngeal pouch, becoming more problematic as the diverticula increase in size. These can be treated surgically and endoscopically.

Rings and webs

An oesophageal web is a thin, membranous tissue flap covered with squamous epithelium. Most acquired webs are located anteriorly in the postcricoid region of the cervical oesophagus and are well seen on barium swallow. They may produce dysphagia. In the ***Plummer–Vinson syndrome*** (or ***Paterson–Brown–Kelly syndrome***), a web is associated with chronic iron deficiency anaemia, glossitis, and angular stomatitis. This rare syndrome affects mainly females and its aetiology is not understood. The web may be difficult to see at

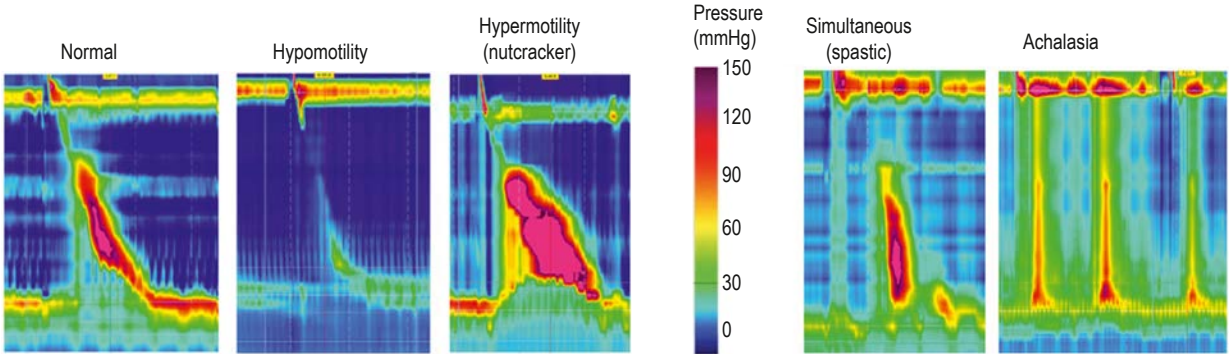

Fig. 22.21 High-resolution manometry of the oesophagus. Results are shown in the normal subject and in patients with hypomotility, hypermotility, simultaneous (spastic) contractions, and achalasia. Changes in colour reflect changes in pressure.

endoscopy and is often ruptured unintentionally by the passage of the endoscope. Dilation of the web is rarely necessary. Iron is given for the iron deficiency.

Lower oesophageal rings

Lower oesophageal rings are of two types:

- ***Mucosal (Schatzki's ring, also called B ring)*** is located at the squamocolumnar mucosal junction and is common (Fig. 22.22). It is associated with a characteristic history of intermittent bolus obstruction.
- ***Muscular (A ring)*** is located proximal to the mucosal ring and is uncommon. It is covered by squamous epithelium and may cause dysphagia.

Management for these rings is usually with reassurance and dietary advice, but dilation is occasionally necessary. After a single dilation, 68% of patients with Schatzki's rings are symptom-free at 1 year and 35% remain symptom-free after 2 years, but only 11% are symptom-free at 3 years. Many also respond to oral PPI, either alone or with dilation.

Benign oesophageal stricture

Peptic stricture (Fig. 22.23) secondary to reflux is the most common cause of benign strictures (for treatment, see 'Peptic stricture' section). They also occur after the ingestion of corrosives, radiotherapy, sclerotherapy of varices, and prolonged nasogastric intubation. Dysphagia is usually treated by endoscopic dilation. Surgery is sometimes required.

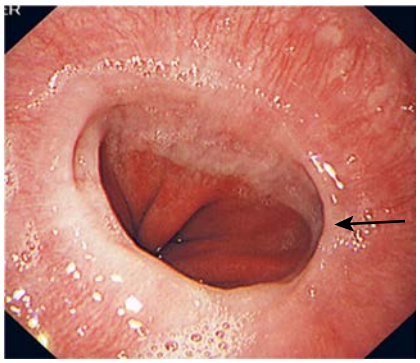

Fig. 22.22 Schatzki's ring. Endoscopic view.

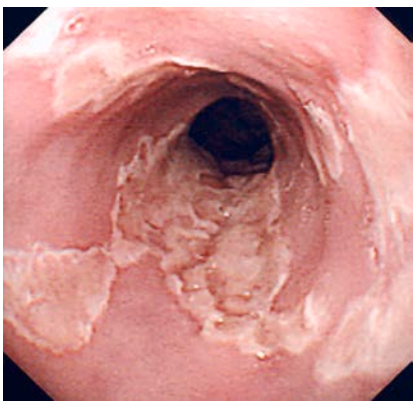

Fig. 22.23 Benign oesophageal reflux stricture. Endoscopic view.

Oesophageal infections

Infection is a cause of painful swallowing and is seen particularly in immunosuppressed (e.g., on chemotherapy) and debilitated patients, and in those with acquired immunodeficiency syndrome (AIDS). Infection can occur with:

- Candida
- herpes simplex
- cytomegalovirus
- *Mycobacterium tuberculosis.*

It is occasionally difficult to distinguish between these disorders on oesophagoscopy, as only widespread ulceration is seen. In candidiasis, the characteristic white plaques are frequently found; oral candidiasis is not always present. The diagnosis of *Candida* infection can be confirmed by examining a direct smear taken at endoscopy, but often infections are mixed and cultures and biopsies must be performed. Tuberculosis causes deep ulceration with associated mediastinal lymphadenopathy.

Management

Most patients on large doses of immunosuppressive agents are treated prophylactically for candidiasis with nystatin, fluconazole, or amphotericin. Antifungal or antiviral treatment is prescribed appropriately for other infections.

Mallory–Weiss syndrome

This is described in the 'Mallory–Weiss tear' section.

Eosinophilic oesophagitis

Eosinophils can be seen in the oesophageal mucosa (which is usually devoid of eosinophils microscopically) due to a variety of causes, such as eosinophilic (or allergic) oesophagitis and GORD.

Eosinophilic oesophagitis (Fig. 22.24) is increasingly recognized but its pathogenesis is unknown. There may be a personal or family history of allergic disorders, such as food allergy, eczema, or asthma.

Patients present with a long history of dysphagia, food impaction, 'heartburn', and oesophageal pain caused by the eosinophil-induced oesophageal inflammation. Usually, the patient is male and white, and has an average age at diagnosis of 35, but eosinophilic oesophagitis is becoming more common in children.

Typical endoscopic abnormalities include mucosal furrowing, loss of vascular pattern due to a thickened mucosa, plaques of eosinophilic surface exudate, and prominent circular folds, but the oesophagus may appear macroscopically normal. Reflux oesophagitis and Schatzki's rings may coexist. Endoscopic forceps biopsies

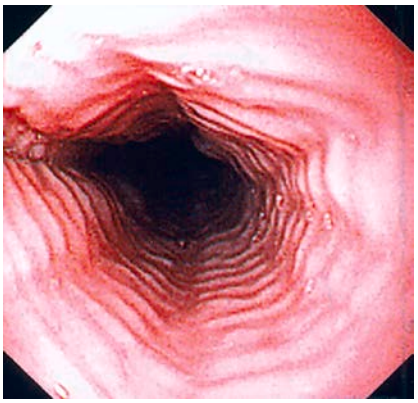

Fig. 22.24 Eosinophilic oesophagitis.

should be taken throughout the oesophagus for histology and eosinophil numbers calculated.

The eosinophilic infiltration of the oesophagus due to ***reflux disease*** tends to have a different microscopic appearance and fewer eosinophils.

Management

First-line treatment is with topical steroids, such as swallowing fluticasone spray or budesonide syrup. If this is not effective, systemic steroids or empirical elimination diets may also be used (dietary treatment is more beneficial in children). A cohort of patients respond to PPIs in the absence of GORD. Dilation is sometimes necessary, with a risk of perforation of 2%.

Oesophageal perforation

Oesophageal perforation most commonly occurs at the time of endoscopic dilation and, rarely, following insertion of a nasogastric tube, gastroscope, or transoesophageal echoprobe. Patients with malignant, corrosive, or post-radiotherapy strictures are more likely to perforate than those with a benign peptic stricture.

Management

This normally involves placement of an expanding covered oesophageal stent, which usually seals the hole. A water-soluble contrast X-ray is performed after 2 to 3 days to check the perforation has been sealed.

Oesophageal rupture

'Spontaneous' oesophageal rupture occurs with violent vomiting (Boerhaave's syndrome), producing severe chest pain and collapse in typical cases. Diagnosis can be difficult because classic symptoms are absent in about one-third of cases, and delays in presentation for medical care are common. Rupture may follow alcohol ingestion. A chest X-ray shows a hydropneumothorax. The diagnosis is made with a water-soluble contrast swallow or on CT. The mortality rate is approximately 35%, making it the most lethal perforation of the gastrointestinal tract. The best outcomes are associated with early diagnosis and definitive surgical management within 12 hours of rupture. If intervention is delayed longer than 24 hours, the mortality rate (even after surgery) rises to above 50%, and to nearly 90% after 48 hours.

Oesophageal tumours

Cancer of the oesophagus

This is the sixth most common cancer worldwide. Squamous cancers occurring in the middle third account for 40% of tumours, and for 15% in the upper third. Adenocarcinomas occur in the lower third of the oesophagus and at the cardia, and represent approximately 45% of tumours. Primary small cell cancer of the oesophagus is extremely rare.

Epidemiology and aetiology

Squamous cell carcinoma

The geographic variation in incidence is greater than for any other carcinoma—often in regions very close to one another. Squamous cell carcinoma (SCC) is common in Ethiopia, China, South and East Africa, and the Caspian regions of Iran. By contrast, North, Central, and West Africa have low rates.

In the UK, the incidence is 5 to 10 per 100 000 and SCC represents 2.2% of all malignant disease. The incidence is decreasing, in contrast to that of adenocarcinoma. SCC of the oesophagus is more common in men (2:1). Risk factors are shown in **Box 22.22**.

Box 22.22 Risk factors for cancer of the oesophagus

Squamous cell carcinoma
- Tobacco smoking
- High alcohol intake
- Plummer–Vinson syndrome
- Achalasia
- Corrosive strictures
- Coeliac disease
- Breast cancer treated with radiotherapy
- Tylosis[a]

Adenocarcinoma
- Longstanding heartburn
- Barrett's oesophagus
- Tobacco smoking
- Obesity
- Breast cancer treated with radiotherapy
- Older age

[a]Tylosis is a rare autosomal dominant condition with hyperkeratosis of the palms and soles.

High levels of alcohol consumption increase the risk of squamous cell cancer of the oesophagus, while tobacco use is associated with an increased incidence of both squamous cell and adenocarcinomas of the oesophagus. Smoking, obesity, and low fruit and vegetable consumption are implicated in approximately 9 in 10 squamous cell cancers of the oesophagus.

Diets rich in fibre, carotenoids, folate, vitamin C, and non-starchy vegetables probably decrease the risk of oesophageal cancer, whereas diets high in saturated fat, cholesterol, and refined cereals have been associated with an increased risk. Red and processed meat intake has been associated with an increased risk of both oesophageal SCC and adenocarcinoma. Conversely, fish and white meat consumption have been inversely associated with risk of oesophageal SCC in case–control studies from Italy, Switzerland, and Uruguay.

Adenocarcinoma

These tumours primarily arise in columnar-lined epithelium in the lower oesophagus. The incidence of this tumour is increasing in Western industrialized countries. It currently accounts for more than 70% of all new oesophageal cancer diagnoses. Extension of an adenocarcinoma of the gastric cardia into the oesophagus can present with the same symptoms. Previous reflux symptoms increase the risk up to eightfold and the risk is proportional to their severity.

Clinical features

Carcinoma of the oesophagus occurs mainly in those aged 60 to 70 years. Dysphagia is progressive and unrelenting. Initially, there is difficulty in swallowing solids but, typically, dysphagia for liquids follows within weeks. Impaction of food causes pain but more persistent pain implies infiltration of adjacent structures.

The lesion may be ulcerative, proliferative, or scirrhous, extending variably around the wall of the oesophagus to produce a stricture. Direct invasion of the surrounding structures and metastases to lymph nodes are more common than disseminated metastases. Weight loss, due to the dysphagia as well as to anorexia, is frequent. Oesophageal obstruction eventually causes difficulty in swallowing saliva, coughing, and aspiration into the lungs.

Weight loss, anorexia, and lymphadenopathy are the most common physical signs.

Investigations

Diagnosis

- ***Endoscopy*** provides histological proof of the carcinoma (Fig. 22.25A).
- ***Barium swallow*** can be useful where the differential diagnosis of dysphagia includes a motility disorder such as achalasia (see Fig. 22.25B).

Staging

The TNM staging system is used (see 'Gastric tumours/Staging' section); it is similar to the one used for gastric cancer. Tumour invasion of the wall of the oesophagus (T), presence of tumour in lymph nodes (N), and metastases (M) are combined into stage categories. Tumours arising in the cervical, thoracic, or abdominal oesophagus, including those that arise from within 5 cm from the gastro-oesophageal junction, share the same TNM staging criteria, but recent reclassification has differentiated between ***squamous*** and ***adenocarcinoma*** cancers.

- ***CT scan*** of the thorax and upper abdomen shows the volume of the tumour, local invasion, peritumoral and coeliac lymph node involvement, and metastases in the lung and elsewhere.
- ***MRI*** is equivalent to CT in local staging but not as good for pulmonary metastases.
- ***Endoscopic ultrasound*** has an accuracy rate of nearly 90% for assessing depth of tumour and infiltration, and of 80% for staging lymph node involvement. It is useful if CT has not already demonstrated that a cancer is too advanced for surgery. A fine-needle aspiration (FNA) of lymph nodes improves staging accuracy. Accurate T staging is necessary, as cancers confined to the superficial mucosa can be removed endoscopically (see Fig. 22.25C).
- ***Laparoscopy*** is useful if the tumour is at the cardia, to look for peritoneal and node metastases.
- ***PET*** after fluorodeoxyglucose is used principally to confirm distant metastases suspected on CT.

Management of oesophageal cancer is discussed in Chapter 41.

Other oesophageal tumours

Most other tumours are rare. ***Gastrointestinal stromal tumours*** (see Chapter 41) and ***leiomyomas*** (both submucosal tumours) are found usually by chance; 10% cause dysphagia or bleeding. Surgical removal is performed for symptomatic lesions or those over 3 cm, which are more likely to harbour malignancy. Small, benign tumours are relatively common and often do not require treatment.

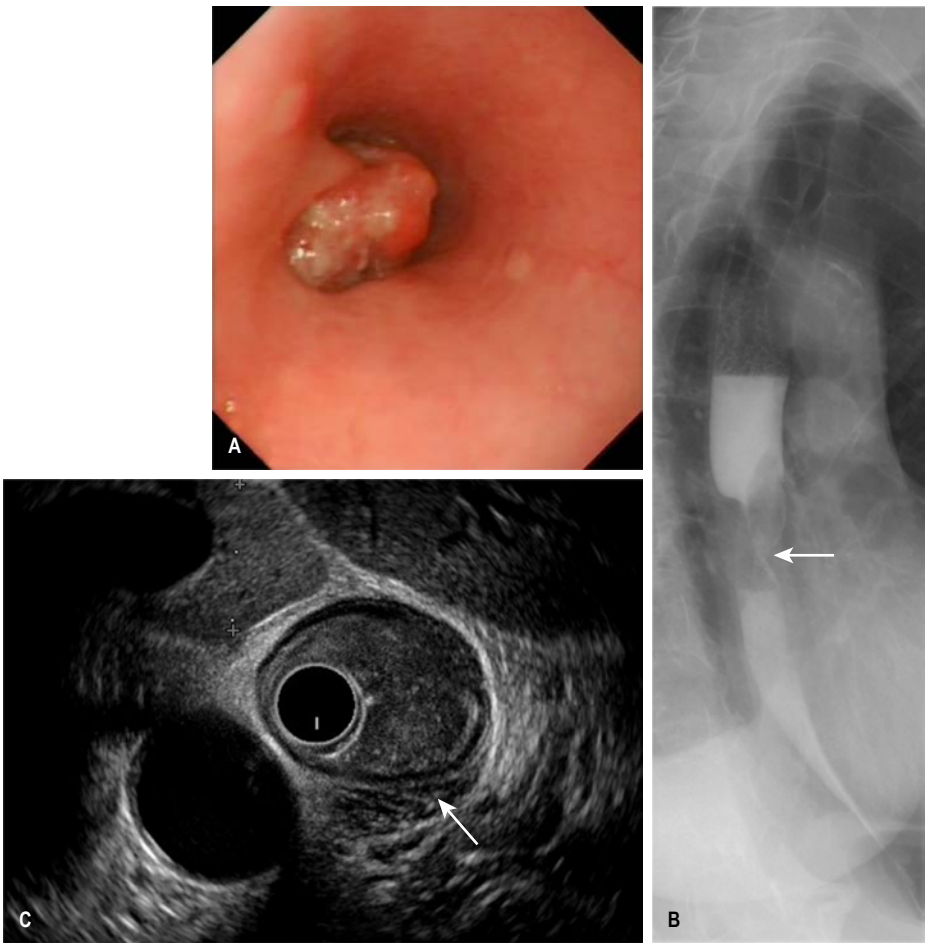

Fig. 22.25 Carcinoma of the oesophagus. **(A)** Endoscopic image. **(B)** Barium swallow demonstrating a tight stricture in the mid-oesophagus *(arrow)* due to oesophageal cancer. **(C)** Endoscopic ultrasound. The central concentric circles are the probe. The *arrow* points to a break in the muscle layer and the soft tissue mass of the carcinoma.

Kaposi's sarcoma is found in the oesophagus as well as the mouth (see Chapter 44) and hypopharynx in patients with AIDS.

Functional oesophageal disorders

The criteria for diagnosis rest mainly on compatible symptoms. However, pathological gastro-oesophageal reflux and eosinophilic oesophagitis may need to be excluded (see 'Eosinophilic oesophagitis' section).

Globus

This presents as:

- persistent or intermittent sensation of a lump or foreign body in the throat
- occurrence of the sensation between meals
- absence of dysphagia and pain on swallowing (odynophagia).

Management is with explanation and reassurance, and a trial of anti-reflux therapy. Antidepressants may be tried.

Functional chest pain of presumed oesophageal origin

This is characterized by episodes of mainly midline chest pain, not burning in nature, that are potentially of oesophageal origin and occur in the absence of a cardiological cause, gastro-oesophageal reflux, and achalasia.

More than half of patients will respond to high-dose acid-suppression therapy in the first week; some will respond to nitrates and calcium-channel blockers.

Antidepressant therapy, such as amitriptyline or the selective serotonin reuptake inhibitor (SSRI) citalopram, has been shown to be effective.

STOMACH AND DUODENUM

Gastritis and gastropathy

'Gastritis' indicates inflammation associated with mucosal injury (although the term is often used loosely by endoscopists to describe 'redness'), and ***'gastropathy'*** indicates epithelial cell damage and regeneration without inflammation.

Gastritis

Several classifications of gastritis (e.g., Sydney classification) have been proposed but are controversial due to lack of correlation between endoscopic and histological findings. *H. pylori* infection is the most common cause of gastritis, with autoimmune gastritis being seen in 5% of cases; the remaining causes include viruses (e.g., cytomegalovirus and herpes simplex), duodenogastric reflux and specific causes, for example, Crohn's, more common in children than adults. Chronic inflammation, particularly if induced by *H. pylori*, can lead to gastric intestinal metaplasia, a precursor to gastric cancer. The role of surveillance in these patients is unclear.

Autoimmune gastritis

This affects the fundus and body of the stomach (pangastritis), leading to atrophic gastritis and loss of parietal cells, with achlorhydria and intrinsic factor deficiency causing the clinical syndrome of 'pernicious anaemia' (see Chapter 38). Metaplasia, usually of the intestinal type, is almost always in the context of atrophic gastritis. Serum autoantibodies to gastric parietal cells are common and non-specific; antibodies to intrinsic factor are rarer and more significant.

Gastropathy

Gastropathy is usually caused by irritants (drugs, NSAIDs and alcohol), bile reflux, and chronic congestion. Acute erosive/haemorrhagic gastropathy can also be seen after severe stress (stress ulcers); secondary to burns (Curling ulcers), trauma, shock, or renal failure; and in portal hypertension (called portal gastropathy). The underlying mechanism for these ulcers is unknown but may be related to an alteration in mucosal blood flow.

Helicobacter pylori infection

Helicobacter pylori is a slow-growing, spiral, Gram-negative, flagellate, urease-producing bacterium (**Fig. 22.26**), which plays a major role in gastritis and peptic ulcer disease. It colonizes the mucous layer in the gastric antrum, but is also found in the duodenum in areas of gastric metaplasia. *H. pylori* is found in greatest numbers under the mucous layer in gastric pits, where it adheres specifically to gastric epithelial cells. It is protected from gastric acid by the juxtamucosal mucous layer, which traps bicarbonate secreted by antral cells, and ammonia produced by bacterial urease.

Epidemiology

The prevalence of *H. pylori* is high in low and middle income countries (80%–90% of the population) and much lower (20%–50%) in high income countries. Infection rates are highest in lower-income groups. Infection is usually acquired in childhood; although the exact route is uncertain, it may be faecal–oral or oral–oral. The incidence increases with age, probably due to acquisition in childhood when hygiene was poorer (cohort effect) rather than infection in adult life, which is most likely far less than 1% per year in high income countries.

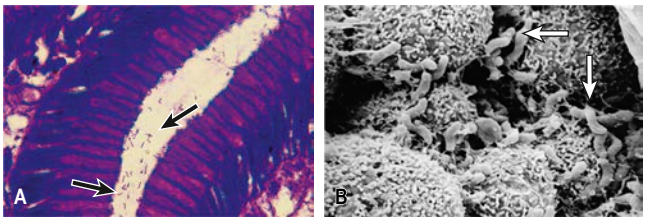

Fig. 22.26 ***Helicobacter pylori.*** **(A)** Organisms *(arrowed)* are shown on the gastric mucosa (cresyl fast violet (modified Giemsa) stain). **(B)** Scanning electron microscopy, showing the spiral-shaped bacterium *(arrowed)*. (*A, Courtesy of Dr Alan Phillips, Department of Paediatric Gastroenterology, Royal Free Hospital.*)

Pathogenesis

The pathogenetic mechanisms are not fully understood, with the majority of the colonized population remaining asymptomatic throughout their life. *H. pylori* is highly adapted to the stomach environment, exclusively colonizing gastric epithelium and inhabiting the mucous layer, or just beneath. It adheres by a number of adhesion molecules including BabA, which binds to the Lewis antigen expressed on the surface of gastric mucosal cells and causes gastritis in all infected subjects. Damage to the gastric epithelial cell is caused by the release of enzymes and the induction of apoptosis through binding to class II major histocompatibility complex (MHC) molecules. The production of urease enables the conversion of urea to ammonium and chloride, which are directly cytotoxic. Ulcers are most common when the infecting strain expresses *CagA* (cytotoxic-associated protein) and *VacA* (vacuolating toxin) genes secondary to a more pronounced inflammatory and immune response. Expression of *CagA* and *VacA* is associated with greater induction of interleukin 8 (IL-8), a potent mediator of gastric inflammation. Genetic variations in the host are also thought to be involved; for example, polymorphisms leading to increased levels of IL-1β are associated with atrophic gastritis and cancer.

Results of *H. pylori* infection

- Inflammation (antral gastritis and gastric intestinal metaplasia).
- Peptic ulcers (duodenal and gastric).
- Gastric cancer (see 'Adenocarcinoma' section).

Antral gastritis

Antral gastritis is the usual effect of *H. pylori* infection. It is normally asymptomatic, although patients without ulcers do sometimes experience relief of dyspeptic symptoms after *Helicobacter* eradication. Chronic antral gastritis causes hypergastrinaemia due to gastrin release from antral G cells. The subsequent increase in acid output is usually asymptomatic but can lead to duodenal ulceration.

Duodenal ulcer

The prevalence of *H. pylori* infection in patients with duodenal ulcers (DUs; Fig. 22.27A) is falling and in the developed world is now between 50% and 75%, whereas duodenal ulceration was once rare in the absence of *H. pylori* infection. This has been attributed to a decrease in prevalence of the bacterium and an increase in NSAID use. Eradication of the infection improves ulcer healing and decreases the incidence of recurrence.

The precise mechanism of duodenal ulceration is unclear, as only 15% of patients infected with *H. pylori* (50%–60% of the adult population worldwide) develop duodenal ulcers. Factors that have been implicated include increased gastrin secretion, smoking, bacterial virulence, and genetic susceptibility.

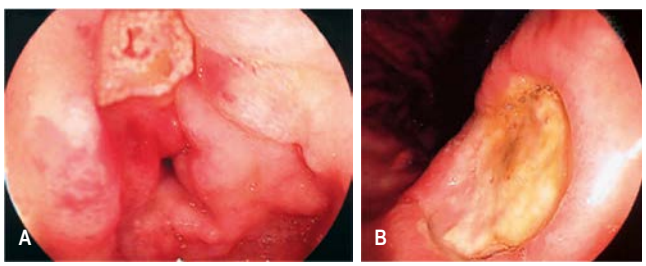

Fig. 22.27 Endoscopic views in *Helicobacter pylori* infection. (A) Duodenal ulcer with inflamed duodenal folds. **(B)** Benign gastric ulcer.

Gastric ulcer

Gastric ulcers (GUs; see Fig. 22.27B) are associated with a gastritis affecting the body as well as the antrum of the stomach (pangastritis), causing parietal cell loss and reduced acid production. The ulcers are thought to occur because of a reduction of gastric mucosal resistance due to cytokine production caused by the infection, or perhaps because of alterations in gastric mucus.

Peptic ulcer disease

A ***peptic ulcer*** consists of a break in the superficial epithelial cells penetrating down to the muscularis mucosa of either the stomach or the duodenum; there is a fibrous base and an increase in inflammatory cells. ***Erosions***, by contrast, are superficial breaks in the mucosa alone. DUs are most commonly found in the duodenal cap; the surrounding mucosa appears inflamed, haemorrhagic, or friable (duodenitis). GUs are most commonly seen on the lesser curve near the incisura, but can be found in any part of the stomach.

Epidemiology of peptic ulcer disease

DUs affect approximately 10% of the adult population and are two to three times more common than GUs.

Ulcer rates are declining rapidly for younger men and increasing for older individuals, particularly females. Both DUs and GUs are common in the elderly. There is considerable geographical variation, with peptic ulcer disease being more prevalent in low and middle income countries related to the high *H. pylori* infection. In the developed world, the percentage of NSAID-induced peptic ulcers is increasing as the prevalence of *H. pylori* declines.

Clinical features of peptic ulcer disease

The characteristic feature of peptic ulcer is recurrent, burning epigastric pain. It has been shown that if a patient points with a single finger to the epigastrium as the site of the pain, this is strongly suggestive of peptic ulcer disease. The relationship of the pain to food is variable and, on the whole, not helpful in diagnosis. The pain of a DU classically occurs at night (as well as during the day) and is worse when the patient is hungry, but this is not reliable. The pain of both GUs and DUs may be relieved by antacids.

Nausea may accompany the pain; vomiting is infrequent but can relieve the pain. Anorexia and weight loss may occur, particularly with GUs. Persistent and severe pain suggests complications, such as penetration into other organs. Back pain suggests a penetrating posterior ulcer. Severe ulceration can occasionally be symptomless, as many who present with acute ulcer bleeding or perforation have no preceding ulcer symptoms.

Untreated, the symptoms of a DU relapse and remit spontaneously. The natural history is for the disease to remit over many years due to the onset of atrophic gastritis and a decrease in acid secretion.

Epigastric tenderness is common in both ulcer and non-ulcer dyspepsia.

Diagnosis of Helicobacter pylori infection

Diagnosis of *H. pylori* is necessary if the clinician plans to treat a positive result. This is usually in the context of active peptic ulcer disease, previous peptic ulcer disease, or mucosa-associated lymphoid tissue (MALT) lymphoma, or to 'test and treat' patients with dyspepsia under the age of 55 with no alarm symptoms (i.e., weight loss, anaemia, dysphagia, vomiting or family history of gastrointestinal cancer). ***Examination*** is usually unhelpful.

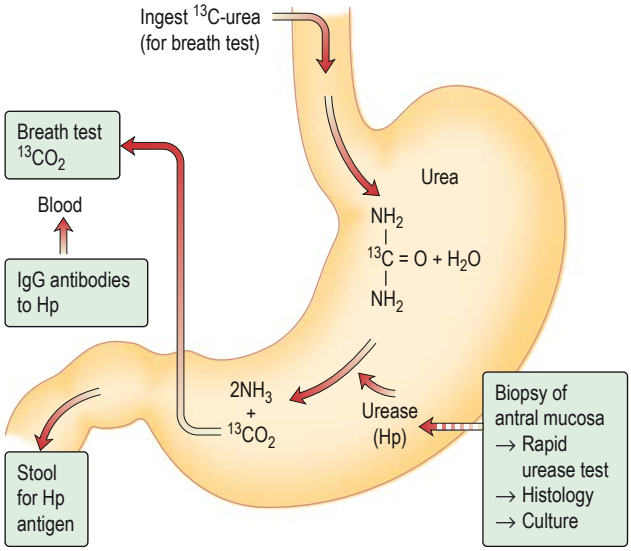

Fig. 22.28 Metabolism of urea by *Helicobacter pylori* (Hp). The different tests available for the detection of *H. pylori* are shown.

Non-invasive methods

- ***Serological tests*** detect immunoglobulin G (IgG) antibodies and are reasonably sensitive (90%) and specific (83%). They have been used in diagnosis and in epidemiological studies. IgG titres may take up to 1 year to fall by 50% after eradication therapy and therefore are not useful for confirming eradication or the presence of a current infection. Antibodies can also be found in the saliva but tests are not as sensitive or specific as serology.
- ***^{13}C-Urea breath test*** (Fig. 22.28) is a reliable test for *H. pylori* and can be used as a screening test. The measurement of $^{13}CO_2$ in the breath after ingestion of ^{13}C-urea requires a mass spectrometer. The test is sensitive (90%) and specific (96%), but the sensitivity can be improved by ensuring the patient has not taken antibiotics in the 4 weeks before the test and PPIs in the previous 2 weeks.
- ***Stool antigen test*** has superseded breath testing as the method used to determine *H. pylori* status. A specific immunoassay, using monoclonal antibodies for the qualitative detection of *H. pylori* antigen, is now widely available. The overall sensitivity is 97.6% and specificity is 96%. The test is useful in the diagnosis of *H. pylori* infection and for monitoring efficacy of eradication therapy. Patients should be off PPIs for 2 weeks but can continue with H_2-blockers. Newer stool antigen tests are being developed that can be performed in the clinic setting, although at present the sensitivity and specificity are not as good as for those performed in the laboratory.

Invasive methods (endoscopy)

- ***Biopsy urease test (Campylobacter-like organism—CLO test).*** Gastric biopsies, usually antral unless additional material is needed to exclude proximal migration, are added to a substrate containing urea and phenol red. If *H. pylori* is present, the urease enzyme that the bacteria produce splits the urea to release ammonia, which raises the pH of the solution and causes a rapid colour change (yellow to red). This enables patients' *H. pylori* status to be determined before they leave the endoscopy suite. The test may be falsely negative if patients are taking PPIs or antibiotics at the time.
- ***Histology.*** *H. pylori* can be detected histologically on routine (Giemsa) stained sections of gastric mucosa obtained at endoscopy. The sensitivity is reduced if a patient is on PPIs, but less so than with the urease test. Sensitivity can be improved with immunohistochemical staining using an anti-*H. pylori* antibody.
- ***Culture.*** Biopsies obtained can be cultured on a special medium, and *in vitro* sensitivities to antibiotics can be tested. This technique is typically used for patients with refractory *H. pylori* infection to identify the appropriate antibiotic regimen; routine culture is rare.

Investigation of suspected peptic ulcer disease

- ***Patients under 55 years of age***, with typical symptoms of peptic ulcer disease who test positive for *H. pylori*, can start eradication therapy without further investigation.
- ***Older patients*** require endoscopic diagnosis (see Fig. 22.27) and exclusion of cancer. All gastric ulcers must be biopsied to exclude an underlying malignancy and should be followed up endoscopically until healing has taken place.
- All patients with 'alarm symptoms' should undergo endoscopy:
  - iron deficiency anaemia
  - weight loss
  - anorexia
  - haematemesis/melaena
  - persistent vomiting
  - epigastric mass.

Management

Eradication therapy

Current recommendations are that all patients with duodenal and gastric ulcers should have *H. pylori* eradication therapy if the bacteria are present. Many patients have incidental *H. pylori* infection with no GU or DU. On balance, whether all such patients should have eradication therapy is controversial.

The increase in the prevalence of GORD and adenocarcinoma of the lower oesophagus in the last few years is currently unexplained, but has been postulated to be linked to eradication of *H. pylori*; this seems unlikely but is not disproven.

Depending on local antibacterial resistance patterns, standard eradication therapies in the developed world are successful in approximately 90% of patients. Re-infection is very uncommon (1%) in high income countries. In low and middle income countries, re-infection is more common, compliance with treatment may be poor, and metronidazole resistance is high (>50%, as it is frequently used for parasitic infections), so failure of eradication is common.

There are many regimens for eradication, but all must take into account that:

- Good compliance is essential.
- There is a high incidence of resistance to metronidazole and clarithromycin, particularly in some populations. Clarithromycin resistance has doubled in Europe in the last decade.
- Oral metronidazole has frequent side-effects.
- Bismuth chelate is unpleasant to take, even as tablets.

Metronidazole, clarithromycin, amoxicillin, tetracycline, and bismuth are the most widely used agents. Resistance to amoxicillin (1%–2%) and tetracycline (<1%) is low, except in countries where they are available without prescription, where resistance may exceed 50%. Quinolones (such as ciprofloxacin), furazolidone, and rifabutin are also used when standard regimens have failed ('rescue therapy'). None of these drugs is effective alone; eradication regimens therefore usually comprise two antibiotics, given with powerful acid suppression in the form of a PPI.

Bismuth-containing quadruple therapy is increasingly advocated as first-line treatment because of increasing clarithromycin resistance; the standard clarithromycin-based triple therapy has been replaced as the treatment of choice in areas where resistance is high.

Example regimens

- Omeprazole 20 mg + clarithromycin 500 mg and amoxicillin 1 g—all twice daily.
- Omeprazole 20 mg + metronidazole 400 mg and clarithromycin 500 mg—all twice daily.

These should be given for 7 or 14 days. Two-week treatments increase the eradication rates but increased side-effects may reduce compliance.

In ***eradication failures*** and in areas of clarithromycin resistance, bismuth chelate (120 mg 4 times daily), metronidazole (400 mg 3 times daily), tetracycline (500 mg 4 times daily), and a PPI (20–40 mg twice daily) for 14 days is used. Sequential courses of therapy are also used in such cases (5 days of PPI and amoxicillin, followed by a 5-day period of PPI with clarithromycin and tinidazole). With the increase in clarithromycin resistance, many are using this quadruple therapy for initial treatment.

Prolonged therapy with a PPI after a course of PPI-based 7-day triple therapy is not necessary for ulcer healing in most *H. pylori*-infected patients. The effectiveness of treatment for uncomplicated duodenal ulcer should be assessed symptomatically. If symptoms persist, breath or stool testing should be performed to check eradication (off PPI therapy).

Patients with a risk of bleeding or those with complications, such as haemorrhage or perforation, should always have a ^{13}C-urea breath test or stool test for *H. pylori* 6 weeks after the end of treatment to be sure that eradication has been successful. Long-term PPIs may be necessary if a rebleed would be likely to be fatal.

General measures

Stopping smoking should be strongly encouraged, as smoking slows mucosal healing.

Patients with gastric ulcers should be routinely re-endoscoped at 6 weeks to confirm mucosal healing and exclude an underlying gastric cancer. Repeat biopsies may be necessary.

Complications of peptic ulcer disease

Haemorrhage

See Chapter 11.

Perforation

The frequency of perforation of peptic ulceration is decreasing, partly because of medical therapy. DUs perforate more commonly than GUs, usually into the peritoneal cavity; perforation into the lesser sac also occurs. Detailed management of perforation is described in the 'Acute peritonitis/Management' section. Laparoscopic surgery is usually performed to close the perforation and drain the abdomen. Conservative management using nasogastric suction, intravenous fluids, and antibiotics is occasionally used in elderly and very sick patients.

Gastric outlet obstruction

The obstruction may be pre-pyloric, pyloric, or duodenal. The obstruction occurs either because there is an active ulcer with surrounding oedema or because the healing of an ulcer has been followed by scarring. However, obstruction due to peptic ulcer disease and gastric malignancy are now uncommon; Crohn's disease or external compression from a pancreatic carcinoma is a more common cause. Adult hypertrophic pyloric stenosis is a very rare cause.

After gastric outlet obstruction, the stomach becomes full of gastric juice and ingested fluid and food, giving rise to the main symptom of vomiting, usually without pain, as the characteristic ulcer pain has abated owing to healing.

Vomiting is infrequent, projectile, and large in volume; the vomitus contains particles of previous meals. On examination of the abdomen, there may be a succussion splash (**Fig. 22.29**). The diagnosis is made by endoscopy but can be suspected from the nature of the vomiting; by contrast, psychogenic vomiting is frequent, small volume, and usually noisy.

Severe or persistent vomiting causes loss of acid from the stomach and a hypokalaemic hypochloraemic metabolic alkalosis (see Chapter 27). Vomiting will often settle with intravenous fluid (0.9% NaCl solutions preferred in the presence of hypochloraemic alkalosis) and electrolyte replacement, gastric drainage via a nasogastric tube, and potent acid suppression therapy. Endoscopic dilation of the pyloric region is useful, as is luminal stenting, and overall, 70% of patients can be managed without surgery.

Surgical treatment and its long-term consequences

Once the mainstay of treatment, surgery is now used in peptic ulcer disease only for complications including:

- recurrent uncontrolled haemorrhage
- perforation, which is oversewn.

No other procedure, such as gastrectomy or vagotomy, is required.

In the past, two types of operation were performed: a partial gastrectomy or a vagotomy. In the latter, either a truncal vagotomy with a pyloroplasty or gastro-jejunostomy was performed, or highly selective vagotomy or proximal gastric vagotomy, which did not require a bypass procedure.

Long-term complications of surgery, which are still seen occasionally, include:

Fig. 22.29 Succussion splash. The patient is rocked gently while auscultating over the epigastrium; the presence of a 'sloshing' noise indicates gastric outlet obstruction. (*From* Clinical Examination, *Fourth Edition. B9780723434542500131/f07-62-9780723434542.*)

- ***Recurrent ulcer*.** If this occurs, check for *H. pylori*; rule out Zollinger–Ellison syndrome (see Chapter 24). Malignancy needs to be excluded in all cases.
- ***Dumping*.** This term describes a number of upper abdominal symptoms (e.g., nausea and distension associated with sweating, faintness, and palpitations) that occur in patients following gastrectomy or gastroenterostomy. It is due to 'dumping' of food into the jejunum, causing rapid fluid shifts from plasma to dilute the high osmotic load with reduction of blood volume. The symptoms are usually mild and patients adapt to them. It is rare for it to be a long-term problem, and if so, the symptoms usually have a functional element. Hypoglycaemia can also occur.
- ***Diarrhoea*.** This was chiefly seen after vagotomy. Recurrent severe episodes occurred in about 1% of patients. Antidiarrhoeals are the usual treatment.
- ***Nutritional complications*.** In the long term, almost any gastric surgery, but particularly gastrectomy, may be followed by:
  - iron deficiency, due to poor absorption
  - folate deficiency, usually due to poor intake
  - vitamin B_{12} deficiency, due to intrinsic factor deficiency
  - weight loss, usually due to reduced intake.

Other *H. pylori*-associated diseases

- ***Gastric adenocarcinoma*.** The incidence of distal (but not proximal) gastric cancer parallels that of *H. pylori* infection in countries with a high incidence of gastric cancer. Serological studies show that people infected with *H. pylori* have a higher incidence of distal gastric carcinoma (see 'Adenocarcinoma' section).
- ***Gastric B-cell lymphoma*.** Over 70% of patients with gastric B-cell lymphomas (MALT) have *H. pylori. H. pylori* gastritis has been shown to contain the clonal B cell that eventually gives rise to the MALT lymphoma (see 'Primary gastric lymphoma' section).

NSAIDs, Helicobacter and ulcers

Aspirin and other NSAIDs deplete mucosal prostaglandins by inhibiting the cyclo-oxygenase (COX) pathway, which leads to mucosal damage. Cyclo-oxygenase occurs in two main forms: COX-1, the constitutive enzyme; and COX-2, inducible by cytokine stimulation in areas of inflammation. COX-2-specific inhibitors have less effect on the COX-1 enzyme in the gastric mucosa; they still produce gastric mucosal damage but less than with other conventional NSAIDs. Their use is limited by concern regarding cardiovascular side-effects.

Some 50% of patients taking regular NSAIDs will develop gastric mucosal damage and approximately 30% will have ulcers on endoscopy. Only a small proportion of patients have symptoms (about 5%) and only 1% to 2% have a major problem: that is, gastrointestinal bleed or perforation. Because of the large number of patients on NSAIDs, including low-dose aspirin for vascular prophylaxis, this is a significant problem, particularly in the elderly.

H. pylori and NSAIDs are independent and synergistic risk factors for the development of ulcers. In a meta-analysis, the odds ratio (OR) for the incidence of peptic ulcer was 61.1 in patients infected with *H. pylori* and also taking NSAIDs, compared with uninfected controls not taking NSAIDs.

Management

- Stop the ingestion of NSAIDs.
- Give a PPI.
- Start *H. pylori* eradication therapy if the patient is *H. pylori*-positive.

In many people with severe arthritis, stopping NSAIDs may not be possible. Therefore use:

- ***An NSAID*** with low GI side-effects at the lowest dose possible. If there is low cardiovascular risk, a COX-2 NSAID can be considered (see Chapter 32).
- ***Prophylactic cytoprotective therapy***, such as PPI or misoprostol (a synthetic analogue of prostaglandin E_1 800 μg/day) for all high-risk patients, that is over 65 years, those with a peptic ulcer history, particularly with complications, and those on corticosteroid or anticoagulant therapy. PPIs reduce the risk of endoscopic duodenal and gastric ulcers and are better tolerated than misoprostol, which causes diarrhoea.

Gastroparesis

Gastroparesis results when there is delayed gastric emptying. There are a number of known causes such as:

- diabetes
- amyloidosis
- scleroderma
- parkinsonism
- multiple sclerosis
- stress
- medications (tricyclic antidepressants, dopamine agonists, calcium-channel blockers, octreotide, cyclosporine, glucagon-like peptide agonists, phenothiazines)
- post-surgical
- idiopathic.

Symptoms include nausea, vomiting, early satiety, fullness, bloating, and upper abdominal pain.

Investigation should exclude mechanical obstruction thus all patients with suspected delayed gastric emptying should undergo an OGD. Further imaging may then be needed with either CT/MRI or a barium meal. Once obstruction has been ruled out, the diagnosis of delayed gastric emptying is confirmed by scintigraphy. This is a nuclear medicine scan that determines the rate of gastric emptying. The patient must fast overnight before eating an isotope-labelled meal. The residual content of the stomach is then measured at 4 hours with more than 10% considered abnormal. Gastroduodenal manometry can help to differentiate between myopathic (amyloid, scleroderma) and neuropathic (diabetes) causes.

Management is directed at relief of symptoms and correction of nutritional deficiencies. Improvement of gastric emptying can sometimes be achieved by medical or surgical treatments, such as pro-motility agents (metoclopramide, domperidone, or erythromycin) or gastric pacemaker insertion. A diet of frequent, small, low-fibre meals can help symptoms in a number of patients. In diabetics, glycaemic control is helpful.

Functional dyspepsia

This is a disorder of gut–brain interaction (DGBI) and it is important to recognize that the majority of patients who present with dyspepsia symptoms are likely to have functional dyspepsia (FD). The main symptoms are those of epigastric pain/burning, early satiety, and postprandial fullness but can include belching, nausea/vomiting, and bloating. The Rome IV criteria state that symptoms need to have occurred for at least 3 months with onset at least 6 months prior to diagnosis. This syndrome overlaps with gastroparesis as one of the most common DGBIs and the two are often difficult to differentiate. It is likely that both disorders are part of the same spectrum with underlying pathological gastric neuromuscular dysfunction. However, there is also a complex interaction between psychopathology, gut barrier function, gut microbiome, immune system, and visceral

sensitivity to physical and chemical stimuli, which underlies these disorders.

Gastric-emptying studies (GES) can show delayed gastric emptying in a subset of patients but the correlation with symptoms is poor. Rapid gastric emptying and failure of proximal stomach accommodation can also be seen on GES. A detailed history can be enough for a positive diagnosis and this should be emphasized to patients. Upper GI endoscopy (± imaging) should be performed in the presence of red-flag symptoms but does not need to be undertaken for a diagnosis to be made.

Central to the management of FD and other DGBIs is clear, empathic communication with the patient. It is important to emphasize the chronic nature of many DGBIs but also that symptom improvement is attainable and patients can take ownership of this aspect of their care. The BSG guidelines for management of FD are very comprehensive and there is an algorithm to aid this (https://gut.bmj.com/content/71/9/1697). Briefly, this entails testing for and eradicating *H. pylori* if present, giving clear lifestyle advice regarding dietary triggers and the importance of exercise, acid suppression or prokinetics if helpful, trial of low-dose neuromodulators (e.g., tricyclic antidepressants such as amitriptyline) and referral for psychological therapies. There are a number of other foregut DGBIs which are listed in **Box 22.23** along with their common features.

Cyclical vomiting syndrome

This syndrome is characterized by typical bouts of intense vomiting lasting for hours to days, separated by periods with no symptoms. It can occur in children or adults. There is a link to migraine headaches but the cause is not known. In some cases, provocative triggers can be identified; for example, there is a specific syndrome associated with frequent cannabis use—cannabinoid hyperemesis syndrome (CHS).

Box 22.23 Foregut disorders of gut–brain interaction

Foregut DGBI	Features and management
Rumination syndrome	Regular vomiting preceded by high-pressure gastric contractions. Short-term bridging NJ feeding to other therapies may be indicated if malnourished.
Cyclical vomiting syndrome	Intermittent bouts of severe nausea and vomiting with periods of normality. Often associated with history of migraines. May need short hospital admission for parenteral fluids and antiemetics.
Centrally mediated abdominal pain and narcotic bowel syndrome	Continuous chronic pain despite escalating doses of narcotics (usually opioids). Optimize nutrition (avoid NG/NJ feeding if possible), reduce opiate doses. May need psychological support.
Somatoform disorder	Multiple overlapping functional symptoms. Needs psychiatric as well as gastroenterological input.
Avoidant Restrictive Food Intake Disorder (ARFID)	Severely restrictive food intake that is **not** driven by body image (i.e., disorded eating rather than an eating disorder) but rather by fear/anxiety/beliefs. Needs psychological and psychiatric input. Enteral tube feeding may be needed in the short term if malnourished.

Diagnosis of cyclical vomiting syndrome is by recognition of the pattern of symptoms and ruling out of other causes. Patients with CHS often report taking lengthy hot showers or baths, which provide short-term symptomatic relief.

Management

Treatment is with antiemetics and intravenous rehydration and electrolyte replacement during bouts, with avoidance of triggers where these are known. Prophylactic treatment of migraine, when it coexists, may help.

Gastric tumours

Adenocarcinoma

Gastric cancer is currently the fourth most common cancer found worldwide and the second leading cause of cancer-related mortality. The incidence increases with age (peak incidence 50–70 years), and it is rare under the age of 30 years. The highest incidence of the disease is found in Eastern Asia, Eastern Europe, and South America. The incidence in men is twice that in women and varies throughout the world, being high in Japan (M: 53/100000, F: 21.3/100000) and Chile, and relatively low in the USA (M: 7/100000, F: 2.9/100000). In the UK, carcinoma of the stomach (**Fig. 22.30**) is the eighth most common cancer (M: 16/100000, F: 9/100000). The overall worldwide incidence of gastric carcinoma is falling, even in Japan, probably due to reductions in the incidence of *Helicobacter* and, before this, improvements in food storage. However, the incidence of proximal gastric cancers is increasing in the West and they have very similar demographic and pathological features to Barrett's-associated oesophageal adenocarcinoma.

Epidemiology and pathogenesis

- ***H. pylori infection*** and distal gastric cancer are strongly linked. *H. pylori* is recognized by the International Agency for Research in Cancer (IARC) as a group 1 (definite) gastric carcinogen. *H. pylori* infection causes chronic gastritis, which eventually leads to atrophic gastritis and pre-malignant intestinal metaplasia (**Fig. 22.31**). Much of the earlier epidemiological data (i.e., the increase of cancer in lower socioeconomic groups) can be explained by the intrafamilial spread of *H. pylori.* Epstein–Barr virus is detected in 2% to 16% of gastric cancers worldwide, but its role in aetiology is not well understood.
- ***Dietary factors*** may also be involved (as both initiators and promoters) and have separate roles in carcinogenesis. Diets high in salt probably increase the risk. Dietary nitrates can be converted

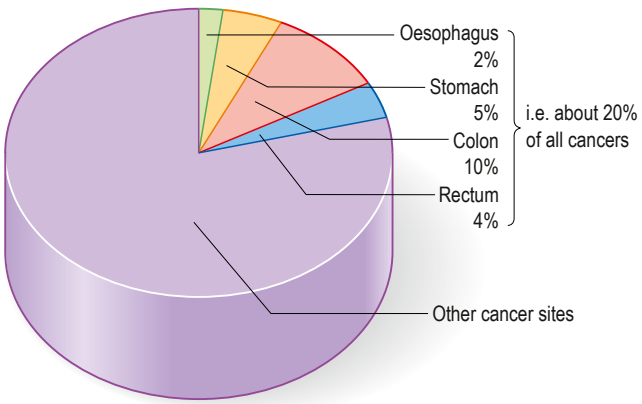

Fig. 22.30 Relative contribution of gastrointestinal sites to all cancers.

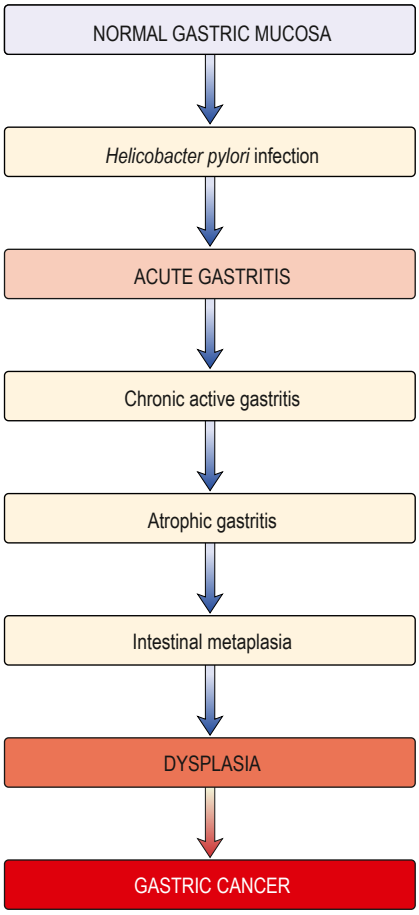

Fig. 22.31 Flow diagram showing the development of gastric cancer associated with *H. pylori* infection.

into nitrosamines by bacteria at neutral pH; nitrosamines are known to be carcinogenic in animals but the evidence in human carcinogenesis is limited. Nitrosamines are also present in the stomach of patients with achlorhydria, who have an increased cancer risk.

- ***Tobacco smoking*** is associated with an increased incidence of stomach cancer.
- ***Genetic abnormality*** is also a factor. The most common abnormality is a loss of heterozygosity (LOH) of tumour suppressor genes such as *p53* (in 50% of cancers, as well as in pre-cancerous states) and the gene encoding adenomatous polyposis coli *(APC)* (in over one-third of gastric cancers). These abnormalities are similar to those found in colorectal cancers. Some rare families with diffuse gastric cancer have been shown to have mutations in the E-cadherin gene *(CDH-1).* There is a higher incidence of gastric cancer in blood group A patients.
- ***First-degree relatives*** of patients with gastric cancer have a two- to threefold increased relative risk of developing the disease, but this may be environmental rather than inherited.
- ***Pernicious anaemia*** carries a small increased risk of gastric carcinoma due to the accompanying atrophic gastritis.
- ***Partial gastrectomy*** (postoperative stomach) carries an increased risk of gastric cancer, whether performed for a GU or DU; this is probably due to untreated *H. pylori* infection.

Screening

Earlier diagnosis has been advocated in an attempt to improve the poor prognosis of gastric cancer. Although the incidence of gastric cancer is falling in Japan, where aggressive screening by barium studies is followed by endoscopy if there is doubt, there is no evidence that screening has had an effect on overall mortality. Similarly, early investigation of dyspepsia has had little effect on mortality, possibly because of the relatively low prevalence of cancer.

Early gastric cancer

Early gastric cancer is defined as a carcinoma that is confined to the mucosa or submucosa, regardless of the presence of lymph node metastases. It is associated with 5-year survival rates of approximately 90%, but many of these patients would have survived 5 years without treatment. In Japan, mass screening with mobile units has increased the proportion of early gastric cancers (EGC) diagnosed. In a large series of patients from the UK with gastric cancer, only 0.7% were identified as having EGC. They are usually detected by chance, as although EGC exists in Western populations, endoscopists do not readily recognize it at present.

Pathology

There are two major types of gastric cancer:

- ***Intestinal (type 1)*** with well-formed glandular structures (differentiated). The tumours are polypoid or ulcerating lesions with heaped-up, rolled edges. Intestinal metaplasia is seen in the surrounding mucosa, often with *H. pylori.* This type is more likely to involve the distal stomach and occur in patients with atrophic gastritis. It has a strong environmental association.
- ***Diffuse (type 2)*** with poorly cohesive cells (undifferentiated) that tend to infiltrate the gastric wall. It may involve any part of the stomach, especially the cardia, and has a worse prognosis than the intestinal type. Loss of expression of the cell adhesion molecule E-cadherin is the key event in the carcinogenesis of diffuse gastric cancers. Unlike type 1 gastric cancers, type 2 cancers have similar frequencies in all geographic areas and occur in a younger population.

Some 50% of gastric cancers in Western countries occur in the proximal stomach.

Clinical features

Symptoms

Around 50% of patients with EGC discovered at screening have no symptoms. Most patients with carcinoma of the stomach have advanced disease at the time of presentation. The most common symptom of advanced disease is epigastric pain, indistinguishable from the pain of peptic ulcer disease; it may be relieved by food and antacids. The pain can vary in intensity but may be constant and severe, and there may also be nausea, anorexia, and weight loss. Vomiting is frequent and can be severe if the tumour encroaches on the pylorus. Dysphagia can occur with tumours involving the fundus. Gross haematemesis is unusual but anaemia from occult blood loss is frequent. No pattern of symptoms is suggestive of EGC.

Widely spreading submucosal gastric cancer causes diffuse thickening and rigidity of the stomach wall and is called ***'linitis plastica'***.

Patients can present at a late stage with malignant ascites or jaundice due to liver involvement. Metastases also occur in bone, brain and lung, producing appropriate symptoms.

Signs

Weight loss is often the dominant feature. Nearly 50% of patients have a palpable epigastric mass with abdominal tenderness. A palpable lymph node is sometimes found in the supraclavicular fossa (Virchow's node, usually on the left side), and metastases are

present in up to one-third of patients at presentation. This cancer is the most frequently associated with dermatomyositis (see Chapter 32) and acanthosis nigricans.

Diagnosis

Gastroscopy (Fig. 22.32) allows biopsies to be taken for histological assessment. Positive biopsies can be obtained in almost all cases of obvious carcinoma, but a negative biopsy does not necessarily rule out the diagnosis. For this reason, 8 to 10 biopsies should be taken from suspicious lesions. Diffuse-type gastric cancer infiltrates the submucosa and muscularis propria and can be undetected on endoscopy; multiple deep biopsies help.

Staging

- ***CT scan of the chest and abdomen*** with a gastric water load can demonstrate gastric wall thickening, lymphadenopathy, and lung and liver secondaries, but has limited ability to determine the depth of local tumour invasion.
- ***Endoscopic ultrasound*** is useful for local staging to demonstrate the depth of penetration of the cancer through the gastric wall and extension into local lymph nodes. It complements CT and ultrasound but is most relevant to confirm that a cancer is confined to the superficial mucosa, before endoscopic resection.
- ***Laparoscopy*** is useful in patients being considered for surgery to exclude serosal disease.
- ***PET and CT/PET*** can be helpful in further delineation of the cancer.

The TNM classification is used. The tumour grade (T) indicates depth of tumour invasion, N denotes the presence or absence of lymph nodes, and M indicates presence or absence of metastases. TNM classification is then combined into stage categories 0 to 4. At presentation, two-thirds of patients are at stage 3 or 4: that is, advanced disease (Box 22.24). The histological grade of the tumour also determines survival.

Management of gastric cancer is discussed in Chapter 41.

Gastrointestinal stromal tumours

Gastrointestinal stromal tumours (GISTs) are a subset of gastrointestinal mesenchymal tumours of varying differentiation. They are usually asymptomatic and found by chance but occasionally they can ulcerate and bleed. There are 200 to 900 new cases each year in the UK. GISTs mostly affect people between 55 and 65 years of age.

These tumours were previously classified as gastrointestinal leiomyomas, leiomyosarcomas, leiomyoblastomas, or schwannomas. Truly benign leiomyomas do occur, mainly in the oesophagus, but GISTs are now recognized as a distinct group of mesenchymal tumours and comprise about 80% of gastrointestinal mesenchymal tumours. They are of stromal origin and are thought to share a common ancestry with the interstitial cells of Cajal. They have varying differentiation, with mutations occurring in the cellular proto-oncogene *KIT* (which leads to activation and cell-surface expression of the tyrosine kinase KIT [CD 117]) in 80%, and also in platelet-derived growth factor receptor-α (PDGFRA) in up to 10% of patients.

Management

Treatment is surgical as far as possible. These tumours generally grow slowly but may be malignant. Imatinib, a tyrosine kinase inhibitor (see Chapter 41), is chosen for unresectable or metastatic disease, and is now used as adjunctive therapy after surgical removal of the primary in the absence of metastatic disease. Some patients are resistant to this; sunitinib can be used as an alternative agent over a short time period.

Primary gastric lymphoma

Mucosa-associated lymphatic tissue (MALT) lymphomas are indolent B-cell marginal zone lymphomas that primarily involve sites other than lymph nodes (gastrointestinal tract, thyroid, breast, or skin). They constitute about 10% of all types of non-Hodgkin's lymphoma (NHL).

Aetiology

About 90% of cases are due to *H. pylori* infection. Chromosome abnormalities t(1;14)(p22; q32) and t(11;18)(q21; q21) have also been noted in this form of NHL.

Box 22.24 Gastric cancer: staging and 5-year survival rates

Stage	TNM[a] stage	5-year survival (%)
1	T1N0M0, T1N1M0 or T2N0M0	88
2	T1N2M0, T2N1M0 or T3N0M0	65
3a	T2N2M0, T3N1M0 or T4N0M0	35
3b	T3N2M0	35
4	T4N1–3M0, TxN3M0 or TxNxM1[b]	5

[a]T, tumour; N, nodes; M, metastases.
[b]Tx indicates any T stage; Nx, any N stage.

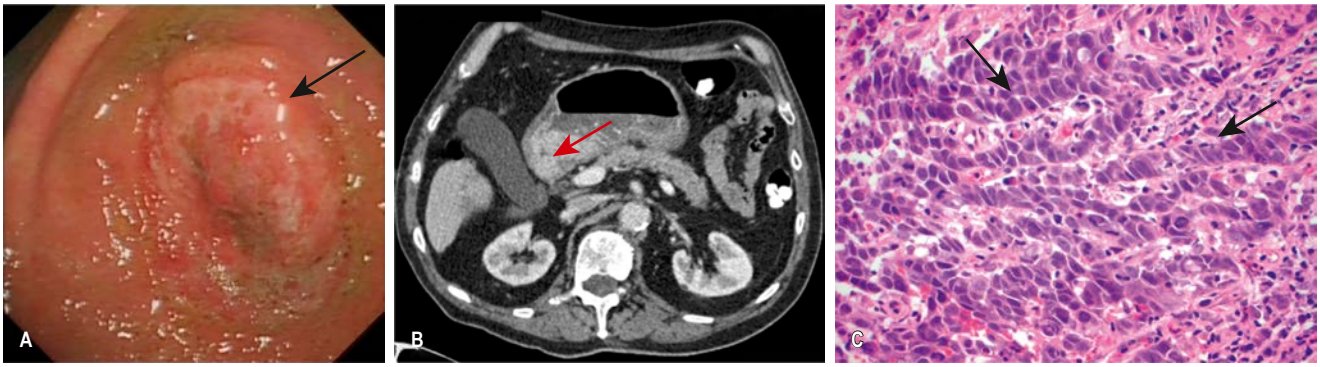

Fig. 22.32 Carcinoma of the stomach. **(A)** Endoscopic picture showing a large, irregular ulcer with rolled edges *(arrowed)*. **(B)** Axial CT scan *(ulcer arrowed)*. **(C)** Histopathology showing an adenocarcinoma *(arrowed)*.

Clinical features

Most patients are diagnosed in their 60s with stage I or stage II disease outside the lymph nodes. Patients have stomach pain, ulcers, or other localized symptoms, but rarely have systemic complaints such as fatigue or fever.

Management

Eradication of *H. pylori* infection may resolve cases of local gastric involvement. After standard eradication regimens, 50% of patients show resolution at 3 months. Other patients may resolve after 12 to 18 months of observation. Stage III or IV disease is treated with surgery or chemotherapy with or without radiation. The prognosis is good, with an estimated 90% 5-year survival.

Gastric polyps

Gastric polyps are found in about 1% of endoscopies, usually by chance. They rarely produce symptoms, but larger lesions can result in anaemia or haematemesis.

Endoscopic biopsy is the usual approach to diagnosis and treatment is possible polypectomy based on histological finding. Occasional large or multiple polyps may require surgery.

- ***Hyperplastic polyps*** are by far the most common type. Most are smaller than 2 cm. The polyps are rarely pre-malignant, but may be accompanied by pre-malignant atrophic gastritis.
- ***Adenomatous polyps*** are usually solitary lesions in the antrum. Approximately 3% progress to gastric cancer, especially if greater than 2 cm in diameter, but they are not a common cause of gastric cancer (compare this with colorectal cancer).
- ***Cystic gland polyps*** contain microcysts that are lined by fundic-type parietal and chief cells. They are located in the fundus and body of the stomach. They are found in otherwise normal subjects, but are especially common in familial polyposis syndromes and patients on PPIs. Their malignant potential is negligible, although low-grade dysplasia is seen in the absence of familial adenomatous polyposis coli (FAP), and high-grade dysplasia exclusively in its presence.
- ***Inflammatory fibroid polyps*** are benign spindle cell tumours infiltrated by eosinophils. Excision of these polyps is indicated because of their propensity to enlarge and cause obstruction.

ACUTE AND CHRONIC GASTROINTESTINAL BLEEDING

Acute upper gastrointestinal bleeding

The differential diagnosis, clinical approach, and emergency management of acute upper gastrointestinal bleeding are discussed in Chapter 11.

Endoscopic management of acute gastrointestinal bleeds

Endoscopy can detect the cause of haemorrhage in 80% or more of cases. These causes include:

- Oesophageal and gastric varices
- Ulcers
- Severe oesophagitis
- Dieulafoy lesion (vascular malformation)
- Malignancy.

It also enables risk stratification and allows therapy to be performed. Current guidance advises that endoscopy should be performed within 24 hours of presentation to hospital. If a patient is acutely unwell and haemodynamically unstable with a large UGI bleed they may need an emergency endoscopy performed under general anaesthetic rather than under sedation in the endoscopy department. Patients with pre-endoscopy Rockall scores of 0 or 1 may be candidates for immediate discharge and early outpatient endoscopy, depending on local policy (see Box 11.41).

The method of endoscopic therapy will depend on the cause of bleeding.

- Oesophageal varices are treated with band ligation if they are large, have high-risk stigmata (cherry red spots, red wale markings), or are actively bleeding.
- Gastric varices cannot be banded and need to be injected with cyanoacrylate glue if they are large, actively bleeding, or have high-risk stigmata.
- Ulcers that are actively bleeding or show stigmata of recent bleeding (visible vessel or adherent clot) should be treated with at least two, and sometimes three, haemostatic methods. These include injection with adrenaline (epinephrine), endoscopic clipping, and thermal coagulation (with heater probe, bipolar probe, or argon plasma coagulation). Dual and triple therapy is more effective than monotherapy in reducing re-bleeding.
- Malignancy-related bleeds are often difficult to control. The surrounding tissue may be very friable and not amenable to endoscopic clipping or thermal coagulation. Haemostatic powders that are applied widely to the bleeding area through a catheter at endoscopy can be very useful here and in challenging ulcers.
- In the case of uncontrollable portal hypertensive bleeding (oesophageal or gastric varices) where endoscopic management is not possible, a Sengstaken-Blakemore tube should be inserted under endoscopic vision. A Danis stent can be used in cases of oesophageal variceal bleeding. These can remain *in situ* for up to a week and do not require a patient to be intubated but are slightly more complex to insert and remove.
- All patients with a gastric ulcer should be rescoped 8 weeks later to check for healing and to rule out a malignancy.
- Antral biopsies for *H. pylori* should be taken although in reality many patients with duodenal ulcers will be commenced on empirical eradication therapy.

Following endoscopy, calculation of the post-endoscopy Rockall score gives an indication of the risk of rebleeding (see Box 11.42). In patients with peptic ulcers, stigmata of recent bleed indicate a higher risk of rebleeding.

Specific conditions associated with acute gastrointestinal bleeding

Oesophageal varices

These are discussed in Chapter 23.

Mallory–Weiss tear

This is a linear mucosal tear occurring at the oesophagogastric junction and produced by a sudden increase in intra-abdominal pressure. It often follows a bout of coughing or retching, and is classically seen after alcoholic ‘dry heaves’. There may, however, be no antecedent history of retching. Most bleeds are minor and discharge is usual within 24 hours. The haemorrhage may be large

but most patients stop spontaneously. Early endoscopy confirms diagnosis and allows therapy such as clipping if necessary. Surgery with oversewing of the tear is rarely needed.

Chronic peptic ulcer

Eradication of *H. pylori* is started as soon as possible (see 'Eradication therapy' section). A PPI is continued for 4 weeks to ensure ulcer healing. Eradication of *H. pylori* should always be checked in a patient who has bled, and long-term acid suppression is given if *H. pylori* eradication cannot be achieved. If bleeding is not controlled, the patient should either undergo angiography and embolization or be referred directly for surgery.

Gastric carcinoma

Most of these patients do not have large bleeds but surgery is occasionally necessary for uncontrolled or repeat bleeding. Usually, surgery can be delayed until the patient has been fully evaluated (see 'Primary gastric lymphoma' section). Oozing from gastric cancer is very difficult to control endoscopically. Radiotherapy can occasionally be successful but its effects are not immediate.

Bleeding after percutaneous coronary intervention

In the era of ever more aggressive percutaneous coronary intervention (PCI), the list of antithrombotic medication grows longer: glycoprotein IIb/IIIa inhibitors, unfractionated heparin, low-molecular-weight heparin, fondaparinux and platelet inhibitors (e.g., clopidogrel, prasugrel, and ticagrelor). Taken in addition to the oral anticoagulants that this group of patients are often taking, these give rise to a gastrointestinal bleeding rate of approximately 2% of patients undergoing PCI (who are on antiplatelet therapy, e.g., clopidogrel), and there is a high mortality of 5% to 10%. It has become increasingly evident in this patient group that gastroscopy should be performed on an urgent basis and not deferred for days or weeks. A bolus of intravenous PPI is administered, followed by an infusion; platelet infusion is given to counter the effect of clopidogrel. Management is difficult, as cessation of antiplatelet therapy has a high risk of acute stent thrombosis and also an associated high mortality. Using a risk assessment score (e.g., Blatchford), a reasonable approach is to temporarily pause antiplatelet therapy in high-risk patients but continue it in low-risk ones. This can be restarted once endoscopic haemostasis has been achieved and the patient is stable. Co-prescribed proton pump inhibition does not decrease the antiplatelet effect of clopidogrel, as was first thought. These patients should be under the combined care of a cardiologist and a gastroenterologist.

Prognosis

The mortality from gastrointestinal haemorrhage has not changed from 5% to 12% over the years, despite many changes in management, mainly because of a demographic shift to more elderly patients with co-morbidity. The lowest mortality rates are achieved in dedicated medical/surgical gastrointestinal units.

Acute lower gastrointestinal bleeding

Massive bleeding from the lower gastrointestinal tract is rare and is usually due to diverticular disease or ischaemic colitis. Common causes of small bleeds are haemorrhoids and anal fissures (**Fig. 22.33**).

Management

Most acute lower gastrointestinal bleeds start and stop spontaneously. The few patients who continue bleeding and are haemodynamically unstable need resuscitation using the same principles as for upper gastrointestinal bleeding (see Chapter 11).

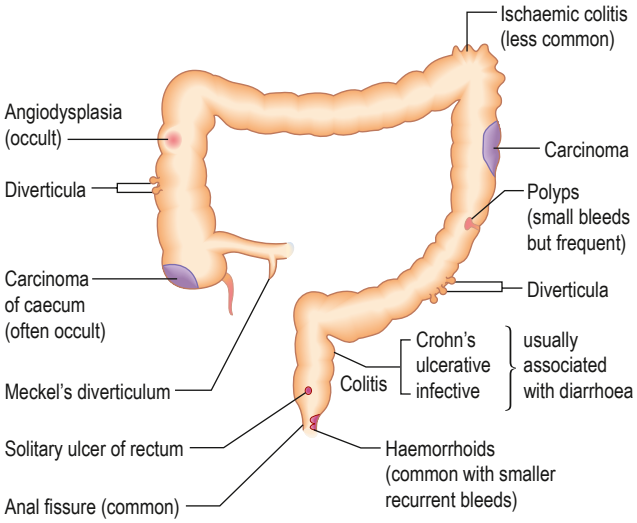

Fig. 22.33 Causes of lower gastrointestinal bleeding. The sites shown are illustrative—many of the lesions can be seen in other parts of the colon.

The diagnosis and management of lower gastrointestinal bleeding can present more of a challenge compared with upper gastrointestinal bleeding—nearly a quarter of patients who present to hospital in the UK with lower gastrointestinal bleeding are discharged home without a definitive diagnosis.

Current guidelines advise that patients who are clinically suspected to have an active bleed or are haemodynamically unstable should undergo an urgent CT angiogram. If this detects an active bleed, this should be treated endoscopically or using interventional radiology techniques, such as embolization. If this is unsuccessful then salvage surgery may be needed in those patients fit to undergo an emergency operation.

Stable patients who present with a lower gastrointestinal bleed should be categorized as a major or minor bleed using a risk assessment tool (e.g., Oakland score which uses age, gender, heart rate, blood pressure, and haemoglobin). Patients who are low risk can be discharged with a plan for outpatient investigation (usually colonoscopy as first line). Patients with a major bleed should be admitted to hospital for lower gastrointestinal endoscopy. If no lesion is found and the patient continues to have bleeding then further investigations with CT angiography and/or video capsule endoscopy (**Fig. 22.34**) can be considered.

In all patients, consideration should be taken with regard to holding or reversing anticoagulants or antiplatelet therapy.

Chronic gastrointestinal bleeding

Patients with chronic bleeding usually present with iron deficiency anaemia (see Chapter 38).

Chronic blood loss producing iron deficiency anaemia in males, and in females after the menopause, is always due to bleeding from the gastrointestinal tract. The primary concern is to exclude cancer, particularly of the stomach or right colon, and coeliac disease. Stool tests detecting occult blood (e.g., faecal immunohistochemical test, FIT) are insufficiently sensitive in this setting.

Diagnosis

Chronic blood loss can occur with any lesion of the gastrointestinal tract that produces acute bleeding (see Figs. 11.24 and 22.33). However, oesophageal varices usually bleed overtly and rarely present as chronic blood loss. Although uncommon in high income

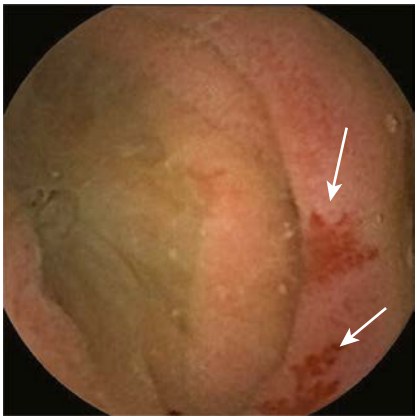

Fig. 22.34 **Angiodysplastic lesions *(arrows)* seen on video capsule endoscopy.**

countries, hookworm is the most common worldwide cause of chronic gastrointestinal blood loss.

History and examination may indicate the most likely site of the bleeding, but if no clue is available, it is usual to investigate both the upper and lower gastrointestinal tract endoscopically at the same session ('top and tail'), especially in males and postmenopausal females:

- ***Upper gastrointestinal endoscopy*** is usually performed first. Duodenal biopsies should always be taken to diagnose coeliac disease, even if coeliac serology has been performed.
- ***Colonoscopy*** follows and any lesion should be biopsied or removed, though it is unsafe to assume that colonic polyps are the cause of chronic blood loss.
- ***Unprepared CT*** scanning is a reasonable test to look for colon cancer in frail patients.
- ***CT colonography*** can be used as an alternative to colonoscopy.

If gastroscopy, colonoscopy, and duodenal biopsy have not revealed the cause, investigation of the small bowel is necessary. ***Capsule endoscopy*** is the diagnostic investigation of choice but currently has no therapeutic ability. Positive diagnostic yield varies from 60% to 85%, depending on series. Bleeding lesions can be identified and later treated with balloon-assisted enteroscopy.

Occasionally, intravenous technetium-labelled colloid may be used to demonstrate a potential bleeding site in a Meckel's diverticulum.

Management

The cause of the bleeding should be dealt with, if found. Oral iron is given to treat anaemia (see Chapter 38), although intravenous infusions are occasionally required. Some patients will require maintenance with regular transfusion as a last resort.

SMALL INTESTINE

Irritable bowel syndrome

Irritable bowel syndrome (IBS) is the most common functional gastrointestinal disorder. In Western populations, up to 1 in 5 people report symptoms consistent with IBS. Approximately 50% will consult their doctors and, of these, up to 30% will be referred by their doctor to a hospital specialist. Up to 40% of all patients seen in specialist gastroenterology clinics will have IBS. Estimates in the UK put the annual cost of IBS to healthcare resources as £45.6 million; in the USA, the cost is higher at $8 billion. In the UK, approximately one-quarter of IBS patients take time off work for periods ranging from 7 to 13 days each year.

The factors that determine whether an IBS sufferer in the community seeks medical advice include higher illness attitude scores and higher anxiety and depression scores than non-consulters. Consulters perceive that their symptoms are more severe than those of non-consulters, and consulting behaviour may be determined by the number of presenting symptoms. Female consulters outnumber male consulters by a factor of 2–3 to 1.

Box 22.25 Non-gastrointestinal features of irritable bowel syndrome

Gynaecological symptoms
- Painful periods (dysmenorrhoea)
- Pain following sexual intercourse (dyspareunia)

Urinary symptoms
- Frequency
- Urgency
- Passing urine at night (nocturia)
- Incomplete emptying of bladder

Other symptoms
- Joint hypermobility
- Back pain
- Headaches
- Bad breath, unpleasant taste in the mouth
- Poor sleeping
- Fatigue

Box 22.26 Some factors that can trigger onset of irritable bowel symptoms

- Affective disorders, for example, depression, anxiety
- Psychological stress and trauma
- Gastrointestinal infection
- Antibiotic therapy
- Sexual, physical, or verbal abuse
- Pelvic surgery
- Eating disorders

IBS—a multisystem disorder

IBS patients suffer from a number of non-intestinal symptoms (**Box 22.25**), which may be more intrusive than the classical features. IBS coexists with chronic fatigue syndrome (see Chapter 30), fibromyalgia (see Chapter 32), and temporomandibular joint dysfunction.

The biopsychosocial conceptualization of the pathogenesis and clinical expression of FGIDs is particularly relevant to IBS (see **Fig. 22.11**), and **Box 22.26** lists some common factors that have been shown to trigger IBS symptoms. Infectious diarrhoea precedes the onset of IBS symptoms in 7% to 30% of patients. Whether this is a factor for all patients or just a small subgroup remains controversial. Risk factors in these patients have been shown to include female sex, severity and duration of diarrhoea, pre-existing adverse life events, and high hypochondriacal anxiety and neurotic scores at the time of the initial illness. Symptoms of anxiety and depression are more common in IBS patients, and stress or adverse life events often precede the onset of chronic bowel symptoms.

Box 22.27 Subtyping irritable bowel syndrome by predominant stool pattern

Type	Description
IBS with constipation (IBS-C)	Hard lumpy stools >25% and loose (mushy) or watery stools <25% of bowel movements
IBS with diarrhoea (IBS-D)	Loose (mushy) or watery stools >25% and hard or lumpy stools <25% of bowel movements
Mixed IBS (IBS-M)	Hard or lumpy stools >25% and loose (mushy) or watery stools >25% of bowel movements
Unsubtyped IBS	Insufficient abnormality of stool consistency to meet criteria for IBS-C, D, or M

Diagnosis

Diagnostic criteria (Rome IV 2016) state that, in the preceding 3 months, there should be at least 1 day per week in the last 3 months of recurrent abdominal pain associated with two or more of the following:

1. Related to defecation.
2. Onset associated with a change in frequency of stool.
3. Onset associated with a change in form (appearance) of stool.

These are useful for comparative studies. Subgroups of IBS patients can be identified according to the criteria listed in **Box 22.27**.

The decision as to whether to investigate and the choice of investigations should be based on clinical judgement. Pointers to the need for thorough investigation are the presence of the above symptoms in association with rectal bleeding, nocturnal pain, fever and weight loss, and a clinical suspicion of organic diarrhoea. A raised stool calprotectin or lactoferrin would suggest inflammation needing further investigation.

Management

Current strategies for the treatment of IBS include therapies which target central and end-organ pathways (**Box 22.28**); these are not mutually exclusive.

Patients with IBS are often worried that their symptoms are due to a serious disease such as cancer. Alarm symptoms much be investigated when present. However, a positive diagnosis of IBS with an explanation of the symptoms and reassurance is often helpful and may require no further investigation or treatment. It is helpful to establish and maintain a good clinician–patient relationship from the beginning. **Box 22.28** shows the overall management strategies used in IBS for those with severe and longstanding problems. Lifestyle and dietary modifications should be the mainstay of management for patients with mild–moderate symptoms with pharmacologic therapy used adjunctively for those who fail to respond or who have more severe symptoms.

Pain/gas/bloat syndrome/midgut dysmotility

Disordered motility and visceral sensation that predominantly affects the small intestine or midgut results in symptoms of pain and bloating without altered defecation. Other symptoms include postprandial fullness, nausea and, on occasions, anorexia and weight loss.

Management of patients with pain/gas/bloat syndrome is not easy, and in some, pain can be chronic and severe. The main approaches are summarized below:

- Narcotics should always be avoided.

Box 22.28 Approaches to the management of the irritable bowel syndrome

Treatment modality	Action
End-organ treatment	
Exploration of dietary triggers	Refer to dietician
High-fibre diet ± fibre supplements for constipation, low FODMAP diet for bloating	Refer to dietician
Alteration of microbiota	Rifaximin has shown short-term benefit in IBS patients without constipation (target I and II trials) Pro- and prebiotics
Antidiarrhoeal drugs for bowel frequency	Loperamide Codeine phosphate Co-phenotrope [a]Eluxadoline
Constipation	5-HT_4 receptor agonist, e.g., prucalopride
Smooth muscle relaxants for pain	Mebeverine hydrochloride Dicycloverine hydrochloride Peppermint oil
Central treatment	
Explanation of physiology and symptoms	At consultation (leaflets with diagrams help)
Psychotherapy	Refer to clinical psychologist (see Chapter 30)
Hypnotherapy	
Cognitive behavioural therapy	Refer to psychiatrist
Antidepressants	Functional diarrhoea—clomipramine Diarrhoea-predominant IBS—tricyclic group, e.g., amitriptyline Constipation-predominant IBS—SSRI, e.g., paroxetine

FODMAP, Fermentable oligo-, di- and monosaccharides and polyols; *SSRI*, selective serotonin reuptake inhibitor.
[a]Eluxadoline—a μ- and κ-opioid receptor agonist and δ-opioid receptor antagonist.

- Central and end-organ-targeted treatment approaches should be combined: for example, the SSRI paroxetine combined with a prokinetic agent, such as domperidone, or a smooth muscle relaxant, such as ***mebeverine***.
- Small bowel bacterial overgrowth can be a contributory feature that can be treated with non-absorbed antibiotics such as ***rifaximin***, however this is expensive and cheaper antibiotics such as doxycycline can also offer symptomatic benefit.
- Research has highlighted the benefit of altering the fermentable components of the diet. A diet with reduced fermentable oligo-, di- and monosaccharides and polyols (low ***FODMAP***) will exclude a range of food types, including garlic, onions, specific beans, fructose-containing fruit, wheat-containing products, and certain natural and synthetic sweeteners. Small sham-diet-controlled clinical trials have shown significant benefits in patients with functional symptoms but long-term randomized controlled studies are necessary.
- The role of **probiotics** for management of IBS patients is not yet clear. A recent meta-analysis found some evidence for the efficacy of various probiotics in helping with symptoms such as pain, bloating, and flatulence but with varying methodological limitations in most of the studies. Two studies found

that *Bifidobacterium infantis* versus placebo led to symptomatic improvement in patients with IBS. It is likely that future work will focus on subgroups of patients, particularly those with diarrhoea-predominant IBS, and aim to correct the microbiome on an individual level according to the particular alterations of the compositional flora rather than give a generic probiotic.

Some patients with pain/gas/bloat syndrome have particularly severe and chronic symptoms, which may be nocturnal. A small subgroup of these has been shown to have manometric features consistent with a diagnosis of ***chronic idiopathic intestinal pseudo-obstruction (CIIP)***, and specifically of an enteric neuropathy. Full-thickness small intestinal biopsies confirm this diagnosis by showing a deficiency of α actin staining in the inner circular layer of smooth muscle. More appropriately, these patients should be considered as having a gastrointestinal neuromuscular disorder of the gut. About 10% of these individuals are subsequently found to have an underlying autoimmune overlap disorder (see Chapter 32).

Management of patients with neuromuscular disorders of the gut requires a multidisciplinary approach, with an emphasis on the management of pain, psychological state, and nutrition. Patients with underlying autoimmune rheumatic disorders may benefit from primary treatment of these. Patients with intestinal failure as a result of CIIP need long-term parenteral nutrition.

Functional diarrhoea

In this form of functional bowel disease, symptoms occur in the absence of abdominal pain. They commonly include:

- the passage of several stools in rapid succession, usually first thing in the morning; no further bowel action may occur that day, or defecation takes place only after meals
- a first stool of the day that is usually formed, the later ones being mushy, looser, or watery
- urgency of defecation
- anxiety, and uncertainty about bowel function with restriction of movement (e.g., travelling)
- exhaustion after defecation.

Chronic diarrhoea without pain is caused by many diseases that are indistinguishable by history from functional diarrhoea. Features that are atypical of a functional disorder (e.g., large-volume stools, rectal bleeding, nutritional deficiency, and weight loss) call for more extensive investigations.

Treatment of functional diarrhoea is with **loperamide**, often combined with a tricyclic antidepressant prescribed at night (e.g., clomipramine 10–30 mg).

Purgative abuse

This is most commonly seen in females who surreptitiously take high-dose purgatives and are often extensively investigated for chronic diarrhoea. The diarrhoea is usually of high volume (>1 L daily) and patients may have a low serum potassium. Biochemical analysis of the stool may help diagnose laxative abuse. Management is difficult, as most patients deny purgative ingestion. Purgative abuse often occurs in association with eating disorders and patients may need psychiatric help.

Malabsorption

In many small bowel diseases, malabsorption of specific substances occurs, but these deficiencies do not usually dominate the clinical picture. An example is Crohn's disease, in which malabsorption of vitamin B_{12} can be demonstrated, but this is not usually the major problem; diarrhoea and general ill-health are the major features.

The major disorders that cause malabsorption are shown in **Box 22.29**. These can broadly be split into three major categories: gastric causes, small intestine causes, and hepato-pancreato-biliary (HPB) causes (plus a number of other miscellaneous causes).

Assessment of malabsorption should focus on the following points, which will help to categorize the cause and determine the severity:

- Is there chronic diarrhoea?
- Are stools pale, bulky, foul smelling, and difficult to flush? If so, this indicates steatorrhoea (the presence of excessive fat within the faeces).
- Is there weight loss?
- Are there abnormalities in the menstrual cycle?
- Does the patient have a condition that predisposes them to malabsorption, such as coeliac disease, chronic pancreatitis, or small bowel Crohn's disease.
- Any unexplained nutrient deficiencies?
- Is there any evidence of anaemia? If so, this suggests global malabsorption.

Investigations should start with blood tests, which should include the following: FBC, U+Es, vitamin B_{12}, folate, ferritin, calcium, serum albumin, serum iron, iron saturation, magnesium, anti-tissue transglutaminase (tTG; see 'Coeliac disease' section), immunoglobulins, 25-hydroxyvitamin D and prothrombin time/INR (loss of fat-soluble vitamins, A, D, E, K).

Other investigations can include the following:

- Stool analysis—faecal fat to confirm steatorrhoea.
- Faecal elastase if suspect pancreatic insufficiency.

? Box 22.29 Disorders of the small intestine causing malabsorption

Gastric causes	Small intestinal causes	HPB causes	Other
Atrophic gastritis	Coeliac disease	Chronic pancreatitis	Lactase deficiency
Pernicious anaemia	Tropical sprue	Bile acid malabsorption	Lymphoma
Zollinger-Ellison syndrome	Bacterial overgrowth	Liver cirrhosis	Diabetic enteropathy
Post-Billroth II surgery	Whipple's disease	Chronic cholestasis	Thyrotoxicosis
Eosinophilic gastroenteritis	Intestinal resection		
	Radiation enteropathy		
	Small bowel Crohn's disease		
	Parasite infection (e.g., *Giardia intestinalis*)		
	Intestinal lymphangiectasia		

Box 22.30 Malabsorption—helpful hints when assessing patients

- Remember malabsorption can present in a very subtle way, not necessarily with weight loss and chronic diarrhoea.
- Sometimes the only findings may be anaemia or mildly raised LFTs (e.g., in coeliac disease).
- Look for nutrient deficiencies.
- It is uncommon for patients with malabsorption to present with abdominal pain—exceptions are Crohn's disease, intestinal pseudo-obstruction, and chronic pancreatitis.
- Remember to ask if there is any history of previous abdominal surgery.
- Check if there is history of recurrent peptic ulcer disease.
- Do not forget to ask about alcohol history.
- Is there a family history of coeliac disease or gluten sensitivity? (1 in 100 people have coeliac disease).

- If tTG positive—proceed to Upper GI Endoscopy with multiple biopsies from second and third parts of the duodenum (coeliac disease).
- Consider CT pancreas or MRCP (especially if history of alcohol excess or chronic pancreatitis).
- If history of adhesions or strictures consider hydrogen breath testing (small intestine bacterial overgrowth).
- Consider MRI small bowel if has anaemia and abdominal pain.
- If history of previous cholecystectomy—perform SeHCAT scan (see 'Bile acid malabsorption' section) to confirm bile salt malabsorption.

It is important to remember that malabsorption does not always present with drastic weight loss and diarrhoea; it can be more subtle and indolent. See **Box 22.30** for a list of helpful hints when assessing a patient with potential malabsorption.

Coeliac disease (gluten-sensitive enteropathy)

Coeliac disease is an autoimmune condition in which there is inflammation of the mucosa of the upper small bowel that improves when gluten is withdrawn from the diet and relapses when gluten is reintroduced. Gluten is the entire protein content of the cereals wheat, barley, and rye. Up to 1% of many populations are affected, though most have clinically silent disease.

Aetiology

The aetiology of coeliac disease is multifactorial with both genetic and environmental factors needed for the disease to manifest. Prolamins (gliadin from wheat, hordeins from barley, secalins from rye) are the damaging factors in these patients. These proteins are resistant to digestion by pepsin and chymotrypsin because of their high glutamine and proline content, and remain in the intestinal lumen, triggering the immune responses that result in coeliac disease. Gliadin peptides pass through the epithelium (para- and/or intracellularly) and are deaminated by tTG, which increases their immunogenicity. Gliadin peptides then bind to antigen-presenting cells, which interact with $CD4^+$ T cells in the lamina propria via HLA class II molecules DQ2 or DQ8. These T cells produce pro-inflammatory cytokines, particularly interferon-γ. $CD4^+$ T cells also interact with B cells to produce endomysial and tTG antibodies. Gliadin peptides also cause release of IL-15 from enterocytes, activating intraepithelial lymphocytes with a natural killer (NK) cell marker. This inflammatory cascade releases metalloproteinases and other mediators, which contribute to the villous atrophy and crypt hyperplasia that are typical of the disease.

The mucosa of the proximal small bowel is predominantly affected, and the mucosal damage decreasing in severity towards the ileum as gluten is digested into smaller 'non-toxic' fragments.

Genetic factors

There is an increased incidence of coeliac disease within families but the exact mode of inheritance is unknown; 10% to 15% of first-degree relatives will have the condition, although it may be asymptomatic. The concordance rate in identical twins is about 70%.

HLA-DQ2 (DQAI*0501, DQBI*0201) and HLA-DQ8 (DQAI*0301, DQBI*0302) are associated with coeliac disease. Over 90% of patients will have HLA-DQ2, compared with 20% to 30% of the general population. Studies in twins and siblings indicate that HLA genes are responsible for less than 50% of the genetic cause of the disease. Many unaffected people also carry these genes, so other factors must also be involved. Non-HLA genes may also contribute to coeliac disease: for example, chromosome regions 19p13.1, 11q, 5q31–33, and 6q21–22. The *CD28/CTLA4/ILO5* gene cluster has also shown linkage with coeliac disease.

Environmental factors

Breast-feeding and the age of introduction of gluten into the diet are significant. Rotavirus infection in infancy also increases the risk; adenovirus-12, which has sequence homology with α-gliadin, was suspected as a causative agent but this is now thought to be unlikely.

Clinical features

Coeliac disease can present at any age. In infancy, it sometimes appears after weaning on to gluten-containing foods. The peak period for diagnosis in adults is in the fifth decade, with a female preponderance. Many patients are asymptomatic (silent) and come to attention because of routine blood tests: for example, a raised MCV, or iron deficiency in pregnancy. The symptoms are very variable and often non-specific; they include tiredness and malaise, often associated with anaemia.

Gastrointestinal symptoms may be absent or mild. Coeliac disease should be tested for in all patients with symptoms suggestive of irritable bowel syndrome. Diarrhoea or steatorrhoea, abdominal pain, and weight loss suggest more severe disease. Mouth ulcers and angular stomatitis are frequent and can be intermittent. Infertility and neuropsychiatric symptoms of anxiety and depression can occur.

Rare complications include tetany, osteomalacia (both manifestations of severe vitamin D deficiency), or gross malnutrition with peripheral oedema. Long-term problems include osteoporosis, which occurs even in patients on long-term gluten-free diets. Neurological symptoms, such as paraesthesia, ataxia (due to cerebellar calcification), muscle weakness, or a polyneuropathy occur; the prognosis for these symptoms is variable. There is an increased incidence of atopy and autoimmune disease, including thyroid disease, type 1 diabetes, and Sjögren's syndrome. Other associated diseases include:

- IBD
- primary biliary cholangitis
- chronic liver disease
- interstitial lung disease
- epilepsy
- IgA deficiency is more common than in the general population.

Physical signs are usually few and non-specific, and are related to anaemia and malnutrition.

Diagnosis

Small bowel biopsy is still considered to be the 'gold standard' for positive diagnosis and is therefore desirable in all but the most clear-cut cases, because treatment involves a life-long diet that is both expensive and socially limiting. However, with the increasing accuracy of serological tests, it is no longer necessary to take duodenal biopsies for suspected coeliac disease in patients without antibodies. For example, in patients undergoing endoscopy for iron deficiency anaemia with negative coeliac serology, the pretest value of small bowel histology is less than 0.03%.

If biopsies are to be taken, four to six forceps biopsies should be taken from the second part of the duodenum and the bulb because the disease is sometimes patchy and it can be difficult to orientate endoscopic biopsies for histological section. Endoscopic signs, including absence of mucosal folds, mosaic pattern of the surface, and scalloping of mucosal folds, are often present; however, their absence is not conclusive because they are markers of relatively severe disease. Patients must be consuming gluten at the time of the endoscopy for the test to be diagnostic.

Histology

Histological changes are of variable severity and are graded using the Marsh–Oberhuber classification (**Box 22.31**) with types 2 and 3 being diagnostically supportive of coeliac disease. Villous atrophy can be caused by other conditions (e.g., tropical sprue, common variable immunodeficiency, non-coeliac enteropathy), but coeliac disease is the most common cause of subtotal villous atrophy.

Serology

Indications for testing include fatigue, persistent diarrhoea, folate or iron deficiency, unexplained abnormal liver biochemistry, a family history of coeliac disease and associated autoimmune disease.

The most sensitive tests are for endomysial (EMA) and tTG antibodies (95% sensitivity). Titres of either of these correlate with the severity of mucosal damage and so they can be used for dietary monitoring. Standard tests use IgA class antibodies. Selective IgA deficiency occurs in 2.5% of coeliac disease patients but only 0.25% of normals. In a few cases, this may render these tests falsely negative. In situations in which CD is strongly suspected in a patient negative for EMA antibodies, IgA levels should be measured; if low, IgG-based tests should then be used (e.g., deaminated gliadin peptide (DGP) antibody).

HLA typing

HLA-DQ2 is present in 90% to 95% of coeliac disease patients and HLA-DQ8 in about 8%—most of the rest. The *absence* of both alleles has a high negative predictive value for coeliac disease. HLA typing can be useful for risk assessment: for example, in patients already on a gluten-free diet, in whom serology would be negative.

Box 22.31 Marsh–Oberhuber classification for histological changes in coeliac disease

Marsh grade	Histological appearance
0	Normal mucosa
1	Increased intraepithelial lymphocytes
2	Crypt hyperplasia
3a	Partial villous atrophy
3b	Subtotal villous atrophy
3c	Total villous atrophy
4	Hypoplasia of small bowel architecture

Other investigations

- ***Haematology*.** Mild or moderate anaemia is present in 50% of cases. Folate deficiency is common, often causing macrocytosis. Vitamin B_{12} deficiency is rare. Iron deficiency, due to malabsorption of iron and increased loss of desquamated cells, is common. A blood film may therefore show microcytes and macrocytes (i.e., a dimorphic picture), as well as hypersegmented polymorphonuclear leucocytes and Howell–Jolly bodies (see Chapter 38) due to splenic atrophy.
- ***Biochemistry*.** *In severe cases*, biochemical evidence of osteomalacia may be seen (low calcium and high phosphate) and there is hypoalbuminaemia.
- ***Imaging*.** A small bowel barium follow-through or MRI enteroclysis may show dilation of the small bowel with slow transit. Folds become thicker, and in severe disease, total effacement is seen. Imaging is mainly used when a complication, such as lymphoma, is suspected.
- ***Bone densitometry*.** Dual-energy X-ray absorptiometry (DXA) should be performed on all patients because of the risk of osteoporosis.
- ***Capsule endoscopy*** (see 'Endoscopy' section). This is used to look for gut abnormalities when a complication is suspected.

Management

Replacement minerals and vitamins, such as iron, folic acid, calcium, and vitamin D, may be needed initially to replace body stores.

Management is with a gluten-free diet for life. Dietary elimination of wheat, barley, and rye usually produces a clinical improvement within days or weeks. Morphological improvement often takes months, especially in adults. Oats are tolerated by most people with CD but must not be contaminated with flour during their production. Meat, dairy products, fruits, and vegetables are naturally gluten-free and are all safe.

Gluten-free products can be expensive, unless subsidized by national health services; however, this is slowly improving as gluten-free diets are becoming more popular among the general population in the industrialized world. Patient support organizations, such as the Coeliac Society (UK), are valuable as information sources and for advice about diet, recipes, and gluten-free processed foods. Referral to a dietician for help with what to eat can be very beneficial for some patients. Despite advice, many patients do not keep to a strict diet but maintain good health. The long-term effects of this low gluten intake are uncertain but osteoporosis can occur, even in treated cases.

The usual cause of ***failure to respond*** to the diet is poor compliance. Dietary adherence can be monitored by serial tests for EMA and tTG. If clinical progress is suboptimal, then a repeat intestinal biopsy should be taken. If the diagnosis is equivocal on the diagnostic mucosal biopsy, or if the patient has already started on a gluten-free diet, then a gluten challenge, that is re-introduction of oral gluten, with evidence of jejunal morphological change, can confirm the diagnosis.

Patients should have ***pneumococcal vaccinations*** (because of splenic atrophy) once every 5 years (see Chapter 38).

Complications

A few patients do not improve on a strict diet and are said to have ***non-responsive coeliac disease***. Many of these patients are still ingesting gluten. A few of the others may have concomitant problems, such as microscopic colitis, IBD, small bowel bacterial overgrowth, or lactase deficiency.

A very small percentage will have the rare complication of ***refractory coeliac disease*** (RCD):

- Type 1 RCD—the lymphocytes are normal and the T-cell receptors are polyclonal; 5-year survival is 93%.
- Type 2—there are abnormal clonal lymphocytes with loss of CD8 and CD3 surface markers. The 5-year survival rate is 40% to 60%.

Very rarely, enteropathy-associated ***T-cell lymphoma (EATCL)*** (8%–20% 5-year survival) or ulcerative jejunitis can occur as part of a spectrum of neoplastic T-cell disorders.

Ulcerative jejunitis presents with fever, abdominal pain, perforation, and bleeding.

Diagnosis of these conditions is with MRI or barium studies, but laparoscopy with full-thickness small bowel biopsies is often required. Steroids and immunosuppressive agents, such as azathioprine, are used in ulcerative jejunitis.

The incidence of ***carcinoma of the oesophagus and small bowel adenocarcinoma***, as well as that of extragastrointestinal cancers, is also increased. Malignancy seems to be unrelated to the duration of the disease but the incidence is reduced by a gluten-free diet.

Dermatitis herpetiformis

This is an uncommon, blistering, subepidermal eruption of the skin associated with a gluten-sensitive enteropathy (see also Chapter 45). Rarely, gross malabsorption occurs, but usually the jejunal morphological abnormalities are not as severe as in coeliac disease. The inheritance and immunological abnormalities are the same as for coeliac disease. The skin condition responds to ***dapsone*** but a gluten-free diet improves both the enteropathy and the skin lesion, and is recommended for long-term benefit.

Non-coeliac gluten intolerance

There is a recognized group of patients who are sensitive to dietary wheat and gluten-containing foods but do not have coeliac disease, in so far as their coeliac serology is negative and duodenal biopsies are normal. These patients have a range of symptoms, including diarrhoea, bloating, and abdominal pain, which improve on avoidance of gluten. The mechanism is not yet clear.

Tropical sprue

This condition presents with chronic diarrhoea and malabsorption, and occurs in residents of or visitors to tropical areas where the disease is endemic: most of Asia, some Caribbean islands, Puerto Rico, and parts of South America. Epidemics occur, lasting up to 2 years; in some areas, repeated epidemics are seen at varying intervals of up to 10 years.

The term tropical sprue is reserved for severe malabsorption (of two or more substances) accompanied by diarrhoea and malnutrition. A mild degree of malabsorption, sometimes following an enteric infection, is quite common in the tropics; it is usually asymptomatic and is sometimes called tropical malabsorption.

Aetiology

The aetiology is unknown but is likely to be infective because the disease occurs in epidemics and patients improve on antibiotics. A number of agents have been suggested but none has been unequivocally shown to be responsible. Different agents could be involved in different parts of the world.

Clinical features

These vary in intensity and consist of diarrhoea, anorexia, abdominal distension, and weight loss. The onset is sometimes acute and occurs either a few days or many years after being in the tropics. Epidemics can break out in villages, affecting thousands of people at the same time. The onset can also be insidious, with chronic diarrhoea and evidence of nutritional deficiency. The clinical features of tropical sprue vary in different parts of the world, particularly as different criteria are used for diagnosis.

Diagnosis

Acute infective causes of diarrhoea must be excluded (**Box 22.8**), particularly *Giardia*, which can produce a syndrome very similar to tropical sprue. Malabsorption should be demonstrated, particularly of fat and vitamin B_{12}. The jejunal mucosa is abnormal, showing some villous atrophy (partial villous atrophy). In most cases, the lesion is less severe than that found in coeliac disease, although it affects the whole of the small bowel. Mild mucosal changes can be seen in asymptomatic individuals in the tropics.

Management

Many patients improve when they leave the sprue area and take folic acid (5 mg daily). Most patients also require an antibiotic to ensure a complete recovery (usually tetracycline 1 g daily for up to 6 months).

Severely ill patients require resuscitation with fluids and electrolytes for dehydration, and nutritional deficiencies should be corrected. Vitamin B_{12} (1000 μg) is also given to all acute cases.

Prognosis

The prognosis is excellent. Mortality is usually associated with water and electrolyte depletion, particularly in epidemics.

Bacterial overgrowth

The gut contains many resident bacteria in the terminal ileum and colon. Anaerobic bacteria, such as *Bacteroides*, bifidobacteria, are 100 to 1000 times more abundant than aerobic bacterial (facultative anaerobes), such as *Escherichia, Enterobacter*, and *Enterococcus*. This gut microflora has major functions, including metabolic ones, such as fermentation of non-digestible dietary residues into short-chain fatty acids as an energy source in the colon.

The microflora that influences epithelial cell proliferation is involved in the development and maintenance of the immune system and protects the gut mucosa from colonization by pathogenic bacteria. Bacteria also initiate vitamin K production.

The upper part of the small intestine is almost sterile, containing only a few organisms derived from the mouth. Gastric acid kills some ingested organisms and intestinal motility keeps bacterial counts in the jejunum low. The normal terminal ileum contains faecal-type organisms, mainly *Escherichia coli* and anaerobes, and the colon has abundant bacteria.

Bacterial overgrowth is normally found in association with a structural abnormality of the small intestine, such as a stricture or diverticulum, although it can occur occasionally in the elderly without such an abnormality. *E. coli* and/or *Bacteroides*, both in concentrations of greater than 10^6/mL, are found as part of a mixed flora. These bacteria are capable of deconjugating and dehydroxylating bile salts, so that unconjugated and dehydroxylated bile salts can be detected in small bowel aspirates.

Clinical features

The clinical features of overgrowth are chiefly diarrhoea and steatorrhoea. There may also be symptoms caused by the underlying small bowel pathology. Steatorrhoea (excess fat within the stool) occurs because of conjugated bile salt deficiency. Some bacteria

can metabolize vitamin B_{12} and interfere with its binding to intrinsic factor, leading to mild B_{12} deficiency (see Chapter 38); it is rarely severe enough to produce a neurological deficit. Some bacteria produce folic acid, giving a high serum folate. Bacterial overgrowth has only minimal effects on the absorption of other substances. Confirmation of bacterial overgrowth is with the hydrogen breath test:

- ***Hydrogen breath test*.** Bacteria are present in the oral cavity so the mouth should be rinsed out with an antiseptic mouthwash beforehand. The appearance of a breath hydrogen peak after ***oral glucose*** is used to estimate mouth-to-caecum transit time. An earlier rise in the breath hydrogen after glucose indicates bacterial breakdown in the small intestine.

  This test is simple to perform and does not involve radioisotopes. However, interpretation is often difficult, and sensitivity and specificity are low.

Management

If possible, the underlying lesion should be corrected (e.g., a stricture should be resected). If this is not possible then initial management should be with the non-absorbable antibiotic rifaximin, usually for 14 days. If using other antibiotics such as doxycycline, tetracycline, metronidazole, or amoxicillin-clavulanate, a 10-day course can be used.

Empirical treatment with a second course of antibiotics can be considered if there is a partial improvement in symptoms or symptoms recur within 3 months of initial antimicrobial treatment.

Limited data indicates that probiotics may be helpful in the management of small intestinal bacterial overgrowth, however, they are not helpful in preventing it.

Bile acid malabsorption

Bile is released from the gall bladder after eating and is essential for fat digestion. In a healthy gut, most of the bile is reabsorbed in the small intestine and recycled (enterohepatic bile acid circulation). However, this reabsorption is interrupted in some patients leading to more bile passing through into the colon. The increased concentration of bile acids in the colon leads to diarrhoea by reducing absorption of water and electrolytes as well as increasing secretion and colonic motility. Causes include:

- Crohn's disease with ileal disease
- ileal resection
- HIV infection
- idiopathic/primary bile acid diarrhoea
- post-infective gastroenteritis
- post-cholecystectomy.

Diagnosis is made by either a trial of medication or with a SeHCAT scan. This is carried out by giving oral ***SeHCAT*** (a synthetic taurine conjugate) and measuring the retention of the bile acid by whole-body counting at 7 days. Patients are managed by giving bile acid sequestrants such as colestyramine or colesevelam. These bind and inactivate the action of bile acids in the colon.

Lactose intolerance

This is a clinical syndrome where ingestion of lactose causes symptoms such as diarrhoea, abdominal pain, bloating, and flatulence. This is occasionally due to lactase deficiency but can also be due to secondary lactose malabsorption (usually due to underlying intestinal disease). There is a high incidence of lactase deficiency in many parts of the world (e.g., the Mediterranean countries and parts of Africa and Asia). There can be variability in symptoms among patients and a crossover with IBS symptoms. Symptoms occur after more than two servings of dairy a day. If lactose intolerance is suspected, the patient can be asked to eliminate lactose from their diet for 5 to 7 days. If symptoms recur on reintroduction of lactose, this is diagnostic of lactose intolerance. Symptoms usually fully resolve after lactose avoidance for 5 to 7 days.

Short bowel syndrome

This is a relatively rare malabsorptive disorder of the bowel that occurs in approximately 15% of patients undergoing an intestinal resection—it usually occurs after a massive resection or following multiple individual resections when less than 180 to 200 cm of the small bowel remains. Causes for intestinal resection include Crohn's disease, malignancy, and vascular diseases. There are causes of functional short bowel syndrome where the length of small bowel is unchanged but its function is significantly reduced. These include radiation enteritis, congenital villous atrophy, refractory sprue, chronic pseudo-obstruction syndrome, and trauma.

The GI tract carries out a number of absorptive functions along its length and removing large sections of bowel can lead to a number of consequences. The clinical presentation and its severity can vary however depending on a number of factors. These include the amount of absorptive surface remaining, any loss of site-specific transporters (e.g., B_{12} in terminal ileum), endocrine loss (e.g., GI hormones), presence of colon and/or ileo-caecal valve.

Malabsorption results in loss of fluids and nutrients leading to weight loss and symptoms of vitamin and micronutrient deficiency. Some of the symptoms can include abdominal pain, diarrhoea/high stoma output, and dehydration.

The following can also occur after ileal resection (**Fig. 22.35**):

- ***Bile-salt-induced diarrhoea*.** Bile salts and fatty acids enter the colon and cause malabsorption of water and electrolytes (see also 'Secretory diarrhoea' section).

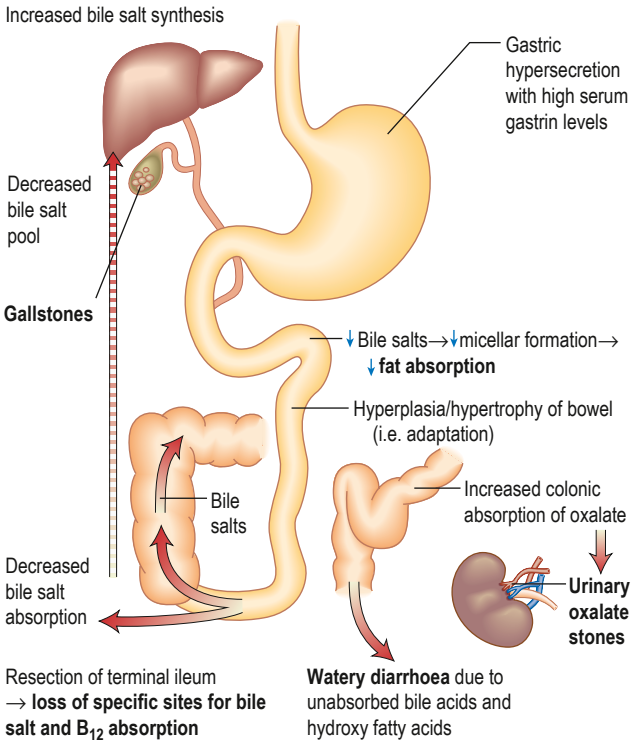

Fig. 22.35 The effects of resecting the distal small bowel.

- ***Steatorrhoea and gallstone formation*.** Increased bile salt synthesis can compensate for loss of approximately one-third of the bile salts in the faeces. Greater loss than this results in decreased micelle formation and steatorrhoea, and lithogenic bile and gallstone formation.
- ***Oxaluria and oxalate stones*.** Bile salts in the colon cause increased oxalate absorption with oxaluria, leading to urinary stone formation.
- ***B_{12} deficiency*.** Low serum B_{12}, macrocytosis, and other effects of B_{12} deficiency are seen.

Following a large intestinal resection, there is a process called intestinal adaptation, which occurs for up to 2 years afterwards and acts to increase the absorptive function of the remaining bowel. The evidence suggests that this happens either through the stimulatory effect of nutrients in the remaining section of small bowel or it is through a process of upregulating the peptide transporter (PepT1) in the colon. Intestinal adaptation is thought to have three phases:

- Phase 1 is the acute phase in the first 1 to 2 months (although can be up to 6) and is characterized by hypersecretion and excess fluid losses.
- Phase 2 sees adaptation occur gradually with improved absorptive function driven by intestinal hormones and growth factors that lead to structural and functional changes in the remaining bowel.
- Phase 3 is the maintenance phase, where maximal adaptation is reached at about 2 years.

Management of fluid and nutrient deficiencies is key and total parenteral nutrition (TPN) is often the mainstay of treatment initially. TPN prescription can be tailored to individual fluid and nutrient needs depending on the remaining section of bowel present. Other management tools include anti-secretory and antidiarrhoeal medications as well as digestive enzymes.

Intestinal failure and TPN are discussed further in Chapter 25. Broadly speaking, patients will often need complete fluid and nutritional support with TPN during phase 1. As the adaptation starts and the patient's absorptive capacity increases throughout phase 2, the PN can slowly be weaned, and once phase 3 is reached the PN can either be weaned completely, reduced in frequency or patients may only need i.v. fluid supplementation.

Whipple's disease

Whipple's disease is a rare infectious bacterial disease caused by *Tropheryma whipplei*. Some 87% of patients are males, and are most commonly white and middle-aged. Clinical features can progress over many years and can include:

- arthritis and arthralgia
- weight loss
- diarrhoea or steatorrhoea
- abdominal pain
- systemic symptoms of fever and weight loss
- peripheral lymphadenopathy and involvement of the heart, lung, joints, and brain occur, simulating many neurological conditions.

Blood tests show features of chronic inflammation and malabsorption. Endoscopy typically shows pale, shaggy duodenal mucosa with eroded, red, friable patches.

Diagnosis

Diagnosis is made by small bowel biopsy. Periodic acid–Schiff (PAS)-positive macrophages are present but are non-specific. On electron microscopy, the characteristic trilaminar cell wall of *T. whipplei* can be seen within macrophages. *T. whipplei* antibodies can be identified by immunohistochemistry. A confirmatory polymerase chain reaction (PCR)-based assay is available.

Management

Treatment is with antibiotics that cross the blood–brain barrier, such as 160 mg trimethoprim and 800 mg sulfamethoxazole (co-trimoxazole) daily for 1 year. This is preceded by a 2-week course of ceftriaxone or streptomycin and penicillin. Treatment periods of less than 1 year are associated with relapse in about 40%. If left untreated, it can be fatal.

Radiation enteritis

Radiation of more than 40 Gy will damage the intestine. The chronic effects of radiation are muscle fibre atrophy, ulcerative changes due to ischaemia, and obstruction due to radiation-induced fibrotic strictures.

Pelvic irradiation is frequently used for gynaecological and urinary tract malignancies, and so the ileum and rectum are the areas most often involved.

At the time of the irradiation, there may be nausea, vomiting, diarrhoea, and abdominal pain, usually improving within 6 weeks of completion of therapy.

Chronic radiation enteritis is diagnosed if symptoms persist for 3 months or more. The prevalence is higher than 15% of patients receiving radiotherapy that includes the abdomen. Abdominal pain due to obstruction is the main symptom. Malabsorption can be due to bacterial overgrowth in dilated segments and mucosal damage. Many patients suffer from increased bowel frequency. ***Management*** is symptomatic, although often unsuccessful in chronic radiation enteritis. Surgery should be avoided if possible, being reserved for obstruction or perforation. Hyperbaric oxygen has been shown to be beneficial but it is not available in many centres.

Acute radiation damage to the rectum produces a ***radiation proctitis*** with diarrhoea and tenesmus, with or without blood. Local steroids sometimes help initially. When the acute phase heals, mucosal telangiectases form and may cause persistent bleeding. If there is resistant anaemia, these can be treated with argon plasma coagulation or, under a light anaesthetic, by packing the rectum with a formalin-soaked swab for 2 minutes, both of which destroy the telangiectases.

Parasite infestation

- ***Giardia intestinalis*** (see Chapter 42) not only produces diarrhoea but also can produce malabsorption with steatorrhoea. Minor changes are seen in the jejunal mucosa and the organism can be found in the jejunal fluid or mucosa.
- ***Cryptosporidiosis*** (see Chapter 42) can also produce malabsorption.
- ***HIV infection***, when uncontrolled, causes patients to be particularly prone to parasitic infestation (**Box 22.32**).

Other causes of malabsorption

- ***Drugs that bind bile salts*** (e.g., colestyramine) and some antibiotics (e.g., neomycin) produce steatorrhoea.
- ***Orlistat*** is used in obesity to reduce fat absorption by inhibiting gastric and pancreatic lipase, so causing diarrhoea and steatorrhoea. A low-fat diet is also necessary, which leads to weight loss.
- ***Thyrotoxicosis*** causes diarrhoea, rarely with steatorrhoea, owing to increased gastric emptying and increased motility.
- ***Zollinger–Ellison syndrome*** is described in Chapter 24.
- ***Intestinal lymphangiectasia*** produces diarrhoea and, rarely, steatorrhoea.

Box 22.32 Gastrointestinal problems in patients with AIDS

Symptoms	Causes
Mouth/oesophagus	
Dysphagia	Herpes simplex virus (HSV)
Retrosternal discomfort	Cytomegalovirus (CMV)
Oral ulceration	Candidiasis
Small bowel/colon	
Chronic diarrhoea Steatorrhoea Weight loss	**Parasites:**
	Entamoeba histolytica
	Giardia intestinalis
	Blastocystis hominis
	Isospora belli
	Microsporidia
	Cyclospora cayetanensis
	Viruses:
	Cytomegalovirus, herpes simplex virus, adenovirus
	Bacteria:
	Salmonella
	Campylobacter
	Shigella
	Mycobacterium avium-intracellulare
	Non-infective enteropathy—cause unknown
Rectum/colon	
Bloody diarrhoea	Bacterial infection (e.g., *Shigella*)
Any site	
Weight loss Diarrhoea	**Neoplasia:**
	Kaposi's sarcoma
	Lymphoma
	Squamous carcinoma
	Infection—disseminated, e.g.,:
	Mycobacterium avium-intracellulare
	Anti-retroviral therapy (ART)

- ***Lymphoma*** that has infiltrated the small bowel mucosa causes malabsorption.
- ***Diabetes mellitus*** (see Chapter 35) causes diarrhoea, malabsorption, and steatorrhoea, sometimes due to bacterial overgrowth from autonomic neuropathy that leads to small bowel stasis.
- ***Hypogammaglobulinaemia***, which is seen in a number of conditions including lymphoid nodular hyperplasia, causes steatorrhoea due either to an abnormal jejunal mucosa or to secondary infestation with *Giardia intestinalis.*

Miscellaneous intestinal diseases

Protein-losing enteropathy

Protein-losing enteropathy refers to intestinal conditions that lead to protein loss, and usually manifest with hypoalbuminaemia. The causes include:

- Crohn's disease
- tumours
- Ménétrier's disease, a condition with giant rugal folds (Fig. 22.36)

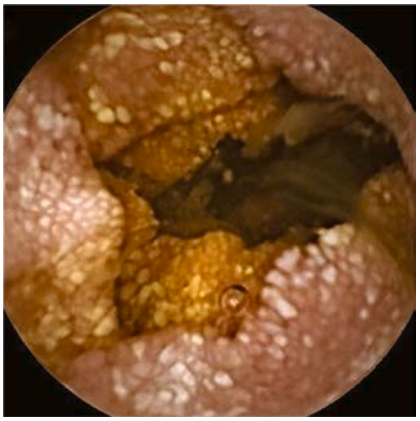

Fig. 22.36 Protein-losing enteropathy showing giant rugal folds.

- coeliac disease
- lymphatic disorders (e.g., lymphangiectasia).

Usually, protein-losing enteropathy forms a minor part of the generalized disorder but, occasionally, hepatic synthesis of albumin cannot compensate for the protein loss, and peripheral oedema dominates the clinical picture. Confirmation of the diagnosis is by measurement of α_1-antitrypsin clearance. It does not require an isotope. Alpha$_1$-antitrypsin is a large molecule (>50 000 daltons), which is resistant to proteolysis. Simultaneous measurements of serum and stool concentration (24-hour collection) are made. The treatment is that of the underlying disorder.

Meckel's diverticulum

This is the most common congenital abnormality of the gastrointestinal tract, affecting 2% to 3% of the population. The diverticulum projects from the wall of the ileum approximately 60 cm from the ileocaecal valve. It is usually symptomless. However, 50% contain gastric mucosa that secretes hydrochloric acid, and peptic ulcers can occur and may bleed or perforate.

Acute inflammation of the diverticulum also occurs and is indistinguishable clinically from acute appendicitis. Rarely, there is obstruction from an associated band.

Management is surgical removal, often laparoscopically.

Tuberculosis

Tuberculosis (TB; see also Chapter 20) can affect the intestine, as well as the peritoneum (see 'Peritoneum' section). In high income countries, most patients are from ethnic minority groups, or are immunocompromised because of HIV or drugs. Intestinal TB is due to reactivation of primary disease caused by *Mycobacterium tuberculosis*. Bovine TB occurs in areas where milk is unpasteurized and is rare in Western countries.

Clinical features

These are abdominal pain, weight loss, anaemia, fever with night sweats, obstruction, right iliac fossa pain, or a palpable mass. The ileocaecal area is most commonly affected, but the colon—and, rarely, other parts of the gastrointestinal tract—can be involved. One-third of patients present acutely with intestinal obstruction or generalized peritonitis; 50% have X-ray evidence of pulmonary TB.

Diagnosis

Differential diagnosis includes Crohn's disease and caecal carcinoma.

- ***Small bowel follow-through*** may show transverse ulceration, and diffuse narrowing of the bowel with shortening of the caecal pole.
- ***Ultrasound, MRI, or CT*** shows additional mesenteric thickening and lymph node enlargement.
- ***Histology and culture of tissue*** is desirable but not always possible. Specimens can be obtained by colonoscopy or laparoscopy but laparotomy is required in some cases. The histological findings include chronic inflammation with caseating granuloma. Acid-fast bacilli may be seen on dedicated stains. However, the histology is not always distinguishable from that of Crohn's disease.

Management

Drug treatment is similar to that for pulmonary TB (see Chapter 20). Treatment should be started if there is a high degree of suspicion.

Amyloidosis

Systemic amyloidosis (see Chapter 36) may affect any part of the gastrointestinal tract. Rectal biopsy may be diagnostic. Occasionally, amyloid deposits occur as polypoid lesions. The symptoms depend on the site of involvement; amyloidosis in the small intestine gives rise to diarrhoea.

Autoimmune rheumatic diseases

Systemic sclerosis (see Chapter 32) most commonly affects the oesophagus, although the small bowel and colon are often found to be involved if investigated. There may be no symptoms of this involvement, but diarrhoea and steatorrhoea can occur due to bacterial overgrowth caused by reduced motility, dilation, and the presence of diverticula.

Intestinal ischaemia

Intestinal ischaemia results from occlusion of arterial inflow, occlusion of venous outflow, or failure of perfusion; these factors may act alone or in combination and usually occur in the elderly.

- ***Arterial inflow occlusion*** can be caused by atheroma, thrombosis, and embolism (cardiac arrhythmia), including cholesterol emboli, aortic disease (occluding ostia of mesenteric vessels), vasculitis (including Takayasu's arteritis) or thromboangiitis.
- ***Venous outflow occlusion*** occurs in 5% to 15% of cases, usually in sick patients with circulatory failure.
- ***Infarction without occlusion*** can occur due to reduced cardiac output, hypotension, and shock, causing reduced intestinal blood flow.

Acute small intestinal ischaemia

An embolus from the heart in a patient with atrial fibrillation is the most common cause and usually occludes the superior mesenteric artery. Patients present with sudden abdominal pain and vomiting, with a distended and tender abdomen and absent bowel sounds. The patient is hypotensive and ill. Surgery is necessary to resect the gangrenous bowel. Mortality is high (up to 90%) and is related to coexisting disease, the development of multiorgan failure (MOF; see Chapter 13), and massive fluid and electrolyte losses in the postoperative period. Survivors may go on to develop nutritionally inadequate short bowel syndrome (see Chapter 25).

Ischaemic colitis

See 'Ischaemic disease of the colon (ischaemic colitis)' section.

Chronic small intestinal ischaemia

This is due to atheromatous occlusion or cholesterol emboli of the mesenteric vessels, and is found particularly in the elderly. Good collateral circulation can minimize clinical effects. The characteristic symptom is postprandial abdominal pain and weight loss. Loud bruits may be heard but, as these are heard in normal subjects, they are of doubtful significance. The diagnosis is made using angiography.

Eosinophilic gastroenteritis

In this condition of unknown aetiology there is eosinophilic infiltration and oedema of any part of the gastrointestinal mucosa. The gastric antrum and proximal small intestine are usually involved, hosting either a localized lesion (eosinophilic granuloma) or diffuse sheets of eosinophils in the serosal and submucosal layers. There is an association with asthma, eczema, and urticaria.

The condition occurs mainly in the third decade. The clinical presentation depends on the site of gut involvement. Abdominal pain, nausea and vomiting, and upper gastrointestinal bleeding occur. Peripheral eosinophilia is present in only 20% of patients. Endoscopic biopsy is useful for making the diagnosis histologically. Radiology may demonstrate mass lesions.

Treatment is with corticosteroids for the widespread infiltration, particularly if peripheral eosinophilia is present.

In some adults, the condition appears to be allergic (allergic gastroenteritis) and is associated with peripheral eosinophilia and high levels of plasma and tissue IgE. The relationship of eosinophilic oesophagitis (see 'Eosinophilic oesophagitis' section) to eosinophilic gastroenteritis is unclear.

Intestinal lymphangiectasia

Dilation of the lymphatics may be primary or secondary to lymphatic obstruction, such as occurs in malignancy or constrictive pericarditis. Hypoproteinaemia with ankle oedema is the main feature. The rare primary form may be detected incidentally as dilated lacteals on a jejunal biopsy or it can produce steatorrhoea of varying degrees. White-tipped villi are seen on capsule endoscopy. Serum immunoglobulin levels are reduced, with low circulating lymphocytes. Management is with a low-fat diet, mid-chain triglycerides, and fat-soluble vitamin supplements as required. Octreotide has a dramatic effect in a few primary cases, although the mechanism of action is unknown.

Abetalipoproteinaemia

This rare congenital disorder is due to a failure of apo B-100 synthesis in the liver and apo B-48 in the intestinal cell, so that chylomicrons are not formed. This leads to fat accumulation in the intestinal cells, lending a characteristic histological appearance to the jejunal mucosa. Clinical features include acanthocytosis (spiky red cells owing to membrane abnormalities), a form of retinitis pigmentosa, and mental and neurological abnormalities. The latter can be prevented by vitamin E injections.

Tumours of the small intestine

The small intestine is relatively resistant to the development of neoplasia and only 3% to 6% of all gastrointestinal tumours and less than 1% of all malignant lesions occur here. The reason for the rarity of tumours is unknown. Explanations include the fluidity and relative sterility of small bowel contents and the rapid transit time, reducing the time of exposure to potential

carcinogens. It is also possible that the high population of lymphoid tissue and secretion of IgA in the small intestine protect against malignancy.

Adenocarcinoma and lymphoma

Adenocarcinoma of the small intestine is rare and found most frequently in the duodenum (in the periampullary region) and in the jejunum. It is the most common tumour of the small intestine, accounting for up to 50% of primary tumours.

Lymphomas are most frequently found in the ileum. These are of the non-Hodgkin's type and must be distinguished from peripheral or nodal lymphomas involving the gut secondarily.

In high income countries, the most common type of lymphoma is the B cell type arising from MALT. These lymphomas tend to be annular or polypoid masses in the distal or terminal ileum, whereas most T-cell lymphomas are ulcerated plaques or strictures in the proximal small bowel.

A tumour similar to Burkitt's lymphoma also occurs and commonly affects the terminal ileum of children in North Africa and the Middle East.

Predisposing factors for adenocarcinoma and lymphoma

Coeliac disease

There is an increased incidence of lymphoma of the T cell type and adenocarcinoma of the small bowel, as well as an unexplained increase in all malignancies, both in the gastrointestinal tract and elsewhere. The reason for the local development of malignancy is unknown. It is now accepted that coeliac disease is a pre-malignant condition but there is no association with the length of the symptoms. Management with a gluten-free diet can reduce the risk of both lymphoma and carcinoma.

Crohn's disease

There is a small increase in the incidence of adenocarcinoma of the small bowel in Crohn's disease.

Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (IPSID) is a rare B cell disorder in which there is proliferation of plasma cells in the lamina propria of the upper small bowel, producing truncated monoclonal heavy chains, without associated light chains. The α heavy chains are found in the gut mucosa on immunofluorescence and can also be detected in the serum. IPSID usually occurs in countries surrounding the Mediterranean, but it has also been found in low and middle income countries in South America and the Far East. It predominantly affects people in lower socioeconomic groups in areas with poor hygiene and a high incidence of bacterial and parasitic infection of the gut. IPSID presents as a malabsorptive syndrome associated with diffuse lymphoid infiltration of the small bowel and neighbouring lymph nodes, progressing in some cases to a lymphoma. The condition has also been documented in the developed world.

Clinically, patients present with abdominal pain, diarrhoea, anorexia, weight loss, and symptoms of anaemia. There may be a palpable mass, and an ultrasound followed by an MRI scan may detect a mass lesion. Endoscopic biopsy is useful where lesions are within reach. Ultrasound and CT may show bowel wall thickening and the involvement of lymph nodes, which is common with lymphoma. Wireless capsule endoscopy can be used where obstruction by the capsule is not likely, but cannot deliver histology.

Management of small intestinal tumours

Adenocarcinoma

Most patients are treated surgically with a segmental resection. The overall 5-year survival rate is 20% to 35%; this varies with the histological grade and the presence or absence of lymph node involvement. Radiotherapy and chemotherapy are used in addition.

IPSID

If there is no evidence of lymphoma, antibiotics, such as tetracycline, should be tried initially. In the presence of lymphoma, combination chemotherapy is used; in one series, the 3- to 5-year survival rate was 58%.

Lymphoma

Most patients require surgery and radiotherapy with chemotherapy for more extensive disease. The prognosis varies with the type. The 5-year survival rate for T cell lymphomas is 25% but is better for B cell lymphomas, varying from 50% to 75%, depending on the grade of lymphoma.

Carcinoid tumours

These originate from the enterochromaffin cells (APUD cells) of the intestine. They make up 10% of all small bowel neoplasms, the most common sites being the appendix and terminal ileum. It is often difficult to be certain histologically whether a particular tumour is benign or malignant. A total of 10% of carcinoid tumours in the appendix present as acute appendicitis, secondary to obstruction. Surgical resection of the tumour is usually performed.

Most carcinoids do not secrete hormones or vasoactive compounds, and may present with liver enlargement due to metastases.

Carcinoid syndrome occurs in only 5% of patients with carcinoid tumours and only when there are liver metastases. Biologically active amines and peptides secreted by carcinoid tumours are usually subject to first-pass metabolism by the liver, but may enter the systemic circulation in patients with liver metastases. Patients complain of spontaneous or induced bluish-red flushing, predominantly on the face and neck, sometimes leading to permanent changes with telangiectases.

Gastrointestinal symptoms consist of abdominal pain and recurrent watery diarrhoea. Cardiac abnormalities are found in 50% of patients and take the form of pulmonary stenosis or tricuspid incompetence. Examination of the abdomen reveals hepatomegaly. The tumours secrete a variety of biologically active amines and peptides, including serotonin (5-hydroxytryptamine, 5-HT), bradykinin, histamine, tachykinins, and prostaglandins. The diarrhoea and cardiac complications are probably caused by 5-HT itself, but the cutaneous flushing is thought to be produced by one of the kinins, such as bradykinin. This is known to cause vasodilation, bronchospasm, and increased intestinal motility.

Diagnosis of carcinoid syndrome

- ***Ultrasound examination*** confirms the presence of liver secondary deposits.
- ***Urine*** shows a high concentration of 5-hydroxyindoleacetic acid (5-HIAA), which is the major metabolite of 5-HT.
- ***Serum chromogranin A*** is raised in nearly all hindgut tumours and 80% to 90% of symptomatic foregut and midgut tumours.

Management of carcinoid syndrome

Treatment is with octreotide and lanreotide; both are octapeptide somatostatin analogues that inhibit the release of many gut hormones. They alleviate flushing and diarrhoea, and can control a carcinoid crisis. Interferon and other chemotherapeutic regimens also

Fig. 22.37 Circumoral pigmentation in Peutz-Jeghers syndrome.

occasionally reduce tumour growth, but have not been shown to increase survival.

Most patients survive for 5 to 10 years after diagnosis.

Peutz–Jeghers syndrome

This consists of mucocutaneous pigmentation (circumoral in 95% of patients, and on the hands in 70% and feet in 60%) and gastrointestinal polyps (**Fig. 22.37**). It has an autosomal dominant inheritance. The gene *STK11* (also known as *LKB1*) that is responsible for Peutz–Jeghers syndrome codes for a serine protein kinase and can be used for genetic analysis. The brown buccal pigment is characteristic of the condition. The polyps, which are hamartomas, can occur anywhere in the gastrointestinal tract but are most frequent in the small bowel. They may bleed or cause small bowel obstruction or intussusception (50% of patients).

Management

Management is by endoscopic polypectomy. Balloon enteroscopy may be necessary to reach all the small bowel polyps. Bowel resection should be avoided if possible, but may be necessary in patients presenting with gangrenous bowel due to intussusception. Follow-up is with yearly pan-endoscopy. There is an increased incidence of gastrointestinal cancers. Non-gastrointestinal cancers also occur with increased frequency, so yearly screening for uterine, ovarian, and cervical cancer should start in the teens, and breast and testicular screening by the age of 20.

Other tumours

Adenomas, lipomas, and stromal tumours (see 'Gastrointestinal stromal tumours' section) are rarely found and are usually asymptomatic and picked up incidentally. They occasionally present with iron deficiency anaemia. In familial adenomatous polyposis (FAP), duodenal adenomas form in one-third of patients and may progress to adenocarcinoma. This is the most common cause of death in FAP patients who have been treated by prophylactic colectomy.

INFLAMMATORY BOWEL DISEASE

Two major forms of IBD are recognized:

- Crohn's disease (CD), which can affect any part of the gastrointestinal tract
- Ulcerative colitis (UC), which affects only the colon.

There is a degree of overlap between these two conditions in their aetiopathogenesis, clinical features, histological and radiological abnormalities; in 10% of cases of IBD-causing colitis, a definitive diagnosis of either UC or CD is not possible and the diagnosis is termed colitis of undetermined type (indeterminate colitis). It is clinically useful to distinguish between UC and CD because of differences in their management, although, in reality, they may represent two aspects of the same disease.

Another form of colitis related to microscopic inflammation is termed microscopic colitis; this is subdivided into lymphocytic and collagenous types (see 'Microscopic colitis' section). The distinction between this and IBD is the absence of macroscopic evidence of inflammation.

Epidemiology

- The incidence of CD varies from country to country but is approximately 4 to 10 per 100 000 annually, with a prevalence of 25 to 100/100 000.
- The incidence of UC is stable at 6 to 15/100 000 annually, with a prevalence of 80 to 150/100 000.

Although both conditions have a worldwide distribution, the highest incidence rates and prevalence have been reported from Northern Europe, the UK, and North America. Both race and ethnic origin affect the incidence and prevalence of CD and UC. Thus, in North America, prevalence rates of CD are lower in Hispanic and Asian people (4.1/100 000 and 5.6/100 000, respectively) compared with white individuals (43.6/100 000). Jewish people are more prone to IBD than any other ethnic group. Prevalence rates also change after migration; thus there is an increasing incidence of CD in the UK-born children of migrants from South-east Asia. Recent studies suggest that the incidence of both CD and UC is increasing in traditional low-prevalence areas such as South-east Asia.

Approximately 25% of patients are diagnosed before their 18th birthday and there is evidence that disease commencing in youth is more extensive and more aggressive than that occurring in older patients.

Aetiology and pathogenesis

Although the aetiology of IBD is unknown, it is increasingly clear that IBD represents the interaction between several co-factors: genetic susceptibility, the environment, the intestinal microbiota, and host immune response (**Fig. 22.38**) See **Box 22.33**.

Genetic factors

CD and UC are complex polygenic diseases and having a positive family history is the largest independent risk factor for development of IBD. Up to 1 in 5 patients with CD and 1 in 6 patients with UC will have a first-degree relative with the disease. The monozygotic and dizygotic twin concordance rates for CD are 20% to 50% and 10%, respectively.

Genome-wide association studies have identified multiple susceptibility loci, and many of the underlying risk variants have been identified. The major genetic factors for CD include the *NOD2 (CARD 15)* gene (nucleotide oligomerization domain 2), the autophagy genes, and the Th17 pathway (IL-23–type 17 helper T cells). The NOD2 protein on chromosome 16 is an intracellular sensor of bacterial peptidoglycan, present in bacterial cell walls (see below). NOD2 is expressed in epithelial cells, macrophages, and endothelial

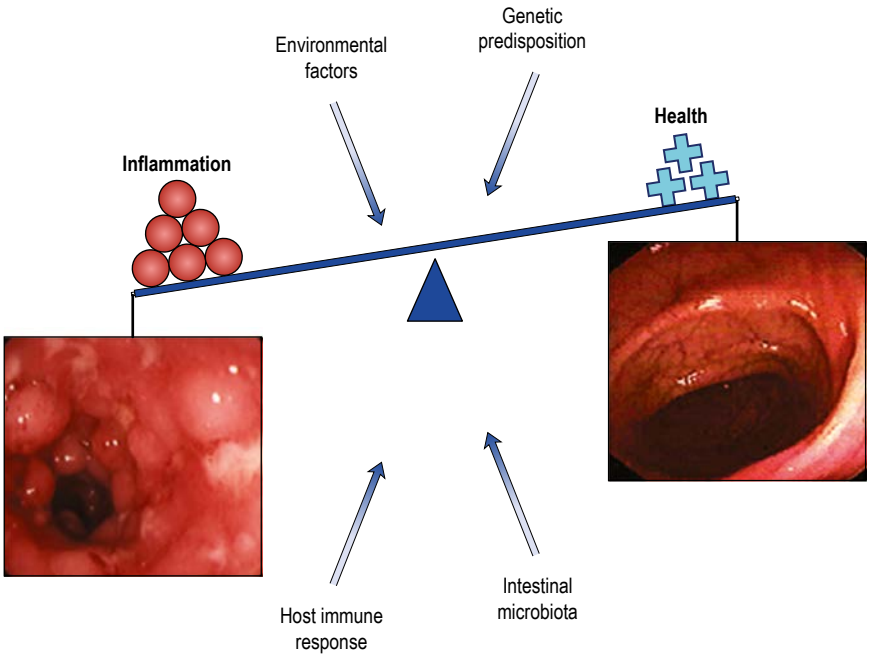

Fig. 22.38 **The aetiopathogenesis of inflammatory bowel disease.**

Box 22.33 Pathogenesis of IBD: summary

- There is overwhelming evidence that inflammatory bowel disease (IBD) is a result of dysregulated immune responses to luminal bacteria and/or their products.
- Evidence suggests that IBD patients demonstrate fundamental differences in the numbers and functionality of intestinal microbiota.
- Various genetic variations that are important in pathways regulating intestinal inflammation have been found.
- Novel agents targeting immune dysregulation, changes in intestinal microenvironment are in operational development.

cells. Individuals who are homozygote or compound heterozygote for one of several mutations in the *NOD2* gene have a significantly increased risk of developing ileal CD. Likewise, mutations in the autophagy genes *ATG16L1* and *IRGM* (immunity-related GTP-ase M-protein) and IL-23 receptor gene increase CD risk, and mutations in genes associated with the mucosal barrier increase UC risk. However, the presence of IBD-associated genes in many unaffected individuals and the failure of the approximately 71 genetic susceptibility loci identified thus far to explain more than around one-fifth of the genetic risk of CD highlight the complexity of the genetic basis of IBD. Specific genetic defects in the IL-10 receptor pathway are associated with a severe form of extremely early-onset colitis and perianal disease in children.

Apart from susceptibility, HLA genes on chromosome 6 also appear to have a role in modifying the disease. The *DRB*0103* allele is linked to a particularly aggressive course of UC and the need for surgery, as well as with colonic CD. *DRB*0103* and *MICA*010* are associated with perianal disease, and *DRB*0701* with ileal CD. For the extraintestinal disease complications and their HLA associations, see 'Extraintestinal manifestations' section.

Environmental and other factors

- ***Smoking*.** Patients with CD are more likely to be smokers, and smoking has been shown to exacerbate CD and increase the risk of disease recurrence after surgery. By contrast, there is an increased risk of UC in non- or ex-smokers and nicotine has been shown to be an effective treatment in one small clinical trial.
- ***NSAIDs*.** NSAID ingestion is associated with both the onset of IBD and flares of disease in patients with an established diagnosis.
- ***Hygiene*.** Poor and large families living in crowded conditions have a lower risk of developing CD. A 'clean' environment may not expose the intestinal immune system to pathogenic or non-pathogenic microorganisms such as helminths, which seems to alter the balance between effector and regulatory immune responses.
- ***Nutritional factors*.** Many foods and food components have been suggested as playing a role in the aetiopathogenesis of IBD (e.g., high sugar and fat intake) but, unfortunately, the results of numerous studies designed to define risk have been equivocal. However, breast-feeding may provide protection against the development of IBD in offspring.
- ***Psychological factors*.** Factors such as chronic stress and depression seem to increase relapses in patients with quiescent disease.
- ***Appendicectomy*.** This appears to be 'protective' against the development of UC, particularly if performed for appendicitis or for mesenteric lymphadenitis before the age of 20. It also influences the clinical course of UC, with a lower incidence of colectomy and reduced need for immunosuppressive therapy. By contrast, appendicectomy may increase the risk of development of CD.

Intestinal microbiota

The gut is colonized by 10 times more bacterial organisms than there are host cells, there being 300 to 400 distinct bacterial species within each host intestine. The intestinal microbiota plays a crucial role in perpetuating intestinal inflammation, in both animal models of disease and patients with IBD. The number of mucosal adherent

bacteria is increased in patients with CD compared to healthy subjects, and diversion of the bacterial component of the faecal stream induces clinical remission. However, there is also evidence of an immunoregulatory role for the commensal microbiota, which protects against intestinal inflammation and upregulates epithelial defence mechanisms in animal models of colitis.

Mechanisms by which the intestinal microbiota may relate to the aetiology of IBD include:

- ***Intestinal dysbiosis*.** There is an alteration in the bacterial flora in patients with CD. Although results vary due to differences in both the patient groups studied and the microbiological method utilized, the most consistent finding in patients with IBD is a reduced diversity of microbial species. In addition, higher concentrations of *Bacteroides* and *E. coli*, and lower concentrations of bifidobacteria and *Faecalibacterium prausnitzii* have been reported in faecal and mucosal samples from patients with CD compared to healthy controls. Lower concentrations of *F. prausnitzii* have been found in patients with active compared with quiescent disease, and low levels of this organism in CD resection specimens predict subsequent endoscopic disease recurrence.
- ***Specific pathogenic organisms*.** It has been shown that there is increased *E. coli* adherence to the ileal epithelial cells in CD, with evidence of invasion into the mucosa. *E. coli's* type 1 pili adhere to a protein called carcinoembryonic antigen-related cell adhesion molecule 6 (CEACAM6). Many authors have also suggested a link between CD and *Mycobacterium paratuberculosis* (MAP), although recent PCR-based studies have failed to confirm this and therapeutic trials of anti-*Mycobacterium tuberculosis* (MTB) therapy were not effective.
- ***Bacterial antigens*.** Bacteria exert their influence by the interaction of ligands such as peptidoglycan-polysaccharides (PG-PS) and LPS with host pattern recognition receptors such as the TLR family (cell surface) and the NOD family (intracellular).
- ***Defective chemical barrier or intestinal defensins*** (see 'Small intestine physiology [innate chemical defence]' section). Evidence suggests a decrease in human α defensin-1 (HD-1) in the mucosa of both CD and UC, and a lack of induction of HD-2, HD-3, and HD-5 in CD.
- ***Impaired mucosal barrier function*.** This may explain the presence of unusual and potentially pathogenic bacteria, such as MAP, *Listeria*, and mucosal adherent *E. coli.* However, their presence does not necessarily imply causation of the disease, and they may reflect previous disease activity.

Intestinal immune system

IBD occurs when the mucosal immune system exerts an inappropriate response to luminal antigens, such as bacteria, which may enter the mucosa via a leaky epithelium (Fig. 22.39). Bacterial ligands interact with the innate and acquired mucosal immune system via TLRs expressed on both epithelial and antigen-presenting cells. Deficiencies occur in the clearance of invading bacteria by aspects of the innate immune system, such as neutrophils, which may allow inappropriate activation of the acquired immune system. In keeping with the genetic susceptibility loci identified, these findings highlight a deficiency in patients with IBD in a component of the inflammasome (an intracellular danger sensor of the innate immune system that can trigger caspase-1-dependent processing of inflammatory mediators, such as IL-1β and IL-18). In addition, individual bacterial species have distinct immunological effects mediated by dendritic cells (DCs), which sample bacteria from the intestinal lumen and direct the subsequent functional differentiation of naïve T cells into effector or regulatory populations. IBD is associated with an imbalance in the relative numbers of intestinal homing effector (Th1 and Th17) and regulatory T-cell populations, which disturbs the normal tolerance to the luminal antigenic load.

The pro-inflammatory cytokines released by these activated effector T cells stimulate macrophages to secrete pro-inflammatory cytokines, such as tumour necrosis factor-alpha (TNF-α), IL-1, and IL-6 in large quantities. These mechanisms result in increased adhesion molecule expression on the intestinal vascular endothelium, which facilitates the recruitment of leucocytes from the circulation and the release of chemokines, all of which lead to tissue damage and also attract more inflammatory cells in a vicious circle.

Pathology

CD is a chronic inflammatory condition that may affect any part of the gastrointestinal tract from the mouth to the anus but has a particular tendency to affect the terminal ileum and ascending colon (ileocolonic disease) (Fig. 22.40). The disease can involve one small area of the gut, such as the terminal ileum, or multiple areas with relatively normal bowel in between (skip lesions). It may also involve the whole of the colon (total colitis), sometimes without macroscopic small bowel involvement. It is also associated with the development of perianal fistulae and fissures (Box 22.34).

UC can affect the rectum alone (proctitis), can extend proximally to involve the sigmoid and descending colon (left-sided colitis), or may involve the whole colon (extensive colitis) (Fig. 22.41). In a few of these patients, there is also inflammation of the distal terminal ileum (backwash ileitis).

Macroscopic changes

In ***CD***, the involved bowel is usually thickened and is often narrowed. Deep ulcers and fissures in the mucosa produce a cobblestone appearance. Intra-abdominal fistulae and abscesses may be seen, which reflect penetrating disease. An early feature is aphthoid ulceration in the colon, usually seen at colonoscopy (Fig. 22.42); later, larger and deeper ulcers appear in a patchy distribution, again producing a cobblestone appearance.

In ***UC***, the mucosa looks reddened and inflamed, and bleeds easily (friability). In severe disease, there may be extensive ulceration, with the adjacent mucosa appearing as post-inflammatory (pseudo-) polyps.

In ***fulminant colonic disease*** of either type, most of the mucosa is lost, leaving a few islands of oedematous mucosa (mucosal islands), and toxic dilation occurs. On healing, the mucosa can return to normal, although there is usually some residual scarring.

Microscopic changes

In ***CD***, the inflammation extends through all layers (transmural) of the bowel, whereas in UC superficial inflammation limited to the mucosa is seen. In CD, there is an increase in chronic inflammatory cells and lymphoid hyperplasia, and in 50% to 60% of patients, granulomas are present. These granulomas are non-caseating epithelioid cell aggregates with Langhans' giant cells.

In ***UC***, the mucosa shows a chronic inflammatory cell infiltrate in the lamina propria. Crypt abscesses and goblet cell depletion are also seen.

These two diseases can usually be differentiated not only on the basis of clinical and radiological data but also on the histological differences seen in the rectal and colonic mucosa obtained by biopsy (Box 22.35).

It is occasionally not possible to distinguish between the two disorders, particularly if biopsies are obtained in the acute phase,

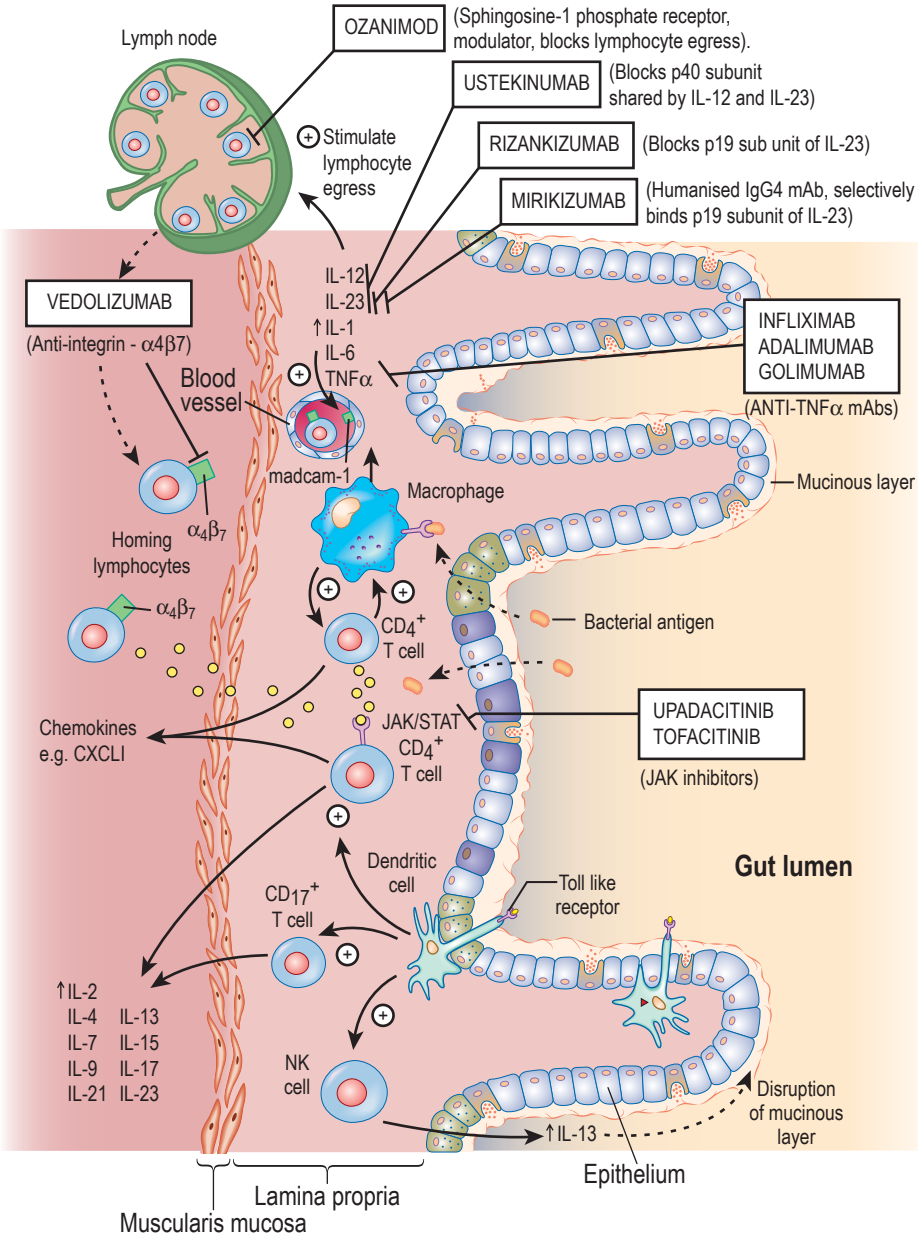

Fig. 22.39 Cellular intestinal mechanisms involved in the pathogenesis of inflammatory bowel disease. Bacterial ligands attach to the epithelium and antigen-presenting cells (e.g., dendritic cells and macrophages) via Toll-like receptors and the NOD protein. The dendritic cells migrate to the Peyer's patches and mesenteric lymph nodes. They present antigens to naïve T cells, releasing a number of cytokines that cause damage. The T-cell subsets enter the blood vessels, where the enterotropic molecules α4-β7 are induced and allow homing back to the gut, causing further damage. Labels show biologics currently approved for treatment of inflammatory bowel disease and their molecular target. *IFN-γ,* Interferon-gamma; *IL,* interleukin; *TGF-β,* transforming growth factor-beta; *TNF-α,* tumour necrosis factor-alpha.

and such patients are considered to have indeterminate colitis. Serological testing for anti-neutrophil cytoplasmic antibodies (ANCA) in UC and anti-*Saccharomyces cerevisiae* antibodies (ASCA) in CD may be of value in differentiating the two conditions (see below), although an exact diagnosis can sometimes be made only after examining a surgical colectomy specimen. Occasionally, examination of the colectomy specimen still does not lead to a diagnosis of CD or UC and the patient is labelled as having indeterminate colitis.

Extraintestinal manifestations

These occur with both diseases (Box 22.36). Joint complications are most common; the peripheral arthropathies are classified as:

- ***Type 1 (pauciarticular)*** attacks are acute and self-limiting (<10 weeks), and occur with IBD relapses; they are associated with other extraintestinal manifestations of IBD activity.
- ***Type 2 (polyarticular)*** arthropathy lasts longer (months to years), is independent of IBD activity and usually associated with uveitis.

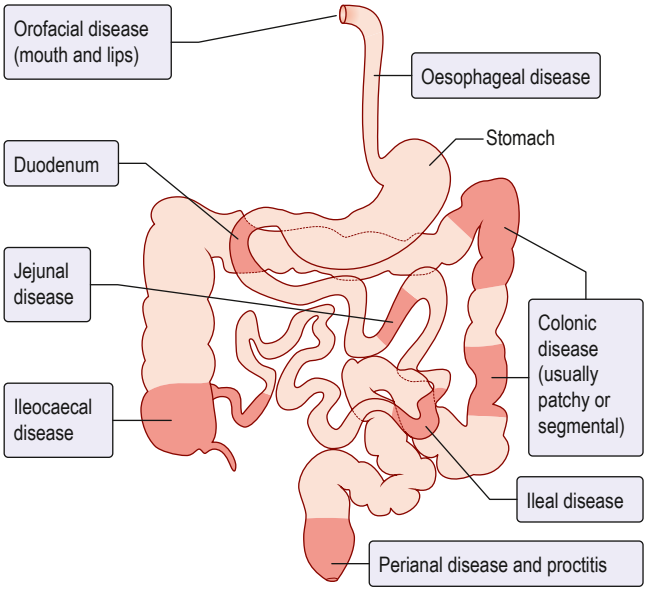

Fig. 22.40 Sites of Crohn's disease.

Box 22.34 Anal and perianal complications of Crohn's disease

- Fissure *in ano* (multiple and indolent)
- Haemorrhoids
- Skin tags
- Perianal abscess
- Ischiorectal abscess
- Fistula *in ano* (may be multiple)
- Anorectal fistulae

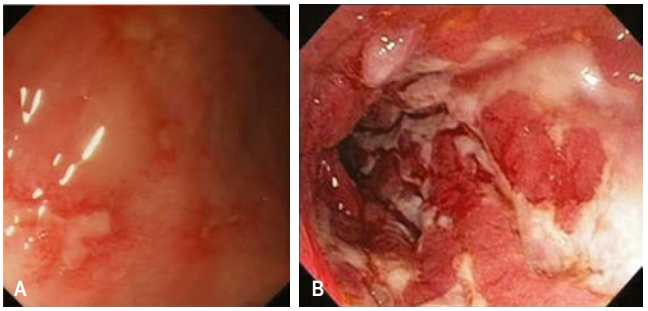

Fig. 22.42 Crohn's disease: colonoscopic appearances. (A) Aphthoid ulcers typical of Crohn's disease. **(B)** Deep, serpiginous ulceration in colonic Crohn's disease.

Box 22.35 Histological differences between Crohn's disease and ulcerative colitis

Histological feature	Crohn's disease	Ulcerative colitis
Inflammation	Deep (transmural) patchy	Mucosal continuous
Granulomas	++	Rare
Goblet cells	Present	Depleted
Crypt abscesses	+	++

Box 22.36 Extragastrointestinal manifestations of inflammatory bowel disease

- Eyes:
  - Uveitis
  - Episcleritis, conjunctivitis
- Joints:
  - Type I (pauciarticular) arthropathy
  - Type II (polyarticular) arthropathy
  - Arthralgia
  - Ankylosing spondylitis
  - Inflammatory back pain
- Skin:
  - Erythema nodosum
  - Pyoderma gangrenosum
- Liver and biliary tree:
  - Sclerosing cholangitis
  - Fatty liver
  - Chronic hepatitis
  - Cirrhosis
  - Gallstones
- Nephrolithiasis
- Venous thrombosis

Joint and other extragastrointestinal manifestations of IBD are shown in **Box 22.36**. There is an association of HLA *DRB1*0103* with pauciarticular large-joint arthritis in UC and CD, and HLA-B44 with small-joint symmetrical arthritis. HLA-B27 is associated with sacroiliitis.

Differential diagnosis

Alternative causes of diarrhoea should be excluded (see **Box 22.8**) and stool cultures (including *C. difficile* toxin assay) must always be performed. However, symptoms persisting beyond 5 days are unlikely to be caused by infective gastroenteritis. Stool microscopy for parasitic diseases such as amoebiasis should be carried out in patients with a relevant travel history. CD should be considered in all individuals with evidence of vitamin malabsorption (e.g., megaloblastic anaemia) or malnourishment, as well as in children with reduced growth velocity. Ileocolonic tuberculosis (see 'Tuberculosis' section) is common in low and middle income countries, such as India, which makes a diagnosis of CD difficult. Microscopy and culture for TB of any available tissue is

essential in these countries. A therapeutic trial of anti-TB therapy may be required. Lymphomas can occasionally involve the ileum and caecum, although they are rare in the patient population at risk from IBD.

Crohn's disease

Clinical features

The major symptoms are diarrhoea, abdominal pain, and weight loss. Constitutional symptoms of malaise, lethargy, anorexia, nausea, vomiting, and low-grade fever may be present and in 15% of these patients there are no gastrointestinal symptoms. Reduced growth velocity and delayed puberty may be the main presenting features in children. Despite the recurrent nature of this condition, some patients have an almost normal lifestyle. However, patients with extensive disease have frequent recurrences and progress from inflammatory to stricturing and penetrating disease. Approximately 50% of patients will require an intestinal resection within 5 years of diagnosis.

Clinical features are very variable and depend partly on the region of the bowel that is affected. The disease may present insidiously or acutely. Abdominal pain can be colicky, suggesting obstruction, but it usually has no special characteristics and sometimes in colonic disease only minimal discomfort is present. Diarrhoea occurs in 80% of all cases and in colonic disease it usually contains blood, making it difficult to differentiate from UC. Steatorrhoea can be present in small bowel disease. Diarrhoea can also be due to bile acid malabsorption, occurring as a consequence of ileal resection or ileal disease.

CD can also present as an emergency with acute right iliac fossa pain mimicking appendicitis. If laparotomy is undertaken, an oedematous, reddened terminal ileum is found. Other causes of an acute ileitis include infections such as *Yersinia* and TB.

CD is complicated by anal and perianal disease, and this is the presenting feature in 25% of cases, often preceding colonic and small intestinal symptoms (see **Box 22.34**). Enteric fistulae—for example, to bladder, vagina, or abdominal wall—occur in 20% to 40% of cases.

Examination

Physical signs are few, apart from loss of weight and signs of malnutrition. Aphthous ulceration of the mouth is often seen. Abdominal examination may be normal, although tenderness and/or a right iliac fossa mass are occasionally found. The mass is due either to inflamed loops of bowel that are matted together or to an abscess, which may also cause psoas muscle irritation. The anus should always be examined to look for oedematous anal tags, fissures, or perianal abscesses.

The presence of extraintestinal features of IBD should be assessed (see **Box 22.36**).

Investigations

Blood tests

- ***Anaemia*** is common and may be the normocytic, normochromic anaemia of chronic disease. However, deficiency of iron and/or folate also occurs. Despite terminal ileal involvement in CD, megaloblastic anaemia due to vitamin B_{12} deficiency is unusual, although serum B_{12} levels can be below the normal range.
- ***Raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)*** are found, as are raised white cell and platelet counts.
- ***Hypoalbuminaemia*** is present in severe disease as part of an acute phase response to inflammation associated with a raised CRP.
- ***Liver biochemistry*** may be abnormal.
- ***Blood cultures*** are required if septicaemia is suspected.
- ***Serological tests*** may reveal negative perinuclear ANCA (pANCA) and positive ASCA (see 'Pathology [microscopic changes]' section, above).

Stool tests

Stool cultures, including *C. difficile* toxin assay, should always be performed if diarrhoea is present. Microscopy for parasites is essential in patients with a relevant travel history. Faecal calprotectin and lactoferrin, both neutrophil-derived proteins indicating intestinal inflammation, are raised in active intestinal disease. Faecal calprotectin is useful for disease monitoring in IBD.

Endoscopy and radiological imaging

- ***Colonoscopy*** is performed if colonic involvement is suspected, except in patients presenting with severe disease (in whom a limited unprepared sigmoidoscopy should be carried out). The findings vary from mild, patchy, superficial (aphthoid) ulceration to more widespread, larger, and deeper ulcers that produce a cobblestone appearance (see **Fig. 22.42**). Endoscopic assessment of the terminal ileum is essential in all patients with suspected CD. Two biopsies should be performed in five areas, including the rectum and terminal ileum.
- ***Upper gastrointestinal endoscopy*** is required to exclude oesophageal and gastroduodenal disease in patients with relevant symptoms and is increasingly being performed in all patients at diagnosis to define the extent of disease accurately as a guide to prognosis.
- ***Small bowel imaging*** is mandatory in patients with suspected CD. The technique used will depend on availability and local expertise. Techniques include barium follow-through, CT scan with oral contrast, small bowel ultrasound, or MRI enteroclysis. An asymmetrical alteration in the mucosal pattern with deep ulceration, and areas of narrowing or structuring may be found. Although disease is commonly confined to the terminal ileum (**Fig. 22.43**), other areas of the small bowel can be involved, and skip lesions with normal bowel are seen between affected sites. Axial imaging allows the diagnosis of extraintestinal sepsis in patients presenting acutely and is therefore preferred in this situation.
- ***Ultrasound scanning*** provides a convenient radiation-free method for assessing disease activity in the ileum and colon and can be performed by appropriately trained gastroenterologists at the bedside.
- ***Perianal MRI or endoanal ultrasound*** is used to evaluate perianal disease.
- ***Capsule endoscopy*** is used in CD patients when radiological examination is normal. A patency capsule assessment is often performed first to exclude strictures of the small bowel that would constitute a contraindication to subsequent capsule endoscopy.
- ***Radionuclide scans*** with indium- or technetium-labelled leucocytes are used in some centres to identify small intestinal and colonic disease inflammation and to localize extraintestinal abscesses.

Disease activity

This can be assessed using simple parameters such as haemoglobin, white cell count, inflammatory markers (raised ESR, CRP, and platelet count), and serum albumin. Formal clinical activity indices (e.g., CD Activity Index or Harvey Bradshaw Index) are used in research studies. Faecal calprotectin is a simple, cheap,

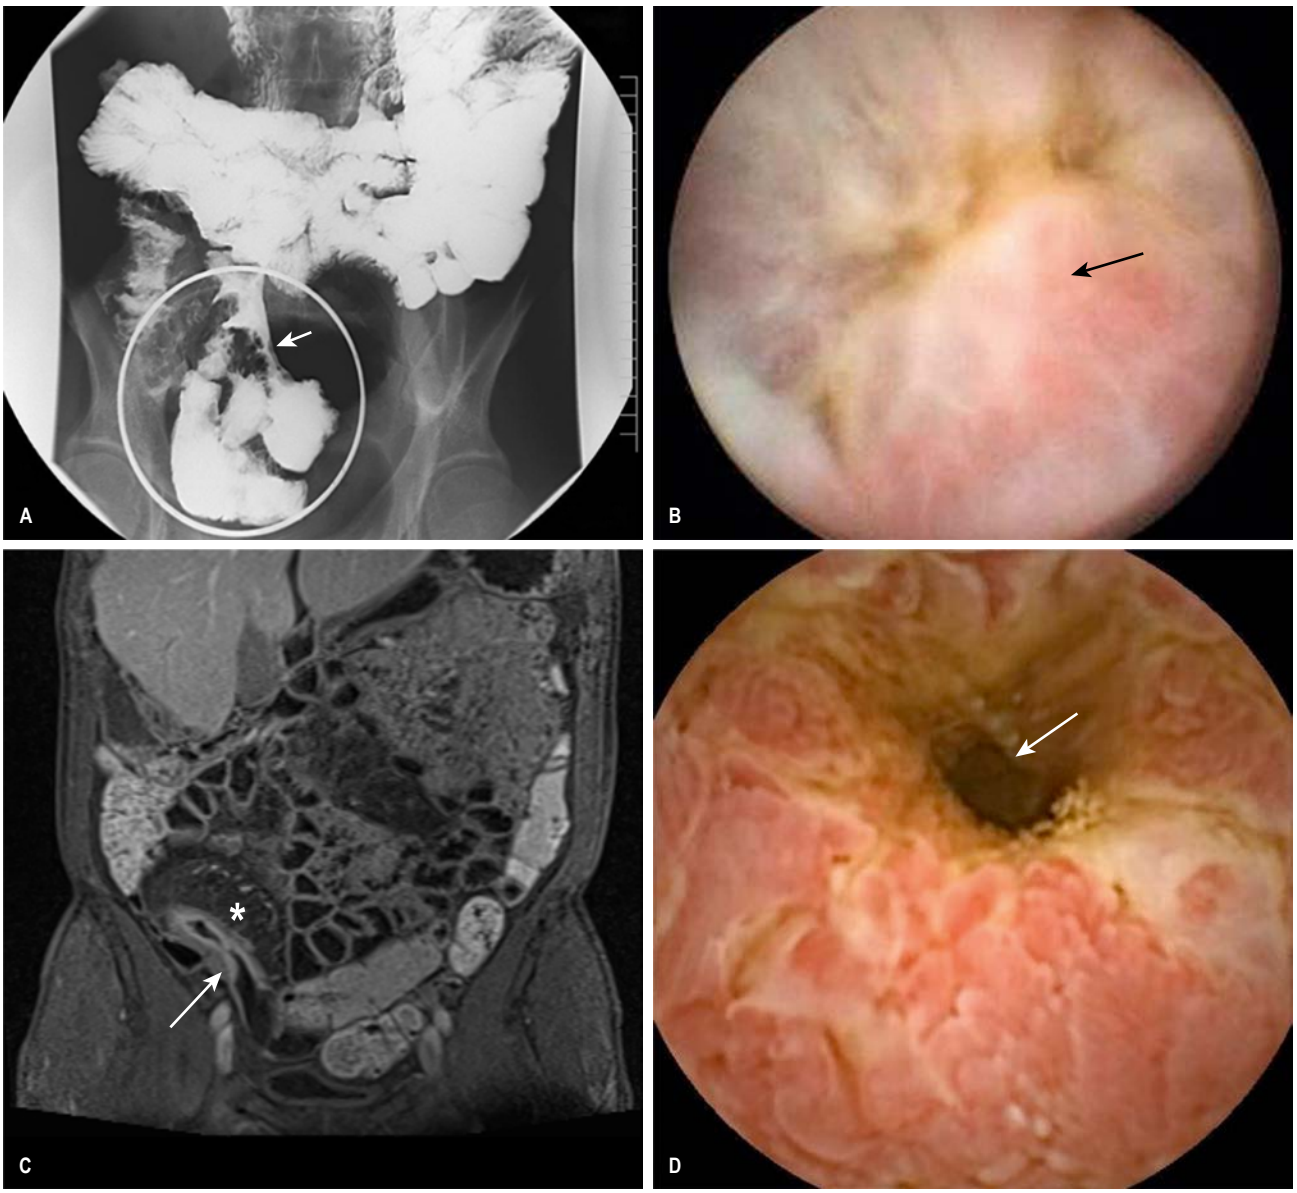

Fig. 22.43 Imaging of the small bowel in Crohn's disease. **(A)** Barium follow-through showing an ulcerated stricture *(arrowed)*, pre-stenotic dilation, and separation of the small bowel loops due to fibro-fatty proliferation. Small bowel follow-through has generally been superseded by small bowel MRI. **(B)** Capsule endoscopy picture of an ileal ulcer in a patient with Crohn's disease *(arrowed)*. **(C)** Post-contrast T1 fat-suppressed coronal image from an MRI enterography examination demonstrates bowel wall thickening of the terminal ileum and mucosal hyperenhancement consistent with active inflammation *(arrow)*. There is also fibrofatty proliferation (*) adjacent to the inflamed bowel consistent with chronic disease and, therefore, the overall appearances represent chronic active Crohn's disease. **(D)** Capsule endoscopy showing an ileal Crohn's disease stricture *(arrowed)*.

non-invasive marker of intestinal inflammation and is widely used, particularly in the outpatient setting, to monitor disease activity and response to treatment.

Medical management of Crohn's disease

See **Box 22.37**.

General considerations

The aims of management are to induce and then maintain clinical remission and to achieve mucosal healing in order to prevent disease progression and complications. Alternative causes for symptoms, such as gastroenteritis, extraintestinal sepsis, stricture formation, functional gastrointestinal disease, or bile salt malabsorption, must be excluded before commencing immunosuppressive therapy. Patients with mild symptoms and no evidence of extensive disease may require symptomatic treatment only. Cigarette smoking should be stopped. Anaemia, if due to vitamin B_{12}, folic acid, or iron deficiency, should be treated with the appropriate replacement. Patients who are intolerant of oral iron should receive an intravenous iron infusion. Most patients can be treated as outpatients, although severe attacks may require admission, and prophylaxis for thromboembolism (see Chapter 40) should be given to all inpatients.

Box 22.37 Options for the medical treatment of Crohn's disease

Induction of remission
- Oral or i.v. glucocorticosteroids
- Enteral nutrition
- Anti-tumour necrosis factor (TNF) antibodies

Maintenance of remission
- Azathioprine, mercaptopurine, methotrexate
- Anti-TNF antibodies

Perianal disease
- Surgical drainage of sepsis
- Ciprofloxacin and metronidazole
- Azathioprine
- Anti-TNF antibodies

Induction of remission

Glucocorticosteroids

These are commonly used to induce remission in moderate and severe attacks of CD (oral prednisolone 30–60 mg/day). Mild to moderate ileocaecal disease should be treated with controlled-release corticosteroids, such as budesonide, which has reduced systemic availability and is associated with a lower frequency and intensity of steroidal side-effects.

Overall remission/response rates vary from 60% to 90%, depending on type, site, and extent of disease. Steroids should be avoided in patients with penetrating intestinal disease or perianal sepsis.

Aminosalicylates

These have been used but there is little evidence to support their efficacy in CD.

Antibiotics

Antibiotics (ciprofloxacin and metronidazole) are used for treating secondary complications of CD (e.g., abscess and perianal disease).

Exclusive enteral nutrition

This consists of pre-mixed nutritional drinks which provide all of a patient's nutritional needs. It is the traditional treatment for moderate to severe attacks of CD in paediatric practice, but is under-utilized in adults due to issues with compliance to the diet. If administered as the sole source of nutrition for 28 days, rates of induction of remission are similar to those obtained with steroids. Relapse rates are high, however, particularly in those with colonic involvement.

Refractory or fulminant disease

Patients with symptoms that do not respond to conventional therapy should be re-assessed to exclude an alternative diagnosis such as a stricture or penetrating abscess. In patients with disease limited to the terminal ileum, surgical resection may be appropriate. In those with more extensive disease, remission should be induced with an anti-TNF agent, either as monotherapy or preferably in combination with an immunosuppressant such as azathioprine (see below).

Maintenance of remission

All patients require regular monitoring to exclude persistent intestinal inflammation. Patients with disease that has a good prognosis (older age at diagnosis, no perianal disease, limited ulceration at index investigations, non-smoker) may not require maintenance therapy. Patients with disease that has a poor prognosis (young age at diagnosis, extensive small bowel disease, deep colonic ulceration, perianal/rectal disease, smoker) or that flares up after induction therapy is withdrawn require long-term maintenance immunosuppression. The goal of maintenance therapy is to prevent disease progression, as well as to reduce the need for corticosteroids, which are associated with a high burden of side-effects. Therapies that induce mucosal healing result in better outcomes. All maintenance therapies require careful monitoring to ensure optimal disease control and prevent side-effects. If there is ongoing evidence of disease activity, adherence should be confirmed and dose optimization or therapy escalation undertaken.

Conventional maintenance therapies

These include ***azathioprine*** (AZA; 2–2.5 mg/kg per day), ***mercaptopurine*** (MP; 1–1.5 mg/kg per day), and ***methotrexate*** (25 mg **once a week** for 8–12 weeks [duration of induction dose dependent on clinical response] then reduce to 15 mg per week) (see **Box 22.37**). Long-term treatment with these drugs is necessary, as the rate of relapse on discontinuation is high. Patient education regarding side-effects and appropriate monitoring for complications is essential and may increase adherence. The key enzyme involved in AZA and MP metabolism is thiopurine methyl transferase (TPMT). This enzyme has a significant genetic variation and deficiencies can result in high circulating levels of thioguanine nucleotides with an increased risk of bone marrow depression. Assays of TPMT activity are available and should be performed before treatment. TPMT deficiency is not the only cause of bone marrow depression, so 3-monthly blood counts should be performed on all patients. Metabolite measurement can be undertaken to assess adherence and ensure optimal dosing.

Anti-TNF agents

These have clear evidence of benefit in the induction and maintenance of remission in patients with CD. They are indicated in patients with disease refractory to conventional immunosuppressive therapy. Early use of anti-TNF therapy is indicated in selected patients with disease that has a poor prognosis (see above). They are also used to treat complex perianal/rectal disease once sepsis has been drained. Available anti-TNF agents include ***infliximab*** (a chimeric anti-TNF-α IgG1 monoclonal antibody), ***adalimumab*** (a fully humanized anti-TNF IgG1 monoclonal antibody), and ***certolizumab pegol*** (a PEGylated Fab′ fragment of a humanized anti-TNF antibody). They neutralize soluble TNF-α, bind to membrane-bound TNF-α, and induce immune cell apoptosis, although the exact mechanism of action is not defined. In clinical trials, they have been shown to exert a steroid-sparing effect and bring about complete mucosal healing in up to one-third of patients in the long term. This results in a reduced need for hospital admission and surgery. These agents should always be used on a regular basis as maintenance therapy, as they are less effective and induce anti-drug antibodies if used episodically. In patients who are naïve to azathioprine, combination therapy increases efficacy and reduces immunogenicity. Their use should be limited to clinicians experienced in the management of CD, as they are associated with significant complications, including opportunistic infections (such as TB), demyelination, and malignancy.

Novel biological therapies

Advances in mucosal immunology have highlighted a variety of targets to resolve the inflammation and symptoms of IBD. Numerous investigational therapies concentrate on inhibiting, suppressing, or

Box 22.38 Biological therapies in IBD

Current therapies	Target molecule	Mechanism of action
Infliximab	Chimeric mAb against TNF-α	Neutralizes soluble TNF-α, binds to membrane-bound TNF-α and induces immune cell apoptosis
Adalimumab	Humanized mAb against TNF-α	Neutralizes soluble TNF-α, binds to membrane-bound TNF-α and induces immune cell apoptosis
Golimumab	Humanized IgG1 kappa mAb against TNF-α	Binds to both the soluble and transmembrane bioactive forms of human TNF-alpha, neutralizing activity
Ustekinumab	Human IgG1 kappa mAb binds to p40 subunit shared by IL-12 and IL-23	Interferes with binding of pro-inflammatory cytokines IL-12 and IL-23 to their cell surface receptors, interfering with NK cell activation and differentiation/activation of $CD4^+$ T cells
Risankizumab	Humanized IgG1 mAb blocks p19 subunit of IL-23	Neutralizes IL-23 preventing its interaction with the IL-23 receptor and activation of downstream signalling cascades
Vedolizumab	Anti-α4β7 integrin	Reduces lymphocyte recruitment to the inflamed intestine
Tofacitinib	Reversibly inhibits Janus kinase (JAK) 1 and JAK3 *in vitro* and to a lesser extent inhibits JAK2 and TYK2	Inhibition of JAK3, results in inhibition of cytokines IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 Inhibition of JAK1, results in inhibition of IL-6, type 1 IFNs, and IFN-γ Some effect on natural killer cell depletion
Upadacitinib	Selective and reversible Janus kinase (JAK) inhibitor inhibiting signalling by JAK1 or JAK 1/3 with functional selectivity over cytokine receptors that signal via pairs of JAK2	JAK inhibition results in inhibition of IL-6- and IFN-γ-related signalling; some effect on natural killer cell depletion
Ozanimod	Sphingosine-1 phosphate receptor modulator	Prevents lymphocyte regression from lymph nodes

altering T-cell differentiation. These biological therapies are summarized in **Box 22.38**. This section covers the novel biological therapies that are now widely used for both CD and UC.

- Vedolizumab is an anti-α4β7 integrin therapy which acts to reduce leucocyte recruitment to the inflamed intestine. This is used in patients with moderately to severely active Crohn's disease or UC who are intolerant to an anti-TNF or in whom it is contraindicated, or in those patients who have had an inadequate response or lost response to an anti-TNF-α agent.
- Ustekinumab targets the IL-12/IL-23 pathway, and is used to treat moderate to severely active Crohn's disease and UC, in those patients who cannot have, or have had an inadequate response to, an anti-TNF-α agent.
- Risankizumab is a humanized IgG1 monoclonal antibody blocking the p19 subunit of IL-23. It is delivered subcutaneously and is effective in achieving and maintaining remission in patients with moderately to severely active Crohn's disease. It is recommended for patients who have failed, not tolerated, or lost response to a previous biological agent, or where anti-TNF-alpha agents are not suitable.
- Ozanimod is an oral sphingosine-1 phosphate receptor modulator which prevents lymphocyte egression from lymph nodes and used to treat adults with moderately to severely active UC.
- Janus kinases (JAKs) are protein tyrosine kinases (TYKs) that cohere to the intracellular domains of transmembrane cytokine receptors of numerous growth factors and cytokines. Once bound, the JAKs become activated leading to phosphorylation of the receptor and the associated signal transducer and activator of transcription (STAT) proteins, which then react and form a dimer which enters the nucleus. They then bind to transcriptional regulatory sites and control cellular responses central in immune defence and in immune-mediated disease.
  - Upadacitinib is a selective JAK-1 inhibitor; it inhibits IL-6- and IFN-γ-related signalling.
  - It is an oral agent used to treat moderate to severely active Crohn's or UC that has not responded well to a previous biologic or if anti-TNF alphas are contraindicated.
  - Tofacitinib reversibly inhibits JAK1 and JAK3 *in vitro* and to a lesser extent inhibits JAK2 and TYK2. Tofacitinib, by inhibition of JAK3, inhibits cytokines IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21; and by JAK1 inhibition, inhibits IL-6, type 1 IFNs, and IFN-γ. Tofacitinib is an oral agent used to treat moderately to severely active UC.
- Important adverse events with JAK inhibitors are venous thromboembolism, major cardiovascular events, herpes zoster infection, and malignancy.

Surgical management of Crohn's disease

Studies prior to the introduction of biological agents suggest that up to 80% of patients will require an operation at some time during the course of their disease. Nevertheless, surgery should be avoided if possible and only minimal resections undertaken, as recurrence (15% per year) is almost inevitable without prophylactic maintenance therapy. The *indications for surgery* are:

- failure of medical therapy, with acute or chronic symptoms producing ill-health
- complications (e.g., toxic dilation, obstruction, perforation, abscesses, enterocutaneous fistula)
- failure to grow in children despite medical treatment
- presence of perianal sepsis; an examination is performed under anaesthetic, the sepsis is drained, and a seton is inserted to ensure ongoing drainage.

In patients with small bowel disease some strictures can be widened (stricturoplasty), whereas others require resection and anastomosis. It is essential to consider postoperative maintenance therapy in patients undergoing ileocolonic resection and anastomosis. All patients should refrain from smoking. There is some evidence that a 3-month course of metronidazole reduces relapse rates. Patients with a high risk of relapse (previous surgery, smoker, penetrating disease at the time of index surgery) should be evaluated for maintenance immunosuppressive therapy. Patients should undergo an ileocolonoscopy to assess the anastomosis for disease

Box 22.39 Definition of a severe attack of ulcerative colitis

- Stool frequency: >6 stools/day with blood +++
- Fever: >37.5°C
- Tachycardia: >90 beats/min
- Erythrocyte sedimentation rate: >30 mm/h
- Anaemia: <100 g/L haemoglobin
- Albumin: <30 g/L

recurrence 6 months after surgery, when further therapy can be agreed with the patient.

When colonic CD involves the entire colon and the rectum is spared or minimally involved, a subtotal colectomy and ileorectal anastomosis may be performed. An eventual recurrence rate of 60% to 70% in the ileum, rectum, or both is to be expected; however, two-thirds of these patients retain a functional rectum for 10 years. If the whole colon and rectum are involved, a panproctocolectomy with an end ileostomy is the standard operation. CD patients are not suitable for a pouch operation (see 'Surgical management of ulcerative colitis' section), as recurrence in the pouch is high.

Problems associated with ileostomies include:

- mechanical problems
- dehydration, particularly if there is a short length of small bowel remaining
- psychosexual problems
- erectile dysfunction in males and reduced fecundity in females (due to prior pelvic surgery)
- recurrence of CD.

Prognosis

The majority of patients have inflammatory disease at diagnosis, although up to 20% will present with complicated disease, including strictures and penetrating disease. If disease is left untreated, its natural history is progression from inflammatory to stricturing and penetrating disease that may require surgery. Up to 50% of patients will require a surgical resection within the first 5 years of disease. The goal of therapy is to target early aggressive therapy at those patients with a poor prognosis. However, predicting disease prognosis at diagnosis is not easy. Features that imply a poor prognosis include young age at diagnosis (<20 years of age), extensive small bowel disease, complex perianal disease and deep ulceration at index colonoscopy.

Ulcerative colitis

Clinical features

The major symptom in UC is diarrhoea with blood and mucus, sometimes accompanied by lower abdominal discomfort. General features include malaise, lethargy and anorexia with weight loss, although these features are not as severe as with CD. Aphthous ulceration in the mouth may be seen. The disease can be mild, moderate or severe (**Box 22.39**), and in most patients runs a course of remissions and exacerbations. Disease extent is defined as limited to the rectum (proctitis), left-sided or extensive (see **Fig. 22.41**).

Proctitis is characterized by the frequent passage of blood and mucus, urgency and tenesmus. There are normally few constitutional symptoms and the stool, when passed, may be solid. Patients are nevertheless greatly inconvenienced by the frequency of defecation.

In an acute attack of left-sided or extensive UC, patients have bloody diarrhoea, passing up to 10 to 20 liquid stools per day. Diarrhoea also occurs at night, with urgency and incontinence that is severely disabling for the patient. Patients with an acute severe flare of colitis require urgent admission for intensive therapy (see Chapter 11).

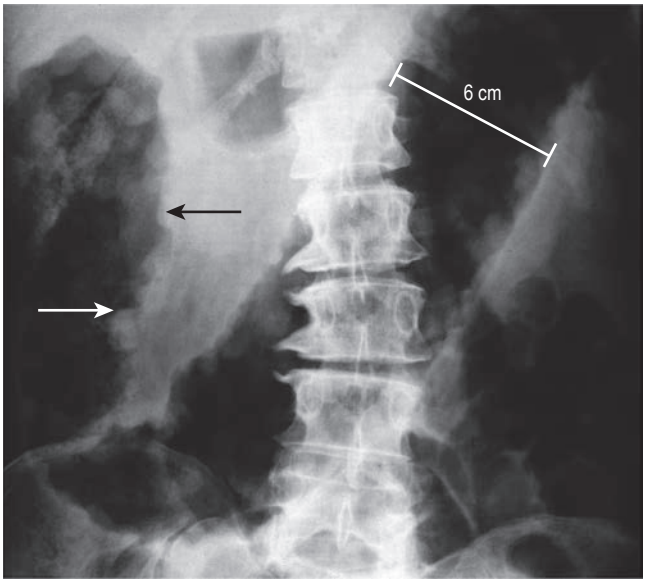

Fig. 22.44 Plain abdominal X-ray showing toxic dilation. The *arrows* indicate mucosal islands.

Toxic megacolon is a serious complication associated with acute severe colitis. The plain abdominal X-ray shows a dilated, thin-walled colon with a diameter of more than 6 cm; it is gas-filled and contains mucosal islands (**Fig. 22.44**). It is a particularly dangerous stage of advanced disease, with impending perforation and a high mortality (15%–25%). Urgent surgery is required in all patients in whom toxic dilation has not resolved within 48 hours, with intensive therapy as above. The differential diagnosis includes an infectious colitis, for example, with *C. difficile* and cytomegalovirus.

Examination

In general, there are no specific signs in UC. The abdomen may be slightly distended or tender to palpation. Tachycardia and pyrexia are signs of severe colitis and mandate admission. The anus is usually normal. Rectal examination will reveal the presence of blood. Sigmoidoscopy is usually abnormal, showing an inflamed, bleeding, friable mucosa. Very occasionally, rectal sparing occurs, with normal proctoscopy.

Investigations

Blood tests

- ***White cell and platelet counts*** are commonly raised in moderate to severe attacks, and iron deficiency anaemia is present.
- ***ESR and CRP*** are often raised; liver biochemistry may be abnormal, with hypoalbuminaemia occurring in severe disease.
- ***pANCA*** may be positive. This is contrary to CD, where pANCA is usually negative (see 'Pathology [microscopic changes]' section, above).

Stool tests and *C. difficile* toxin

These should always be performed to exclude infective causes of colitis. Stool microscopy to exclude amoebiasis is mandated in patients with a relevant travel history. Faecal calprotectin/lactoferrin will be elevated.

Colonoscopy

Endoscopy with mucosal biopsy is the 'gold standard' investigation for the diagnosis of UC. Colonoscopy also allows assessment of disease

activity and extent. In patients with long-term colitis, chromoendoscopy is used to diagnose dysplasia. Full colonoscopy should not be performed in severe attacks of disease for fear of perforation; instead, a limited unprepared FS should be used to confirm diagnosis.

Imaging

A plain abdominal X-ray is essential in patients suffering acute severe attacks to exclude colonic dilation. However, the extent of disease is not reliably assessed using this investigation. Other imaging modalities are rarely used in the assessment of patients with UC, as endoscopy is preferred. However, inflammation of the colonic wall is detected on ultrasound, as is the presence of free fluid within the abdominal cavity.

Medical management of ulcerative colitis

Wherever possible, patients with IBD should be managed in patient-focused IBD clinics with access to a full multidisciplinary team (MDT). The mainstay of treatment for mild and moderate disease of any extent is an aminosalicylate, which acts topically in the colonic lumen. The active moiety of these drugs is 5-aminosalicylic acid (5-ASA), which is absorbed in the small intestine. Therefore, the various aminosalicylate preparations are designed to deliver the active 5-ASA to the colon. This is achieved by binding of 5-ASA with an azo bond to sulfapyridine (sulfasalazine), 4-aminobenzoyl-β-alanine (balsalazide), or to 5-ASA itself (olsalazine), coating with a pH-sensitive polymer, packaging of 5-ASA in microspheres, or a combination of these. The azo bonds are broken down by colonic bacteria to release 5-ASA within the colon.

The mode of action of 5-ASA in IBD is unknown, although it may involve the intracellular peroxisome proliferator-activated receptor (PPAR)-γ signalling pathway. The aminosalicylates have been shown to be effective in inducing remission in mild to moderately active disease, and maintaining remission in all forms of disease. There is also evidence that they are chemopreventive for UC-associated colorectal cancer. 5-ASA can rarely cause renal disease.

Proctitis

Rectal 5-ASA suppositories are the first-line treatment. Topical steroids are less effective than 5-ASA preparations. Oral 5-ASA can be added to increase remission rates. Some cases of proctitis do not respond to 5-ASA treatment and require oral prednisolone.

Left-sided colitis

Topical 5-ASA enemas are the first-line treatment. The addition of an oral 5-ASA will increase remission rates. Patients who do not respond to this or have worsening symptoms require oral prednisolone.

Extensive colitis

Patients with mild to moderate symptoms can be treated with an oral 5-ASA at an adequate dose. The additional of a 5-ASA enema increases remission rates. Patients who do not respond to this or have worsening symptoms require oral prednisolone.

Refractory/severe colitis of any extent

Patients with colitis that is refractory to standard conventional therapies should be investigated to ensure adherence to therapy, confirm active colitis, and exclude infection, including biopsies to exclude reactivation of CMV colitis. They should then receive biological therapy with either an anti-TNF agent (infliximab, adalimumab, or golimumab) or an anti-integrin therapy (vedolizumab), or tofacitinib, an oral inhibitor of Janus kinase 1-3, which became available in 2018 for the treatment of adults with moderately to severely active UC. See 'Novel biological therapies' section for further discussion.

Patients with severe colitis (**Box 22.39**) and those who do not respond to oral prednisolone should be admitted to hospital for treatment (see Chapter 11).

Salvage therapy

Salvage therapy to avoid colectomy is required for patients with a CRP higher than 45 mg/L or more than eight bowel motions after 3 days of intravenous hydrocortisone. Continuing steroid therapy alone in this situation will delay the inevitable colectomy and increase mortality. Salvage medical therapies with clear evidence of benefit in controlled clinical trials are intravenous infliximab infusion or ciclosporin 2 mg/kg per day as a continuous infusion. The majority of patients are commenced on infliximab rather than ciclosporin. Patients with extensive ulceration may require higher induction doses of infliximab. Patients with a low albumin level have been shown to have a lower response rate to salvage therapy. These agents should only be used by experienced gastroenterologists who are part of an MDT with colorectal surgeons. Patients should be weaned off steroids rapidly, once salvage therapy has commenced, to reduce morbidity. Those who respond should be treated with oral ciclosporin or further infliximab infusions, as appropriate, while maintenance thiopurine therapy is commenced.

Potential future therapies

Alicaforsen is an inhibitor of intracellular adhesion molecule-1. Alicaforsen enemas have demonstrated efficacy in the treatment of distal ulcerative colitis as well as pouchitis in clinical trials.

An autologous stem cell transplantation trial in refractory Crohn's disease—low-intensity therapy evaluation (ASTIClite) is currently underway. It is looking to assess whether stem cell transplantation, with a low-intensity chemotherapy regimen, can reduce the symptoms and activity of Crohn's disease and enhance quality of life, compared to current standard care. The trial will also assess the safety of the procedure, explore the mechanisms involved in immune reconstitution, and determine whether patients who experience recurrent disease after the stem cell transplant will respond to treatments that had not worked previously. Finally, the trial aims to assess the long-term safety and efficacy in patients undergoing stem cell transplantation over a minimum of a further 4 years.

Surgical management of ulcerative colitis

While the treatment of UC remains primarily medical, surgery continues to have a central role because it may be life-saving, is curative, and eliminates the long-term risk of cancer. The main indications for surgery are severe colitis that fails to respond to medical therapy, and chronic active therapy-refractory disease. Other indications are listed in **Box 22.40**. In expert centres,

Box 22.40 Indications for surgery in ulcerative colitis

Fulminant acute attack
- Failure of medical treatment
- Toxic dilation
- Haemorrhage
- Imminent perforation

Chronic disease
- Incomplete response to medical treatment/steroid-dependent
- Dysplasia on surveillance colonoscopy

laparoscopic surgery is often used to improve postoperative pain, recovery time, and cosmesis.

In acute disease, subtotal colectomy with end ileostomy and preservation of the rectum is the operation of choice. At a later date, a number of surgical options are available and are best carried out in a specialist colorectal centre. These include proctectomy with a permanent ileostomy; to avoid a permanent ileostomy, an ileo-anal pouch procedure can be performed (Fig. 22.45). The ileo-anal pouch is anastomosed to the anus at the dentate line following excision of the remaining rectum. One-third of patients, however, will experience ***'pouchitis'***, inflammation of the pouch mucosa with clinical symptoms of diarrhoea, bleeding, fever and, at times, exacerbation of extracolonic manifestations (Fig. 22.46). The incidence of pouchitis is twice as high in patients with primary sclerosing cholangitis and is also raised in patients with a positive ANCA and backwash ileitis prior to colectomy. Two-thirds of pouchitis cases will recur as either acute relapsing or chronic unremitting forms. The mainstay of treatment is antibiotics (metronidazole with or without ciprofloxacin). Treatment is not always satisfactory and steroids may be required. The probiotic VSL#3 has been shown to be effective in preventing the onset of pouchitis and in maintaining remission in patients with antibiotic-treated pouchitis to induce mucosal healing.

Course and prognosis

One-third of patients with distal inflammatory proctitis due to UC will develop more proximal disease, with 5% to 10% developing total colitis. One-third of patients with UC will have a single attack and the others will follow a relapsing course. One-third of patients with UC will undergo colectomy within 20 years of diagnosis.

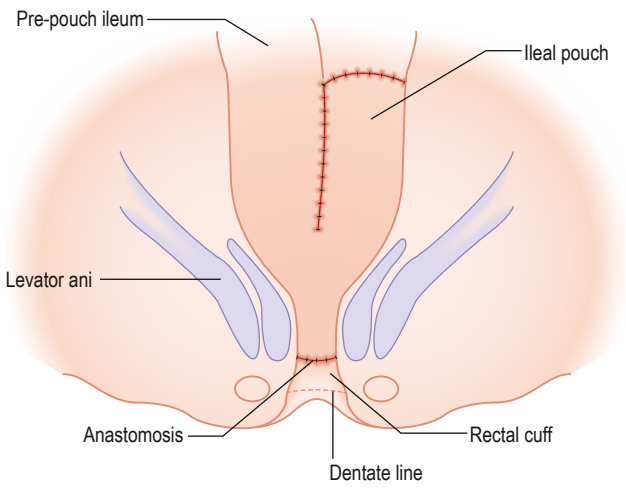

Fig. 22.45 An ileo-anal pouch for ulcerative colitis.

Cancer in inflammatory bowel disease

Patients with UC and extensive Crohn's colitis have an increased incidence of developing dysplasia and subsequent colon cancer. The risk of dysplasia is related to the extent and duration of disease, as well as the presence of untreated mucosal inflammation. A family history of colorectal cancer and the presence of primary sclerosing cholangitis also increase the risk. Appropriate colonoscopic screening strategies according to guidelines are used by many, although evidence for overall benefit is still uncertain. A 40-year analysis of colonoscopy surveillance for neoplasia in UC, conducted at St Mark's Hospital in the UK, suggested that surveillance may have a significant role in reducing the risk of advanced and interval colorectal cancer.

Mortality in inflammatory bowel disease

Population-based studies demonstrate that mortality in UC is similar to that in the general population. The two exceptions are patients with severe colitis, who have a slightly higher mortality in the first year after diagnosis, and patients aged over 60 at the time of diagnosis. Although it is currently unclear whether there is a slightly higher overall mortality in patients with CD, those with extensive jejunal and ileal disease and those with gastric and duodenal disease have been shown to have a relatively higher mortality.

Microscopic colitis

Patients with this group of disorders present with chronic or fluctuating watery diarrhoea. Although the macroscopic features on colonoscopy are normal, the histopathological findings on biopsy are abnormal. There are three distinct forms of microscopic inflammatory colitis:

- ***Microscopic UC*.** There is a chronic inflammatory cell infiltrate in the lamina propria, with deformed crypt architecture and goblet cell depletion, with or without crypt abscesses. Treatment is as for UC; many patients respond to treatment with aminosalicylates alone.
- ***Microscopic lymphocytic colitis*.** There is surface epithelial injury, prominent lymphocytic infiltration in the surface epithelium, and increased lamina propria mononuclear cells.
- ***Microscopic collagenous colitis*.** There is a thickened subepithelial collagen layer (>10 μm) adjacent to the basal membrane, and increased infiltration of the lamina propria with lymphocytes and plasma cells, and surface epithelial cell damage. It is predominantly a disorder of middle-aged or elderly females, and is associated with

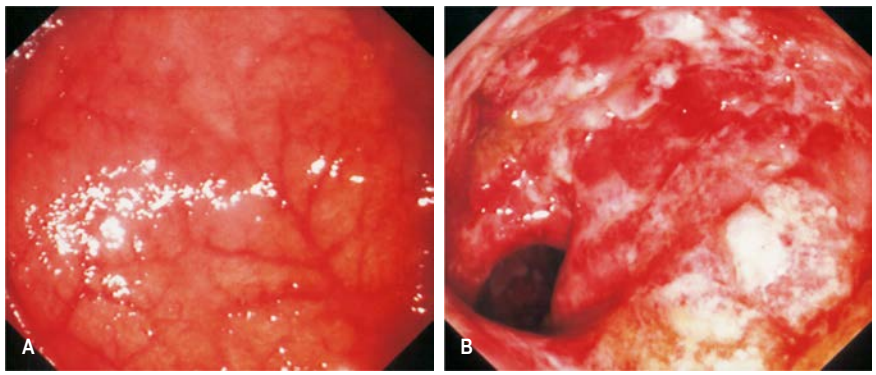

Fig. 22.46 Pouchitis: fibreoptic sigmoidoscopic appearances. **(A)** Mild changes. **(B)** Severe haemorrhagic ulceration.

a variety of autoimmune disorders (arthritis, thyroid disease, limited cutaneous scleroderma, and primary biliary cirrhosis).

The incidence of both microscopic lymphocytic and collagenous colitis is increased in patients with coeliac disease and this must be excluded. Treatment of microscopic and collagenous colitis is usually with budesonide. There is also evidence of benefit for aminosalicylates, bismuth-containing preparations and, if refractory, prednisolone, and azathioprine. A small number of patients with microscopic lymphocytic and collagenous colitis have coexisting bile acid malabsorption and can thus respond to colestyramine. Prognosis is good.

COLON AND RECTUM

Miscellaneous colonic conditions

Clostridium difficile-associated diarrhoea and pseudomembranous colitis

Clostridium difficile infection (CDI) is a common hospital-acquired infection and can be a significant cause of morbidity, especially among the elderly. It frequently occurs following antibiotic therapy due to disruption of the normal gut flora. The following antibiotics are particularly associated with CDI:

- fluoroquinolones
- clindamycin
- cephalosporins
- penicillins
- (macrolides and co-trimoxazole are less frequently associated).

Clinical features include profuse diarrhoea, which can lead to hypovolaemia and shock if severe. The white blood cell count is often significantly elevated and endoscopically there may be pseudomembranous colitis (severe inflammation of the bowel wall lining). Complications include ileus, toxic megacolon, and bowel perforation. If megacolon or perforation is suspected then patients should have urgent imaging (X-ray or CT).

Diagnosis is made with a positive test for *C. difficile* toxin A and B. A positive test for glutamate dehydrogenase (GDH) antigen is not necessarily indicative of active infection, simply that the patient is a carrier of the pathogen.

Treatment

Initial treatment regimens are detailed in **Box 22.9**. For recurrent or refractory CDI, antibiotics such as rifaximin or fidaxomicin can be useful. However, recently faecal microbiota transplantation (FMT) has become increasingly common. For this procedure, a solution of donor stool is given to the patient either through a nasogastric tube or via FS. The donor stool has been carefully selected from a centralized stool bank where all donors have had their blood and stool extensively screened for infection.

Megacolon

The term 'megacolon' is used to describe a number of congenital and acquired conditions in which the colon is dilated. In many instances, it is secondary to chronic constipation; in some parts of the world, Chagas' disease is a common cause.

In all young patients with megacolon, Hirschsprung's disease should be excluded. In this condition, which presents in the first years of life, an aganglionic segment of the rectum (megarectum) gives rise to constipation and subacute obstruction. Occasionally, Hirschsprung's disease affecting only a short segment of the rectum can be missed in childhood. A preliminary rectal biopsy is performed and stained for ganglion cells in the submucosal plexus. In doubtful cases, a full-thickness biopsy should be obtained. A frozen section is stained for acetylcholinesterase, which is elevated in Hirschsprung's disease. Manometric studies show failure of relaxation of the internal sphincter, which is diagnostic of Hirschsprung's disease. This condition can be successfully treated surgically.

Treatment of other causes of a megacolon is similar to that of slow-transit constipation, but saline washouts and manual removal of faeces are sometimes required.

Faecal incontinence

Of the healthy population over the age of 65, 7% experience a degree of incontinence. Incontinence is classified as minor (inability to control flatus or liquid stool, causing soiling) or major (frequent and inadvertent evacuation of stool of normal consistency); see **Box 22.41** for common causes. Obstetric injury is a common cause and sphincter defects have been found in up to 30% of primiparous women. Endoanal ultrasonography or pelvic MRI is the investigation of choice in the assessment of anal sphincter damage (**Fig. 22.47**). Neurophysiological investigation of pudendal nerve function, anal sensation, and anal sphincter function may be required to elicit the cause of the problem.

Initial ***management*** of minor incontinence is bowel habit regulation. Loperamide is the most potent antidiarrhoeal agent, which also increases internal sphincter tone.

? Box 22.41 Aetiology of faecal incontinence

- Congenital:
  - For example, surgery for imperforate anus
- Anal sphincter dysfunction:
  - Structural damage: surgery—anorectal, vaginal hysterectomy; obstetric injury during childbirth; trauma; radiation; perianal Crohn's disease
  - Pudendal nerve damage: childbirth
  - Perineal descent: prolonged straining at stool
- Rectal prolapse
- Faecal impaction with overflow diarrhoea
- Severe diarrhoea:
  - For example, ulcerative colitis, functional diarrhoea, irritable bowel syndrome
- Neurological and psychological disorders:
  - Spinal trauma (S2–S4)
  - Spina bifida
  - Stroke
  - Multiple sclerosis
  - Diabetes mellitus (with autonomic involvement)
  - Dementia
  - Psychological illness

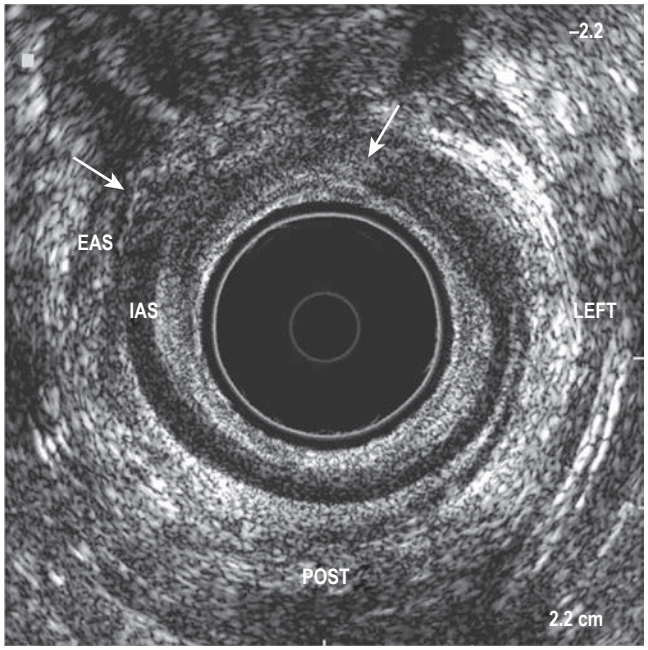

Fig. 22.47 Endoanal ultrasound scan. Axial mid-canal image, showing a large tear between 10 and 1 o'clock *(arrowed)* following vaginal delivery, involving the external anal sphincter (EAS) and internal anal sphincter (IAS), resulting in faecal incontinence. (*Courtesy of Professor Clive Bartram, Princess Grace Hospital, London.*)

Biofeedback is effective in some people with faecal incontinence associated with impaired function of the puborectalis muscle and the external anal sphincter. Sacral spinal nerve stimulation has been shown to be effective in the treatment of patients with a functionally deficient but morphologically intact external anal sphincter. Surgery may be required for anal sphincter trauma and should only be carried out in specialist centres.

Ischaemic disease of the colon (ischaemic colitis)

Occlusion of branches of the superior mesenteric artery (SMA) or inferior mesenteric artery (IMA), often in the older age group, commonly presents with sudden onset of abdominal pain and the passage of bright red blood *per rectum*, with or without diarrhoea. There may be signs of shock and evidence of underlying cardiovascular disease. The anatomy of the vascular supply to the colon results in a watershed area at the splenic flexure, which is therefore the most common site affected. This condition has also been described in females taking the contraceptive pill, patients on nicorandil, and those with thrombophilia and small- or medium-vessel vasculitis.

Examination

On examination, the abdomen may be distended and tender. A straight abdominal X-ray often shows thumb-printing (a characteristic sign of ischaemic disease) at the splenic flexure. Patients are likely to display signs of cardiovascular shock and may have a lactic acidosis.

Differential diagnosis and investigations

The differential diagnosis includes other causes of acute colitis. Patients often require an urgent CT scan to exclude perforation. An unprepared FS is the diagnostic investigation of choice; biopsies showing epithelial cell apoptosis and lamina propria fibrosis are characteristic. A colonoscopy should be performed when the patient has fully recovered to exclude the formation of a stricture at the site of disease and confirm mucosal healing. Patients without evidence of underlying cardiovascular disease should be screened for thrombophilia and vasculitis.

Management

Most patients settle on symptomatic treatment. A few patients show progressive signs of peritonism and imminent perforation, and require urgent surgery.

Diverticular disease

Diverticula are frequently found in the colon and occur in 50% of patients over the age of 50 years. They are most frequent in the sigmoid, but can be present throughout the whole colon.

Terminology:

- ***diverticulosis*** indicates the presence of diverticula
- ***diverticulitis*** implies that these diverticula are inflamed
- ***diverticular colitis*** refers to crescentic inflammation on the folds in areas of diverticulosis.

It is perhaps better to use the more general term ***diverticular disease***, as it is often difficult to be sure whether the diverticula are inflamed. The precise mechanism of diverticula formation is not known. There is thickening of the muscle layer and, because of high intraluminal pressures, pouches of mucosa extrude through the muscular wall through weakened areas near blood vessels to form diverticula. An alternative explanation is cholinergic denervation with increasing age, which leads to hypersensitivity and increased uncoordinated muscular contraction. Diverticular disease seems to be related to the low-fibre diet eaten in high income countries and is rare in rural Africa.

Diverticulitis occurs when faeces obstruct the neck of the diverticulum, causing stagnation and allowing bacteria to multiply and produce inflammation. This can then lead to bowel perforation (peridiverticulitis), abscess formation, fistulae into adjacent organs, haemorrhage and even generalized peritonitis.

Clinical features and investigations

Diverticular disease is asymptomatic in 95% of cases and is usually discovered incidentally on colonoscopy or barium enema examination. No treatment other than advice to increase dietary fibre is required in those patients. In symptomatic patients, intermittent left iliac fossa pain or discomfort and an erratic bowel habit commonly occur, which are difficult to differentiate from the irritable bowel syndrome. In severe disease, luminal narrowing results in severe pain and constipation. In the absence of clinical signs of acute diverticulitis, a colonoscopy or 'virtual colonoscopy' (see 'Endoscopy' section) is the investigation of choice (**Fig. 22.48**). Barium enema combined with FS is also used.

Management

Management of uncomplicated symptomatic disease is with a well-balanced (soluble and insoluble) fibre diet (20 g/day), with smooth muscle relaxants if required. Antibiotics and admission to hospital are not required for uncomplicated disease.

Acute diverticulitis

The pathophysiology of diverticulitis is associated with altered gut motility, increased luminal pressure, and a disordered colonic

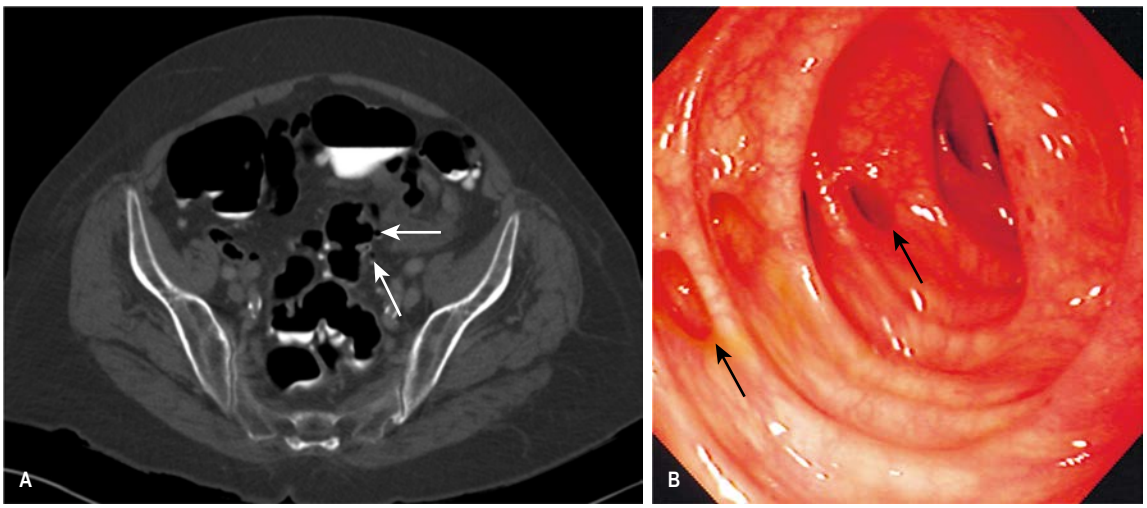

Fig. 22.48 Diverticular disease. **(A)** Axial CT colonography image demonstrating diverticular disease (diverticulosis) of the sigmoid colon *(arrows)*. **(B)** Diverticula *(arrowed)* seen on colonoscopy.

microenvironment. Acute diverticulitis most commonly affects diverticula in the sigmoid colon. It presents with severe pain in the left iliac fossa, often accompanied by fever and constipation. These symptoms and signs are similar to those of appendicitis but are located on the left side. On examination, the patient is often febrile with a tachycardia. ***Abdominal examination*** shows tenderness, guarding, and rigidity on the left side of the abdomen. A palpable tender mass is sometimes felt in the left iliac fossa.

Investigations

- ***Blood tests*** often reveal a polymorphonuclear leucocytosis. The ESR and CRP are raised.
- ***CT colonography*** (Fig. 22.49) will show colonic wall thickening, diverticula, and often pericolic collections and abscesses. There is usually a streaky increased density extending into the immediate pericolic fat with thickening of the pelvic fascial planes. These findings are diagnostic of acute diverticulitis (95% sensitivity and specificity) and differ from those of malignant disease. Sigmoidoscopy and colonoscopy are not performed during an acute attack.
- ***Ultrasound examination*** is often more readily available and is cheaper. It can demonstrate thickened bowel and large pericolic collections, but is less sensitive than CT.

Management

Mild attacks can be treated on an outpatient basis using oral antibiotics such as ciprofloxacin and metronidazole. Patients with signs of systemic upset (fevers, tachycardia), significant abdominal pain, or co-morbidity require bowel rest, intravenous fluids, and intravenous antibiotic therapy. Recent large trials of 5-ASA therapy have shown minor benefit in preventing recurrent diverticulitis. Repeat attacks often require surgery.

Complications of diverticular disease

- ***Perforation*** usually occurs in association with acute diverticulitis, and can lead to formation of a paracolic or pelvic abscess or generalized peritonitis. Surgery may be required.
- ***Fistula formation*** into the bladder, causing dysuria or pneumaturia, or into the vagina, causing discharge.
- ***Intestinal obstruction*** (see 'Intestinal obstruction' section), usually after repeated episodes of acute diverticulitis.
- ***Bleeding*** is sometimes massive. In most cases, the bleeding stops and the cause of the bleeding can be established by colonoscopy and sometimes angiography. In rare cases, emergency segmental colectomy is required.
- ***Mucosal inflammation*** occurs in areas of diverticula, giving the appearance of a segmental colitis at endoscopy that may resemble Crohn's disease.

Anorectal disorders

Pruritus ani

Pruritus ani, or an itchy bottom, is common. Perianal excoriation results from scratching. Usually, the condition results from haemorrhoids or overactivity of sweat glands. ***Management*** consists of enhancing toilet hygiene, keeping the area dry, and avoiding the use of perfumed moisturizing creams. Secondary causes include threadworm *(Enterobius vermicularis)* infestation, fungal infections (e.g., candidiasis), and perianal eczema, which should be treated appropriately.

Haemorrhoids

Haemorrhoids (primary—internal; second degree—prolapsing; third degree—prolapsed) usually cause rectal bleeding, discomfort, and pruritus ani. Patients may notice red blood on their toilet paper and blood on the outside of their stools. They are the most common cause of rectal bleeding (see Fig. 22.33). Diagnosis is made by inspection, rectal examination, and proctoscopy.

Management

If symptoms are minor, no treatment is required apart from advice about avoiding constipation. Suppositories containing a local anaesthetic and corticosteroids are helpful. If symptoms are more severe, rubber band ligation or injection of a sclerosant can be used. Haemorrhoidal artery ligation operation (HALO) uses Doppler ultrasound to identify and ligate feeding arteries to the haemorrhoids and is being used more frequently in place of surgery.

Anal fissures

An anal fissure is a tear in the sensitive skin-lined lower anal canal distal to the dentate line, which produces pain on defecation. It can

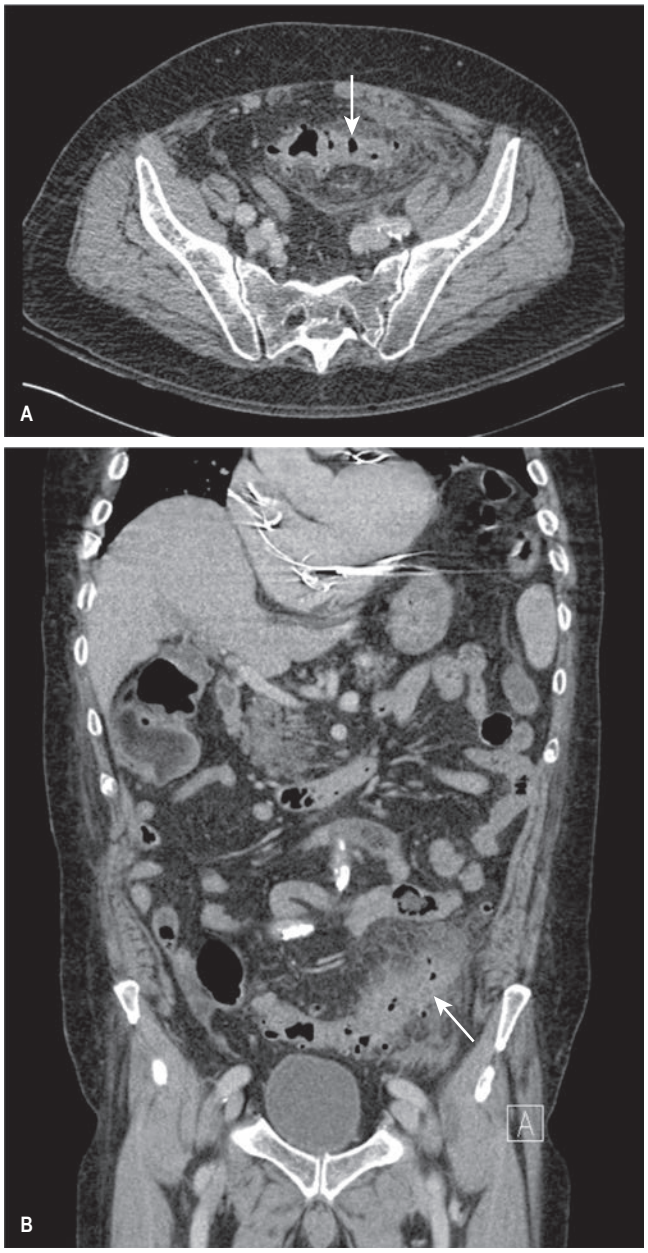

Fig. 22.49 CT colonography. Axial **(A)** and coronal **(B)** CT images demonstrate bowel wall thickening involving the sigmoid colon at the site of diverticular disease and inflammation of the adjacent mesenteric fat consistent with acute diverticulitis *(arrow)*.

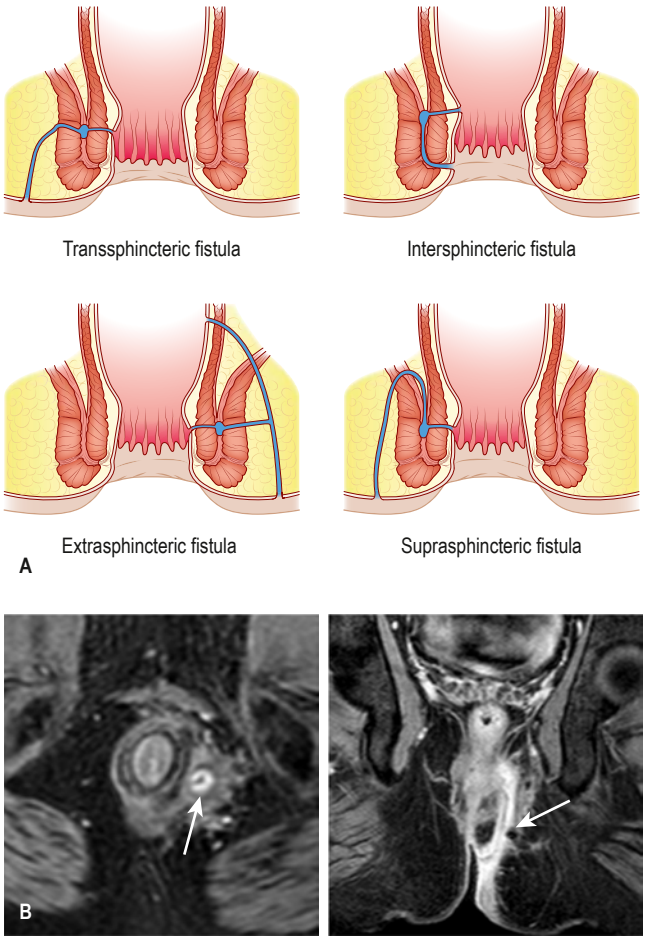

Fig. 22.50 Perianal fistulae. **(A)** Common sites. **(B)** Fistulae and sepsis in Crohn's disease *(arrowed)*. An MRI of the pelvis showing a complex extrasphincteric horseshoe tract with extension to the ischio-anal fossae (right; *arrowed*).

be an isolated primary problem in young to middle-aged adults or may occur in association with Crohn's disease or ulcerative colitis, in which case perianal abscesses and anal fistulae can complicate the fissure.

Diagnosis can usually be made on the history alone and confirmed on perianal inspection. Rectal examination is often not possible because of pain and sphincter spasm. The spasm not only causes pain but also impairs wound healing. In severe cases, proctoscopy and sigmoidoscopy should be performed under anaesthesia to exclude other anorectal diseases. Initial treatment is with local anaesthetic gel and stool softeners. Use of 0.4% glyceryl trinitrate and 2% diltiazem ointments is of benefit. Botulinum toxin is used in chronic fissures but lateral subcutaneous internal sphincterotomy is also employed for severe cases.

Fistula in ano and anorectal abscesses

The anatomy of perianal fistulae may be simple or complex (Fig. 22.50). The fistulae usually present as abscesses and heal after the abscess is incised. In other cases, a small, discharging pilonidal sinus may be noted by the patient.

Endoanal ultrasonography, MRI, and/or examination under anaesthetic are usually required to define the primary and any secondary tracks, exclude sepsis, and detect any associated disease, such as Crohn's disease and tuberculosis. Management is with surgical incision and drainage with antibiotics.

Rectal prolapse, intussusception, and solitary rectal ulcer syndrome

All these conditions are thought to be related, rectal prolapse being the unifying pathology. Some patients with solitary rectal ulcer syndrome (SRUS) do not have prolapse but strain excessively and ulcerate the anterior rectal wall, which is forced into the anus during attempts at defecation. Constipation and chronic straining may be precipitating causes. Patients commonly present with slight bleeding and mucus on defecation, tenesmus, and a sensation of anal obstruction.

SRUS is commonly located on the anterior wall of the rectum within 13 cm of the anal verge, and is sometimes difficult to distinguish from cancer and Crohn's disease during endoscopic

examination. SRUS has typical histological features of non-specific inflammatory changes with bands of smooth muscle extending into the lamina propria.

Asymptomatic SRUS should not be treated. Symptomatic patients should be advised to stop straining and measures should be taken to soften the stool. If rectal prolapse can be demonstrated during defecation, this should be repaired; in severe cases, surgical treatment by rectopexy may be indicated. Surgical treatment for complete rectal prolapse is also required.

Colonic tumours

Colon polyps and polyposis syndromes

A colonic polyp is an abnormal growth of tissue projecting from the colonic mucosa. Polyps range from a few millimetres to several centimetres in diameter and are single or multiple, pedunculated, sessile, or 'flat' (Fig. 22.51).

Many histological types of polyp are found in the colon (Box 22.42). However, adenomas are the precursor lesions in most cases of colon cancer.

Classification of colorectal polyps

Classification is summarized in Box 22.42.

Sporadic adenomas

An adenoma is a benign, dysplastic tumour of columnar cells or glandular tissue. Adenomas have tubular, tubulovillous, or villous morphology. The vast majority of adenomas are not inherited and are termed 'sporadic'. Although many sporadic adenomas do not become malignant in the patient's lifetime, they have a tendency to progress to cancer via increasing grades of dysplasia due to progressive accumulation of genetic changes (adenoma–carcinoma sequence). Factors favouring malignant transformation in colorectal polyps, and the relation between adenoma size and likelihood of cancer, are shown in Box 22.43.

The progression from benign polyp to cancer is shown in Fig. 22.52.

The likelihood of an adenoma being present increases with age; it is rare before the age of 30 years. By the age of 60 to 70,5% of asymptomatic subjects will have a polyp equal to or longer than 1 cm, or cancer with no symptoms, and up to 50% will have at least one small (less than 1 cm) adenoma. Removal of polyps at colonoscopy and subsequent surveillance reduce the risk of development of colon cancer by approximately 80%. Techniques such as chromoscopy, using dye spray or narrow band imaging, are being used to assist in their detection (flat adenomas account for approximately 12% of all adenomas).

Polyps in the rectum and sigmoid often present with rectal bleeding. More proximal lesions rarely produce symptoms and most are diagnosed on barium enema, CT colonography, or on colonoscopy performed for screening or for other reasons. Large villous adenomas can present with profuse diarrhoea with mucus and hypokalaemia.

Once a polyp has been found, it is almost always possible to remove it endoscopically. Surveillance guidelines dictate the frequency of repeat investigations:

- at 5 years, if 1 or 2 adenomas <1 cm are found
- at 3 years, if there are 3 to 4 small adenomas or at least 1 that is >1 cm
- at 1 year, if there are ≥5 small adenomas or there are ≥3, at least 1 of which is >1 cm.

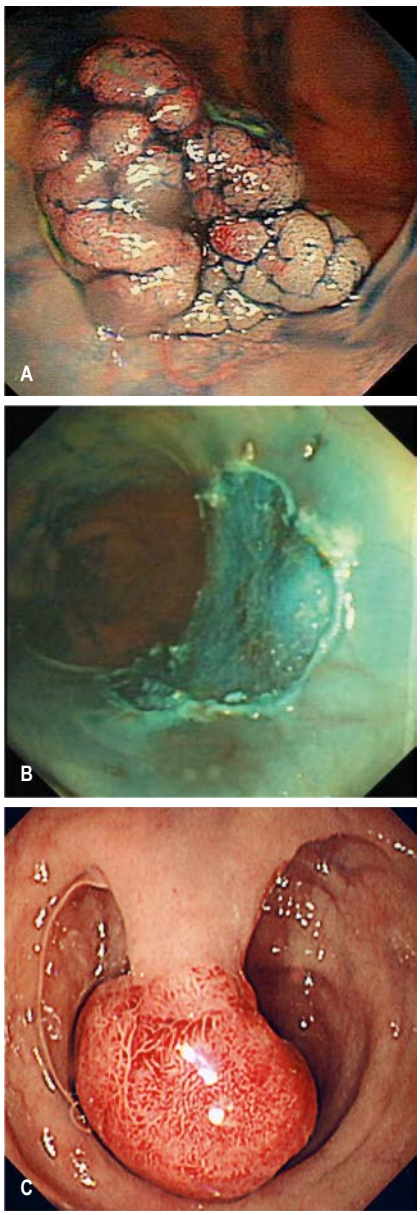

Fig. 22.51 Colonoscopic appearance of sessile and pedunculated polyps. **(A)** A sessile flat polyp with Indigo carmine. **(B)** Colon after resection of a sessile polyp. **(C)** A large pedunculated polyp.

If any doubt exists about the completeness of excision of any polyp, then an earlier repeat examination is suggested.

Sessile serrated adenomas

Serrated polyps form a heterogeneous group of colorectal lesions that includes the benign hyperplastic polyps (HPs), and the premalignant sessile serrated adenoma (SSA) and traditional serrated adenoma (TSA). They are characterized by the saw-tooth appearance of the crypt epithelium. It is now recognized that approximately 30% of colorectal cancers (particularly those in the right colon) originate from these lesions. Progression of serrated polyps is thought to occur via a distinct pathway from the adenoma–carcinoma sequence, with involvement of *BRAF* gene mutations and gene promoter hypermethylation (CpG island methylator phenotype, or

Box 22.42 Classification of colorectal polyps and polyposis syndromes

Histology	Polyposis syndrome	Defective gene	Inheritance	CRC risk
Hyperplastic	Hyperplastic polyposis	*BRAF*		Yes
Hamartoma	Juvenile polyposis	*MADH4* or *BMPR1A*	AD	10%–70%
	Peutz–Jeghers syndrome	*STK11*	AD	Yes
	Cowden's syndrome	*PTEN*	AD	10%?
	Lhermitte–Duclos disorder	*PTEN*	AD

Box 22.43 Factors affecting risk of malignant change in an adenoma

Factor	Higher risk	Lower risk
Size	>1.5 cm	<1 cm
Type	Sessile or flat	Pedunculated
Histology	Severe dysplasia	Mild dysplasia
	Villous architecture	Tubular architecture
	Squamous metaplasia	
Number	Multiple polyps	Single polyp

CIMP; see 'Colorectal cancer [genetics]' section, later). Microsatellite instability can be detected in both the adenoma–carcinoma and the serrated pathways. Endoscopic resection of SSAs and TSAs with appropriate surveillance is recommended.

Inherited polyposis syndromes

About 5% of colorectal cancers have a well-defined single-gene basis.

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant condition arising from germline mutations of the *APC* gene, located on chromosome 5q21–q22. More than 825 different mutations have been identified. Penetrance is virtually 100%. It is characterized by the presence of hundreds to thousands of colorectal and duodenal adenomas. The mean age of adenoma development is 16 years; the average age at which colorectal cancer develops is 39 years. Tracing and screening of relatives are essential, and affected individuals should be offered a prophylactic colectomy. Surgical options include colectomy and ileorectal anastomosis, which requires lifelong surveillance of the rectal stump, or a restorative proctocolectomy or pouch procedure with complete removal of rectal mucosa.

Cystic gland polyps, predominantly in the proximal stomach, and duodenal adenomas are frequently found in FAP, as well as other extraintestinal lesions such as osteomas, epidermoid cysts, and desmoid tumours. The duodenal adenomas may progress to cancer and are the most common cause of death in colectomized patients with FAP. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in many families with FAP. Other cancers in FAP include thyroid, pancreatic, and hepatoblastomas.

APC gene mutations can be found in about 80% of families with FAP. Once the mutation has been identified in an index case, other family members can be tested for the mutation, and screening can then be directed at mutation carriers. If a mutation cannot be found in a known FAP case, all family members should undergo clinical screening with regular colonoscopy.

Attenuated FAP may be missed as it presents later (average age 44 years) and has fewer polyps (<100), which tend to occur on the right side of the colon rather than on the left. It may be indistinguishable from sporadic cases but the gene mutation is in the *APC* germline.

MYH-associated polyposis

MUT Y homologue-associated polyposis (MYH-AP) is an autosomal recessive inherited syndrome of multiple colorectal adenomas and cancer. *MYH* is a base-excision-repair gene that corrects oxidative DNA damage. MYH-AP may account for 7% to 8% of families with the FAP phenotype in whom *APC* mutations cannot be found. Subjects with multiple adenomas or an FAP phenotype without *APC* mutations and with a family history compatible with a recessive pattern of inheritance should be tested for MYH-AP.

Lynch syndrome

In Lynch syndrome (previously called hereditary non-polyposis colon cancer, HNPCC), polyps are formed in the colon and may progress rapidly to colon cancer. It affects 1:5000 people, causing 3% to 10% of colorectal cancer cases.

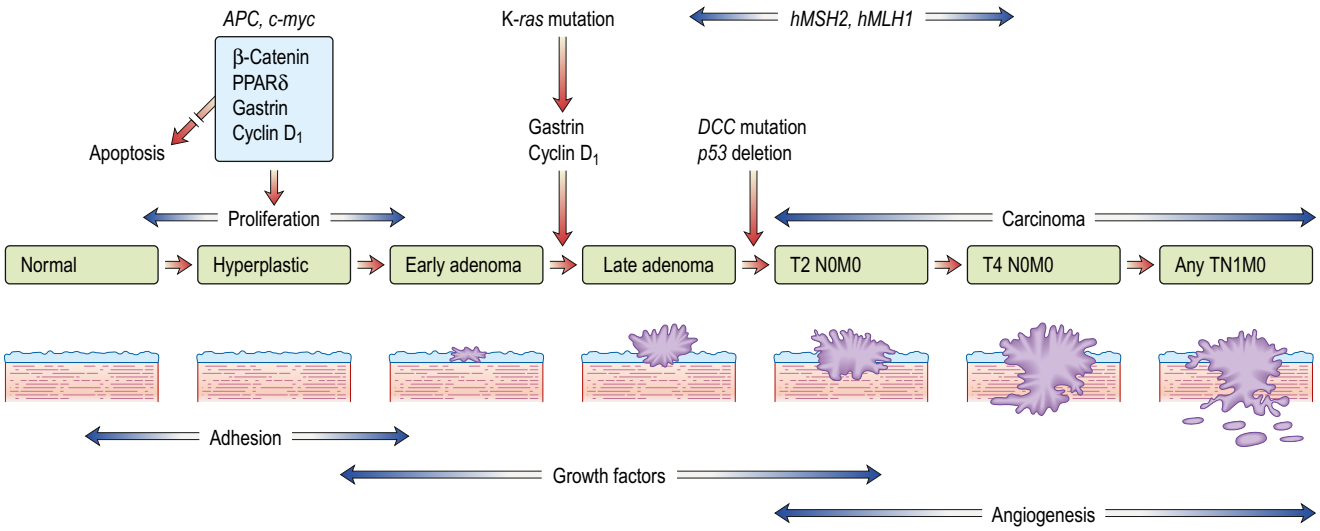

Fig. 22.52 The adenoma–carcinoma progression sequence, showing genetic mutations at different stages. *APC,* Adenomatous polyposis coli; *PPARδ,* peroxisome proliferator-activated receptor delta.

Box 22.44 Diagnostic criteria for Lynch syndrome

Modified Amsterdam criteria

- One individual diagnosed with CRC (or extracolonic Lynch tumours) before age 50 years
- Two affected generations
- Three affected relatives, one a first-degree relative of the other two
- FAP excluded
- Tumours verified by pathological examination

Bethesda guidelines

- CRC diagnosed in patient who are younger than 50 years
- Presence of synchronous, metachronous CRC, or other Lynch tumours, irrespective of age
- CRC with the MSI-H histology diagnosed in a patient who is younger than 60 years
- CRC diagnosed in one or more first-degree relative with a Lynch-related tumour, with one of the cancers being diagnosed under the age of 50 years
- CRC diagnosed in two or more first- or second-degree relatives with Lynch-related tumours, irrespective of age

The disease is caused by a mutation in one of the DNA mismatch repair genes, usually *hMSH2* or *hMLH1*, although others (*hMSH6, PMS1*, and *PMS*) have been reported. Mismatch repair genes are responsible for maintaining the stability of DNA during replication. Inheritance is autosomal dominant. The defect in function of the mismatch repair mechanism causes naturally occurring, highly repeated, short DNA sequences known as microsatellites to be shorter or longer than normal, a phenomenon called microsatellite instability (MSI).

Onset of cancer is earlier than in sporadic cases, at age 40 to 50 or younger. Tumours have a predilection for the right colon, in contrast to sporadic cases. In contrast to FAP, the lifetime risk of colon cancer (penetrance of the gene) in mutation carriers is 70% to 80%. Other cancers are also more common in Lynch syndrome: stomach, small intestine, bladder, skin, brain, and hepatobiliary system. Female patients are at risk for endometrial and ovarian cancer.

The diagnosis is made from the family history of colon cancer at a young age and the presence of associated cancers in the family. These are formalized in the various editions of the Amsterdam and the Bethesda criteria (**Box 22.44**).

Turcot's syndrome

This consists of FAP or Lynch syndrome (HNPCC) with brain tumours.

Gardner's syndrome

This involves, in addition to FAP, desmoid tumours, osteomas of the skull, and other lesions.

Hamartomatous polyps

These are commonly large and stalked. The inherited syndromes show autosomal dominant inheritance and include:

- ***Juvenile polyps***, which occur mainly in children and teenagers, and are found mainly in the colon; histologically, they show mucus retention cysts. Most are sporadic, but a syndrome of juvenile polyposis is defined as: more than three to five juvenile colonic polyps, juvenile polyps throughout the gastrointestinal tract, or any number of polyps with a family history. This is an autosomal dominant condition and the relevant gene has been identified (see **Box 22.42**). The polyps are a cause of bleeding and intussusception in the first decade of life. There is also an increased risk of colonic cancer (relative risk (RR) of 34), and surveillance and removal of polyps must be undertaken.
- ***Peutz–Jeghers syndrome*** (see 'Peutz–Jeghers syndrome' section).
- ***PTEN hamartoma–tumour syndrome*** (PHTS), which includes Cowden's syndrome, Bannayan–Riley–Ruvalcaba syndrome, and all syndromes caused by germline phosphatase and tensin homologue *(PTEN)* mutations. Cowden's (multiple hamartoma) syndrome is associated with characteristic skin stigmata, and by intestinal polyps regarded as hamartomas but with a mixture of cell types. These patients have an increased risk of various extraintestinal malignancies (thyroid, breast, uterine and ovarian). These syndromes are uncommon and together account for less than 1% of colon cancer cases.

Colorectal carcinoma

Colorectal cancer (CRC) is the third most common cancer worldwide and the second most common cause of cancer death in the UK.

Each year approximately, 40 000 new cases are diagnosed in England and Wales (68% colon, 32% rectal cancer), and CRC is

Box 22.45 Risk factors in colorectal cancer

Increased risk
- Increasing age
- Animal fat (saturated) and red meat consumption
- Sugar consumption
- Colorectal polyps
- Family history of colon cancer or colonic polyps
- Chronic inflammatory bowel disease
- Obesity (body and abdominal)
- Smoking
- Alcohol misuse
- Acromegaly
- Abdominal radiotherapy
- Ureterosigmoidostomy

Decreased risk
- Vegetable, garlic, milk, calcium consumption
- Exercise (colon only)
- Aspirin (including low-dose) and other NSAIDs

NSAIDs, Non-steroidal anti-inflammatory drugs.

registered as the cause of death in about half this number. The prevalence rate per 100 000 (at all ages) is 53.5 for males and 36.7 for females. The incidence increases with age; the average age at diagnosis is 60 to 65 years. Approximately 20% of patients in the UK have distant metastases at diagnosis. The disease is much more common in Westernized countries than in Asia or Africa.

Factors related to risk of colorectal cancer are shown in **Box 22.45**.

Genetics

Most colorectal cancers develop as a result of progression from normal mucosa to adenoma to invasive cancer. This progression is controlled by the accumulation of abnormalities in a number of critical growth-regulating genes and can be divided into three main pathways:

- ***Chromosomal instability (CIN).*** CIN is the most common cause of conventional adenomas throughout the colon. This pathway involves the sequential accumulation of genetic mutations in tumour suppressor genes, usually initiated by a mutation in the gene encoding adenomatous polyposis coli *(APC).*
- ***CpG island methylator phenotype.*** CpG island methylator phenotype (CIMP) tumours arise via the serrated neoplasia pathway and have a marked predilection for the proximal colon. Following an initiating genetic mutation in the genes encoding *BRAF* or *KRAS*, these lesions progress via *epigenetic* silencing of tumour suppressor and mismatch repair (MMR) genes by promoter methylation. This pathway is epitomized by the serrated polyposis syndrome (see 'Sessile serrated adenomas' section). The stepwise accumulation of genetic mutations in onco- and tumour suppressor genes that underpins the SCRC carcinogenesis pathway is well established and has significantly altered worldwide clinical practice. For example, mutations in KRAS appear to have importance as predictive factors for lack of response to certain oncological therapies. Activating KRAS mutations, which are identified in approximately 40% to 45% of CRCs, are associated with resistance to treatments that target the epidermal growth factor receptor (EGFR), such as cetuximab and panitumumab.
- ***Microsatellite instability.*** Microsatellite instability (MSI) tumours are also more commonly located in the proximal colon. They arise from defective DNA repair through inactivation of mismatch repair genes, epitomized by the germline mutation of MMR genes seen in Lynch syndrome (HNPCC).

This molecular classification can help to distinguish clinical characteristics, such as patient demographics, tumour distribution, response to therapy, and prognosis.

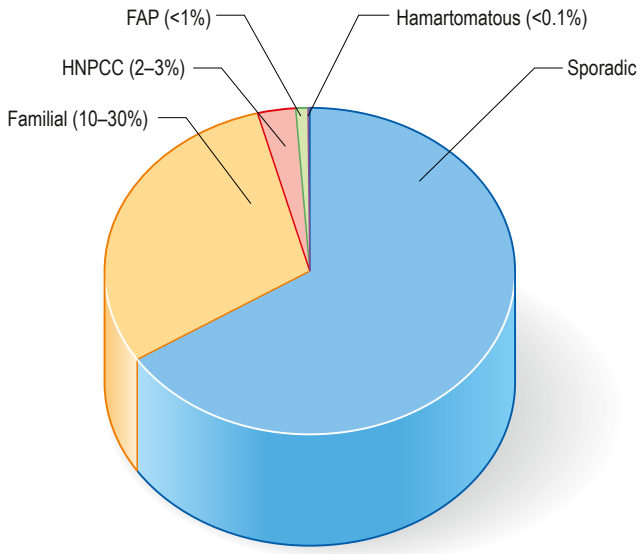

Fig. 22.53 Percentages of colon cancer according to family risk. *FAP,* Familial adenomatous polyposis; *HNPCC,* hereditary non-polyposis colorectal cancer (Lynch syndrome).

Box 22.46 Lifetime risk of colorectal cancer (CRC) in first-degree relatives of a CRC patient

Individuals affected	Risk
Population risk	1 in 50
One first-degree relative affected (any age)	1 in 17
One first-degree and one second-degree relative affected	1 in 12
One first-degree relative affected (age < 45)	1 in 10
Two first-degree relatives affected	1 in 6
Autosomal dominant pedigree	1 in 2

From Houlston RS, Murday V, Harocopos C et al. Screening and genetic counselling for relatives of patients with colorectal cancer in a family cancer clinic. Br Med J *1990; 301:366–368.*

Cancer families

A family history of CRC confers an increased risk to relatives. Family history is, next to age, the most common risk factor for CRC. FAP (**Fig. 22.53**) is the best-recognized syndrome predisposing to CRC but represents less than 1% of all colorectal cancers. Lynch syndrome (HNPCC) accounts for 3% to 10% of familial cancer (see 'Lynch syndrome' section).

Additionally, some colon cancers arise, at least in part, from an inherited predisposition, so-called familial risk (**Box 22.46**). Estimates of their frequency range from 10% to 30% of all CRC but the genes involved have yet to be identified. The risk of CRC can be estimated from a family history matched with empirical risk tables, so that appropriate advice regarding screening can be offered.

Most CRCs are, however, sporadic and occur in individuals without a strong family history (**Fig. 22.54**).

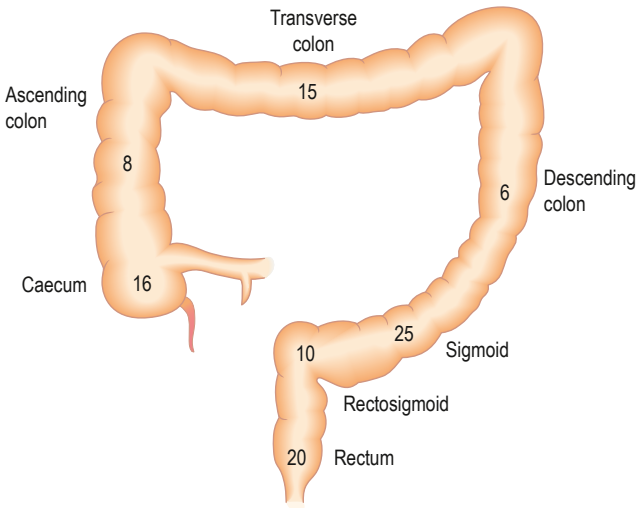

Fig. 22.54 Distribution of sporadic colorectal cancer. Only 60% are in the range of flexible sigmoidoscopy.

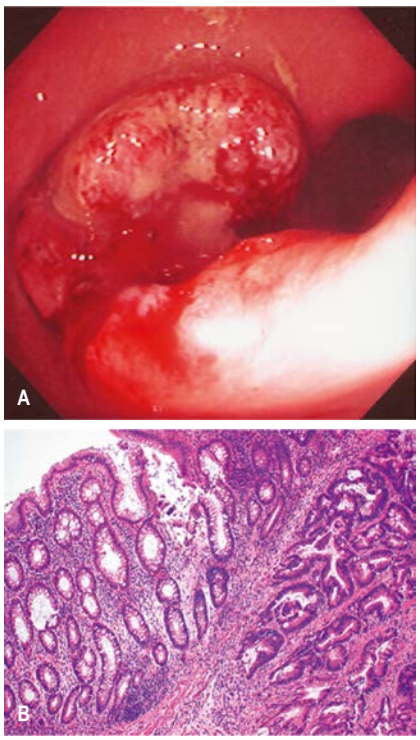

Fig. 22.55 Carcinoma in the ascending colon. (A) Colonoscopic appearance of a large irregular ulcer. **(B)** Histopathology showing an adenocarcinoma.

Pathology

CRC, which usually takes the form of a polypoid mass with ulceration, spreads by direct infiltration through the bowel wall. It involves lymphatics and blood vessels with subsequent spread, most commonly to the liver and lung. Synchronous cancers are present in 2% of cases. Histology is adenocarcinoma with variably differentiated glandular epithelium and mucin production. 'Signet ring' cells, in which mucin displaces the nucleus to the side of the cell, are relatively uncommon and generally have a poor prognosis.

Clinical features

Symptoms suggestive of colorectal cancer include change in bowel habit with looser and more frequent stools, rectal bleeding, tenesmus, and symptoms of anaemia. A rectal or abdominal mass may be palpable. Cancers arising in the caecum and right colon are often asymptomatic until they present as an iron deficiency anaemia. Cancer may present with intestinal obstruction.

Patients aged over 35 to 40 years presenting with new large bowel symptoms should be investigated. Digital examination of the rectum is essential and examination of the colon should be performed in all cases.

Screening for CRC

The UK has introduced a national screening programme using stool testing for blood in patients aged 60 to 64 years, in which positive tests have identified that 10% have cancer and 40% have adenomas. A randomized trial in Norway has found an increased number of early-stage cancers in the screened population but a high incidence of interval cancers, arising between biennial screens. Patients with an increased risk of developing bowel cancer (those with a family history of familial adenomatous polyposis or Lynch's syndrome [hereditary non-polyposis colorectal cancer]) will have a more intensive screening programme, starting at an earlier age.

- ***FOB tests*** have been studied as a screening test for colorectal cancer. Several large randomized studies have demonstrated a reduction in cancer-related mortality of 15% to 33%. Immunologically based FOB tests are superior to the conventional guaiac-based systems. The disadvantage of screening with FOB is its relatively low sensitivity, which means many negative colonoscopies. In FOB test screen-positive patients in the UK National Bowel Cancer Screening Programme (NHS BCSP), about 10% have cancer, 40% have adenomas and the colon is normal in 50%. Faecal immunochemical tests (FIT) for blood—FIT for haemoglobin are more specific than guaiac tests because FIT detects only human globin and therefore does not detect upper gastrointestinal bleeding (since the globin is digested in transit). Additionally, foods with peroxidase activity do not produce a positive reaction. FIT has replaced FOBt in the bowel cancer screening programme in the UK since April 2018.
- ***Flexible sigmoidoscopy*** screening has been shown to reduce the mortality from CRC, but not overall mortality.
- ***Colonoscopy*** is the 'gold standard' technique for examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been implemented in the UK for subjects between 60 and 69 who have a positive FOB. Cancer has been detected in 8% to 12% of patients, 75% of which was located in the left colon; 72% of detected cancers are at an 'early' stage (10% polyp cancer, 32% stage I, and 30% stage II).
- ***CT colonography*** ('virtual colonoscopy', see Fig. 22.10) is increasingly being used.

Investigations

- ***Colonoscopy*** is the 'gold standard' for investigation and allows biopsy for histology. Biopsy of the tumour is mandatory, usually at endoscopy (Fig. 22.55).
- ***Double-contrast barium enema*** can visualize the large bowel but has now been superseded by CT colonography.
- ***Endoanal ultrasound and pelvic MRI*** are used for staging rectal cancer.

- ***Chest, abdominal and pelvic CT*** scanning evaluate tumour size, local spread, and liver and lung metastases, contributing to tumour staging.
- ***PET scanning*** is useful for detecting occult metastases and for evaluation of suspicious lesions found on CT or MRI.
- ***MRI*** is also useful for evaluating suspicious lesions found on CT or ultrasound, especially in the liver.
- ***Serum carcinoembryonic antigen (CEA)*** is of little use for primary diagnosis and should not be performed as a screening test. It is useful for follow-up; rising levels suggest recurrence.
- ***Faecal occult blood (FOB) tests*** are used for mass population screening.

Management

The management of CRC is discussed in the Chapter 41.

Follow-up

All patients who have surgery should have a total colonoscopy performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second 'clearance' colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and CEA measurements; rising levels of CEA suggest recurrence. Annual CT scanning of the chest and abdomen to detect operable liver metastases should be performed for up to 3 years post surgery.

THE ACUTE ABDOMEN

This section deals with the acute abdominal conditions that cause the patient to be hospitalized within a few hours of the onset of pain (Box 22.47). If they are recognized quickly as an emergency, a reduction in morbidity and mortality can be achieved. Although a specific diagnosis should be attempted, the immediate problem in management is to decide whether an 'acute abdomen' exists and whether surgery is required.

Diagnosis

History

This should include previous operations, any gynaecological problems, and presence of any concurrent medical condition.

Box 22.47 Common causes of acute abdominal pain

Diagnosis	%[a]
Non-specific abdominal pain	35
Acute appendicitis	30
Gall bladder disease	10
Gynaecological disorders	5
Intestinal obstruction	5
Perforated ulcer/dyspepsia	5
Renal colic	2
Urinary tract infection	2
Diverticular disease	2
Other diagnoses	4

[a]Percentages are approximate and vary in different communities.

Pain

The onset, site, type, and subsequent course of the pain should be determined as accurately as possible. In general, the pain of an acute abdomen can be either constant (usually owing to inflammation) or colicky (because of a blocked 'tube'). The inflammatory nature of a constant pain will be supported by a raised temperature, tachycardia, and/or a raised white cell count. If these are normal, then other causes (e.g., musculoskeletal, aortic aneurysm), even rare ones (e.g., porphyria), should be considered. Colicky pain can be due to an obstruction of the gut, biliary system, urogenital system, or uterus. These cases will probably require conservative management initially, along with analgesics. If a colicky pain becomes a constant pain, then inflammation of the organ may have supervened (e.g., strangulated hernia, ascending cholangitis, or salpingitis).

A ***sudden onset*** of pain suggests:

- perforation (e.g., of a duodenal ulcer)
- rupture (e.g., of an ectopic pregnancy)
- torsion (e.g., of an ovarian cyst)
- acute pancreatitis
- infarction (e.g., mesenteric).

Back pain suggests:

- pancreatitis
- rupture of an aortic aneurysm
- renal tract disease.

Inflammatory conditions (e.g., appendicitis) produce a more gradual onset of pain. With peritonitis, the pain is continuous and may be made worse by movement. Many inflammatory conditions can progress to those listed as having a sudden onset due to complications.

Vomiting

Vomiting may accompany any acute abdominal pain but, if persistent, suggests an obstructive lesion of the gut. The character of the vomit should be asked about. Does it contain blood, bile, or small bowel contents?

Other symptoms

Any change in bowel habit or of urinary frequency should be documented and, in females, a gynaecological history, including last menstrual period, should be taken.

Physical examination

The general condition of the person should be noted. Do they look ill or shocked? Large volumes of fluid may be lost from the vascular

compartment into the peritoneal cavity or into the lumen of the bowel, giving rise to hypovolaemia: that is, a pale, cold skin, a weak, rapid pulse, and hypotension.

The abdomen

- ***Inspection.*** Look for the presence of scars, distension, or masses.
- ***Palpation.*** The abdomen should be examined gently for sites of tenderness and the presence or absence of guarding. Guarding is involuntary spasm of the abdominal wall and indicates peritonitis. This can be localized to one area or may be generalized, involving the whole abdomen.
- ***Bowel sounds.*** Increased high-pitched, tinkling bowel sounds indicate fluid obstruction; this occurs because of fluid movement within the dilated bowel lumen. Absent bowel sounds suggest peritonitis. In an obstructed patient, absent bowel sounds may be due to strangulation, ischaemia, or ileus. It is essential for the hernial orifices to be examined if intestinal obstruction is suspected.

Vaginal and rectal examination

Vaginal examination can be very helpful, particularly in diagnosing gynaecological causes of an acute abdomen (e.g., a ruptured ectopic pregnancy). Rectal examination is less helpful, as localized tenderness may be due to any cause; it may show blood on the glove.

Other observations

- ***Temperature.*** Fever is more common in acute inflammatory processes.
- ***Urine.*** Examine for:
  - blood—suggests urinary tract infection or renal colic
  - glucose and ketones—ketoacidosis can present with acute pain
  - protein and white cells—to exclude acute pyelonephritis.
- ***Medical causes.*** These should be borne in mind (Box 22.48).

Investigations

- ***Blood count.*** A raised white cell count occurs in inflammatory conditions.
- ***Serum lipase or amylase.*** High levels (more than five times normal) indicate acute pancreatitis. Raised levels below this can occur in any acute abdomen and should not be considered diagnostic of pancreatitis.
- ***Serum electrolytes.*** These are not particularly helpful for diagnosis but are useful for general evaluation of the patient.
- ***Pregnancy test.*** A urine dipstick is used for females of childbearing age.
- ***X-rays.*** An erect chest X-ray is useful to detect air under the diaphragm caused by a perforation (Fig. 22.56). Dilated loops of bowel or fluid levels are suggestive of obstruction on abdominal X-ray (Fig. 22.57).
- ***Ultrasound.*** This is useful in the diagnosis of acute cholangitis, cholecystitis, and aortic aneurysm, and in expert hands it is reliable in the diagnosis of acute appendicitis. Gynaecological and other pelvic causes of pain can be detected.
- ***CT scan.*** Spiral CT of the abdomen and pelvis is the most accurate investigation in most acute emergencies. It should be used more often to avoid unnecessary laparotomies.
- ***Laparoscopy.*** This is used increasingly as a diagnostic tool prior to proceeding with surgery, particularly in men and women over the age of 50 years. In addition, therapeutic procedures, such as appendicectomy, can be performed.

Box 22.48 Medical causes of acute abdomen

- Referred pain:
  - Pneumonia
  - Myocardial infarction
- Functional gastrointestinal disorders
- Renal causes:
  - Pelviureteric colic
  - Acute pyelonephritis
- Metabolic causes:
  - Diabetes mellitus
  - Acute intermittent porphyria
  - Lead poisoning
  - Familial Mediterranean fever
- Haematological causes:
  - Haemophilia and other bleeding disorders
  - Henoch–Schönlein purpura
  - Sickle cell crisis
  - Polycythaemia vera
  - Paroxysmal nocturnal haemoglobinaemia
- Vasculitis

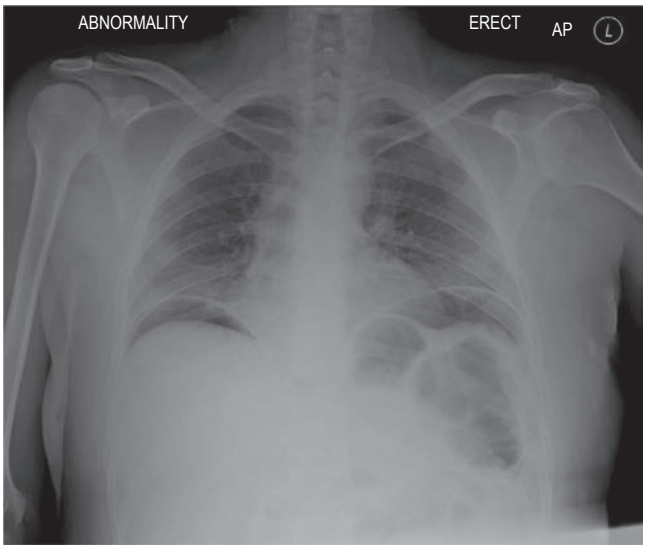

Fig. 22.56 Erect chest radiograph demonstrating free gas under the diaphragm (pneumoperitoneum).

Acute appendicitis

This is a common surgical emergency and affects all age groups. Appendicitis should always be considered in the differential diagnosis if the appendix has not been removed.

Acute appendicitis mostly occurs when the lumen of the appendix becomes obstructed with a faecolith; however, in some cases, there is only generalized acute inflammation. If the appendix is not removed at this stage, gangrene occurs with perforation, leading to a localized abscess or to generalized peritonitis.

Clinical features

Most patients present with abdominal pain; in many, it starts vaguely in the centre of the abdomen, becoming localized to the right iliac fossa in the first few hours. Nausea, vomiting, anorexia, and occasional diarrhoea can occur.

Examination of the abdomen usually reveals tenderness in the right iliac fossa, with guarding due to the localized peritonitis. There may be a tender mass in the right iliac fossa.

Fig. 22.57 Abdominal radiograph demonstrating multiple dilated loops of small bowel consistent with small bowel obstruction.

Although raised white cell counts, ESR and CRP are helpful, other laboratory tests can be less valuable. An ultrasound scan can detect an inflamed appendix and can also indicate an appendix mass or other localized lesion. CT is highly sensitive (98.5%) and specific (98% negative predictive value; 99.5% positive predictive value), and reduces the incidence of removal of a 'normal' appendix. With the use of these investigations, the incidence of 'normal' appendix histology has fallen to 15% to 20%.

Differential diagnosis

- Non-specific mesenteric lymphadenitis—may mimic appendicitis.
- Acute terminal ileitis due to Crohn's disease or *Yersinia* infection.
- Gynaecological causes:
  - inflamed Meckel's diverticulum
  - functional bowel disease.

Management

The appendix is removed by laparoscopic surgery. If an appendix mass is present, the patient is usually treated conservatively with intravenous fluids and antibiotics. The pain subsides over a few days and the mass usually disappears over a few weeks. Interval appendicectomy is recommended at a later date to prevent further acute episodes.

Gynaecological causes of an acute abdomen

Ruptured ectopic pregnancy

The fallopian tube is the most common extrauterine site of implantation. Delayed diagnosis is the major cause of morbidity. Most patients will present with recurrent low abdominal pain associated with vaginal bleeding. Diagnosis is usually made with abdominal and transvaginal ultrasound. Most patients can be managed by laparoscopic salpingostomy or salpingectomy.

Ovarian causes

- Rupture of 'functional' ovarian cysts in the middle of the cycle (Mittelschmerz).
- Torsion or rupture of ovarian cysts.

Acute salpingitis

Most cases are associated with sexually transmitted infection. Patients commonly present with bilateral low abdominal pain, a fever, and vaginal discharge. In the ***Fitz-Hugh–Curtis syndrome***, *Chlamydia* infection tracks up the right paracolic gutter to cause a perihepatitis. Patients can present with acute right hypochondrial pain, fever, and mildly abnormal liver biochemistry.

Acute peritonitis

Localized peritonitis

There is virtually always some degree of localized peritonitis with all acute inflammatory conditions of the gastrointestinal tract (e.g., acute appendicitis, acute cholecystitis). Pain and tenderness are largely features of this localized peritonitis. The treatment is for the underlying disease.

Generalized peritonitis

This is a serious condition, resulting from irritation of the peritoneum owing to infection (e.g., perforated appendix) or from chemical irritation due to leakage of intestinal contents (e.g., perforated ulcer). In the latter case, superadded infection gradually occurs; *E. coli* and *Bacteroides* are the most common organisms.

The peritoneal cavity becomes acutely inflamed, with production of an inflammatory exudate that spreads throughout the peritoneum, leading to intestinal dilation and paralytic ileus.

Clinical features

In perforation, the onset is sudden with acute, severe abdominal pain, followed by general collapse and shock. The patient may improve temporarily, only to become worse later as generalized toxaemia occurs.

When peritonitis is secondary to inflammatory disease, the onset is less rapid, the initial features being those of the underlying disease.

Investigations

Investigations should always include an erect chest X-ray. X-ray is used to detect free air under the diaphragm, and serum amylase is measured to diagnose acute pancreatitis, which is treated conservatively. Imaging with ultrasound and/or CT should always be performed for diagnosis.

Management

Peritonitis is treated surgically after adequate resuscitation and the re-establishment of a good urinary output. This includes insertion of a nasogastric tube, intravenous fluids, and antibiotics. Surgery has a two-fold objective:

- peritoneal lavage of the abdominal cavity
- specific treatment of the underlying condition.

Complications

Any delay in the treatment of peritonitis produces more profound toxaemia and septicaemia, which may lead to the development of

Box 22.49 Causes of intestinal obstruction

Small intestinal obstruction
- Adhesions (80% in adults)
- Hernias
- Crohn's disease
- Intussusception
- Obstruction due to extrinsic involvement by cancer

Colonic obstruction
- Carcinoma of the colon
- Sigmoid volvulus
- Diverticular disease

multiorgan failure (see Chapter 13). Local abscess formation can occur and should be suspected if a patient continues to remain unwell postoperatively, with a swinging fever, high white cell count and continuing pain. Abscesses are commonly pelvic or subphrenic, and can be localized and drained using ultrasound and CT scanning techniques.

Intestinal obstruction

Most intestinal obstruction is due to a mechanical block. Sometimes the bowel does not function, leading to a paralytic ileus. This occurs temporarily after most abdominal operations and with peritonitis. The most common cause in adults is adhesions (**Box 22.49**).

Obstruction of the bowel leads to bowel distension above the block, with increased secretion of fluid into the distended bowel. Bacterial contamination takes place in the distended stagnant bowel. In strangulation, the blood supply is impeded, leading to gangrene, perforation, and peritonitis unless urgent treatment of the condition is undertaken.

Clinical features

The patient complains of abdominal colic, vomiting, and constipation without passage of wind. In upper gut obstruction the vomiting is profuse, but in lower gut obstruction it may be absent.

Examination of the abdomen reveals distension with increased bowel sounds. Marked tenderness suggests strangulation, and urgent surgery is necessary. Examination of the hernial orifices and rectum must be performed. X-ray of the abdomen reveals distended loops of bowel proximal to the obstruction. Fluid levels are seen in small bowel obstruction on an erect film. In large bowel obstruction, the caecum and ascending colon are distended. An instant, water-soluble Gastrografin enema without air insufflation may help to demonstrate the site of the obstruction. CT can localize the lesion accurately and is the investigation of choice.

Management

Initial management is by resuscitation with intravenous fluids (mainly 0.9% saline with potassium) and decompression. Many cases will settle on conservative management, but an increasing temperature, raised pulse rate, increasing pain, and a rising white cell count require urgent scanning and possible exploratory laparotomy.

Laparotomy with removal of the obstruction will be necessary in some cases of small bowel obstruction. If the bowel is gangrenous owing to strangulation, gut resection will be required. A few patients (e.g., those with Crohn's disease) may have recurrent episodes of incomplete intestinal obstruction that can be managed conservatively. In large bowel obstruction due to malignancy, a self-expanding metal stent can be used, followed by elective surgery. In critically ill patients, a defunctioning colostomy may be needed. Volvulus of the sigmoid colon can be managed by the passage of a flexible sigmoidoscope or a rectal tube to un-kink and deflate the bowel, but recurrent volvulus may require sigmoid resection.

Acute colonic pseudo-obstruction

A clinical picture mimicking mechanical obstruction may develop in patients who do not have a mechanical cause. In more than 80% of cases, it complicates other clinical conditions, such as:
- intra-abdominal trauma, pelvic, spinal and femoral fractures
- postoperative states (abdominal, pelvic, cardiothoracic, orthopaedic, neurosurgical)
- intra-abdominal sepsis
- pneumonia
- metabolic disorders (e.g., electrolyte disturbances, malnutrition, diabetes mellitus, Parkinson's disease)
- drugs—opiates (particularly after orthopaedic surgery), antidepressants, antiparkinsonian drugs.

Patients present with rapid and progressive abdominal distension and pain. X-ray shows a gas-filled large bowel. Management is of the underlying problem (e.g., withdrawal of opiate analgesia), together with a trial of intravenous neostigmine therapy. Patients should be monitored and consideration should be given to surgery if the diameter of the caecum exceeds 14 cm.

Peritoneum

Anatomy and physiology

The peritoneal cavity is a closed sac lined by mesothelial cells; these produce surfactant, which acts as a lubricant within the peritoneal cavity. The cavity contains <100 mL of serous fluid containing <30 g/L of protein.

The mesothelial cells lining the diaphragm have gaps that allow communication between the peritoneum and the diaphragmatic lymphatics. Approximately one-third of fluid drains through these lymphatics, the remainder through the parietal peritoneum. These mechanisms allow particulate matter to be removed rapidly from the peritoneal cavity.

Complement activation is an early defence mechanism and is followed rapidly by upregulation of the peritoneal mesothelial cells and migration of polymorphonuclear neutrophils and macrophages into the peritoneum.

Mast cells release potent mediators of inflammation, including histamine and eicosanoids, and interact with T cells to generate an immune response.

The peritoneum-associated lymphoid tissue includes the omental milky spots, the lymphocytes within the peritoneal cavity, and the draining lymph nodes. B cells with a unique $CD5^+$ are common. This defence system plays a major role in localizing peritoneal infection.

Disorders affecting the peritoneum

Conditions that can affect the peritoneum are shown in **Box 22.50**.

Peritonitis can be acute or chronic, as seen in TB. Most cases of infective peritonitis are secondary to gastrointestinal disease, but it occurs occasionally without intra-abdominal sepsis in ascites due to liver disease. Very rarely, fungal and parasitic infections (e.g., amoebiasis, candidiasis) can also cause primary peritonitis. Peritonitis is discussed further in the 'Acute peritonitis' section.

Box 22.50 Diseases of the peritoneum

Infective (bacterial) peritonitis
- Secondary to gut disease, for example, appendicitis
- Perforation of any organ
- Chronic peritoneal dialysis
- Spontaneous, usually in ascites with liver disease
- Tuberculosis

Neoplasia
- Secondary deposits (e.g., from ovary, stomach)
- Primary mesothelioma

Vasculitis
- Rheumatic autoimmune disease
- Polyserositis (e.g., familial Mediterranean fever)

The peritoneum can be involved by secondary malignant deposits, and the most common cause of ascites in a young to middle-aged woman is an ovarian carcinoma.

A ***subphrenic abscess*** is usually secondary to infection in the abdomen and is characterized by fever, malaise, pain in the right or left hypochondrium, and shoulder-tip pain. An erect chest X-ray may show gas under the diaphragm, impaired movement of the diaphragm on screening, and/or a pleural effusion. Ultrasound is usually diagnostic. Percutaneous catheter drainage inserted under CT or ultrasound guidance and antibiotics constitute highly successful therapy.

Ascites is associated with all diseases of the peritoneum. The fluid that collects is an exudate with a high protein content. It is also seen in liver disease. The mechanism, causes, and investigation of ascites are discussed in Chapter 11.

Peritoneal adhesions

Adhesions form as a result of abdominal or pelvic surgery, or inflammation in the abdominoperitoneal cavity. They cause a variety of conditions, including adhesive small bowel obstruction (ASBO), chronic abdominal pain, complications during future surgery, and female infertility when they involve the fallopian tubes or ovaries. There is no satisfactory medical or surgical treatment and so surgical techniques have been developed to minimize peritoneal injury.

Retroperitoneal fibrosis (peri-aortitis)

This is a rare condition, in which there is a marked fibrosis over the posterior abdominal wall and retroperitoneum. It is associated with raised serum IgG4 levels and is described in Chapter 26.

Tuberculous peritonitis

This is the second most common form of abdominal TB. Three subgroups can be identified: wet, dry, and fibrous.
- In patients with the ***wet*** type, ascitic fluid should be examined for protein concentration (>20 g/L) and tubercle bacilli (rarely found).
- In the ***dry*** form, patients present with subacute intestinal obstruction, which is due to tuberculous small bowel adhesions.
- In the ***fibrous*** form, patients present with abdominal pain, distension, and ill-defined, irregular, tender abdominal masses.

The diagnosis of peritoneal TB can be supported by findings on ultrasound or CT screening (mesenteric thickening and lymph node enlargement). A histological diagnosis is not always required before instituting treatment. In some patients, careful laparoscopy (to avoid perforation) may have to be performed, and rarely laparotomy.

Management

Drug treatment is similar to that for pulmonary TB (see Chapter 20) and should be supervised by chest physicians who have experience in dealing with contacts.

CORE SKILLS AND KNOWLEDGE

Liver disease is common and its incidence is rising, predominantly because of viral hepatitis in low and middle income countries, and alcohol and obesity in developed ones, although obesity and alcohol are increasingly common causes of liver disease in low and middle income countries. It remains a major cause of mortality and morbidity, with death occurring secondary to cirrhosis and hepatocellular carcinoma.

Hepatologists divide their time between inpatient work (decompensated chronic liver disease and acute liver failure both require intensive inpatient management) and clinic work (managing patients with stable liver disease and diagnosing patients newly referred from primary care). Many also perform procedures such as endoscopic retrograde cholangiopancreatography (ERCP) or endoscopic ultrasound (EUS); and some subspecialize in the management of alcohol cessation, viral hepatitis, or liver transplantation.

Key skills in hepatology include:

- Managing patients with decompensated chronic liver disease, including variceal bleeding, ascites, and encephalopathy, and those presenting with acute liver failure
- Appreciating the role of history, examination, imaging, blood tests, and liver biopsy in the diagnosis of patients newly presenting with evidence of liver disease
- Understanding the natural history of hepatitis B and C infection and the effective available treatments
- Empathy and understanding to tackle alcoholism and obesity.

Opportunities to learn hepatology include attending ward rounds on inpatient liver units, participating in outpatient clinics, observing the work of specialist nurses who manage increasing numbers of patients with chronic liver disease, learning how to perform paracentesis safely on medical day units, and watching interventional endoscopy (variceal banding) and ERCP procedures being performed.

CLINICAL SKILLS

History

Both acute and chronic liver disease are often asymptomatic, especially in the early stages. Taking a history in hepatology involves not only asking about symptoms but also establishing the presence of common risk factors for liver disease to help establish a diagnosis (Box 23.1).

Asking about alcohol

This requires gentleness and tact (Box 23.2). Patients often underestimate their alcohol intake or degree of dependence. This history should be non-judgemental, and help should be offered through referral to alcohol support services if patients express a desire to become abstinent.

Examination

In acute liver disease there may be a few signs, apart from jaundice and an enlarged liver. In the cholestatic phase of the illness, pale stools and dark urine are present.

The figure on the next page illustrates the various signs associated with chronic liver disease, although physical examination is occasionally normal even in patients with advanced disease.

Investigations

A detailed overview of the diagnostic investigations used in liver disease begins at the 'Investigations in the patient with liver disease' section. Fig. 23.1 illustrates how these investigations may be employed in an outpatient setting for a patient referred from primary care with raised liver transaminases.

Box 23.1 Taking a history in liver disease

Symptoms of acute liver disease
- May be asymptomatic and anicteric
- Symptomatic disease, often viral, producing malaise, anorexia, and fever
- Jaundice (see later), often appearing as the illness progresses

Symptoms of chronic liver disease
- Non-specific symptoms, particularly weakness, anorexia, and fatigue
- Right hypochondrial pain due to liver distension
- Abdominal distension due to ascites
- Ankle swelling due to fluid retention
- Haematemesis and melaena from variceal haemorrhage
- Pruritus due to cholestasis—often an early symptom of primary biliary cholangitis (PBC)
- Endocrine dysfunction: gynaecomastia, loss of libido and amenorrhoea
- Confusion and drowsiness due to hepatic encephalopathy

Past medical history
- Any previous disease affecting the liver, biliary tract, pancreas, or gut
- Heart failure (risk of congestive hepatopathy)
- History of autoimmune disease (↑risk of autoimmune liver disorders)
- Features of metabolic syndrome: obesity, diabetes, gout, hypercholesterolaemia (risk of NAFLD)

Medications
- Recent antibiotic use (several cause cholestasis)
- Paracetamol overdose
- Full medication history, establishing whether any cause liver damage

Family history
- History of jaundice, liver disease, or specific diseases such as haemochromatosis

Alcohol use
- Take a detailed history (see later)

Risk factors for viral hepatitis
- Childhood spent in countries where hepatitis B or C is endemic
- Contaminated needles—unsafe tattoos, injecting drug use
- High-risk unprotected sexual activity

Box 23.2 Taking an alcohol history in patients with liver disease

Extent of use
- Preferred type of alcohol (beer, wine, spirits); strength where relevant ('super-strength' beers can be up to 10% ethanol)
- Daily consumption (in cans, bottles or glasses, subsequently converted to units)
- Number of abstinent days per week
- Frequency of consuming more than eight units on one occasion
- Duration of alcohol use, and changing use over this time

Degree of dependence
- Number of times alcohol has interfered with regular activities (e.g., going to work)
- Number of times the person has been unable to stop drinking once they have started
- Need for a morning drink to 'get going'
- Feelings of guilt about alcohol consumption
- Concern on the part of family and friends about alcohol use
- Injuries to self or others caused by alcohol

Views on abstinence
- Awareness of risks of current level of alcohol use (if this exceeds target levels)
- Willingness to cut down versus abstaining completely
- Previous attempts to give up
- Previous experiences of support groups, including Alcoholics Anonymous, and cognitive behavioural therapy
- Sources of support: family members, close friends, social or religious groups

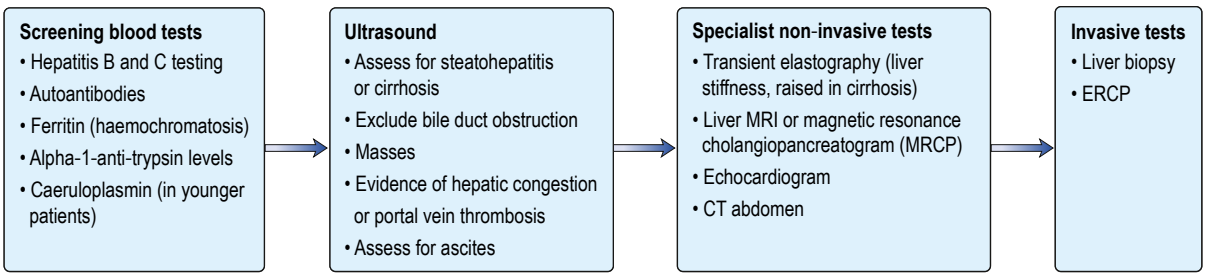

Fig. 23.1 Use of diagnostic investigations in an outpatient setting. This scheme would be appropriate for a patient referred from primary care with raised liver transferases.

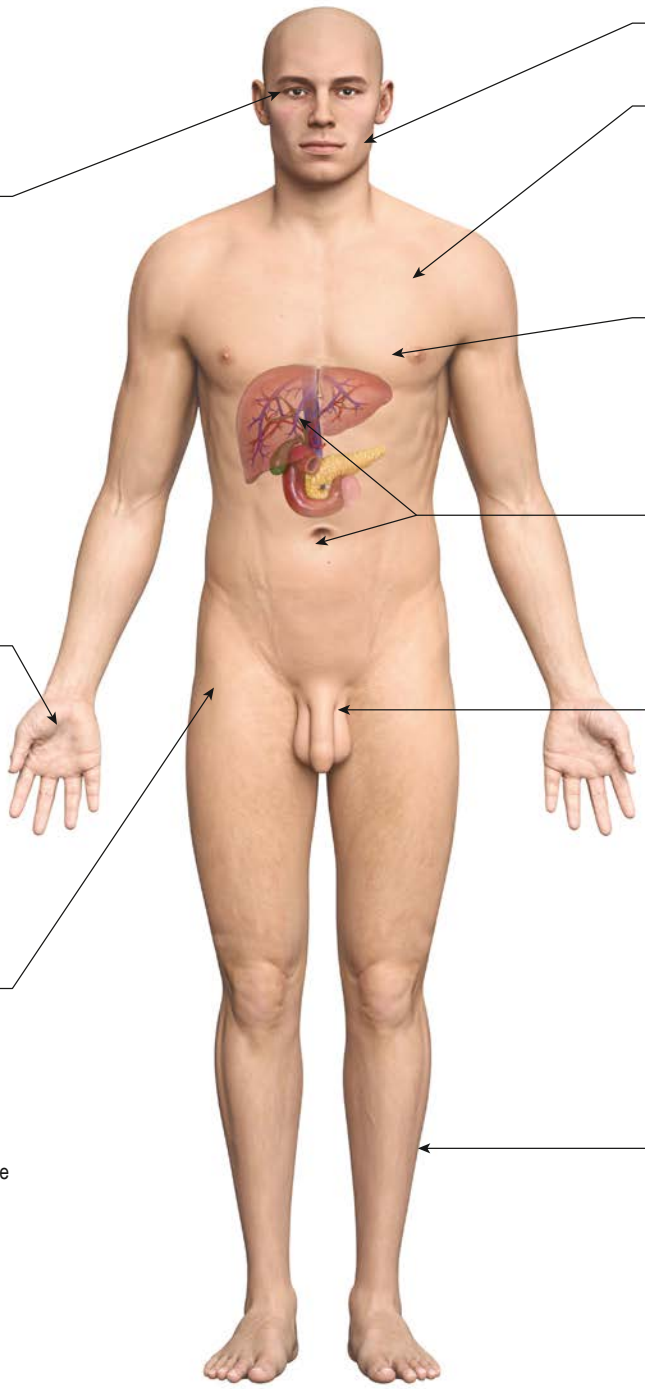

General
Jaundice
Smell of alcohol/fetor hepaticus
Encephalopathy
Weight loss

Eyes
- Jaundice
- Kayser–Fleischer rings (Wilson's disease)
- Xanthelasma (on eyelids)

Hands
Flapping tremor
Palmar erythema
Dupuytren's contracture (alcohol)
Nails
- Clubbing
- Leuconychia

Skin
Scratch marks

NB: Often patients with liver disease have very few signs.

Parotid swelling

Spider naevi

Gynaecomastia

Abdomen
Scars
Distension (ascites – shifting dullness)
Dilated superficial veins
Hepatomegaly (small in cirrhosis)
Splenomegaly
Tumour
Palpable gall bladder

Testicular atrophy

Oedema (pitting)
Bruises

BACKGROUND

The aetiology of liver disease differs from region to region. In the developed world, liver inflammation is most often due to obesity, the metabolic syndrome (metabolic dysfunction–associated steatotic liver disease or MASLD, formerly referred to as non-alcoholic fatty liver disease or NAFLD), metabolic dysfunction–associated steatohepatitis (MASH, formerly non-alcoholic steatohepatitis) and alcohol excess. In the developing world, chronic viral infection with either hepatitis B or hepatitis C is the leading cause of liver mortality, although there are now excellent treatments for hepatitis C while obesity is increasing globally. Liver disease is the third leading cause of premature death in the UK, where there has been a 63.6% increase in liver disease–related premature deaths over the past two decades, with alcohol-related liver disease deaths increasing by 74.2%. Complications of liver disease account for 1 million deaths worldwide, with increasing prevalence in recent years and globally, about half a billion people suffer from chronic viral hepatitis. Effective health education and the improvement in public health, along with vaccination programmes, should help to stop the spread of viral infections and hopefully reduce risk factors for the metabolic syndrome (diabetes, hypertension, and obesity).

Cirrhosis represents the final common pathway for liver diseases and is characterized by progressive fibrosis of the liver parenchyma, which leads to portal hypertension (elevated blood pressure within the portal vein) and deterioration of liver function. In decompensated cirrhosis (ascites, hepatic encephalopathy, or variceal bleeding) the median overall survival is 2 years, which is a far worse prognosis than for many cancers.

Imaging techniques enable the liver, biliary tree, and pancreas to be visualized with precision, which can increase earlier diagnosis. Liver transplantation is an established therapy for both acute and chronic liver disease.

ANATOMY OF THE LIVER AND BILIARY SYSTEM

Liver

The liver is the body's largest internal organ (1.2–1.5 kg) and is situated in the right hypochondrium. A functional division into the larger right lobe (containing caudate and quadrate lobes) and the left lobe is made by the middle hepatic vein. The liver is further subdivided into eight segments (Fig. 23.2) by divisions of the right, middle, and left hepatic veins. Each segment has its own portal pedicle, permitting individual segment resection at surgery.

The hepatic blood supply constitutes 25% of the resting cardiac output and is delivered via two main vessels, entering via the liver hilum (porta hepatis):

- ***The hepatic artery***, a branch of the coeliac axis, supplies 25% of the hepatic blood flow. The hepatic artery autoregulates flow, ensuring a constant total blood flow.
- ***The portal vein*** drains most of the gastrointestinal tract and the spleen. It supplies 75% of hepatic blood flow. The normal portal pressure is 5 to 8 mmHg; flow increases after meals.

The blood from these vessels is distributed to the segments and flows into the sinusoids via the portal tracts.

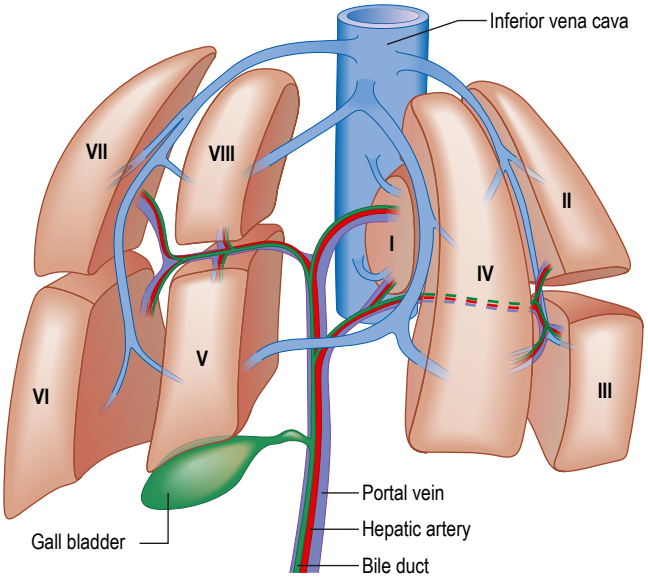

Fig. 23.2 Segmental anatomy of the liver. The eight hepatic segments are shown: I, caudate lobe; II–IV, left hemiliver; V–VIII, right hemiliver.

Blood leaves the sinusoids, entering branches of the hepatic vein, which join into three main branches before entering the inferior vena cava.

The ***caudate lobe*** is an autonomous segment, as it receives an independent blood supply from the portal vein and hepatic artery, and its hepatic vein drains directly into the inferior vena cava.

Lymph, formed mainly in the perisinusoidal space, is collected in lymphatics that are present in the portal tracts. These small lymphatics enter larger vessels, which eventually drain into the portal system.

The ***acinus*** is the functional hepatic unit. This consists of parenchyma supplied by the smallest portal tracts containing portal vein radicles, hepatic arterioles, and bile ductules (Fig. 23.3). The hepatocytes near this triad (zone 1) are well supplied with oxygenated blood and are more resistant to damage than the cells nearer the terminal hepatic (central) veins (zone 3).

The ***sinusoids*** lack a basement membrane and are loosely surrounded by specialist fenestrated endothelial cells and Kupffer cells (phagocytic cells). Sinusoids are separated by plates of liver cells (hepatocytes). The subendothelial space between the sinusoids and hepatocytes is the space of Disse, which contains a matrix of basement membrane constituents and stellate cells (see Fig. 23.21).

Stellate cells store retinoids in their resting state and contain the intermediate filament, desmin. When activated (to myofibroblasts), they are contractile and regulate sinusoidal blood flow. Endothelin and nitric oxide play a major role in modulating stellate cell contractility. Stellate cells are activated by a wide variety of inflammatory cytokines (such as tumour necrosis factor-alpha, TNF-α); once activated, they generate extracellular matrix proteins, including collagen, leading to fibrosis and eventually cirrhosis. Under appropriate conditions, stellate cells can also produce proteases that degrade the extracellular matrix, leading to reversal of fibrosis. The balance between collagen production and degradation is critical to the

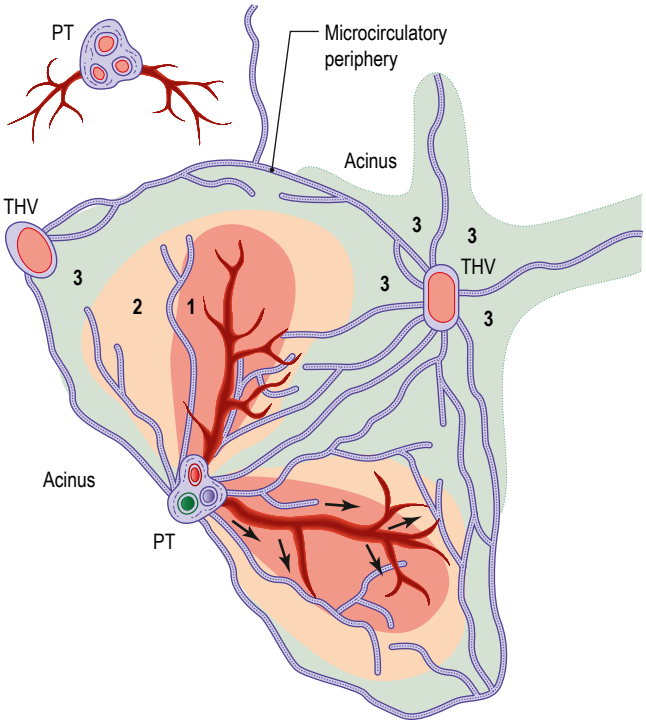

Fig. 23.3 The acinus. Zones 1, 2, and 3 represent areas supplied by blood, zone 1 being best oxygenated. Zone 3 is supplied by blood remote from afferent vessels and is in the microcirculatory periphery of the acinus. The perivascular area (the star-shaped green area around the terminal hepatic venule, THV) is formed by the most peripheral parts of zone 3 and is made up of several adjacent acini; it is the least well-oxygenated area. *PT,* Portal triad.

progression of liver scarring and cirrhosis development/resolution (see 'Cirrhosis [pathogenesis]' section).

Biliary system

Bile canaliculi form a network between the hepatocytes. These join to form thin bile ductules near the portal tract, which, in turn, enter the bile ducts in the portal tracts. These then combine to form the right and left hepatic ducts, which leave each liver lobe. The hepatic ducts join at the porta hepatis to form the common hepatic duct. The cystic duct connects the gall bladder to the lower end of the common hepatic duct. The gall bladder lies under the right lobe of the liver and stores and concentrates hepatic bile; its capacity is approximately 50 mL. The common bile duct is formed at the junction of the cystic and common hepatic ducts and is 8 mm in diameter or less, passing through the head of the pancreas, and narrowing at its lower end to pass into the duodenum. The common bile duct and pancreatic duct open into the second part of the duodenum, most often through a common channel at the ampulla of Vater, which contains the muscular sphincter of Oddi. This contracts rhythmically and prevents all of the bile from entering the duodenum, by maintaining a higher pressure than the gall bladder in the fasting state.

FUNCTIONS OF THE LIVER

Protein metabolism

See also Chapter 25.

Synthesis and storage

The liver is the principal site of synthesis of all circulating proteins, apart from γ-globulins (produced in lymphoid tissue). The liver receives amino acids from the intestine and muscles and, by controlling the rate of gluconeogenesis and transamination, regulates plasma levels. Plasma contains 60 to 80 g/L of protein, mainly albumin, globulin, and fibrinogen.

Albumin has a half-life of 16 to 24 days, and 10 to 12 g is synthesized daily. Its main functions are to maintain intravascular oncotic (colloid osmotic) pressure, and to transport water-insoluble substances such as bilirubin, hormones, fatty acids, and drugs. Reduced synthesis of albumin over prolonged periods produces hypoalbuminaemia and is seen in chronic liver disease and malnutrition. Hypoalbuminaemia is also found in hypercatabolic states (e.g., trauma, burns, and sepsis) and in diseases associated with an excessive loss (e.g., nephrotic syndrome or protein-losing enteropathy).

Transport or carrier proteins, such as transferrin and caeruloplasmin, acute phase, and other proteins (e.g., α_1-antitrypsin and α-fetoprotein) are also produced in the liver.

The liver also synthesizes all coagulation factors (except for one-third of factor VIII)—that is, fibrinogen, prothrombin, factors V, VII, IX, X, and XIII, proteins C and S, and antithrombin (see Chapter 38), as well as components of the complement system. The liver stores large amounts of certain vitamins, particularly A, D, and B_{12}, lesser amounts of others (vitamin K and folate), and minerals—iron in ferritin and haemosiderin, and copper.

Degradation (nitrogen excretion)

Amino acids are degraded by transamination and oxidative deamination to produce ammonia, which is then converted to urea and excreted by the kidneys. This is the major pathway for the elimination of nitrogenous waste. Failure of this process occurs in severe liver disease.

Carbohydrate metabolism

Glucose homeostasis and maintenance of blood sugar are major functions of the liver. It stores approximately 80 g of glycogen. In the immediate fasting state, blood glucose is maintained either by glucose release from glycogen breakdown (glycogenolysis) or by synthesis of new glucose (gluconeogenesis). Sources for gluconeogenesis are lactate, pyruvate, amino acids from muscles (mainly alanine and glutamine), and glycerol from lipolysis of fat stores. In prolonged starvation, ketone bodies and fatty acids are used as alternative sources of fuel as body tissues adapt to a lower glucose requirement (see Chapter 25).

Lipid metabolism

Fats are insoluble in water and are transported in plasma as protein–lipid complexes (lipoproteins). These are discussed in detail in Chapter 19.

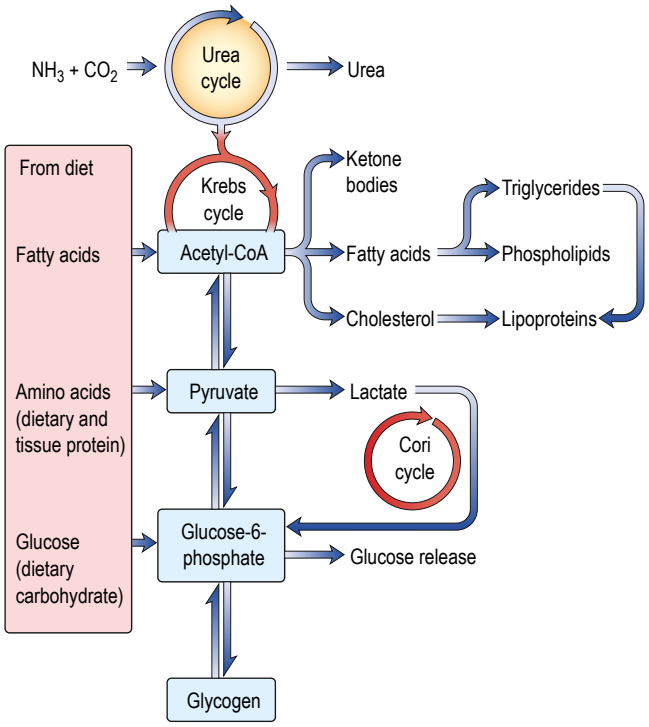

Fig. 23.4 Interrelationships of protein, carbohydrate, and lipid metabolism in the liver.

The liver has a major role in the metabolism of lipoproteins. It synthesizes very low-density lipoproteins (VLDLs) and high-density lipoproteins (HDLs). HDLs are the substrate for lecithin-cholesterol acyltransferase (LCAT), which catalyzes the conversion of free cholesterol to cholesterol ester (see later). Hepatic lipase removes triglyceride from intermediate-density lipoproteins (IDLs) to produce low-density lipoproteins (LDLs), which are degraded by the liver after uptake by specific cell-surface receptors (see Fig. 19.3).

Triglycerides are mainly of dietary origin but are also formed in the liver from circulating free fatty acids (FFAs) and glycerol, and incorporated into VLDLs. Oxidation or *de novo* synthesis of FFAs occurs in the liver, depending on availability of dietary fat.

Cholesterol may be of dietary origin but most is synthesized from acetyl-coenzyme A (acetyl-CoA) in the liver, intestine, adrenal cortex, and skin. It either occurs as free cholesterol or is esterified with fatty acids; this reaction is catalyzed by LCAT. This enzyme is reduced in severe liver disease, increasing the ratio of free cholesterol to ester, which alters membrane structures. One result of this is the red cell abnormalities (e.g., target cells) seen in chronic liver disease. Phospholipids (e.g., lecithin) are synthesized in the liver. The complex interrelationships between protein, carbohydrate, and fat metabolism are shown in Fig. 23.4.

Formation of bile

Bile secretion and bile acid metabolism

Bile consists of water, electrolytes, bile acids, cholesterol, phospholipids, and conjugated bilirubin. Two processes are involved in bile secretion across the canalicular membrane of the hepatocyte—***bile salt-dependent*** and ***bile salt-independent*** processes—each contributing about 230 mL/day. Another 150 mL/day is produced by bile ductule epithelial cells.

Bile formation requires uptake of bile acids and other organic and inorganic ions across the basolateral (sinusoidal) membranes by multiple transport proteins (sodium taurocholate co-transporting polypeptide [NTCP] and sodium-independent organic anion-transporting polypeptide 2 [OATP2]; Fig. 23.5). This process is driven by sodium/potassium adenosine triphosphatase (Na^+/K^+-ATPase) in the basolateral membranes. Intracellular transport across hepatocytes is partly through microtubules and partly by cytosol transport proteins.

Bile acids are also synthesized in hepatocytes from cholesterol, the rate-limiting step being those catalyzed mainly by cholesterol-7α-hydroxylase and the P450 enzymes (CYP7A1 and CYP8B1).

The farnesoid X bile acid receptor blocks bile acid formation from cholesterol and also regulates the transport proteins (NTCP, OATP2) that increase bile acid uptake by the liver. It is a target for a new class of therapeutic drugs, farnesoid X receptor (FXR) agonists (see section on 'Bile acid receptors in liver disease').

The canalicular membrane contains multispecific organic anion transporters, mainly ATPase-dependent (ATP binding cassette), the multidrug-resistant protein 2 (MRP2), multidrug-resistant protein 3 (MDR3), and the bile salt excretory pump (BSEP), which carry a broad range of compounds including bilirubin diglucuronide, glucuronidated and sulphated bile acids, and other organic anions against a concentration gradient into the biliary canaliculus. Na^+ and water follow the passage of bile salts by diffusion across the tight junction between hepatocytes (a bile salt-dependent process). In the bile salt-independent process, water flow is due to other osmotically active solutes such as glutathione and bicarbonate.

Secretion of a bicarbonate-rich solution is stimulated mainly by secretin and inhibited by somatostatin. This involves several membrane proteins, including the Cl^-/HCO_3^- exchanger and the cystic fibrosis transmembrane conductance regulator that controls Cl^- secretion, and water channels (aquaporins) in cholangiocyte membranes.

The bile acids are excreted into bile and pass via the common bile duct into the duodenum. The two primary bile acids—cholic acid and chenodeoxycholic acid (see Fig. 23.5)—are conjugated with glycine or taurine, which increases their solubility. Intestinal bacteria convert these acids into secondary bile acids, deoxycholic and lithocholic acid. Fig. 23.6 shows the enterohepatic circulation of bile acids.

The average total bile flow is 600 mL/day. During fasting, half flows into the duodenum and half is diverted into the gall bladder. The gall bladder mucosa absorbs 80%–90% of the water and electrolytes but is impermeable to bile acids and cholesterol. Following a meal, the I cells of the duodenal mucosa secrete cholecystokinin, which stimulates contraction of the gall bladder and relaxation of the sphincter of Oddi, allowing bile to enter the duodenum. An adequate bile flow is dependent on bile salts being returned to the liver by the enterohepatic circulation.

Bile acids act as detergents; their main function is lipid solubilization. Bile acid molecules have both a hydrophilic and a hydrophobic end. In aqueous solutions they form micelles, with

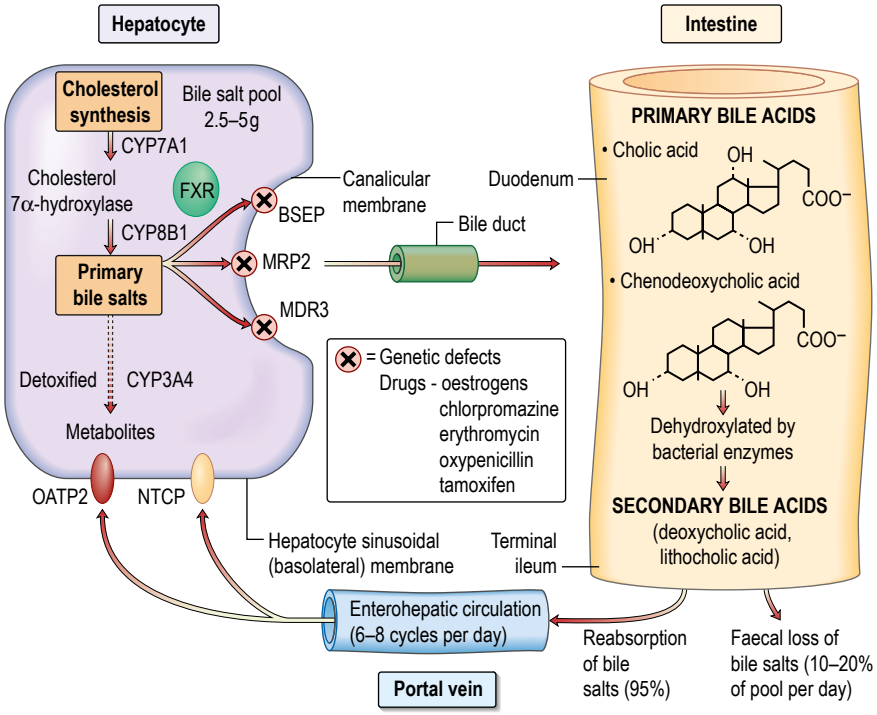

Fig. 23.5 Cholesterol synthesis and its conversion to primary and secondary bile acids. All bile acids are normally conjugated with glycine or taurine. *BSEP,* Bile salt export pump; *FXR,* nuclear farnesoid X receptor; *MDR3,* multidrug-resistant protein 3; *MRP2,* multidrug-resistant protein 2; *NTCP,* sodium taurocholate co-transporting polypeptide; *OATP2,* sodium-independent organic anion-transporting polypeptide 2.

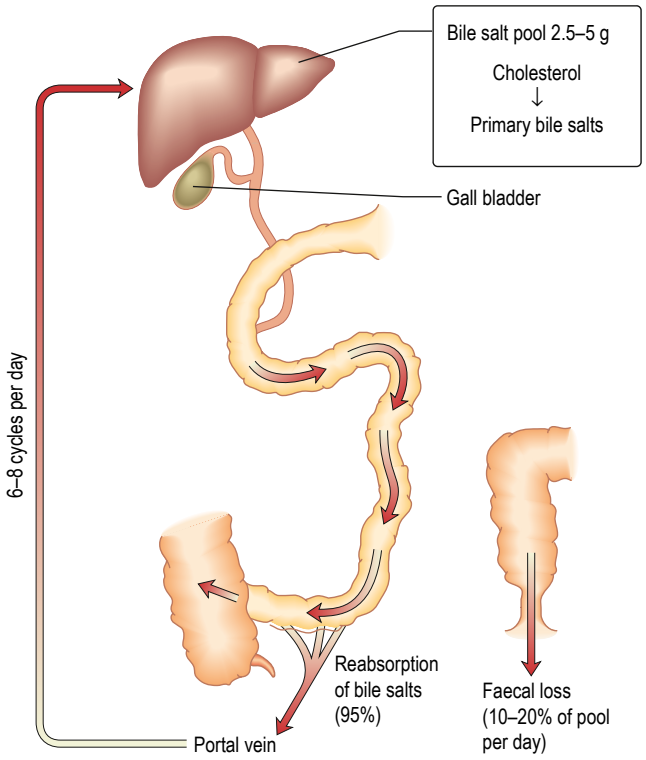

Fig. 23.6 Recirculation of bile acids. The bile salt pool is relatively small and the entire pool recycles six to eight times via the enterohepatic circulation. Synthesis of new bile acids compensates for faecal loss.

their hydrophobic (lipid-soluble) ends in the centre. Micelles are expanded by cholesterol and phospholipids (mainly lecithin), forming mixed micelles.

Bile acid receptors in liver disease

Bile acids have been identified as crucial cell signalling molecules that regulate multiple biological processes. Bile acids are endogenous ligands for FXR and TGR5, a G-protein coupled receptor. Gain- and loss-of-function studies have demonstrated that both are involved in the regulation of lipid and carbohydrate metabolism and inflammatory responses. These receptors may therefore be potential targets for treatment of MASLD (see 'Metabolic dysfunction–associated steatotic liver disease' section), and phase III trials of the FXR agonist obeticholic acid have completed in MASH with the drug outperforming placebo in helping more patients with pre-cirrhotic MASH achieve at least one stage of liver fibrosis improvement with no worsening of MASH. However, the drug failed to significantly resolve MASH and in addition, the drug had no benefit in more severe cirrhotic MASH patients. To date, it has not been approved for MASH therapy. Obeticholic acid has been approved for the second-line treatment of primary biliary cholangitis (PBC) following trial results demonstrating an improvement in liver blood tests. Finally, obeticholic acid showed potential beneficial effect for primary sclerosing cholangitis (PSC) in a phase II study. In cirrhotic animal models, this drug reduced both portal hypertension and gut bacterial translocation. However, hepatic decompensation, liver failure, and death have been reported when Child B or C cirrhosis patients are dosed more frequently than recommended, with the US Food and Drug Administration (FDA) releasing a black box warning for the use of obeticholic acid in

patients with decompensated cirrhosis and so it remains uncertain whether it will emerge as a treatment for portal hypertension.

Bilirubin metabolism

Bilirubin is produced mainly from the breakdown of mature red cells by Kupffer cells in the liver and reticuloendothelial system; 15% of bilirubin is formed from catabolism of other haem-containing proteins, such as myoglobin, cytochromes, and catalases.

Normally, 250 to 300 mg (425–510 mmol) of bilirubin are produced daily. The iron and globin are removed from haem and reused. Biliverdin is formed from haem and reduced to form bilirubin. The bilirubin produced is unconjugated and water insoluble, due to internal hydrogen bonding, and is transported to the liver attached to albumin. Bilirubin dissociates from albumin and is taken up by hepatic cell membranes and transported to the endoplasmic reticulum by cytoplasmic proteins, where it is conjugated with glucuronic acid and excreted into bile. The microsomal enzyme uridine diphosphoglucuronosyl transferase catalyzes the formation of bilirubin monoglucuronide and then diglucuronide. This conjugated bilirubin is water soluble; it is actively secreted into biliary canaliculi and excreted into the intestine within bile (see **Fig. 38.8**). It is not absorbed from the small intestine because of its large molecular size. In the terminal ileum, bacterial enzymes hydrolyze the molecule, releasing free bilirubin, which is then reduced to urobilinogen; some of this is excreted in the stools as stercobilinogen. The remainder is absorbed by the terminal ileum, passes to the liver via the enterohepatic circulation, and is re-excreted into bile. Urobilinogen bound to albumin enters the circulation and is excreted in urine via the kidneys. When hepatic excretion of conjugated bilirubin is impaired, a small amount is strongly bound to serum albumin and is not excreted by the kidneys; it accounts for persisting hyperbilirubinaemia after cholestasis has resolved.

Hormone and drug inactivation

The liver catabolizes hormones such as insulin, glucagon, oestrogens, growth hormone, glucocorticoids, and parathyroid hormone. It is also the prime target organ for many hormones (e.g., insulin). It is the major site for the metabolism of drugs (see 'Drug metabolism' section) and alcohol (see 'Alcohol and alcoholic liver disease' section). Fat-soluble drugs are converted to water-soluble substances that facilitate their excretion in the bile or urine. Cholecalciferol is converted to 25-hydroxycholecalciferol.

Immunological function

The liver plays a key role in the innate immune response and acts as a 'sieve' for bacterial and other antigens carried to it by the portal vein from the gastrointestinal tract (see 'Gut–liver axis' section).

Hepatocytes are responsible for biosynthesis of 80%–90% of innate immune proteins, including complement components and many secreted pattern-recognition receptors (PRRs) expressed by host cells. Kupffer cells, which account for 80%–90% of the total population of fixed tissue macrophages, are a critical component of the mononuclear phagocytic system and are central to both the hepatic and the systemic responses to pathogens. Following stimulation by endotoxin, the Kupffer cells release interleukin (IL)-6, IL-8, and TNF-α, and, in combination with liver sinusoidal cells, are responsible for the elimination of molecular wastes from the body.

In addition, liver lymphocytes are rich in innate immune cells, including natural killer and T-cell receptor $\gamma\delta$ T cells. Finally, nonparenchymal liver cells express high levels of membrane-bound PRRs, such as Toll-like receptor cells (TLRs). Not only does innate immunity in the liver play a key role in host defence against microbial infection and tumour formation but it also contributes to the pathogenesis of acute and chronic liver diseases, including alcoholic liver disease (see 'Alcohol and alcoholic liver disease' section).

INVESTIGATIONS IN THE PATIENT WITH LIVER DISEASE

Investigative tests can be divided into:

- **Blood tests:**
  - Liver 'function' tests: serum albumin and bilirubin; prothrombin time (PT).
  - Liver biochemistry: aspartate aminotransferase (AST) and alanine aminotransferases (ALT)—an increase reflects hepatocellular damage; serum alkaline phosphatase (ALP) and gamma-glutamyl transpeptidase (γ-GT)—an increase reflects cholestasis; total protein.
  - Viral markers.
  - Additional blood investigations: haematological, biochemical, immunological, markers of liver fibrosis, and genetic analysis.
- ***Imaging techniques***—to define gross anatomy.
- ***Liver biopsy***—for histology.

Blood tests ordered for 'liver function' are usually processed by an automated multichannel analyzer to produce serum levels of bilirubin, aminotransferases, ALP, γ-GT, and total proteins. These routine tests are markers of liver damage but not actual tests of 'function' *per se*. Subsequent investigations are often based on these tests.

Blood tests

Useful blood tests for certain liver diseases are shown in **Box 23.3**.

Liver function tests

Serum albumin

This is a marker of synthetic function and is useful for gauging the severity of chronic liver disease, with a falling serum albumin, which is a poor prognostic sign. In acute liver disease, initial albumin levels may be normal. Interpretation of a low albumin can be difficult when other causes of hypoalbuminaemia (e.g., sepsis) are present.

Bilirubin

Serum bilirubin is normally almost all unconjugated. In liver disease, increased serum bilirubin (conjugated) is usually accompanied by other abnormalities in liver biochemistry. Differentiation between conjugated or unconjugated bilirubin is only necessary in congenital disorders of bilirubin metabolism (see later) or to exclude haemolysis.

Prothrombin time

PT is also a marker of synthetic function. Because of its short half-life, it is a sensitive indicator of both acute and chronic liver disease. Vitamin K deficiency should be excluded as the cause of a prolonged PT by giving an intravenous bolus (10 mg) of vitamin K.

Box 23.3 Useful blood and urine tests for certain liver diseases

Test	Disease
Anti-mitochondrial antibody	Primary biliary cholangitis
Anti-nuclear, smooth muscle (actin), liver/kidney microsomal antibody	Autoimmune hepatitis
Raised serum immunoglobulins:	
IgG	Autoimmune hepatitis
IgG4	Autoimmune hepatitis/cholangiopathy and pancreatitis
IgM	Primary biliary cholangitis
Viral markers	Hepatitis A, B, C, D, E, and others
α-Fetoprotein	Hepatocellular carcinoma
Serum iron, transferrin saturation, serum ferritin	Hereditary haemochromatosis
Serum and urinary copper, serum caeruloplasmin	Wilson's disease
α_1-Antitrypsin	α_1-Antitrypsin deficiency (cirrhosis ± emphysema)
Anti-nuclear cytoplasmic antibodies (ANCA)	Primary sclerosing cholangitis
Markers of liver fibrosis (see 'Markers of liver fibrosis' section)	Non-alcoholic fatty liver disease
	Hepatitis C
Genetic analyses	For example, *HFE* gene (hereditary haemochromatosis), α_1-antitrypsin

Vitamin K deficiency commonly occurs in biliary obstruction, as the low intestinal concentration of bile salts results in poor absorption of vitamin K.

Prothrombin times vary in different laboratories, depending on the thromboplastin used in the assay. The international normalized ratio (INR) was developed to standardize anticoagulation with coumarin derivatives but is very variable in liver disease and causes large differences when included in prognostic scores for cirrhosis across different centres. A rising INR in patients with liver disease that is not corrected by vitamin K is a poor prognostic sign.

Liver biochemistry

Aminotransferases

These enzymes (often referred to as transaminases) are contained in hepatocytes and leak into the blood with liver cell damage. Two enzymes are measured:

- ***Aspartate aminotransferase*** (AST) is primarily a mitochondrial enzyme (80%; 20% in cytoplasm) and is also present in heart, muscle, kidney, and brain. High levels are seen in hepatic necrosis, myocardial infarction, and muscle injury, for example, following very strenuous exercise and congestive cardiac failure.
- ***Alanine aminotransferase*** (ALT) is a cytosol enzyme, more specific to the liver, so that a rise occurs only with liver disease. The ALT:AST ratio is a useful clinical indicator:
- In viral hepatitis, ALT is greater than AST unless cirrhosis is present, in which case AST is greater than ALT.
- In alcoholic liver disease and steatohepatitis, the AST is often greater than the ALT.
- In patients with viral hepatitis, an AST:ALT ratio of more than 1 indicates cirrhosis.
- In patients with liver disease without cirrhosis, in whom AST is greater than ALT, alcohol or obesity is the most likely aetiological agent.

Alkaline phosphatase

Alkaline phosphatase (ALP) is present in hepatic canalicular and sinusoidal membranes, and also in bone, intestine, and placenta. If necessary, its origin can be determined by electrophoretic separation of isoenzymes or bone-specific monoclonal antibodies. In clinical practice, if the γ-GT is also abnormal, the ALP is presumed to come from the liver.

Serum ALP is raised in both intrahepatic and extrahepatic cholestatic disease of any cause, due to increased synthesis. In cholestatic jaundice, levels may be four to six times the normal limit. Raised levels also occur with hepatic infiltrations (e.g., metastases) and in cirrhosis, frequently in the absence of jaundice.

Gamma-glutamyl transpeptidase

This is a microsomal enzyme present in liver and also in many tissues. Its activity can be induced by numerous drugs such as phenytoin, warfarin, and rifampicin, and by alcohol. If the ALP is normal, a raised serum γ-GT can be a useful guide to alcohol intake. However, mild elevations of γ-GT are common, even with minimal alcohol consumption, and it is also raised in fatty liver disease. In the absence of other liver function test abnormalities, a slightly raised γ-GT can safely be ignored. In cholestasis, the γ-GT rises in parallel with the ALP, as it has a similar pathway of excretion.

Total proteins and globulin fraction

The globulin fraction is often raised in autoimmune hepatitis; if it falls, this indicates successful therapy.

Viral markers

Viruses are a major cause of liver disease. Virological studies have a key role in diagnosis; markers are available for most common viruses that cause hepatitis.

Haematological tests

A full blood count may show thrombocytopenia. Thrombocytopenia is a common finding in cirrhosis and is often aggravated by alcohol-induced bone marrow suppression. A low platelet count (below the lower limit of normal—150 × 10^9/L) should be regarded as indicative of cirrhosis, unless another cause can be found. In alcohol excess, red blood cells are often macrocytic.

Biochemical tests

- ***α_1-Antitrypsin*** enzyme deficiency can produce cirrhosis.
- ***α-Fetoprotein*** is normally produced by the fetal liver. Its reappearance in increasing and high concentrations in adults indicates hepatocellular carcinoma (HCC). Increased concentrations in pregnancy in blood and amniotic fluid suggest fetal neural tube defects. Blood levels are also slightly raised with regenerative liver tissue in patients with hepatitis or chronic liver disease and teratomas.
- ***Urinary copper*** is raised, and serum copper and caeruloplasmin are low in Wilson's disease (see 'Wilson's disease [progressive hepatolenticular degeneration]' section).

Immunological tests

Serum immunoglobulins

Increased γ-globulins are thought to result from reduced phagocytosis by sinusoidal and Kupffer cells of the gut-absorbed antigens.

These antigens then stimulate antibody production in the spleen, lymph nodes, and portal tract lymphoid and plasma cell infiltrates. In PBC the predominant raised serum immunoglobulin is IgM, while in autoimmune hepatitis it is IgG. IgG4 is raised in autoimmune pancreatitis/cholangitis (see Chapter 24).

Serum autoantibodies

- ***Anti-mitochondrial antibody (AMA)*** in serum is found in over 95% of patients with PBC (see 'Primary biliary cholangitis' section). Several different AMA subtypes are described, depending on their antigen specificity, and are also found in autoimmune hepatitis and other autoimmune diseases. AMA is demonstrated by an immunofluorescent technique and is neither organ- nor species-specific. The M2 subtype is specific for PBC.
- ***Nucleic, smooth muscle (actin), liver/kidney microsomal antibodies*** can be found in serum, often in high titre, in patients with autoimmune hepatitis. These serum antibodies are also present in other autoimmune conditions and other liver diseases.
- ***Anti-nuclear cytoplasmic antibodies (ANCA)*** can be found in the serum of patients with PSC (see 'Primary sclerosing cholangitis' section).

Markers of liver fibrosis

Fibrosis plays a key role in the outcome of many chronic liver diseases, and accurate assessment of fibrosis is critical for the appropriate management of many liver disorders. A variety of systems have been developed to assess the extent of liver fibrosis and these range from algorithms of varying degrees of complexity that use standard haematological and biochemical tests, to novel biomarkers. Simple algorithms include the ***APRI*** (*a*spartate aminotransferase to *p*latelet *r*atio *i*ndex) score or FIB-4 index (that uses age, ALT, AST, and platelet count), while more complex commercial tests include the ***fibrotest algorithm***. Novel biomarker–based algorithms include those based on measurements of hyaluronic acid, procollagen III amino terminal peptide, and tissue inhibitor of metalloproteinase I (TIMP-1), all combined in the ***enhanced liver fibrosis (ELF) test***. Many of these markers were developed for chronic hepatitis C initially but are often successfully applied to other liver disorders, especially non-alcoholic fatty liver disease. The current assays have a high sensitivity/specificity for the detection or absence of cirrhosis but are less effective at detecting intermediate levels of fibrosis. Combining mechanical non-invasive fibrosis tests, such as transient elastography (see below), with fibrosis markers allows many patients to avoid a liver biopsy to assess fibrosis.

Genetic analysis

These tests are performed routinely for haemochromatosis (*HFE* gene) and for α_1-antitrypsin deficiency. Markers are also available for the most frequent abnormal genes in Wilson's disease (see 'Wilson's disease [progressive hepatolenticular degeneration]' section).

Imaging techniques

Ultrasound examination

This non-invasive, safe, and relatively cheap technique involves analysis of the reflected ultrasound beam detected by a probe moved across the abdomen. The normal liver appears as a relatively homogeneous structure. The gall bladder, common bile duct, pancreas, portal vein, and other structures in the abdomen can be visualized. ***Abdominal ultrasound*** is useful in:

- Detection of extrahepatic obstruction (the bile duct is usually dilated, particularly in advanced disease). Note that opiates may cause biliary dilation without obstruction, and so scans in injecting drug users often show extrahepatic biliary dilation.
- Assessment of a jaundiced patient (to exclude obstruction) (see 'Differential diagnosis of jaundice' section).
- Assessment of hepatomegaly/splenomegaly.
- Detection of gallstones (see **Fig. 24.3**).
- Assessment of focal liver disease to detect lesions larger than 1 cm.
- Assessment of portal and hepatic vein patency.
- Assessment of the hepatic parenchyma—diffuse fatty infiltration often leads to a 'bright' appearance on ultrasound but experience is required to distinguish this from normal variation.
- Identification of cirrhosis—in advanced cirrhosis, the liver edge is irregular and the spleen is often enlarged, however, a normal ultrasound does not exclude cirrhosis.
- Assessment of lymph node enlargement.

Other abdominal masses can be delineated and biopsies obtained under ultrasonic guidance.

Colour Doppler ultrasound

This will demonstrate vascularity within a lesion, and the direction of portal and hepatic vein blood flow.

Hepatic stiffness (transient elastography)

Using an ultrasound transducer, a vibration of low frequency and amplitude is passed through the liver, the velocity of which correlates with hepatic stiffness. Stiffness (measured in kilopascal, kPa) increases with worsening liver fibrosis with sensitivity and specificity of 80% to 95%, compared to liver biopsy. Elastography can reliably exclude cirrhosis and, in patients with cirrhosis, increasing liver stiffness is associated with a higher risk of complications. Elastography is less effective for determining lesser degrees of fibrosis. It cannot be employed in the presence of ascites and morbid obesity, and is affected by inflammatory tissue and congestion, for example, in the presence of right-sided cardiac failure.

Acoustic radiation force impulse is also incorporated into standard B mode ultrasonography and has similar physical principles to transient elastography.

Computed tomography examination

Computed tomography (CT), during or immediately after intravenous contrast, shows both arterial and portal venous phases of enhancement, enabling more precise characterization of a lesion and its vascular supply (**Fig. 23.7**). Retrospective analysis of data allows multiple overlapping slices to be obtained with no increase in the radiation dose, providing excellent visualization of the size, shape, and density of the liver, pancreas, spleen, lymph nodes and lesions in the porta hepatis. Multiplanar and three-dimensional reconstruction in the arterial phase can create a CT angiogram, often making formal invasive angiography unnecessary. CT also provides guidance for biopsy. It has advantages over ultrasound in detecting calcification and is useful in obese subjects, although ultrasound is usually the first imaging modality to be used to investigate liver disease.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) produces cross-sectional images in any plane within the body and does not involve radiation. It is the most sensitive investigation for focal liver disease but can also assess fibrosis. Diffuse liver disease alters the T1 and T2 characteristics. Other fat-suppression modes, such as ***short T1 inversion recovery (STIR)***, allow good differentiation between haemangiomas and other lesions. Contrast agents such as intravenous gadolinium, which allow further characterization of lesions, are suitable for those with iodine allergy, and provide angiography and

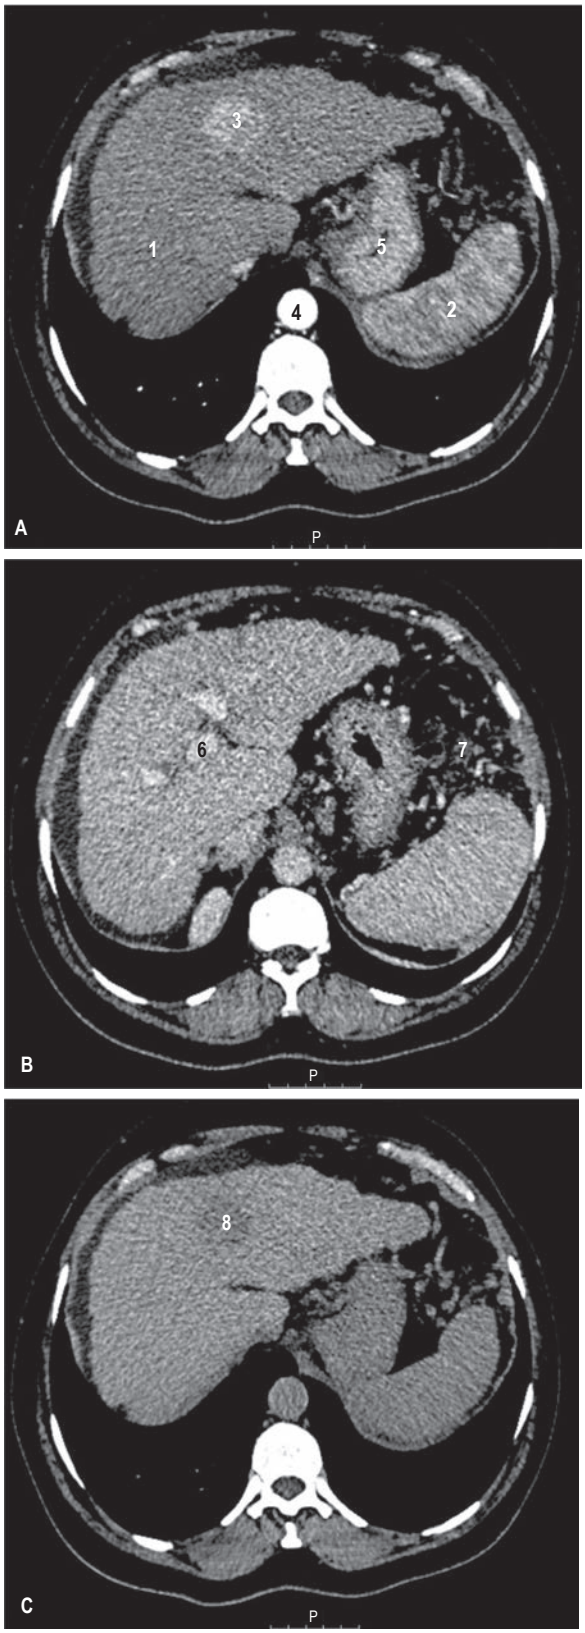

Fig. 23.7 Triple-phase liver CT showing a hepatocellular carcinoma. The liver has an irregular contour consistent with cirrhosis and there are splenic and gastric varices. The arterial phase **(A)** demonstrates an enhancing lesion, which is poorly seen on the portal venous phase **(B)** but demonstrates washout on the delayed phase imaging **(C)** consistent with hepatocellular carcinoma. (1) Liver; (2) spleen; (3) lesion; (4) aorta; (5) stomach; (6) portal vein; (7) varices; (8) washout of lesion.

venography of the splanchnic circulation. Use of these agents has superseded direct arteriography.

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) involves the manipulation of data acquired by MRI. A heavily T2-weighted sequence enhances visualization of the 'water-filled' bile ducts and pancreatic ducts to produce high-quality images of ductal anatomy. This non-invasive technique is replacing diagnostic (but not therapeutic) endoscopic retrograde cholangiopancreatography (see Chapter 24) and is usually the next test to be applied if a biliary abnormality is present on ultrasound examination.

Endoscopy

Upper gastrointestinal endoscopy is used for diagnosis and treatment (band ligation) of varices, detection of portal hypertensive gastropathy, and detection of associated lesions such as peptic ulcers. Colonoscopy may show portal hypertensive colopathy. Capsule endoscopy can identify small intestinal varices.

Endoscopic retrograde cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) outlines the biliary and pancreatic ducts (see Chapter 24).

Angiography

This is performed by selective catheterization of the coeliac axis and hepatic artery. It outlines the hepatic vasculature and the abnormal vasculature of hepatic tumours, but CT and MRI have replaced diagnostic angiography. It may be used to identify lower gastrointestinal bleeding, including variceal, and treat this by embolizing the culprit vessel using small metal coils.

Radionuclide imaging and hepatic venous cannulation have been superseded by cross-sectional imaging and transjugular intrahepatic measurement of portal pressure.

Liver biopsy

Histological examination of the liver is valuable in the differential diagnosis of diffuse or localized parenchymal disease and its severity. Liver biopsy is routinely performed as a day-case procedure. The indications and contraindications are shown in **Box 23.4**. The mortality rate is less than 0.02% when the technique is performed by experienced operators.

Liver biopsy guided by ultrasound or CT is performed under a local anaesthetic via a percutaneous approach in the right intercostal space. A transjugular approach is used when liver histology is essential for management but coagulation abnormalities or ascites prevent the percutaneous approach.

Most ***complications*** of liver biopsy occur within 24 hours (usually in the first 2 hours). They are often minor and include abdominal or shoulder pain that settles with analgesics. Minor intraperitoneal bleeding can occur, but this settles spontaneously. Rare complications include major intraperitoneal bleeding, haemothorax and pleurisy, biliary peritonitis, haemobilia, and transient septicaemia. Haemobilia produces biliary colic, jaundice, and melaena within 3 days of the biopsy.

Box 23.4 Indications for and contraindications to liver biopsy

Diagnosis
- Multiple parenchymal liver diseases
- Abnormal liver tests of unknown aetiology
- Fever of unknown origin
- Focal or diffuse abnormalities on imaging studies (rarely for hepatocellular carcinoma)
- Unexplained hepatomegaly
- Drug-related liver disease
- Post liver transplant

Prognosis
- Staging of known parenchymal liver disease, e.g., hepatitis B/C, non-alcoholic fatty liver disease, primary biliary cholangitis, autoimmune hepatitis, primary sclerosing cholangitis
- Haemochromatosis and alcohol-induced liver disease

Management
- Development of treatment plans based on histological analysis

Usual contraindications to percutaneous needle biopsy
- Uncooperative patient
- Prolonged INR (>1.5)
- Platelets $<60 \times 10^9$/L
- Ascites
- Extrahepatic cholestasis

JAUNDICE

Jaundice (icterus) is detectable clinically when the serum bilirubin is over 50 μmol/L (3 mg/dL). It may be divided into:
- ***haemolytic jaundice***—increased bilirubin load for the liver cells
- ***congenital hyperbilirubinaemias***—defects in conjugation
- ***hepatic jaundice***—including hepatocellular (parenchymal) liver disease and biliary duct obstruction.

Haemolytic jaundice

The increased breakdown of red cells (see **Fig. 38.8**) leads to an increase in production of bilirubin. The resulting jaundice is usually mild (serum bilirubin of 68–102 μmol/L, or 4–6 mg/dL), as normal liver function can easily manage the increased bilirubin. Unconjugated bilirubin is not water-soluble and therefore does not pass into urine: hence 'acholuric jaundice'. Urinary urobilinogen is increased.

The causes are those of haemolytic anaemia (see Chapter 38), and clinical features of anaemia, jaundice, splenomegaly, gallstones, and leg ulcers may be seen.

Investigations show anaemia with markers of haemolysis (e.g., reticulocytosis, elevated lactate dehydrogenase) and elevated unconjugated bilirubin, but normal serum ALP, transferases, and albumin. Serum haptoglobulins are low if haemolysis is intravascular.

Congenital hyperbilirubinaemias (non-haemolytic)

Unconjugated types

Gilbert's syndrome

This is the most common familial unconjugated hyperbilirubinaemia and affects 2% to 7% of the population. It is asymptomatic and usually detected incidentally with a raised bilirubin (17–102 μmol/L, or 1–6 mg/dL). All other liver biochemistry is normal and there are no signs of liver disease. There is a family history of jaundice in 5% to 15% of patients. Most patients have reduced levels of UDP-glucuronosyl transferase (UGT-1) activity; this is the enzyme that conjugates bilirubin with glucuronic acid.

Mutations occur in the gene (*UGT1A1* promoter region) encoding this enzyme, with an expanded nucleotide repeat consisting of two extra bases in the upstream 5′ promoter element. This abnormality appears to be required for the syndrome to occur but is not in itself sufficient for clinical manifestation (phenotypic expression).

Establishing the diagnosis is necessary to provide reassurance and prevent unnecessary investigations. The raised unconjugated bilirubin is diagnostic and rises on fasting and during mild illness. The reticulocyte count is normal, excluding haemolysis, and no treatment is necessary.

Crigler–Najjar syndrome

This is very rare. Only patients with type II (autosomal dominant) disease, with a decrease in, rather than absence (type I—autosomal recessive) of, UGT survive into adult life. Liver histology is normal. Transplantation is the only effective treatment but advances in gene therapy may soon provide alternative options (see Chapter 5).

Conjugated types

Dubin–Johnson and Rotor's syndromes

Dubin–Johnson and Rotor's syndromes (autosomal recessive) are due to defects in hepatic bilirubin handling. The prognosis is good in both. In the Dubin–Johnson syndrome the liver is black owing to melanin deposition.

Benign recurrent intrahepatic cholestasis

This is rare and presents in early adulthood. Recurrent attacks of acute cholestasis occur without progression to chronic liver disease. Jaundice, severe pruritus, steatorrhoea, and weight loss may develop. Serum γ-GT is normal. Benign recurrent intrahepatic cholestasis may be associated with intrahepatic cholestasis of pregnancy (see Chapter 48). Genetic testing is available and there are two forms: BRIC1 is caused by mutations in the *ATP8B1* gene and BRIC2 by mutations in the *ABCB11* gene. Both are autosomal recessive. Treatment includes medications to manage symptoms and occasionally specialized therapies, such as nasobiliary drainage, to shorten episodes.

Progressive familial intrahepatic cholestasis syndromes

Progressive familial intrahepatic cholestasis (PFIC) syndromes are a heterogeneous group of autosomal recessive conditions defined by defective secretion of bile acids due to mutations in various transporter genes (see **Figs. 23.5** and **24.2**).
- In ***type 1*** (PFIC1), with cholestasis in the first weeks of life, the γ-GT is normal and the genetic defect lies in the *ATP8B1* gene.
- In ***type 2*** (PFIC2), there is frequently a non-specific giant cell hepatitis that progresses to cholestasis; again, γ-GT is normal and the gene involved is *ABCB11.*
- In ***type 3*** (PFIC3), deficient canalicular phosphatidylcholine transport and accumulation of toxic bile acids cause liver damage, which can lead to cirrhosis and is due to mutations in the *ABCB4* gene.

Liver transplantation is currently the only cure for these syndromes.

Hepatic jaundice (acquired)

This condition can be divided into jaundice due to parenchymal liver damage or cholestasis, which may be intra- or extrahepatic. The causes are shown in **Fig. 23.8**.

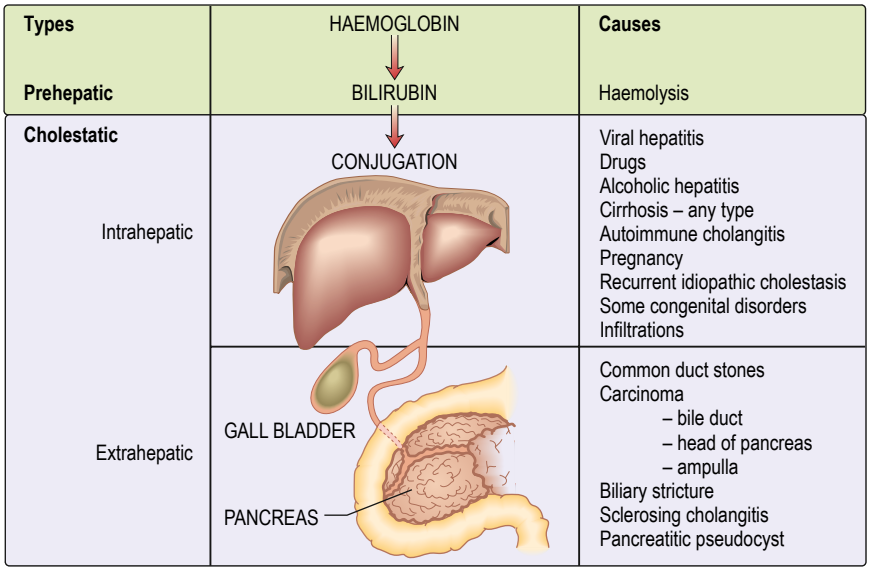

Fig. 23.8 **Causes of jaundice.**

- ***Hepatic jaundice*** is due to damage to hepatocytes leading to a failure in both bilirubin uptake and excretion.
- ***Extrahepatic cholestasis*** is due to large duct obstruction of bile flow at any point in the biliary tract distal to the bile canaliculi.
- ***Intrahepatic cholestasis*** occurs because of failure of bile secretion, which may be caused by intrinsic defects in bile secretion or inflammation in the intrahepatic ducts.

Clinically in cholestatic jaundice the stools are pale with dark urine, and the serum bilirubin is conjugated and these features are much less marked in hepatic jaundice. Intrahepatic and extrahepatic cholestatic jaundice must be differentiated, as their clinical management is entirely different.

Differential diagnosis of jaundice

Hepatic jaundice may occur in previously healthy people who have an acute hepatic illness or may develop in patients with cirrhosis who have 'decompensated'. The management of decompensated cirrhosis is described in the 'Cirrhosis' section but all patients with jaundice should be questioned closely about risk factors for chronic liver disease to determine whether this is a true acute presentation rather than an 'acute on chronic' illness. The history often gives a clue to the diagnosis. Certain causes of jaundice are more likely in particular categories of people. For example, a young person is more likely to have infectious hepatitis, so questions should be asked about drug and alcohol misuse, and sexual behaviour. An elderly person with gross weight loss is more likely to have a carcinoma. All patients may complain of malaise. Abdominal pain occurs in patients with biliary obstruction by gallstones, and sometimes with an enlarged liver there is pain resulting from distension of the capsule.

Questions should be appropriate to the particular situation, and the following aspects of the history should be covered:

- ***Country of origin.*** The incidence of hepatitis B virus (HBV) and hepatitis C virus (HCV) infection is increased in many parts of the world (see 'Hepatitis B' and 'Hepatitis C' sections).
- ***Duration of illness.*** A history of jaundice with prolonged weight loss in an older patient suggests malignancy. A short history, particularly with a prodromal illness of malaise, suggests an infectious hepatitis.
- ***Recent outbreak of jaundice.*** An outbreak in the community suggests hepatitis A virus (HAV).
- ***Intravenous drug use, or recent injections or tattoos.*** These all increase the chance of HBV and HCV infection.
- ***Men having sex with men.*** There is an increased chance of HBV and HCV infection.
- ***Female sex workers.*** There is an increased chance of HBV infection.
- ***Medical treatment in the developing world.*** There is an increased risk of HBV and HCV due to poorly sterilized equipment or administration of unscreened blood or blood products.
- ***Alcohol consumption.*** A history of drinking habits should be taken, although many patients often understate their consumption.
- ***Drugs (particularly those taken in the previous 2–3 months).*** Many drugs, including over-the-counter and herbal preparations, cause jaundice (see 'Drugs and the liver' section).
- ***Travel.*** Certain areas have a high risk of HAV infection, as well as hepatitis E virus (HEV), but HAV is common in the UK and HEV is common in travellers to the Indian subcontinent.
- ***Family history.*** Patients with, for example, Gilbert's disease may have family members who experience recurrent jaundice.
- ***Recent surgery.*** Surgery on the biliary tract or for carcinoma is relevant.
- ***Environment.*** People engaged in recreational activities in rural areas, as well as farm and sewage workers, are at risk for leptospirosis, hepatitis E, and exposure to chemicals.
- ***Fevers or rigors.*** These are suggestive of cholangitis or possibly a liver abscess.

Clinical features

The signs of acute and chronic liver disease should be looked for (see figure in 'Clinical skills' section). Certain additional signs may be helpful:

- ***Hepatomegaly.*** A smooth, tender liver is seen in hepatitis and in extrahepatic obstruction, but a knobbly, irregular liver suggests metastases or cirrhosis. Causes of hepatomegaly are shown in **Box 23.5**.
- ***Splenomegaly.*** This indicates portal hypertension when signs of chronic liver disease are present. The spleen can also be 'tipped' occasionally in viral hepatitis. In alcoholic cirrhosis, in particular, the spleen may not be grossly enlarged and may not be palpable.

Box 23.5 Causes of hepatomegaly

Apparent
- Low-lying diaphragm
- Riedel's lobe
- Cirrhosis (early)

Inflammation
- Hepatitis
- Schistosomiasis
- Abscesses (pyogenic or amoebic)

Cysts
- Hydatid
- Polycystic

Metabolic
- Fatty liver
- Amyloid deposition
- Glycogen storage disease

Haematological
- Leukaemias
- Lymphoma
- Myeloproliferative disorders
- Thalassaemia

Tumours
- Primary and secondary carcinoma

Venous congestion
- Heart failure
- Constrictive pericarditis
- Hepatic vein occlusion

Biliary obstruction
- Particularly extrahepatic

- ***Ascites.*** This is found in cirrhosis but can also be due to other causes (see Box 23.20).
- ***Palpable gall bladder.*** This occurs with a carcinoma of the pancreas obstructing the bile duct.
- ***Generalized lymphadenopathy.*** This suggests a lymphoma.
- ***Cold sores*** are often seen with a herpes simplex virus hepatitis.

Investigations

Jaundice is not itself a diagnosis and the cause should always be sought. The cause is either excessive haemolysis, parenchymal liver damage (hepatic jaundice), or biliary obstruction—either within or outside the liver. Liver biochemistry confirms the jaundice and may help in the diagnosis, but the most useful test is an ultrasound examination which identifies extrahepatic obstruction.

Ultrasound will demonstrate:
- the size of the bile ducts, which are dilated in extrahepatic biliary obstruction (Fig. 23.9)
- the level of the obstruction
- the cause of the obstruction in virtually all patients with tumours and in 75% of patients with gallstones.

The pathological diagnosis of any mass lesion can be made by fine-needle aspiration cytology (sensitivity approximately 60%) or by needle biopsy (sensitivity approximately 90%).

A flow diagram for the general investigation of the jaundiced patient is shown in Fig. 23.10.

Liver biochemistry

In hepatitis, serum AST and ALT tend to be high early in the disease, with only a small rise in serum ALP. Conversely, in extrahepatic obstruction, the ALP is high, with a smaller rise in aminotransferases. However, these findings alone cannot be relied on to make a diagnosis in an individual case and in obstructive jaundice the ALP changes may follow the ALT changes. The PT is often prolonged in longstanding liver disease and the serum albumin is low.

Haematological tests

In haemolytic jaundice the bilirubin is raised and the other liver biochemistry is normal. A raised white cell count may indicate infection (e.g., cholangitis). A leucopenia often occurs in viral hepatitis, while abnormal mononuclear cells suggest infectious mononucleosis (Epstein–Barr virus) and a Monospot test should be performed.

Other blood tests

These include tests to confirm the presence of specific causes of acute or chronic liver disease, such as AMA for PBC. HIV status should be established.

HEPATITIS

- ***Acute parenchymal liver damage*** can be caused by many agents (Fig. 23.11).
- ***Chronic hepatitis*** is defined as any hepatitis lasting for 6 months or longer and is classified according to the aetiology (Box 23.6). Chronic viral hepatitis is the principal cause of chronic liver disease, cirrhosis, and HCC worldwide.

Acute hepatitis

Pathology

Although some histological features are suggestive of the aetiological factor, most changes are non-specific. Hepatocytes show degenerative changes (swelling, cytoplasmic granularity, vacuolation) and undergo necrosis (becoming shrunken, containing eosinophilic Councilman bodies). The distribution of these changes may vary with aetiology but necrosis is usually maximal in zone 3. The extent of the damage is very variable between individuals, even when they are affected by the same agent; at one end of the spectrum, single and small groups of hepatocytes die (spotty or focal necrosis), while at the other end, there is multiacinar necrosis involving a substantial part of the liver (massive hepatic necrosis) and resulting in acute hepatic failure. Between these extremes, there is limited confluent necrosis with collapse of the reticulin framework, leading to linking (bridging) between the central veins, between the central veins and portal tracts, and between the portal tracts. The extent of the inflammatory infiltrate is also variable but portal tracts and lobules are infiltrated mainly by lymphocytes. Other variable features include cholestasis in zone 3 and fatty change, the latter being prominent in hepatitis due to alcohol or certain drugs.

Chronic hepatitis

Pathology

The pathological features are often diagnostic. Chronic inflammatory cell infiltrates, comprising lymphocytes, plasma cells, and sometimes lymphoid follicles, are usually present in the portal tracts. The amount of inflammation varies from mild to severe. In addition, there may be:
- loss of definition of the portal/periportal limiting plate—interface hepatitis (damage is due to apoptosis rather than necrosis)
- lobular change, focal lytic necrosis, apoptosis, and focal inflammation
- confluent necrosis
- fibrosis, which may be mild, bridging (across portal tracts) or severe cirrhosis.

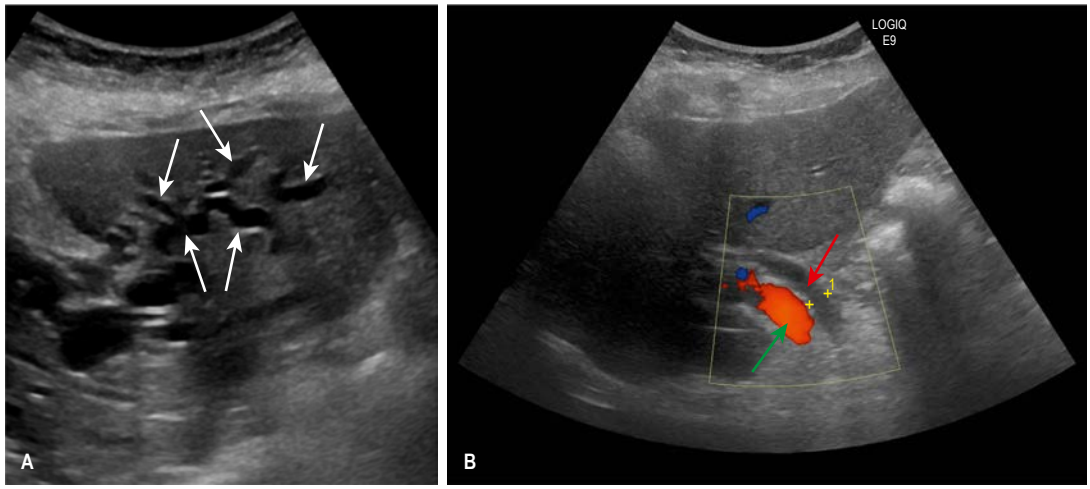

Fig. 23.9 Liver ultrasound. (A) Markedly dilated intrahepatic ducts *(arrowed)*. **(B)** A dilated common bile duct *(red arrow)*. A duct with a diameter of 6 mm or less is normal; however, it can be of larger calibre and still not represent pathology in some circumstances, such as in elderly patients and after cholecystectomy. Several factors must therefore be considered when deciding what is normal for a patient. Normal colour flow is demonstrated in the portal vein *(green arrow)*.

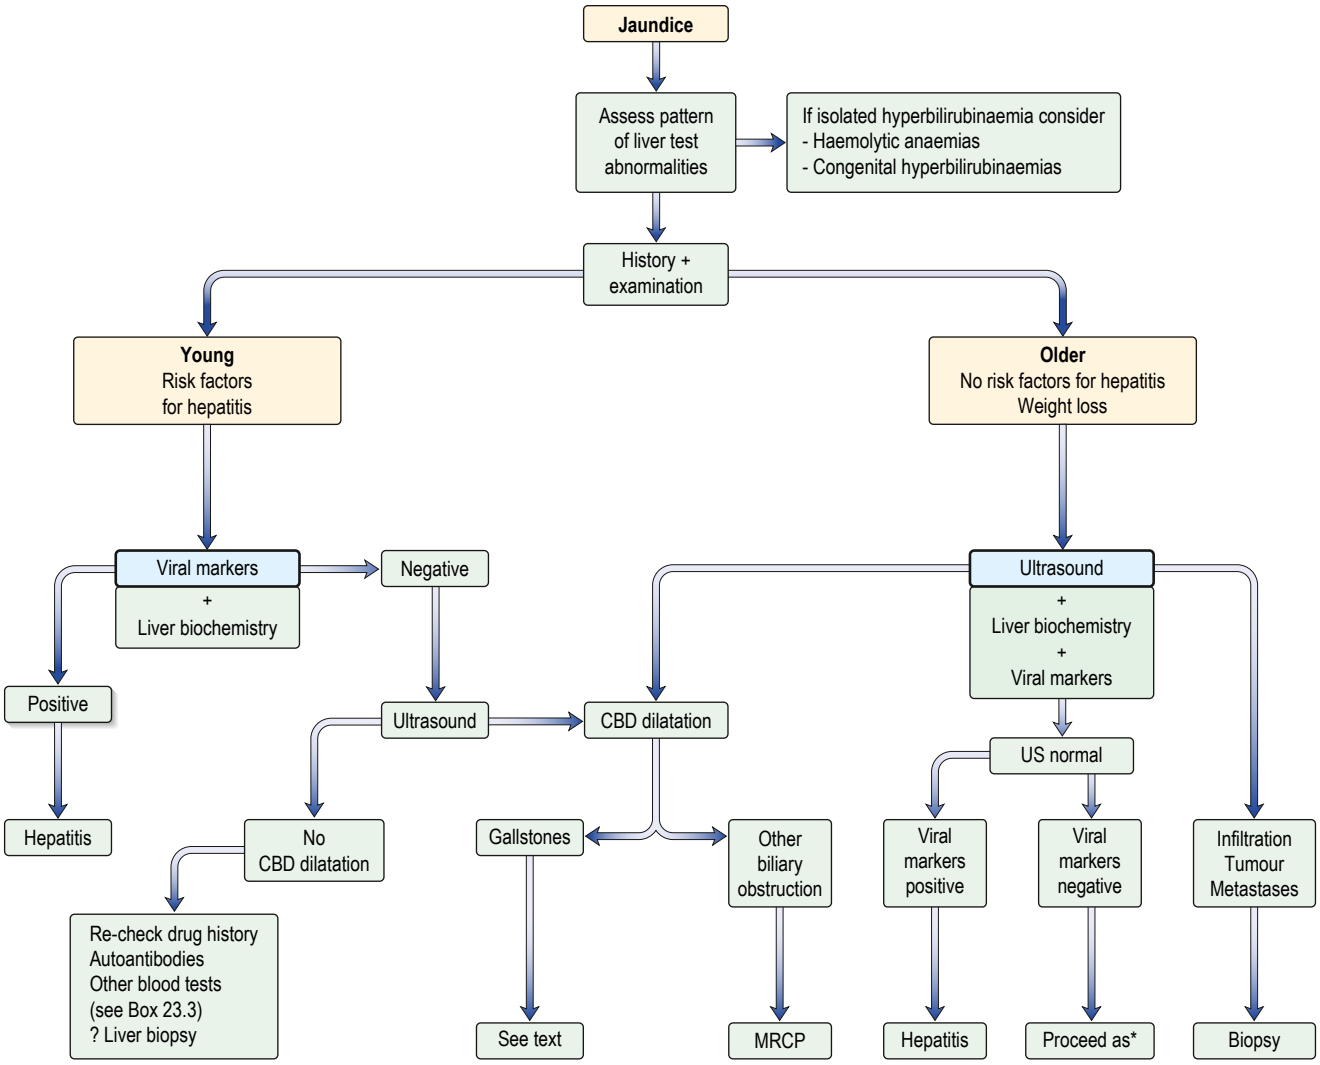

Fig. 23.10 Approach to the patient with jaundice. *CBD,* Common bile duct; *MRCP,* magnetic resonance cholangiopancreatography; *US,* ultrasound. *Proceed as in bottom left box (Re-check drug history…)

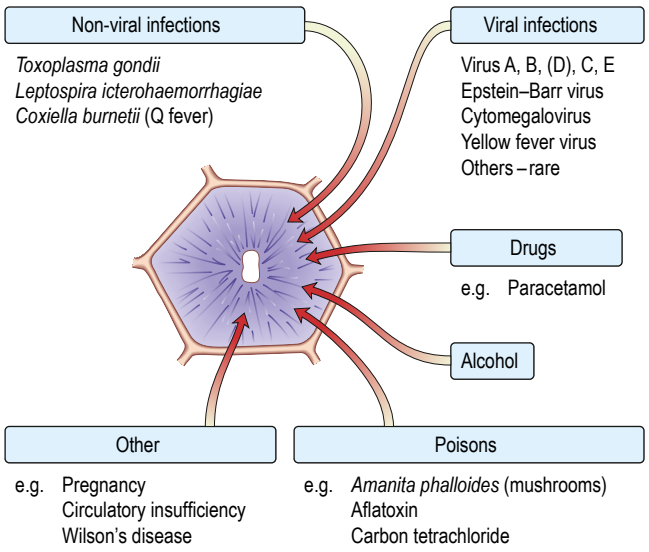

Fig. 23.11 Some causes of acute parenchymal damage.

Box 23.6 Causes of chronic hepatitis

- Metabolic:
  - Non-alcoholic fatty liver disease
- Alcohol-induced
- Viral:
  - Hepatitis B ± hepatitis D
  - Hepatitis C
  - Hepatitis E (immunosuppressed)
- Drugs:
  - (e.g., methyldopa, isoniazid, ketoconazole, nitrofurantoin)
- Autoimmune
- Hereditary:
  - Wilson's disease, haemochromatosis.

Unusual causes include infections (syphilis, tuberculosis, various tropical infections), infiltrative diseases, including amyloidosis and lymphoma, and ingestion of toxins.

The overall severity of the hepatitis is judged by the degree of hepatitis and inflammation (grading), and the severity of fibrosis or cirrhosis (staging). In chronic viral hepatitis there are various scoring systems. For example, the ***Knodell scoring system*** (histological activity index) uses the sum of four factors (periportal or bridging necrosis, intralobular degeneration and focal necrosis, portal inflammation, and fibrosis). The ***Ishak score*** stages fibrosis from 0 (none) to 6 (cirrhosis). The ***METAVIR system*** has four stages. Scoring systems are used for drug trials and for assessing progression of disease, but are not quantitative measures of fibrosis and different systems may be used for different diseases (for example, the ***Brunt scoring system*** is usually applied to NAFLD, and the METAVIR system is reserved for hepatitis C).

Viral hepatitis

The differing features of the common forms of viral hepatitis are summarized in **Box 23.7**. Two different patterns are recognized: acute hepatitis with rapid onset of infection and, usually, rapid resolution; and chronic viral hepatitis, which is asymptomatic and often detected on routine blood tests or during screening for infection. Hepatitis A always and hepatitis E usually cause acute infections, while hepatitis B, C, and D may cause acute or chronic disease.

Hepatitis A

Epidemiology

Hepatitis A is common worldwide, often occurring in epidemics. The disease is usually seen in the autumn and affects children and young adults. Spread of infection is mainly by the faeco-oral route and arises from ingestion of contaminated food or water (e.g., shellfish). Overcrowding and poor sanitation facilitate spread, and outbreaks of infection have occurred in men who have sex with men. There is no carrier state. In the UK it is a notifiable disease.

Hepatitis A virus

Hepatitis A virus (HAV) is a picornavirus (**Fig. 23.12**). It has a single serotype, as only one epitope is immunodominant. It replicates in the liver, is excreted in bile, and then excreted in the faeces for about 2 weeks before the onset of clinical illness and for up to 7 days after. The disease is maximally infectious just before the onset of jaundice. HAV particles can be demonstrated in the faeces by electron microscopy.

Clinical features

The viraemia causes the patient to feel unwell, with non-specific symptoms that include nausea and anorexia. Many recover at this stage and remain anicteric. An anicteric infection is common in children and confers lifetime immunity. In the developing world, improvements in hygiene have reduced early infection and, paradoxically, led to an increase in symptomatic infection in exposed adults.

After 1 or 2 weeks, some patients become jaundiced and symptoms often improve. Persistence of nausea, vomiting, or any mental confusion warrants assessment in hospital. As the jaundice deepens, the urine becomes dark and the stools are pale. The liver is moderately enlarged and the spleen may be palpable. Occasionally, tender lymphadenopathy is seen, with a transient rash in some cases. Thereafter, the jaundice lessens and, in the majority of cases, the illness is over within 3 to 6 weeks. Extrahepatic complications are rare but include arthritis, vasculitis, myocarditis, and acute kidney injury. A biphasic illness occasionally occurs, with the return of jaundice and, classically, a more severe 'second phase', which is cholestatic (cholestatic viral hepatitis) with an increase in the ALP rather than the aminotransferases; thus, it runs a prolonged course of 7 to 20 weeks. Rarely, the disease may be very severe with acute hepatitis, liver coma, and death; this is more common in the elderly. The typical sequence of events after HAV exposure is shown in **Fig. 23.13**.

Investigations

Liver biochemistry

- ***Prodromal stage:*** The serum bilirubin is usually normal. A raised serum AST or ALT, which can sometimes be over many thousands, precedes the jaundice.
- ***Icteric stage:*** The serum bilirubin reflects the level of jaundice. Serum AST reaches a maximum of 1 to 2 days after the appearance of jaundice, and may rise above 500 IU/L. Serum ALP is usually less than 300 IU/L.

After the jaundice has subsided, the aminotransferases may remain elevated for some weeks and occasionally for up to 6 months.

Haematological tests

There is leucopenia with a relative lymphocytosis. Very rarely, there is a Coombs'-positive haemolytic anaemia or an associated aplastic anaemia. The PT is prolonged in severe cases. The erythrocyte sedimentation rate (ESR) is raised.

Box 23.7 Some features of viral hepatitis

[a]Chronic hepatitis in immunosuppressed patients.
HBsAg, Hepatitis B surface antigen.

Viral markers: antibodies to HAV

IgG antibodies are common in the general population but an anti-HAV IgM means an acute infection. In areas of high prevalence, most children have antibodies by the age of 3 years following asymptomatic infection.

Other tests

Further tests are not necessary in the presence of an IgM antibody but liver biochemistry must be followed to establish a return to normal levels. Severity should be assessed by changes in PT and not by the level of AST/ALT.

Differential diagnosis

Differentiation must be made from all other causes of jaundice, but in particular from other types of viral and drug-induced hepatitis.

Prognosis

The prognosis is excellent, with most patients making a complete recovery. The mortality in young adults is 0.1% but increases with age. Death is due to acute hepatic failure.

There is no reason to stop alcohol consumption, other than for the few weeks when the patient is ill. Patients may complain of debility for several months following resolution of the symptoms and biochemical parameters. This is known as post-hepatitis syndrome and treatment is by reassurance. HAV hepatitis never progresses to chronic liver disease.

Management

There is no specific treatment, and rest and dietary measures are unhelpful. Corticosteroids have no benefit. Admission to hospital is not usually necessary.

Prevention

Control of hepatitis depends on good hygiene. The virus is resistant to chlorination but is killed by boiling water for 10 minutes.

Active immunization

A formaldehyde-inactivated HAV vaccine is given to people travelling frequently to endemic areas, patients with chronic liver disease, those with haemophilia, and workers in frequent contact with hepatitis cases (e.g., in residential institutions for patients with learning disabilities). Community outbreaks can be interrupted by vaccination. A single dose produces antibodies that persist for at least 1 year, with immunity lasting beyond 10 years. This obviates the need for a booster injection in healthy individuals.

Passive immunization

Normal human immunoglobulin is used in line with the manufacturers' recommendations if exposure to HAV is for less than 2 weeks. HAV vaccine should also be given.

Hepatitis B

Epidemiology

The hepatitis B virus (HBV) is present worldwide and there are an estimated 220 million carriers. The UK and the USA have a low

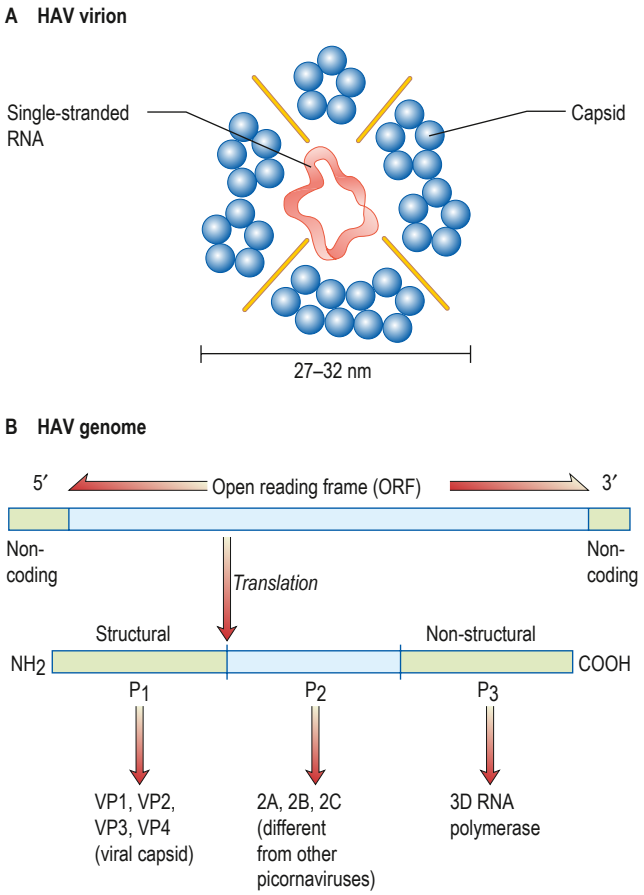

Fig. 23.12 Hepatitis A. (A) The hepatitis A (HAV) virion consists of four polypeptides (VP1–VP4), which form a tight protein shell, or capsid, containing the RNA. The major antigenic component is associated with VP1. **(B)** Arrangement of the HAV genome.

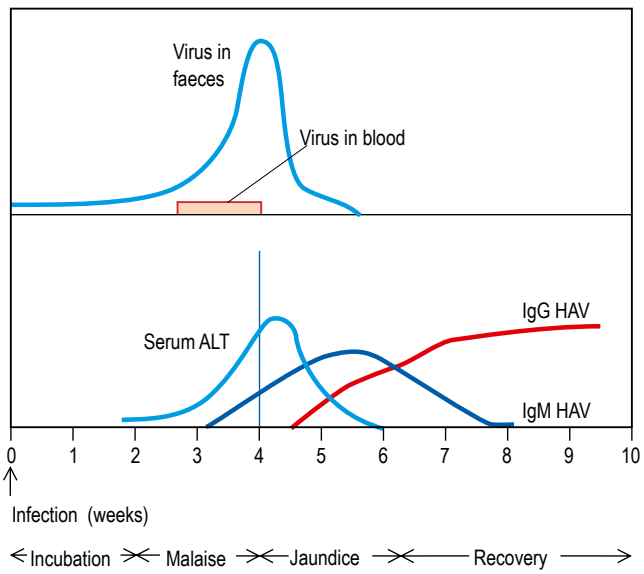

Fig. 23.13 Hepatitis A virus (HAV): sequence of events after exposure. *ALT,* Alanine aminotransferase; *Ig,* immunoglobulin.

carrier rate (0.5%–2%) but this rises to 10% to 20% in parts of Africa and the Middle and Far East and immigrants from these countries retain the high prevalence rates seen in their country of origin.

Vertical transmission from mother to child, usually during parturition or soon after birth, and rarely *in utero*, is the usual means of transmission worldwide, although in Africa transmission from other infected children is common during the early childhood years. HBV is not transmitted by breast-feeding.

Horizontal transmission occurs, particularly in children, through minor abrasions or close contact with other children, and HBV can survive on household articles, such as toys or toothbrushes, for prolonged periods. Childhood chronic HBV is associated with very high levels of viral replication (up to 10^{10} IU/mL), ensuring that high levels of virus are present in minute amounts of blood thus facilitating viral spread.

HBV spread also occurs by the intravenous route (e.g., by transfusion of infected blood or blood products, or by contaminated needles employed by drug users, tattooists, or acupuncturists) or by close personal contact, such as during sexual intercourse, particularly in men who have sex with men. The virus can be found in semen and saliva.

Hepatitis B virus

The complete infective virion or Dane particle is a 42 nm particle comprised of an inner core or nucleocapsid (27 nm), surrounded by an outer envelope of surface protein (hepatitis B surface antigen, HBsAg). This surface coat is produced in excess by the infected hepatocytes and can exist separately from the whole virion in serum and body fluid as 22 nm particles or tubules.

The HBV genome is variable, and genetic sequencing can be used to define the different HBV genotypes, A–H. There is a strong correlation between genotypes and geographical areas. ***Genotype A*** is found in Northwest Europe, North America, and Central Africa; ***B*** in South-east Asia (including China, Taiwan, and Japan); ***C*** in South-east Asia; ***D*** in southern Europe, India, and the Middle East; ***E*** in West Africa; ***F*** in South and Central America, in American Indians and in Polynesia; ***G*** in France and the USA; and ***H*** in Central and South America. These genotypes may influence the chance of responding to interferon treatment (A more than B; C more than D) but all genotypes respond equally well to nucleoside analogues.

The core or nucleocapsid is formed of core protein (HBcAg), containing incompletely double-stranded circular DNA and DNA polymerase/reverse transcriptase. One strand is almost a complete circle and contains overlapping genes that encode both structural proteins (pre-S, surface [S], core [C]) and replicative proteins (polymerase [P] and X). The other strand is variable in length. DR1 and DR2 are direct repeats necessary for HBV synthesis during viral replication (Fig. 23.14).

HBeAg is a protein formed via specific self-cleavage of the pre-core/core gene product, which is secreted separately by the cell.

Hepatitis B mutants

Mutations occur in the various reading frames of the HBV genome (Fig. 23.14). These mutants can emerge in patients with chronic HBV infection (escape mutants) or can be acquired by infection.

HBsAg mutants are produced by alterations in the 'a' antigenic determinants of the HBsAg proteins, usually with a substitution of glycine for arginine at position 145. This results in changes in the antibody-binding domain and may render the vaccine ineffective, although spread of vaccine-resistant virus has not proved problematic. In patients with some HBV genotypes (particularly genotype D), a mutation in the ***pre-core region***, when a guanosine (G) to adenosine (A) change creates a stop codon (TAG), prevents the production of HBeAg (the secreted form of HBcAg) but the synthesis of HBcAg is unaffected. This mutation may be associated with

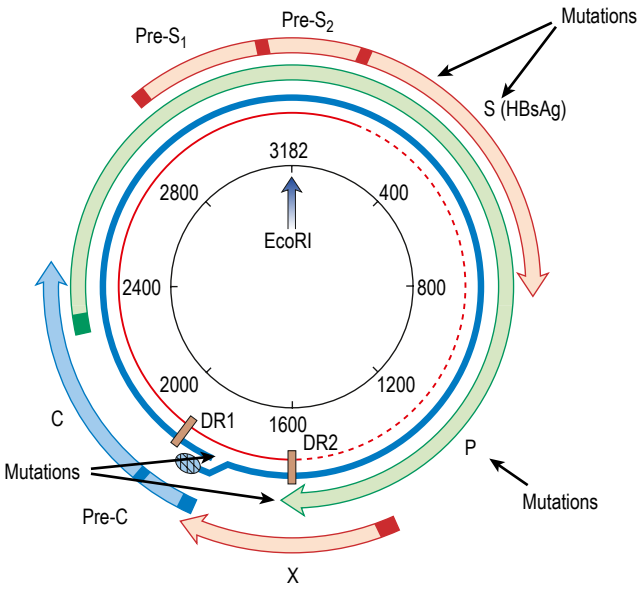

Fig. 23.14 Hepatitis B virus (HBV) genome. The viral DNA is partially double-stranded (*red incomplete circle* and *blue circle*). The long strand *(blue)* encodes seven proteins from four overlapping reading frames (S, surface [Pre-S_1, Pre-S_2, S]; C, core [Pre-C, C]; P, polymerase [P]; and X gene [X]). EcoRI restriction enzyme-binding site is included as a reference point. *DR,* Direct repeat; *HBsAg,* hepatitis B surface antigen.

HBeAg-negative disease but other mutations in the core promoter region of the virus also give rise to HBeAg-negative disease.

DNA polymerase mutants occur, particularly following treatment with the first generation of directly acting antiviral drugs, such as lamivudine.

Pathogenesis

Pre-S_1 and pre-S_2 regions are involved in attachment to the hepatocyte receptor—the sodium taurocholate co-transporting polypeptide (NTCP). After penetration into the cell the virus loses its coat and the virus core is transported to the nucleus without processing. The transcription of HBV into messenger RNA takes place when the HBV DNA is converted into a closed covalent circular form (cccDNA), which acts as a template for RNA transcription. The transcribed RNA is then reverse-transcribed by the viral polymerase protein to HBV DNA, which is circularized and packaged. Hence HBV, like HIV, replicates via reverse transcription that introduces errors into the replication cycle (reverse transcriptase enzymes are error-prone) but allows production of viral DNA that can integrate into the host genome. Unsurprisingly, some drugs (e.g., lamivudine and tenofovir) that are active against the HIV polymerase also have effects on the HBV polymerase.

Translation into HBV proteins (Box 23.8), as well as replication of the genome, takes place in the endoplasmic reticulum; the proteins are then packaged together and exported from the cell. There is excess production of non-infective HBsAg particles, which are extruded into the circulation.

HBV is not usually directly cytopathic (although high replication levels in immunosuppressed individuals can lead to direct toxicity) and liver damage is produced by the host immune response.

HBV-specific cytotoxic CD8 T cells recognize the viral antigen via human leucocyte antigen (HLA) class I molecules on the infected hepatocytes. However, suppressor or regulatory T cells inhibit these cytotoxic cells, leading to viral persistence and chronic

Box 23.8 Hepatitis B virus (HBV) proteins

HBV protein	Significance
Core	Protein of core particle; forms nucleocapsids
Pre-core (HBeAg)	Pre-core/core cleaves to HBeAg; good marker of active replication and role in inducing immunotolerance
Surface (HBsAg)	Envelope protein of HBV; basis of current vaccine
Pre-S_2Pre-S_1	HBV binding and entry into hepatocytes
Polymerase	Viral replication
X protein	Transcriptional and transactivator activity

HBV infection. Th1 responses (IL-2, interferon-gamma) are thought to be associated with viral clearance, and Th2 (IL-4, 5, 6, 10, 13) responses with the development of chronic infection and disease severity. Viral persistence in patients with a poor cell-mediated response leads to an asymptomatic, inactive, chronic HBV infective state. However, a 'better' response results in continuing hepatocellular damage, with the development of chronic hepatitis.

Chronic HBV infection progresses through a series of four distinct phases (Fig. 23.15).

- ***Phase 1 HBeAg-positive chronic HBV infection.*** The natural history of childhood-acquired HBV is shown in the figure. In this first early phase there is high-level viral replication, with HBeAg, which is not associated with an immune-mediated liver injury response and does not cause liver damage. This was previously called the 'immunotolerant phase' of HBV but it is now clear that an immune response does develop, although why this does not lead to an obvious hepatitis has not yet been established. This phase matures into the next adolescent phase.
- ***Phase 2 HBeAg-positive chronic HBV infection.*** During adolescence, liver damage often develops, with fluctuating raised transferases (ALT) in the presence of high levels of HBeAg-positive infection. This was previously termed the 'immunoactive phase' but it is now recognized that the change from 'inactive' to 'active' disease is complex and not simply related to changes in immune tolerance. In some patients this disease phase will progress to cirrhosis and treatment in this phase may lead to seroconversion from HBeAg-positive to HBeAg-negative.
- ***Phase 3 HBeAg-negative chronic HBV infection.*** In many patients the disease evolves to a quiescent phase (previously termed the 'inactive carrier' phase), when host immune responses suppress viral replication, leading to low-level HBV DNA (<2000 IU/mL), absence of HBeAg and normal ALTs. In some patients the virus is eventually cleared with the loss of HBsAg.
- ***Phase 4 HBeAg-negative chronic HBV infection.*** In a proportion of patients with inactive HBV, disease will reactivate as they age, and this final phase is characterized by high-level viral replication (HBV DNA $10^5/10^6$) but negative HBeAg and raised ALT. In this phase, fluctuating ALT levels may lead to misdiagnosis and so liver function and HBV DNA should be tested four times a year to establish the diagnosis in patients who are HBeAg-negative. This disease phase is often associated with viral mutations (see earlier).

HCC can develop at all stages of disease but is more common in those with high levels of HBV DNA.

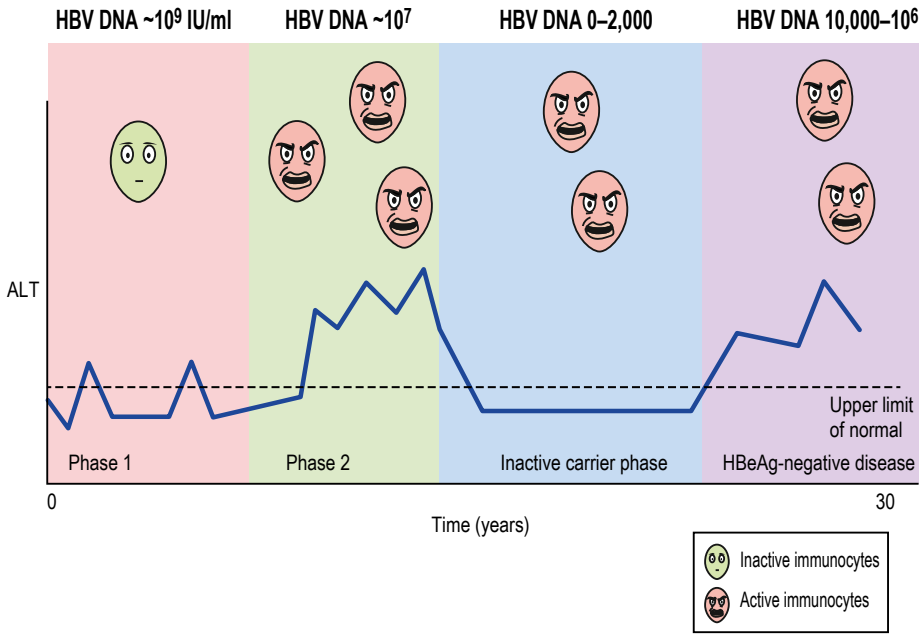

Fig. 23.15 Natural history of childhood-acquired hepatitis B virus (HBV). **Phase 1:** HBeAg-positive chronic HBV infection: early disease is characterized by high-level viraemia with HBeAg (the secreted form of HBcAg) and a minimal immune response, not leading to any significant liver damage (i.e., there is no acute hepatitis). **Phase 2:** HBeAg-positive chronic HBV infection: fluctuating liver function tests (tests of alanine aminotransferase, ALTs) and ongoing liver damage that may lead to cirrhosis. Treatment in this phase may lead to seroconversion. In many the immunoactive phase is followed by a period of immune control **(the 'inactive carrier' phase)**, when host immune responses suppress viral replication, leading to low-level HBV DNA (<2000 IU/mL), absence of HBeAg and normal ALTs. In some patients the virus is eventually cleared, with the loss of HBsAg; in many, however, viral reactivation occurs with viral mutations, leading to **HBeAg-negative disease** with high levels of viral replication (HBV DNA $10^5/10^6$) and ALT in the absence of HBeAg. Note that, in this phase, fluctuating ALTs may lead to misdiagnosis, and so the ALTs and HBV DNA should be tested four times a year to establish the diagnosis in patients who are HBeAg-negative. (N.B. Unlike children, adults commonly develop an acute hepatitis leading to viral clearance in the overwhelming majority [see Fig. 23.16]).

Immunosuppression, such as occurs during chemotherapy, aggravates all phases of HBV and a particular problem is seen in patients with HBeAg-negative, inactive disease, where the presence of normal liver biochemistry provides a false sense of security. HBV reactivation is common in such patients and has a high mortality. It is essential for all those due to receive chemotherapy to be screened for HBsAg, and those who have chronic HBV should receive prophylactic antiviral therapy, such as tenofovir or entecavir. Profound immunosuppression, such as occurs during bone marrow transplantation, or rituximab therapy, can lead to disease reactivation in patients who have lost all traces of HBV, and in those with evidence of HBV exposure (i.e., those with antibodies against hepatitis B—anti-hepatitis B core or anti-hepatitis B surface antibodies); consideration of prophylactic therapy or close monitoring is required.

Clinical features of acute hepatitis B infection

The sequence of events following acute HBV infection is shown in Fig. 23.16. However, in many, the infection is subclinical. When HBV infection is acquired perinatally, an acute hepatitis does not usually occur and chronic infection develops. In adults, an acute infection is common and the virus is cleared in approximately 99% of patients. The clinical picture is the same as that found in HAV infection, although the illness may be more severe. In addition, a serum sickness-like immunological syndrome may be seen. This consists of rashes (e.g., urticaria or a maculopapular rash) and polyarthritis affecting small joints in up to 25% of cases in the prodromal period. Fever is usual. Extrahepatic immune complex-mediated conditions, such as an arteritis or glomerulonephritis, are occasionally seen.

Investigations

These are generally the same as for hepatitis A.

Specific tests

The markers for HBV are shown in Box 23.9. HBsAg is looked for initially; if it is found, a full viral profile is performed. In acute infection, as HBsAg may be cleared rapidly and anti-HBc IgM is diagnostic, patients must be tested for both HBsAg and anti-core antibodies if HBV is suspected. HBV DNA is the most sensitive index of viral replication. In all patients with HBsAg testing for hepatitis delta (HDV) should be performed.

Prognosis

The majority of patients recover completely, acute hepatic failure occurring in up to 1%. Some patients go on to develop chronic hepatitis and the outcome depends on several factors, chiefly the age of the patient.

Management of acute hepatitis

This is mainly symptomatic. However, patients should have their HBV markers monitored. Several experts suggest that entecavir

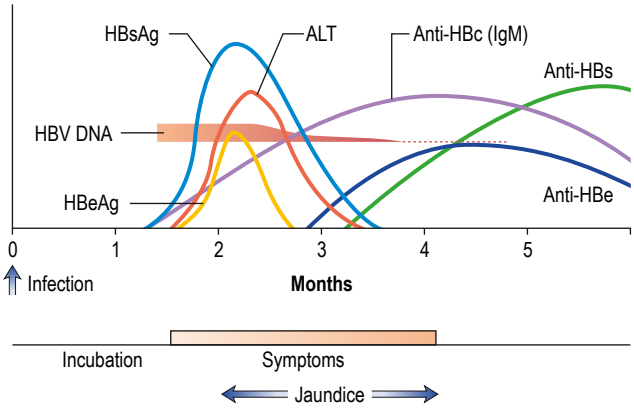

Fig. 23.16 Time course of the events and serological changes following acute infection with hepatitis B virus (HBV)—such as typically occurs in infected adults. ***Antigens:*** HBsAg appears in the blood from about 6 weeks to 3 months after an acute infection and then disappears. HBeAg rises early and usually declines rapidly. ***Antibodies:*** Anti-HBs appear late and indicate immunity. Anti-HBc is the first antibody to appear and high titres of IgM anti-HBc suggest an acute and continuing viral replication. It persists for many months. IgM anti-HBc may be the only serological indicator of recent HBV infection in a period when HBsAg has disappeared and anti-HBs are not detectable in the serum. Anti-HBe appears after the anti-HBc and its appearance relates to a decreased infectivity: that is, a low risk. *ALT,* Alanine aminotransferase.

Box 23.9 Significance of viral markers in hepatitis B

Marker	Significance
Antigens	
HBsAg	Acute or chronic infection
HBeAg	Acute hepatitis B Persistence implies: Continued infectious state Development of chronicity
HBV DNA	Implies viral replication Found in serum and liver Levels indicate response to antiviral treatment
Antibodies	
Anti-HBs	Immunity to HBV; previous exposure; vaccination
Anti-HBe	Seroconversion
Anti-HBc	
IgM	Acute hepatitis B (high titre) Chronic hepatitis B (low titre)
IgG	Past exposure to hepatitis B (HBsAg-negative)

or tenofovir should be given for the persistent presence of HBeAg beyond 12 weeks, and in some patients who are very ill.

Prevention

A highly effective vaccine prevents HBV infection and this is now widely deployed, although some countries still rely on the avoidance of risk factors (see earlier) and selective vaccination of high-risk groups. The important role of vaccination in the prevention of mother-to-child transmission is discussed later. Infectivity is highest in those with the e antigen and/or HBV DNA in their blood. Recent changes in the use of antiviral agents for chronic HBV infection recommend therapy for most people with high levels of viraemia, which is likely to reduce viral transmission still further.

Immunization

Vaccination is obligatory in most high income countries (the UK recently added HBV to the childhood vaccination schedule), as well as countries with high endemicity, and has been shown to reduce mortality and morbidity.

Active and passive (combined) prophylaxis with vaccination and immunoglobulin should be given to non-vaccinated healthcare staff with accidental needlestick injury; all newborn babies of HBsAg-positive mothers; and unvaccinated regular sexual partners of HBsAg-positive patients who have been found to be HBV-negative.

For adults, a dose of 500 IU of specific hepatitis B immunoglobulin (HBIg) (200 IU for newborns) is given; the vaccine (i.m.) is given at another site.

Prevention of mother-to-child transmission of HBV offers the potential to arrest transmission of this infection and, eventually, lead to the elimination of HBV as a global public health issue. The WHO has issued recommendations on the elimination of HBV and a key component of this is the prevention of mother-to-child transmission by identification of infected mothers and vaccination of all children. In women with high levels of virus additional steps to prevent transmission to their children include treatment during pregnancy with oral antiviral agents to lower the viral load and passive vaccination of children with antibodies against HBsAg.

Active immunization

This is with a recombinant yeast vaccine, produced by insertion of a plasmid containing the gene of HBsAg into a yeast.

Dosage regimen

Three injections (at 0, 1, and 6 months) are given into the deltoid muscle; this gives long-term protection in over 90% of patients. People who are over 50 years of age or clinically ill and/or immunocompromised (including those with human immunodeficiency virus [HIV] infection or acquired immunodeficiency syndrome [AIDS]) have a poor antibody response; more frequent and larger doses may be required and a small proportion of people do not respond to current vaccines. It is not cost-effective to check antibody levels prior to active immunization. There are few side-effects from the vaccine.

Chronic hepatitis B virus infection

Following an acute HBV infection, which may be subclinical, approximately 1% to 10% of patients will not clear the virus and will develop a chronic HBV infection. Infected children invariably develop chronic infection and mother-to-child transmission explains the very high prevalence of chronic HBV worldwide. Many patients with chronic infection are asymptomatic, but may develop symptoms and signs of chronic liver disease or extrahepatic manifestations of chronic HBV infection as described in 'Clinical features of acute hepatitis B infection'.

Investigations

These may show a moderate rise in aminotransferases but infection with normal aminotransferases is common. The serum bilirubin is often normal. HBsAg and HBV DNA are found in the serum, sometimes with HBeAg. Increasingly quantitation of the amount of HBsAg is performed since those with low levels are more likely to lose virus with antiviral treatment.

Histologically, there is a full spectrum of changes, from near normal with only a few lymphocytes and interface hepatitis to full-blown cirrhosis. HBsAg may lend a 'ground-glass' appearance to

the cytoplasm on haematoxylin and eosin staining, and this can be confirmed on orcein staining or, more specifically, immunohistochemical staining. HBcAg can also be demonstrated in hepatocytes by appropriate immunohistochemical staining.

Management of chronic hepatitis B

The proven safety of the oral antiviral medications used to treat chronic HBV infection has led to recommendations that the majority of patients with HBV DNA levels greater than 2000 IU/mL should be offered therapy. In the past therapy was restricted to those with high-level viral replication (HBV DNA levels >10 000 IU/mL) who also had evidence of ongoing liver damage (raised ALT levels or evidence of fibrosis on liver biopsy or non-invasive assessment, such as transient elastography) but there is an emerging consensus that this approach, which requires repeated, at least annual, assessment of patients is too restrictive and that most viraemic patients should be treated. Patients who have normal liver function and very low levels of viraemia (HBV DNA levels less than 2000) do not require treatment but must be reviewed regularly (every 6 or 12 months) with an assessment of HBV DNA and liver function tests to determine whether or not they have developed activation of their disease.

The lifetime risk of malignancy is increased in all patients who are HBsAg-positive, and males over 40 and females over 50 should be offered 6-monthly screening by abdominal ultrasound and α-fetoprotein testing for early detection of HCC.

Aim of therapy

The goals are to prevent disease progression and, ideally, eliminate HBsAg.

- ***Oral nucleotides*** suppress viral replication and are used for prolonged periods of time.
- ***Interferon*** is an immunostimulator that induces an immune response, leading to prolonged remission after discontinuation of therapy. It is now rarely used but may be re-introduced as a component of curative treatment regimens with emerging antiviral drugs.

In patients receiving long-term oral antiviral agents, liver fibrosis regresses. Even those with cirrhosis may recover, and the liver may remodel and lose all traces of fibrosis. The risk of liver cancer appears to be reduced in those taking long-term oral nucleotides but a residual risk remains and screening for liver cancer should continue in those receiving treatment.

Antiviral agents

Oral antiviral therapy for HBV (entecavir and tenofovir-containing agents) is very effective and almost all compliant patients respond with a decrease in HBV DNA to undetectable levels and a reduction in liver inflammation (**Box 23.10**). Both HBeAg-positive and HBeAg-negative patients respond equally well. Long-term viral suppression has been shown to reverse fibrosis, and even patients with cirrhosis respond with reversion of fibrosis. Resistance is not seen with tenofovir and is extremely rare with entecavir in patients not previously treated with older agents. Resistance-prone drugs, like ***lamivudine***, are no longer recommended. A small proportion of patients develop an immune response leading to loss of HBeAg and, very rarely, loss of HBsAg. However, the majority of patients who commence oral antiviral agents will require very prolonged treatment, perhaps life-long. Some patients with low levels of HBsAg who discontinue therapy after several years go on to eliminate HBsAg, often with a transient increase in liver inflammation, but a tiny proportion develop liver failure when treatment is stopped. Studies are in progress to determine the factors that predict beneficial outcomes following treatment discontinuation. ***Entecavir*** and ***tenofovir*** are the drugs of choice for HBV, and both agents are associated with very few side-effects and an excellent response. The affordable, off-patent, tenofovir disoproxil fumarate (TDF) may occasionally provoke renal Fanconi syndrome (a syndrome of renal tubular dysfunction accompanied by urinary phosphate wasting and reduction of bone mineral density) but this is most often seen when using TDF in patients with HIV infection and is extremely rare in people with HBV disease alone. This rare side-effect may be avoided by the use of the more expensive tenofovir alafenamide. Combination therapy has little benefit and a single drug should be used. New treatments that target alternative steps in the viral life cycle (e.g., polymerization of the core protein) or augment the immune response (e.g., 'checkpoint inhibitors', see Chapter 41) are under evaluation, as they carry the possibility of finite therapy with loss of HBsAg).

Pegylated interferon-alfa-2a (180 μg once a week s.c.) is now rarely used in people with chronic HBV infection and is usually restricted to those who are HBeAg-positive with active disease. Some patients (25%–45%, depending on genotype—A and B respond best) lose HBeAg and move to the 'inactive' HBeAg-negative phase of disease. A proportion then goes on to lose HBsAg some years after treatment discontinuation. Patients with higher serum aminotransferase values (three times the upper limit of normal), who are younger and have viral loads below 10^7 IU/mL, respond best to treatment. Patients with concomitant HIV respond poorly and those with cirrhosis should not receive interferon. Response can be assessed during therapy by measuring the serum levels of HBsAg: if these fall after 3 months, a favourable outcome is likely, and most doctors stop therapy after 3 months if the HBsAg level remains unchanged. In patients with HBeAg-negative HBV, pegylated interferon-alfa-2a is occasionally used, as it offers a finite duration of therapy. A proportion of patients with active disease (high ALT, increased HBV DNA) convert to inactive disease, and response can be assessed by an early decline in HBsAg.

Side-effects of treatment include an acute influenza-like illness occurring 6 to 8 hours after the first injection. This usually disappears after subsequent injections but malaise, headaches, and myalgia are common; depression, reversible hair loss, and bone marrow depression and infection may also occur.

Box 23.10 Factors predictive of a sustained response to treatment in chronic hepatitis B

Duration of disease
- Short

Liver biochemistry
- High serum aminotransferases

Histology
- Active liver disease (mild to moderate)

Viral levels
- Low HBV DNA levels

Other
- Absence of immunosuppression
- Female gender
- Acquisition in adulthood
- Delta virus negative
- Rapidity of response to oral therapy

Prognosis

The clinical course of hepatitis B is very variable; treatments have improved survival, stopped progression of fibrosis, and enabled regression of fibrosis. Established cirrhosis is associated with a poor prognosis. ***HCC*** is a frequent association and is one of the

most common carcinomas in HBV-endemic areas such as the Far East. Surveillance for HCC must continue, even when HBV DNA is negative in patients who have HBsAg and are not treated, and also in those rendered negative by therapy. The incidence of HCC is being reduced by routine HBV vaccination of all children.

Hepatitis D

This is caused by the hepatitis D virus (HDV or delta virus), an incomplete RNA particle enclosed in a shell of HBsAg; it belongs to the *Deltaviridae* family. The virus is unable to replicate on its own but is activated by the presence of HBV. It is common in some parts of the world, including Eastern Europe (Romania, Bulgaria), North Africa, and the Brazilian rainforest. Hepatitis D viral infection can occur either as a co-infection or as a superinfection.

- ***Co-infection*** of HDV and HBV is clinically indistinguishable from an acute icteric HBV infection but a biphasic rise of serum aminotransferases may be seen. ***Diagnosis*** is confirmed by finding serum IgM anti-HDV in the presence of IgM anti-HBc. IgM anti-delta appears at 1 week and disappears by 5 to 6 weeks (occasionally 12 weeks), when serum IgG anti-delta is seen. The HDV RNA is an early marker of infection. The infection may be transient but the clinical course is variable.
- ***Superinfection*** results in an acute flare-up of previously quiescent chronic HBV infection. A rise in serum AST or ALT may be the only indication of infection. ***Diagnosis*** is made by finding HDV RNA or serum IgM anti-HDV at the same time as IgG anti-HBc. Active HBV DNA synthesis is reduced by delta superinfection and patients are usually negative for HBeAg with low HBV DNA.

Acute hepatic failure can follow both types of infection but is more common after co-infection. HDV RNA in the serum and liver can be measured and is found in acute and chronic HDV infections.

Chronic hepatitis D

This is a relatively infrequent chronic hepatitis but spontaneous resolution is rare. Between 60% and 70% of patients will develop cirrhosis, and more rapidly than with HBV infection alone. In 15% the disease is rapidly progressive, with development of cirrhosis in only a few years. The diagnosis is made by finding anti-delta antibody in a patient with chronic liver disease who is HBsAg-positive. It can be confirmed by finding HDV in the liver or HDV RNA in the serum by reverse transcription polymerase chain reaction (PCR).

Management

Treatment of patients with active liver disease (raised ALT levels and/or inflammation on biopsy) is with pegylated interferon-alfa-2a for 12 months, although response rates are very low. The HBsAg entry inhibitor bulevirtide reduces HDV RNA levels when administered long term and is increasingly used, either in isolation or in combination with oral nucleotides or interferon, to reduce the rate of progression of hepatitis delta–associated liver disease. Therapy must be continued for more than 1 year and it is not yet clear whether prolonged remission after cessation of treatment can be achieved with very long-term treatment. The drug is self-administered as a subcutaneous daily injection and the chief side-effect is local injection site inflammation.

Hepatitis C

Epidemiology

An estimated 70 million people are infected with this virus worldwide. The prevalence rate of infection ranges from 0.4% in Europe and 1% to 3% in Southern Europe (possibly linked to intramuscular injections of vaccines or other medicines) to 6% in Africa; in Egypt, the rates were as high as 19%, owing to parenteral antimony treatment for schistosomiasis. The virus is transmitted by blood and blood products, and was common in people with haemophilia treated before screening of blood products was introduced. The incidence in intravenous drug users is high (40%–60%). The low rate of HCV infection in high-risk groups—such as men who have sex with men, sex workers, and attendees at sexually transmitted infection clinics—suggests a limited role for sexual transmission. Vertical transmission from a healthy mother to child can occur but is rare (approximately 5%). Other routes of community-acquired infection (e.g., close contact) are extremely rare. In 20% of cases the exact mode of transmission is unknown.

Hepatitis C virus

Hepatitis C virus (HCV) is a single-stranded RNA virus of the *Flaviviridae* family. The RNA genome is approximately 10 kb in length, encoding a polyprotein product consisting of structural (capsid and envelope) and non-structural viral proteins (**Fig. 23.17**). Comparisons of subgenomic regions, such as E1, NS4, or NS5, have allowed variants to be classified into six genotypes, which have differing geographical distributions. Variability is distributed throughout the genome, with the non-structural gene of different genotypes showing 30% to 50% nucleotide sequence disparity. Genotypes 1a and 1b account for 70% of cases in the USA and 50% in Europe, while genotype 3 is common in the Indian subcontinent and genotype 4 is prevalent in Egypt. There is a rapid change in envelope proteins, making it difficult to develop a vaccine. Antigens from the nucleocapsid regions have been used to develop enzyme-linked immunosorbent assays (ELISAs). The current assay, ELISA-3, incorporates antigens NS3, NS4, and NS5 regions.

Clinical features

Most acute infections are asymptomatic, about 10% of patients having a mild influenza-like illness with jaundice and a rise in serum aminotransferases. Most patients will not be diagnosed until they present, years later, with evidence of abnormal transferase values at health checks or with chronic liver disease.

Investigations

Investigation is by evaluation of HCV RNA and HCV antibodies; HCV RNA can be detected from 1 to 8 weeks after infection. Anti-HCV tests are usually positive 8 weeks from infection. Patients with acute HCV infection should be tested on several occasions, as many have fluctuating viraemia during the first few months of infection, with periods of undetectable HCV RNA followed by virological relapse. Viral clearance is confirmed by multiple tests for HCV RNA over a period of many months.

Management

In acute infection spontaneous viral clearance is relatively common but therapy is effective and most experts recommend early treatment to reduce the risk of chronic infection and prevent transmission. Therapy almost always leads to viral clearance (see ‘Chronic hepatitis C infection [management]’, later). Needle-stick injuries sustained from patients with HCV must be followed and treated early, although the vast majority (>97%) do not go on to develop viraemia. For the treatment of patients with co-infection with HIV, see Chapter 44.

Prognosis

Some 85% to 90% of asymptomatic patients develop chronic liver disease. A higher percentage of symptomatic patients ‘clear’ the virus, with only 48% to 75% going on to chronic liver disease.

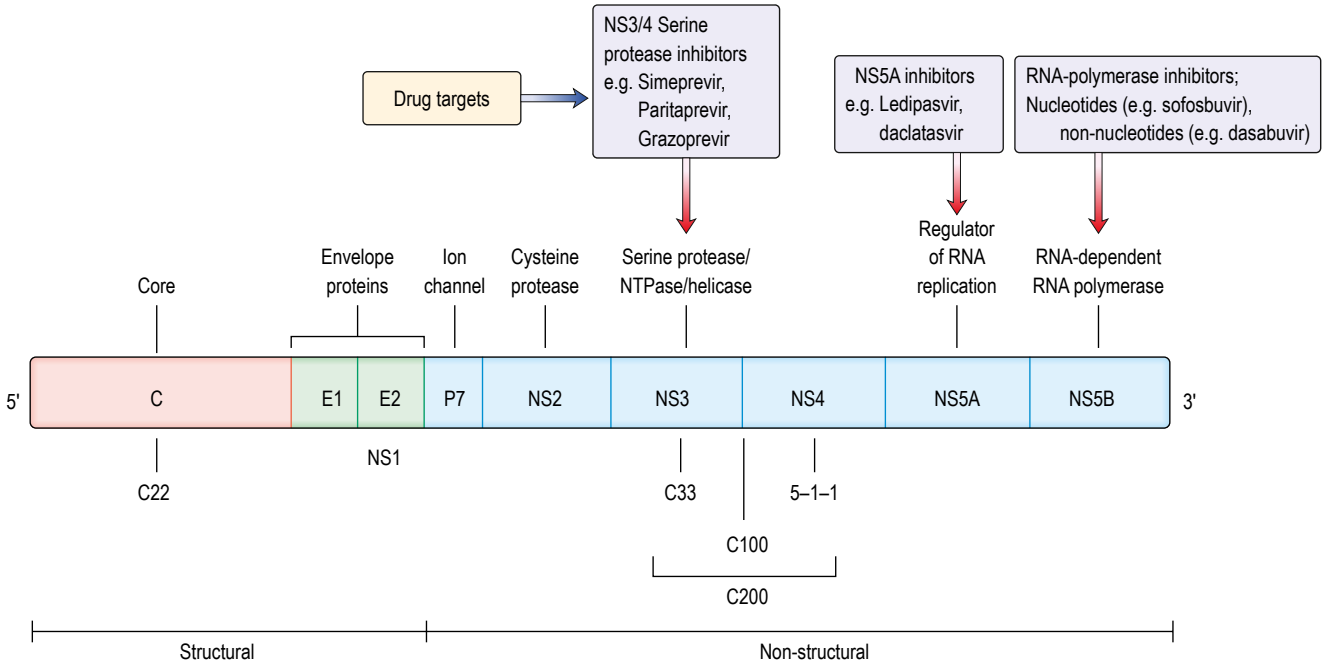

Fig. 23.17 Hepatitis C virus. This is a single-stranded RNA virus with viral proteins. Targets for recent drugs are shown. *C,* Core; *E,* envelope; *NS,* non-structural.

Chronic hepatitis C infection

Pathogenesis

As with hepatitis B infection, cytokines in the Th2 phenotypes are both profibrotic and cause the development of chronic infection. A dominant CD4 Th2 response, with a weak CD8 interferon-gamma response, may lead to rapid fibrosis. Th1 cytokines are antifibrotic and thus a dominant CD4 Th1 and CD8 cytolytic response may cause less fibrosis.

Clinical features

Patients with chronic HCV infection are usually asymptomatic, the disease only being discovered following a routine biochemical test when mild elevations in the aminotransferases (usually ALT) are noticed (50%). The elevation in ALT may be minimal and fluctuating (Fig. 23.18), and some patients have a persistently normal ALT (25%), the disease being detected by checking HCV antibodies (e.g., in blood donors). Non-specific malaise and fatigue are common in chronic infection and often reverse following viral clearance. Extrahepatic manifestations are seen, including arthritis, cryoglobulinaemia with or without glomerulonephritis, and porphyria cutanea tarda. There is a higher incidence of diabetes, and associations with lichen planus, sicca syndrome, and non-Hodgkin lymphoma.

Chronic HCV infection causes slowly progressive fibrosis that leads, over decades, to cirrhosis. After 20 years of infection, 16% of patients have developed cirrhosis; the proportion that will ultimately develop cirrhosis after a lifetime of infection remains unknown but is likely to be higher than the proportions reported after short-term follow-up. Factors associated with rapid progression of HCV fibrosis include excess alcohol consumption, co-infection with HIV, obesity, diabetes, and infection with genotype 3. Once cirrhosis has developed, some 3% to 5% per year will develop decompensated cirrhosis and approximately 3% will develop liver cancer. Unlike HBV infection, HCV rarely causes liver cancer in the absence of cirrhosis. In most parts of the world, HCV was spread (either by injection drug use or by poorly sterilized medical devices) in the 1970s. Given the slow development of cirrhosis, current mathematical models of disease burden predict a massive increase in HCV-related end-stage liver disease over the next decade which may be avoided by widespread treatment with current antiviral agents.

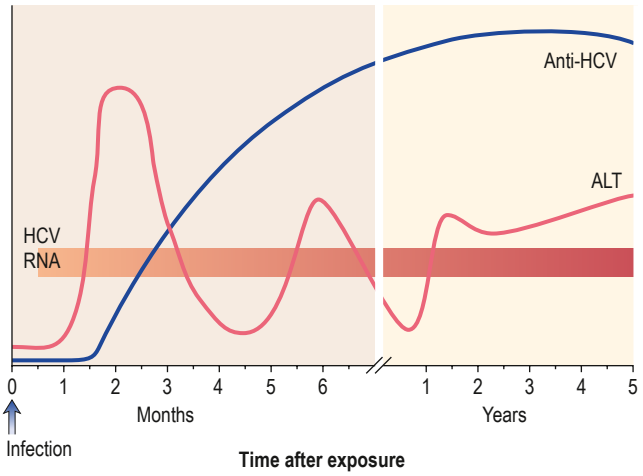

Fig. 23.18 Time course of the events and serological changes seen following infection with hepatitis C virus. *ALT,* Alanine aminotransferase.

Investigations

Diagnosis is made by finding HCV antibody in the serum using third-generation ELISA-3 tests. A proportion of patients with spontaneous clearance will have undetectable HCV RNA in the serum (measured by PCR) but most individuals who are antibody-positive will be viraemic. The level of viraemia varies from a few thousand to many millions of viral copies per millilitre, although current practice is to present viral load measurements in international units (IU). Disease progression and treatment outcome are not influenced by the viral load. The availability of pan-genotypic treatments removes the

need to assess viral genotype pre-treatment but this is still necessary when genotype specific treatments are in use.

Management

The aim of treatment is to eliminate the HCV RNA from the serum in order to:

- stop the progression of active liver disease
- prevent transmission of the virus
- prevent the development of HCC.

A clinical cure is determined by a sustained virological response (SVR), defined by a negative HCV RNA by PCR 3 months after the end of therapy.

Antiviral agents

Treatment for HCV infection is now based on direct-acting antiviral agents that are administered orally. These drugs target enzymes in the virus—usually the polymerase, NS5a protein or NS3/4 protease. Therapy may involve a nucleotide inhibitor of the polymerase (sofosbuvir) combined with an NS5a inhibitor. This combination may be pan-genotypic (sofosbuvir/velpatasvir or sofosbuvir/daclatasvir) or specific for genotypes 1 and 4 (sofosbuvir/ledipasvir), and involves a single tablet given once a day for 8 to 12 weeks. An alternative strategy is to use a protease inhibitor–based regimen (either glecaprevir or grazoprevir) combined with an NS5a inhibitor. Glecaprevir is combined with pibrentasvir and involves three tablets a day for 8 weeks in patients without cirrhosis or for 12 weeks in those with cirrhosis. The regimen is effective in all viral genotypes. Grazoprevir is combined with elbasvir and is used as a single tablet that is taken for 12 weeks and is effective in patients with genotypes 1 and 4. All of the treatment regimens eliminate virus in more than 95% of patients; in the very few who do not respond to therapy a 'rescue' treatment involving sofosbuvir/velpatasvir and the pan-genotypic protease inhibitor voxilaprevir is licensed and eliminates virus in over 90% of patients. Following viral clearance, liver fibrosis progression is halted and may even reverse, but in patients with cirrhosis the risk of liver cancer persists (albeit at a reduced level). Patients who do not have cirrhosis can be discharged from follow-up after successful therapy, defined as undetectable virus 12 weeks after discontinuation of treatment, but those with cirrhosis should continue on a program of surveillance for malignancy.

The extraordinary effectiveness of the oral antiviral regimens against HCV, combined with their excellent safety profile, has led to campaigns to identify and treat all patients with HCV, and the World Health Organization has a goal of eliminating HCV by 2030. If this can be achieved, it will represent the first time that a viral infection has been controlled without an effective vaccine. Elimination of hepatitis C requires widespread screening for infection, rapid introduction of pan-genotypic treatments, and minimal monitoring of patients while on therapy, although patients with decompensated cirrhosis may require additional support. This approach has been adopted in Egypt and has led to virtual elimination of the infection with a Presidential Program involving mobile treatment units and access to sofosbuvir/daclatasvir for those found to be infected. Other countries are adopting similar approaches and success will depend upon healthcare workers ensuring that all those at risk (i.e., born in a high-risk country or having past exposure to injecting drugs) are tested and treated.

Hepatitis E

Hepatitis E virus (HEV) is an RNA virus (*Hepeviridae* family; **Fig. 23.19**); it causes disease that is clinically very similar to hepatitis A. It is enterally transmitted and two patterns of disease are recognized.

- In countries with poor sanitation, outbreaks with HEV genotypes 1 and 2 occur, usually due to contaminated water.

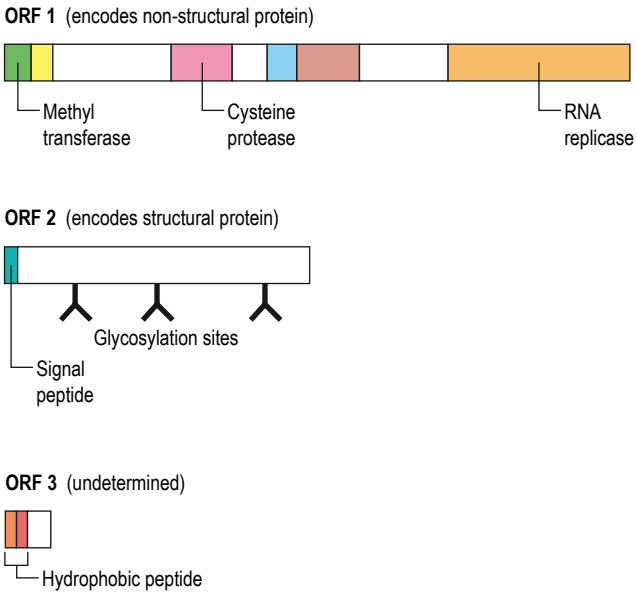

Fig. 23.19 Hepatitis E genome. A single-stranded RNA genome with three open reading frames (ORFs).

- Low-level ongoing infection via contaminated meat products (often pork or boar-containing sausages) is now frequently seen throughout the world due to genotype 3 infection and the majority of elderly people in the UK have evidence of exposure.

Epidemic HEV with genotypes 1 and 2 has a mortality from fulminant hepatic failure of 1% to 2%, which rises to 20% in pregnant women but hepatic failure is much less common in sporadic genotype 3 infection. There is no carrier state and infection does not progress to chronic liver disease, except in some immunosuppressed patients. Non-hepatic manifestations including neurological (Guillain-Barré and encephalitis), haematological (thrombocytopaenia), and renal (glomerulonephritis) complications are increasingly identified. An ELISA for IgG and IgM anti-HEV is available for diagnosis. HEV RNA can be detected in the serum or stools by PCR. Prevention and control depend on good sanitation and hygiene; a vaccine has been developed and used successfully in China. In patients who are immunocompromised, HEV infection may lead to chronic infection, which is treated by reduction of the immunosuppression and/or introduction of the broad-spectrum antiviral agent ribavirin.

Hepatitis non-A–E

Approximately 10% to 15% of acute viral hepatitides cannot be typed and are described as hepatitis non-A–E. GB agent (hepatitis G virus, HGV) and transfusion-transmitted virus (TTV) agents have not been documented as causing disease in humans.

Acute hepatitis due to other infectious agents

Abnormal liver biochemistry is frequently found in a number of acute infections. The abnormalities are usually mild and have no clinical significance. Further information about these diseases can be found in Chapter 42.

Infectious mononucleosis

Infectious mononucleosis is due to the Epstein–Barr (EB) virus. Mild jaundice, associated with minor abnormalities of liver biochemistry, is extremely common but 'clinical' hepatitis is rare. Hepatic

histological changes occur within 5 days of onset; the sinusoids and portal tracts are infiltrated with large mononuclear cells but the liver architecture is preserved. A Paul–Bunnell or Monospot test is usually positive, and atypical lymphocytes are present in the peripheral blood. Treatment is symptomatic.

Cytomegalovirus

Cytomegalovirus (CMV) can cause acute hepatitis, usually a 'glandular fever-type syndrome', in healthy individuals but is more severe in those with an impaired immune response. Only the latter need treatment with valganciclovir or ganciclovir.

CMV DNA is positive in blood; CMV IgM is also positive but there are false-positive reactions. Liver biopsy shows intranuclear inclusions and giant cells.

Herpes simplex

Very occasionally, the herpes simplex virus causes a generalized acute infection, particularly in the immunosuppressed patient and occasionally in pregnancy. Aminotransferases are usually massively elevated. Liver biopsy shows extensive necrosis. Aciclovir is used for treatment.

Toxoplasmosis

The clinical picture in toxoplasmosis is similar to that of infectious mononucleosis, with abnormal liver biochemistry, but the Paul–Bunnell test is negative.

Yellow fever

Yellow fever is a viral infection carried by the mosquito *Aedes aegypti*; it can cause acute hepatic necrosis. There is no specific treatment.

Adenovirus

There has been a recent surge in cases of acute severe hepatitis in previously healthy children under the age of 10, many reported from the UK. Growing evidence links these to adenovirus (subtype 41) and adeno-associated virus type 2 in genetically susceptible individuals. Adenovirus is also an occasional cause of hepatitis in immunosuppressed adult patients.

ACUTE HEPATIC FAILURE

Acute liver failure (ALF) is defined as acute liver injury with encephalopathy and deranged coagulation (INR > 1.5) in a patient with a previously normal liver. The time of development of jaundice to encephalopathy varies from 7 days (hyper-acute) to 8 to 28 days (acute) and 21 to 26 weeks (subacute). Occasionally, patients may have previous liver damage: for example, D virus superinfection in a previous carrier of HBsAg.

Box 23.11 Causes of acute hepatic failure

Viruses
- HAV, HBV, (HDV), HEV; rarely, HCV
- Cytomegalovirus
- Haemorrhagic fever viruses
- Herpes simplex virus
- Paramyxovirus
- Epstein–Barr virus

Drugs (examples)
- Paracetamol (acetaminophen)
- Antibiotics (ampicillin–clavulanate, ciprofloxacin, doxycycline, erythromycin, isoniazid, nitrofurantoin, tetracycline)
- Antidepressants (amitriptyline, nortriptyline)
- Antiepileptics (phenytoin, valproate)
- Anaesthetic agents (halothane)
- Lipid-lowering medications (atorvastatin, lovastatin, simvastatin)
- Immunosuppressive agents (cyclophosphamide, methotrexate)
- NSAIDs
- Salicylates (as a result of Reye's syndrome, see 'Hepatic mitochondrial injury syndromes')
- Disulfiram, flutamide, gold, propylthiouracil
- Illicit drugs (e.g., 'ecstasy' or cocaine)
- Herbal/alternative medicines (ginseng, pennyroyal oil, *Teucrium polium* chaparral or germander tea, kawa kawa)

Toxins
- Amanita phalloides mushroom toxin
- Bacillus cereus toxin
- Cyanobacteria toxin
- Organic solvents (e.g., carbon tetrachloride)
- Yellow phosphorus

Hepatic failure in pregnancy
- Acute fatty liver of pregnancy (AFLP)
- HELLP (*h*aemolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets)

Vascular causes
- Ischaemic hepatitis
- Budd–Chiari syndrome
- Hepatic sinusoidal obstruction syndrome
- Portal vein thrombosis
- Hepatic arterial thrombosis (consider post transplant)

Metabolic causes
- α_1-antitrypsin deficiency
- Fructose intolerance
- Galactosaemia
- Lecithin-cholesterol acyltransferase deficiency
- Reye's syndrome
- Tyrosinaemia
- Wilson's disease

Malignancies
- Primary (usually HCC, rarely cholangiocarcinoma)
- Secondary (extensive hepatic metastases or infiltration)

Miscellaneous
- Adult-onset Still's disease
- Heatstroke
- Primary graft non-function in liver transplant

ALF is a rare but often life-threatening syndrome that is due to acute hepatitis from many causes (**Box 23.11**). These causes vary throughout the world; drug-induced liver injury (DILI) is the most common cause in 'Western' countries (paracetamol overdose is common in the UK—50% of cases). HCV only rarely causes acute hepatic failure.

Histologically, there is multiacinar necrosis involving a substantial part of the liver. Severe fatty change is seen in pregnancy (see Chapter 45) and Reye's syndrome (see 'Hepatic mitochondrial injury syndromes') or following intravenous tetracycline administration.

Clinical features

Examination shows a jaundiced patient with a small liver and signs of hepatic encephalopathy. The mental state varies from slight drowsiness, confusion, and disorientation (grades I and II) to unresponsive coma (grade IV) with convulsions. Fetor hepaticus is common but ascites and splenomegaly are rare. Fever, vomiting, hypotension,

and hypoglycaemia occur. Neurological examination shows spasticity and hyper-reflexia; plantar responses remain flexor until late. Cerebral oedema develops in up to 80% of patients with ALF but is far less common with subacute failure; its severe consequences, intracranial hypertension and brain herniation, have fallen substantially over the last 30 years and now only account for a minority of patient deaths. Other complications include bacterial and fungal infections, gastrointestinal bleeding, respiratory arrest, kidney injury (acute tubular necrosis), and pancreatitis.

Investigations

- Routine tests (see 'Investigations in the patient with liver disease' section).
- For suspected paracetamol overdoses, levels must be measured. Importantly, a low paracetamol level on admission is not uncommon, particularly in 'staggered' overdoses and may be misinterpreted as being below the treatment threshold for *N*-acetyl cysteine (NAC) infusions. If there is any doubt, NAC should be given (see also Chapter 15).
- There is hyperbilirubinaemia, high serum aminotransferases, and low levels of coagulation factors, including prothrombin and factor V. Aminotransferases are not useful indicators of the course of the disease, as they tend to fall along with the albumin with progressive liver damage.
- An electroencephalogram (EEG) is sometimes helpful in grading the encephalopathy.
- Ultrasound will define liver size and may indicate underlying liver pathology.

Management

There is no specific treatment, but patients should be managed in a specialized unit and early referral is encouraged. Transfer criteria to these units are shown in **Box 23.12**. The use of NAC has been extended to empirical treatment of non-paracetamol ALF, however, there is inconsistent evidence for a role. Given its excellent safety profile and that paracetamol may frequently be a co-factor for ALF, many will prescribe it. Supportive therapy, as for hepatic encephalopathy, is necessary (see 'Portosystemic encephalopathy [management]'). Continuous renal replacement therapy (RRT) lowers circulating ammonia concentration and is associated with improved survival in ALF and should be considered for those with hepatic encephalopathy. When signs of raised intracranial pressure (which may be measured directly) are present, 20% mannitol (1 g/kg body weight) should be infused intravenously; this dose may need to be repeated. Dexamethasone is not of value. Hypoglycaemia, hypokalaemia, hypomagnesaemia, hypophosphataemia, and hypocalcaemia should be anticipated and corrected with a 10% glucose infusion (checked by 2-hourly capillary blood glucose testing), potassium, magnesium, phosphate, and calcium supplements, respectively. Hyponatraemia should be corrected with hypertonic saline. Patients are often catabolic and enteral nutrition should be started if patients cannot maintain oral intake; protein feeding can be transiently held in hyperammonemic patients. Coagulopathy is managed with intravenous vitamin K, platelets, blood, or fresh frozen plasma and patients are given a proton pump inhibitor (PPI) to prevent gastrointestinal bleeding, although substantial bleeding complications are uncommon. Prophylaxis against bacterial and fungal infection is routine, as infection is a frequent cause of death and may preclude liver transplantation, although there is no strong evidence supporting this approach. Suspected infection should be treated immediately with appropriate antibiotics. Renal and respiratory failure should be treated as necessary. Liver transplantation has been a major advance for patients with ALF. It is difficult to judge the timing or the necessity for transplantation, but there are guidelines based on validated prognostic indices of survival (see later).

Box 23.12 Transfer criteria to specialized units for patients with acute liver injury

- INR > 3.0
- Presence of hepatic encephalopathy
- Hypotension after resuscitation with fluid
- Metabolic acidosis
- Prothrombin time (seconds) > interval (hours) from overdose (paracetamol cases)

Prognosis

Outcomes with medical management alone, at least for some causes of ALF, are now excellent, with a study supporting better long-term outcomes than emergency liver transplant. Poor prognostic variables indicating a need to discuss with a liver transplant unit, as incorporated in British and European acute liver failure guidelines, are shown in **Box 23.13**.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis (AIH) is a progressive inflammatory liver condition with a 75% female preponderance. Approximately 40% of AIH patients have a family history of autoimmune disease (e.g., pernicious anaemia, thyroiditis, or coeliac disease), and at least 20% have concomitant autoimmune diseases or will develop them during follow-up.

Pathogenesis

The pathogenesis of AIH is incompletely understood, although evidence increasingly demonstrates that genetic susceptibility, molecular mimicry, and impaired immunoregulatory networks contribute to the initiation and perpetuation of the autoimmune attack. Liver damage is thought to be mediated primarily by T-cell–mediated events ($CD4^+$ T cells) against liver antigens, producing a progressive necro-inflammatory process that leads to fibrosis and cirrhosis. However, no clear trigger mechanism has been found.

Box 23.13 Poor prognostic variables in acute hepatic failure indicating a need for discussion with a liver transplant unit

Non-paracetamol (acetaminophen) causes

- pH < 7.30 or HCO_3 < 18 mmol/L
- INR > 1.8
- Oliguria/renal failure or Na < 130 mmol/L
- Encephalopathy, hypoglycaemia, or metabolic acidosis
- Bilirubin > 300 μmol/L

Paracetamol overdose

- Arterial pH < 7.30 or HCO_3 < 18 mmol/L
- INR > 3.0 on day two or >4.0 thereafter
- Oliguria and/or acute kidney injury
- Altered level of consciousness
- Hypoglycaemia
- Elevated arterial lactate (>4 mmol/L) unresponsive to fluid resuscitation

INR, International normalized ratio.

Clinical features

There are two peaks in presentation. In the peri- and postmenopausal group, patients may be asymptomatic, or present with fatigue and abnormalities in liver biochemistry or the presence of chronic liver disease on examination. In the teens and early twenties, the disease (often type II) presents as an acute hepatitis with jaundice and very high aminotransferases, which do not improve with time. This age group often has clinical features of cirrhosis and patients who are ill may also have features of an autoimmune disease, such as fever, migratory polyarthritis, glomerulonephritis, pleurisy, pulmonary infiltration, or lung fibrosis.

There are rare overlap syndromes with PBC and PSC, existing concomitantly or developing consecutively.

Investigations

Liver biochemistry

The serum aminotransferases are high, with lesser elevations in the ALP and bilirubin. The serum γ-globulins are high: frequently twice normal, particularly the IgG. The biochemical pattern is similar in both types.

Haematology

A mild normochromic normocytic anaemia with thrombocytopenia and leucopenia is present, even before portal hypertension and splenomegaly. The PT is often high.

Autoantibodies

Two types of autoimmune hepatitis have been recognized:

- ***Type I with antibodies*** (titres >1:80):
  - anti-nuclear (ANA)
  - anti-smooth muscle (anti-actin).
- ***Type II with antibodies:*** anti-liver/kidney microsomal (anti-LKM1). The main target is cytochrome P4502D6 (CYP2D6) on liver cell plasma membranes.
- A third type of AIH (AIH-3) was proposed, positive for anti-soluble liver antigen (SLA) and negative for conventional autoantibodies. However, subsequent studies showed that anti-SLA is also present in typical cases of AIH-1 and AIH-2. Adult patients positive for anti-SLA only, and therefore having *bona fide* AIH-3, are rare. Approximately 13% of patients lack the autoantibodies listed.

Liver biopsy

Since transferases and IgG levels do not reflect disease activity, liver biopsy is mandatory to confirm the diagnosis and evaluate disease severity. The biopsy (**Fig. 23.20**) commonly shows chronic active hepatitis with inflammation and interface hepatitis. This reflects the changes of chronic hepatitis described in the 'Chronic hepatitis' section. The amount of interface hepatitis is variable but tends to be high in untreated patients. Lymphoid follicles are less often seen than in hepatitis C, and plasma cell infiltration is frequent. Fibrosis is present in all but the mildest forms of the disease and approximately one-third of patients have cirrhosis at presentation.

Management

Prednisolone 30 mg is given daily for at least 2 weeks, followed by slow reduction to a maintenance dose of 5 to 15 mg daily. Azathioprine should be added, 1 to 2 mg/kg daily, as a steroid-sparing agent and, in some, as sole long-term maintenance therapy. Levels of thiopurine methyltransferase (TPMT) should be obtained before treatment is started (see Chapter 22). Other agents that have been used in resistant cases include budesonide (in non-cirrhotic patients), mycophenolate, ciclosporin, and tacrolimus.

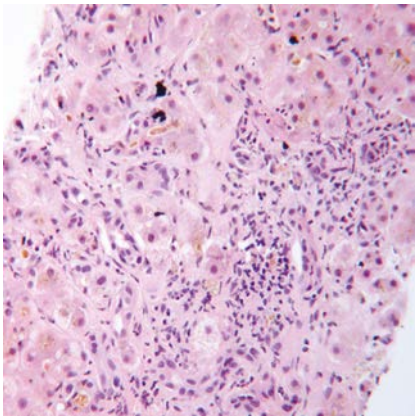

Fig. 23.20 Chronic active hepatitis. Note the inflammation with interface hepatitis (haematoxylin and eosin, ×10).

Prognosis

Steroid and azathioprine therapy induce remission in over 80%; indeed, this response forms part of the diagnostic criteria. Treatment is life-long in most, although withdrawal may be considered after 2 to 3 years of biochemical remission. Those with initial cirrhosis are more likely to relapse following withdrawal and require indefinite therapy. Liver transplantation is performed if treatment fails, although the disease may recur. HCC occurs less frequently than with viral-induced cirrhosis. The risk of malignancy (particularly of the skin) associated with chronic low-dose azathioprine therapy has been reported to be 1.4 times normal.

DRUG-INDUCED CHRONIC HEPATITIS

Several drugs can cause a chronic hepatitis similar to autoimmune hepatitis (see **Box 23.27**). Patients are often female, present with jaundice and hepatomegaly, and have raised serum aminotransferases and globulin levels. Improvement follows drug withdrawal but exacerbations can occur with re-introduction. Isoniazid, amiodarone and methotrexate can cause chronic histological changes. With rare exceptions, patients with pre-existing chronic liver disease are not more susceptible to drug injury.

CHRONIC HEPATITIS OF UNKNOWN CAUSE

As increasing numbers undergo routine blood tests, mild elevations in serum aminotransferases and γ-GT are commonly found. Many will have no symptoms or signs of liver disease. All known aetiological agents should be excluded, risk factors for MASLD evaluated, and tests carried out to exclude liver diseases. Liver biopsy should be performed if the elevation in aminotransferases (>100 IU/L) persists for over a year but often only non-specific changes are found.

METABOLIC DYSFUNCTION–ASSOCIATED STEATOTIC LIVER DISEASE

Metabolic dysfunction–associated steatotic liver disease or MASLD, formerly referred to as non-alcoholic fatty liver disease or NAFLD, is now the most common cause of chronic liver disease in many high income countries. MASLD is a spectrum of liver diseases comprised of metabolic dysfunction–associated steatotic liver (MASL) and metabolic dysfunction–associated steatohepatitis (MASH, formerly non-alcoholic steatohepatitis). Whereas MASL has negligible risk of progression, 10% to 30% of MASH patients may develop cirrhosis or HCC. MASL and MASH have traditionally been considered as two separate clinical entities, rather than two points on a disease continuum. However, studies that have evaluated sequential liver biopsies are challenging this notion and have found that both patients with MASL and those with MASH have the potential to develop progressive liver disease, suggesting that MASL, MASH and fibrosis progression are a continuum rather than separate diagnoses. Indeed, one large study showed no difference in liver-related adverse events between definite MASH and severe steatosis. However, patients with advanced fibrosis at presentation were much more likely to progress than those without, and it is these patients therefore that require follow-up. In this cohort, complications of cirrhosis were the third most common cause of death, following cardiovascular events and non-hepatic malignancies.

Risk factors for MASLD are obesity, hypertension, type 2 diabetes, and hyperlipidaemia, such that MASLD is considered to be the liver component of the metabolic syndrome (see Chapter 37) and reflected in the recent change in nomenclature. Most patients are asymptomatic, although hepatomegaly may be present. Mild increases in serum aminotransferases and/or γ-GT (with ALT greater than AST) are frequently the sole liver biochemical abnormality or it is often detected on routine abdominal ultrasound examination. Despite the high prevalence of MASLD, well-defined screening recommendations are currently lacking.

Pathogenesis

Histological changes follow a spectrum similar to that of alcohol-induced hepatic injury and range from simple fatty change to fat and inflammation (MASH), fibrosis, and cirrhosis.

Oxidative stress injury and other factors lead to lipid peroxidation in the presence of fatty infiltration and inflammation. Fibrosis may then occur, enhanced by insulin resistance, which induces connective tissue growth factor.

Investigations

- ***Ultrasound*** demonstration of steatosis in the absence of other injurious causes, such as alcohol, usually provides the diagnosis.
- ***Elastography*** (see 'Hepatic stiffness [transient elastography]' section) is frequently used to evaluate the degree of fibrosis but may not be technically possible in the morbidly obese.
- ***Liver biopsy*** allows staging of the disease. Although no definitive guidelines exist, clinicians may perform a biopsy if a diagnosis of MASH or advanced fibrosis is considered likely.

Management

- All MASLD patients require ***lifestyle advice*** aimed at weight loss, increased physical activity, and attention to cardiovascular risk factors. Although evidence is lacking for statins as treatment for MASLD, they are frequently indicated for co-morbid conditions (e.g., diabetes) and can be prescribed to patients with mild-to-moderately abnormal liver enzymes with a low risk of causing adverse liver events. Calorie restriction is recommended, aimed at losing 0.5 to 1 kg per week until target weight is achieved. A Mediterranean diet, high in vegetables, fruits, nuts, beans, cereals, grains, fish, and unsaturated fats such as olive oil, together with a lower intake of meat and dairy foods, may be the healthiest diet for MASLD. A reduction of more than 7% to 9% in body weight has been associated with reduced steatosis, hepatocellular injury, and hepatic inflammation. However, less then 35% of overweight or obese adults with MASLD receiving usual care in a large study in the USA achieved ≥5% weight reduction during a median follow-up of 39 months.
- ***Pioglitazone*** or vitamin E may be used for those with biopsy-proven MASH, when lifestyle intervention has failed. Meta-analysis data demonstrated that pioglitazone significantly improved liver steatosis, inflammation and, to a lesser degree, fibrosis. However, it is associated with weight gain and reports of congestive cardiac failure, bladder cancer, and reduced bone density. Conversely, pioglitazone reduces death, myocardial infarction, and stroke in diabetes patients. The risks and benefits to each patient should be evaluated accordingly and pioglitazone is infrequently used in clinical practice.
- ***Vitamin E*** (800 IU/day) is an antioxidant that improves steatohepatitis. It should be noted that various meta-analyses have raised concerns against the long-term use of vitamin E including increased risk of hemorrhagic stroke and prostate cancer. Again, this is not frequently used.
- Weight loss following ***bariatric surgery*** leads to reduced steatosis, steatohepatitis, and fibrosis. The optimum technique is unknown and long-term data are lacking, although initial concerns about worsening fibrosis have not been borne out. Bariatric surgery should be avoided in those with advanced cirrhosis and portal hypertension, but gastric bypass and sleeve gastrectomy (see Chapter 37) have been shown to achieve weight loss and improve obesity-related co-morbidities in Child–Pugh A cirrhotic patients.
- ***Semaglutide:*** use of this glucagon-like peptide 1 (GLP-1) agonist leads, on average, to more than 10% weight loss. In the UK NICE has recommended the use of semaglutide for obesity, alongside a reduced-calorie diet and increased physical activity to adults who have at least one weight-related co-morbidity and a body mass index (BMI) of at least 35 kg/m^2. A phase II trial of MASH F2/3 patients (i.e., with significant or advanced fibrosis) showed significantly improved MASH resolution but no effect on fibrosis. A further trial in MASH cirrhosis showed no effect on resolution or fibrosis stage.

Hepatocellular carcinoma

The yearly cumulative incidence of HCC is 2.6% in patients with MASH cirrhosis and ultrasound surveillance should therefore be performed 6-monthly. Hyperinsulinaemia and obesity are risk factors for many malignancies and HCC may occur in MAFL/MASH patients in the absence of cirrhosis, although this is rare.

Liver transplantation

MASH cirrhosis is the most rapidly growing indication for transplantation in the USA, the leading cause in females and the second leading cause overall. Survival is comparable to that in other indications, and although recurrence occurs post transplant (4%–25%), it does not appear to have an impact on graft survival. Patients frequently have multiple cardiovascular risk factors that must be managed aggressively. UK guidelines suggest that bariatric surgery could be considered at transplantation for the morbidly obese.

New treatments for MASH

There has been substantial industry investment in pharmacotherapies for MASH, with the pipeline currently crowded at mid-stage. Two companies are in the process of submitting approvals in the USA for use of their drugs in non-cirrhotic MASH, obeticholic acid (FXR agonist, see also 'Bile acid receptors in liver disease' section) and resmetirom (selective thyroid hormone receptor-β agonist; THR-beta agonist). Notably obeticholic acid did not show benefit for MASH cirrhosis. Other agents in trials include elafibranor, a dual peroxisome proliferator-activated receptor (PPAR)α/δ agonist; cenicriviroc, a dual antagonist of C-C chemokine receptor types 2 and 5; selonsertib, an apoptosis signal-regulating kinase 1 inhibitor; and liraglutide, a glucagon-like peptide. It is highly likely that the landscape of treatments for MASH will change substantially over the next few years.

However, it is imperative to tackle obesity at source: for example, through public health campaigns, taxation of high-sugar food, reduction in processed food within the diet, education, increased activity, and vegetable consumption. Prevention of obesity, especially in children and adolescents, will most likely be far superior to the effects of these drugs.

CIRRHOSIS

In cirrhosis, the liver architecture is diffusely abnormal and interferes with liver blood flow and function; this leads to the clinical manifestations of portal hypertension and liver failure.

Aetiology

Causes of cirrhosis are shown in **Box 23.14**. Alcohol is currently the most common cause in the West but is likely to be superseded by MASLD; viral infection is the most common aetiological factor worldwide. All patients with cirrhosis must be investigated to exclude treatable causes (e.g., viral or autoimmune hepatitis).

Pathogenesis

Although the liver has a remarkable capacity to adapt to injury through tissue repair, chronic injury results in inflammation, matrix deposition, necrosis, and angiogenesis, all of which lead to fibrosis (**Fig. 23.21**). Liver injury causes necrosis and apoptosis, releasing cell contents and reactive oxygen species (ROS). This activates hepatic stellate cells and tissue macrophages through the CC-chemokine ligand 2–CC-chemokine receptor 2 (CCL2–CCR2) axis. These cells phagocytose necrotic and apoptotic cells and secrete pro-inflammatory mediators, including transforming growth factor-beta (TGF-β); this leads to transdifferentiation of stellate cells to myofibroblasts and platelet-derived growth factor (PDGF), which stimulates myofibroblast proliferation. Macrophages degrade scar matrix by secretion of matrix metalloproteinases (MMPs), but this is inhibited by concurrent myofibroblast and macrophage production of tissue inhibitors of metalloproteinases (TIMPs). This results in progressive matrix deposition and scar accumulation. Increased gut permeability and hepatic lipopolysaccharide–Toll-like receptor 4 (LPS–TLR4) signalling also promotes fibrogenesis. Repetitive or chronic injury and inflammation perpetuate this process.

If the cause of fibrosis is eliminated (e.g., through treatment of viral hepatitis), resolution (complete reversal to near-normal liver architecture) of early fibrosis can occur. In cirrhosis, regression (improvement, not reversal) occurs, which improves clinical outcomes. Antifibrotic therapies are an active research area but currently liver transplantation is the only available treatment for liver failure.

? Box 23.14 Causes of cirrhosis

Common

- Alcohol
- Hepatitis B ± D
- Hepatitis C
- Non-alcoholic fatty liver disease (NAFLD)

Others

- Primary biliary cholangitis
- Secondary biliary cirrhosis
- Autoimmune hepatitis
- Hereditary haemochromatosis
- Hepatic venous congestion
- Budd–Chiari syndrome
- Wilson's disease
- Drugs (e.g., methotrexate)
- α_1-antitrypsin deficiency
- Cystic fibrosis
- Galactosaemia
- Glycogen storage disease
- Veno-occlusive disease
- Idiopathic (cryptogenic)
- ? Other viruses

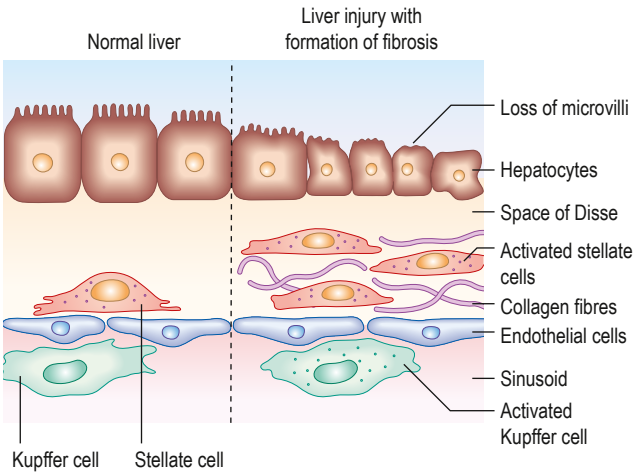

Fig. 23.21 Pathogenesis of fibrosis. The normal liver is shown on the left. Activation of the stellate cell is followed by proliferation of fibroblasts and deposition of collagen.

Pathology

The characteristic features of cirrhosis are regenerating nodules separated by fibrous septa, and loss of lobular architecture within the nodules (**Fig. 23.22A–C**). Two types are described:

- ***Micronodular cirrhosis.*** Regenerating nodules are usually less than 3 mm in size with uniform involvement of the liver; often caused by alcohol or biliary tract disease.
- ***Macronodular cirrhosis.*** The nodules are of variable size and normal acini may be seen within larger nodules; often caused by chronic viral hepatitis.

A mixed picture with small and large nodules occurs occasionally.

Symptoms and signs are described in the figure in 'Clinical skills' section.

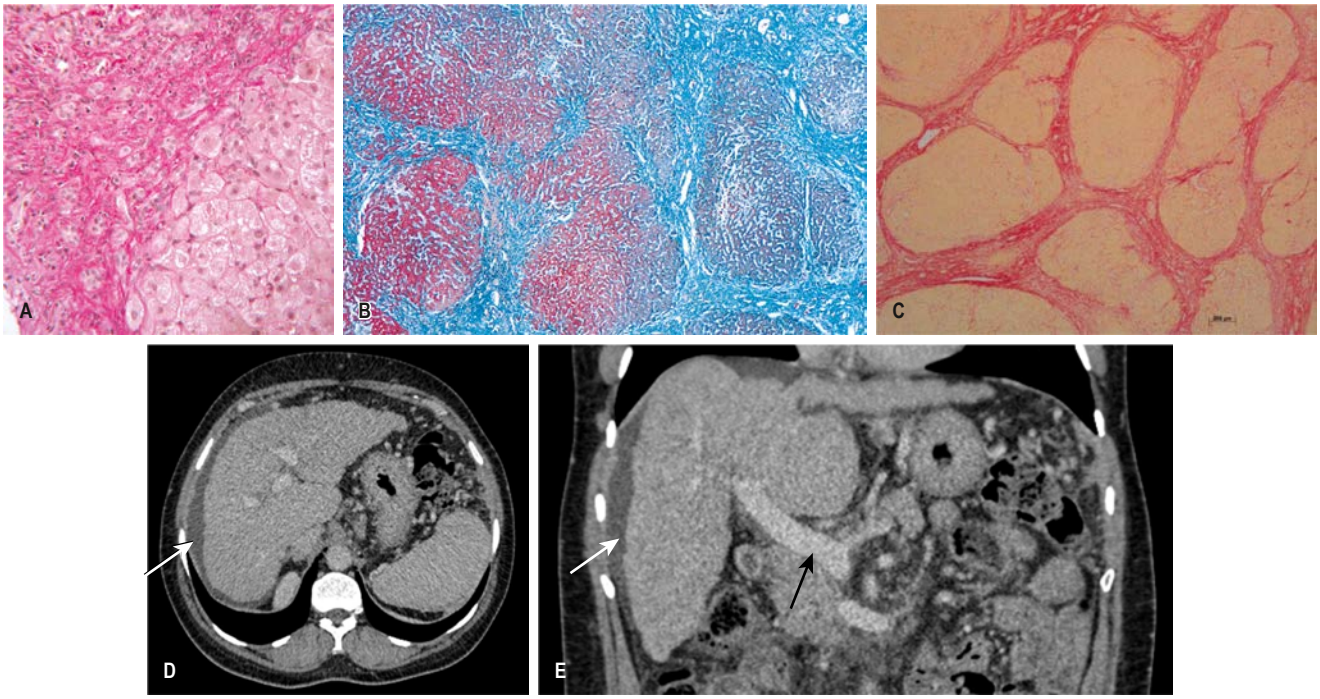

Fig. 23.22 Pathology of cirrhosis. **(A)** Haematoxylin and eosin histological view (×10). **(B)** Histological appearance (Giemsa stain) showing nodules of liver tissue of varying size, surrounded by fibrosis. **(C)** Picrosirius red stain of collagen used for morphometric evaluation of fibrosis. **(D)** Axial CT image showing an irregular contour of the liver consistent with cirrhosis. There are splenic, gastric and oesophageal varices and a small volume of ascites *(arrowed)*. **(E)** Coronal CT image of the liver demonstrates an irregular contour to the liver consistent with cirrhosis. The portal vein is patent *(black arrow)*. There is small-volume ascites *(white arrow)*.

Investigations

Investigations aim to assess the severity and type of liver disease.

Severity

- ***Liver function.*** Serum albumin and PT are the best indicators of liver function; the outlook is poor if the albumin level is less than 25 g/L and the degree to which the PT is prolonged is commensurate with disease severity.
- ***Liver biochemistry.*** This may be normal, depending on the severity of disease. In most cases, there is a slight elevation in the serum ALP and serum aminotransferases. In decompensated cirrhosis, all biochemistry is deranged.
- ***Serum electrolytes.*** Low sodium occurs in severe liver disease due to a defect in free water clearance or excess diuretic therapy.
- ***Serum creatinine.*** An elevated concentration of more than 130 μmol/L is a marker of poor prognosis.
- ***Biomarkers.*** In the enhanced liver fibrosis (ELF) test, which assesses fibrosis, a value of less than 7.7 indicates none to mild, 7.7 to 9.8 moderate, and 9.8 or more indicates severe disease.

In addition, a serum α-fetoprotein of more than >200 ng/mL is strongly suggestive of HCC.

Type

This can be determined by:

- viral markers
- serum autoantibodies
- serum immunoglobulins
- iron indices and ferritin
- copper and caeruloplasmin (see 'Wilson's disease [progressive hepatolenticular degeneration]/Investigations' section
- α_1-antitrypsin (see 'Alpha$_1$-antitrypsin deficiency' section)
- genetic markers.

Serum copper and serum α_1-antitrypsin should always be measured in young people with cirrhosis. Total iron-binding capacity (TIBC) and ferritin should be measured to exclude hereditary haemochromatosis; genetic markers are also available (see 'Hereditary haemochromatosis' section).

Imaging

- ***Ultrasound examination*** can demonstrate changes in the size and shape of the liver. Fatty change and fibrosis produce a diffusely increased echogenicity. In established cirrhosis, there may be marginal nodularity of the liver surface and distortion of the arterial vascular architecture. The patency of the portal and hepatic veins can be evaluated. Ultrasound is useful for detecting HCC.
- ***Transient elastography*** is increasingly used to avoid liver biopsy (see 'Hepatic stiffness [transient elastography]' section). Technical limitations preclude its use in patients with ascites or morbid obesity but it is suitable for most. If the reading is high (>25), portal hypertension is likely, and some experts recommend that endoscopy to identify varices should be restricted to patients with high fibroscan scores.
- ***CT scanning*** (see 'Computed tomography examination' section) is also helpful. **Fig. 23.22D and E** shows hepatosplenomegaly and the dilated collaterals seen in chronic liver disease. Arterial phase contrast-enhanced scans are useful for detecting HCC.
- ***Endoscopy*** is performed for the detection and treatment of varices and portal hypertensive gastropathy. If identified, varices

Box 23.15 Poor prognostic indicators in cirrhosis

Blood tests
- Low albumin (<28 g/L)
- Low serum sodium (<125 mmol/L)
- Prolonged prothrombin time >6 sec above normal value
- Raised creatinine >130 μmol/L

Clinical
- Persistent jaundice
- Failure of response to therapy
- Ascites
- Haemorrhage from varices, particularly with poor liver function
- Neuropsychiatric complications developing with progressive liver failure
- Small liver
- Persistent hypotension
- Aetiology (e.g., alcoholic cirrhosis, if the patient continues drinking)

can be treated by banding or injection sclerotherapy or medically with non-selective beta blockers. Colonoscopy is occasionally carried out for portal hypertensive colopathy.

- ***MRI scanning*** is useful in the diagnosis of both malignant and benign tumours such as haemangiomas, and MR cholangiography can demonstrate the biliary tree anatomy and MR angiography vascular anatomy.

Liver biopsy

This remains the 'gold standard' for confirming the type and severity of liver disease. Adequate samples, in terms of length and number of complete portal tracts, are necessary for diagnosis and staging/grading of chronic viral hepatitis; in macronodular cirrhosis, the core of liver may fragment, causing sampling errors. Immunocytochemical stains can identify viruses, bile ducts, angiogenic structures, and oncogenic markers. Chemical measurement of iron and copper is necessary to confirm a diagnosis of iron overload or Wilson's disease. Digital image analysis of picrosirius red staining can be used to quantitate collagen in biopsy specimens (see **Fig. 23.22C**).

Management

Patients should undergo 6-monthly ultrasound to screen for the early development of HCC (see 'Hepatocellular carcinoma' section), as all therapeutic strategies work best with small, single tumours.

Treatment of the underlying cause may arrest or improve cirrhosis for viral or autoimmune hepatitis. Patients with compensated cirrhosis should lead a normal life. Those at risk should receive hepatitis A and B vaccinations. The only dietary restriction is reduction of salt intake (≤2 g sodium per day, equivalent to ≤5 g dietary salt). Alcohol should be avoided for any cause of cirrhosis, as should non-steroidal anti-inflammatory drugs (NSAIDs), which may precipitate gastrointestinal bleeding or renal impairment.

For patients with decompensated cirrhosis, management focuses on prevention and treatment of its complications, such as hepatic encephalopathy, ascites, and variceal bleeding, described elsewhere in this chapter.

Prognosis

Prognosis is extremely variable. Ascites is the most common complication of cirrhosis, and this clinical presentation represents a watershed moment with patients' median survival falling from greater than 12 years for compensated cirrhosis to approximately 2 years. Poor prognostic indicators are shown in **Box 23.15**.

There are a number of prognostic classifications with the most commonly used, the Child–Pugh score (A, B, and C; **Box 23.16**) and the Model for End-stage Liver Disease (MELD; **Box 23.17**). MELD focuses on serum bilirubin, creatinine, and the INR and is widely used as a predictor of mortality in patients awaiting liver transplantation. Modifications of the MELD score (e.g., UKELD) are used in some countries.

Box 23.16 Scoring systems in cirrhosis: modified Child–Pugh classification

Score	1	2	3
Ascites	None	Mild	Moderate/severe
Encephalopathy	None	Mild	Marked
Bilirubin (μmol/L)	<34	34–50	>50
Albumin (g/L)	>35	28–35	<28
Prothrombin time (sec over normal)	<4	4–6	>6

Add above scores for your patient for survival figures below:
Child's A (<7): 82% survival at 1 year, 45% at 5 years, 25% at 10 years
Child's B (7–9): 62% survival at 1 year, 20% at 5 years, 7% at 10 years
Child's C (10+): 42% survival at 1 year, 20% at 5 years, 0% at 10 years

Box 23.17 Scoring systems in cirrhosis: Model of End-stage Liver Disease (MELD)

$$3.8 \times \mathrm{LN}(\text{bilirubin in mg/dL}) + 9.6 \times \mathrm{LN}(\text{creatinine in mg/dL}) + 11.2 \times \mathrm{LN}(\mathrm{INR}) + 6.4^{a}$$

To convert:
- bilirubin from μmol/L to mg/dL, divide by 17
- creatinine from μmol/L to mg/dL, divide by 88.4

MELD scores (with no complications):
- Score <10: 97% survival at 1 year
- Score 30–40: 70% at 1 year

[a]Check online.
INR, International normalized ratio; *LN*, natural logarithm.

Acute-on-chronic liver failure

Acute-on-chronic liver failure (ACLF) refers to the condition of patients hospitalized for an acute complication of cirrhosis accompanied by organ failure(s); it has a high short-term mortality. ACLF is considered distinct from traditional decompensated cirrhosis, based not only on the presence of organ failure(s) and high mortality rate, but also on younger age, alcohol aetiology, higher prevalence of certain precipitating events (e.g., bacterial infections or active alcohol excess), and a higher level of systemic inflammation. It is estimated to occur in a third of patients hospitalized with decompensated cirrhosis.

Liver assist devices

As the liver has great potential to regenerate, extracorporeal liver support devices may allow patients with liver failure to be bridged to recovery or transplantation. Current approaches include the use of biological devices that contain hepatocytes and those that function as detoxification devices, and artificial liver support systems. However, no device has yet shown benefit in large multicentre randomized trials. A recent phase II study using the DIALIVE device showed promise.

Gut–liver axis

The liver is exposed to gut-derived bacterial components that have little consequence in health, as an effective gut barrier limits the transport of bacterial components to the liver. In advanced

liver disease the intestinal barrier function is compromised due to changes in gut motility, an increase in intestinal permeability, and suppression of gut immunological functions. This leads to bacteria and bacterial components (e.g., endotoxin, lipopolysaccharide) entering the portal circulation and being transported to the liver, activating Toll-like receptors and producing an inflammatory response. This cross-talk between the intestinal microbiota and the liver is referred to as the gut–liver axis and is seen as a key pathophysiological mechanism in the progression of liver disease and development of the complications of cirrhosis. Antibiotics and non-selective beta-blockers intercept the gut–liver axis by ***blocking bacterial translocation***, which is likely to account for their beneficial effects in reducing portal pressure, variceal haemorrhage, and spontaneous bacterial peritonitis (SBP). However, absorbable antibiotics will lead to the selection of resistant bacteria. Rifaximin, a poorly absorbed antibiotic used to treat hepatic encephalopathy, specifically affects the gut flora and has a low risk for inducing resistance; it may therefore have a role for this indication.

Liver transplantation

This is the only established treatment for advanced liver disease. Shortage of donors is a major problem in all high income countries and in some, such as Japan or South Korea, living-related donors form the majority.

Indications

These include:

- ***acute liver disease:*** acute hepatic failure of any cause (see 'Acute hepatic failure' section)
- ***chronic liver disease:*** usually for complications of cirrhosis that are no longer responsive to therapy.

The timing of transplantation depends on donor availability. All patients with end-stage cirrhosis (Child's grade C; MELD score ≥20; UKELD score ≥49) and those with debilitating symptoms should be referred to a transplant centre. In addition, specific extrahepatic complications of cirrhosis, even with preserved liver function, such as hepatopulmonary syndrome and porto-pulmonary hypertension, can be reversed by transplantation.

- ***Primary biliary cholangitis.*** Patients should be transplanted when their serum bilirubin persistently exceeds 100 μmol/L or when they have intractable pruritus.
- ***Chronic hepatitis B if HBV DNA-negative*** or levels are falling with effective therapy. Following transplantation, recurrence of hepatitis is prevented by hepatitis B immunoglobulin and nucleoside analogues in combination.
- ***Chronic hepatitis C.*** Following the introduction of the directly acting antiviral drugs, rates of transplantation for HCV have fallen substantially; for example, a reduction from 10.5% in 2013 to 4.7% in 2016 was seen in the UK.
- ***Autoimmune hepatitis.*** In patients who have failed to respond to medical treatment; the disease can recur.
- ***Alcoholic liver disease.*** Well-motivated patients who have stopped drinking without improvement of liver disease are offered a transplant, with frequent counselling. It has been shown that transplantation may represent life-saving treatment in patients with severe alcoholic hepatitis who are not responding to medical therapy, however, further studies are awaited. Early liver transplantation is an emerging therapy for acute severe alcoholic hepatitis, and multiple small studies have demonstrated that 'highly selected' patients have comparable 1- and 3-year survival to those with chronic liver disease following transplantation. However, not all caregivers agree that the usual expectation of demonstrated alcohol abstinence prior to transplantation should be waived and further data are needed.
- ***Primary metabolic disorders.*** Examples are Wilson's disease, hereditary haemochromatosis, and α_1-antitrypsin deficiency.
- ***MASH cirrhosis.*** In view of the increasing rates of obesity, this is highly likely to become the most frequent indication for transplantation.
- ***Other conditions*** include PSC, polycystic liver disease, and metabolic diseases such as primary oxaluria.

Contraindications

Absolute contraindications include active sepsis outside the hepatobiliary tree, malignancy outside the liver, liver metastases (except neuroendocrine), and a lack of psychological commitment on the part of the patient.

Relative contraindications are mainly anatomical considerations that make surgery more difficult, such as extensive splanchnic venous thrombosis. With exceptions, patients aged 70 years or over are not usually given a transplant. In HCC the recurrence rate is high unless there are fewer than three small (<3 cm) lesions or a solitary nodule of less than 5 cm (Milan criteria).

Preparation for surgery

Pre-transplant work-up includes confirmation of the diagnosis, ultrasound and cross-sectional imaging, and radiological demonstration of the hepatic arterial and biliary trees, as well as assessment of cardiorespiratory and renal status. In view of the ethical and financial implications of transplantation, regular psychosocial and possibly psychiatric support is vital.

The donor should be ABO-compatible (HLA matching is not necessary) and have no evidence of active sepsis, malignancy, or HIV, HBV, or HCV infection. Younger donors (<50 years) lead to better graft function. The donor liver is cooled and stored on ice; its preservation time may be up to 20 hours. The recipient operation takes approximately 8 hours and rarely requires a large blood transfusion. Deceased donor livers (from donors after brain or circulatory death) may consist of whole graft, split grafts (for two recipients), or reduced grafts. Live donors may be healthy individuals or patients with, for example, familial amyloid polyneuropathy, whose livers can be transplanted into others when they themselves receive a donor liver (so-called domino transplant). The mortality of right lobe donors is between 1 in 200 and 1 in 400. Recent advances in devices for storing donated liver prior to transplantation may allow livers to be used that were previously considered unsuitable.

Box 23.18 Complications and effects of cirrhosis

- Portal hypertension and gastrointestinal haemorrhage
- Ascites
- Portosystemic encephalopathy
- Hepatocellular carcinoma
- Bacteraemias, infections
- Renal failure
- Hepatopulmonary syndrome

The operative mortality of liver transplant recipients is very low and most postoperative deaths occur in the first 3 months. Sepsis and haemorrhage can be serious complications. Opportunistic infections occur owing to immunosuppression. Various immunosuppressive agents have been used: tacrolimus—alone or in combination with azathioprine or mycophenolate mofetil—steroids, sirolimus, and micro-emulsified ciclosporin are the most common.

Rejection

- ***Acute or cellular rejection*** usually occurs 5 to 10 days post transplant; it can be asymptomatic or there may be a fever. On biopsy, a pleomorphic portal infiltrate is seen with prominent eosinophils, bile duct damage, and endothelialitis of the blood vessels. This responds well to immunosuppressive therapy.
- ***Chronic ductopenic rejection*** is seen between 6 weeks and 9 months post transplant, with disappearing bile ducts (vanishing bile duct syndrome, VBDS), and an arteriopathy with narrowing and occlusion of the arteries. Early ductopenic rejection is rarely reversed by immunosuppression and often requires retransplantation.
- ***Graft-versus-host disease*** is extremely rare.

Prognosis

Elective liver transplantation in low-risk patients has a 90% 1-year survival and a 70% to 85% 5-year survival. Patients require lifelong immunosuppression, although doses can be reduced over time without significant problems. Future strategies to reduce immunosuppression requirements after transplant may include infusion of autologous regulatory T cells. HCV cirrhosis, PSC, and HCC are conditions in which long-term survival after transplantation is compromised by disease recurrence.

Complications and effects of cirrhosis

These are shown in **Box 23.18**.

Portal hypertension

The portal vein is formed by the union of the superior mesenteric and splenic veins. Normal pressure is 5 to 8 mmHg with only a small gradient across the liver to the hepatic vein, in which blood is returned to the heart via the inferior vena cava. Portal hypertension is classified according to the site of obstruction:

- ***pre-hepatic***—blockage of the portal vein before the liver
- ***intrahepatic***—distortion of the liver architecture, either pre-sinusoidal (e.g., schistosomiasis) or post-sinusoidal (e.g., cirrhosis)

Box 23.19 Causes of portal hypertension

Prehepatic
- Portal vein thrombosis

Intrahepatic

Pre-sinusoidal
- Schistosomiasis; sarcoidosis
- Primary biliary cholangitis

Sinusoidal
- Cirrhosis (e.g., alcoholic)
- Partial nodular transformation
- Congenital hepatic fibrosis

Post-sinusoidal
- Veno-occlusive disease
- Budd–Chiari syndrome

Post-hepatic
- Right heart failure (rare)
- Constrictive pericarditis
- Inferior vena cava obstruction

- ***post-hepatic***—venous blockage outside the liver (rare).

As portal pressure rises above 10 to 12 mmHg, the compliant venous system dilates and collaterals form within the systemic venous system. The main sites of collaterals are the gastro-oesophageal junction, rectum, left renal vein, diaphragm, retroperitoneum, and the anterior abdominal wall via the umbilical vein.

The collaterals at the gastro-oesophageal junction (varices) are superficial and are prone to rupture whereas portosystemic anastomoses at other sites rarely cause symptoms. Rectal varices are frequently found (30%) if looked for and can be differentiated from haemorrhoids, which are lower in the anal canal. The microvasculature of the gut becomes congested, giving rise to portal hypertensive gastropathy and colopathy, in which there is punctate erythema and erosions, which can bleed.

Pathophysiology

Following liver injury and fibrogenesis, the contraction of activated myofibroblasts (mediated by endothelin, nitric oxide, and prostaglandins) contributes to increased resistance to blood flow. This increased resistance leads to portal hypertension and opening of portosystemic anastomoses in both pre-cirrhotic and cirrhotic livers. Neo-angiogenesis also occurs. The hyperdynamic circulation of cirrhosis (caused by nitric oxide, cannabinoids, and glucagon) leads to peripheral and splanchnic vasodilation. This, combined with plasma volume expansion due to sodium retention (see 'Ascites' section), leads to portal hypertension.

Aetiology

The most common cause is cirrhosis (**Box 23.19**). Others are described here.

Pre-hepatic causes

Extrahepatic blockage due to portal vein thrombosis can be caused by congenital portal venous abnormalities, neonatal sepsis of the umbilical vein, or inherited prothrombotic conditions, such as factor V Leiden or primary myeloproliferative disorders with or without *JAK2* mutations (see Chapter 38).

Patients present with gastrointestinal bleeding, often at a young age. They have normal liver function and prognosis following bleeding is therefore excellent.

The portal vein blockage can be identified by ultrasound with Doppler imaging; CT is also used.

Treatment for variceal bleeding is usually repeated endoscopic therapy or prophylaxis with non-selective beta-blockade. Splenectomy is performed only if there is isolated splenic vein thrombosis. Anticoagulation prevents further thrombosis and intestinal infarction and does not increase the risk of bleeding.

Intrahepatic causes

Cirrhosis is by far the most common cause but others include:

- ***Non-cirrhotic portal hypertension*** is characterized by mild portal tract fibrosis on liver histology. The aetiology is unknown but arsenic, vinyl chloride, anti-retroviral therapy, and other toxins have been implicated. A similar disease is frequently found in India. The liver lesion does not progress and prognosis is good.
- ***Schistosomiasis*** with extensive pipe-stem fibrosis occurs in endemic areas such as Egypt and Brazil. Often there is concomitant liver disease, such as HCV infection, which was transmitted by non-sterile equipment.
- ***Other causes*** include congenital hepatic fibrosis, and nodular regenerative hyperplasia and partial nodular transformation.

Post-hepatic causes

Prolonged severe heart failure with tricuspid incompetence or constrictive pericarditis can cause portal hypertension. The Budd–Chiari syndrome is described in the 'Budd–Chiari syndrome' section.

Clinical features

Patients are often asymptomatic, the only clinical evidence being splenomegaly, although features of chronic liver disease may exist (see the figure in 'Clinical skills' section).

Variceal haemorrhage

Approximately 90% of patients with cirrhosis will develop gastro-oesophageal varices over 10 years but only one-third of these will bleed. Bleeding is likely to occur with large varices, or in those with red signs at endoscopy, and in severe liver disease.

Management

Management can be divided into:

- the active bleeding episode
- prevention of rebleeding
- prophylactic measures to prevent the first haemorrhage.

Despite the therapeutic techniques available, prognosis ultimately depends on the severity of the underlying liver disease with overall 6-week mortality from variceal haemorrhage 15% to 25%, reaching 50% in Child's grade C.

Initial management of acute variceal bleeding

See **Fig. 23.23**, and also the general management of gastrointestinal haemorrhage in Chapter 11.

Resuscitation

- ***Assess*** the patient: pulse, blood pressure, and conscious state.
- Insert a ***large-bore intravenous line*** and obtain ***blood*** for group and crossmatching, haemoglobin, PT/INR, serum creatinine and electrolytes, liver biochemistry, and blood cultures.
- ***Restore blood volume*** with plasma expanders or, if possible, blood transfusion. See the treatment of shock for more detail (see Chapter 13). Prompt correction, but not over-correction, of hypovolaemia is necessary in cirrhosis patients, as their baroreceptor reflexes are diminished. A target haemoglobin of 80 g/L is sufficient, and this lessens the likelihood of early rebleeding.
- Perform an ***ascitic tap***.
- Monitor for alcohol withdrawal and treat with lorazepam or oxazepam (the half-life of chlordiazepoxide will increase in advanced liver disease, amplifying the risk of adverse events). Give intravenous thiamine.
- Start prophylactic antibiotics. These treat and prevent infection and reduce early rebleeding and mortality, although most of these studies were performed many years ago. Given the improvement of endoscopic techniques and the increasing burden of anti-microbial resistance, universal prophylaxis may no longer be required and patients that recover quickly should have antibiotics stopped at 48 or 72 hours unless there is evidence of ongoing infection.

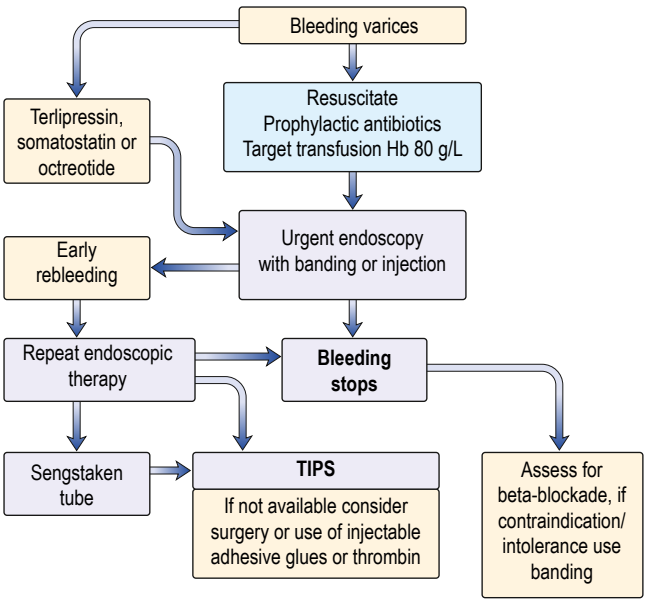

Fig. 23.23 Management of gastrointestinal haemorrhage due to oesophageal varices. *Hb,* Haemoglobin; *TIPS,* transjugular intrahepatic portosystemic shunt.

Urgent endoscopy

Endoscopy (**Fig. 23.24**) should be performed to confirm the diagnosis and to exclude bleeding from other sites (e.g., gastric ulceration) and portal hypertensive gastropathy/*g*astric *a*ntral *v*ascular *e*ctasia (GAVE). The latter describes chronic gastric congestion, punctate erythema, and gastric erosions, which may contribute to chronic anaemia. Portal hypertensive gastropathy and GAVE are distinct entities; management of portal hypertensive gastropathy is centred on reduction in portal pressures with beta-blockers, whereas treatment of GAVE is endoscopic and uses various ablative techniques.

Variceal banding

Banding of oesophageal varices is performed by mounting a band on the tip of the endoscope, sucking the varix into the end of the scope, and dislodging the band over the varix using a trip-wire mechanism.

Between 15% and 20% of bleeding comes from gastric varices, which are associated with a greater mortality (up to 40%); endoscopic injection of cyanoacrylate is the best treatment.

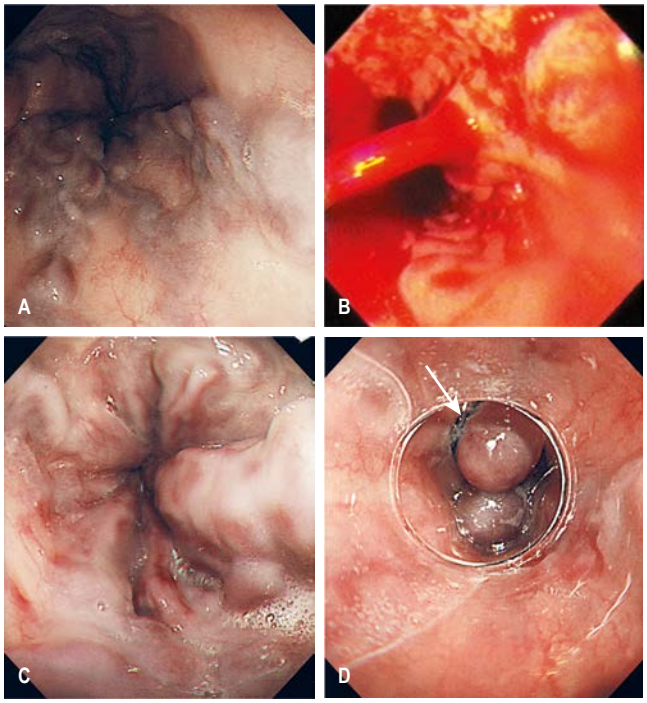

Fig. 23.24 Endoscopic views of oesophageal varices. **(A)** Gross varices. **(B)** Blood spurting from a varix. **(C)** Following a recent bleed. **(D)** Varices with a band in place *(arrowed)*. *(A, C, and D, Courtesy of Dr Peter Fairclough.)*

Overall, haemostasis is achieved in 80% to 90% of patients. Best practice is to perform the endoscopy with the patient under general anaesthetic to provide appropriate airway support, and with critical care support.

Other measures

Vasoconstrictor therapy

This is used to restrict portal inflow by splanchnic arterial constriction and has shown benefit when used in combination with endoscopic techniques.

- ***Terlipressin.*** This is the only vasoconstrictor shown to reduce mortality. The dose is 2 mg every 4 to 6 hours, with many units favouring the longer dosing interval to reduce adverse effects including painful vasoconstriction in the hands and feet. Treatment is typically stopped once satisfactory haemostasis has been achieved and longer courses have not been associated with a survival benefit. Terlipressin should not be given to patients with ischaemic heart disease. The patient may complain of abdominal colic, and may defecate and have facial pallor owing to generalized vasoconstriction.
- ***Somatostatin.*** This reduces bleeding with few side-effects and is given as an initial 250 µg bolus followed by a continuous infusion of 250 µg/hour. Somatostatin is reserved for patients with contraindications to terlipressin.

Balloon tamponade

Balloon tamponade is used if endoscopic therapy has failed or if there is exsanguinating haemorrhage. The usual balloon tube is a four-lumen Sengstaken–Blakemore, which should be left in place for no more than 12 hours and removed in the endoscopy room prior to follow-up endoscopy. The tube is passed into the stomach and the gastric balloon inflated with air and pulled back. It should be positioned in close apposition to the gastro-oesophageal junction to prevent the cephalad variceal blood flow to the bleeding point. The oesophageal balloon should be inflated only if bleeding is not controlled by the gastric balloon alone.

Haemostasis is achieved in up to 90%. However, the balloon may cause serious complications, such as aspiration pneumonia, oesophageal rupture, and mucosal ulceration. The procedure is also very unpleasant for the patient.

A self-expanding covered metal stent (Danis), which has a wire loop to enable removal and is introduced orally or endoscopically, can be placed over the varices. This is effective and has the advantages that it does not impair swallowing, cannot be removed by uncooperative patients, and allows post-endoscopic investigation. The stent is removed 7 days after insertion. Evidence supports that the Danis stent improves the short-term control of bleeding compared with a balloon tamponade when there is endoscopic failure and it can be left in place for longer, allowing time to stabilize the patient.

Additional management of the acute episode

- ***Measures to prevent encephalopathy.*** Portosystemic encephalopathy (PSE) can be precipitated by a large bleed (blood contains protein). Management is as outlined on in the 'Portosystemic encephalopathy/Management' section.
- ***Nursing.*** Patients require high-dependency/intensive care nursing. They should remain nil by mouth until bleeding has stopped.
- ***Reduction in acid secretion.*** PPIs are widely used but may cause increased incidence of *Clostridium difficile* and other infections. Sucralfate 1 g four times daily can reduce oesophageal ulceration following endoscopic therapy.

Management of an acute rebleed

Rebleeding occurs in approximately 15% to 20% within 5 days. The source should be established by endoscopy and this is sometimes related to ulceration or slippage of a ligation band. Endoscopy should be performed once only to control rebleeding. If haemostasis cannot be achieved, then transjugular intrahepatic portosystemic shunting (TIPS) will be necessary.

Transjugular portosystemic shunting

TIPS is performed when bleeding cannot be controlled either acutely or following a rebleed. Under X-ray guidance, a guidewire is passed from the jugular vein into the liver and the portal vein. After balloon expansion of the tract between the hepatic and portal veins, an expandable, covered metal shunt is placed over the wire to form a channel between the systemic and portal venous systems. It reduces the hepatic sinusoidal and portal vein pressure by creating a total shunt. There is an increased risk of portal-systemic encephalopathy. Stent stenosis or thrombosis is far less frequent now that 'covered' stents are used, as opposed to the 'bare metal' stents employed previously. Collaterals arising from the splenic or portal veins can be selectively embolized.

A recent observational study in 671 patients validated the survival benefit of 'pre-emptive' TIPS (within 72 hours of admission) in those with cirrhosis and acute variceal haemorrhage, and at high risk for treatment failure. Most of the benefit was seen in patients with Child–Pugh class C disease. However, widespread implementation of this approach represents a significant challenge for many healthcare systems, and despite strong supporting evidence, most centres have not adopted it at present. A randomized controlled trial will shortly begin in the UK to test this approach.

Emergency surgery

This is performed very rarely when other measures fail. Oesophageal transection and ligation of the feeding vessels to the bleeding varices or acute portosystemic shunt surgery is performed.

Prevention of recurrent variceal bleeding (secondary prophylaxis)

The risk of bleeding recurring without prophylaxis is 60% to 80% over a 2-year period, with an approximate mortality of 20% per episode.

Prophylactic long-term measures

Non-selective beta-blockade

Oral propranolol or carvedilol to reduce the resting pulse rate by 25% decreases portal pressure. Portal inflow is reduced by a decrease in cardiac output (β_1) and by blockade of β_2 vasodilator receptors on the splanchnic arteries, leaving an unopposed vasoconstrictor effect. Significant reduction of hepatic venous pressure gradient (HVPG, measured by hepatic vein catheterization) is associated with very low rates of rebleeding, particularly if below 12 mmHg. Data have emerged demonstrating that additional α_1-adrenergic blockade, causing vasodilation with carvedilol, may increase the number of patients with a reduction in HVPG compared to propranolol.

Endoscopic treatment

Repeated courses of banding at 2 to 4 weekly intervals lead to obliteration of varices and markedly reduce rebleeding. Between 30% and 40% of varices return per year, so follow-up endoscopy should be performed at 1 to 3 months after obliteration and then every 6 to 12 months. Complications of banding include oesophageal ulceration, mediastinitis, and rarely, strictures.

Combination therapy reduces overall bleeding compared to endoscopic therapy alone but with no overall improvement in mortality. A pragmatic approach is therefore to give combination therapy to those who can tolerate beta-blockade, and band ligation alone to those who cannot.

Surgery

- ***Surgical portosystemic shunting*** is associated with an extremely low risk of rebleeding and is used if TIPS is not available. Hepatic encephalopathy is a significant complication. The 'shunts' are usually an end-to-side portocaval anastomosis or a selective distal splenorenal shunt (Warren shunt).
- ***Devascularization procedures***, including oesophageal transection, do not produce encephalopathy and can be used when there is splanchnic venous thrombosis.
- ***Liver transplantation*** (see 'Liver transplantation' section) is the best option when there is poor liver function.

Prophylactic measures (primary prophylaxis)

Patients with cirrhosis and significant varices that have not bled should be prescribed non-selective beta-blockers. This reduces the chances of upper gastrointestinal bleeding by approximately 50%, may increase survival and is cost-effective. If there are contraindications or the patient cannot tolerate beta-blockers, variceal banding is an option. A large-scale trial comparing the efficacy of banding versus carvedilol for primary prophylaxis was unable to complete due to disruption caused by the COVID-19 pandemic.

Box 23.20 Serum–ascites albumin gradient

High serum–ascites albumin gradient (>11 g/L)

- Portal hypertension of any cause
  - Pre-hepatic e.g., portal vein thrombosis
  - Intrahepatic e.g., cirrhosis
  - Post-hepatic e.g., constrictive pericarditis
  - See **Box 23.19** for complete list

Low serum–ascites albumin gradient (<11 g/L)

- Ascites without portal hypertension
  - Peritoneal carcinomatosis
  - Peritoneal tuberculosis
  - Pancreatitis
  - Nephrotic syndrome

Ascites

Ascites, fluid within the peritoneal cavity, is a common complication of cirrhosis. Several factors underlie its pathogenesis:

- ***Sodium and water retention*** results from peripheral arterial vasodilation (secondary to increased nitric oxide, atrial natriuretic peptide, and prostaglandins), which causes a reduction in the effective blood volume. This reduction activates the sympathetic nervous system and the renin–angiotensin system, promoting salt and water retention (see **Fig. 27.5**).
- ***Portal hypertension*** exerts a local hydrostatic pressure, leading to increased hepatic and splanchnic production of lymph, and transudation of fluid into the peritoneal cavity.
- ***Low serum albumin*** (due to poor liver function) may further contribute by reducing plasma oncotic pressure.

In patients with ascites, urine sodium excretion rarely exceeds 5 mmol in 24 hours. Loss of sodium from extrarenal sites accounts for approximately 30 mmol in 24 hours. Under these circumstances, a normal daily sodium intake of 120 to 200 mmol results in a positive sodium balance of approximately 90 to 170 mmol in 24 hours (equivalent to 600–1300 mL of fluid retained).

Clinical features

Abdominal swelling may develop over days or several weeks. Precipitating factors include continued excessive alcohol consumption, infection/sepsis, development of an HCC, or splanchnic vein thrombosis. Mild abdominal pain and discomfort are common but, if more severe, should raise the suspicion of SBP (see later). Respiratory distress and difficulty eating accompany tense ascites.

The presence of fluid is confirmed clinically by demonstrating shifting dullness. Many patients also have peripheral oedema. A pleural effusion (usually right-sided) may be found and arises from the passage of ascites through congenital diaphragmatic defects.

Investigations

A diagnostic aspiration of 10 to 20 mL of fluid should be obtained for:

- ***Cell count.*** A neutrophil count of more than 250 cells/mm^3 is indicative of an underlying (usually spontaneous) bacterial peritonitis.
- ***Gram stain and culture.***
- ***Protein measurement.*** Serum–ascites albumin gradient (SAAG)—(serum albumin)—(ascitic fluid albumin) can be calculated to help distinguish between ascites due to portal hypertension (SAAG > 11 g/L) or ascites associated with non-liver disease–related abnormalities of the peritoneum, such as neoplasia (SAAG < 11 g/L) (**Box 23.20**). A high SAAG reflects relative

concentration of albumin in the circulation as fluid crosses the peritoneal membrane due to increased hydrostatic pressure resulting from portal hypertension; ascites due to inflammatory or malignant diseases of the peritoneum is not associated with this phenomenon, and SAAG is thus low.

- ***Cytology.*** A search should be made for malignant cells.
- ***Amylase.*** Pancreatic ascites should be excluded.

Management

The aim is both to reduce sodium intake and to increase renal sodium excretion, producing a net reabsorption of fluid from the ascites into the circulating volume. The maximum rate at which ascites can be mobilized is 500 to 700 mL in 24 hours (see later).

- ***Serum electrolytes, creatinine, and estimated glomerular filtration rate (eGFR).*** For hospitalized patients, check on alternate days; weigh the patient and measure urine output daily.
- ***Bed rest.*** This will cause a diuresis by improving renal perfusion but is rarely helpful.
- ***Dietary sodium restriction.*** It is possible to reduce sodium intake to 40 mmol in 24 hours and still maintain an adequate protein and calorie intake with a palatable diet.
- ***Drugs.*** Many contain significant amounts of sodium (up to 50 mmol daily). Examples include antacids and antibiotics (particularly penicillins and cephalosporins). Sodium-retaining drugs (NSAIDs, corticosteroids) should be avoided.
- ***Fluid restriction.*** This is unnecessary unless the serum sodium is lower than 128 mmol/L (see later).
- ***Diuretics.*** The diuretic of choice is the aldosterone antagonist spironolactone, starting at 100 mg daily. Chronic administration produces gynaecomastia. Eplerenone 25 mg once daily does not cause gynaecomastia.

The aim of diuretic therapy should be to produce a net loss of fluid approaching 700 mL in 24 hours (0.7 kg weight loss, or 1.0 kg if peripheral oedema is present). Although 60% of patients respond on this regimen, the spironolactone can be increased gradually to 400 mg daily if necessary, providing there is no hyperkalaemia. Urinary sodium may be used to titrate the dose. A loop diuretic, such as furosemide 20 to 40 mg or bumetanide 0.5 mg or 1 mg daily, is added if response is poor. These loop diuretics have several potential disadvantages, including hyponatraemia, hypokalaemia, and volume depletion.

Diuretics should be temporarily discontinued if a rise in serum creatinine occurs, representing over-diuresis and hypovolaemia, or if there is hyperkalaemia or worsening encephalopathy. Hyponatraemia almost always represents haemodilution secondary to a failure to clear free water (usually a marker of reduced renal perfusion), and diuretics should be stopped if the sodium falls below 128 mmol/L. Vaptans (see Chapter 27), vasopressin V_2-receptor antagonists that increase free water clearance, have a small beneficial effect on hyponatraemia and ascites but do not affect mortality, complications of cirrhosis or renal failure; routine use in cirrhosis cannot be recommended.

Shunts

A TIPS may be inserted to treat resistant ascites, providing there is no spontaneous PSE and there is minimal disturbance of renal function. Frequency of paracentesis and diuretic use is reduced, and nutrition is enhanced. Survival may also improve.

A peritoneo-bladder conduit, by means of an implantable, rechargeable, battery-powered pump, has been developed for use in patients with advanced cirrhosis and resistant ascites (Alfapump). This removes ascites from the peritoneal cavity into the urinary bladder, to be eliminated through urination. Studies have shown a reduction in the need for large-volume paracentesis but also several complications, including pain and infection, occur and this is not widely available.

In patients requiring end-of-life care, insertion of a long-term abdominal drain (LTAD) may allow ascites management outside of a hospital setting. These have been used successfully in patients whose ascites is due to malignancy and are currently being assessed in a large-scale randomized trial in the UK.

Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP) represents a serious complication that is an indication for referral for transplant assessment; it occurs in up to 18% of patients with ascites who have undergone decompensation. The infecting organisms gain access to the peritoneum by haematogenous spread; most are *Escherichia coli*, *Klebsiella*, or enterococci, although gram-positive organisms such as *Streptococcus pneumoniae* and staphylococcal species have increased significantly in recent years. The condition should be suspected in any patient with ascites who deteriorates, as pain and pyrexia are frequently absent. Diagnostic aspiration should always be performed. A raised neutrophil count in ascites is sufficient evidence alone to start immediate treatment. A broad-spectrum antibiotic is used, with subsequent alteration according to culture results *in combination with infusions of human albumin solution*. Evidence has emerged that use of non-selective beta-blockers should be carefully considered/stopped following diagnosis of SBP, as prescription may be associated with increased risk of renal impairment. Mortality is 10% to 15%. Recurrence is common (70% within a year) and secondary prevention—for example, with norfloxacin 400 mg daily—reduced incidence of SBP in a study of 80 patients. Primary prophylaxis of SBP in patients with low ascites protein levels below 10 to 15 g/L or severe liver disease may prevent hepatorenal syndrome and improve survival. However, the most studied agent, norfloxacin, is not available in the UK and fluoroquinolones have been given a boxed warning by the FDA, and restricted use has been advised by the Medicines and Healthcare products Regulatory Agency (MHRA) and (European Medicines Agency (EMA) because of increased incidence of musculoskeletal, vascular, and nervous system side-effects. There has also been an increase in anti-microbial resistance in liver cirrhosis patients over the last decade. A large-scale UK randomized trial of co-trimoxazole for primary prophylaxis is due to report in 2025. The benefits and harms of antibiotics must be carefully considered.

Portosystemic encephalopathy

Portosystemic encephalopathy (PSE) is a chronic neuropsychiatric syndrome that is secondary to cirrhosis. Acute encephalopathy can occur in acute hepatic failure (see 'Acute hepatic failure' section). PSE can arise in portal hypertensive patients due to spontaneous 'shunting', or in those with surgical or TIPS shunts.

Pathogenesis

In cirrhosis, the portal blood bypasses the liver via collaterals, and 'toxic' metabolites pass directly to the brain to produce encephalopathy. Ammonia-induced alteration of brain neurotransmitter balance, especially at the astrocyte–neuron interface, is considered to be the leading pathophysiological mechanism. Ammonia is produced by the breakdown of protein by intestinal bacteria. Other implicated substances are FFAs and mercaptans; accumulation of false neurotransmitters (octopamine) or activation of the γ-aminobutyric acid (GABA) inhibitory neurotransmitter system may

Box 23.21 Factors precipitating portosystemic encephalopathy

- High dietary protein
- Gastrointestinal haemorrhage
- Constipation
- Infection, including spontaneous bacterial peritonitis
- Fluid and electrolyte disturbance due to diuretic therapy or paracentesis
- Drugs (e.g., any central nervous system depressant)
- Portosystemic shunt operations, TIPS
- Any surgical procedure
- Progressive liver damage
- Development of hepatocellular carcinoma

also be responsible. Increased blood levels of aromatic amino acids (tyrosine and phenylalanine) and reduced branched-chain amino acids (valine, leucine, and isoleucine) also occur.

Clinical features

An acute onset often has a precipitating factor (**Box 23.21**). The patient becomes increasingly drowsy and comatose.

Chronically, there is a disorder of personality, mood, and intellect, with a reversal of normal sleep rhythm. These changes may fluctuate and a collateral history should be obtained. The patient is irritable, confused, and disorientated, and has slow, slurred speech. General features include nausea, vomiting, and weakness. There is hyper-reflexia and increased tone. Coma occurs as the encephalopathy becomes more marked. Convulsions are very rare, and if they do occur, other causes must be considered.

Signs include:

- fetor hepaticus (a sweet smell to the breath)
- a coarse flapping tremor seen when the hands are outstretched and wrists hyperextended (asterixis)
- constructional apraxia, with the patient being unable to write or draw a five-pointed star
- decreased mental function, which can be assessed by using the serial sevens test or a trail-making (or connection) test.

Investigations

Diagnosis is clinical.

Additional investigations

- ***EEG*** shows a decrease in the frequency of the normal α-waves (8–13 Hz) to 1.5 to 3 Hz. These changes occur before coma supervenes.
- ***Visual evoked responses*** (see Chapter 28) also detect subclinical encephalopathy.
- ***Arterial blood ammonia*** can be useful for the differential diagnosis of coma and for following a patient with PSE but is not always available.

Management

- ***Identify and remove the possible precipitating cause***, such as cerebral depressant drugs, constipation or electrolyte imbalance due to over-diuresis.
- ***Give purgation and enemas*** to empty the bowels of nitrogenous substances. Lactulose (10–30 mL three times daily) is an osmotic purgative that reduces the colonic pH and limits ammonia absorption. Lactilol (β-galactoside sorbitol 30 g daily) is metabolized by colonic bacteria and is comparable in efficacy.
- ***Maintain nutrition***, if necessary, via a fine-bore nasogastric tube, and do not restrict protein for more than 48 hours.
- **Rifaximin** is a poorly absorbed semisynthetic antibiotic based on rifamycin that is licenced for secondary prevention of PSE.
- ***Consider stopping or reduce diuretic therapy.***
- ***Give intravenous fluids*** if evidence of dehydration (beware of too much sodium).
- ***Treat infection.***
- ***Increase protein*** in the diet to the limit of tolerance as encephalopathy improves.
- ***Embolize collaterals.*** In selected patients, embolization of collaterals that bypass the liver may improve liver blood flow and reduce encephalopathy.

Prognosis

Acute encephalopathy in acute hepatic failure has a very poor prognosis associated with that of the disease itself. In cirrhosis, chronic PSE adversely affects prognosis, but the course is very variable. Very rarely with chronic portosystemic shunting, an organic syndrome with cerebellar signs or choreoathetosis develops, as well as myelopathy leading to a spastic paraparesis due to demyelination. These patients require referral to a liver transplant centre.

Renal failure (hepatorenal syndrome)

The hepatorenal syndrome typically occurs in patients with advanced cirrhosis, portal hypertension, jaundice, and ascites. The urine output is low with a low urinary sodium concentration, a maintained capacity to concentrate urine (i.e., intact tubular function), and almost normal renal histology. The renal failure is therefore described as 'functional'. It is often precipitated by over-vigorous diuretic therapy, NSAIDs, diarrhoea, paracentesis, and infection, particularly SBP.

The mechanism is similar to that of ascites, with extreme peripheral vasodilation leading to decreased effective blood volume and consequent hypotension (see 'Ascites' section). This causes increased plasma renin, aldosterone, noradrenaline (norepinephrine), and vasopressin, leading to renal vasoconstriction. There is an increased pre-glomerular vascular resistance that causes blood to be directed away from the renal cortex. This leads to a reduced GFR and plasma renin remains high. Salt and water retention occurs, with reabsorption of sodium from the renal tubules.

Eicosanoids have been incriminated in the pathogenesis, supported by precipitation of the syndrome by inhibitors of prostaglandin synthase, such as NSAIDs.

Diuretic therapy should be stopped and intravascular hypovolaemia corrected, for which albumin is recommended. Terlipressin with intravenous albumin improved renal function in 32% of patients compared to 17% with placebo, but not 3-month survival in a US large-scale trial with increased adverse events, especially pulmonary oedema seen in the terlipressin arm. Noradrenaline can be used as an alternative vasoconstrictor. Liver transplantation is the best option. In patients who are candidates for transplantation, haemodialysis can be used as a bridging option but is frequently difficult to perform, and survival is generally limited by the severity of the hepatic failure.

Hepatopulmonary syndrome

This is hypoxaemia in patients with advanced liver disease due to intrapulmonary vascular dilation with no evidence of primary pulmonary disease. The patients have features of cirrhosis with spider naevi and clubbing, as well as cyanosis. Most are asymptomatic, but with more severe disease become breathless on standing. Transthoracic echocardiography shows intrapulmonary shunting and arterial blood gases confirm hypoxaemia. These changes are improved with liver transplantation.

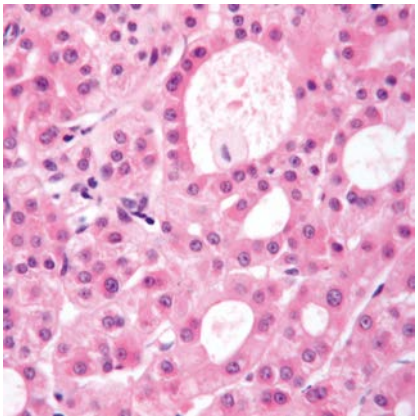

Fig. 23.25 Primary biliary cholangitis. Portal tract inflammation with lymphocytes and plasma cells (haematoxylin and eosin, ×10).

Porto-pulmonary hypertension

This occurs in 1% to 2% of patients with cirrhosis and portal hypertension. It may respond to medical therapy (e.g., intravenous epoprostenol, or oral bosentan and sildenafil). Severe pulmonary hypertension is a contraindication to liver transplantation.

Primary hepatocellular carcinoma

This is discussed in the 'Primary malignant tumours' section.

Types of cirrhosis

Alcohol related liver cirrhosis

This is discussed in the 'Alcohol and alcoholic liver disease' section.

Primary biliary cholangitis

Primary biliary cholangitis (PBC; Fig. 23.25) is a chronic disorder with progressive destruction of small interlobular bile ducts, leading to cirrhosis. Females aged 40 to 50 years constitute 90% of patients. PBC is diagnosed increasingly frequently in its milder forms. The prevalence is approximately 7.5 per 100 000, with a 1% to 6% increase in first-degree relatives. PBC has been called 'chronic non-suppurative destructive cholangitis', a term more descriptive of the early lesion, which emphasizes the fact that true cirrhosis occurs only in the later stages.

Aetiology

The aetiology is unknown, but an immunological basis is well described. Serum anti-mitochondrial antibodies (AMA) are found in almost all patients. The mitochondrial antigen M2 is specific to PBC and five M2-specific antigens have been identified. The presence of AMA in high titre is unrelated to the clinical or histological picture and its role in pathogenesis is unclear. Antibodies against nuclear antigens, such as anti-gp210, are present in 50% of patients and correlate with progression towards liver failure.

It seems likely that an environmental factor acts on a genetically predisposed host via molecular mimicry, initiating autoimmunity. *E. coli* and *Novosphingobium aromaticivorans* antibodies are present in high titre.

The synthesis of IgM is increased, which is thought to be due to the failure of the switch from IgM to IgG antibody synthesis. No specific associated class II major histocompatibility complex (MHC) loci have been found.

Clinical features

Asymptomatic patients are discovered on routine examination or screening, and may have hepatomegaly, a raised serum ALP or autoantibodies.

Pruritus is often the earliest symptom. Fatigue, which is frequently disabling, may accompany the pruritus, particularly in progressive cases. When jaundice appears, hepatomegaly is usually present. Pigmented xanthelasma on eyelids or deposits of cholesterol in the creases of the hands may be seen.

Associated disorders

Autoimmune disorders (e.g., Sjögren's syndrome, scleroderma, thyroid disease) occur with increased frequency. Keratoconjunctivitis sicca (dry eyes and mouth) is seen in 70% of cases. Renal tubular acidosis, membranous glomerulonephritis, coeliac disease and interstitial pneumonitis are also associations.

Investigations

- ***Mitochondrial antibodies***—measured routinely by ELISA (in titres >1:160)—are present in over 95% of patients; M2 antibody is 98% specific. Other non-specific antibodies (e.g., anti-nuclear factor and smooth muscle) may also be present.
- ***High serum alkaline phosphatase*** is often the only liver biochemistry abnormality.
- ***Serum cholesterol*** is raised.
- ***Serum IgM*** may be very high.
- ***Ultrasound*** can show a diffuse alteration in liver architecture.
- ***Liver biopsy*** shows characteristic histological features of a portal tract infiltrate, mainly of lymphocytes and plasma cells; approximately 40% have granulomas. Most of the early changes are in zone 1. Later, there is damage to and loss of small bile ducts with ductular proliferation. Portal tract fibrosis and, eventually, cirrhosis are seen.

Hepatic granulomas are also seen in sarcoidosis, tuberculosis, schistosomiasis, drug reactions, brucellosis, and parasitic infestation (e.g., strongyloidiasis).

Differential diagnosis

The classical picture presents little difficulty with diagnosis (and can be confirmed by biopsy, although this is only necessary if another cause is being considered). A group of patients with the histological changes of PBC but the serology of autoimmune hepatitis are termed as having autoimmune cholangitis and respond to steroids and azathioprine.

In the jaundiced patient, extrahepatic biliary obstruction should be excluded by ultrasound or MRCP.

Management

- ***Ursodeoxycholic acid*** (10–15 mg/kg) improves bilirubin and aminotransferase levels. It should be given early in the asymptomatic phase, as these patients benefit, whereas no benefit is achieved in advanced disease. In patients who do not respond

to ursodeoxycholic acid, obeticholic acid is approved for use and effectively reduces the serum alkaline phosphatase, a marker for long-term survival. The most clinically relevant adverse effect is dose-related pruritus.

- ***Steroids*** may improve biochemical and histological disease but cause osteoporosis and other side-effects, and should not be used.
- Malabsorption of ***fat-soluble vitamins (A, D, and K)*** occurs, and supplementation is required.
- ***Bisphosphonates*** are needed for osteoporosis. Despite raised serum lipid concentrations, PBC is not associated with an increased cardiovascular disease risk, and strategies for prevention of vascular events should be tailored to the individual.
- Pruritus is difficult to control; ***colestyramine*** is helpful, although unpalatable. ***Rifampicin***, and ***naloxone*** and ***naltrexone*** (opioid antagonists) and sertraline have been shown to be of benefit. Intractable pruritus may be relieved by plasmapheresis.
- The lack of effective medical therapy has made PBC a major indication for ***liver transplantation*** (see 'Liver transplantation' section).
- Fatigue is common and can be severely debilitating; there is no proven therapy. Liver transplant is associated with improvement but a substantial number of patients still suffer fatigue following transplant.

Complications

Complications are those of cirrhosis. In addition, osteoporosis and, rarely, osteomalacia and a polyneuropathy occur.

Prognosis

Prognosis is very variable. Asymptomatic patients and those presenting with pruritus only will survive for more than 20 years. Symptomatic patients with jaundice have a more rapidly progressive course and may die of liver failure or bleeding varices within 5 years. Liver transplantation should therefore be offered when the serum bilirubin is persistently above 100 μmol/L.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by fibrosing inflammatory destruction of both the intra- and extrahepatic bile ducts. In 75% of patients, PSC is associated with inflammatory bowel disease (usually ulcerative colitis); it is not unusual for PSC to predate the onset of inflammatory bowel disease. The causes are unknown but genetic susceptibility to PSC is associated with the HLA-A1-B8-DR3 haplotype. The autoantibody pANCA (anti-neutrophil cytoplasmic antibody) is found in the serum of 60% of cases. Seventy per cent of patients are male and the average age of onset is approximately 40 years. Secondary PSC is seen in patients with HIV and cryptosporidium (see Chapter 44) and may follow ketamine misuse.

Clinical features

With increasing screening of patients who have inflammatory bowel disease, PSC is detected at an asymptomatic phase with abnormal liver biochemistry, usually a raised serum ALP. Symptomatic presentation is usually with fluctuating pruritus, jaundice, and cholangitis.

Diagnosis

The typical biliary changes associated with PSC may be identified by MRCP. The cholangiogram characteristically shows irregularity of calibre of both intra- and extrahepatic ducts, although either may be involved alone (**Fig. 23.26**).

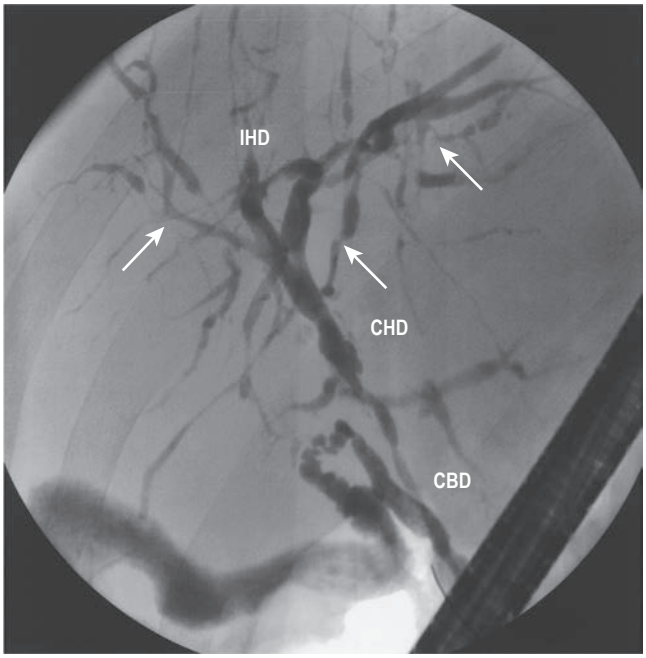

Fig. 23.26 Primary sclerosing cholangitis. An endoscopic cholangiogram showing the typical features of primary sclerosing cholangitis. There are calibre irregularities of the intrahepatic ducts (IHD). There is also minor stricturing of the extrahepatic ducts at the confluence between the common bile duct (CBD) and the common hepatic duct (CHD).

Pathology

Histology can be contributory; it shows inflammation of the intrahepatic biliary radicles with associated scar tissue, classically described as having the appearance of 'onion skin'. These changes range from minor inflammatory infiltrates to the level of established cirrhosis.

Management

PSC is a slowly progressive lesion (symptoms and biochemical tests may fluctuate), which ultimately leads to liver cirrhosis and associated decompensation. Recurrent cholangitis may be a feature before the onset of cirrhosis. Cholangiocarcinoma occurs in up to 15% of patients (see 'Cholangiocarcinoma' section and Chapter 24).

The only proven treatment is liver transplantation. Ursodeoxycholic acid has been evaluated extensively but there is no evidence of benefit and high-dose therapy (30 mg/kg) may be deleterious. In a small minority the dominant lesion is sited in the extrahepatic ducts (see **Fig. 23.26**). Such lesions may be amenable to endoscopic biliary intervention with balloon dilation and temporary stent placement (see Chapter 24).

Secondary biliary cirrhosis

Cirrhosis can result from prolonged (for months) large-duct biliary obstruction. Causes include bile duct strictures, gallstones, and sclerosing cholangitis. An ultrasound examination and MRCP, sometimes followed by ERCP or percutaneous transhepatic cholangiography (where the ducts are cannulated under ultrasound guidance through the skin) if cannulation is difficult, are performed to outline the ducts, and any remedial cause is treated.

Hereditary haemochromatosis

Hereditary haemochromatosis (HH) is an inherited disease characterized by excess iron deposition in various organs, leading to eventual fibrosis and functional organ failure. There are four main types of inherited disorders:

- ***type 1*** HFE: the ***HFE*** gene (mutation C282Y) is the most common and is on chromosome 6
- ***type 2A:*** the juvenile ***HJV*** gene (mutation G320V); ***type 2B:*** the juvenile ***HAMP*** gene (mutation 93delG)
- ***type 3*** TfR2: the ***TfR2*** gene (mutation Y250X)
- ***type 4*** ferroportin: the ***SLC40A1*** gene (mutation V162del).

All are transmitted by an autosomal recessive gene, apart from the ferroportin iron overload, which is dominantly transmitted.

HH has a prevalence in White people (homozygotes) of 1 in 400, but very variable phenotypic expression and a heterozygote (carrier) frequency of 1 in 10. It is the most common single-gene disorder in White people. Although HH occurs worldwide, it is less common in people without European ancestry.

Aetiology

Between 85% and 90% of patients with overt HH are homozygous for the Cys 282 Tyr (C282Y mutation): that is, type 1 *HFE*. A second mutation (His 63 Asp, H63D) occurs in about 25% of the population and is in complete linkage disequilibrium with Cys 282 Tyr.

HH Type 3 occurs in southern Europe and is associated with TfR2, a transferrin receptor isoform. The other types, ferroportin-related (type 4) and juvenile forms (2A and 2B), are much rarer.

Dietary intakes of iron and chelating agents (ascorbic acid) may be relevant. Iron overload may be present in alcoholics; alcohol excess *per se* does not cause HH, although there is a history of excess alcohol intake in 25% of patients.

Mechanism of damage

The *HFE* gene protein interacts with the transferrin receptor 1, which is a mediator in intestinal iron absorption (see Fig. 38.11). Iron is taken up by the mucosal cells inappropriately, exceeding the binding capacity of transferrin.

Hepcidin, a protein synthesized in the liver (Fig. 23.27), is central to the control of iron absorption; it is increased in iron deficiency states and decreased with iron overload. The mutations described disrupt hepcidin expression, leading to unregulated absorption of dietary iron from the gut via ferroportin channels on the basolateral surface of enterocytes and uninhibited iron overload.

Hepatic expression of the hepcidin gene is decreased in HFE haemochromatosis, facilitating liver iron overload. Excess iron is then gradually taken up by the liver and other tissues over a long period. It seems likely that it is the iron itself that precipitates fibrosis.

Pathology

In symptomatic patients the total body iron content is 20 to 40 g, compared with 3 to 4 g in a normal person. The iron content is particularly increased in the liver (Fig. 23.28) and pancreas (50–100 times normal) but is also higher in other organs (e.g., endocrine glands, heart, and skin).

In established cases the liver shows extensive iron deposition and fibrosis. Early in the disease, iron is deposited in the periportal hepatocytes (in pericanalicular lysosomes). Later, it is distributed widely throughout all acinar zones, biliary duct epithelium, Kupffer cells, and connective tissue. Cirrhosis is a late feature.

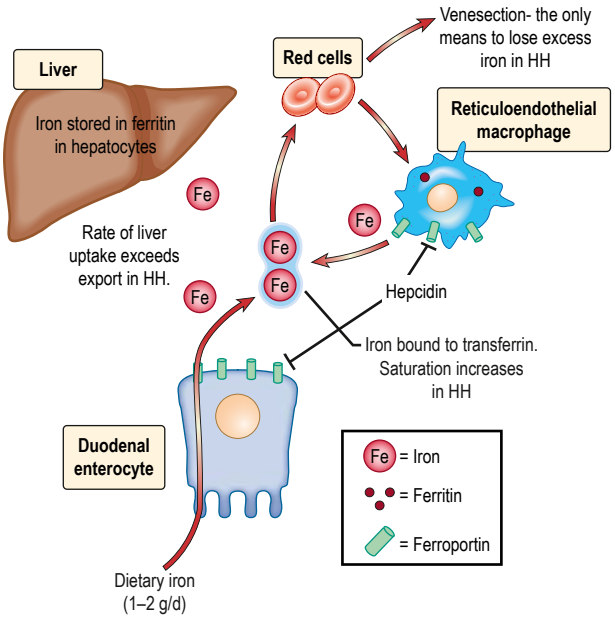

Fig. 23.27 The circulation of iron from the duodenal enterocyte to and from the liver, red cells, and reticuloendothelial macrophages is dysregulated in hereditary haemochromocytosis. Iron is absorbed from the intestine (see Fig. 38.11) via ferroportin channels on the basolateral surface of enterocytes and circulates bound to transferrin. The reticuloendothelial cells clear old erythrocytes and release iron to circulate and be stored as ferritin in the liver. The liver is the major site of production of the peptide hormone hepcidin which blocks ferroportin, preventing transit of iron across the gut and release of iron from reticuloendothelial cells. Reduced levels of hepcidin in HH result in unregulated absorption and release of iron to the circulation and progressive accumulation in tissue stores, particularly the liver. *Fe,* Iron.

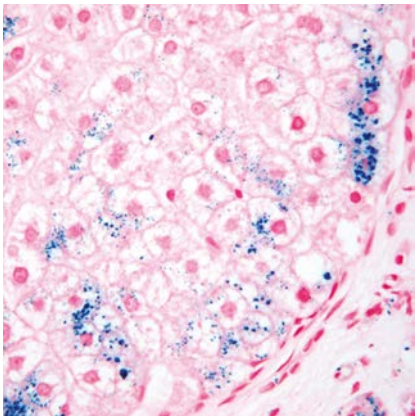

Fig. 23.28 Cirrhotic nodule in haemochromatosis. Note the iron overload *(blue)* (Perls, ×25).

Clinical features

The course of the disease depends on a number of factors, including sex, dietary iron intake, presence of associated hepatotoxins (especially alcohol), and genotypes. Overt clinical manifestations occur more frequently in males; the reduced incidence in females is probably explained by physiological blood loss and a smaller dietary intake of iron. Most affected individuals present in the fifth decade. The classic triad of bronze skin pigmentation (due to

melanin deposition), hepatomegaly, and diabetes mellitus is present only in cases of gross iron overload.

Hypogonadism secondary to pituitary dysfunction is the most common endocrine feature. Deficiency of other pituitary hormones is also found but symptomatic endocrine deficiencies, such as loss of libido, are very rare. Cardiac manifestations, particularly heart failure and arrhythmias, are common, especially in younger patients. Calcium pyrophosphate is deposited asymmetrically in both large and small joints (chondrocalcinosis), leading to an arthropathy. The exact relationship of chondrocalcinosis to iron deposition is uncertain.

Complications

A recent large study showed that among males, HFE p.C282Y homozygosity was significantly associated with increased risk for incident primary hepatic malignancy and excess mortality, but these increased risks were not seen for females. For male C282Y homozygotes up to age 75 years, the lifetime risk of primary hepatic malignancy was 7.2% (95% CI, 3.9–13.1) compared with 0.6% (95% CI, 0.4–0.7) for males with neither variant. HCC has been described only very rarely in non-cirrhotic patients in whom the excess iron stores have been removed.

Investigations

Homozygotes

- ***Serum iron*** is elevated (>30 μmol/L) in 90% with a reduction in the TIBC and a transferrin saturation of more than 45%.
- ***Serum ferritin*** is elevated (usually >500 μg/L or 240 nmol/L).
- ***Liver biochemistry*** is often normal, even with established cirrhosis.

Heterozygotes

Heterozygotes may have normal biochemical tests or modest increases in serum iron transferrin saturation (>45%) or serum ferritin (usually >400 μg/L).

Genetic testing

If iron studies are abnormal, genetic testing is performed.

Liver biopsy

This is not required for diagnosis but is useful to establish the extent of tissue damage, assess tissue iron and measure the hepatic iron concentration (>180 μmol/g dry weight of liver indicates haemochromatosis).

Mild degrees of parenchymal iron deposition in patients with other forms of cirrhosis, particularly if due to alcohol, can often cause confusion with true homozygous HH.

Magnetic resonance imaging

MRI shows a dramatic reduction in the signal intensity of the liver and pancreas owing to the paramagnetic effect of ferritin and haemosiderin. A highly T2-weighted, gradient recalled echo (GRE) technique detects all clinically relevant liver iron overload (>60 μmol/g of liver). In secondary iron overload (haemosiderosis), which involves the reticuloendothelial cells, the pancreas is spared, enabling distinction between these two conditions.

Management

Venesection

This prolongs life and may reverse tissue damage; the risk of malignancy still remains if cirrhosis is present. All patients should have excess iron removed as rapidly as possible. This is achieved using venesection of 500 mL performed twice weekly for up to 2 years: that is, 160 units with 250 mg of iron per unit, which equals 40 g removed. During venesection, serum iron and ferritin and the mean corpuscular volume (MCV) should be monitored. These fall only when available iron is depleted. Three or four venesections per year are required to prevent re-accumulation of iron. Serum ferritin should remain within the normal range.

Manifestations of the disease usually improve or disappear, except for diabetes, testicular atrophy, and chondrocalcinosis. The requirements for insulin often diminish in diabetic patients. Testosterone replacement is frequently helpful.

In the rare patient who cannot tolerate venesection (because of severe cardiac disease or anaemia), chelation therapy with desferrioxamine, either intermittently or continuously by infusion, has been successful in removing iron.

Screening

In all cases of HH, all first-degree family members must be screened to detect early and asymptomatic disease. *HFE* mutation analysis is performed with measurement of transferrin saturation and serum ferritin.

In the general population, serum iron and transferrin saturation are the best and cheapest tests available.

Wilson's disease (progressive hepatolenticular degeneration)

Dietary copper is normally absorbed from the stomach and upper small intestine. Copper is transported to the liver loosely bound to albumin; in the liver, it is incorporated into apocaeruloplasmin, forming caeruloplasmin, a glycoprotein synthesized in the liver, and secreted into the blood. The remaining copper is normally excreted in the bile and excreted in faeces.

Wilson's disease is a very rare inborn error of copper metabolism that results in copper deposition in various organs, including the liver, the basal ganglia of the brain, and the cornea. It is potentially treatable and all young patients with liver disease must be screened for this condition.

Aetiology

Wilson's disease is an autosomal recessive disorder with a molecular defect within a copper-transporting ATPase encoded by a gene (designated *ATP7B*) located on chromosome 13. It affects between 1 in 30 000 and 1 in 100 000 individuals. Over 300 mutations have been identified, the most frequent being His 1069 Gly (H1069Q), found in approximately 50% of White patients; compound heterozygotes are common. This mutation is rare in India and Asia. Wilson's disease occurs worldwide, particularly in countries where consanguinity is common. There is a failure of both incorporation of copper into procaeruloplasmin, which leads to low serum caeruloplasmin, and biliary excretion of copper. There is a low serum caeruloplasmin in over 80% of patients but this is not the cause of the copper deposition. The precise mechanism for the failure of copper excretion is not known.

Pathology

The liver histology is not diagnostic and varies from that of chronic hepatitis to macronodular cirrhosis. Stains for copper show a periportal distribution but this can be unreliable (see later). The basal ganglia are damaged and show cavitation, the kidneys demonstrate tubular degeneration, and erosions are seen in bones.

Clinical features

Children usually present with hepatic problems, whereas young adults have more neurological problems, such as tremor, dysarthria, involuntary movements, and eventually dementia. The liver disease varies from episodes of acute hepatitis, especially in children (which can go on to acute hepatic failure), to chronic hepatitis or cirrhosis.

Typical signs are those of chronic liver disease with neurological signs of basal ganglia involvement (see Chapter 28). A specific sign is the Kayser–Fleischer ring, caused by copper deposition in Descemet's membrane in the cornea. It appears as a greenish-brown pigment at the corneoscleral junction and frequently requires slit-lamp examination for identification. It may be absent in young children.

Investigations

- ***Serum copper and caeruloplasmin*** are usually reduced but can be normal.
- ***Urinary copper*** is usually increased to 100 to 1000 μg in 24 hours (1.6–16 μmol); normal levels are less than 40 μg (0.6 μmol).
- ***Liver biopsy*** aids diagnosis, which depends on measurement of the amount of copper in the liver (>250 μg/g dry weight), although high levels of copper are also found in the liver in chronic cholestasis.
- ***Haemolysis and anaemia*** may be present.
- ***Genetic analysis*** is limited but selected exons are screened according to population groups.

Management

- Lifetime treatment with ***penicillamine***, 1.5 to 2 g daily in divided doses, is effective in chelating copper. If treatment is started early, clinical and biochemical improvement can occur. Urinary copper levels should be monitored and the drug dose adjusted downwards after 2 to 3 years. Serious side-effects of the drug occur in 10% and include skin rashes, leucopenia, skin changes, and renal damage.
- ***Trientine*** (750–1250 mg per day in divided doses) and ***zinc acetate*** (150 mg/day) are used as maintenance therapy and for asymptomatic cases. All siblings and children of patients should be screened (*ATP7B* mutation analysis is useful) and treatment with zinc is given, even in the asymptomatic, if there is evidence of copper accumulation. A diet low in copper (i.e., excluding chocolate and peanuts) is advised.

Prognosis

Early diagnosis and effective treatment have improved the outlook. Neurological damage is, however, permanent. Acute hepatic failure or decompensated cirrhosis should be treated by liver transplantation.

Alpha$_1$-antitrypsin deficiency

A deficiency of α_1-antitrypsin (α_1-AT, see also Chapter 20) is sometimes associated with liver disease and pulmonary emphysema (particularly in smokers). Part of a family of serine protease inhibitors, or serpin superfamily, α_1-AT is a glycoprotein. Deficiency of α_1-AT is a genetic disorder and 1 in 10 northern Europeans carries an abnormal gene.

The protein is a 394-amino acid 52 kDa acute phase protein that is synthesized in the liver and constitutes 90% of the serum α_1-globulin seen on electrophoresis. Its main role is to inhibit the proteolytic enzyme, neutrophil elastase.

The gene is located on chromosome 14. The genetic variants of α_1-AT are characterized by their electrophoretic mobilities as medium (M), slow (S), or very slow (Z). The normal genotype is protease inhibitor MM (PiMM), the homozygote for Z is PiZZ, and the heterozygotes are PiMZ and PiSZ. S and Z variants are due to a single amino acid replacement of glutamic acid at positions 264 and 342 of the polypeptide, respectively. This results in decreased synthesis and secretion of the protein by the liver as protein–protein interactions occur between the reactive centre loop of one molecule and the β-pleated sheet of a second (loop sheet polymerization).

How this causes liver disease is uncertain. It is postulated that failure of secretion of the abnormal protein leads to an accumulation in the liver, leading to liver damage.

Clinical features

The majority of patients with clinical disease are homozygotes with a PiZZ phenotype. Some may present in childhood and a few require transplantation. Approximately 10% to 15% of adult patients will develop cirrhosis, usually over the age of 50 years, and 75% will have respiratory problems. Approximately 5% of patients die of their liver disease. Heterozygotes (e.g., PiSZ or PiMZ) may develop liver disease but the risk is small.

Investigations

- ***Serum α_1-antitrypsin*** is low, at 10% of the normal level in the PiZZ phenotypes, and 60% of normal in the S variant.

Histologically, periodic acid–Schiff (PAS)-positive, diastase-resistant globules that contain α_1-AT are seen in periportal hepatocytes. Fibrosis and cirrhosis can be present.

Management

There is no treatment, apart from managing the complications of liver disease. Patients with hepatic decompensation should be assessed for liver transplantation and should stop smoking.

ALCOHOL AND ALCOHOLIC LIVER DISEASE

Alcohol is consumed in large quantities all over the world and in many countries, alcohol consumption is a major medical and social problem (see Chapter 30). It increases morbidity and mortality in a variety of ways, including effects on heart disease, stroke, cancers, and neurological/psychiatric problems, as well as liver disease, and is associated with nutritional deficiencies and abnormal metabolism of drugs.

Box 23.22 The main pathways of ethanol oxidization

Alcohol dehydrogenase

$$\underset{\text{(ethanol)}}{CH_3CH_2OH} + NAD^+ \xrightarrow{ADH} \underset{\text{(acetaldehyde)}}{CH_3CHO} + NADH + H^+ \quad [1]$$

Liver microsomal ethanol oxidizing system (MEOS)

- Includes the specific P450 enzyme, CYP2EI, which is induced by ethanol

$$CH_3CH_2OH + NADPH + H^+ + O_2 \xrightarrow{MEOS} CH_3CHO + NADP + 2H_2O \quad [2]$$

Ethanol (ethyl alcohol) is oxidized, in the steps shown in **Box 23.22**, to acetaldehyde. Acetaldehyde is then converted to acetate, 90% in the liver mitochondria. Acetate is released into the blood and oxidized by peripheral tissues to carbon dioxide and water.

Alcohol dehydrogenases are found in many tissues and it has been suggested that enzymes present in the gastric mucosa may contribute substantially to ethanol metabolism.

Ethanol itself produces 29.3 kJ/g (7 kcal/g), but many alcoholic drinks also contain sugar, which increases their calorific value. For example, 1 pint of beer provides about 1045 kJ (250 kcal), so heavy drinkers will be unable to lose weight if they continue to drink.

Effects of excess alcohol consumption

Excess consumption of alcohol leads to two major problems, both of which can be present in the same patient:

- alcohol dependence syndrome (see Chapter 30)
- physical damage to various tissues.

Each unit of alcohol (defined as 10 mL [7.9 g] of pure ethanol) corresponds to about half a pint of normal beer, one single measure of spirit, or half a glass of wine (**Fig. 23.29**). An intake of less than 14 units per week is generally considered to be safe. All the long-term effects of excess alcohol consumption are due to excess ethanol, irrespective of the type of alcoholic beverage; that is, beer and spirits are no different in their long-term effects. Short-term effects, such as hangovers, depend on additional substances, particularly other alcohols such as isoamyl alcohol, which are known as congeners. Brandy and bourbon contain the highest percentage of congeners.

The amount of alcohol that produces damage varies and not everyone who drinks heavily will suffer physical damage. For example, only 20% of people who drink heavily develop cirrhosis of the liver. The effect of alcohol on different organs of the body is not the same; in some patients, the liver is affected; in others, the brain or muscle. The differences may be genetically determined. Thiamine deficiency contributes to neurological (confusion, Wernicke–Korsakoff's syndrome; see Chapter 28) and some of the non-neurological manifestations (cardiomyopathy).

The susceptibility of different organs to damage is variable and the figures given in **Box 23.23** are provided only as a guide to sensible drinking. Heavy drinkers who persist for many years are at greater risk than heavy sporadic drinkers. Women are advised not to drink alcohol at all during pregnancy because consumption of even small amounts of alcohol can lead to fetal growth restriction and may also increase the risk of miscarriage. The fetal alcohol syndrome is characterized by intellectual disabilities, dysmorphic features, and growth impairment; it occurs in fetuses of alcohol-dependent women.

A summary of the physical effects of alcohol is given in **Box 23.24**. Details of these diseases are discussed in the relevant chapters. The effects of alcohol withdrawal are discussed in Chapter 11.

Specific public health and clinical guidance on prevention and management of alcohol-related disorders has been produced by NICE. The clinical guidelines specifically address alcohol withdrawal, Wernicke's encephalopathy, and both alcohol-related liver and pancreatic diseases.

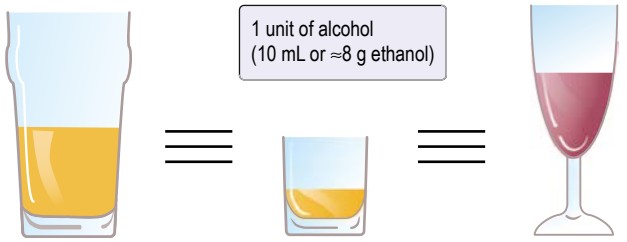

Fig. 23.29 Measures containing one unit of alcohol. The percentage refers to the proportion of alcohol by volume (vol/vol). The alcohol content of beers, spirits, and wines can vary substantially.

Box 23.23 Guide to sensible alcohol drinking

Weekly maximum

- 14 units for both men and women

To help achieve this

- Use a standard measure
- Do not drink during the daytime
- Have alcohol-free days each week

Remember

- Health can be damaged without being 'drunk'. Regular heavy intake is more harmful than occasional binges
- Do not drink to 'drown sorrows'
- In the UK, the drink-before-driving limit of alcohol in the blood is 800 mg/L
- 1 unit of alcohol is eliminated per hour; therefore spread drinking time
- Food decreases absorption and therefore results in a lower blood alcohol level
- Four to five units are sufficient to put the blood alcohol level over the legal driving limit in a 70 kg man (less in a lighter person)

Alcoholic liver disease

In general, the effects of a given intake of alcohol on the liver seem to be worse in females. The following figures are for males and should be reduced by about 30% for females:

- ***High risk:*** 160 g ethanol per day (20 single drinks)
- ***Medium risk:*** 80 g ethanol per day (10 single drinks)
- ***Little risk:*** 40 g ethanol per day (5 single drinks).

Ethanol is metabolized in the liver by two pathways, resulting in an increase in the NADH/NAD ratio. The altered redox potential causes increased hepatic fatty acid synthesis with decreased fatty acid oxidation; both events lead to hepatic accumulation of fatty acid, which is then esterified to glycerides.

The changes in oxidation–reduction also impair carbohydrate and protein metabolism and are the cause of the centrilobular necrosis of the hepatic acinus that is typical of alcohol damage. TNF-α release from Kupffer cells causes the release of reactive oxygen species, leading in turn to tissue injury and fibrosis.

Acetaldehyde is formed by the oxidation of ethanol, and its effect on hepatic proteins may well be a factor in producing liver cell damage. The exact mechanism of alcoholic hepatitis and cirrhosis is unknown, but since only 10% to 20% of people who drink heavily will develop cirrhosis, a genetic predisposition is recognized. Genome-wide association studies (GWAS) have identified

Box 23.24 Physical effects of excess alcohol consumption

the *PNPLA3, TM6SF2,* and *HSD17B13* genes as risk factors for chronic liver disease progression. Immunological mechanisms have also been proposed, with the release of cytokines, particularly IL-8, which is a neutrophil chemoattractant and infiltration with neutrophils is a feature of alcoholic hepatitis.

Alcohol can enhance the effects of the toxic metabolites of drugs (e.g., paracetamol) on the liver, as it induces microsomal metabolism via the microsomal ethanol oxidizing system (MEOS; see **Box 23.23**).

Pathology

Alcohol can produce a wide spectrum of liver disease, from fatty change to hepatitis and cirrhosis.

Fatty liver

The metabolism of alcohol invariably produces fat in the liver (**Fig. 23.30**), mainly in zone 3. This is minimal with small amounts of alcohol, but with larger amounts the cells become swollen with fat (steatosis). There is no liver cell damage. The fat disappears on stopping alcohol. Steatosis is also seen in MASLD (see 'Metabolic dysfunction–associated steatotic liver disease' section).

In some cases, collagen is laid down around the central hepatic veins (perivenular fibrosis) and this can progress to cirrhosis without a preceding hepatitis. Alcohol directly affects stellate cells, transforming them into collagen-producing myofibroblast cells).

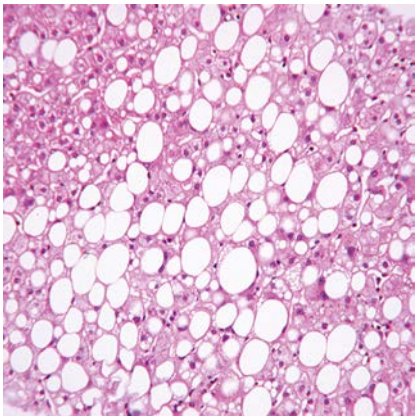

Fig. 23.30 Liver steatosis. (Haematoxylin and eosin, ×10.)

Alcoholic hepatitis

In addition to fatty change, there is infiltration by polymorphonuclear leucocytes and hepatocyte necrosis, mainly in zone 3. Dense cytoplasmic inclusions called Mallory bodies are sometimes seen in hepatocytes, and giant mitochondria are also a feature. Mallory bodies are suggestive of, but not specific for, alcoholic damage, as they can be found in other liver diseases, such as Wilson's disease and PBC. If alcohol consumption continues, alcoholic hepatitis may progress to cirrhosis.

Alcoholic cirrhosis

This is classically of the micronodular type, but a mixed pattern is also seen accompanying fatty change; evidence of pre-existing alcoholic hepatitis may be present.

Clinical features

Fatty liver

There are often no symptoms or signs. Vague abdominal symptoms of nausea, vomiting, and diarrhoea are due to the more general effects of alcohol on the gastrointestinal tract. Hepatomegaly, sometimes huge, can occur, together with other features of chronic liver disease.

Alcoholic hepatitis

The clinical features vary in degree:
- The patient may be well, with few symptoms, the hepatitis being apparent only on the liver biopsy in addition to fatty change.
- Mild to moderate symptoms of ill-health, occasionally with mild jaundice, may occur. Signs include all the features of chronic liver disease. Liver biochemistry is deranged and the diagnosis is made on liver histology.
- In the severe case, often superimposed on alcoholic cirrhosis, the patient is ill, with jaundice and ascites. Abdominal pain is frequently present and a high fever is associated with the liver necrosis. On examination there is deep jaundice, hepatomegaly, sometimes splenomegaly, and ascites with ankle oedema. The signs of chronic liver disease are also present.

Alcoholic cirrhosis

This represents the final stage of liver disease from alcohol use. Nevertheless, patients can be very well with few symptoms. On examination, there are usually signs of chronic liver disease (see the figure in 'Clinical skills' section). The diagnosis is confirmed by liver biopsy.

The patient usually presents with one of the complications of cirrhosis. In many cases there are features of alcohol dependency (see Chapter 30), as well as evidence of involvement of other systems, such as polyneuropathy.

Investigations

Fatty liver

An elevated MCV often indicates heavy drinking. Liver biochemistry shows mild abnormalities with elevation of both serum aminotransferase enzymes. The γ-GT level is a useful test for determining whether the patient is taking alcohol. With severe fatty infiltration, marked changes in all liver biochemical parameters can occur. Ultrasound or CT will demonstrate fatty infiltration, as will liver histology. Elastography (see 'Hepatic stiffness [transient elastography]' section) can be used to estimate the degree of fibrosis.

Alcoholic hepatitis

Investigations show a leucocytosis with markedly deranged liver biochemistry and elevated:

- serum bilirubin
- serum AST and ALT (AST often greater than ALT)
- serum ALP
- PT.

A ***low serum albumin*** may also be found. Rarely, hyperlipidaemia with haemolysis ***(Zieve syndrome)*** may occur.

Liver biopsy, if required, is performed by the transjugular route because of the prolonged PT.

Alcoholic cirrhosis

Investigations are as for cirrhosis in general.

Management and prognosis

General management

All patients should stop drinking alcohol. Delirium tremens (a withdrawal symptom) is treated with diazepam. Intravenous thiamine should be given empirically to prevent Wernicke–Korsakoff encephalopathy. Bed rest is necessary, along with a diet high in protein and vitamin supplements. Parenteral nutrition is sometimes required. Patients must be advised to participate in alcohol cessation programmes. The likelihood of abstention is dependent on many factors, particularly social and family ones.

Fatty liver

The patient is advised to stop drinking alcohol; the fat will disappear and the liver biochemistry usually returns to normal. Small amounts of alcohol can be drunk subsequently, as long as patients are aware of the problems and can control their consumption.

Alcoholic hepatitis

In severe cases the alcoholic hepatitis leads to acute decompensation and the patient requires admission to hospital. Nutrition must be maintained with enteral feeding, if necessary, and vitamin supplementation is given. Steroid therapy has been widely used in patients with a discriminant function (DF) score of more than 32 but a multicentre UK study from 2015, which included over 1000 patients, suggested that there was no survival benefit and there was an increased infection risk in those taking steroids. If steroids are prescribed, current guidelines emphasize early identification of non-responders to limit unnecessary exposure and minimize risk using tools such as the Lille score (>0.45 indicates poor response to steroids, which can therefore be stopped; **Box 23.25**).

Box 23.25 Lille score for alcoholic hepatitis

(*Calculator at* http://www.lillemodel.com)

R = 3.19 − (0.101 × age in years) + (0.147 × albumin on admission in g/L) + (0.0165 × change in bilirubin level from day 0 to day 7 in μmol/L) − (0.206 × renal insufficiency [0 if absent, 1 if present][a]) − (0.0065 × bilirubin day 0 in μmol/L) − (0.0096 × INR)

Score = EXP(−R)/[1 + EXP(−R)]

A score of <0.16 indicates a 96% chance of survival at 28 days; ≥0.56 indicates a 55% chance of survival at 28 days.

[a]Creatinine >115 μmol/L.
INR, International normalized ratio.

Box 23.26 Glasgow alcoholic hepatitis score

Score	1	2	3
Age	<50	>50	
White cell count (×10⁹/L)	<15	>15	
Urea (nmol/L)	<5	>5	
Bilirubin (μmol/L)	<125	125–250	>250
INR	<1.5	1.5–2.0	>2.0

Poor prognosis = total score >9.

INR, International normalized ratio.

Discriminant function

$$DF = [4.6 \times \text{prothrombin time above control in seconds}] + \text{bilirubin (mg/dL)}$$

Bilirubin mmol/L ÷ 17 to convert to mg/dL.

Severe = >32.

Other prognostic tools include the Glasgow score (**Box 23.26**), with a score of more than 9 indicating the 28-day mortality is 75% and the MELD score (see **Box 23.17**).

Infection must be excluded or concomitantly treated, although a large RCT did not support prophylactic antibiotics to improve survival. Treatment for encephalopathy and ascites may be required. Granulocyte colony–stimulating factor therapy may improve outcomes in severe AH. However, there was substantial heterogeneity observed in a meta-analysis with conflicting results between Asian and European studies, and G-CSF cannot currently be recommended for AH, especially in Europe.

Patients are advised to stop drinking for life, as this is undoubtedly a pre-cirrhotic or cirrhotic condition. The prognosis is variable: despite abstinence, liver disease is progressive in many patients but abstinence significantly improves survival. Unfortunately, many return to drinking. In severe cases the mortality is at least 50%; with a PT twice normal, progressive encephalopathy, and acute kidney injury, the mortality approaches 90%. Early liver transplantation for severe alcoholic hepatitis has been shown to have very acceptable short to intermediate-term patient survival and rates of alcohol use post-transplant, however, long-term outcomes are uncertain, as are how best to select and manage these patients before this becomes an accepted indication for liver transplant.

Alcoholic cirrhosis

The management of cirrhosis is described in the 'Cirrhosis/Management' section. Again, all patients are advised to stop drinking

for life. Abstinence from alcohol results in an improvement in prognosis, with a 5-year survival of 90%, but with continued drinking this falls to 60%. In advanced disease (i.e., jaundice, ascites, and haematemesis) the 5-year survival rate falls to 35% with most of the deaths occurring in the first year. Liver transplantation results in good survival. A trial of abstention to establish whether liver disease can improve is mandatory; prior to consideration to be added to the transplant list and patients often sign a contract with their clinicians regarding their abstinence, both before and after transplantation, and specific follow-up regarding alcohol use is recommended.

HCC is a complication, particularly in men.

BUDD–CHIARI SYNDROME

In this condition there is obstruction to the venous outflow of the liver owing to occlusion of the hepatic vein. In one-third of patients the cause is unknown but specific causes include hypercoagulability states (e.g., paroxysmal nocturnal haemoglobinuria, polycythaemia vera) or thrombophilia (see Chapter 40), the contraceptive pill, and leukaemia. Other causes include occlusion of the hepatic vein owing to posterior abdominal wall sarcomas, renal or adrenal tumours, HCC, hepatic infections (e.g., hydatid cyst), congenital venous webs, radiotherapy, or trauma to the liver.

Clinical features

The acute form presents with abdominal pain, nausea, vomiting, tender hepatomegaly, and ascites (a fulminant form that occurs particularly in pregnant females). In the chronic form there is enlargement of the liver (particularly the caudate lobe), mild jaundice, ascites, a negative hepatojugular reflux, and splenomegaly with portal hypertension.

Investigations

Investigations show a high protein content in the ascitic fluid and characteristic liver histology with centrizonal congestion, haemorrhage, fibrosis, and cirrhosis. Ultrasound, CT, or MRI will demonstrate hepatic vein occlusion with diffuse abnormal parenchyma on contrast enhancement. The caudate lobe is spared because of its independent blood supply and venous drainage. There may be compression of the inferior vena cava. Pulsed Doppler sonography or colour Doppler is useful, as it shows abnormalities of flow in the hepatic vein. Thrombophilia screening is mandatory. Multiple defects of coagulation occur. Thrombosis of the portal vein is present in up to 20% of patients.

Differential diagnosis

A similar clinical picture can be produced by inferior vena caval obstruction, right-sided cardiac failure, or constrictive pericarditis, and appropriate investigations should be performed.

Management

Thrombolytic therapy can be given acutely. Ascites should be treated, as should any underlying cause (e.g., polycythaemia). Congenital webs should be treated radiologically or resected surgically. TIPS is the treatment of choice and surgical portocaval shunts are reserved for those who fail this treatment, providing there is no caval obstruction or severe caval compression when a caval stent can be inserted. Liver transplantation is the first-choice treatment for ***chronic*** Budd–Chiari syndrome and the fulminant form. Life-long anticoagulation is mandatory following TIPS and transplantation.

Prognosis

The prognosis depends on the aetiology however, a step-wise approach to therapy, as described earlier, can lead to a 5-year survival rate of nearly 85%.

Valla DC. Budd–Chiari syndrome/hepatic venous outflow tract obstruction. *Hepatol Int* 2018; 12(Suppl 1):168–180.

HEPATIC SINUSOIDAL OBSTRUCTION SYNDROME

Hepatic sinusoidal obstruction syndrome (SOS, previously known as veno-occlusive disease) is due to injury of the hepatic veins and presents similarly to the Budd–Chiari syndrome. It was originally described in Jamaica, where ingestion of toxic pyrrolizidine alkaloids in bush tea (made from plants of the genera *Senecio*, *Heliotropium*, and *Crotalaria*) caused damage to the hepatic veins, but it can be seen in other parts of the world. It also occurs as a complication of chemotherapy and total body irradiation, used before allogeneic bone marrow transplantation. The development of SOS after bone marrow transplantation carries a high mortality. Treatment is supportive, with control of ascites and hepatocellular failure. TIPS has been used in a few cases. Defibrotide is recommended for prophylactic use before bone marrow transplantation in children and adults with a high risk of SOS (e.g., pre-existing hepatic disease or prior treatment with gemtuzumab ozogamicin).

FIBROPOLYCYSTIC DISEASES

These diseases are usually inherited and lead to the presence of cysts or fibrosis in the liver, kidney, and occasionally the pancreas, and other organs.

Polycystic disease of the liver

Multiple cysts can occur in the liver as part of autosomal dominant polycystic disease of the kidney (see Chapter 26). These cysts are usually asymptomatic but occasionally cause abdominal pain and distension. Liver function is normal and complications such as oesophageal varices are very rare. The prognosis is excellent and depends on the kidney disease.

Solitary cysts

These are usually found by chance during imaging and are mainly asymptomatic.

Congenital hepatic fibrosis

In this rare condition the liver architecture is normal but there are broad collagenous fibrous bands extending from the portal tracts. Congenital hepatic fibrosis is often inherited as an autosomal recessive condition but can also occur sporadically. It usually presents in childhood with hepatosplenomegaly, and portal hypertension is common. It may present later in life and can be misdiagnosed as cirrhosis.

A wedge biopsy of the liver may be required to confirm the diagnosis. The outlook is good and the condition should be distinguished from cirrhosis. Patients who bleed do well after endoscopic therapy of varices (or a portocaval anastomosis) because of their good liver function.

Congenital intrahepatic biliary dilation (Caroli's disease)

In this rare, non-familial disease there are saccular dilations of the intrahepatic or extrahepatic ducts. It can present at any age (although it usually does so in childhood) with fever, abdominal pain, and recurrent attacks of cholangitis with gram-negative septicaemia. Jaundice and portal hypertension are absent. Diagnosis is by ultrasound, percutaneous transhepatic cholangiography, and MRCP. There is an increased risk of biliary malignancy.

LIVER ABSCESS

Pyogenic abscess

Pyogenic abscesses are uncommon; they may be single or multiple. The most common used to be a portal pyaemia from intra-abdominal sepsis (e.g., appendicitis or perforations) but nowadays the aetiology is not known in many cases. In the elderly, biliary sepsis is a common cause. Other causes include trauma, bacteraemia, and direct extension from, for example, a perinephric abscess.

The most common organism is *E. coli. Streptococcus milleri* and anaerobic organisms such as *Bacteroides* are often seen. Others include *Enterococcus faecalis*, *Proteus vulgaris*, and *Staphylococcus aureus*. Often the infection is mixed.

Clinical features

Some patients present with malaise lasting several days or even months. Others can present with fever, rigors, anorexia, vomiting, weight loss, and abdominal pain. In these patients a gram-negative septicaemia with shock can occur. On examination there may be little of note; alternatively, the patient may be toxic, febrile, and jaundiced. In such patients the liver is tender and enlarged, and there may be a pleural effusion or a pleural rub in the right lower chest.

Investigations

Patients are often investigated for 'pyrexia of unknown origin' and most investigations will be normal.

- ***Serum bilirubin*** is raised in 25% of cases.
- ***Normochromic normocytic anaemia*** may occur, usually accompanied by a polymorphonuclear leucocytosis.

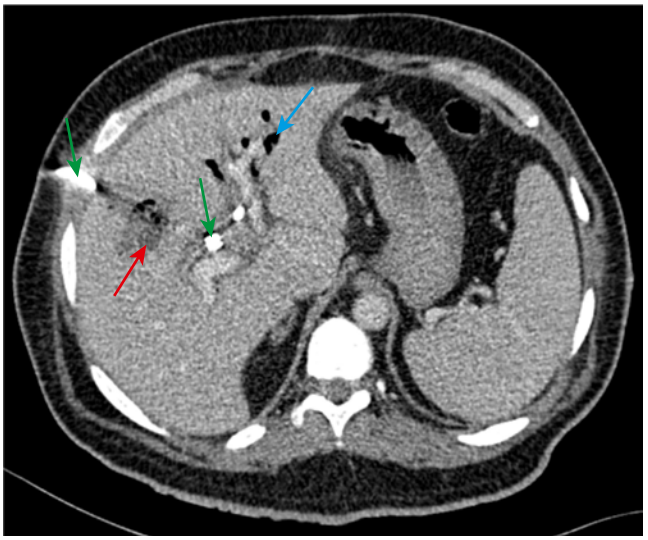

Fig. 23.31 Axial CT image demonstrating a fluid- and gas-containing lesion consistent with a liver abscess *(red arrow)*. The patient has an external biliary drain *in situ (green arrows)* and there is gas in the biliary tree (aerobilia) *(blue arrow)*.

- ***Serum ALP, ESR, and CRP*** are often raised.
- ***Serum vitamin B_{12}*** is very high, as it is stored in and subsequently released from the liver.
- ***Blood cultures*** are positive in only 30% of cases.

Imaging

Ultrasound is useful for detecting abscesses. A CT scan may be of value in complex and multiple lesions (Fig. 23.31). A chest X-ray will show elevation of the right hemidiaphragm, with a pleural effusion in the severe case. Depending on age, imaging of the colon and biliary tree may be necessary to find the source of infection.

Management

Aspiration of the abscess should be attempted under ultrasound control. Antibiotics should initially cover gram-positive, gram-negative, and anaerobic organisms until the causative organism is identified.

Further drainage via a large-bore needle under ultrasound control or surgically may be necessary if resolution is difficult or slow. Any underlying cause must be treated.

Prognosis

The overall mortality depends on the nature of the underlying pathology but has been reduced to approximately 16% with needle aspiration and antibiotics.

Amoebic abscess

This occurs worldwide and must be considered in patients travelling from endemic areas. *Entamoeba histolytica* (see Chapter 42) can be carried from the bowel to the liver in the portal venous system, leading to portal inflammation with the development of multiple microabscesses and, eventually, single or multiple large abscesses.

Clinically, the onset is usually gradual but may be sudden. There is fever, anorexia, weight loss, and malaise. There is often no history of dysentery. On examination the patient looks ill and has tender hepatomegaly and signs of an effusion or consolidation in the base of the right side of the chest. Jaundice is unusual.

Investigations

These are as for pyogenic abscess, plus:

- ***Serological tests for amoeba*** (e.g., haemagglutination, amoebic complement fixation test, ELISA). These are always positive, particularly if there are bowel symptoms; they remain positive after a clinical cure and therefore do not indicate current disease. A repeat negative test, however, is good evidence against an amoebic abscess.
- ***Diagnostic aspiration of fluid*** looking like anchovy sauce.

Management

Metronidazole 800 mg three times daily is given for 10 days. Aspiration is used in patients failing to respond, in those with multiple and sometimes large abscesses, and in those with abscesses in the left lobe of the liver or impending rupture. To clear infection from the intestine paromomycin or diloxanide must also be taken.

Complications

Complications include rupture, secondary infection, and septicaemia.

OTHER INFECTIONS OF THE LIVER

Schistosomiasis

Schistosoma mansoni and *S. japonicum* affect the liver but *S. haematobium* rarely does so (see also Chapter 42). During their life cycle the ova reach the liver via the venous system and obstruct the portal branches, producing granulomas, fibrosis, and inflammation, but not cirrhosis.

Clinical features and investigations

Clinically, there is hepatosplenomegaly and portal hypertension, which is particularly severe with *S. mansoni*.

Investigations show a raised serum ALP, and ova can be found in the stools (centrifuged deposits) and in rectal and liver biopsies. Skin tests and other immunological tests often give false results and may also be positive because of past infection.

Management

Treatment is with praziquantel, but fibrosis still remains with a potential risk of portal hypertension and associated bleeding, characteristically pre-sinusoidal due to intense portal fibrosis.

Hydatid disease

Cysts caused by *Echinococcus granulosus* are single or multiple. They usually occur in the lower part of the right lobe. The cyst has three layers: an outside layer derived from the host, an intermediate laminated layer, and an inner germinal layer that buds off brood capsules to form daughter cysts (see also Chapter 42).

Clinical features and investigations

Clinically, there may be no symptoms or there may be a dull ache and swelling in the right hypochondrium.

Investigations show a peripheral eosinophilia in 30% of cases and usually a positive hydatid complement fixation test or haemagglutination (85%). Plain abdominal X-ray may show calcification of the outer coat of the cyst. Ultrasound and CT scan demonstrate cysts and may show diagnostic daughter cysts within the parent cyst (**Fig. 23.32**).

Management

Medical treatment (e.g., with albendazole 10 mg/kg, which penetrates into large cysts) results in cysts becoming smaller. Puncture, aspiration, injection, re-aspiration (PAIR) has been used since the 1980s. Fine-needle aspiration is undertaken under ultrasound control with chemotherapeutic cover. Surgery can be performed with removal of the cyst intact, if possible, after first sterilizing the cyst with alcohol, saline, or cetrimide. Chronic calcified cysts can be left; there have been no well-designed clinical trials for any therapy.

Complications and prognosis

These include rupture into the biliary tree or other organs, or intraperitoneally, with spread of infection. The prognosis without any complications is good, although there is always a risk of rupture. ***Preventative measures*** include deworming pet dogs and preventing pets from eating infected carcasses, as well as veterinary control programmes.

Echinococcus multilocularis causes alveolar echinococcosis and is almost exclusively a hepatic disease, with a high mortality if not treated. Early diagnosis enables radical surgery and then continued chemosuppression.

Acquired immunodeficiency syndrome

The liver is often involved in AIDS and is a significant cause of morbidity or mortality. HIV itself is not the cause of the liver abnormalities. Clinical hepatomegaly is common (60% of patients). The following are seen, although less frequently in areas where anti-retroviral therapy (ART) is available:

- ***Pre-existing/coincidental viral hepatitis.*** The hepatitis (HBV, HCV, HDV) progresses more rapidly and is a leading cause of death.
- ***Neoplasia.*** Kaposi's sarcoma and non-Hodgkin lymphoma may be seen, and there is an increased risk of HCC.
- ***Opportunistic infection*** (e.g., *Mycobacterium tuberculosis*, *M. avium-intracellulare*, *Cryptococcus*, *Candida albicans*, toxoplasmosis).
- ***Drug hepatotoxicity.***
- ***Secondary sclerosing cholangitis***.
- ***Non-cirrhotic portal hypertension.*** This is associated with ART and is more common in people who have had profound immunosuppression and received early nucleotides, such as didanosine (DDI). The incidence is believed to be declining with the introduction of early ART and less toxic drugs.

LIVER DISEASE IN PREGNANCY

See Chapter 48.

LIVER TUMOURS

Secondary liver tumours

The most common liver tumour is a secondary (metastatic) tumour, particularly from the gastrointestinal tract (from the distribution

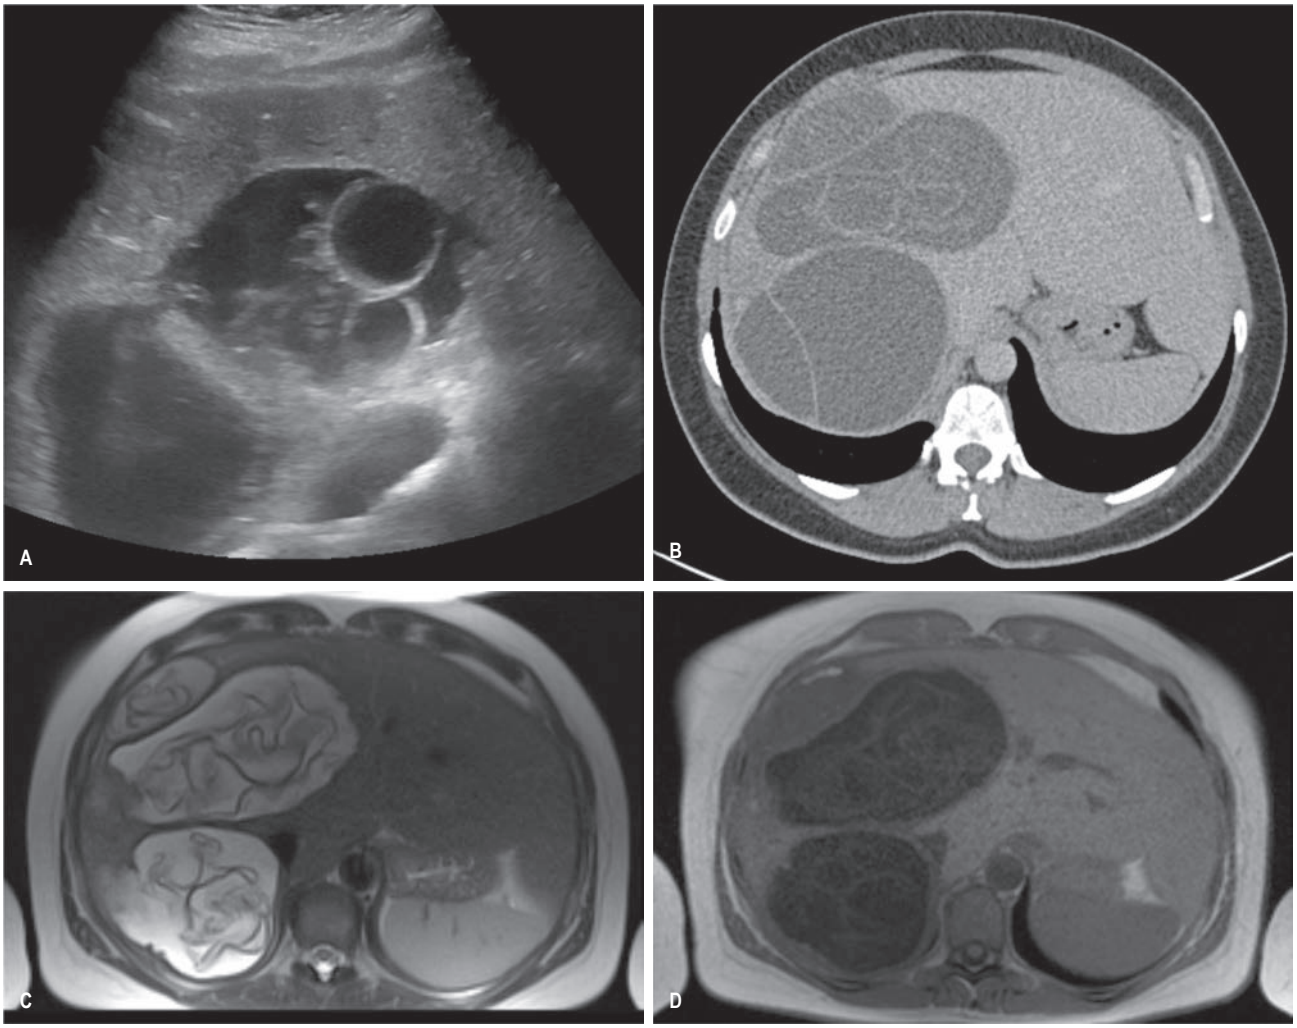

Fig. 23.32 Multimodality imaging from the same patient demonstrating hydatid cysts containing multiple daughter cysts. **(A)** Ultrasound. **(B)** CT. **(C)** T2-weighted MRI. **(D)** T1-weighted MRI.

of the portal blood supply), breast, or bronchus. Secondary liver tumours are usually multiple.

Clinical features

These are variable but usually include weight loss, malaise, upper abdominal pain, and hepatomegaly, with or without jaundice.

Investigations

Ultrasound is the primary investigation, with CT or MRI to define metastases and look for a primary. The serum ALP is almost invariably raised.

Management

This will depend on the site of the primary and the burden of liver metastases. The best results are obtained in colorectal cancer with few hepatic metastases. If the primary tumour is removed and hepatic resection is performed, reasonable survival rates are possible. Chemotherapy is used, particularly with breast cancer. Radiofrequency ablation of the metastases is an alternative to surgery. Thermal therapy and cryotherapy are also used.

Primary malignant tumours

Primary liver tumours may be benign or malignant.

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the sixth most common cancer worldwide and the fourth leading cause of cancer-related death globally.

Aetiology

HBV infection is the most prominent risk factor for HCC development, accounting for approximately 50% of cases. The risk attributed to HCV infection has substantially decreased due to the very high cure rates with antiviral drugs, although those with cirrhosis are still at high risk for HCC incidence even after HCV clearance. In areas where HBV is prevalent, 90% of patients with this cancer are positive for HBV with 80% of HCC cases having cirrhosis, whereas cirrhosis is always present in HCV patients that develop HCC. The development of HCC is related to the integration of viral HBV DNA into the genome of the host hepatocyte (see 'Hepatitis B virus [pathogenesis]'), and to the degree of viral replication (>10 000 copies/mL). Primary liver cancer is also associated with other forms of cirrhosis, such as alcoholic cirrhosis, NAFLD-associated cirrhosis, and haemochromatosis. It occurs two to three times more often in males than females, and males have poorer survival rates and higher recurrence rates after treatment. Other aetiological factors include aflatoxin (a metabolite of a fungus found in groundnuts) and androgenic anabolic steroids.

Pathology

The tumour is either single or occurs as multiple nodules throughout the liver. Histologically, it consists of cells resembling hepatocytes. It can metastasize via the hepatic or portal veins to the lymph nodes, bones, and lungs.

Clinical features

The clinical features include weight loss, anorexia, fever, an ache in the right hypochondrium, and ascites. The rapid development of these features in a cirrhotic patient is suggestive of HCC. On examination, an enlarged, irregular, tender liver may be felt. Increasingly, due to surveillance, HCC is found without symptoms in patients with cirrhosis.

Investigations

- Routine liver biochemistry, full blood count, serum creatinine, and electrolytes.
- ***Serum α-fetoprotein*** may be raised but is normal in approximately 40% of patients.
- ***Ultrasound*** scans show filling defects in 90% of cases.
- ***MRI with contrast or triple phase (see Fig. 23.33D–F).*** CT scans (**Fig. 23.33A–C**) identify HCC but it can be difficult to confirm the diagnosis in lesions smaller than 1 cm, where the diagnostic accuracy of MRI is higher.
- ***Tumour biopsy*** (**Fig. 23.34**), particularly under ultrasonic guidance, is rarely used for diagnosis, as imaging techniques readily show characteristic appearances (hypervascularity of the nodule and lack of portal vein washout) and because seeding along the biopsy tract can occur.

Management and prognosis

See Chapter 41.

Prevention

Persistent HBV infection, usually acquired after perinatal infection, is a strong risk factor for HCC in many parts of the world, such as South-east Asia. Widespread vaccination against HBV has reduced the annual incidence of HCC in Taiwan.

Cholangiocarcinoma

Cholangiocarcinomas are increasing in incidence and can be extrahepatic or intrahepatic (see also Chapters 24 and 41). Intrahepatic adenocarcinomas arising from the bile ducts account for approximately 10% of primary tumours of the liver and biliary tract. They are not associated with cirrhosis or hepatitis B. In the Far East, they may be associated with infestation with *Clonorchis sinensis* or *Opisthorchis viverrini*. The clinical features are similar to those of primary HCC, except that jaundice is frequent with hilar tumours, and cholangitis is more common. There is an increased association with inflammatory bowel disease and PSC (see Chapter 24).

Surgical resection is rarely possible and patients usually die within 6 months. Transplantation is contraindicated, outside of specialized protocols.

Benign tumours

The most common benign tumour is a ***haemangioma*** and occurs in approximately 10% of people. They are usually small and single but can be multiple and large. Haemangiomas are usually found incidentally on ultrasound, CT, or MRI, and have characteristic appearances. They require no treatment.

Hepatic adenomas are rare benign tumours, more common in females and associated with oral contraceptives. Obesity, non-alcoholic steatohepatitis, and metabolic syndromes are associated with hepatic adenomatosis. They are associated with risks of haemorrhage and malignant transformation and can present with abdominal pain or intraperitoneal bleeding. Elective resection is recommended in all males with adenomas (as malignant potential is greater) and in females with adenomas greater than 5 cm. Resection may also be required for patients with abdominal pain.

MISCELLANEOUS CONDITIONS OF THE LIVER

Hepatic mitochondrial injury syndromes

These syndromes, in which there is mitochondrial damage with inhibition of β-oxidation of fatty acids, can be categorized as having the following causes:

- ***Genetic***, with abnormalities that include medium-chain acyl-coenzyme A dehydrogenase deficiency, leading to microsteatosis.
- ***Toxins*** leading to liver failure, which include aflatoxin and cerulide (produced by *Bacillus cereus*); the latter causes food poisoning (see Chapter 42).
- ***Drugs*** (e.g., i.v. tetracycline, valproic acid, and nucleoside reverse-transcriptase inhibitors), which can produce a fatal microsteatosis.
- ***Idiopathic***, the best known being fatty liver of pregnancy (see Chapter 48) and Reye's syndrome. The latter, caused by inhibition of β-oxidation and uncoupling of oxidative phosphorylation in mitochondria, leads in children to an acute encephalopathy and diffuse microvesicular fatty infiltration of the liver. Aspirin ingestion and viral infections have been implicated as precipitating agents. Mortality is about 50%, usually due to cerebral oedema.

Idiopathic adult ductopenia

This unexplained condition is characterized by pruritus and cholestatic jaundice. Histology of the liver shows a decrease in intrahepatic bile ducts in at least 50% of the portal tracts, together with the features of cholestasis and marked fibrosis or cirrhosis. In most, the disease is progressive and the only treatment is liver transplantation.

Indian childhood cirrhosis

This condition of children is seen in the Indian subcontinent. The cause is unknown. Eventually, there is development of a micronodular cirrhosis with excess copper in the liver.

Hepatic porphyrias

These are dealt with in Chapter 36.

Cystic fibrosis

Cystic fibrosis (see also Chapter 20) mainly affects the lung and pancreas, but patients can develop fatty liver, cholestasis, and cirrhosis. The aetiology of the liver involvement is unclear.

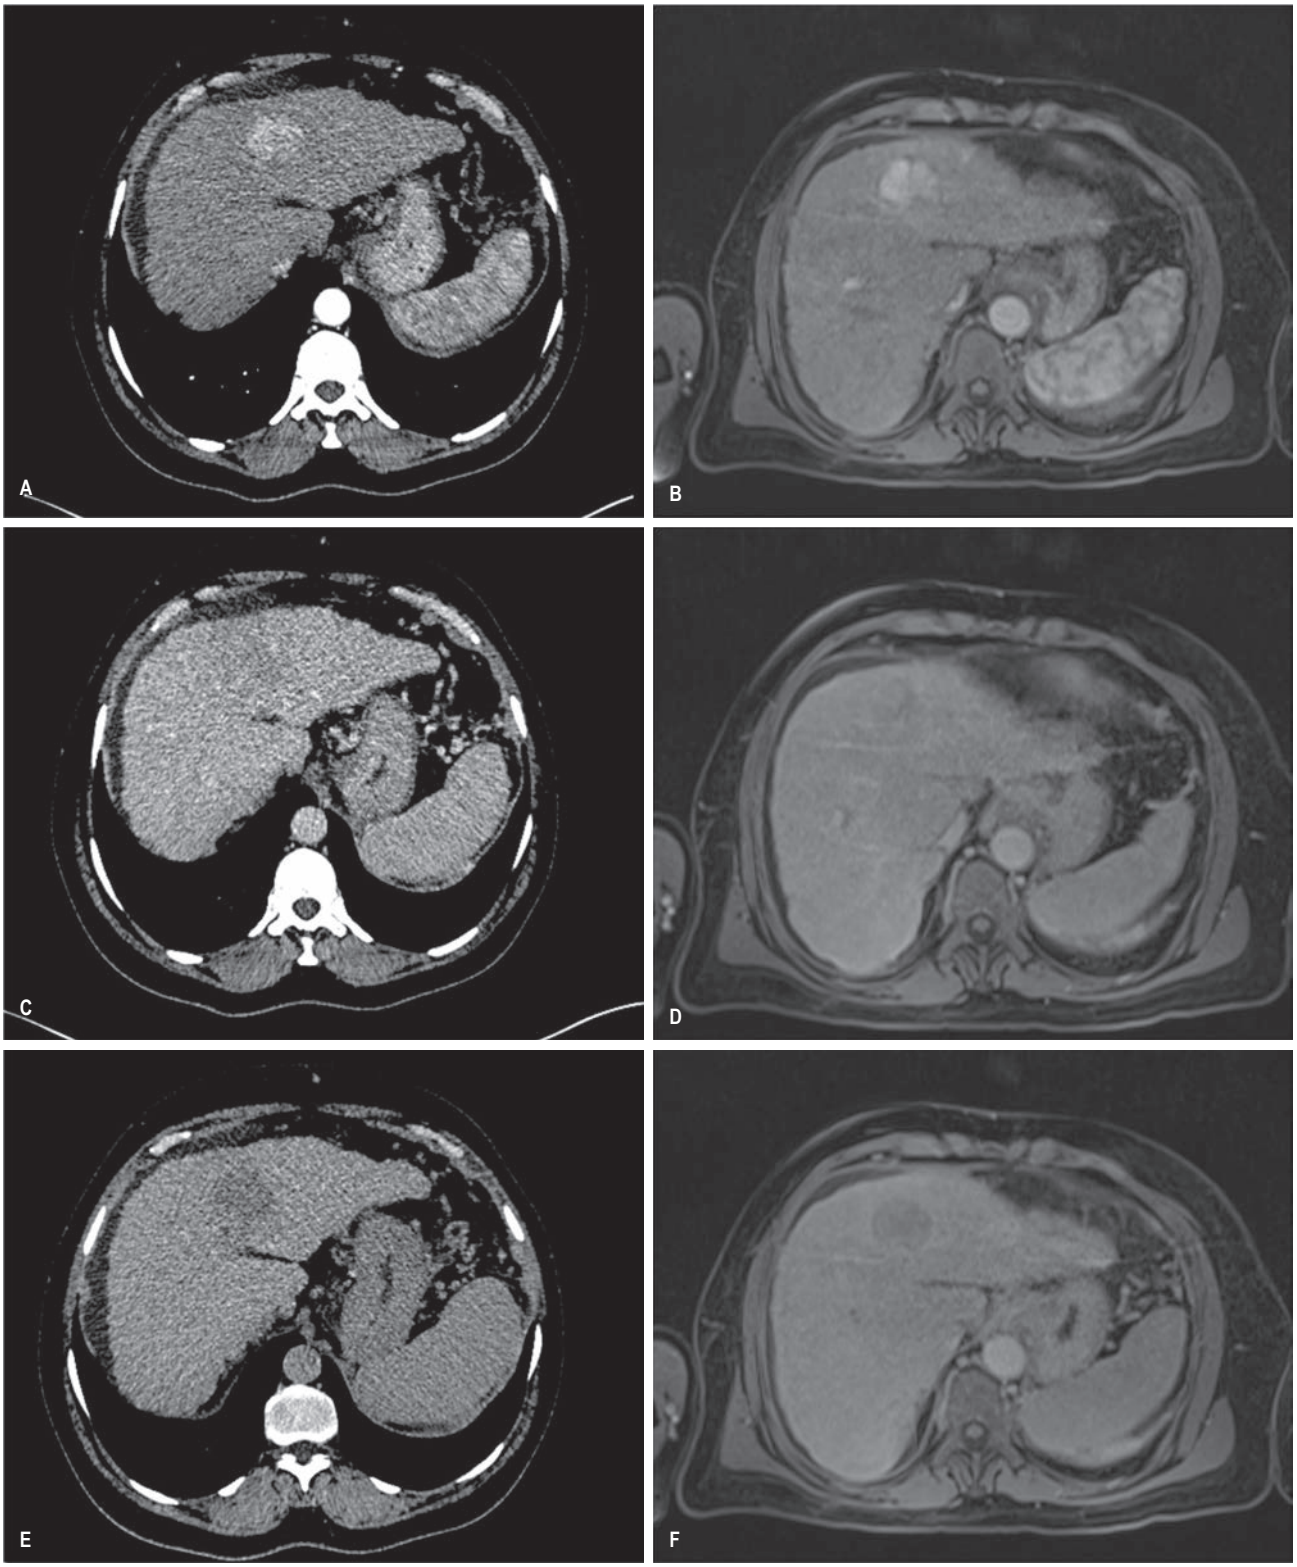

Fig. 23.33 Hepatocellular carcinoma (HCC). Two cases of HCC on **(A–C)** multiphasic contrast-enhanced CT and **(D–F)** MRI. HCC classically demonstrates enhancement on the arterial phase imaging (A, D) and washout on more delayed phases of imaging. In both cases there is subtle washout on the portal venous phase imaged (B, E) with more definite washout on the delayed phase imaging (C, F).

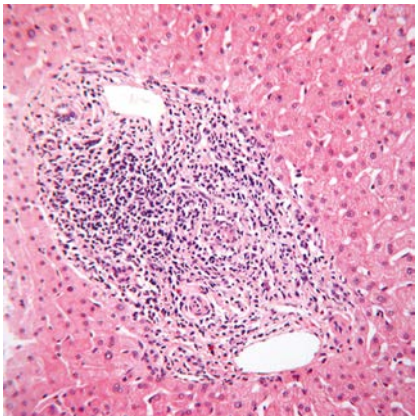

Fig. 23.34 Hepatocellular carcinoma. (Haematoxylin and eosin, ×25.)

Coeliac disease

Abnormal liver biochemical tests are common in coeliac disease (see also Chapter 22) and return to normal with a gluten-free diet. A tissue transglutaminase test should be performed if hepatic causes are not found when investigating abnormal liver biochemistry.

DRUGS AND THE LIVER

Drug metabolism

The liver is the major site of drug metabolism. Drugs are converted from fat-soluble to water-soluble substances that can be excreted in the urine or bile. This metabolism of drugs is mediated by a group of mixed-function enzymes (see Chapter 7).

Drug hepatotoxicity

Many drugs impair liver function. When abnormal liver biochemical tests are found, drugs should always be considered as a cause, particularly when other causes have been excluded. Damage to the liver by drugs (DILI) is usually classified as being either predictable (or dose-related) or non-predictable (not dose-related) (see **Box 7.9**). However, there is considerable overlap and at least ***six mechanisms*** may be involved in the production of damage:

1. disruption of intracellular calcium homeostasis
2. disruption of bile canalicular transport mechanisms
3. formation of non-functioning adducts (enzyme–drug), which may then lead to
4. presentation on the surface of the hepatocyte as new immunogens (attacked by T cells)
5. induction of apoptosis
6. inhibition of mitochondrial function, which prevents fatty acid metabolism and accumulation of both lactate and reactive oxygen species.

The predominant mechanism or combination of mechanisms determines the type of liver injury: that is, hepatitic, cholestatic, or immunological (skin rashes, fever, and arthralgia, i.e., serum sickness syndrome). Eosinophilia and circulating immune complexes and antibodies are occasionally detected.

When a small amount of hepatotoxic drug whose effect is dose-dependent (e.g., paracetamol) is ingested, a large proportion of it undergoes conjugation with glucuronide and sulphate, while the remainder is metabolized by microsomal enzymes to produce toxic derivatives that are immediately detoxified by conjugation with glutathione. If larger doses are ingested, the former pathway becomes saturated and the toxic derivative is produced at a faster rate. Once the hepatic glutathione is depleted, large amounts of the toxic metabolite accumulate and produce damage (see Chapter 15).

The 'predictability' of drugs to produce damage can, however, be affected by metabolic events preceding their ingestion. For example, chronic alcohol users may become more susceptible to liver damage because of the enzyme-inducing effects of alcohol, or ill or starving patients may become susceptible because of the depletion of hepatic glutathione produced by starvation. Many other factors, such as environmental or genetic effects, may be involved in determining the 'susceptibility' of certain patients to certain drugs.

The incidence of drug hepatotoxicity is 14 per 100 000 population with a 6% mortality. It is the most common cause of acute liver failure in the USA. Liver transplantation is used.

Hepatitic damage

The type of damage produced by various drugs is shown in **Box 23.27**. Most reactions occur within 3 months of starting the drug. Monitoring liver biochemistry in patients on long-term treatment, such as anti-tuberculosis therapy, is mandatory. If a drug is suspected of causing hepatic damage, it should be stopped immediately. Liver biopsy is of limited help in confirming the diagnosis, but occasionally, hepatic eosinophilia or granulomas may be seen. Diagnostic challenge with subtherapeutic doses of the drug is sometimes required after the liver biochemistry has returned to normal, to confirm the diagnosis.

Individual drugs

Paracetamol

In high doses, paracetamol produces liver cell necrosis (see earlier). The toxic metabolite binds irreversibly to liver cell membranes. Overdosage is discussed in Chapter 15.

Steroid compounds

Cholestasis is caused by natural and synthetic oestrogens, as well as methyltestosterone. These agents interfere with canalicular biliary flow by blocking MRP2 and MDR3 (see **Fig. 23.5**) and cause a pure cholestasis.

Cholestasis is rare with the contraceptive pill because of the low dosage used. However, the contraceptive pill is associated with an increased incidence of gallstones, hepatic adenomas (rarely, HCCs), the Budd–Chiari syndrome, and peliosis hepatis. The latter condition, which also occurs with anabolic steroids, consists of dilation of the hepatic sinusoids to form blood-filled lakes.

Phenothiazines

Phenothiazines (e.g., chlorpromazine) can produce a cholestatic picture owing to a hypersensitivity reaction. This occurs in 1% of patients, usually within 4 weeks of starting the drug. Typically, it is associated with a fever and eosinophilia. Recovery occurs on stopping the drug.

Anti-tuberculous chemotherapy

Isoniazid produces elevated aminotransferases in 10% to 20% of patients. Hepatic necrosis with jaundice occurs in a smaller percentage. The hepatotoxicity of isoniazid is related to its metabolites and is dependent on acetylator status. Rifampicin produces hepatitis, usually within 3 weeks of starting the drug, particularly

Box 23.27 Liver damage produced by some drugs

Types of liver damage	Drugs	
Zone 3 necrosis	Carbon tetrachloride *Amanita* mushrooms Paracetamol	Salicylates Piroxicam Cocaine
Zone 1 necrosis	Ferrous sulphate	
Microvesicular fat	Sodium valproate	Tetracyclines
Steatohepatitis	Amiodarone Synthetic oestrogens	Nifedipine
Fibrosis	Methotrexate Other cytotoxic agents Arsenic	Vitamin A Retinoids
Vascular		
Sinusoidal dilation	Contraceptive drugs	Anabolic steroids
Peliosis hepatis	Azathioprine Oral contraceptives	Anabolic steroids, e.g., danazol
Veno-occlusive	Pyrrolizidine alkaloids (*Senecio* in bush tea)	Cytotoxics—cyclophosphamide
Acute hepatitis	Isoniazid Rifampicin Methyldopa Atenolol Enalapril Verapamil Ketoconazole	Cytotoxic drugs Clonazepam Disulfiram Niacin Volatile liquid anaesthetics, e.g., halothane Infliximab
Chronic hepatitis	Methyldopa Nitrofurantoin	Fenofibrate Isoniazid
General hypersensitivity	Sulphonamides, e.g., Sulphasalazine Co-trimoxazole Fansidar Penicillins, e.g., Flucloxacillin Ampicillin Amoxicillin Co-amoxiclav NSAIDs, e.g., Salicylates Diclofenac	Allopurinol Anti-thyroid, e.g., Propylthiouracil Carbimazole Quinine, e.g., quinidine Diltiazem Anticonvulsants, e.g., phenytoin
Canalicular cholestasis	Sex hormones Ciclosporin Chlorpromazine Haloperidol Erythromycin Flucloxacillin	Fucidin Cimetidine/ranitidine Nitrofurantoin Imipramine Azathioprine Oral hypoglycaemics
Biliary sludge	Ceftriaxone	
Sclerosing cholangitis	Hepatic arterial infusion of 5-fluorouracil	
Hepatic tumours	Pills with high hormone content (adenomas)	
Hepatocellular carcinoma	Contraceptive pill	Danazol
Nodular regenerative hyperplasia	Azathioprine	Some anti-retroviral therapies

Note: Anti-HIV drugs, e.g., maraviroc, cause hepatic dysfunction.
NSAID, Non-steroidal anti-inflammatory drug.

in patients on high doses. Pyrazinamide produces abnormal liver biochemical tests and, rarely, liver cell necrosis.

Amiodarone

This leads to a steatohepatitis histologically, and liver failure if the drug is not stopped in time.

Sodium valproate

This causes mitochondrial injury with microvesicular steatosis. Intravenous carnitine should be used as an antidote.

Drug prescribing for patients with liver disease

The metabolism of drugs is impaired in severe liver disease (with jaundice and ascites), as the removal of many drugs depends on liver blood flow and the integrity of the hepatocyte. In general, therefore, the effect of drugs is prolonged by liver disease and also by cholestasis. This is further accentuated by portosystemic shunting, which diminishes the first-pass extraction of drugs. With hypoproteinaemia, there is decreased protein binding of some drugs,

and bilirubin competes with many drugs for the binding sites on serum albumin. In patients with PSE, care must be taken in prescribing drugs with a central depressant action, such as narcotics like codeine and anxiolytics. Other common drugs to be avoided in cirrhosis include angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (which may provoke hepatorenal syndrome), and NSAIDs (which cause bleeding).

CORE SKILLS AND KNOWLEDGE

In high-income countries, up to 15% of the adult population have gallstones, which are the leading cause of hepatobiliary disease; although in many they do not cause symptoms, acute pancreatitis and ascending cholangitis are serious conditions with a significant mortality. Cancers of the pancreas and gall bladder are not uncommon, and often present late.

Patients with diseases of the biliary tract and pancreas may be cared for as inpatients and outpatients by general surgeons, gastroenterologists, or hepatologists, depending on local services, with complex disease being looked after in specialist centres where there is hepatobiliary surgical, radiological, and endoscopic support. Endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic ultrasound (EUS) are core procedures, allowing a range of interventions including stone extraction, stent placement, and direct biopsy of lesions.

Key skills in this field include:

- Managing emergency conditions, such as ascending cholangitis and acute pancreatitis
- Being aware of the need for vigilance in the early diagnosis of pancreatic cancer and cholangiocarcinoma.

Opportunities for learning about biliary tract and pancreatic disease include searching out, interviewing, and examining inpatients with these conditions (who may be cared for on general surgical or gastrointestinal wards), observing ERCP and EUS procedures, and seeking to understand the treatment strategies employed. Attending an upper gastrointestinal surgical clinic and acute surgical on call, a surgical list to observe a laparoscopic cholecystectomy, and an upper gastrointestinal multidisciplinary team meeting may all prove useful.

BACKGROUND

Biliary and pancreatic disease places a major burden on healthcare systems worldwide. In the West, acute pancreatitis and gallstone disease are the two most common gastrointestinal causes of urgent hospital admission. Pancreatic and biliary tree neoplasms carry a poor prognosis, pose significant diagnostic challenges, and are increasing in incidence.

Patients with upper abdominal pain (acute or chronic), cholestasis (painless or painful), or insidious onset of weight loss commonly present in primary and secondary care. Such presentations can represent major underlying pathology and should warrant prompt and appropriate investigation.

Key skills for managing pancreatobiliary disease include the ability to:

- recognize patterns of liver enzyme derangement, including cholestasis
- manage severe sepsis complicating biliary disease
- select a rational imaging modality for upper abdominal pain
- recognize and manage nutritional deficiency in patients with acute and chronic pancreatitis
- recognize and institute management of diabetes that is due to pancreatitis (see Chapter 35).

Management of pancreatobiliary disease may require the appropriate use of

- antibiotics in the management of biliary sepsis
- pancreatic enzyme supplements
- fat-soluble vitamin supplements (vitamins A, D, and K)
- proton pump inhibitors to improve pancreatic enzyme function
- chemotherapy and immunotherapy drugs in the management of pancreatobiliary adenocarcinoma.

Ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) technologies enable the biliary tree and pancreas to be visualized with increasing resolution. Widespread use of such imaging has led to improved diagnosis but also to a burgeoning need to characterize and manage incidental, small, often asymptomatic lesions, particularly cysts in the pancreas.

Endoscopic diagnosis of pancreatobiliary disease has been enhanced by improvements in EUS technology, and the

reemergence of direct cholangioscopy for visualization of the bile duct. Therapeutic endoscopy and laparoscopic surgery are now widely available and permit a minimally invasive approach to the management of almost all gallstone disease, and to the resection or palliation of pancreatobiliary cancer.

GALL BLADDER AND BILIARY SYSTEM

The structure and function of the biliary system and the formation of bile are discussed in Chapter 23.

BILIARY SYSTEM (FIG. 24.1)

Bile canaliculi form a network between the hepatocytes. These join to form thin bile ductules, which, in turn, enter the bile ducts in the portal tracts. These then combine to form the right and left hepatic ducts, which leave each liver lobe. The hepatic ducts join at the porta hepatis to form the common hepatic duct. The cystic duct connects the gall bladder to the lower end of the common hepatic duct. The gall bladder lies under the right lobe of the liver, and stores and concentrates hepatic bile; its capacity is approximately 50 mL. The common bile duct (CBD) is formed at the junction of the cystic and common hepatic ducts, and is 8 mm or less in diameter, passing through the head of the pancreas and narrowing at its lower end to pass into the duodenum. The CBD and pancreatic duct open into the second part of the duodenum, most often through a common channel at the ampulla of Vater, which contains the smooth muscle sphincter of Oddi. This contracts rhythmically and prevents all of the bile from entering the duodenum, by maintaining a higher pressure than the gall bladder in the fasting state.

Gallstones

Gallstone disease represents a major cause of patient morbidity, particularly in the Western world, and has a major impact on healthcare economics. Gallstones may be present at any age but are unusual before the third decade. Their prevalence is strongly influenced by both age and sex. There is a progressive increase in the presence of gallstones with age and the prevalence is two to three times higher in females than in males, although this difference is less marked in the sixth and seventh decades. At this age the prevalence ranges

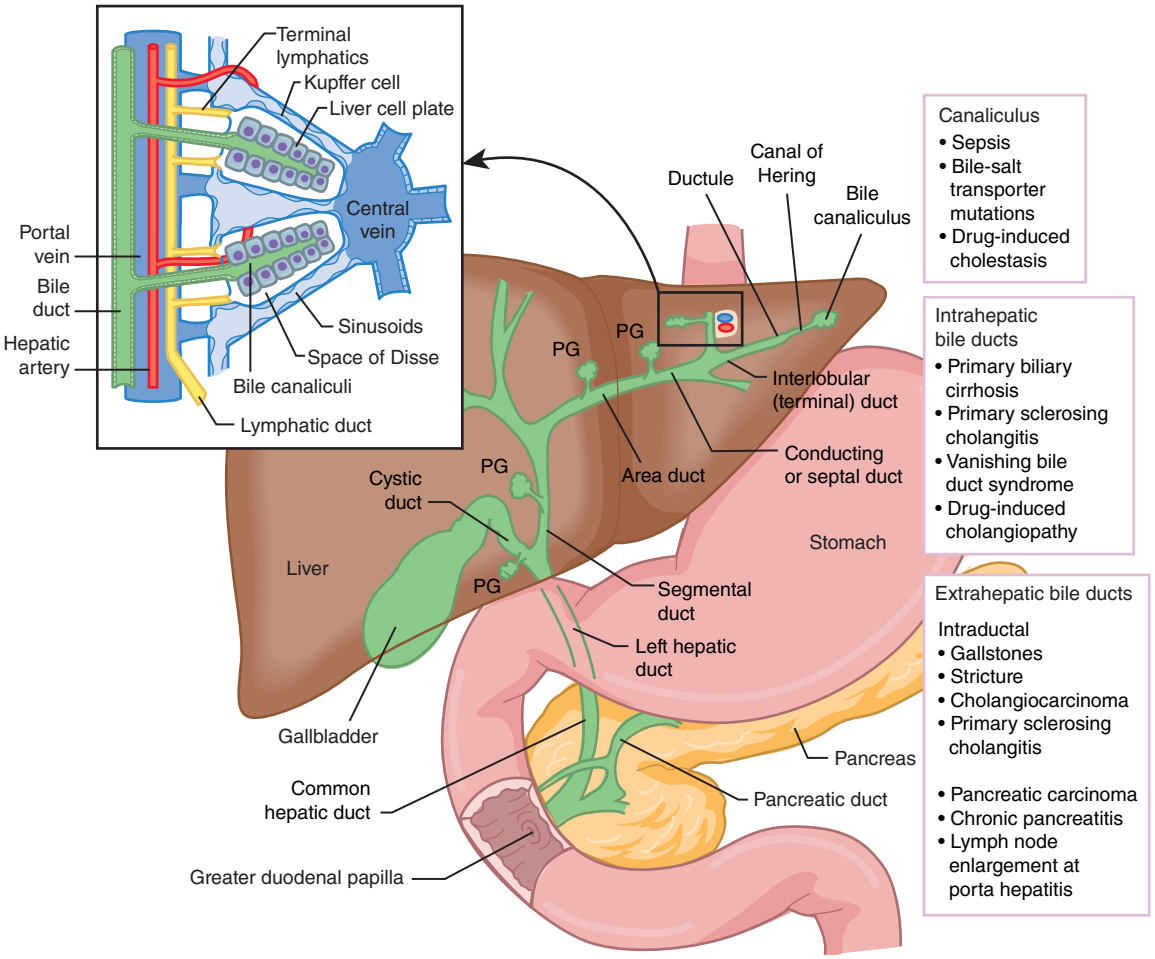

Fig. 24.1 Structure of the biliary system. The various structures of the biliary system are shown schematically. The large segmental ducts have small adjacent peribiliary glands (PG). The finer branches are highlighted in the box at the upper left of the image. The boxes at the right show various biliary tract diseases at the specific levels affected. *PBC,* Primary biliary cholangitis; *PSC,* primary sclerosing cholangitis. *(From Lefkowitch, J. H. [2021].* Scheuer's liver biopsy interpretation *[10th ed.]. Elsevier, p. 59.)*

between 20% and 30%. The increase in life expectancy is reflected in a greater burden of symptomatic gallstone disease. There are considerable racial differences, gallstones being more common in Scandinavians, South Americans, and Native North Americans but less so in Asian and African groups. These racial differences may reflect both genetic and dietary factors. Some of these differences are being eroded by the adoption of Western diets containing high cholesterol in countries with emerging economies.

Pathogenesis

Types of gallstone

The large majority of gallstones are of two types: cholesterol stones (containing >50% cholesterol) and, less frequently, pigment stones, predominantly composed of calcium bilirubinate or polymer-like complexes with calcium, copper, and some cholesterol.

Cholesterol gallstones

This type of stone accounts for 85% of gallstones in the Western world. The formation of cholesterol stones is the consequence of cholesterol crystallization from gall bladder bile. This is dependent on three factors:

- cholesterol supersaturation of bile
- crystallization-promoting factors within bile
- motility of the gall bladder.

The majority of cholesterol is derived from hepatic uptake from dietary sources. However, hepatic biosynthesis may account for up to 20%. The rate-limiting step in cholesterol synthesis is β-hydroxyβ-methylglutaryl-CoA (HMG-CoA) reductase, which catalyzes the first step: that is, the conversion of acetate to mevalonate.

- The cholesterol formed is cosecreted with phospholipids into the biliary canaliculus as unilamellar vesicles.
- Cholesterol will crystallize into stones only when the bile is supersaturated with cholesterol relative to the bile salt and phospholipid content. This can occur as a consequence of excess cholesterol secretion into bile, which, in some instances, has been shown to be due to an increase in HMG-CoA reductase activity.
- Increased secretion of cholesterol into bile has also been associated with insulin resistance and the metabolic syndrome (see Chapter 37).
- A high-cholesterol diet increases biliary cholesterol secretion and decreases bile salt synthesis and the bile salt pool in cholesterol gallstone subjects but not in controls.

These findings suggest that increased intestinal uptake of cholesterol could play a role in gallstone pathogenesis. In support of this observation, pharmacological inhibition of cholesterol absorption prevents gallstone formation in a mouse model. Ezetimibe is a highly selective intestinal cholesterol absorption inhibitor, suppressing the uptake of dietary and biliary cholesterol across the brush border membrane of the enterocyte. This may offer a potential therapy for the management/prevention of gallstone formation in patients and it remains under investigation.

While cholesterol supersaturation of bile is essential for cholesterol stone formation, many individuals in whom such supersaturation occurs will never develop stones. It is the balance between cholesterol crystallizing and solubilizing factors that determines whether cholesterol will crystallize out of solution. A number of lipoproteins have been reported as putative crystallizing factors.

Statins are effective in the treatment of hypercholesterolaemia by competitively inhibiting HMG-CoA reductase. There is emerging evidence that statins reduce cholesterol secretion into bile and, by doing so, promote gallstone dissolution. The prevalence of gallstone disease in patient groups taking statins for the management of hypercholesterolaemia appears to be reduced.

Leptin (see Chapter 37) has been shown to increase cholesterol secretion into bile. While obesity is a risk factor for cholelithiasis, rapid weight loss (for instance, due to following a very low-calorie diet) also results in an increased risk of cholesterol gallstones, which may relate to *relative* elevations in leptin levels observed in those affected.

An alternative mechanism of supersaturation is a decreased bile salt content, which may occur as a consequence of bile salt loss (e.g., terminal ileal resection or ileal involvement with Crohn's disease).

The ***composition of the bile salt pool*** may also influence the ability to maintain cholesterol in solution. There is evidence that an increased proportion of deoxycholic acid (a hydrophobic bile acid) in the bile acid pool may predispose to cholesterol stone formation. This has been linked with slow colonic transit, during which cholic acid, the primary bile acid, may undergo microbial enzyme metabolism, yielding deoxycholic acid, which is then absorbed back into the bile salt pool (see **Fig. 23.5**).

Evidence from ***epidemiological***, family, and twin studies points to the role of genetic factors in gallstone formation. A number of lithogenic genes have been identified, which may interact with environmental factors. The process of bile formation is maintained by a network of adenosine triphosphate-binding cassette (ABC) transporters in the hepatocyte canalicular membrane, which enables biliary secretion of cholesterol, bile salts, and phospholipids. This process is regulated by the nuclear receptors farnesoid X receptor (FXR) and liver X receptor (LXR). Loss-of-function mutations in specific ABC transporter genes have been associated with cholesterol gallstones secondary to bile salt and phospholipid deficiencies within the nascent bile (**Fig. 24.2**). However, monogenic susceptibility appears uncommon. There are rare cases in which a single missense mutation of the multidrug-resistant *(MDR3)* gene has been associated with extensive intra- and extrahepatic cholelithiasis at an early age (<40 years).

Gall bladder motility represents a further factor that may influence the cholesterol crystallization from supersaturated bile. There is evidence from animal models that gall bladder stasis leads to cholesterol crystallization mediated by hypersecretion of mucin. Abnormalities of gall bladder motility have been suggested as factors in such circumstances as pregnancy, multiparity, and diabetes, as well as octreotide-related gall bladder stones (see Chapter 34). Recognized risk factors for cholesterol gallstones are shown in **Box 24.1**.

Bile pigment stones

The pathogenesis of pigment stones is entirely independent of cholesterol gallstones. There are two main types of pigment gallstone: black and brown.

Black pigment gallstones are composed of calcium bilirubinate and a network of mucin glycoproteins that interlace with salts, such as calcium carbonate and/or calcium phosphate. These stones range in colour from deep black to very dark brown and have a glass-like cross-sectional surface on fracturing. Because hyperbilirubinaemia is the critical risk factor, black stones are associated with all major ***haemolytic anaemias***, such as spherocytosis, sickle cell disease, and thalassaemia, and also with subclinical haemolysis from prosthetic valve replacements, malaria, hypersplenism from hepatic cirrhosis, and foot trauma in long-distance runners. An increased prevalence of black pigment gallstones is also seen

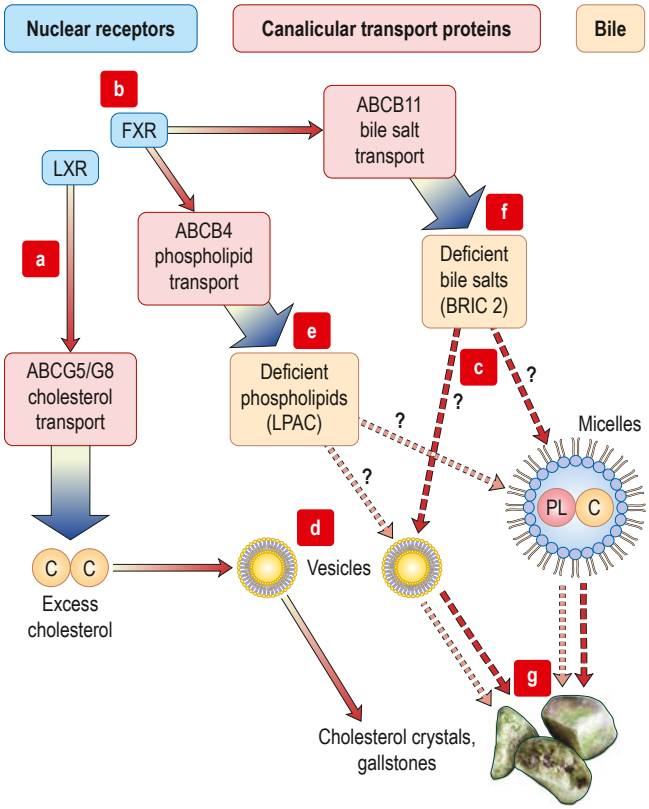

Fig. 24.2 Nascent bile formation at the hepatocytic canalicular membrane, biliary cholesterol solubilization, and gallstone formation. **(a)** ABCG5/G8 transports cholesterol into bile (regulated by nuclear receptor LXR). **(b)** ABCB11 and ABCB4 transport bile salts and phosphatidylcholine into bile (regulated by nuclear receptor FXR). **(c)** Bile cholesterol is solubilized in mixed micelles or contained in cholesterol–phospholipid vesicles. **(d)** Most gallstones are caused by excess biliary cholesterol secretion and subsequent crystallization from supersaturated vesicles (continuous lines). **(e)** Low phospholipid (PL)-associated cholelithiasis (LPAC) occurs if there is deficient phospholipid in bile due to function mutations in gene ABCB4. **(f)** Benign recurrent intrahepatic cholestasis (BRIC) type 2 is characterized by deficient bile salts in bile due to function mutations in gene ABCB11. **(g)** In both LPAC and BRIC type 2 there is an increased risk of gallstone formation.

Box 24.1 Risk factors for cholesterol gallstones

- Increasing age
- Sex (F>M)
- Family history and genetics
- Multiparity
- Obesity ± metabolic syndrome
- Rapid weight loss
- Diet (e.g., high in animal fat/low in fibre)
- Drugs (e.g., contraceptive pill)
- Ileal disease or resection
- Liver cirrhosis
- Spinal cord injury
- Diabetes mellitus
- Acromegaly treated with octreotide
- Total parental nutrition

in Gilbert's syndrome (see Chapter 23), which is associated with enhanced biliary secretion of monoglucuronosyl bilirubin.

There is evidence that bile salt loss into the colon (consequent on ileal resection or ileal disease) promotes solubilization and colonic reabsorption of bilirubin. This enhances the enterohepatic circulation and biliary secretion of bilirubin with the formation of gallstones. Pigment stones have also been linked with bacterial colonization of the biliary tree. Some pigment stones have been shown to contain bacteria, many of which produce glucuronidase and phospholipase, factors that are known to facilitate stone formation. It is speculated that this subclinical bacterial colonization of the bile duct is responsible for pigment stone formation.

Brown pigment stones are usually of a muddy hue and, on cross-section, seem to have alternating brown and tan layers. These stones are composed of calcium salts of fatty acids, as well as calcium bilirubinate. They are almost always found in the presence of bile stasis and/or biliary infection. Brown stones can form in any part of the biliary tree secondary to chronic stasis and the presence of anaerobic bacterial infection.

The ***Oriental hepatolithiasis syndrome (recurrent pyogenic cholangitis)*** is the most serious manifestation of pigment stone disease. Biliary strictures are formed, possibly due to bacterial infection or fluke infestation within the extrahepatic and intrahepatic bile ducts. *Ascaris lumbricoides*, *Clonorchis sinensis*, and *Opisthorchis viverrini* are parasites most commonly associated with this condition. Brown stones may also be the cause of recurrent bile duct stones following cholecystectomy and are also found in the intrahepatic bile ducts in stenosing biliary disease such as Caroli's syndrome and primary sclerosing cholangitis (PSC).

Clinical features

The majority of gallstones are asymptomatic and remain so during a person's lifetime. Gallstones are increasingly detected as an incidental finding at the time of either abdominal radiography or ultrasound scanning (Fig. 24.3). Over a 10- to 15-year period, approximately 20% of these stones will be the cause of symptoms and 10% will involve severe complications. Once gallstones have become symptomatic, there is a strong trend towards recurrent complications, often of increasing severity. Gallstones do not cause dyspepsia, fat intolerance, flatulence, or other vague upper abdominal symptoms.

The clinical syndromes associated with gallstones are shown in Fig. 24.4.

Biliary colic

Biliary colic is the term used for the pain associated with the temporary obstruction of the cystic or CBD by a stone usually migrating from the gall bladder. Despite the term 'colic', the pain of stone-induced ductular obstruction is of sudden onset, severe but constant (not like a 'colic'), and has a crescendo characteristic. Some patients relate the symptoms to over-indulgence with food, particularly when it has a high fat content. The most common time of day for such an episode is in the mid-evening, lasting until the early hours of the morning.

The initial site of pain is usually the epigastrium but there may be a right upper quadrant component. Radiation may occur over the right shoulder and right subscapular region.

Nausea and vomiting frequently accompany more severe attacks. An attack may be terminated spontaneously after a number of hours or by the administration of opiate analgesia. More protracted pain, particularly when associated with fevers and rigors,

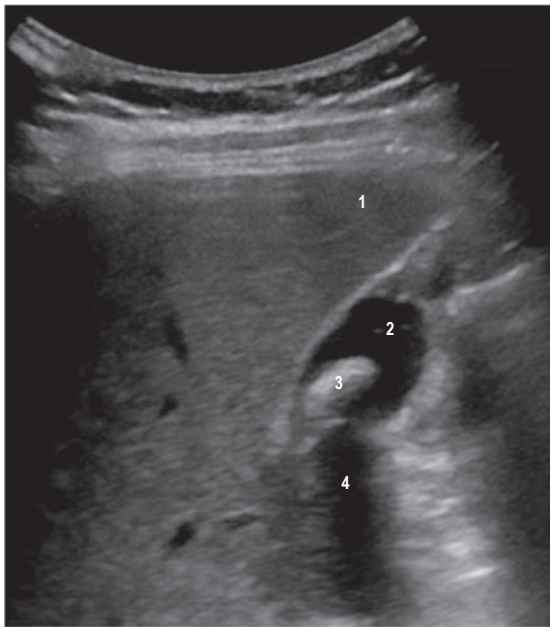

Fig. 24.3 Abdominal ultrasound image demonstrating a gallstone in the gall bladder. This is casting an acoustic shadow, as the ultrasound waves are unable to travel through the gallstone; the structures beneath are therefore not seen. (1) Liver; (2) gall bladder; (3) gallstone; (4) acoustic shadow.

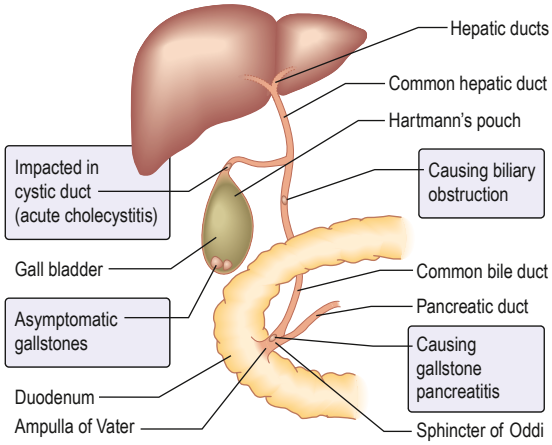

Fig. 24.4 Clinical presentation of gallstones.

suggests secondary complications such as cholecystitis, cholangitis, or gallstone-related pancreatitis (see later).

Acute cholecystitis

The initial event in acute cholecystitis is the obstruction of gall bladder emptying. In 95% of cases a gall bladder stone can be identified as the cause (Fig. 24.5). Such obstruction results in an increase of gall bladder glandular secretion, leading to progressive distension that, in turn, may compromise the vascular supply to the gall bladder.

There is also an inflammatory response secondary to retained bile within the gall bladder. Infection is a secondary phenomenon following this sequence of obstructive, inflammatory, and vascular events.

The initial clinical features of an episode of cholecystitis are similar to those of biliary colic described earlier. Over a number of hours, however, there is progression with severe localized right upper quadrant abdominal pain corresponding to parietal peritoneal involvement in the inflammatory process. The pain is associated with tenderness and muscle guarding or rigidity. This is frequently manifest by Murphy's sign, consisting of pain on taking a deep breath when the examiner's fingers are on the approximate location of the gall bladder. Occasionally, the gall bladder can become distended by pus (an empyema) and, rarely, an acute gangrenous cholecystitis develops, which can perforate, with generalized peritonitis.

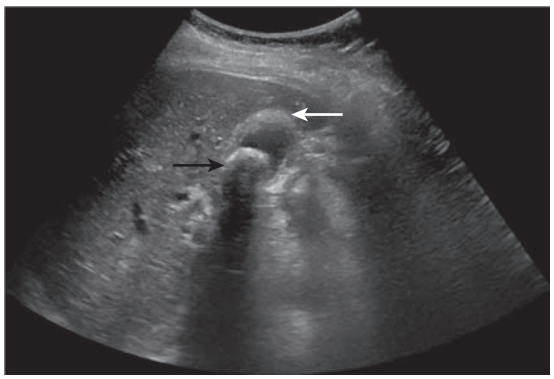

Fig. 24.5 Abdominal ultrasound image demonstrating acute cholecystitis. There is gall bladder wall thickening *(white arrow)* and a large gallstone *(black arrow)*.

Investigations

Biliary colic as a consequence of a stone in the neck of the gall bladder or cystic duct is unlikely to be associated with significant abnormality of laboratory tests. ***Abdominal ultrasound scan*** is the single most useful investigation for the diagnosis of gallstone-related disease (see Fig. 24.3).

Acute cholecystitis is usually associated with a moderate leucocytosis and raised inflammatory markers (e.g., C-reactive protein, CRP). Serum bilirubin, alkaline phosphatase, and aminotransferase levels may be marginally elevated in the presence of cholecystitis alone, even in the absence of bile duct obstruction. More significant elevation of the bilirubin and alkaline phosphatase is in keeping with bile duct obstruction. Abdominal ultrasound has a positive predictive value of 92% and a negative predictive value of 95% in patients with a clinical history in keeping with acute cholecystitis and positive Murphy's sign. Look for:

- ***gallstones*** within the gall bladder, particularly when these are obstructing the gall bladder neck or cystic duct
- ***focal tenderness*** elicited by the ultrasound probe placed over the underlying gall bladder
- ***thickening of the gall bladder wall***, which may also be seen with hypoalbuminaemia, portal hypertension, and acute viral hepatitis.

Gallstones are a common finding in an ageing population, and in the absence of specific symptoms great care should be taken when determining whether the gallstones are responsible for any symptoms.

Differential diagnosis

Typical cases of biliary colic are usually suspected on the clinical history. The differential diagnosis includes irritable bowel syndrome (spasm of the hepatic flexure), carcinoma of the right side of the colon, atypical peptic ulcer disease, renal colic, and pancreatitis.

The differential diagnosis of acute cholecystitis includes a number of other conditions marked by severe right upper quadrant pain

and fever: for example, acute episodes of pancreatitis, perforated peptic ulceration, or an intrahepatic abscess. Conditions above the right diaphragm, such as basal pneumonia, as well as myocardial infarction, may mimic the clinical picture on occasion.

Management

Cholecystectomy

Cholecystectomy is the treatment of choice for virtually all patients with symptomatic gall bladder stones. In patients admitted with specific gallstone–related complications (see later), cholecystectomy should be carried out during the period of that admission to prevent the risk of recurrence. For those presenting with pain alone, an elective procedure can be planned but the waiting time should be minimized to avoid the high risk of recurrent symptoms (approximately 30% over 4 months) and the need for another hospital admission.

Cholecystectomy should not be performed in the absence of typical symptoms just because stones are found on investigation. There is an ongoing debate as to whether prophylactic cholecystectomy is justified in young patients found to have small stones. Such patients have a long period over which they may develop symptomatic disease and small stones are an independent risk factor for the potentially serious complication of gallstone pancreatitis. The most recent guidance available does not recommend prophylactic surgery for asymptomatic gall bladder stones.

The laparotomy approach to cholecystectomy has now been replaced by the laparoscopic technique. Postoperative pain is minimized with only a short period of ileus and the early ability to mobilize the patient. Laparoscopic cholecystectomy can be safely carried out on a day-care basis in an elective setting in otherwise fit patients. This has considerable cost benefits over open cholecystectomy, which is now reserved for a small proportion of patients with contraindications, such as extensive previous upper abdominal surgery, ongoing bile duct obstruction, or portal hypertension.

In approximately 5% of cases, a laparoscopic cholecystectomy is converted to an open operation because of technical difficulties: in particular, adhesions in the right upper quadrant or difficulty in identifying the biliary anatomy.

Specific complications of cholecystectomy

These include a biliary leak, either from the cystic duct or the gall bladder bed. Injury to the bile duct itself occurs in up to 0.5% of laparoscopic operations and may have serious long-term sequelae in the form of a bile duct stricture and secondary biliary liver injury. Injuries to the extrahepatic biliary tree are more likely with variant duct anatomy, such as a low cystic duct insertion or draining of the cystic duct into the right posterior ducts rather than the CBD. There is an overall mortality of 0.2% associated with cholecystectomy.

Acute cholecystitis

The initial management is conservative, consisting of keeping the patient nil by mouth and administering intravenous fluids, opiate analgesia, and intravenous antibiotics. Bacteria that are commonly associated with cholecystitis include *Escherichia coli*, *Bacteroides fragilis*, *Klebsiella*, *Enterococcus*, and *Pseudomonas* species. Antibiotic selection is dictated by local policy and is guided by the severity of any associated sepsis and the result of any blood culture. Options include extended-spectrum cephalosporins (e.g., ceftriaxone) in combination with metronidazole, piperacillin/tazobactam, or imipenem/meropenem.

Cholecystectomy is usually delayed for a few days to allow the symptoms to settle but can then be carried out quite safely in the majority of cases.

When the clinical situation fails to respond to this conservative management, particularly if there is increasing pain and fever, an empyema or gangrene of the gall bladder may have occurred. In this circumstance, urgent imaging (transabdominal ultrasound or CT scan) is required to define the pathology. Surgical intervention is usually needed, although a radiologically placed gall bladder drain can be used as a temporizing measure for the management of an empyema. The placement of a drain is the best option in patients who are considered unfit for early surgery (because of ongoing sepsis or significant co-morbidity). EUS-guided placement of a lumen apposing metal stent (LAMS) between the obstructed gall bladder and the stomach or duodenum has now been adopted by many centres to drain gall bladder empyema when surgery is not feasible.

Stone dissolution and shock wave lithotripsy

These nonsurgical techniques for the management of gall bladder stones are used infrequently but may have a role in a few highly selected patients who may not be fit for cholecystectomy or have declined the surgical option.

Stone dissolution

Pure or near-pure cholesterol stones can be solubilized by increasing the bile salt content of bile. Most experience is with oral ursodeoxycholic acid. The approach requires long-term therapy and the recurrence rate of gallstones is high when therapy is stopped. Additional pharmacological tools for treating cholesterol gallstones include cholesterol-lowering agents that inhibit hepatic cholesterol synthesis (statins) or intestinal cholesterol absorption (ezetimibe), or drugs acting on specific nuclear receptors involved in cholesterol and bile acid homeostasis (see Chapter 23).

Extracorporeal shock wave lithotripsy (ESWL)

A shock wave can be directed either radiologically or by ultrasound on to gall bladder stones. This technique has been shown to have high rates of technical success but only in a restricted patient population. The cystic duct requires patency for stone fragments to pass and rates of post-fragmentation biliary colic are high (~50%). Recurrence rates are high but may be reduced by the pharmacological approaches discussed earlier. The role of extracorporeal shock wave lithotripsy (ESWL) in managing gall bladder stones is therefore not clear.

Post-cholecystectomy syndrome

This refers to right upper quadrant pain, often biliary in type, which occurs a few months after the cholecystectomy but may be delayed for several years. The patients often comment that the pain is identical to that for which the original operation was carried out. In many cases, this syndrome is related to a functional large bowel disorder with colonic spasm at the hepatic flexure (hepatic flexure syndrome). It may be speculated that a functional gut disorder may have been responsible for the original pain that led to the cholecystectomy. In a small proportion of patients the pain is the result of a retained CBD stone; in a further subsection sphincter of Oddi dysfunction (SOD) is a potential cause.

Sphincter of Oddi dysfunction

Sphincter of Oddi dysfunction (SOD) is a clinical syndrome of biliary or pancreatic pain and is caused by either:

- sphincter of Oddi stenosis, for example following prior instrumentation or passage of stones; *or*

- sphincter of Oddi hypertension.

A full history of the type of pain is performed, as well as an assessment of serum liver biochemistry and lipase or amylase during, and between, episodes of pain.

Biliary SOD

In ***type I*** disease, patients have biliary-type pain with *both* raised serum bilirubin, alkaline phosphatase, or aminotransferases during episodes *and* a distended CBD on imaging.

In ***type II*** disease, patients have biliary-type pain and *either* abnormal liver biochemistry during episodes *or* a distended CBD.

In ***type III*** disease, there is recurrent biliary-type pain but no abnormality in the liver biochemistry and a normal calibre CBD.

Management is as follows:

- Type I SOD usually responds to endoscopic sphincterotomy.
- Type II SOD sometimes responds to endoscopic sphincterotomy.
- Type III SOD does not respond to endoscopic sphincterotomy and therefore this should not be performed.

Pancreatic SOD

In ***type I*** disease, patients have recurrent pancreatic pain, a raised serum lipase or amylase, and a dilated pancreatic duct.

In ***type II*** disease, patients have recurrent pancreatic pain with *either* transient elevation of pancreatic enzymes *or* a dilated pancreatic duct.

In ***type III*** disease, patients have pain but neither an elevated lipase or amylase nor a dilated pancreatic duct.

Management is as follows:

- Types I and II SOD may respond to endoscopic sphincterotomy.
- Type III SOD with pain only does not respond to endoscopic sphincterotomy.

Common bile duct stones

The classical features of CBD stones are biliary colic, fever, and jaundice (acute cholangitis). This triad is present only in a minority of patients. Abdominal pain is the most common symptom and has the typical features of biliary colic (see earlier). Jaundice is a variable accompaniment and is almost always preceded by abdominal pain. A patient with bile duct stones may experience sequential episodes of pain, only some of which are accompanied by jaundice. In contrast to malignant bile duct obstruction, the level of jaundice associated with CBD stones characteristically tends to fluctuate. In the elderly or immunocompromised patient, cholangitis may present with very non-specific symptoms, and only associated abnormal liver biochemistry may point to the diagnosis.

Fever is present only in a minority of cases but indicates biliary sepsis and sometimes associated septicaemia. The presence of biliary sepsis is an adverse prognostic factor.

A minority of patients with bile duct stones are discovered incidentally during imaging for gall bladder disease or other intra-abdominal pathology. Some 15% of patients undergoing cholecystectomy will have stones within the bile duct that are detected only at the time of operative cholangiography. The frequency of asymptomatic bile duct stones resulting in complications is not well documented. It is likely that many such stones will pass into the duodenum without causing symptoms. However, the potential for serious complication is well recognized; in most circumstances, incidentally identified bile duct stones are removed (see later).

Examination

If the patient is examined between episodes, there may be no abnormal physical finding. During a symptomatic episode the patient may be jaundiced with a fever and associated tachycardia. There is tenderness in the right upper quadrant, varying from mild to extremely severe.

More widespread abdominal tenderness extending from the epigastrium to the left upper quadrant, associated with distension, may indicate associated stone-related pancreatitis (see later).

Investigations

Laboratory tests

- ***Full blood count*** is usually normal in the presence of uncomplicated bile duct stones.
- ***An elevated neutrophil count*** and raised inflammatory markers (erythrocyte sedimentation rate [ESR] and CRP) are frequent accompaniments of cholangitis.
- ***The raised serum bilirubin*** tends to be mild and often transient. Very high concentrations of bilirubin (>200 μmol/L) almost always reflect complete bile duct obstruction.
- ***Serum alkaline phosphatase and γ-glutamyl transpeptidase*** are similarly elevated in proportion to the degree of hyperbilirubinaemia.
- ***Aminotransferase levels*** are usually mildly elevated, but with complete bile duct obstruction there may be very marked rises of 10 to 15 times the normal value. The alanine aminotransferase is characteristically higher than the aspartate aminotransferase. These high levels may lead to an initial misdiagnosis of a hepatitic process.
- ***Serum lipase or amylase levels*** are often mildly elevated in the presence of bile duct obstruction but are markedly so if stone-related pancreatitis has occurred.
- ***Prothrombin time*** may be prolonged if bile duct obstruction has occurred and is sustained over several days; this reflects decreased absorption of vitamin K.

Imaging

- ***Transabdominal ultrasound*** is the initial imaging technique of choice. ***Bile duct obstruction*** is characterized by dilation of intrahepatic biliary radicles, which are usually readily detected by the ultrasound scan. It may, however, not be possible to identify the cause of obstruction. Stones situated in the distal CBD are poorly visualized by transabdominal ultrasound and up to 50% are missed. The detection of stones within the gall bladder is poorly predictive of the cause of bile duct obstruction. Asymptomatic gallstones are common (up to 15%) in patients who are 65 years and older. Conversely, in 5% to 10% of patients with bile duct stones, no calculi can be seen within the gall bladder.
- ***Magnetic resonance cholangiography (MRC)*** delineates the fluid column within the biliary tree and is a sensitive technique for the detection of CBD stones in the presence of a dilated duct. The technique may be less accurate in the absence of duct dilation (see the role of EUS, later) (Fig. 24.6).
- ***CT scanning*** is an alternative way to detect bile duct dilation. Opaque stones are more readily identifiable within the bile duct than radiolucent cholesterol stones. CT scanning also provides a means of excluding other causes of bile duct obstruction, such as carcinoma of the head of the pancreas.
- ***EUS*** (Fig. 24.7) has enabled high-resolution imaging of the CBD, gall bladder, and pancreas, although, unlike the preceding imaging techniques, it is an invasive procedure. The EUS probe in the duodenum is in close proximity to the distal CBD and hence can identify the large majority of stones at this level. This technique is particularly useful for identifying small calculi (microcalculi) in a non-dilated CBD.

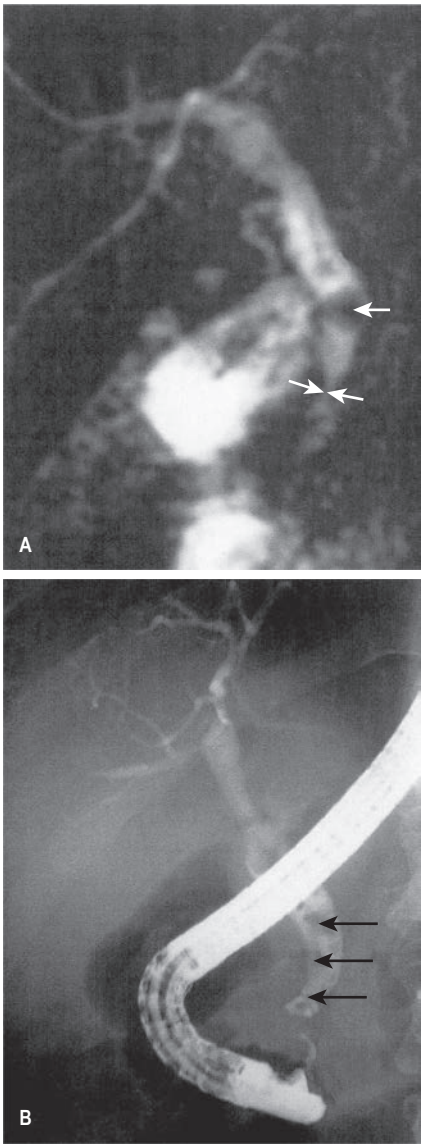

Fig. 24.6 A patient presenting with abdominal pain and jaundice. **(A)** A magnetic resonance cholangiogram (MRC) shows evidence of a distal common bile duct stricture *(bottom arrows)* with a stone in the bile duct proximal to this *(top arrow)*. **(B)** An endoscopic retrograde cholangiopancreatogram (ERCP) in the same patient confirms the details identified in the MRC scan. The stones *(arrowed)* were removed at the time of the ERCP after initial dilation of the stricture.

- ***Endoscopic retrograde cholangiography (ERC).*** In experienced hands, visualization of the CBD will be successful in 98% of cases, providing good documentation of bile duct stones (Fig. 24.8; see also Fig. 24.6) and the facility to immediately proceed to sphincterotomy and stone clearance. However, small stones can still be missed. ERC is an invasive procedure with recognized risks. In almost all circumstances, this is now a therapeutic tool used to remove stones that have been identified by the less invasive investigations described earlier.

Differential diagnosis

Cholangitis may occur independently of gallstones in any condition associated with impaired biliary drainage. It is commonly linked with primary abnormalities of the biliary tree, such as sclerosing

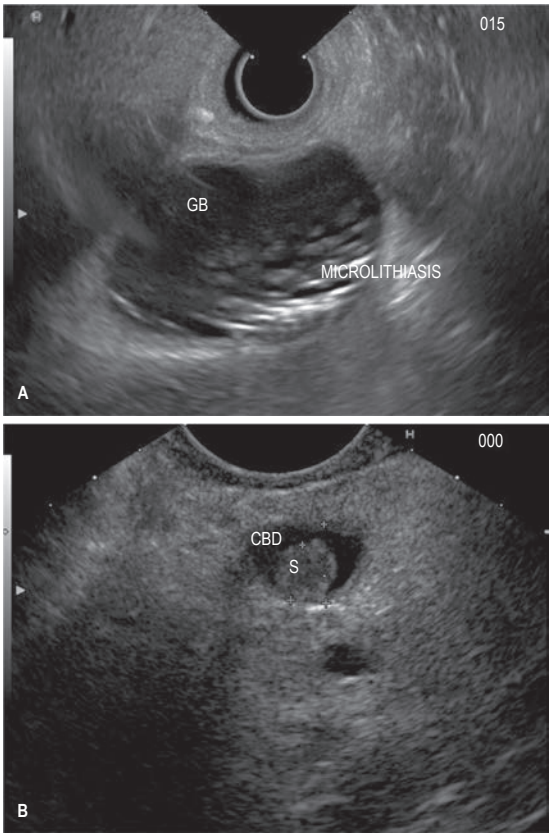

Fig. 24.7 An endoscopic ultrasound (EUS) scan with the probe in the first part of the duodenum. **(A)** The gall bladder (GB) and multiple small, echo-poor stones within (microlithiasis). The patient had presented with recurrent episodes of unexplained abdominal pain. **(B)** The common bile duct (CBD) and a stone (S) clearly identified within the lumen.

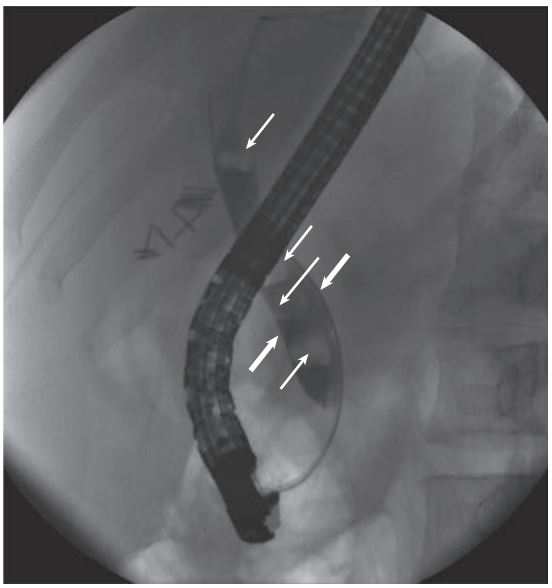

Fig. 24.8 An endoscopic retrograde cholangiopancreatogram (ERCP) carried out in a patient with abdominal pain, fluctuating jaundice, and fever. The cholangiogram shows a dilated common bile duct *(between thick arrows)* and multiple stones within *(arrowed)*. These stones were removed at the time of ERCP by means of balloon and basket retrieval. Note the multiple clips to the left of the upper bile duct, which were placed at a prior laparoscopic cholecystectomy.

cholangitis and Caroli's syndrome (a congenital disorder leading to ectasia/dilation of the intrahepatic bile ducts). Cholangitis may also complicate post-traumatic or surgery-associated bile duct strictures. It is unusual in malignant bile duct obstruction unless there has been prior endoscopic or surgical intervention. Jaundice may also be a feature of acute cholecystitis in the absence of bile duct stones. A stone impacted in the neck of the gall bladder (Hartmann's pouch) or the cystic duct itself may compress and obstruct the bile duct (Mirizzi's syndrome). CBD stones may produce pain, but in the absence of jaundice, the differential diagnosis is that of biliary colic (see earlier).

Management

Acute cholangitis has a high morbidity and mortality, particularly in the elderly or those with serious co-morbidity. Successful management depends on intravenous antibiotics (as for acute cholecystitis) and urgent bile duct drainage. In most circumstances the latter is achieved by the endoscopic retrograde approach (ERC, see earlier). Access to the bile duct is achieved by sphincterotomy and thereafter the stones can be removed by either balloon or basket catheters. In the severely ill patient a plastic stent (a small tube prosthesis) can be inserted into the bile duct to maintain bile drainage without the need to remove the stones, minimizing the time required to complete the procedure. The residual stones can then be cleared and the stent removed endoscopically when the patient has recovered from the acute episode. If endoscopic drainage is not available or is prevented by an inability to access the second part of the duodenum, a radiologically placed percutaneous transhepatic biliary drain (PTBD) represents an alternative management option. Surgical drainage during an acute cholangitic episode has been associated with a high mortality and has been replaced by the endoscopic or percutaneous approach.

Urgent endoscopic bile duct clearance is also indicated in some patients with acute gallstone pancreatitis but only when this coexists with persisting bile duct obstruction (see later). Patients who have retained CBD stones after a previous cholecystectomy are also optimally managed by endoscopic clearance.

Patients shown to have CBD stones as well as gall bladder stones may be treated using different approaches:

- ***At the time of laparoscopic cholecystectomy***, which can also include exploration of the CBD via the cystic duct or via direct choledochotomy. By using these techniques the surgeon can extract stones from the CBD. The skills and time required for bile duct exploration are considerably greater than those for laparoscopic cholecystectomy alone. This single-procedure approach minimizes the length of hospital admission. Concerns around an increased risk of bile duct injury with bile duct exploration have not been confirmed in controlled studies.
- ***An independently timed endoscopic approach***, either immediately before or after the cholecystectomy. Removal of CBD stones by this method is preferred in the UK. Large bile duct stones (>10 mm) may present a significant challenge to endoscopic removal. Mechanical lithotripsy facilitates stone fragmentation and removal into the duodenum. Extracorporeal shock wave stone fragmentation has been used but is not widely available. The recently increased availability of endoscopic cholangioscopy (with direct visualization of the bile duct) has facilitated intraductal lithotripsy, utilizing electrohydraulic or laser probes.
- ***A combined laparoscopic and endoscopic approach***, in which an ERC and duct clearance are carried out under the same anaesthetic used for the laparoscopic cholecystectomy. This approach leads to a shortened hospital stay and the need for only one anaesthetic.

Complications of gallstones

- Acute cholecystitis and acute cholangitis are discussed in the 'Acute cholecystitis' and 'Common bile duct stones' sections.
- Gallstone-related pancreatitis is discussed in the 'Gallstone pancreatitis' section.
- Gallstones can occasionally erode through the wall of the gall bladder into the intestine, giving rise to a biliary enteric fistula. Passage of a gallstone through to the small bowel can give rise to an ileus or true obstruction.
- There is little evidence that gallstones are associated with an increased risk of adenocarcinoma of the gall bladder (see 'Carcinoma of the gall bladder' section).

MISCELLANEOUS CONDITIONS OF THE BILIARY TRACT

Gall bladder

There are a number of non-calculous conditions of the gall bladder, some of which have been associated with symptoms.

Acalculous cholecystitis

Almost 10% of gall bladders removed for biliary symptoms are shown to have chronic inflammation within the wall but an absence of gallstones. Such cases are described as acalculous cholecystitis. In many instances the gall bladder inflammation is minor and of doubtful significance. In some cases, chemical inflammation of the gall bladder may occur from reflux of pancreatic enzymes back into the biliary tree, usually through the common channel at the ampulla of Vater. Bacterial and viral infections of the gall bladder have been recognized as a cause of acalculous cholecystitis. The decision to carry out cholecystectomy in the absence of defined gall bladder stones should be guided by the specific features of the history and by evidence of a diseased gall bladder wall on ultrasound scanning.

A distinct subtype of acalculous cholecystitis is characterized by severe necroinflammation of the gall bladder and generally occurs in an elderly and already critically ill group of patients, usually after major trauma or surgery. Around 20% of these patients develop inflammatory masses with subsequent cholestasis and jaundice; gall bladder perforation is a frequent complication. Morbidity and mortality are very high, and aggressive management of sepsis with antibiotics and cholecystostomy (percutaneous gall bladder drainage) or urgent cholecystectomy is required.

Cholesterolosis of the gall bladder

In cholesterolosis, cholesterol and other lipids are deposited in macrophages within the lamina propria of the gall bladder wall. These may be diffusely situated, giving a granular appearance to the gall bladder wall, or on occasion may be more discrete, giving a polypoid appearance (see later). Cholesterolosis of the gall bladder may coexist with gallstones but also occurs independently. Some degree of gall bladder cholesterolosis is found in up to 26% of laparoscopic cholecystectomy specimens, and as an incidental finding in up to 12% of autopsies in an elderly population. Interestingly, in contrast to cholelithiasis, rates are equal in males and females. It is doubtful whether isolated gall bladder cholesterolosis is a cause of symptoms.

Adenomyomatosis of the gall bladder

Adenomyomatosis is a gall bladder abnormality characterized by hyperplasia of the mucosa, thickening of the muscle wall, and multiple intramural diverticula (the so-called 'Rokitansky–Aschoff sinuses').

The condition is usually detected as an incidental finding during investigation for possible gall stone disease. It has been suggested that this condition is secondary to increased intraluminal gall bladder pressure but this is not proven. Gallstones frequently coexist, particularly when the adenomyomatosis is in a segmental distribution, but there is no evidence to support a direct relationship. It is unlikely that adenomyomatosis alone is a cause of biliary symptoms and it is not considered a pre-malignant state.

Chronic cholecystitis

There are no symptoms or signs that can conclusively be shown to be due to chronic cholecystitis. Symptoms attributed to this condition are vague, such as indigestion, upper abdominal discomfort, or distension. There is no doubt that gall bladders studied histologically can show signs of chronic inflammation and, occasionally, a small, shrunken gall bladder is found either radiologically or on ultrasound examination. However, these findings can be seen in asymptomatic people and therefore this clinical diagnosis should not be made. Most patients with chronic right hypochondrial pain are suffering from functional bowel disease (see Chapter 22).

Extrahepatic biliary tract

Primary sclerosing cholangitis

In up to 40% of patients with primary sclerosing cholangitis (PSC; see also Chapter 23) the clinical course is influenced by a dominant hilar or distal biliary stricture. This is particularly relevant in those patients who do not have established advanced liver involvement, in whom maintenance of bile flow may protect the liver from secondary biliary injury. Drainage with a surgical hepaticojejunostomy has been beneficial in some cases, but outcomes of such restricted surgery in PSC are generally inferior to those of orthotopic liver transplantation. Repeated endoscopic balloon dilation of the dominant stricture, with or without temporary short-term stenting, has been associated with sustained improvement in jaundice and even prolonged transplant-free survival. A significant minority of dominant strictures in PSC, particularly those at the hilum, represent development of an associated cholangiocarcinoma (see later). Development of cholangiocarcinoma in this context carries a very poor prognosis and surgical resection is rarely feasible. A benign dominant stricture in a non-cirrhotic patient, with recurrent cholangitis, refractory jaundice, and pruritus, may be an indication for orthotopic liver transplantation. Superadded cholangiocarcinoma in PSC was previously an absolute contraindication to orthotopic liver transplantation in most healthcare systems. However, liver transplantation is now an option in a small subset of PSC patients who develop hilar cholangiocarcinoma.

Autoimmune cholangitis

Immunoglobulin (Ig) G4–associated cholangitis is the biliary manifestation of a multisystem fibro-inflammatory disorder in which affected organs have a characteristic lymphoplasmacytic infiltrate rich in IgG4-positive cells (see Chapter 6). The original description of this condition was in the context of autoimmune pancreatitis and around 70% of these patients have evidence of IgG4 cholangiopathy (see 'Autoimmune chronic pancreatitis' section). However, IgG4 cholangiopathy can exist in the absence of pancreatic involvement.

The large majority of cases are recognized in middle-aged or elderly men. Presentation is varied, depending on the systems involved, but may include abdominal pain and jaundice. Both intra- and extrahepatic biliary strictures may be seen and the findings may be misinterpreted as representing cholangiocarcinoma or PSC. The diagnosis relies on clinical suspicion, confirmation of an elevated serum IgG4 level, a typical lymphocytoplasmic infiltrate on histological examination of involved tissue, and clinical response to glucocorticosteroid treatment. The condition is almost always responsive to steroids but can lead to hepatic failure.

Biliary cysts (choledochal malformation)

Cystic malformations may occur anywhere in the biliary tree, although they are most commonly extrahepatic. The resulting dilation of the bile duct may be of saccular, diverticular, or fusiform configuration. In many cases there is an associated abnormal pancreatobiliary junction—a congenital malunion where the pancreatic duct drains directly into the CBD. The majority of symptomatic cases present in childhood with features of cholangitis, jaundice, or a palpable mass. The formation of stones and sludge within the cystic segment may predispose to acute relapsing pancreatitis. In adult life, choledochal cysts may be a differential diagnosis in patients presenting with symptoms suggestive of bile duct stones. Extrahepatic bile duct cysts must be fully resected to avoid recurrent biliary sepsis, as well as reduce the risk (approximately 15%) of subsequent cholangiocarcinoma.

Benign bile duct strictures

Benign strictures are a recognized complication of biliary surgery. They may result from inadvertent direct stapling of the duct, or may be a secondary consequence of ischaemic injury (often in association with a bile duct leak). Strictures may also occur at the level of any bile duct anastomosis, either enteric or duct-to-duct. Biliary stricturing is also a rare complication of major trauma to the right upper quadrant. The inflammation and fibrosis of chronic pancreatitis commonly impinge on the intrapancreatic portion of the CBD (see later). This can result in cholestasis, jaundice, and cholangitis.

In most cases, initial therapy includes endoscopic balloon dilation of the stricture and temporary bile duct stenting (see later). This may provide definitive management, but in some cases, surgical intervention with hepaticojejunostomy is required.

Haemobilia

Haemobilia describes blood in the biliary tree. This may be a consequence of liver trauma or a complication of liver surgery. Biopsy of the liver and erosion of a gallstone or hepatobiliary tumour into adjacent vascular structures are also well-recognized causes. The result is a fistula between a blood vessel and a bile duct.

Haemobilia may be a cause of significant gastrointestinal blood loss and should be suspected when melaena is accompanied by right-sided upper abdominal pain and jaundice, particularly in the context of recent hepatobiliary intervention. However, the bleeding may occur without any overt biliary symptoms. If the diagnosis is suspected, bleeding may be managed by occlusion of the feeding blood vessel by radiological embolization. Some patients will require surgery to control the bleeding point.

Tumours of the biliary tract

Gall bladder polyps

Polyps of the gall bladder are a common finding, being seen in approximately 4% of all patients referred for hepatobiliary

ultrasonography. The vast majority of these are small (<5 mm) and non-neoplastic; they are inflammatory in origin or composed of cholesterol deposits (see earlier). Adenomas are the most common benign neoplasm of the gall bladder. Only a proportion of these have cancerous potential. The only reliable predictor of malignant risk is polyp size (>10 mm). Cholecystectomy is recommended for any polyp of 10 mm or larger in diameter.

Carcinoma of the gall bladder

Adenocarcinoma of the gall bladder represents 1% of all cancers. The mean age of occurrence is the early sixties, with a female-to-male ratio of 3:1. Gall bladder stones are often found in association with gall bladder cancer; gallstones have been suggested as an aetiological factor but this relationship remains unproven. Diffuse calcification of the gall bladder (porcelain gall bladder), considered to be the end stage of chronic cholecystitis, has been associated with cancer of the gall bladder and is an indication for early cholecystectomy. Adenomatous polyps of the gall bladder in excess of 10 mm in diameter are also recognized as pre-malignant lesions (see earlier).

Carcinoma of the gall bladder may be detected incidentally at the time of planned cholecystectomy for gallstones; in such circumstances, resection of an early lesion may be curative. Radical surgery with negative resection margins offers the only potential cure. However, early lymphatic spread to the liver and adjacent biliary tract precludes curative resection in more advanced lesions. Palliative chemotherapy treatment may be given, usually with gemcitabine (a nucleoside analogue) and cisplatin (a platinum-containing anticancer drug), with some evidence of a modest improvement in survival which is improved further with the addition of durvalumab (an immune checkpoint inhibitor). A small proportion of cases are sensitive to radiotherapy. However, the generally advanced stage of disease at presentation means that the overall 5-year survival is less than 5%.

Cholangiocarcinoma

Cancers of the biliary tree (see also Chapter 23) are classified as intrahepatic (above the hilum of the liver) or extrahepatic (involving the hilum or bile duct distal to the hilum). The latter are classified either on the TMN classification (see **Box 41.12**) or on the site of the lesion (Bismuth–Corlette classification of biliary strictures). These malignancies represent approximately 1% of all cancers. A number of associations have been identified, such as that with choledochal malformation (see earlier) and that with PSC (see 'Primary sclerosing cholangitis' section). Chronic infection of the biliary tree with parasitic liver flukes, particularly *O. viverrini* or *C. sinensis*, has also been strongly implicated in areas where they are endemic. Extrahepatic bile duct malignancy usually presents with jaundice and may be confirmed on imaging tests, initially ultrasound and thereafter CT and, in particular, magnetic resonance cholangiopancreatography (MRCP; **Fig. 24.9**). Typical findings are of a bile duct stricture with proximal biliary dilation, with or without a visible mass. Histopathological diagnosis often proves difficult because the malignant cells are relatively few and contained within a dense stroma. Endoscopically obtained cytology specimens have only 30% sensitivity. This yield can be enhanced by using additional endoscopic sampling techniques, such as transpapillary biopsy, and analytical enhancements, such as fluorescent *in situ* hybridization. The recent application of direct endoscopic cholangioscopy has enabled direct visualization of biliary lesions and targeted biopsy.

Cholangiocarcinoma is often detected at a late stage and is characterized by early perineural, vascular, and lymphatic spread.

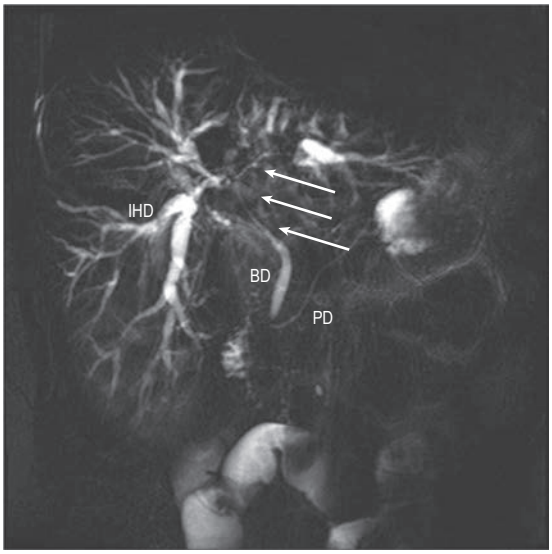

Fig. 24.9 Magnetic resonance cholangiopancreatography (MRCP) image of hilar cholangiocarcinoma extending into the left main duct. There is a normal-calibre distal bile duct (BD) and pancreatic duct (PD). The common hepatic duct and left main duct are strictured *(arrowed)*. There is marked intrahepatic duct (IHD) dilation.

In a minority of cases, complete surgical resection is feasible, offering the only chance of cure. Cholangiocarcinoma of the CBD may be amenable to a limited bile duct resection. Very distal lesions require a pancreatoduodenectomy (Whipple procedure), and perihilar lesions frequently require partial hepatic resection in addition to biliary resection. In an increasing number of centres neoadjuvant chemoradiation therapy followed by orthotopic liver transplantation has been used to cure localized hilar cholangiocarcinoma. Results from this approach show promise, but liver transplantation is an option for only a minority of cholangiocarcinoma patients in healthcare systems where it is available.

The majority of patients with cholangiocarcinoma are treated palliatively with biliary decompression (see later) and gemcitabine- and cisplatin-based chemotherapy regimens, more recently with the addition of durvalumab.

Secondary malignant involvement of the biliary tree

Carcinoma of the head of the pancreas frequently presents with CBD obstruction and jaundice. Metastases to the bile duct from distant cancers are uncommon. Melanoma is the most frequent neoplasm to do so. Infiltration of the bile duct is not uncommon in disseminated lymphoma. Other carcinomas that may give rise to bile duct metastases, in order of frequency, are those arising in the lung, breast, and colon, as well as those from the pancreas (metastatic as compared to direct infiltration).

Management

Palliation of malignant bile duct obstruction

All patients must be fully staged for operability using the imaging techniques described earlier. However, in the greater proportion of patients the treatment is palliative. Relief of bile duct obstruction has been shown to improve quality of life considerably and, with pain control, is the mainstay of effective palliation. Effective biliary decompression is also critical in jaundiced patients who wish to proceed with palliative chemotherapy. ERC permits the insertion of

stents into the biliary tree to re-establish bile flow. The initial use of plastic stents has largely been replaced by self-expanding metal stents that have considerably longer periods of patency (Fig. 24.10). In the small proportion of patients in whom ERC and bile duct drainage is not possible, the percutaneous route offers an alternative method of stent placement under radiological control. The placement of LAMS endoscopically using EUS has now emerged as another safe and effective way of decompressing an obstructed, very dilated CBD into the duodenum, when ERC and stent placement is not feasible.

PANCREAS

Anatomy and function

Structure

The pancreas extends retroperitoneally across the posterior abdominal wall from the second part of the duodenum to the spleen. Anatomically, it is divided into a head, which rests within the concavity of the duodenum; a body, lying behind the base of the stomach; and a tail, which ends abutting the spleen (Fig 24.11). The neck of the pancreas lies between the body and head, and is in front of the superior mesenteric artery and vein. The head of the pancreas surrounds these two vessels. An uncinate process emerges from the lower part of the head, lying behind the superior mesenteric artery. The pancreas consists of exocrine and endocrine cells. The exocrine pancreas comprises 98% of the parenchyma.

The functional unit of the exocrine pancreas is composed of an acinus and its draining ductule. A ductule from the acinus drains into interlobular (intercalated) ducts, which, in turn, drain into the main pancreatic ductal system. The main pancreatic duct itself joins the CBD to enter the duodenum as a short single duct at the ampulla of Vater.

The endocrine component is scattered throughout the gland in the form of pancreatic islets (of Langerhans).

Exocrine function

The pancreatic acinar cells are responsible for the production of digestive enzymes. These include amylase, lipase, colipase, phospholipase, and the proteases (trypsin and chymotrypsin). These enzymes are stored within the acinar cells in secretory granules and are released by exocytosis (Fig. 24.12). The enzymes released by the acinar cells are transported into the duodenum by a high-volume pancreatic secretion, the majority of which is produced by the ductal cells. This fluid has a high concentration of bicarbonate, which neutralizes the gastric acid that has emptied into the duodenum. The neutralization of gastric acid is essential to facilitate pancreatic enzyme activity, which is pH dependent (requiring a neutral pH).

After ingestion of a meal, pancreatic exocrine secretion is regulated by cephalic, gastric, and intestinal stimuli. The cephalic phase is stimulated by behavioural cues related to the sight, smell, and

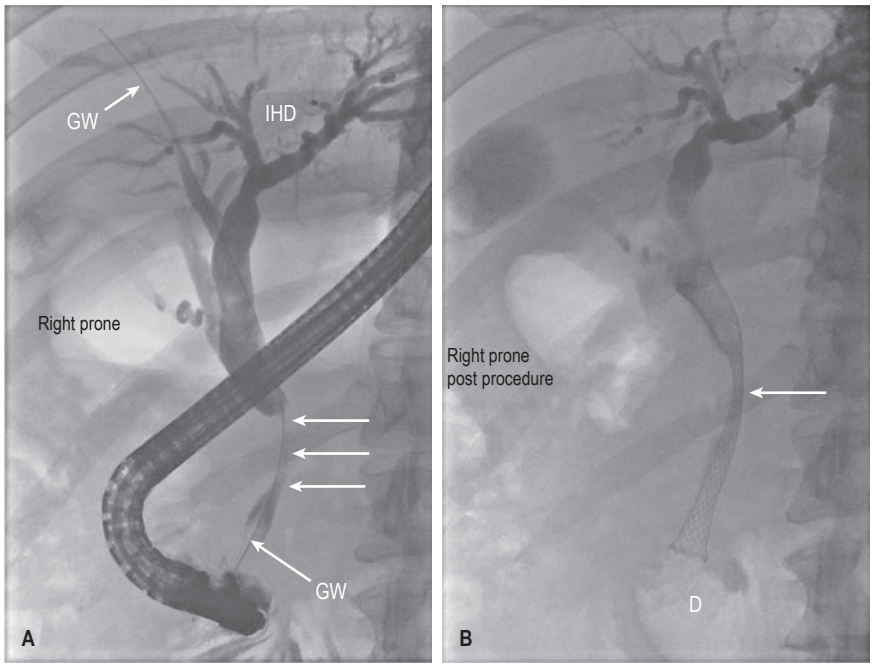

Fig. 24.10 An endoscopic retrograde cholangiopancreatogram in a patient presenting with painless jaundice. **(A)** There is a tight stricture in the mid-common bile duct extending proximally over 4 cm (extent defined by *arrows*). The intrahepatic ducts (IHD) proximally are dilated. A guidewire (GW) has been placed endoscopically across the stricture. **(B)** A self-expanding metal stent has been placed across the stricture and released. The stent is compressed at the level of the stricture *(arrowed)* but will open fully over 24 hours. The contrast in the intrahepatic ducts has largely drained through the stent. The distal margin of the stent is in the duodenum (D).

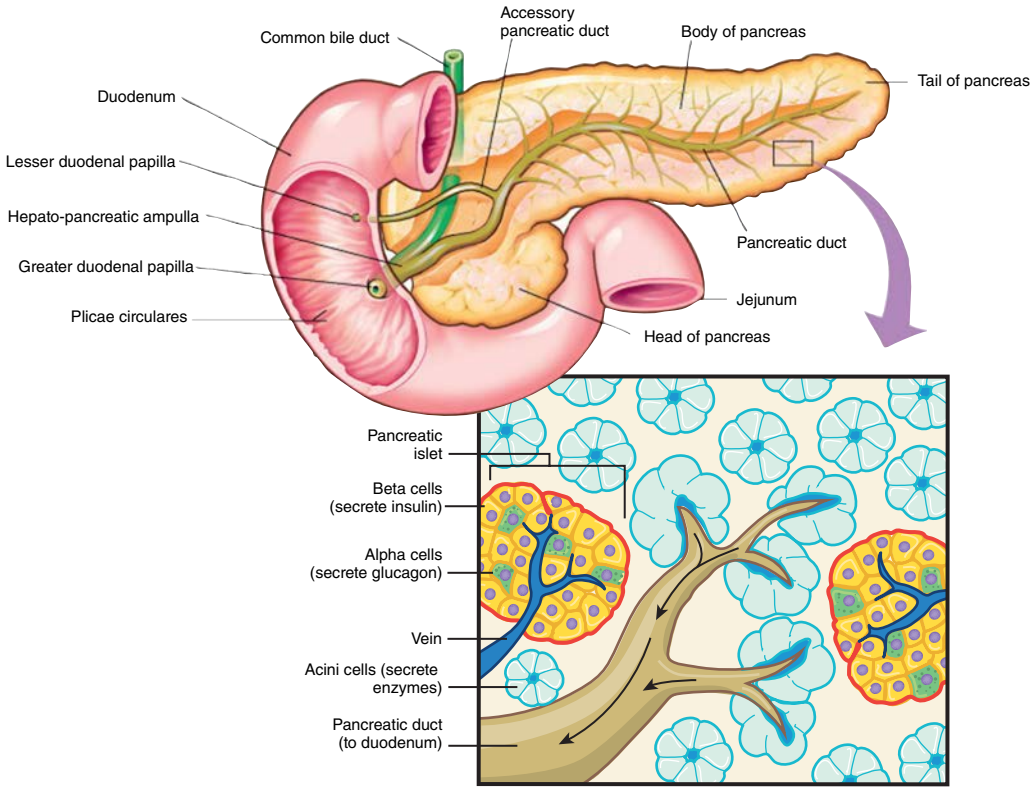

Fig. 24.11 Anatomy and structure of the pancreas. The box at the foot of the image illustrates the microscopic organization of the exocrine (acini) and endocrine (islets) components of the pancreas. The pancreas. *(From Thibodeau GA, Patton KT:* Anatomy & physiology *, ed 5, St. Louis, 2003, Mosby.)*

taste of food. The input from these sensory stimuli is integrated in the central nervous system at the dorsal vagal complex, and the output is transmitted to the exocrine pancreas via the vagus nerve. The gastric phase of pancreatic secretion results from the effects of the meal in the stomach. The major stimulus of pancreatic secretion in the gastric phase is gastric distension, which causes secretion of an enzyme-rich fluid with little secretion of water and bicarbonate. This phase is also under vagal control. The intestinal phase of pancreatic secretion starts when protein, fat, and gastric acid from the stomach enter the duodenum and continues for the duration of the digestive period. It is mediated by both hormones and enteropancreatic vagovagal reflexes. Feedback regulatory events eventually terminate pancreatic secretion.

- ***Cholecystokinin (CCK)*** plays a major role in meal-stimulated digestive enzyme secretion during the intestinal phase of pancreatic secretion. The hormone is produced in specialized gut endocrine cells (I cells) of the mucosa of the small intestine and is secreted in response to intraluminal food. There are no CCK receptors in human pancreatic cells, and CCK acts via receptors on vagal afferent fibres to stimulate pancreatic secretion.
- ***Secretin*** is also released from specialized enteroendocrine cells of the small intestine during a meal and in particular during duodenal acidification. Secretin has a direct effect on the pancreatic acinar cells, as well as the ductal cells. There is also a vagal-mediated secretory response. Secretin action is mediated via G-coupled receptors and calcium-mediated enzyme release. Secretin results in a bicarbonate-rich pancreatic secretion.

The efficiency of the digestive phase of pancreatic secretion requires a negative feedback mechanism to bring the process to a close. Completion of the postprandial secretory phase involves both neural and hormonal control.

- ***Pancreatic polypeptide*** is released from the islet cells of the pancreas in response to a meal and has an inhibitory effect on acinar enzyme secretion, via both a local effect and central receptors.
- ***Somatostatin***, present within the pancreas, stomach, and central nervous system, also has an inhibitory effect. It is released in response to food and its effect is mediated by both direct pancreatic acinar inhibition and a central nervous system inhibitory component.
- ***Peptide YY (PYY)***, contained in endocrine cells of the distal small intestine, is released by nutrients within the ileum and inhibits pancreatic secretion by acting on the acinar cells themselves, as well as centrally via the inhibitory regulation of vagal nerve.

There is also evidence that proteases within the duodenal lumen also have a negative feedback effect on acinar secretion. The gut-related peptides leptin and ghrelin, as well as influencing appetite behaviour, are also regulatory factors in the exocrine function of the pancreas. This effect is believed to occur via hypothalamic centres.

Endocrine pancreas

This consists of hormone-producing cells arranged in nests or islets (islets of Langerhans). The hormones produced are secreted directly into the circulation and there is no access to the pancreatic ductular system. There are ***five main types of islet cell*** corresponding to different secretory components:

- Beta cells are the most common and are responsible for insulin production.

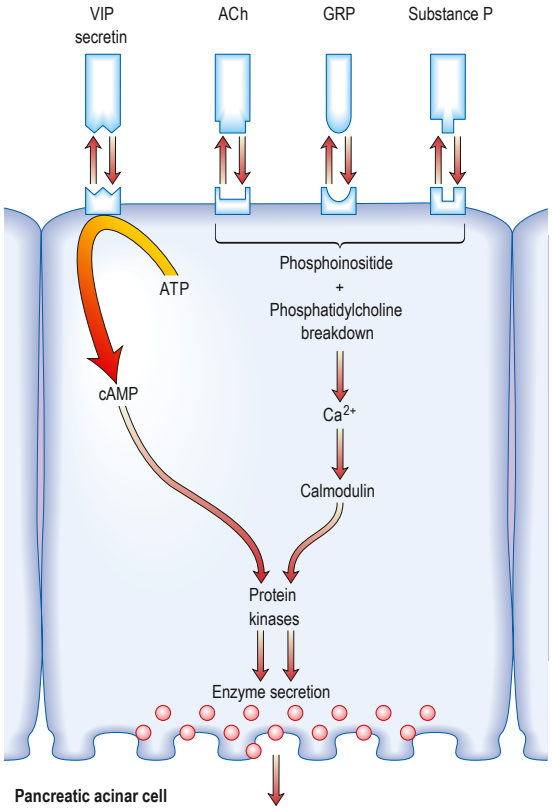

Fig. 24.12 Stimulation of digestive enzyme secretion from the acinar cell. G-protein-coupled receptors have been identified for vasoactive intestinal peptide (VIP), secretin, acetylcholine (ACh), gastrin-releasing polypeptide (GRP), and substance P. There are no cholecystokinin (CCK) receptors in humans. *ATP,* Adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate.

- Alpha cells produce glucagon.
- D cells produce somatostatin.
- PP cells produce pancreatic polypeptide.
- Enterochromaffin cells produce serotonin.

A number of other hormones have been identified within the endocrine pancreas, including gastrin-releasing peptide, neuropeptide Y, and galanin. These are believed to be neurotransmitters active in the neuro-gastrointestinal axis.

Investigations

Assessment of exocrine function

Pancreatic exocrine function is assessed in the investigation of patients with possible chronic pancreatic disease. Clinically evident fat malabsorption does not occur until there has been an 85% to 90% reduction in pancreatic lipase and is therefore a very late manifestation of pancreatic disease.

Direct tests of pancreatic function

These tests rely on the analysis of a duodenal aspirate following pancreatic stimulation, using either naso-duodenal tube or endoscopic aspiration. The original test involved pancreatic stimulation with the oral administration of a specified meal (Lundh meal) then replaced with intravenous secretin and CCK. The aspirate was assessed for pancreatic enzymes and bicarbonate production. These procedures are invasive and require meticulous technique, and so are now rarely used.

Non-invasive indirect tests of pancreatic function

Faecal tests

- ***Faecal elastase*** is an enzyme produced in the pancreas; as it is not degraded in the intestine, it has high concentrations within the faeces. Diminished levels are seen in moderate and severe pancreatic insufficiency. This assay has replaced the faecal chymotrypsin test. It is unaffected by the administration of oral pancreatic enzyme supplements as these do not contain elastase. However, as it relies on the concentration of elastase within the stool sample, it can render false low results in the context of diarrhoea or water contamination during sample collection, due to dilutional effects.
- ***Faecal fat estimation.*** This is rarely performed.

Oral pancreatic function tests

- ***N-benzoyl-L-tyrosyl-p-aminobenzoic acid*** (basis of the PABA test) and ***fluorescein dilaurate*** are oral compounds utilized in pancreatic function tests. They are digested by pancreatic enzymes, releasing substrates that are excreted and measured in the urine. Both tests are commercially available and have good sensitivity in moderate to severe pancreatic exocrine failure.

Clinical application of pancreatic function tests

While the invasive duodenal aspiration tests represent the most sensitive and specific means of assessing pancreatic function, they are very rarely used. The non-invasive tests are widely available but are highly sensitive only in the detection of severe pancreatic insufficiency. The faecal elastase test (in a commercially available form) provides similar sensitivity and specificity, and is the test of choice as a screening tool for pancreatic insufficiency.

Pancreatic imaging

Imaging (see Chapter 23) has a pivotal role in the investigation and management of pancreatic disease, which covers the spectrum of acute, chronic, and malignant conditions.

- ***A plain abdominal X-ray*** may show the calcification associated with chronic pancreatitis, particularly when alcohol is the aetiology.
- ***Transabdominal ultrasound*** of the pancreas usually offers reasonable views of the pancreas; it is a useful screening investigation for inflammation or neoplasia, and is reasonably sensitive for detection of gallstone disease in a patient with pancreatitis. Views may be limited by overlying bowel gas, and ultrasound should not be relied on in the exclusion of pancreatic neoplasia if clinical suspicion exists.
- ***CT scan*** with contrast enhancement and following a specific pancreatic protocol remains the 'gold standard' imaging technique for the investigation of pancreatic disease.
- ***MRI scanning*** represents an alternative to CT. MRCP gives clear definition of the pancreatic duct, as well as the biliary tree. Gallstones may also be identified in the biliary tree using MRI/MRCP.
- ***Endoscopic ultrasound (EUS)*** is very useful for identifying distal CBD stones, which may be the cause of an episode of acute pancreatitis. EUS can identify the early changes of chronic pancreatitis before these are evident with other imaging methods. There is also a role for this technique in staging the operability of pancreatic adenocarcinoma, particularly with respect to vascular invasion. EUS is now considered the imaging technique of choice for investigating cystic lesions of the pancreas (see later). The technique allows fine-needle aspiration or biopsy, as well

as the therapeutic option of cyst drainage using plastic or more recently LAMS. EUS is a sensitive means of detecting small pancreatic tumours, particularly those of neuroendocrine origin.

- ***Endoscopic retrograde cholangiopancreatography (ERCP)*** is an invasive procedure and, while having a good safety profile, is associated with a small risk of serious adverse events: in particular, the precipitation of acute pancreatitis. The availability of MRCP and EUS has provided alternative means of defining pancreatic pathology. ERCP retains a therapeutic role in pancreatic disease (see later).
- ***^{18F}Fluorodeoxyglucose positron emission tomography (FDG-PET)/CT and ^{68}gallium-DOTATATE PET/CT*** are scintigraphic techniques with a high diagnostic accuracy in patients with suspected neuroendocrine tumours, including those of the pancreas. They are also useful in defining the location of a neuroendocrine tumour, identifying multifocal small lesions, evaluating treatment options, and detecting metastatic disease.

In summary, an initial transabdominal ultrasound, supplemented by CT, provides sufficient diagnostic information for most inflammatory and neoplastic conditions of the pancreas. MRI and MRCP are now widely available and provide additional information, particularly with respect to pancreatic ductular and biliary anatomy. EUS is a useful, albeit more invasive, tool for the investigation of both benign and malignant disease of the pancreas, and facilitates fine-needle aspiration and biopsy of targetable lesions.

PANCREATITIS

Classification

Pancreatitis is divided into ***acute*** and ***chronic***. By definition, acute pancreatitis is a process that occurs on the background of a previously normal pancreas and can return to normal after resolution of the episode. Nevertheless, acute alcoholic pancreatitis occurs only in chronic misuse of alcohol. In chronic pancreatitis there is continuing inflammation with irreversible structural changes.

In practice, the differentiation between acute and chronic pancreatitis may be difficult. Any of the causes of acute pancreatitis, if untreated, may result in recurrent episodes, classified as ***acute relapsing pancreatitis*** and eventually bringing about permanent structural changes. In other cases, recurrent episodes of acute pancreatitis may represent exacerbations of an underlying chronic process.

Acute pancreatitis

Acute pancreatitis is a syndrome of inflammation of the pancreatic gland initiated by any acute injury. The causes of acute pancreatitis are listed in **Box 24.2**. In the Western world, gallstones and alcohol account for the vast majority of episodes. Alcohol also causes chronic pancreatitis (see later). The severity of the pancreatitis may range from mild and self-limiting to extremely severe, with extensive pancreatic and peripancreatic necrosis, as well as haemorrhage. In the most severe form (approximately 10% of cases) the mortality is between 40% and 80%.

Pathogenesis

This is still not completely understood. A precipitating event, such as gallstones or alcohol, is thought to induce the acute episode. Whatever the nature of the initiating insult, the pancreatic inflammatory response is secondary to the premature and exaggerated activation of digestive enzymes, principally trypsin, within the pancreas itself. In severe cases the subsequent cascade of autodigestion, microvascular injury, systemic inflammatory response, and bacterial translocation can result in a devastating outcome.

? Box 24.2 Causes of acute pancreatitis

Common
- Gallstones
- Alcohol
- Iatrogenic (post-ERCP, surgery)
- Idiopathic (<10%)

Less common
- Trauma
- Infections, e.g., mumps, Coxsackie B, HIV, adenovirus
- Pancreatic tumours
- Hereditary
- Congenital pancreatic abnormalities, e.g., pancreas divisum
- Metabolic, e.g., hypercalcaemia, hypertriglyceridaemia
- Venom, e.g., scorpion stings, spider
- Sphincter of Oddi dysfunction (see 'Sphincter of Oddi dysfunction' section)
- Miscellaneous
- Drugs (see next section)

Drugs
- Azathioprine/mercaptopurine
- Didanosine
- Oestrogens
- Antibiotics, e.g., tetracycline
- Valproic acid
- Furosemide
- Sulphonamides
- Aminosalicylates
- Corticosteroids
- Metronidazole
- ACE inhibitors
- DPP-4 inhibitors
- Incretin mimetics (GLP-1 agonists)

Gallstone pancreatitis

The inducing effect is obstruction to pancreatic drainage at the ampulla by a stone or associated oedema. In this pathological situation, trypsinogen is cleaved (by cathepsin B) to trypsin, and trypsin degradation by chymotrypsin C is impaired and quickly overwhelmed. Intracellular calcium also increases and may also cause early activation of trypsinogen with upregulation of nuclear factor kappa B, leading to extensive acinar cell damage.

Alcohol-induced pancreatitis

There is evidence that alcohol interferes with calcium homeostasis in pancreatic acinar cells. In addition, activation of pancreatic stellate cells by acetaldehyde occurs, with production of collagen and then matrix proteins.

Clinical features

Acute pancreatitis is a differential diagnosis in any patient with upper abdominal pain. The pain usually begins in the epigastrium, accompanied by nausea and vomiting. As inflammation spreads throughout the peritoneal cavity, the pain becomes more intense. Involvement of the retroperitoneum frequently leads to back pain.

The patient may give a history of previous similar episodes or be known to have gallstones. An attack may follow an alcoholic binge. However, in many cases, there are no obvious aetiological factors.

Physical examination at the time of presentation may show little more than a patient in pain with some upper abdominal tenderness but no systemic abnormalities. In severe disease the patient has a

tachycardia and hypotension, and is oliguric. Abdominal examination may show widespread tenderness with guarding, as well as reduced or absent bowel sounds. Specific clinical signs that support a diagnosis of severe necrotizing pancreatitis include periumbilical ***(Cullen's sign)*** and flank bruising ***(Grey Turner's sign)*** (Fig. 24.13). In patients with gallstone aetiology the clinical picture may also include jaundice or cholangitis.

Diagnosis

Blood tests

- ***Serum amylase*** is a sensitive test to diagnose acute pancreatitis if it is greater than three times the upper limit of normal. It performs best when measured within 24 hours of the onset of pain due to a relatively short half-life. A number of other conditions may occasionally cause a very elevated amylase (Box 24.3). Amylase levels gradually fall back towards normal over the next 3 to 5 days. With a late presentation the serum amylase level may give a false-negative result.
- ***Urinary amylase*** levels may be diagnostic, as they remain elevated over a longer period of time.
- ***Serum lipase*** levels are also raised in acute pancreatitis and remain elevated for a longer period of time than amylase levels, increasing diagnostic sensitivity in patients presenting more than 24 hours after onset of pain. Sensitivity is also increased compared to amylase in alcoholic pancreatitis where repeated episodes of inflammation may result in a progressive depletion of pancreatic enzymes; this is due to the higher content of lipase than amylase in pancreatic acinar tissue. As a result of these perceived advantages, many hospitals have now adopted serum lipase over amylase as their first-line test for acute pancreatitis.
- ***CRP level*** is useful in assessing disease severity and prognosis.
- ***Other baseline investigations*** include a full blood count, serum creatinine and electrolytes, blood glucose, liver biochemistry, plasma calcium, and arterial blood gases. These are documented at presentation and then repeated at 24 and 48 hours, providing a basis for assessing the severity of an attack (see later).

Fig. 24.13 Cullen's sign (periumbilical bruising) and Grey Turner's sign (flank bruising) coexisting in a patient with acute pancreatitis. These signs are observed infrequently in severe pancreatitis as haemorrhagic fluid tracks from the pancreas into the anterior abdominal wall and retroperitoneum. (Coexistence of Cullen's and Grey Turner's signs in Acute Pancreatitis 2009 AJM.)

Box 24.3 Elevation of serum amylase unrelated to pancreatitis

Leakage of upper gastrointestinal contents into the peritoneum
- Upper gastrointestinal perforation
- Biliary peritonitis
- Intestinal infarction

Inherited abnormalities of amylase
- Macroamylasaemia

Reduced clearance
- Acute or chronic renal impairment

Salivary disorders
- E.g., parotitis, salivary gland calculus

Radiology

- An erect ***chest X-ray*** is mandatory to exclude gastroduodenal perforation, which may also raise serum pancreatic enzymes (see Box 24.3). A supine abdominal film is generally not required but may show gallstones (if calcified) or pancreatic calcification.
- An ***abdominal ultrasound scan*** is used as a screening test to identify a possible biliary (gallstone) cause of pancreatitis. Gallstones are difficult to detect in the distal CBD but dilated intrahepatic ducts may occur in the presence of bile duct obstruction. Stones within the gall bladder are not sufficient to justify a diagnosis of gallstone-related pancreatitis. The ultrasound may also demonstrate pancreatic swelling and necrosis, as well as peripancreatic fluid collections if present. In severe pancreatitis the pancreas may be difficult to visualize because of gas-filled loops of bowel.
- ***Contrast-enhanced CT scanning*** is essential in all but the mildest attacks of pancreatitis. It should be performed after 72 hours to assess the extent of pancreatic necrosis. CT provides very valuable prognostic information. Later, repeated CT scans can detect other complications, including fluid collections, abscess formation, and pseudocyst development (Fig. 24.14).
- ***MRI (MRCP)*** assesses the degree of pancreatic damage and identifies gallstones within the biliary tree. MRI is particularly useful to differentiate between fluid and solid inflammatory masses.
- ***ERCP*** is used as a treatment measure to remove bile duct stones in selected cases of gallstone-related pancreatitis (see later).

Assessment of disease severity

The majority of cases of acute pancreatitis are mild and run a short, self-limiting course. However, approximately 25% follow a more complicated course and in 10% this is life-threatening. The revised Atlanta criteria define mild, moderately severe, or severe pancreatitis and are summarized in Box 24.4; they require assessment of organ failure using the Modified Marshall scoring system (Box 24.5). In practice, patients with moderately severe acute pancreatitis should be managed as having severe disease until sustained improvement is seen.

In severe cases mortality may be as high as 80%. The initial clinical course is marked by a systemic inflammatory response syndrome (SIRS), haemodynamic instability, and multiple organ failure. The consequences of SIRS, including respiratory and acute kidney injury, account for most of the mortality within the first 7 days of an episode of severe acute pancreatitis. After 7 days the majority of deaths are linked to delayed complications, such as sepsis due to infected collections or haemorrhage due to inflammatory effects on major vessels.

Accurate identification of patients likely to progress to severe pancreatitis permits appropriate monitoring and intensive care to be put in place. Early clinical assessment has been shown to have poor sensitivity for predicting a severe attack. Similarly, individual laboratory tests have very limited value. Therefore, multiple factors

Box 24.4 Severity of acute pancreatitis: revised Atlanta criteria 2013

Mild
- Absence of organ failure
- Absence of local complications

Moderate/severe
- Local complication and/or transient organ failure (<48 hours)

Severe
- Persistent organ failure (>48 hours), defined by the modified Marshall score for the evolution of organ failure (see **Box 24.5**)

have been used to develop clinical scoring systems. The ***Glasgow and Ranson scoring systems*** (**Boxes 24.6 and 24.7**) are based on such parameters and have been shown to have 80% sensitivity for predicting a severe attack, although only after 48 hours from presentation. The ***Acute Physiology and Chronic Health Evaluation (APACHE) II score*** has been extensively adopted as a means of assessing the severity of a wide spectrum of illness. It is based on common physiological and laboratory values, patient age, and the presence or absence of other chronic health problems, including obesity (**Box 24.8**). This scoring system appears to have a high sensitivity and can be applied as early as 24 hours after onset of symptoms. There is evidence that obesity affects the outcome of an episode of pancreatitis, perhaps because adipose tissue is a substrate for activated enzyme activity, worsening the inflammatory reaction. All scoring systems for predicting the severity of acute pancreatitis have proven to have modest utility in clinical practice. However, systematic classification tools can guide consistent clinical assessment and are certainly necessary in clinical studies and audit of outcomes.

Management

The initial management of acute pancreatitis is similar for all causes. A multiple factor scoring system (ideally, APACHE II with a modification for obesity) should be used at the end of the first 24 hours after presentation to allow identification of patients with a predicted severe attack. This should be repeated at 48 hours to identify a further subgroup that appears to be moving into the severe category. These patients should be managed in a high-dependency or intensive care unit and the case should be discussed with a specialist pancreatic unit at an early stage. Even patients outside the severe category may require considerable supportive care.

Early fluid losses in acute pancreatitis may be large, requiring well-maintained intravenous access and a urinary catheter to monitor circulating volume and renal function. Arterial and central venous catheterization may be necessary to facilitate close monitoring of haemodynamic status and permit repeat sampling of arterial blood gases. An initial moderate fluid resuscitation regimen is now preferred to an aggressive fluid resuscitation regimen (due to heightened risks of fluid overload), but careful monitoring of haemodynamic parameters remains essential to avoid under-resuscitation of patients with moderate or severe pancreatitis.

- ***Nasogastric suction.*** This prevents abdominal distension and vomitus, and hence the risk of aspiration pneumonia.
- ***Baseline arterial blood gases.*** These are a key predictive factor for severity of an episode and determine the need for continuous oxygen administration.
- ***Prophylactic antibiotics.*** Controlled data for the use of antibiotics are available but the results are not uniform in showing benefit, particularly in demonstrating improved mortality. There is some evidence that the β-lactam imipenem reduces the incidence of infected pancreatic necrosis. Antibiotics should usually be reserved for cases where cholangitis or infected necrotic tissue is strongly suspected and, if possible, the choice should be guided by blood culture results.
- ***Analgesia requirements.*** Opiates are usually required for immediate post-presentation pain control. Unless there is prompt control of pain, a patient-controlled system of administration is indicated to provide continuous and adequate pain relief. Fentanyl has been used widely for this application. There is a theoretical risk that morphine and diamorphine might exacerbate pancreatic ductular hypertension by causing sphincter of Oddi contraction. Although there are no clinical data to support this risk, some clinicians avoid these drugs in acute pancreatitis.
- ***Feeding.*** In a severe episode there is little likelihood of oral nutrition for a number of weeks. Total parenteral nutrition has been associated with a high risk of infection and so enteral nutrition is preferred. In the absence of gastroparesis, most patients will tolerate nasogastric administration of feed without exacerbation of pain. In those with gastroparesis or poorly tolerated nasogastric feeding (exacerbation of pain or precipitation of nausea and

vomiting), post-pyloric feeding should be instituted by the endoscopic placement of a nasojejunal tube.

- ***Anticoagulation.*** Low-molecular-weight heparin should be given for prophylaxis of deep vein thrombosis.

In a small proportion of patients, multiorgan failure will develop in the first few days after presentation, reflecting the extent of SIRS. Such patients may require positive-pressure ventilation and renal support (see Chapter 13).

Gallstone-related pancreatitis

In patients with gallstone-related pancreatitis and associated bile duct obstruction (particularly when complicated by cholangitis), endoscopic intervention with sphincterotomy and stone extraction is the treatment of choice. In the absence of bile duct obstruction, sphincterotomy and stone extraction are of proven benefit only when the episode of pancreatitis is predicted to be severe. In less severe cases of gallstone-related pancreatitis the presence of residual bile duct stones can be assessed electively by MRCP or EUS in the recovery phase of the acute episode; if stones are present, they can be removed by ERCP. To prevent a recurrent episode of gallstone pancreatitis, cholecystectomy should be carried out as soon as feasible after the acute episode has resolved.

Complications

These are listed in **Box 24.9**. After the first 7 days, the prognosis of acute pancreatitis is most closely related to the extent of pancreatic necrosis. This can be most accurately assessed by contrast-enhanced CT, which should be carried out in all patients with severe disease after the first week. Extensive necrosis (>50% of

the pancreas) is associated with a high risk of further complicated disease, frequently requiring radiological, endoscopic, or surgical intervention.

In this minority of patients with extensive necrosis of the pancreatic and peripancreatic tissues, superimposed infection is associated with a greatly increased risk of mortality. A 'step-up', minimally invasive approach is now preferred, with open surgical debridement avoided if possible. Long courses of antibiotics are given, and percutaneous drainage and EUS-guided endoscopic LAMS placement with necrosectomy are used to clear infected collections. The aims of such interventions are to control infection, evacuate devitalized tissues (the culture medium for invasive infection), and promote conditions for healing.

The best outcomes from intervention are achieved when debridement is delayed until at least 4 weeks after the onset of pancreatitis. When the damaged area has been walled off and liquefaction has begun, a pseudocyst develops.

Prognosis

The vast majority of patients with a mild to moderate episode of acute pancreatitis will make a full recovery with no long-term sequelae. Recurrent episodes of pancreatitis may occur, particularly if there has been any long-term pancreatic ductular damage. Patients with more severe acute pancreatitis may develop pancreatic insufficiency with respect to both exocrine (malabsorption) and endocrine function (diabetes); both carry their own significant, lifelong morbidity.

Chronic pancreatitis

Aetiology

In high-income countries, alcohol is reported to be the only aetiological factor in 60% to 80% of cases. There is a sizeable list of other reported aetiological factors, which can be categorized into toxic–metabolic, genetic, autoimmune, recurrent acute or severe acute pancreatitis, obstructive and idiopathic causes (**Box 24.10**).

Box 24.10 Causes of chronic pancreatitis

- Alcohol
- Chronic kidney disease
- Hereditary:
  - Cystic fibrosis
  - Trypsinogen and inhibitory protein defects
- Tropical chronic pancreatitis
- Obstructive
- Trauma
- Idiopathic
- Hypercalcaemia
- Recurrent acute pancreatitis
- Autoimmune (immunoglobulin G4)

Pathogenesis

There is increasing evidence that an increase in activated trypsin within the pancreas is a common pathway for the development of chronic pancreatitis. This may occur because of premature activation of trypsinogen to trypsin, or of impaired inactivation/clearance of the activated enzyme from the pancreas. It is believed that the increased or prolonged intrapancreatic enzyme activity leads to the precipitation of proteins within the duct lumen in the shape of plugs. These then form a nidus for calcification and cause ductal obstruction, leading to ductal hypertension and further pancreatic damage (**Fig. 24.15**).

In the case of alcohol-related chronic pancreatitis, ethanol increases intracellular calcium, promoting trypsinogen activation to trypsin, as well as diminishing the protective inactivation pathway. The observation that the majority of people drinking excess alcohol do not develop pancreatitis suggests that the disease process is a complex interaction of different mechanisms. It is proposed that the alcohol is only one factor that interacts with other environmental and genetic influences (see later).

Genetic aspects of chronic pancreatitis

Several genetic factors have been identified that influence the process of trypsin activation and inactivation. Cationic trypsinogen is the major form of trypsinogen produced in the pancreas and is encoded by the *PRSS1* gene (**Fig. 24.16**). Gain-of-function mutations of this gene are recognized as the major factor in hereditary pancreatitis, an autosomal dominant condition with high penetrance.

Calcium levels within the pancreas have a role in the process of activation and inactivation of trypsinogen/trypsin and are, in part, modulated by the calcium-sensing receptor (CASR). Mutations coding for this receptor have been associated with pancreatitis and are believed to facilitate the damaging effects of alcohol on the pancreas.

The serine protease inhibitor Kazal type 1 *(SPINK-1)* is a specific trypsin inhibitor and is co-secreted with trypsinogen by the acinar cells. Loss-of-function mutations of the *SPINK-1* gene have been associated with the development of chronic pancreatitis and identified as a factor in the development of tropical pancreatitis (almost certainly interacting with environmental triggers).

Chymotrypsin C is produced in trace amounts by the acinar cells and has also been shown to have a role in trypsin degradation. Loss-of-function mutations of the encoding gene have been identified in patients with chronic pancreatitis.

The cystic fibrosis transmembrane conductance regulator *(CFTR)* is expressed on the apical surface of the acinar cells and

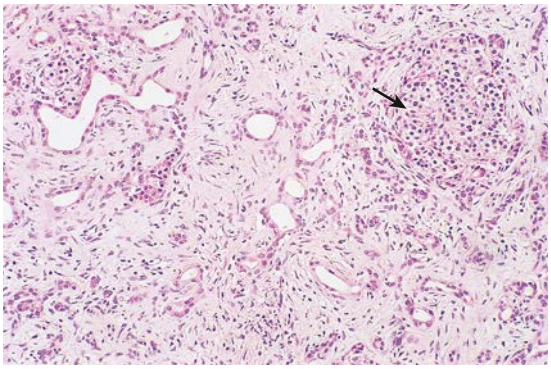

Fig. 24.15 Histology of chronic pancreatitis. There is considerable loss of acini and replacement by fibrosis. Inflammatory cells are relatively inconspicuous at this late stage. Islets of Langerhans (one is *arrowed*) sometimes escape destruction but their loss can result in diabetes mellitus. *(From Underwood JC [ed.]. General and Systematic Pathology, 4th edn. Edinburgh: Churchill Livingstone; 2004, with permission.)*

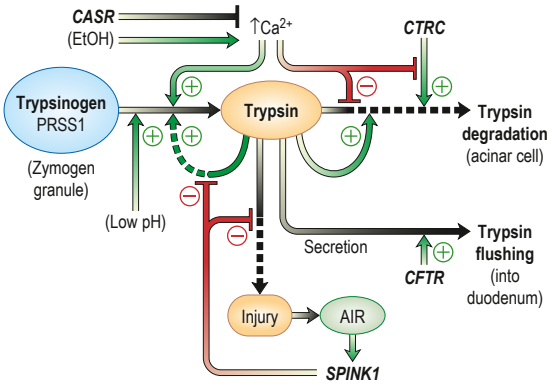

Fig. 24.16 Genetic factors in trypsinogen activation and trypsin inactivation. Early activation of trypsinogen to trypsin within the pancreas is crucial in the development of pancreatitis. Trypsinogen activation is promoted by cationic trypsinogen mutations (*PRSS1+*), active trypsin, high calcium (Ca^{2+}), and low pH. Calcium levels are regulated in part by calcium-sensing receptor (CASR) and dysregulated by ethanol (EtOH). Active trypsin degradation is facilitated by CTRC and by other active trypsin molecules, but blocked by high calcium. Active trypsin within the pancreas leads to pancreatic injury, which causes an acute inflammatory response (AIR). AIR upregulates expression of serine protease inhibitor Kazal 1 (SPINK-1), which blocks active trypsin and therefore prevents further activation of trypsinogens and limits further tissue injury. Cystic fibrosis transmembrane conductance regulator (CFTR) represents an extra-acinar cell mechanism to eliminate trypsin by flushing it out of the pancreatic duct and into the duodenum. *(Adapted from Whitcomb DC. Genetic aspects of pancreatitis.* Ann Rev Med *2010; 61:413–424.)*

is responsible for maintaining a high-volume, bicarbonate-rich pancreatic secretion. This high-volume secretion is responsible for flushing the activated trypsin into the duodenum. The homozygote or complex heterozygote *CFTR* mutations associated with the cystic fibrosis disease state are almost always manifest by perinatal/early pancreatic exocrine failure (see 'Cystic fibrosis' section). An increased frequency of a single *CFTR* mutation in patients with idiopathic chronic pancreatitis has been identified.

The identification of a genetic component to the development of chronic pancreatitis has led to speculation that, in many cases, the evolution of the disease is dependent on the complex interaction of gene–gene and gene–environmental factors.

Autoimmune chronic pancreatitis

Two types of autoimmune chronic pancreatitis (ACP) have been identified. The ***most common variant (type 1)*** is seen predominantly in middle-aged men and is associated with raised serum and tissue levels of IgG4. Other autoantibodies, including those directed towards nuclear and smooth muscle antigens, are also observed. Extrapancreatic tissue involvement is common, including the biliary tree (autoimmune cholangitis; see earlier), as well as thyroid, salivary gland, and renal tissue (see Chapter 6). In all these disorders there is a raised serum IgG4 level and, pathologically, there is a dense lymphoplasmacytic infiltrate with many IgG4-positive plasma cells, a mild to moderate eosinophil infiltrate, and an obliterative phlebitis in some organs. ACP is one of the few settings in which the pathogenesis of the disease may be independent of the activated trypsin pathways.

The ***second variant (type 2)*** tends to occur in early midlife with an equal sex distribution and does not have the autoimmune markers or IgG4-positive cells. Some 30% of cases are associated with inflammatory bowel disease. Disease is much more likely to be restricted to the pancreas and lacks the associations with other organ/tissue involvement seen with the type 1 variant. The hallmark of both types of autoimmune pancreatitis is evidence of responsiveness to steroids (see later).

The presentation of autoimmune pancreatitis is varied, particularly in type 1, in which extrapancreatic disease may predominate. Abdominal pain and weight loss are common features; jaundice may be an early symptom, both secondary to bile duct obstruction by the inflamed head of pancreas, and a manifestation of the cholangitis seen in type 1 cases.

Clinical features

Epigastric pain is the most common presentation of chronic pancreatitis, often radiating into the back. The pattern of pain may be episodic, with short periods of severe pain, or is chronic and unremitting. For those with an alcohol-related aetiology, exacerbations of the pain may follow further alcohol excess, although this is not a uniform relationship. Alcohol excess or meals with a high fat content may also lead to exacerbations of pain, independent of the aetiology.

During periods of abdominal pain, anorexia is common and weight loss may be severe. This is particularly so in those patients with chronic, unremitting symptoms. Exocrine insufficiency may develop at any time and occasionally malabsorption is the presenting feature in the absence of abdominal pain. Diabetes occurs in approximately 30% of cases and is usually a late event in the disease process, almost always following the development of exocrine insufficiency. Jaundice secondary to obstruction of the CBD during its course through the fibrosed head of the pancreas may also occur and may be a presenting feature in a small proportion of patients.

Investigations

The extent to which investigations are required is dependent on the clinical setting.

- ***Serum amylase and lipase*** levels may be elevated, but in advanced disease there may not be sufficient residual acinar tissue to produce this elevation.
- ***Serum IgG4 levels*** should be measured in those cases with suspected autoimmune pancreatitis.

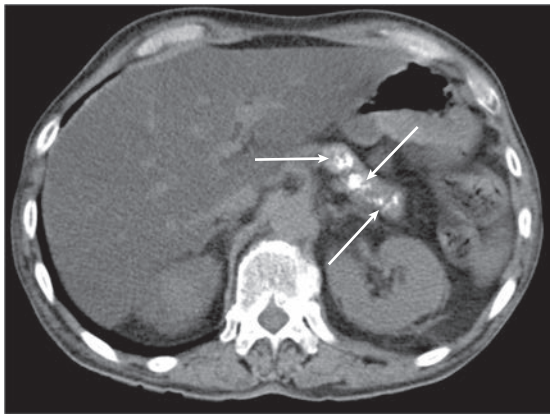

Fig. 24.17 Contrast-enhanced CT scan in a patient with chronic pancreatitis. Multiple calcific densities *(arrowed)* are demonstrated along the line of the main pancreatic duct.

- ***Faecal elastase*** level will be low in the majority of patients with moderate to severe pancreatic disease.
- ***Gene mutation analysis*** should be carried out in selected cases when the aetiology is uncertain. This is most relevant in patients presenting below the age of 40. Common mutations of the *PRSS1*, *SPINK-1*, and *CFTR* encoding genes are available via reference centres.
- ***Transabdominal ultrasound scan*** is frequently used for initial assessment.
- ***Contrast-enhanced CT scanning*** provides a more detailed assessment. In the presence of pancreatic calcification and a dilated pancreatic duct, the diagnosis of chronic pancreatitis can be readily established (Fig. 24.17). This may be much more difficult when these features are not present.
- ***MRI with MRCP*** is utilized to define more subtle abnormalities of the pancreatic duct, which may be seen in non-dilated chronic pancreatitis. Administration of intravenous secretin during an MRCP can afford dynamic images of pancreatic duct distension that offer an indirect measure of pancreatic exocrine function.
- ***MRCP*** has replaced diagnostic ERCP in the diagnosis of chronic pancreatitis. It has particular utility in defining ductal anatomy, strictures, and leaks.
- ***EUS*** is used increasingly when doubt about the diagnosis remains after non-invasive imaging, or specifically when complications of chronic pancreatitis, including pseudocyst formation and the possible development of malignancy, need assessment.

Differential diagnosis

The differential diagnosis is that of pancreatic malignancy. Carcinoma of the pancreas can reproduce many of the symptoms and imaging abnormalities that are commonly seen with chronic pancreatitis. The diagnosis of malignancy should be considered in patients with a short history when there is a localized pancreatic mass. Considerable difficulties may arise when a malignancy develops on the background of established chronic pancreatitis (the latter being a recognized pre-malignant lesion).

High-quality imaging is able to define malignant features with a localized mass lesion, local invasion, and lymph node enlargement. EUS with fine-needle biopsy provides the most accurate diagnosis of a potential mass lesion.

Management

In patients with alcohol-related chronic pancreatitis, long-term abstinence is likely to be of benefit, although this has been difficult to prove. Tobacco smoking is also an independent and strong risk factor for chronic pancreatitis and pancreatic cancer, and smoking cessation is strongly recommended. Autoimmune pancreatitis is steroid-responsive and failure to respond would put the diagnosis in question. Relapse is common when the steroids are withdrawn, and long-term immunomodulators (e.g., azathioprine) may be required.

Abdominal pain

For short-term flare-ups of pain, a combination of a non-steroidal anti-inflammatory drug (NSAID) and an opiate (tramadol) is usually sufficient for symptomatic relief. In patients with chronic unremitting pain, this may be inadequate and also risks opiate dependence.

Tricyclic antidepressants (e.g., amitriptyline) and membrane-stabilizing agents (e.g., pregabalin) are used for chronic pain and reduce the need for opiates. Coeliac axis nerve block may produce good pain relief but is unreliable in its efficacy and duration of action. In the majority of patients, some spontaneous improvement in pain control occurs with time. After a 6- to 10-year period, some 60% of patients will become pain-free. For recurrent severe or debilitating chronic pain, both endoscopic and surgical interventions have been used. Such intervention is indicated in patients with a dilated pancreatic duct upstream of a pancreatic duct stricture or stone. The endoscopic approach has centred on improving duct drainage by removing intraductal stones and duct stenting to maintain patency. ESWL has been used to fragment stones within the head of the pancreas.

Surgical intervention usually involves a duct drainage procedure, which can be combined with partial resection of the diseased pancreas. Trials have reported improved pain control following surgical intervention, as compared with the endoscopic approach. However, many patients have a high level of debility (and often continued alcohol excess) and are unsuitable for major surgery due to co-morbidity or technical factors such as the presence of varices within the operative field. In such circumstances, endoscopic therapy is justified as a first measure and there is no evidence that this adversely influences subsequent surgery.

Malabsorption

The steatorrhoea associated with pancreatic exocrine insufficiency may be intrusive, with up to 30 mmol of fat lost per 24 hours. This will usually improve with pancreatic enzyme supplements. Current preparations are presented in the form of microspheres, which reduce the problems of acid degradation in the stomach. An acid suppressor (H_2-receptor antagonist or proton pump inhibitor) is also given. Despite this, a proportion of patients continue to suffer malabsorption, usually reflecting the inadequate mixing of the pancreatic supplements with the food, as well as the low pH in the duodenum secondary to inadequate pancreatic bicarbonate production. There is no justification to reduce fat intake below the recommended levels of a normal diet, as this will contribute to the malnutrition seen in patients with chronic pancreatitis. Dietetic input is valuable for the management of malabsorption and also for monitoring and alleviating the malnutrition that is often seen secondary to abdominal pain and secondary food aversion.

Diabetes

Diabetes associated with pancreatic endocrine failure is termed type 3C diabetes and may be difficult to control, with a rapid progression

from oral hypoglycaemic agents to an insulin requirement. Labile blood sugar levels are a common problem secondary to inadequate glucagon production by the damaged pancreas.

Autoimmune pancreatitis

Most patients respond to glucocorticoid therapy, for example prednisolone 40 mg daily for 4 to 6 weeks. Relapses are treated with azathioprine or with rituximab.

Specific complications

The most common structural complication of chronic pancreatitis is a ***pancreatic pseudocyst***, a fluid collection surrounded by granulation tissue. These usually occur in relationship to a period of enhanced inflammatory activity within the pancreas giving abdominal pain but may develop silently during what would appear to be a stable phase. Intra- or retroperitoneal rupture, bleeding, or cyst infection may occur. The larger cysts may occlude nearby structures, including the duodenum and the bile duct. In pseudocysts less than 6 cm in diameter, spontaneous resolution can be anticipated. In larger cysts that have been present for a period longer than 6 weeks, resolution is less common and a long-term complication rate of approximately 30% can be anticipated. Many pseudocysts are closely opposed to the posterior wall of the stomach or duodenum and can be successfully drained endoscopically using EUS. A direct fistula is created between the pseudocyst lumen and the gastric or duodenal lumen, which is then kept patent by the insertion of removable stents. This approach will be successful in approximately 75% of cases. Surgical drainage is required for failures of endoscopic therapy or in circumstances where the pseudocyst anatomy does not allow endoscopic access.

Ascites and, occasionally, ***pleural effusions*** can be a direct consequence of chronic pancreatitis when there has been disruption of the main pancreatic duct. A high amylase level in the ascites or pleural fluid confirms the aetiology. Such disruptions of the main pancreatic duct require surgical intervention or ERCP and pancreatic duct stent placement.

There is an increased risk of ***pancreatic cancer*** in patients with chronic pancreatitis. The risk of malignancy is closely related to the duration of the inflammatory process. The highest incidence has been reported in hereditary pancreatitis, with a 50-fold increase and a lifetime risk as high as 40%. This reflects the early onset (in childhood) of the disease. Increases of 20- to 30-fold have been described in patients carrying other gene mutations and early onset of disease. The lifetime risk of malignancy in other causes of chronic pancreatitis, such as alcohol, which develop much later, is 10% to 15%. Cancer surveillance programmes have been proposed for the very high-risk groups (hereditary pancreatitis and other causes of early-onset disease), usually starting around the age of 40 years and relying on yearly imaging and tumour marker measurement.

Cystic fibrosis

Some 85% of people with cystic fibrosis (see Chapter 20) will have pancreatic exocrine failure, and in the majority of these this will develop *in utero* or the perinatal period. Malabsorption and failure to thrive are common presentations in the perinatal period and first year of life, and diabetes will develop subsequently in 30% of these patients during their lifetime.

In the remaining 15% of cases there is sufficient pancreatic exocrine secretion, which may persist throughout the patient's lifetime. This reflects residual *CFTR* function and is associated with class IV and V mutations. These patients tend to present later in life and have less severe pulmonary involvement, although this is not uniform. Some of these cases will progress to pancreatic exocrine insufficiency at variable times in the course of their disease. A small proportion develop symptomatic pancreatitis as part of this process.

The ***management*** of pancreatic exocrine insufficiency in cystic fibrosis is necessary to optimize growth and overall nutrition. ***Pancreatic enzyme supplements*** are closely titrated against the level of steatorrhoea. ***Fat intake*** should be maintained to avoid nutritional deficit. A daily ***lipase intake*** of up to 10 000 units/kg body weight is required. The efficacy of the supplements may be improved by the use of a ***proton pump inhibitor***. These drugs reduce the risk of acid denaturation of the enzymes. Despite optimization of the use of enzyme supplements, a degree of fat malabsorption may persist. This reflects other luminal abnormalities of fat absorption in cystic fibrosis that are related to viscous mucus, small bowel bacterial colonization, and poor mixing of the food with bile.

PANCREATIC CANCER

The many types of pancreatic cancer can be divided into two main groupings. The vast majority of cases occur in the exocrine component of the pancreas. There are several subtypes of exocrine pancreatic cancer but their diagnosis and treatment have much in common. A small minority of pancreatic cancers arise in the endocrine tissue of the pancreas and have different clinical characteristics.

Pancreatic adenocarcinoma

The incidence of pancreatic cancer in the West has been estimated at approximately 10 cases per 100 000, with a slight increase in incidence over the last 10 years. The diagnosis is rarely made in individuals younger than 40 years of age, and the median age at diagnosis is 71 years. Approximately 60% of patients with this condition are male. It is the eighth leading cause of death from cancer in males and the ninth leading cause of death from cancer in females worldwide. Some 96% of pancreatic cancers are adenocarcinoma in type and the large majority are of ductal origin.

Aetiology

Smoking is associated with a twofold increase. Excessive intake of alcohol or coffee and excessive use of aspirin have also been implicated. There is an increased incidence of pancreatic cancer among patients with a history of diabetes and chronic pancreatitis. The risk of developing pancreatic cancer is most marked in those patients with a genetic mutation predisposing to chronic pancreatitis (there is a 50 times increased risk in the presence of a *PRSS-1* mutation; see **Fig. 24.16**). Although it is estimated that 5% to 10% of pancreatic cancers have an inherited component, the genetic basis for familial

aggregation has not been identified in most cases. A subgroup of such high-risk kindreds carry germline mutations of DNA repair genes, such as *BRCA2* and the partner and localizer of *BRCA2*. Among people with a known family history of pancreatic cancer in a first-degree relative, the relative risk of pancreatic cancer developing is increased by a factor of 2, 6, and 30 in people with one, two, and three affected family members, respectively (Box 24.11).

Pathogenesis

Data suggest that pancreatic cancer results from the successive accumulation of gene mutations (Fig. 24.18). The cancer originates in the ductal epithelium and evolves from pre-malignant lesions to fully invasive cancer. The lesion called ***pancreatic intraepithelial neoplasia (PanIN)*** is the best-characterized histological precursor of pancreatic cancer. The progression from minimally dysplastic epithelium (PanIN grades 1A and 1B) to more severe dysplasia (grades 2 and 3) and finally to invasive carcinoma is paralleled by the successive accumulation of mutations. More than 90% of cases of PanIN of all grades have *KRAS* mutations. The mutational inactivation of the *CDKN2A*, *p53*, and *SMAD* family member *(SMAD4)* tumour suppressors is detected with increasing frequency in type 2 and type 3 lesions of PanIN, suggesting that they are rate-limiting events for tumour progression. Exome-sequencing studies have identified additional loss-of-function mutations encoding components of the SWI/SNF nucleosome remodelling complex, which are cumulatively detected in approximately 10% to 15% of pancreatic adenocarcinomas, as well as other, less frequent alterations.

Box 24.11 Relative risks of pancreatic cancer in patients with a family history or associated gene mutations

Risk factor	Relative risk
Familial pancreatic cancer	
Two first-degree relatives affected	18
Three first-degree relatives affected	57
Hereditary pancreatic cancer syndromes	
BRCA2 mutation	5.9
Familial atypical multiple mole melanoma (FAMMM)	16
Peutz–Jeghers's syndrome	36
Hereditary pancreatitis	50

A small percentage of pancreatic adenocarcinomas arise from cystic lesions, including ***intraductal papillary mucinous neoplasm (IPMN)*** and ***mucinous cystic neoplasia*** (see later). There is evidence that these cystic neoplasms demonstrate a similar multistep genetic and histological progression to invasive adenocarcinoma, although there are recognized differences in the mutational events that occur.

Clinical features

Approximately two-thirds of pancreatic cancers are located in the head of the pancreas, and the remainder in the body and tail (Fig. 24.19). Patients with pancreatic cancer most commonly present with abdominal pain, anorexia, and weight loss. Many have experienced low-grade symptoms for a number of months before they present for investigation. New onset of depressive symptoms has also been identified as an early manifestation. In many cases the onset of these non-specific symptoms is at a stage when there is already advanced local or metastatic disease. The pain associated with pancreatic cancer frequently radiates through into the back and, in some cases, is partially relieved by leaning forwards. Jaundice is a common, and maybe an early, manifestation of tumours of the ampulla and pancreatic head. This reflects the occlusion or compression of the distal CBD as it traverses the head of pancreas before entering the duodenum at the level of the ampulla.

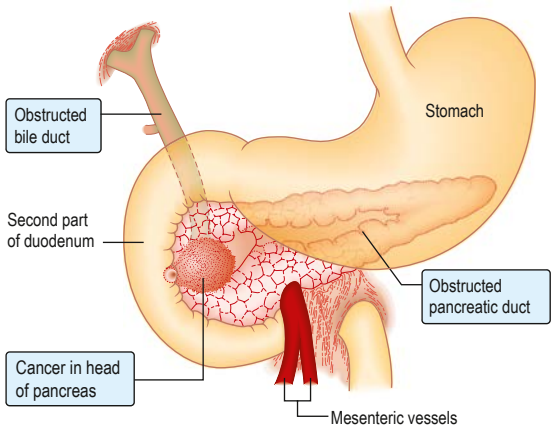

Fig. 24.19 Carcinoma of the head of the pancreas. The close relationship of a carcinoma of the head of pancreas to the surrounding structures.

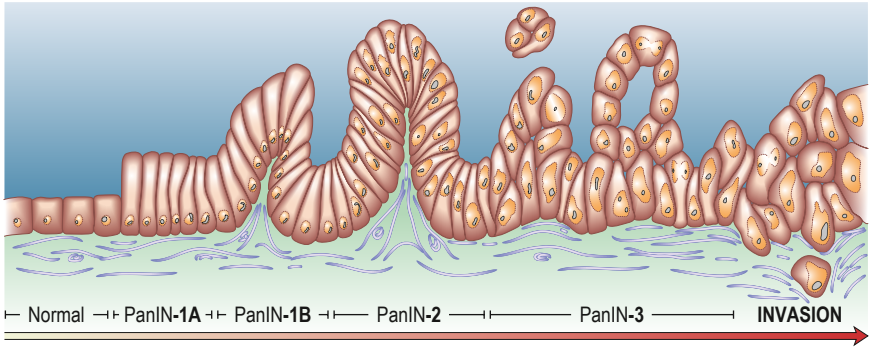

Fig. 24.18 Genetic model for the development of pancreatic ductal adenocarcinoma. The stages indicate histological progression with specific gene alterations. *PanIN,* Pancreatic intraepithelial neoplasia. *(Modified from Maitra A, Adsay NV, Argani P et al. Multicomponent analysis of the pancreatic adenocarcinoma progression model using a pancreatic intraepithelial neoplasia tissue microarray.* Mod Pathol *2003;16:902–912, with permission from the Nature Publishing Group.)*

The patient may have noticed pale stools, dark urine, and itching associated with bile duct obstruction in the absence (or prior to the onset) of detectable jaundice. Diabetes is present in at least 50% of patients with pancreatic cancer and may predate other manifestations of disease. The obstruction of the pancreatic duct by the cancer may also lead to symptoms of malabsorption and overt steatorrhoea. An episode of symptomatic pancreatitis may, on occasion, be the presenting clinical picture. Other unusual presenting features can include thromboembolic phenomena, polyarthritis, and skin nodules. These manifestations, distant to the tumour itself, have not been fully explained but may precede the development of a detectable pancreatic mass lesion by many months.

Signs

At the time of first presentation, there may be an absence of physical signs. Evidence of weight loss is common. Jaundice may be present, with associated excoriations prompted by pruritus. In a proportion of cases the gall bladder will be palpable ***(Courvoisier's sign)*** and secondary to an obstructed bile duct (or cystic duct). A palpable epigastric or central abdominal mass may be present as a reflection of advanced local disease. Liver metastases may be reflected in hepatomegaly.

Diagnosis and investigations

Patients with pancreatic adenocarcinoma frequently present for investigation at a late stage of tumour development, precluding curative surgery. In many cases, symptoms have been present for a number of months but have not led to investigation that is specifically aimed at confirming or excluding a pancreatic cancer. To improve outcomes from this cancer there is increasing emphasis on earlier diagnosis. This is focused on targeted investigation in patients recognized as high-risk (see earlier). More emphasis is also placed on earlier referral for investigation in patients over the age of 40 who have low-grade symptoms that persist after initial assessment and empirical therapy. The upper gut symptoms frequently prompt referral for an upper gastrointestinal endoscopy. In most cases this will not add diagnostic information and it is essential that a negative endoscopy does not delay further investigation—in particular, CT imaging. Increasing efforts have been made to detect possible early pancreatic cancer in patients newly diagnosed with diabetes. This includes NICE guidance on cancer screening that GPs consider an urgent CT scan, or an urgent ultrasound scan if CT is not available, to assess for pancreatic cancer in people aged 60 and over with weight loss and new-onset diabetes. However, it is important to note that less than 1% of patients newly diagnosed with diabetes will be diagnosed with pancreatic cancer within three years of that diabetes diagnosis.

- ***Transabdominal ultrasound*** is the initial imaging investigation in the majority of patients. In the presence of bile duct obstruction this will confirm dilated intrahepatic bile ducts, as well as a mass in the head of the pancreas. Ultrasound is less reliable when the cancer is found in the body and tail of the pancreas because of overlying bowel gas, and has a sensitivity of detection of 60%. A negative transabdominal ultrasound scan should not be considered as excluding the diagnosis of pancreatic cancer.
- ***Contrast-enhanced CT scan*** should confirm the presence of a mass lesion in most cases of pancreatic adenocarcinoma (Fig. 24.20). Lymph node involvement and metastatic disease will also be identified. If there is a high index of suspicion, a dual-phase pancreatic protocol CT scan should be requested from the outset. A high-quality pancreatic protocol CT is required as a staging procedure prior to planned curative surgery. Extending the CT to the chest will exclude pulmonary metastases.
- ***EUS*** is the most sensitive (>85%) non-surgical procedure for the detection of pancreatic cancer (Fig. 24.21). In most cases, it does not add to the diagnostic and staging information provided by the CT scan. However, the procedure is valuable for the definition of small (<2 cm) lesions of the pancreas, which may be missed on CT. EUS is now the approach of choice for obtaining histological confirmation of the underlying malignancy. A histological/cytological diagnosis is essential prior to planned chemotherapy. There are concerns that needle sampling of the tumour prior to a planned curative resection might lead to cancer cell seeding. This has been reported as a rare event (1%–2%).
- ***MRI and PET-CT scanning*** are useful techniques in patients when the local tumour or possibility of metastases has not been adequately defined. PET-CT is generally required in patients going forward for curative resection.

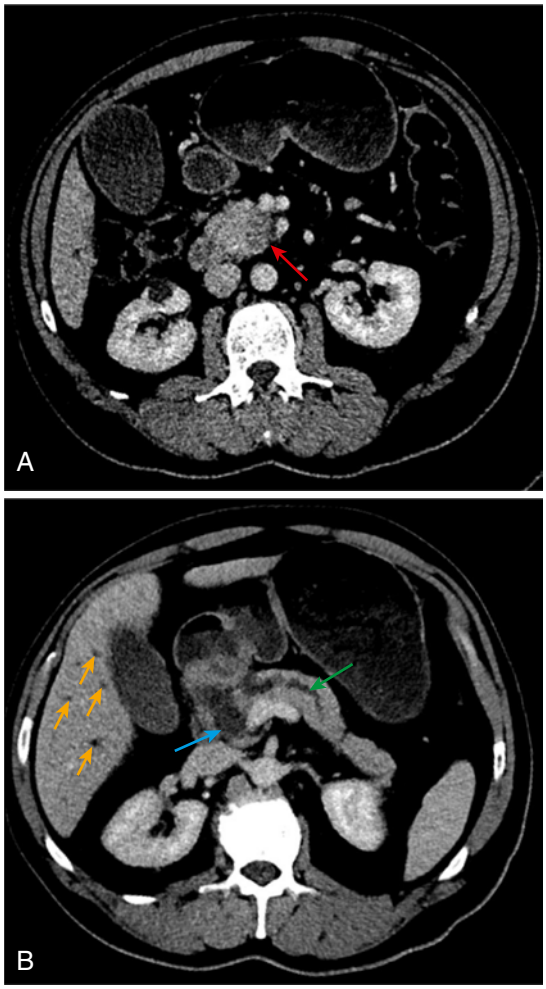

Fig. 24.20 Axial CT images demonstrating pancreatic cancer. **(A)** An image through the pancreatic head demonstrates a low-attenuation lesion in the head of the pancreas that is contacting the superior mesenteric artery and superior mesenteric vein *(arrowed)*. **(B)** A more superior image demonstrates dilation of both the pancreatic duct *(green arrow)* and common bile duct *(blue arrow)* (known as the double duct sign) due to compression of the ducts by the mass. Dilated intrahepatic ducts are also visible in the imaged portion of the liver *(yellow arrows)*.

- ***Several tumour markers*** have been evaluated for the diagnosis and monitoring of pancreatic cancer. The CA19–9 has reasonable sensitivity (80%) but a high false-positive rate. In individual patients, single values of these tumour markers may be of little help but a progressive elevation over time is often diagnostic; in such circumstances, tumour marker levels can be used to monitor response to treatment.

Differential diagnosis

The diagnosis should not be difficult in the presence of painless jaundice or epigastric pain radiating into the back with progressive weight loss. Unfortunately, many patients present with less specific symptoms including lethargy, poorly localized pain, change in bowel habit, and weight loss. Imaging, particularly abdominal CT, should be performed if pancreatic cancer is suspected. IgG4-related autoimmune pancreatitis is now recognized as a differential diagnosis in patients presenting with abdominal pain, jaundice, and an abnormal pancreas on imaging (localized or diffuse enlargement; see earlier). Pancreatic cancer may rarely present with recurrent episodes of typical acute pancreatitis.

Management

Please see Chapter 41.

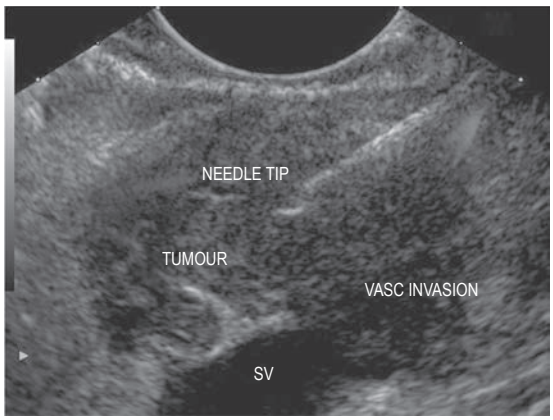

Fig. 24.21 An EUS scan with the probe in the distal stomach in a patient with pancreatic cancer. The patient presented with intractable periumbilical pain. A mass lesion of the pancreatic body is defined (tumour). There is invasion by the lesion into the splenic vein (SV, vasc invasion). The line of a transendoscopic needle is seen (needle tip), which has been placed under the guidance of the ultrasound probe to obtain a needle aspirate for cytological diagnosis.

Pancreatic cystic neoplasms

Cystic lesions of the pancreas are common. Around 75% will be pseudocysts (see 'Pancreatitis/Specific complications') but, of the remainder, the majority are true cystic neoplasms. Careful characterization of lesions with CT and MRI and discussion in a specialist pancreatic multidisciplinary team meeting are crucial. There is a high potential for the development of malignancy in large, true cystic neoplasms and therefore resection is generally recommended. The decision to operate may be difficult in patients with small (<3 cm) lesions of the head of the pancreas (in the absence of confirmed malignancy at presentation) and in those with significant co-morbidity. An initially conservative approach with follow-up imaging is then justified. Differentiation between pseudocysts and true cystic neoplasms may be difficult, even with multiple imaging techniques. EUS and fine-needle aspiration are frequently helpful in characterizing cystic lesions of the pancreas. EUS appearance (**Fig. 24.22**), cytology, and the measurement of cyst fluid carcinoembryonic antigen, glucose, and amylase may help to categorize cystic lesions and identify malignant change.

Serous cystadenomas are composed of multiple small, cystic cavities lined by cuboidal, glycogen-rich, mucin-poor cells. These lesions tend to occur in an elderly age group and are often an asymptomatic finding. Malignant transformation in a serous cystadenoma is extremely rare and so surgical resection is rarely required. Larger serous cystadenomas may cause local compressive complications, including pain, which may warrant surgical resection.

Solid pseudopapillary neoplasms are rare lesions, usually found in females in their fourth decade; they may occur anywhere in the pancreas. Resection is required, as around 20% show malignant features on histological examination.

Mucinous cystadenomas are almost exclusively found in females, usually in the fifth or sixth decade, and are sited in the pancreatic body and tail. Multilocular cysts are lined by tall, mucin-synthesizing cells. Around 20% of these lesions are malignant at the time of presentation and the majority appear to have malignant potential. Surgical resection is generally recommended.

IPMN is a pancreatic cystic neoplasm that can arise in either the main pancreatic duct (main duct IPMN) or its side branches (branch duct IPMN). The majority are found in males between the ages of 60 and 70. Presentation is usually with pancreatic pain but branch duct IPMN is often an incidental finding. IPMNs are slowly progressive but carry a significant malignant potential. Generally, all main duct IPMNs and large branch duct IPMNs should be resected. Small branch duct IPMNs have a much lower malignant potential and are generally kept under radiological surveillance.

Cystic degeneration of a pancreatic adenocarcinoma or pancreatic neuroendocrine tumour can occur.

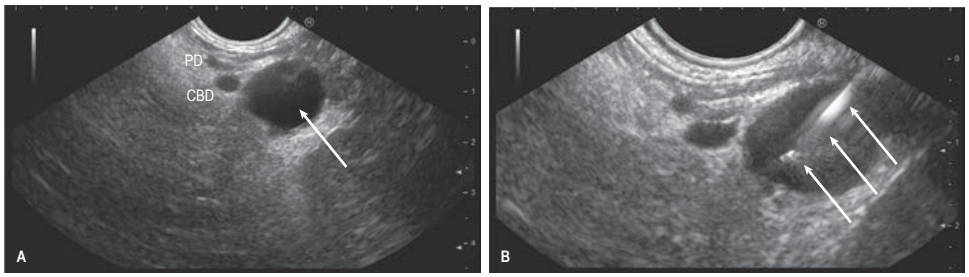

Fig. 24.22 Linear EUS images. (A) A cystic lesion *(arrowed)* in the head of the pancreas; the common bile duct (CBD) and pancreatic duct (PD) are also visible. The lesion is an intraductal papillary mucinous neoplasm. **(B)** The same lesion being sampled by fine needle aspiration for cytology, fluid amylase, and fluid carcinoembryonic antigen estimation. The needle is *arrowed*.

Pancreatic neuroendocrine tumours

Pancreatic neuroendocrine tumours (NETs) are thought to arise from the cells of the islets of Langerhans and can secrete a variety of active hormones, most frequently insulin. Pancreatic NETs have increased in incidence over the last two decades, reaching an incidence of 4–5/1 000 000 population. They represent a heterogeneous group of tumours with varying symptomology, tumour biology, and prognosis. Between 25% and 50% of the patients present with symptoms related to hormones released from the tumour. The remainder has 'non-functioning' tumours that may be an incidental finding or present with symptoms related to tumour bulk, such as obstruction, jaundice, bleeding, or abdominal mass. The increasing incidence of pancreatic NETs has been attributed in part to the widespread use of high-resolution cross-sectional imaging, leading to incidental diagnosis of asymptomatic lesions.

In addition to insulin and glucagon, pancreatic NETs may synthesize ectopic hormones that are not usually found in the pancreas, such as gastrin, adrenocorticotrophin, vasoactive intestinal peptide, and growth hormone. While many pancreatic endocrine tumours are multihormonal, one peptide tends to predominate and is responsible for any clinical syndrome (see later). Non-functioning pancreatic NETs often contain peptide hormone on immunostaining but this remains functionally inactive. The majority of endocrine pancreatic tumours are malignant in their behaviour. Between 10% and 15% of pancreatic NETs are linked to an inherited syndrome, such as the multiple endocrine neoplasia type 1 (MEN-1) (see Chapter 34) or von Hippel–Lindau (VHL) syndrome (see Chapter 26).

Clinical syndromes

Insulinoma is described in Chapter 34.

A ***gastrinoma*** accounts for approximately 1 in 1000 cases of duodenal ulcer disease. The ulceration results from hypersecretion of gastric acid secondary in response to high serum gastrin concentrations, secreted by the pancreatic tumour (Zollinger–Ellison's syndrome). Recurrent severe duodenal ulceration occurs, with only a partial response to acid suppression. The diagnosis is confirmed by an elevated gastrin level. High-dose proton pump inhibitors are used to suppress symptoms.

A ***VIPoma*** is an endocrine pancreatic tumour producing vasoactive intestinal polypeptide (VIP). This causes secretory diarrhoea secondary to the stimulation of adenyl cyclase within the enterocyte (Verner–Morrison or watery diarrhoea syndrome). The clinical syndrome is one of profuse watery diarrhoea, hypokalaemia, and a metabolic acidosis. To produce the syndrome, the tumours are usually in excess of 3 cm in diameter.

Glucagonomas are rare α-cell tumours that are responsible for a syndrome of migratory necrolytic dermatitis, weight loss, diabetes mellitus, deep vein thrombosis, anaemia, and hypoalbuminaemia. The diagnosis is made by measuring pancreatic glucagon in the serum.

Somatostatinomas are rare malignant D-cell tumours of the pancreas. These tumours cause diabetes mellitus, gallstones, and diarrhoea/steatorrhoea. They can be diagnosed by high serum somatostatin levels.

Investigations

Diagnosis is based on a combination of biochemical and histopathological markers. The biochemical diagnosis includes measurement of circulatory chromogranin A or specific hormones such as gastrin, insulin, glucagon, and VIP. The histopathology includes features such as positive staining for chromogranin A and specific hormones such as gastrin, pro-insulin, and glucagon.

Tumour localization depends on cross-sectional imaging, including CT and MRI scanning. The majority of NETs express somatostatin receptors, and a radiolabelled somatostatin analogue (such as octreotide) provides a means of tumour localization using scintigraphy. PET scanning with ^{18}F-FDG-PET/CT or ^{68}Ga-DOTATATE PET/CT is now widely used in the localization of primary disease and any metastases.

Identification of the primary and possibly metastatic lesions may be difficult despite multiple imaging techniques. EUS is the most sensitive means of detecting small primary NETs in the pancreas. It also offers the opportunity to undertake fine needle biopsy of lesions, affording a histological diagnosis (**Fig. 24.23**).

Management

Treatment of pancreatic NETs requires a multidisciplinary approach and depends on the presence or absence of metastatic (usually hepatic) disease. Where possible, surgical resection of the primary lesion is the optimal management of pancreatic endocrine tumours, as it offers the only possible cure. The propensity of many endocrine tumours to metastasize early precludes a cure in many cases. Debulking of the tumour, including liver metastases, is frequently carried out to facilitate systemic treatment.

Somatostatin analogues, such as octreotide and lanreotide, are used to control hormonal-related symptoms and also have a tumour-modulating effect. Radionuclide therapy using somatostatin analogues (peptide receptor radionuclide therapy [PRRT] with ^{177}Lutetium-DOTATATE) has proven benefit in patients with tumours that express a high content of somatostatin receptors.

Newer ***targeted and immunological systemic treatments*** used in the management of advanced pancreatic NET include everolimus (an mTOR inhibitor) and sunitinib (a tyrosine kinase inhibitor). Pancreatic NETs show a very high degree of vascularization, as well as abundant production and secretion of growth factors. There is evidence of benefit from anti-angiogenesis therapy utilizing vascular endothelial growth factor (VEGF) antagonists.

The ***chemotherapeutic agents*** temozolomide in combination with capecitabine or streptozotocin + 5-fluorouracil are the first-line chemotherapy regimens used to treat non-resectable pancreatic NET.

In patients with extensive liver metastases, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In many cases the tumours are slowly progressive and may allow a reasonable quality of life for many years.

CORE SKILLS AND KNOWLEDGE

It is vital that healthcare professionals consider nutrition as a contributor to health. Patients should be screened for under-nutrition on admission to hospital and referred to dieticians and nutrition teams for assessment. This is usually followed by the setting of nutritional goals and an individualized nutritional care plan. This is especially relevant where patients cannot swallow (such as for patients who have suffered a stroke) or in those who are hypercatabolic (e.g., during critical illness). Clinical nutrition and intestinal failure lie within the specialism of gastroenterology.

Key skills in nutrition include:

- Developing an awareness of patients at risk of malnutrition and performing a nutritional assessment
- Understanding the role of dietary supplements and clinically assisted nutrition
- Being aware of syndromes associated with specific micronutrient deficiencies
- Understanding the classification of intestinal failure and the treatment principles.

Opportunities for learning about nutrition include shadowing dieticians reviewing patients in the community or as inpatients, attending specialist nutrition ward rounds led by gastroenterologists, or attending multidisciplinary meetings. The nutrition multidisciplinary team usually consists of a mix of gastroenterologists, dieticians, nutrition clinical nurse specialists, pharmacists, and surgeons with an interest in intestinal failure if reconstructive surgery can be performed to restore nutritional autonomy.

CLINICAL SKILLS

Assessment and diagnosis of malnutrition

Screening

Detection of malnutrition begins with screening using validated tools. Early identification of individuals at risk is essential. The Malnutrition Universal Screening Tool (MUST, see **Fig. 25.1**) is the most commonly used screening tool in the UK. It consists of three parts:

1. Body mass index (BMI)
2. History of recent unintentional weight loss
3. Acute disease effect

Composite scoring results in the stratification of patients into low-, medium-, or high-risk categories for malnutrition and guides the user to develop an individualized treatment plan. BMI is calculated using the following equation: BMI = mass (kg)/height^2 (m). A normal BMI is considered to fall between 18.5 and 24.9 kg/m^2, with <18.5 kg/m^2 considered underweight, ≥25 kg/m^2 considered overweight, and ≥30 kg/m^2 classed as obese. For black, Asian, and some other minority ethnic groups, the normal BMI range is 18 to 23 kg/m^2, owing to the increased risk of developing conditions such as type 2 diabetes mellitus with a lower BMI than observed in white populations.

Another screening tool, the Nutritional Risk Score 2002 (NRS-2002), is validated among hospital inpatient populations and is used widely across Europe. In addition to nutritional components, severity of disease is also incorporated into the score to reflect the expected increase in nutritional requirements.

The aim of the screening process is to identify patients who require a more detailed nutritional assessment and formulation of a targeted individualized management plan. Re-screening of inpatients at 7-day intervals is recommended.

Nutritional assessment

Once patients have been identified as being at risk of under-nutrition, physiological and nutritional measures are used to confirm and quantify this risk. This is usually undertaken by a dietician who

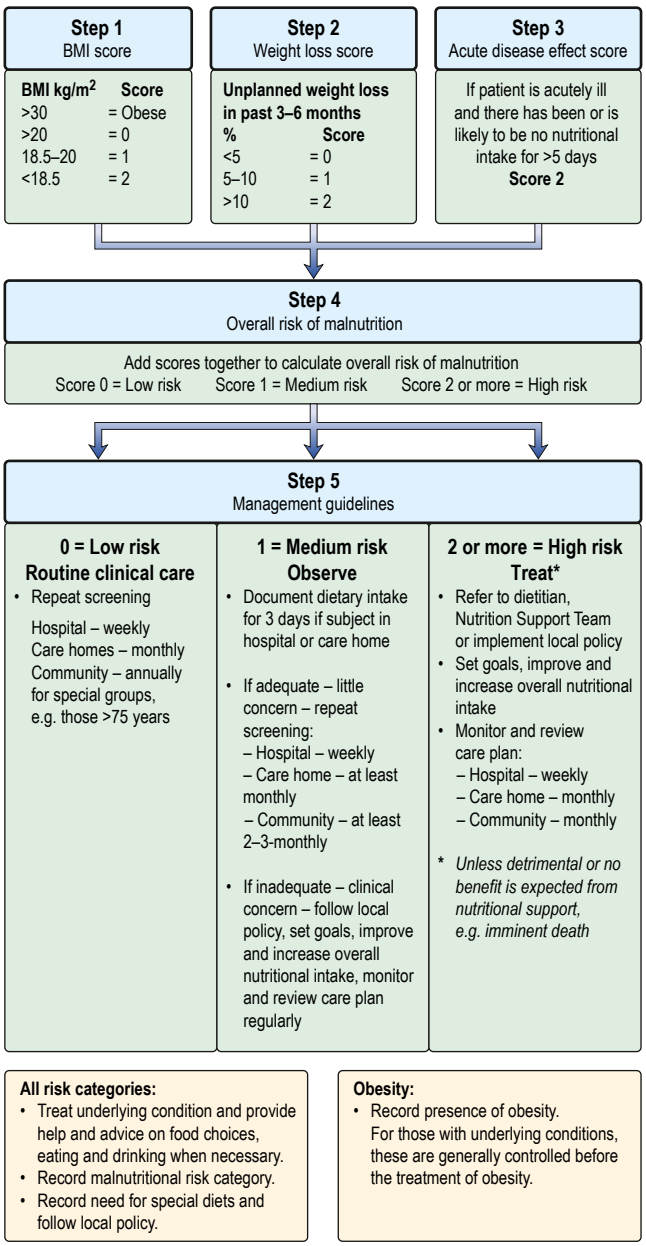

Fig. 25.1 Malnutrition Universal Screening Tool (MUST). *BMI,* Body mass index. *(With permission from the British Association for Parenteral and Enteral Nutrition (BAPEN), at: http://www.bapen.org.uk.)*

will perform a thorough assessment looking at the patient holistically. Assessment should take an 'ABCDE' approach (see **Fig. 25.2**).

Clinical examination

Bedside clinical examination can elicit the signs of malnutrition and the underlying driving pathology. A collection of specific signs may indicate particular nutritional deficiencies and subsequent complications. **Fig. 25.3** illustrates clinical features of malnutrition and how they relate to particular conditions.

Global assessment tools

Global assessment tools are then used to confirm formally a diagnosis of malnutrition and establish its severity in order to inform nutritional intervention. One such tool is the Subjective Global Assessment (SGA, **Fig. 25.4**), which refers to an overall evaluation of a patient's history and physical examination and uses structured clinical parameters to diagnose malnutrition. The SGA has been validated in multiple clinical scenarios and can predict morbidity and mortality associated with malnutrition.

Recently, the Global Leadership Initiative on Malnutrition (GLIM) published updated international criteria on the diagnosis of under-nutrition. These are divided into two categories: phenotypic criteria and aetiological criteria. The phenotypic criteria are (1) non-volitional weight loss, (2) low BMI, and (3) reduced muscle mass. The aetiological criteria are (1) reduced food intake or assimilation and (2) disease burden or inflammation. A diagnosis of malnutrition can be made when an individual meets at least one phenotypic and one aetiological criterion. The phenotypic criteria are well-established manifestations of under-nutrition, whereas the aetiological criteria help to determine treatment intervention. The phenotypic criteria also determine the degree of severity of malnutrition. Features such as >10% weight loss within the past 6 months and/or a BMI < 18.5 and/or severe muscle mass deficit are considered severe.

Management

Once under-nutrition has been confirmed using the above measures, a management plan with nutritional intervention can be developed (**Fig. 25.5**). This must take into consideration the above factors, goals of treatment (i.e., weight gain, improving or restoring function), and an assessment of the risk of re-feeding (see 'Re-feeding syndrome' section).

MALNUTRITION: INTRODUCTION AND BACKGROUND

Nutrition is essential for health. A number of acute and chronic illnesses negatively impact on food intake and metabolism, resulting in under-nutrition and consequent increased morbidity and mortality. Additionally, food intake determines health and plays a major role in conditions such as cardiovascular disease, diabetes, and cancer.

The term malnutrition is used to describe a deficiency, excess, or imbalance of nutrients, which can lead to adverse effects on body composition, function, and clinical outcome. The focus of this chapter will be on under-nutrition. Overnutrition and obesity are covered in Chapter 37. Under-nutrition remains a major clinical and public health concern worldwide.

Globally, malnutrition affects approximately 1 billion people. In low- and middle-income countries, the lack of food and poor usage of available food, often in association with coexistent inflammatory processes, often result in under-nutrition and micronutrient deficiencies. Worldwide, in 2011, 165 million children under 5 years of age were affected by growth stunting, and at least 52 million by muscle wasting. Under-nutrition is also common in the UK, affecting over 3 million people. This can be disease related or a

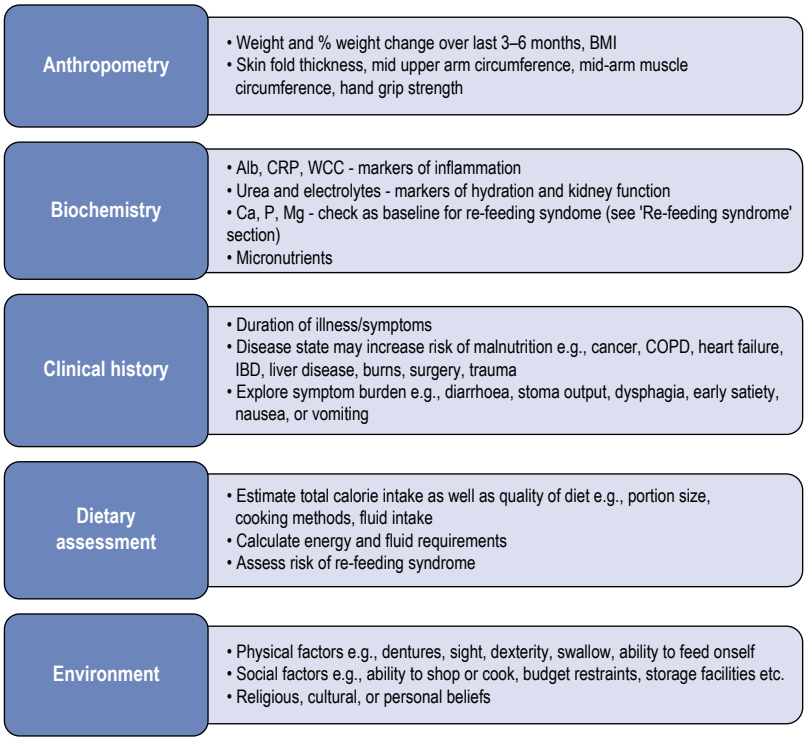

Fig. 25.2 The ABCDE approach to nutritional assessment. *Alb,* Albumin; *BMI,* body mass index; *Ca,* calcium; *CRP,* C-reactive protein; *Mg,* magnesium; *P,* phosphate; *WCC,* white cell count.

consequence of psychosocial circumstances (**Box 25.1**). According to one report by The British Association of Parenteral and Enteral Nutrition (BAPEN), 25% to 34% of patients admitted to hospital and 30% to 42% of elderly people admitted to care homes are at risk of malnutrition.

Malnutrition has negative effect on the function and recovery of all body systems (**Box 25.2**). In the hospital setting, malnutrition is associated with longer length of stay, increased morbidity and mortality. Crucially, unlike other risk factors, it is also modifiable with cheap and safe interventions. It therefore presents an ideal opportunity for intervention and it is vital that healthcare professionals are trained to assess for, diagnose, and treat malnutrition.

MECHANISMS IN UNDER-NUTRITION

Dietary requirements

In the UK, dietary reference values for food, energy, and nutrients are stated as ***reference nutrient intakes*** (RNIs), on the basis of data from the Food and Agriculture Organization (FAO-WHO), United Nations University (UNU) expert committee, and elsewhere. The RNI is sufficient, or more than sufficient, to meet the nutritional needs of 97.5% of healthy people in a population. Most people's daily requirements are less than this, and so an ***estimated average requirement (EAR)*** is also given, which will certainly be adequate for most. A lower reference nutrient intake (LRNI), which fails to meet the requirements of 97.5% of the population, is also given. The RNI figures quoted in this chapter are for the age group 19 to 50 years. These represent values for healthy subjects and are not always appropriate for patients with disease.

Water and electrolyte balance

Water and electrolyte balance is dealt with fully in Chapter 27. About 1 L of water is required in the daily diet to balance insensible losses but much more is usually drunk, the kidneys being able to excrete large quantities. The daily RNI for sodium is 70 mmol (1.6 g) but daily sodium intake varies in the range 90 to 440 mmol (2–10 g). These are needlessly high intakes of sodium, which are thought to play a role in causing hypertension (see Chapter 18). The World Health Organization (WHO) also recommends at least 90 mmol (3.5 g) of potassium, which would reduce blood pressure and cardiovascular risk of stroke and coronary artery disease.

Energy

Food is necessary to provide the body with energy (**Fig. 25.6**). The SI unit of energy is the joule (J), and 1 kJ = 0.239 kcal. The conversion factor of 4.2 kJ, equivalent to 1.00 kcal, is used in clinical nutrition.

Energy balance

Energy balance is the difference between energy intake and energy expenditure. Weight gain or loss is a simple but accurate way of indicating differences in energy balance.

There are two approaches to assessing energy requirements for subjects who are weight-stable and close to energy balance:

- assessment of energy intake
- assessment of total energy expenditure.

Energy intake

Energy intake can be estimated from dietary surveys and, in the past, this has been used to decide daily energy requirements. However, measurement of energy expenditure gives a more accurate assessment of requirements.

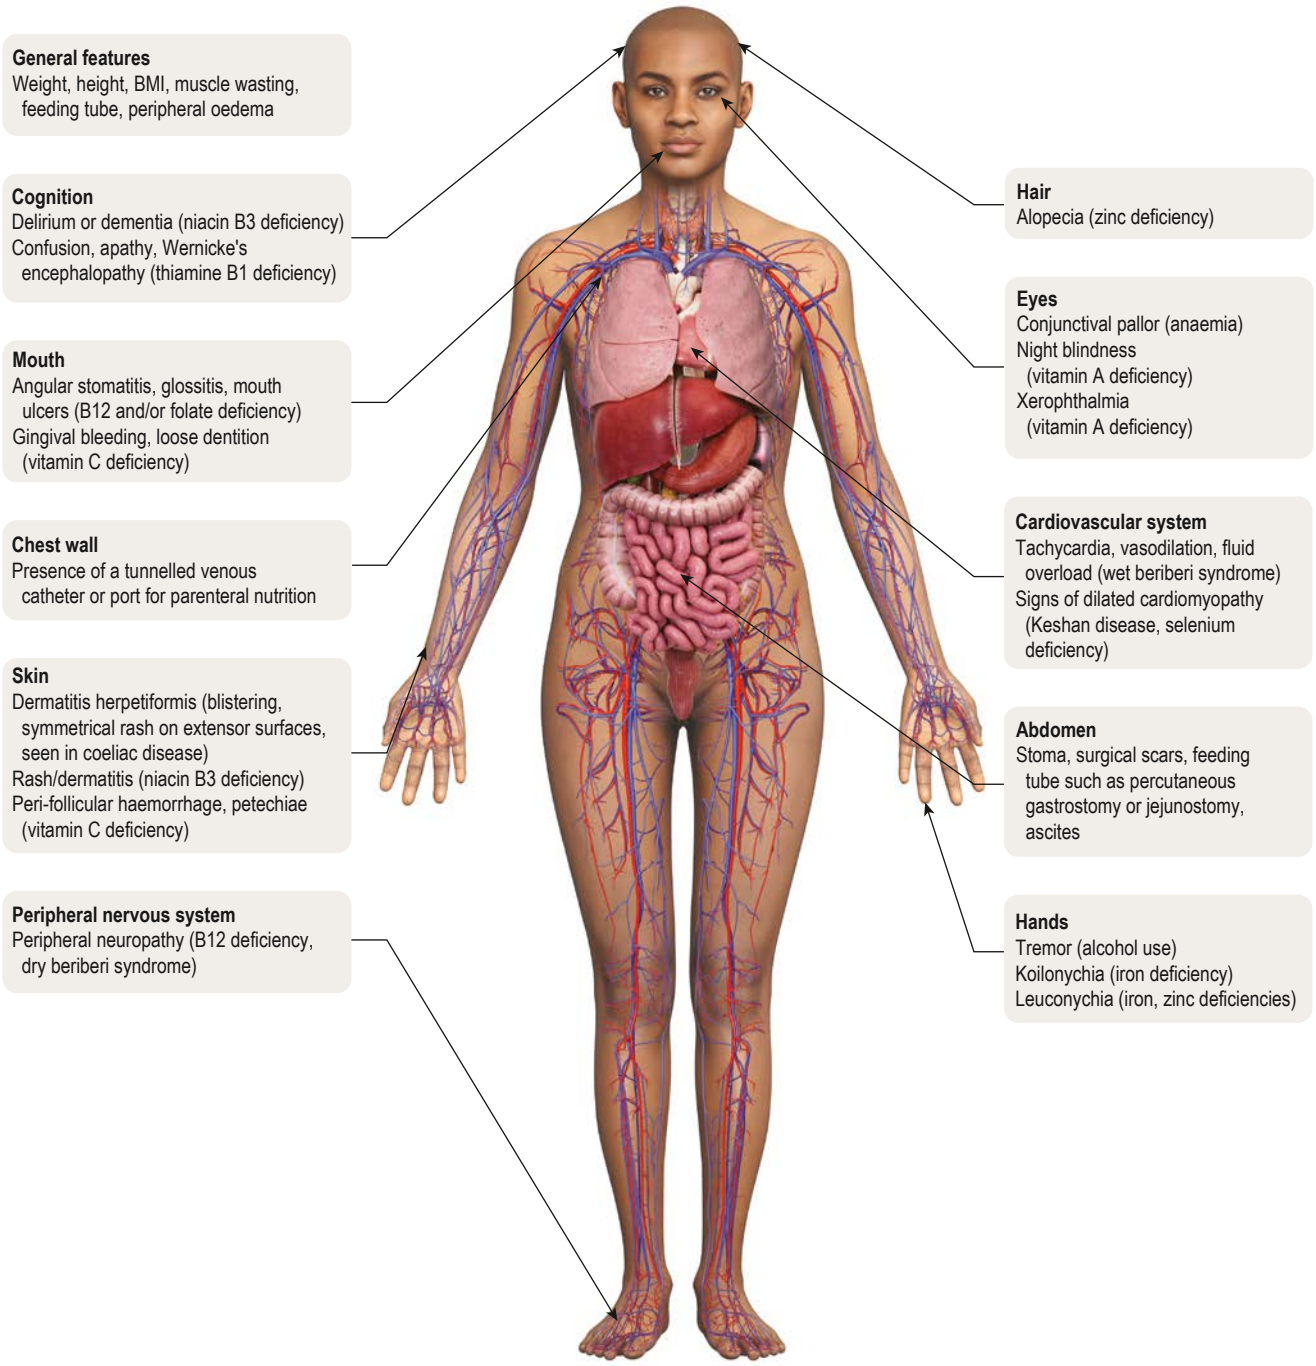

Fig. 25.3 **Examination: clinical features of malnutrition.**

Energy expenditure

Daily energy expenditure (Fig. 25.7) is the sum of:

- the basal metabolic rate (BMR)
- the thermic effect of food eaten
- occupational activities
- non-occupational activities.

Total energy expenditure can be measured using a double-labelled water technique. Water containing the stable isotopes ^{2}H and ^{18}O is given orally. As energy is expended, carbon dioxide and water are produced. The difference between the rates of loss of the two isotopes is used to calculate the carbon dioxide production, which is then used to calculate energy expenditure. This can be done on urine samples over a 2- to 3-week period with the subject ambulatory. The technique is accurate, but it is expensive and requires the availability of a mass spectrometer. An alternative tracer technique for measuring total energy expenditure is to estimate CO_2 production by isotopic dilution. A subcutaneous infusion of labelled bicarbonate is administered continuously by a minipump, and urine is collected to measure isotopic dilution by urea, which is formed from CO_2. Other methods for estimating energy expenditure, such as heart rate monitors or activity monitors, are also available but are less accurate.

SUBJECTIVE GLOBAL ASSESSMENT RATING FORM	
Patient name: ID #: Date:	
HISTORY	
WEIGHT/WEIGHT CHANGE: ***(Included in K/DOQI SGA)*** **1. Baseline Wt:** _____(Dry weight from 6 months ago) **Current Wt:** _____(Dry weight today) **Actual Wt loss/past 6 mo:** _____ **% loss:** _____(actual loss from baseline or last SGA) **2. Weight change over past two weeks:** _____No change _____Increase _____Decrease	**Rate 1–7**
DIETARY INTAKE No change_____(Adequate) No change_____(Inadequate) 1. Change: Sub optimal intake:_____Protein_____Kcal_____Duration_____ Full liquid:_____Hypocaloric liquid_____Starvation_____	
GASTROINTESTINAL SYMPTOMS ***(Included in K/DOQI SGA-anorexia or causes of anorexia)*** **Symptom:** **Frequency:*** **Duration:+** _____ None _____ _____ _____ Anorexia _____ _____ _____ Nausea _____ _____ _____ Vomiting _____ _____ _____ Diarrhea _____ _____ Never, daily, 2–3 times/wk, 1–2 times/wk > 2 weeks, < 2 weeks	
FUNCTIONAL CAPACITY **Description** **Duration:** _____ No dysfunction _____ _____ Change in function _____ _____ Difficulty with ambulation _____ _____ Difficulty with activity (Patient specific "normal") _____ _____ Light activity _____ _____ Bed/chair ridden with little or no activity _____ _____ Improvement in function _____	b
DISEASE STATE/COMORBIDITIES AS RELATED TO NUTRITIONAL NEEDS Primary diagnosis_____Comorbidities_____ Normal requirements ____Increased requirements ____Decreased requirements _____ Acute metabolic stress: _____ None _____Low _____Moderate _____High	
PHYSICAL EXAM	
_____ Loss of subcutaneous fat (Below eye, triceps, biceps, chest) ***(Included in K/DOQI SGA)*** ____Some areas _____All areas _____ Muscle wasting (Temple, clavicle, scapula, ribs, quadriceps, calf, knee, interosseous ***(Included in K/DOQI SGA)*** ____Some areas _____All areas _____ Edema (Related to under-nutrition/use to evaluate weight change)	
OVERALL SGA RATING	
Very mild risk to well-nourished = 6 or 7 most categories or significant, continued improvement. **Mild–moderate** = 3, 4, or 5 ratings. No clear sign of normal status or severe malnutrition. **Severely malnourished** = 1 or 2 ratings in most categories/significant physical signs of malnutrition.	

Fig. 25.4 Subjective Global Assessment tool.

BMR can be calculated by measuring oxygen consumption and CO_2 production, but it is more usually taken from standardized tables (Box 25.3) that only require knowledge of the subject's age, weight, and sex.

The ***physical activity ratio*** (PAR) is expressed as multiples of the BMR for both occupational and non-occupational activities of varying intensities (Box 25.4).

In the UK, the estimated 'average' daily requirement (EAR) for energy is:

- for a 55-year-old female—8700 kJ (2079 kcal)
- for a 55-year-old male—10 800 kJ (2581 kcal).

Energy requirements increase during the growing period, with pregnancy and lactation, and sometimes following infection or trauma. For example, the EAR for pregnant women in the third trimester increases by 800 kJ per day (200 kcal/day). In general, the increased BMR associated with inflammatory or traumatic conditions is counteracted, or more than counteracted, by a decrease in physical activity, so that total energy requirements are not increased.

In the basal state, energy demands for resting muscle are 20% of the total energy required, those for abdominal viscera 35% to 40%, those for brain 20% and those for heart 10%. There can be more than a 50-fold increase in muscle energy demands during exercise.

Energy stores

Although virtually all body fat and glycogen are available for oxidation, less than half the protein is available for oxidation. Fig. 25.8 shows that fat accounts for the largest reserves of energy in both

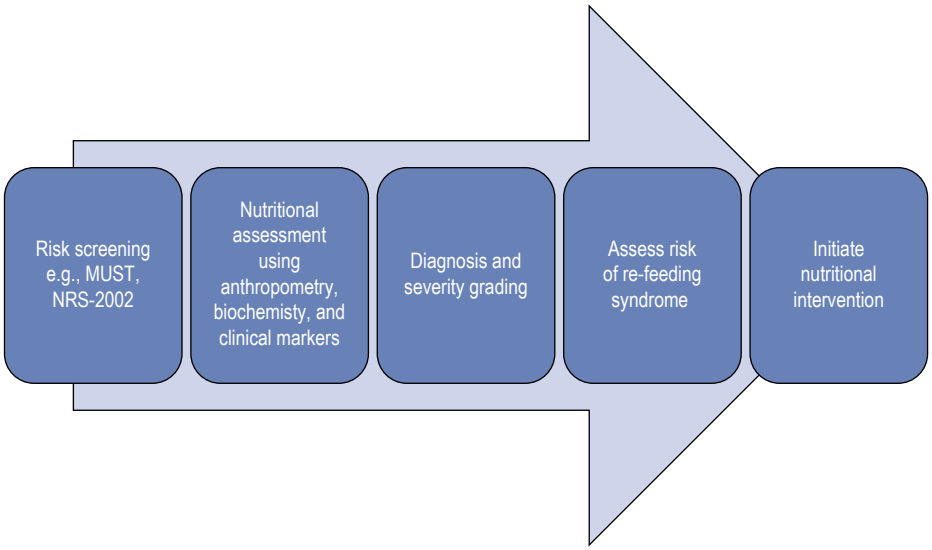

Fig. 25.5 **Process of nutritional screening and assessment.**

Box 25.1 Who is at risk of under-nutrition?

- Older patients, particularly if they are living in a care home or nursing home
- People with chronic illnesses such as chronic inflammatory conditions, chronic liver disease, cancer
- People with chronic progressive conditions such as degenerative neuromuscular conditions or dementia
- People who abuse alcohol or drugs
- Patients affected by social deprivation such as poverty or social isolation, limited mobility, inability to feed self, or lack of transport
- Physical factors such as poor dentition

Box 25.2 Consequences of under-nutrition

- Reduced muscle mass and strength (sarcopenia)
- Impaired gut integrity and immunity
- Decreased immune function with increased susceptibility to infections and slow wound healing
- Depression and/or apathy
- Reduced cardiac output
- Impaired liver function and fatty change

lean and obese subjects. The size of the stores determines survival during starvation.

Body weight

Body weight depends on energy balance. Intake depends not only on food availability but also on a number of complex interrelationships that include the stimulus of appetizing food, the role of hunger, metabolic changes (e.g., hypoglycaemia), and the pleasure and habit of eating. Some people are able to keep their body weight constant within a few kilograms for many years, but most gradually increase their weight owing to a small but continuous increase of intake over expenditure. A gain or loss of energy of 25 to 29 MJ (6000–7000 kcal) would, respectively, increase or decrease body weight by approximately 1 kg.

Protein

In the UK, the adult daily RNI for protein is 0.75 g/kg, with protein representing at least 10% of the total energy intake. Most affluent people eat more than this, consuming 80 to 100 g of protein per day. The total amount of nitrogen excreted in the urine represents the balance between protein breakdown and synthesis. In order to maintain nitrogen balance, at least 40 to 50 g of dietary protein is needed. The amount of protein oxidized can be calculated from the amount of nitrogen excreted in the urine over 24 hours using the following equation:

$$\text{Grams of protein required} = \text{urinary nitrogen} \times 6.25$$

(most proteins contain about 16% of nitrogen)

In healthy individuals, urinary nitrogen excretion reflects protein intake. However, excretion does not match intake in catabolic conditions (negative N balance), or during growth or repletion following an illness (positive N balance).

Protein contains many ***amino acids:***

- ***Indispensable (essential).*** There are nine amino acids that cannot be synthesized and must be provided in the diet: tryptophan, histidine, methionine, threonine, isoleucine, valine, phenylalanine, lysine, and leucine.
- ***Dispensable (non-essential).*** These are amino acids that can be synthesized in the body (some may still be needed in the diet unless adequate amounts of their precursors are available).

Animal proteins (e.g., in milk, meat, and eggs) contain a good balance of all the indispensable amino acids, but many proteins from vegetables are deficient in at least one indispensable amino acid. In low- and middle-income countries, protein intake derives mainly from vegetable proteins.

Loss of protein from the body (negative N balance) occurs not only because of inadequate protein intake but also because of inadequate energy intake. When there is loss of energy from the body, more protein is directed towards oxidative pathways and, eventually, gluconeogenesis for energy.

Role of amino acids

- ***Glutamine*** is quantitatively the most significant amino acid in the circulation and in inter-organ exchange.
- ***Alanine*** is released from muscle; it is deaminated and converted into pyruvic acid before entering the citric acid cycle.
- ***Homocysteine*** is a sulphur-containing amino acid that is derived from methionine in the diet. A raised plasma concentration is an independent risk factor for vascular disease.

Labourer	3.0
Reading/eating	1.2
Household/cooking	2.1
Gardening/golf	3.7
Jogging/swimming/football	6.9

Amino acids are utilized to synthesize products other than protein or urea. For example:

- ***Glycine*** is required for haem production.
- ***Tyrosine*** is required for melanin and thyroid hormones.
- ***Glutamine, aspartate, and glycine*** are required for nucleic acid bases.
- ***Glutamate, cysteine, and glycine*** are required for glutathione, which is part of the defence system against free radicals.

Fat

Fat is required as part of a healthy and balanced diet; it contains essential fatty acids (EFAs) and carries the fat-soluble vitamins (A, D, E, and K). Dietary fat is chiefly in the form of triglycerides, which are esters of glycerol and free fatty acids. Fatty acids vary in chain length and in saturation.

The ***essential fatty acids*** are linoleic and α-linolenic acid, both of which are precursors of prostaglandins. Eicosapentaenoic and docosahexaenoic acid are also necessary, but can be manufactured to a limited extent in the tissues from linoleic and linolenic acid, and thus a dietary supply is not essential.

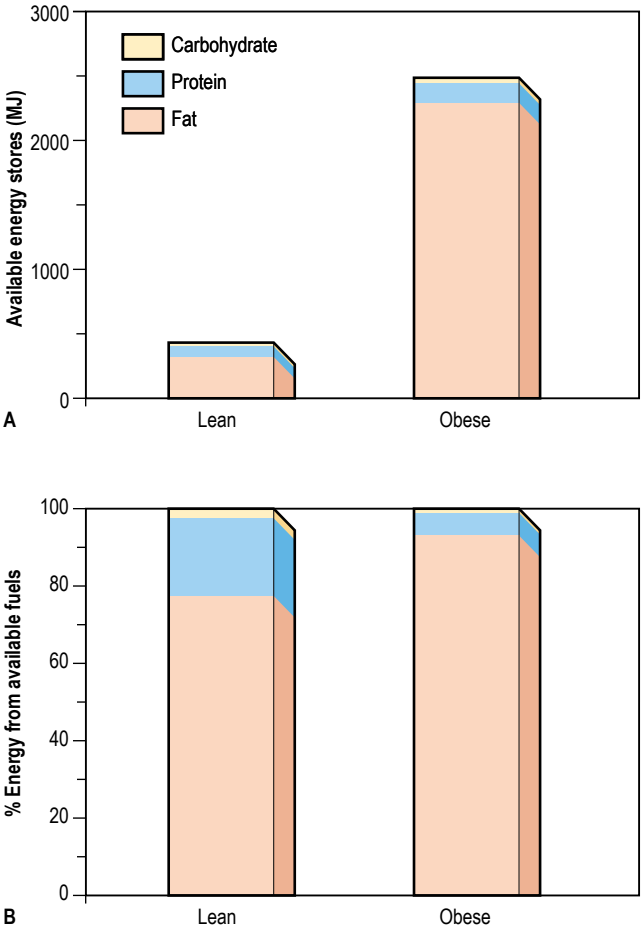

Fig. 25.8 Available energy reserves from different fuels. Values are shown for a lean hypothetical 70-kg adult and an obese 140-kg adult. **(A)** Expressed in MJ. **(B)** Expressed as a percentage of the total.

EFA deficiency can occur in starvation-related malnutrition (see below), and it has been clearly defined as a clinical entity in patients on long-term parenteral nutrition who receive glucose and protein, with no fat. Alopecia, thrombocytopenia, anaemia, and dermatitis can occur within weeks.

Synthesis of triglycerides, sterols, and phospholipids is very efficient. Even with low-fat diets, subcutaneous fat stores can be normal. ***Dietary fat*** provides 37 kJ (9 kcal) of energy per gram. A high-fat intake has been associated with a number of conditions including obesity, cardiovascular disease, type 2 diabetes, and steatotic liver disease. Dietary fats can be broken down into saturated and trans (the unhealthy fats) and monounsaturated and polyunsaturated fats (the healthy fats). Omega-3 is found within polyunsaturated fats, such as oily fish, sunflower oil, and seeds.

Carbohydrate

Carbohydrates are readily available in the diet, providing 17 kJ (4 kcal) per gram of energy (15.7 kJ (3.75 kcal) per gram monosaccharide equivalent). Carbohydrate intake comprises:

- polysaccharides (starch, fibre)
- disaccharides (mainly sucrose)
- monosaccharides (glucose and fructose).

Carbohydrate is cheap, compared with other foodstuffs; a great deal is therefore eaten, usually more than required. WHO suggests that sugar intake should be less than 5% of a person's total energy consumption.

Dietary fibre

Dietary fibre, is often removed in the processing of food. Types of fibre include cellulose, hemicelluloses, pectins, and gums. These are not digested by gut enzymes and therefore pass into the large intestine, where they are partly broken down by colonic bacteria, producing gas and volatile fatty acids, such as butyrate. Foods rich in dietary fibre include wholemeal bread, wholegrain cereals, brown pasta or rice, fruit, and potato skins. Fibre increases faecal bulk and is therefore helpful in the treatment of constipation. The recommended daily intake of fibre for adults in the UK is 30 g, but on average this is much less. Each extra gram of fibre daily adds approximately 3 to 5 g to the daily stool weight.

The healthy diet

Globally, examples of healthy diets include the Mediterranean or Nordic diets. These diets tend to be low in saturated fats but higher in fibre, oily fish, vegetable oils, and spreads which contain unsaturated fats. These diets also tend to be lower in processed meats, salt, and refined sugars.

Starvation-related under-nutrition

Starvation uncomplicated by disease is relatively uncommon in high-income countries, although some degree of under-nutrition is seen in socially deprived areas. Starvation remains a global issue. The 2021 United Nations Report stated that 828 million people are affected by hunger and the number continues to rise. Events such as conflicts and wars, the COVID-19 global pandemic and frequent extreme climate events are resulting in rising rates of food insecurity, hunger, and under-nourishment worldwide. The next section will focus on the mechanisms of starvation and its clinical manifestations, which are most often seen in less economically developed countries.

Pathophysiology of starvation

In the first 24 hours following low dietary intake, the body relies on the breakdown of hepatic glycogen to glucose as an energy source (Fig. 25.9). Hepatic glycogen stores are limited and therefore gluconeogenesis is soon necessary to maintain glucose levels. Gluconeogenesis takes place mainly from pyruvate, lactate, glycerol, and amino acids, especially alanine and glutamine. The majority of protein breakdown takes place in muscle, with eventual loss of muscle bulk.

Lipolysis, the breakdown of the body's fat stores, also occurs. This process is inhibited by insulin, although serum levels of this hormone diminish as starvation continues. Stored triglyceride is hydrolyzed by lipase to glycerol, which is used for gluconeogenesis, and also to non-esterified fatty acids, which can be used directly as a fuel or oxidized in the liver to ketone bodies.

Adaptive processes take place as starvation continues, to prevent available protein from being completely utilized. There follows a decrease in metabolic rate and total body energy expenditure. Central nervous metabolism changes from glucose as a substrate to ketone bodies. Gluconeogenesis in the liver decreases, as does protein breakdown in muscle, and both of these processes are inhibited directly by ketone bodies. Most of the energy at this stage comes from adipose tissue, with some gluconeogenesis from amino acids, particularly from alanine in the liver and glutamine in the kidney.

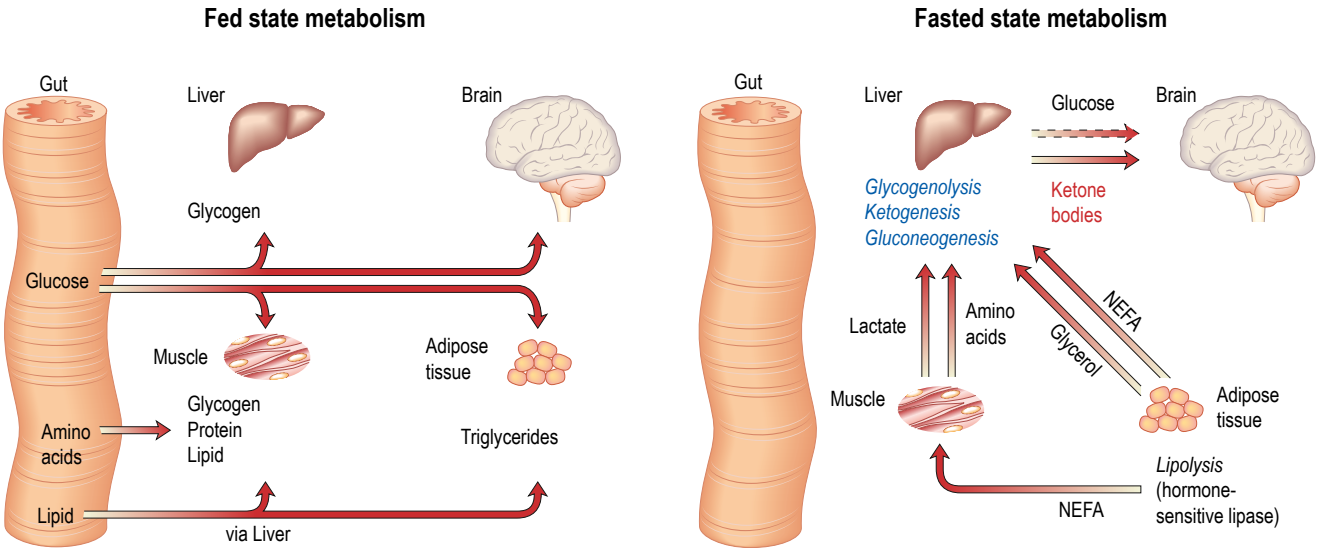

Fig. 25.9 Metabolism in the fed and the fasted state. *NEFA,* Non-esterified fatty acids.

The *metabolic response to prolonged starvation* differs between lean and obese individuals. One of the major differences concerns the proportion of energy derived from protein oxidation, which determines the proportion of weight loss from lean tissues. This proportion may be up to three times smaller in obese subjects than in lean subjects. It can be regarded as an adaptation that depends on the composition of the initial reserves (see Fig. 25.8). This means that deterioration in body function is more rapid in lean subjects, and survival time is shorter in lean subjects (approximately 2 months) compared with the obese (in whom it can be at least several months).

Following trauma or shock, some of the adaptive changes do not take place. Glucocorticoids and cytokines (see below) stimulate the ubiquitin–proteasome pathway in muscle, which is responsible for accelerated proteolysis in muscle in many catabolic illnesses. In starvation, there is a decrease in BMR, while in inflammatory and traumatic disease, there is often an increase in BMR. These changes all result in continuing gluconeogenesis with massive muscle breakdown, and further reduction in survival time.

Regulation of metabolism

Tissue metabolism is regulated by multiple coordinated processes. Some are rapid, involving nerves, while others are slower, involving circulating substrates and hormones. Factors include:

- *Circulating substrate concentrations.* The uptake and metabolism of ketone bodies, which serve as the major fuel for the brain during prolonged starvation, are primarily determined by the circulatory concentration, which can increase up to 5 mmol/L or more. The liver is responsible for the production of ketone bodies, which is, in turn, controlled by the availability of fatty acids derived from adipose tissue. Substrates may also compete with each other for metabolism; for example glucose competes with non-esterified fatty acids for uptake and metabolism in muscle and heart (the glucose–fatty acid cycle), and this is independent of hormones.
- *Blood flow.* The delivery of substrates to tissues depends not only on their circulating concentration but also on the blood flow to tissues. In many tissues, there is coupling between metabolic activity and blood flow, with arterioles regulating blood flow to the tissue according to demand; for example blood flow to muscle increases during exercise.
- *Signals.* Hormones and other signals, such as cytokines (see below), regulate intracellular metabolism.

Insulin/glucagon ratios in the fed and fasted state

In the fed state, insulin/glucagon ratios are high. Insulin promotes synthesis of glycogen, protein, and fat, and inhibits lipolysis and gluconeogenesis.

In the fasted state, insulin/glucagon ratios are low. Glucagon acts mainly on the liver and has no action on muscle. It increases glycogenolysis and gluconeogenesis, as well as increasing ketone body production from fatty acids. It also stimulates lipolysis in adipose tissue. Catecholamines have a similar action to glucagon but also affect muscle metabolism. These agents both act via cyclic adenosine monophosphate (cAMP) to stimulate lipolysis, producing free fatty acids that can then act as a major source of energy.

Proportion of lean-to-fat tissue

During weight loss uncomplicated by disease, the proportion of lean-to-fat tissue loss (or proportion of energy derived from protein metabolism) is greater in lean than overweight/obese individuals.

During acute disease, loss of lean tissue, which is associated with protein oxidation, can be particularly rapid. Hormones such as corticosteroids, pro-inflammatory cytokines, and insulin resistance are all involved.

Role of cytokines

The metabolic response to trauma, injury, and inflammation depends on the balance between *pro*-inflammatory (e.g., tumour necrosis factor, TNF; interleukin-2, IL-2) and *anti*-inflammatory cytokines (e.g., IL-10), and the production of many of these cytokines is influenced by genetic polymorphisms. Since many chronic diseases have an inflammatory component, these changes have wide-reaching metabolic implications. Cytokines such as IL-1, IL-6, and TNF play a significant role in regulating metabolism. In acute diseases, they contribute to the catabolic process, glycogenolysis, and acute phase protein synthesis. TNF, which inhibits lipoprotein lipase, is one of a number of 'cachexia factors' in patients with cancer. It is unclear how these cytokines interact with central feeding

Fig. 25.10 Malnourished children. **(A)** Marasmus. **(B)** Kwashiorkor. *(Courtesy of Dr Paul Kelly.)*

pathways to cause anorexia. However, in animal models of both cancer and inflammatory bowel disease, many peripheral and central mediators of appetite are involved. For example, neuropeptide Y levels in the hypothalamus are often inappropriately low, leading to a reduced drive to feed.

Starvation-related malnutrition leads to a depression of immunological defences, resulting in an increased susceptibility to infection. This also detrimentally affects muscle strength and fatigue, reproductive function (e.g., in anorexia nervosa, see Chapter 30), wound healing, and psychological function (depression, anxiety, loss of libido).

In children, growth failure is a key element in the diagnosis of starvation-related malnutrition. WHO standards for optimal growth in children of 0 to 4 years have been adopted by low- and middle-income and high-income countries. They aim to reflect optimal rather than prevailing growth in both high-income and low- and middle-income countries, since they describe children born after a healthy pregnancy to non-smoking, relatively affluent mothers who breast-fed their children exclusively or predominantly for the first 6 months of life. The general principles of management are similar in high-income and low- and middle-income countries but resources are required to manage the problems once they have been identified. When malnutrition is apparent and the underlying aetiology cannot be corrected immediately some form of nutritional support is necessary (see later).

Clinical features

Severe acute malnutrition (SAM) as a result of near-total starvation produces unique clinical appearances in children that are virtually never seen in high-income countries. Seventeen million children in 2017 had SAM and this is 2.5% of all the children under 5 in the world. Children under 5 years may present with the following:

- *Kwashiorkor* occurs typically in a young child displaced from breast-feeding by a new baby. It is often precipitated by infections such as measles, malaria, and diarrhoeal illnesses. The child is apathetic and lethargic with severe anorexia. There is generalized oedema with skin pigmentation and thickening (**Fig. 25.10B**). The hair is dry and sparse, and may become reddish or yellow in colour. The abdomen is distended owing to hepatomegaly and/or ascites. The serum albumin is always low. The exact cause is unknown, but theories related to diet (low in protein and high in carbohydrate) and free radical damage in the presence of inadequate antioxidant defences have been proposed.
- *Marasmus* is the childhood form of starvation, which is associated with obvious wasting. The child looks emaciated, and there is obvious muscle wasting and loss of body fat. There is no oedema. The hair is thin and dry (**Fig. 25.10A**). The child is not as apathetic or anorexic as with kwashiorkor. Diarrhoea is frequently present and signs of infection must be looked for carefully.

The *WHO classification of severe malnutrition* (**Box 25.5**) makes no distinction between kwashiorkor and marasmus because the approach to treatment is similar in both. The WHO classification of chronic under-nutrition in children is based on standard deviation (SD) scores. Thus, children with an SD score between –2 and –3 (between 3 and 2 SD scores below the median, corresponding to a value between 0.13 and 2.3 centiles) can be regarded as being at moderate risk of under-nutrition; below an SD score of –3, there is a risk of severe malnutrition. A low weight-for-height is a measure of thinness (wasting when pathological) and a low height-for-age is a measure of shortness (stunting when pathological). Those with oedema and clinical signs of severe malnutrition are classified as having oedematous malnutrition.

Box 25.5 Classification of childhood malnutrition

	Moderate malnutrition	Severe malnutrition[a]
Symmetrical oedema	No	Yes: oedematous malnutrition[b]
Weight-for-height SD score	–3 to –2 (70–79%)[c]	<–3 (<70%)[c] (severe wasting)[d]
Height-for-age SD score	–3 to –2 (85–89%)[c]	<–3 (<85%)[c] (severe stunting)

[a]The diagnoses are not mutually exclusive.
[b]Older classifications use the terms kwashiorkor and marasmic kwashiorkor instead.
[c]Percentage of the median National Centre for Health Statistics/WHO reference.
[d]Called marasmus (without oedema) in the Wellcome classification and grade II in the Gomez classification.

Starvation in adults may lead to extreme loss of weight, depending on the severity and duration. Patients may crave food, be apathetic, or complain of cold and weakness with a loss of subcutaneous fat and muscle wasting. The WHO classification is based on BMI, with a value less than 18.5 kg/m^2 indicating malnutrition (severe malnutrition if <16.0 kg/m^2).

Severely malnourished adults and children are very susceptible to respiratory and gastrointestinal infections, leading to an increased mortality in these groups.

Investigations

Investigations to consider, although not always practical in certain settings in the developing world, include:

- *Blood tests* such as full blood count, iron studies, urea and electrolytes, haematinics, serology testing, and blood film. They may show the following results:
  - Anaemia due to folate and iron deficiency is often present, but the haematocrit may be high owing to dehydration
  - Eosinophilia may suggest parasitic infection
  - Electrolyte disturbances
  - Malarial parasites
  - Acute or chronic viral infection, such as human immunodeficiency virus (HIV)
- *Stools* for ova, cysts, and parasites
- *Chest radiography* may reveal pulmonary tuberculosis.

Management

Management must involve the provision of protein and energy supplements and the control of infection. The approach to the treatment of children is described below. Adults do not usually suffer from such severe malnutrition but the same general principles of treatment should be followed.

Resuscitation and stabilization

The severely ill child will require:

- correction of fluid and electrolyte abnormalities
- treatment of shock
- treatment of hypoglycaemia (blood glucose <3 mmol/L), hypothermia (reduce heat loss, and provide additional heat if necessary), and infection (antibiotics). These often coexist.

The standard WHO *oral hydration solution* has a high sodium and low potassium content and is not suitable for severely malnourished children. Instead, the rehydration solution for malnutrition (ReSoMal) is recommended. It is commercially available but can also be produced by modification of the standard WHO oral hydration solution.

Infection is common (**Box 25.6**). Diarrhoea is often due to bacterial or protozoal overgrowth; metronidazole is very effective and is often given routinely. Parasites are also common and, as facilities for stool examination are usually not available, oral mebendazole 100 mg twice daily should be given for 3 days. In high-risk areas, antimalarial therapy is given. A previous study in Malawi suggested that the addition of antibiotics to therapeutic regimens for uncomplicated SAM in children less than 5 years of age is associated with a significant improvement in recovery and mortality.

Large doses of vitamin A are also given because deficiency of this vitamin is common. After the initial resuscitation, further stabilization over the next few days is undertaken, as indicated in **Box 25.7**.

Re-feeding

During the initial management of the acute situation, a balanced diet with sufficient protein and energy is given to maintain a steady state. Large increases in energy can lead to heart failure, circulatory collapse, and death (see later section on *Re-feeding syndrome*). If necessary, fluids and food should be given by nasogastric tube. All severely malnourished children have vitamin and mineral deficiencies and they should receive multivitamin supplementation with folic acid, zinc, and copper.

Box 25.6 Infections seen in severe acute malnutrition in low- and middle-income countries

- Diarrhoea
  - Bacteria
  - Protozoa
  - Helminths
- Malaria
- Tuberculosis
- HIV infection
- Measles
- Respiratory infections

Rehabilitation

Gradually, as the child improves, more energy can be given and during rehabilitation, weight gain is achieved by providing extra energy and protein ('catch-up weight gain'). Children who have been severely ill need constant attention throughout the convalescent period, as home conditions are often poor and feeds are refused. Sensory stimulation and emotional support are major components of management during both the stabilization and rehabilitation phases. The treatment of underlying chronic infective conditions, such as HIV, malaria, and tuberculosis, is also necessary.

Care setting

In some parts of the world where malnutrition is widespread, insufficient hospital facilities emphasize the need for outpatient and community-based programmes, although these require investment, political will, and time to build to full capacity. Programmes may involve the use of ready-to-use therapeutic foods, such as energy-dense pastes with minerals and vitamins, without the need to add water, which could potentially contaminate the food.

Prognosis

Children with extreme malnutrition have a mortality of over 50%. By careful management, this can be reduced significantly to less than 10%, depending on the availability of facilities and trained staff. Treatment of underlying disease is essential. Neural development takes place in the first years of life, a time when severe starvation–associated malnutrition is frequently seen. There is evidence that intellectual impairment and behavioural abnormalities occur in severely affected children. Physical growth is also impaired. These effects may be limited by improved standards of living, balanced diets, and freedom from infection over prolonged periods.

Prevention

Prevention depends not only on the availability of adequate nutrients but also on the education of both governments and individuals in the importance of good nutrition and immunization (**Box 25.8**). Short-term programmes are useful for acute shortages of food, but long-term programmes involving improved agriculture are equally necessary. Food supplements (and additional vitamins) should be given to 'at-risk' groups by adding high-energy food (e.g., milk powder, meat concentrates) to the diet. Pregnancy and lactation

Box 25.7 Timeframe for the management of the child with severe malnutrition (10-step approach recommended by WHO)

Management	Stabilization		Rehabilitation	Follow-up
	Days 1–2	*Days 3–7*	*Weeks 2–6*	*Weeks 7–26*

- **B**reast-feeding supplemented by food after 6 months
- **I**mmunization: against measles, tetanus, pertussis, diphtheria, polio, and tuberculosis
- **F**amily planning

are times of high energy requirement and supplements have been shown to be beneficial.

Re-feeding syndrome

While there is no clear internationally defined definition of re-feeding syndrome, it can be described as severe fluid and electrolyte shifts related to metabolic complications in malnourished patients after the re-introduction of nutrition. It was first described following World War II, when released prisoners of war developed cardiac failure on introduction of nutrition following a prolonged period of starvation.

Pathophysiology

During starvation, reduced carbohydrate intake leads to reduced insulin secretion and increased glucagon secretion resulting in utilization of glycogen stores. Glycogen stores within the liver and skeletal muscle are metabolized into glucose, to provide energy for the body's essential processes. Once glycogen stores are consumed, gluconeogenesis from other substrates is relied on, in particular fat followed by protein sources. This results in protein, fat, electrolyte, and vitamin depletion and intolerance to sodium and water. To conserve energy expenditure, the action of cellular pumps is reduced, with electrolytes (phosphate, potassium, and magnesium) able to leak across the cell membrane. Thiamine deficiency occurs due to its water-solubility and inability to be stored.

When feeding resumes, the reintroduction of carbohydrate results in a surge of insulin release. This stimulates glycogen, fat, and protein synthesis. This process relies on phosphate and magnesium, together with co-factors such as thiamine. Insulin also drives potassium into cells via the sodium-potassium adenosine triphosphatase (ATPase) pump, which also transports glucose. The overall effect results in hypokalaemia, hypomagnesemia, hypophosphatemia, thiamine deficiency, and salt and water retention.

Ultimately this can cause cardiac, respiratory, and neuromuscular complications including altered myocardial function and respiratory distress. Thiamine deficiency can result in Wernicke-Korsakoff syndrome. The clinical effects and consequences of re-feeding syndrome are outlined in **Box 25.9**.

Risk factors

The UK National Institute of Health and Care Excellence (NICE) guidance states that patients should be considered at risk of re-feeding syndrome if one or more of the following factors are present:

- BMI < 16 kg/m^2
- Unintentional weight loss >15% in past 3 to 6 months
- Little or no nutritional intake for >10 days
- Low serum levels of potassium, phosphate, or magnesium before feeding.

Additionally, patients should be considered at risk of re-feeding syndrome if two or more of the following are present:

- BMI < 18.5 kg/m^2
- Unintentional weight loss >10% in past 3 to 6 months
- Little or no nutritional intake for >5 days
- History of alcohol misuse or drugs including insulin, chemotherapy, antacids, or diuretics.

Conditions associated with a greater risk of re-feeding syndrome include chronic alcohol use disorder, cancer, and anorexia nervosa.

Management and prevention of re-feeding syndrome

If a patient is considered to be at risk of re-feeding syndrome, the following steps should be taken:

- nutritional support should be commenced at a maximum of 10 to 20 kcal/kg/day, with levels increased slowly to meet needs over 4 to 7 days guided by dieticians and clinical judgement
- restoration of circulating volume with strict and regular fluid balance assessment to minimize risk of sodium and fluid overload
- daily monitoring of serum potassium, phosphate, and magnesium levels and proactive replacement
- provision of thiamine intravenously, for example Pabrinex Intravenous High Potency solution which contains water-soluble vitamins B_1, B_2, B_3, B_6, and vitamin C.

Box 25.9 Clinical effects and consequences of re-feeding syndrome

Electrolyte disturbance	CVS effects	Respiratory effects	CNS effects
Hypophosphataemia	Arrhythmias Altered myocardial function Cardiac failure	Acute respiratory failure	Weakness/paralysis Paraesthesia Confusion/delirium Seizures Coma Rhabdomyolysis
Hypokalaemia	Arrhythmias Cardiac arrest	Respiratory depression	Paralysis Paraesthesia Rhabdomyolysis
Hypomagnesaemia	Arrhythmias	Respiratory depression	Ataxia Seizures Coma Muscle tremors Paraesthesia Tetany
Low-serum thiamine levels	Cardiac failure Cardiomegaly	Pulmonary oedema Pleural effusions	Ataxia Coma Wernicke's encephalopathy

CNS, Central nervous system; *CVS*, cardiovascular system.

Nutrition and ageing

Most populations in high-income countries are ageing, with the current average life expectancy in the UK standing at 80.9 years. Furthermore, populations are becoming increasingly multimorbid. More than half of the population aged over 60 have multimorbid conditions. Ageing is a degenerative process that, in combination with disease, is linked to anabolic resistance and increased catabolism. This places older men and women at high risk of developing pathological weight loss and eventually under-nutrition. The process of ageing is also considered to be a low-level inflammatory state. This combination of catabolic and inflammatory processes interacts with psychosocial factors such as cognitive impairment, social isolation, and bereavement resulting in malnutrition. The prevalence of under-nutrition in older adults is significant, affecting over 10% of people over the age of 65. Under-nutrition is consistently associated with increased morbidity and mortality, with large-scale prospective studies demonstrating that being underweight is more strongly associated with death than obesity in older adults. The immune system, in particular, is sensitive to nutrient depletion leading to increased susceptibility to infection, poor wound healing, and pressure sore development.

Sarcopenia is a progressive and generalized skeletal muscle disorder that is associated with increased likelihood of adverse outcomes including falls, fractures, physical disability, and mortality. Sarcopenia was previously thought to be solely a disorder of older people and associated with ageing. However, it is now recognized to begin earlier in life and have a causal link with chronic inflammatory conditions. Low muscle strength is the principal determinant.

Maintenance of physical activity continues to be necessary for overall health, regardless of age. However, energy expenditure among older people is reduced, meaning a lower energy requirement. For people aged 60 and above, irrespective of age, the daily energy requirement has been set at approximately 1.5×BMR. Owing to reduced fat-free mass (from an average of 60 kg to 50 kg in men, and from 40 kg to 35 kg in women), overall BMR is reduced.

Nutritional deficits in the elderly are common and may be due to many factors, such as dental problems, depression, and lack of motivation. Significant malnourishment in high-income countries is usually secondary to social problems or disease. In elderly people resident in nursing or care homes, multiple nutrient deficiencies are common. Vitamin D supplementation (colecalciferol 20 μg [800 units] daily) may be required because of poor diet or inadequate sunlight exposure. Owing to the high prevalence of osteoporosis in elderly people, an increased daily calcium intake (1–1.5 g/day) is often recommended.

MICRONUTRIENTS AND DEFICIENCIES

The term micronutrient relates to vitamins and minerals essential to the maintenance of tissue function and homeostasis. In the majority of individuals, a healthy balanced diet should provide adequate intake. Deficiency can result in clinical symptoms and metabolic consequences. There are several factors that can contribute to micronutrient deficiency. These include:

- Environment, poverty, and social deprivation
- Chronic gastrointestinal conditions and malabsorption
- Obesity or post-bariatric surgery
- Chronic alcohol use

- Medications such as metformin, diuretics, and proton pump inhibitors
- Restrictive diets.

Micronutrient replacement depends on whether the deficiency occurs at an individual or population level, with provision of micronutrients considered a priority for the WHO. While sole preparations can be administered, it is worthwhile considering multivitamin replacements as deficiencies can often coexist.

Fat-soluble vitamins

Fat-soluble vitamins (A, D, E, K) are absorbed in the small intestine and follow lipid metabolism pathways. Patients at risk of deficiency include those with pancreatic insufficiency, post-cholecystectomy, inflammatory bowel disease, chronic liver disease, and intestinal failure.

Vitamin A

Vitamin A (retinol) is part of the family of retinoids, which is present in food and the body as esters combined with long-chain fatty acids. The richest food source is liver, but it is also found in milk, butter, cheese, egg yolks, and fish oils. Retinol or carotene is added to margarine in the UK and other countries. β-carotene is the main carotenoid found in green vegetables, carrots, and other yellow and red fruits. β-carotene is cleaved in the intestinal mucosa by carotene dioxygenase, yielding retinaldehyde, which can be reduced to retinol. Retinol is stored in the liver and is transported in plasma bound to an α-globulin, retinol-binding protein (RBP).

Function

Vitamin A has several metabolic roles, most importantly:

- Retinaldehyde in its *cis* form is found in the opsin proteins in the rods (rhodopsin) and cones (iodopsin) of the retina (see Chapter 31). Light causes retinaldehyde to change to its *trans* isomer, and this leads to changes in membrane potentials that are transmitted to the brain.
- Retinol and retinoic acid are involved in the control of cell proliferation and differentiation.

Vitamin A deficiency

Worldwide, vitamin A deficiency and xerophthalmia (see below) are major causes of blindness in young children, despite intensive preventative programmes.

Xerophthalmia has been classified by the WHO (**Box 25.10**). Impaired adaptation, followed by night blindness, is the first effect. There is dryness and thickening of the conjunctiva and the cornea (xerophthalmia occurs as a result of keratinization). Bitot's spots—white plaques of keratinized epithelial cells—are found on the conjunctiva of young children with vitamin A deficiency. These spots can, however, be seen without vitamin A deficiency, possibly caused by exposure. Corneal softening, ulceration, and dissolution (keratomalacia) eventually occur, superimposed infection is a frequent accompaniment and both lead to blindness (**Fig. 25.11**).

Diagnosis

In parts of the world where deficiency is common, diagnosis is made on the basis of the clinical features, and deficiency should always be suspected if any degree of malnutrition is present. Blood levels of vitamin A will usually be low, but the best guide to diagnosis is a response to replacement therapy.

Box 25.10 Classification of xerophthalmia by ocular signs

Ocular signs	Classification
Night blindness	XN
Conjunctival xerosis	XIA
Bitot's spot	X2
Corneal xerosis	X2
Corneal ulceration/keratomalacia <1/3 corneal surface	X3A
Corneal ulceration/keratomalacia >1/3 corneal surface	X3B
Corneal scar	XS
Xerophthalmic fundus	XF

(From WHO/UNICEF/IVACG 1988.)

Management

Urgent treatment with retinol palmitate 100 000 units orally (30 mg equivalent) should be given. In the presence of vomiting and diarrhoea, 30 mg of vitamin A is given intramuscularly. Referral for specialist ophthalmic treatment is necessary in severe cases.

Prevention

Most Western diets contain sufficient amounts of dairy products and green vegetables, but vitamin A is added to foodstuffs (e.g., margarine) in some countries. Vitamin A is not destroyed by cooking.

In some low- and middle-income countries, vitamin A supplements are given at the time a child attends for measles vaccination. Food fortification programmes are another approach. Education of the population is necessary and in particular, pregnant women and children should be encouraged to eat green vegetables and yellow fruits.

Possible adverse effects of vitamin A excess

- ***High intakes of vitamin A.*** Chronic ingestion of retinol can cause liver and bone damage, hair loss, double vision, vomiting, headaches, and other abnormalities.
- ***Retinol is teratogenic.*** The incidence of birth defects in infants is high with vitamin A intakes of more than 3 mg a day during pregnancy. In pregnancy, extra vitamin A or consumption of liver is not recommended in the UK. However, β-carotene is not toxic.

Vitamin D

Vitamin D is discussed in more detail in Chapter 33, where the most common manifestations of deficiency are outlined (rickets

and osteomalacia). Vitamin D status is assessed by measurement of 25-hydroxyvitamin D in the serum. Vitamin D receptors are distributed widely in human tissues but their function in many non-musculoskeletal tissues still remains poorly understood. Vitamin D status has been linked to a wide range of diseases, including:

- cardiovascular disorders (ischaemic heart disease, heart failure, hypertension)
- respiratory disorders (chest infections)
- renal disorders (progression of renal disease)
- endocrine disorders (type 1 and type 2 diabetes)
- neuropsychiatric disorders (depression, cognitive deficits)
- cancer (e.g., prostate, breast, colon) and mortality from various causes
- multiple sclerosis (see Chapter 28).

It has therefore been suggested that vitamin D may have a role in global health, and not just the health of the musculoskeletal system. Reduced circulating concentrations of vitamin D can result not only from lack of exposure to sunlight and a poor diet but also from inflammation, smoking, and obesity.

Vitamin E

Vitamin E is group of vitamins rich in antioxidant properties that offer protection from harmful free radicals linked to cancer and cardiovascular disease. Existing in eight forms, α-tocopherol is the naturally occurring bioavailable form absorbed in the small intestine. Vegetables and seed oils, including soya bean, saffron, sunflower, cereals, and nuts, are the main sources. Animal products are poor sources of the vitamin. Vitamin E is absorbed with fat and transported in the blood largely in LDLs. Deficiency is rare and often asymptomatic, and can occur in severe malnutrition.

Function

The biological activity of vitamin E results principally from its antioxidant properties. In biological membranes, it contributes to membrane stability. It protects cellular structures against damage from a number of highly reactive oxygen species, including hydrogen peroxide, superoxide, and other oxygen radicals. Vitamin E may also affect cell proliferation and growth.

Vitamin E deficiency

Deficiency is seen only in children with abetalipoproteinaemia (see Chapter 22) and in patients on long-term parenteral nutrition. The severe neurological deficit (gross ataxia) can be prevented with vitamin E injections.

Vitamin K

Vitamin K is found as phylloquinone (vitamin K_1) in green, leafy vegetables, dairy products, and rapeseed and soya bean oils. Intestinal bacteria can synthesize the other major form of vitamin K, menaquinone (vitamin K_2), in the terminal ileum and colon. Vitamin K is absorbed in a similar manner to other fat-soluble substances in the upper small gut. Some menaquinones must also be absorbed, as this is the major form found in the human liver.

Function

Vitamin K is a co-factor that is necessary for the production not only of blood clotting factors (II, VII, IX, and X, and other proteins involved in coagulation) but also of proteins that are necessary for the formation of bone. Vitamin K is a co-factor for the post-translational carboxylation of specific protein-bound glutamate residues in γ-carboxyglutamate (Gla). Gla residues bind calcium ions to phospholipid templates, and this action on factors II, VII, IX, and X, and on proteins C and S, is required for coagulation to take place. Bone osteoblasts contain three vitamin K–dependent proteins: osteocalcin, matrix Gla protein, and protein S, which have a role in bone matrix formation. Osteocalcin contains three Gla residues, which bind tightly to the hydroxyapatite matrix, depending on the degree of carboxylation; this leads to bone mineralization. There is, however, no convincing evidence that vitamin K deficiency or antagonism affects bone other than rapidly growing bone.

Vitamin K deficiency

Vitamin K deficiency results in inadequate synthesis of clotting factors, which leads to an increase in the prothrombin time and haemorrhage. It has also been linked to bone health, but there is inadequate evidence to support the routine use of vitamin K to prevent osteoporosis and reduce fracture risk. Deficiency occurs in the newborn, in cholestatic jaundice, and with concomitant use of vitamin K antagonists.

The newborn

Deficiency occurs in the newborn owing to:

- poor placental transfer of vitamin K
- modest quantities of vitamin K in breast milk
- the lack of hepatic stores of menaquinone (due to a lack of intestinal bacteria in the neonate).

Deficiency leads to a haemorrhagic disease of the newborn, which can be prevented with prophylactic vitamin K. Vitamin K (phytomenadione 1 mg, intramuscularly) is administered to all neonates after the risks have been discussed with parents and consent has been obtained.

Cholestatic jaundice

When bile flow into the intestine is interrupted, malabsorption of vitamin K occurs as no bile salts are available to facilitate absorption and the prothrombin time increases. This can be corrected by giving 10 mg of phytomenadione intramuscularly or intravenously. (Note that an increased prothrombin time caused by liver disease does not respond to vitamin K injection, there being no shortage of vitamin K—just reduced synthesis of clotting factors.) In patients with chronic cholestasis (e.g., primary biliary cholangitis), oral therapy with a water-soluble preparation, menadiol sodium phosphate 10 mg daily, is used.

Concomitant vitamin K antagonists

Oral anticoagulants, such as warfarin, antagonize vitamin K. Antibacterial drugs also interfere with the bacterial synthesis of vitamin K.

Water-soluble vitamins

Vitamin C (ascorbic acid)

Humans are unable to synthesize ascorbic acid from glucose, meaning that adequate dietary intake is essential to achieve normal concentrations. Vitamin C is present in citrus fruits, potatoes, and vegetables. Ascorbic acid has many important actions including the promotion of iron absorption and formation of cross-linking in connective tissues. Most absorption occurs within the jejunum and terminal ileum.

Vitamin C deficiency (scurvy)

The clinical syndrome associated with vitamin C deficiency is known as scurvy. Patients at risk of this and in whom deficiency should be suspected include the elderly and those who are socially deprived

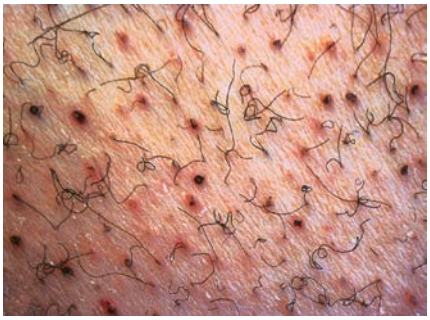

Fig. 25.12 Scurvy. Corkscrew hairs and perifollicular haemorrhage on the lower extremity. *(From Bolognia JL, Jorrizzo JL, Schaffer JV [eds].* Dermatology, *3rd edn. St Louis: Mosby; 2012, with permission.)*

or have alcohol use disorder. Deficiency results in defective collagen synthesis leading to the following symptoms:

- Keratosis of hair follicles with 'corkscrew' hair (Fig. 25.12)
- Perifollicular haemorrhages
- Swollen, spongy gums with bleeding and loosening of teeth
- Spontaneous bruising and haemorrhage
- Failure of wound healing
- Anaemia.

Plasma levels and leucocyte-platelet layer can be used to make a laboratory-based diagnosis; however, this is rarely done in clinical practice. Treatment is with 250 mg of ascorbic acid in daily divided doses and symptoms improve dramatically with treatment.

B vitamins

B vitamins are water-soluble vitamins that act as coenzymes and precursors essential for metabolism. They are generally absorbed in the small intestine. Box 25.11 outlines the essential functions of B vitamins, dietary sources, clinical features of deficiency, and in whom to suspect deficiency.

Clinical conditions as a manifestation of B vitamin deficiencies

Pellagra

The clinical syndrome associated with niacin (vitamin B_3) deficiency is known as pellagra. Pellagra is characterized by the '4 Ds': (1) dermatitis (Fig. 25.13), (2) delirium, (3) diarrhoea, and (4) death. The skin manifestation is a photosensitive, blistering, and erythematous rash which affects the sun-exposed areas. One should suspect this deficiency in patients with malnutrition, alcohol use disorder, and/or homelessness. The presentation can often mimic alcohol withdrawal or intoxication or mental illness. Treatment with intravenous B vitamin supplementation (Pabrinex) is indicated, especially as other water-soluble vitamin deficiencies are likely to coexist.

Beriberi

This clinical condition arising as a result of thiamine (vitamin B_1) deficiency is now confined to the poorest areas of South-east Asia. There are two main clinical types of beriberi, which, surprisingly, rarely occur together.

- ***Dry beriberi*** usually presents insidiously with a symmetrical polyneuropathy. The initial symptoms are heaviness and stiffness of the legs, followed by weakness, numbness, and pins and needles. The ankle jerk reflexes are lost and eventually signs of polyneuropathy may progress to involve the trunk and arms. Cerebral involvement occurs, producing the picture of the Wernicke–Korsakoff syndrome (Chapter 28).
- ***Wet beriberi*** causes oedema. Initially, this is of the legs, but it can extend to involve the whole body, with ascites and pleural effusions. The peripheral oedema may mask the accompanying features of dry beriberi. Thiamine deficiency impairs pyruvate dehydrogenase with accumulation of lactate and pyruvate, producing peripheral vasodilatation and eventually oedema. The heart muscle is also affected and heart failure occurs, causing a further increase in the oedema. Initially, there are warm extremities, a full, fast, bounding pulse, and a raised venous pressure ('high-output state'), but eventually heart failure advances and a poor cardiac output ensues. The electrocardiogram may show conduction defects.

Infantile beriberi occurs, usually acutely, in breast-fed babies at approximately 3 months of age. The mothers show no signs of thiamine deficiency but presumably their body stores must be virtually nil. The infant becomes anorexic, develops oedema, and has some degree of aphonia. Tachycardia and tachypnoea develop and, unless treatment is instituted, death occurs quickly.

Both dry and wet forms of beriberi respond well to thiamine supplementation if diagnosed and treated early. For wet beriberi, a rapid disappearance of oedema after thiamine is diagnostic. Other causes of oedema must be considered (e.g., renal or liver disease), while the polyneuropathy of dry beriberi is indistinguishable from that due to other causes, which thus require careful exclusion. The diagnosis is confirmed by measurement of the circulating thiamine concentration or transketolase activity in red cells using fresh heparinized blood.

Wernicke-Korsakoff syndrome

In the developed world, thiamine deficiency is usually seen in the context of alcohol dependence and re-feeding syndrome. Rarely, wet beriberi syndrome can develop and this will need to be distinguished from alcohol-related cardiomyopathy. Usually however, thiamine deficiency will manifest with Wernicke-Korsakoff syndrome. This syndrome consists of dementia, ataxia, ophthalmoplegia, and nystagmus. If treated promptly it can be reversible. Treatment is with intravenous thiamine replacement for 2 weeks.

Minerals

Calcium

Essential for bone and tooth formation. Dairy foods are rich sources of calcium. Postmenopausal women and those following a lactose-free diet are at risk of deficiency. Calcium absorption from the gastrointestinal tract is vitamin D dependent. Increased calcium is required in pregnancy and lactation, when dietary intake must be increased. Calcium deficiency is usually due to vitamin D deficiency.

Chloride

Essential for gastric hydrochloric acid production and therefore the process of digestion. Renal disease can put patients at risk of deficiency.

Chromium

Essential for lipid and carbohydrate metabolism and insulin action. Short bowel syndrome is a risk factor.

Copper

Required for nervous system and immune system health, and for the production of caeruloplasmin. It is found in nuts and shellfish. Deficiency can present with cardiac arrhythmias and myeloneuropathy. Menkes' disease is a rare sex-linked recessive condition, with

Box 25.11 B vitamins: functions, sources, and deficiency and replacement

B vitamin	Actions	Dietary source	Deficiency	Who to suspect in	Replacement
B_1 thiamine	Essential for energy release from carbohydrates DNA and RNA production	Fish Fortified flour	Wernicke's encephalopathy Beriberi syndrome (see text)	Chronic alcohol use Liver disease Re-feeding	i.v. Pabrinex or oral thiamine
B_2 riboflavin	Co-factor for energy production, cellular function, and fat metabolism	Leafy vegetables Additional riboflavin is synthesized by colonic microbiota	Rare Symptoms include dry skin, angular stomatitis, and thyroid problems		Vitamin B compound strong 1–2 tablets tds
B_3 niacin	Energy production	Fortified processed foods Poultry	Rare Pellagra (see text)	Elderly Homeless Chronic alcohol use	i.v. Pabrinex or 300 mg oral nicotinamide daily
B_5 pantothenic acid	Synthesizes co-factor A, catabolic and metabolic reactions	Meat Dairy produce	Fatigue Anorexia		Oral pantothenic acid 5 mg daily
B_6 pyridoxine	Group of 6 compounds required for protein metabolism	Meat Potatoes	Microcytic anaemia Depression Dry skin Paraesthesia	Chronic alcohol use Dialysis Isoniazid use (tuberculosis)	Oral pyridoxine 20–50 mg 1–3 times per day
B_7 biotin	Regulates gene expression Immune response	Fish Eggs	Dry skin Brittle nails Depression	Chronic alcohol use Short bowel syndrome	Oral biotin 10 mg daily
B_9 folate	Essential coenzyme for RNA and DNA transfer and cell division	Leafy green vegetables Nuts	Megaloblastic anaemia Pancytopenia	Chronic alcohol use Drugs such as methotrexate, sulfasalazine, phenytoin, trimethoprim can cause folate deficiency	Folic acid 5 mg od Preconception folic acid (400 mcg) is required to reduce risk of neural tube defects
B_{12} vitamins	Blood cell production CNS function	Fish Dairy foods	Macrocytic anaemia Glossitis Peripheral neuropathy	Pernicious anaemia Post-gastrectomy Metformin use Proton pump inhibitor use e.g., omeprazole, lansoprazole Nitrous oxide abuse	IM hydroxocobalamin 1 mg 3 times per week for 2 weeks then 1 mg every 3 months or PO cyanocobalamin 10–150 mcg daily

a mutation in the copper-transporting gene *ATP7A*. Infants with this abnormality develop growth failure, intellectual disabilities, bone lesions, and brittle hair. Copper toxicity occurs in Wilson's disease (see Chapter 23).

Fluoride

Essential for dental health, with fluoridated toothpastes, mouthwashes, and fluoridated water supplies needed to maintain concentrations. In areas where the level of fluoride in drinking water is less than 1 part per million (0.7–1.2 mg/L), dental caries are relatively more prevalent. Fluoridation of the water provides 1 to 2 mg daily, resulting in a reduction of tooth decay in children by about 50%. There is little fluoride in food. Fluoride-containing toothpaste may add up to 2 mg/day.

Iodine

Essential for the production of thyroid hormones. Many areas throughout the world lack iodine in the soil, and so iodine deficiency, which impairs brain development, is a WHO priority. Two billion people worldwide (one-third of whom are children) have insufficient iodine intake. Endemic goitre (Fig. 25.14) occurs in remote areas where the daily intake is below 70 μg, and in those parts 1% to 5% of babies are born with congenital hypothyroidism (with severe stunting, learning difficulty, and a goitre). In these areas, iodized oil should be given intramuscularly to all reproductive women every 3 to 5 years. Salt iodization is now practised in many countries and is a simple, cost-effective way to prevent deficiency.

Iron

The most abundant trace element within the human body. It is required to maintain normal physiological processes and for energy metabolism. The main function of iron is as a functional component of haem, participating in oxygen binding and transport. Iron is also involved in cellular processes such as DNA synthesis, cell proliferation, and gene regulation. Dietary sources include red meat and fortified grain products. Worldwide, iron deficiency is the most common nutritional deficiency. Patients with underlying gastrointestinal

cancers and menstruating and pregnant women are at risk of deficiency, which can present with a microcytic anaemia.

Magnesium

Essential to maintain muscle, nerve, and cardiovascular function and as a co-factor for many chemical reactions in the body. Dietary sources include leafy vegetables, nuts, and seeds. Malabsorptive gastrointestinal diseases and diuretic use predispose to deficiency. Magnesium deficiency can present with myopathy, fatigue, cardiac arrhythmias, and seizures. Biochemically, hypokalaemia frequently coexists due to the role of magnesium in cellular potassium uptake.

Manganese

Essential co-factor needed for amino acid, cholesterol, glucose, and carbohydrate metabolism. Dietary sources include leafy vegetables, nuts, and grains. Deficiency is rare. Toxicity is more of an area for concern, which can cause neurological problems such as tremor, gait disturbance, and facial spasms. Patients on long-term parenteral nutrition, and also patients with chronic liver disease are at risk of toxicity.

Molybdenum

Essential for co-factor production needed for drug and toxin metabolism. Deficiency is rare as high amounts are present in many foods, including grains and legumes.

Phosphate

A component of phospholipids found in RNA, DNA, and ATP. Absorption occurs in the first half of the small bowel, from foods including dairy produce and fish. Deficiency can present with bone pain, weakness, and paraesthesia, which can develop acutely in refeeding syndrome. Hyperphosphataemia is seen in renal failure as a result of reduced excretion.

Potassium

An intracellular cation that forms part of the sodium–potassium ATP transporter channel which maintains adequate fluid balance. Diarrhoea and vomiting increase losses, with diuretics also reducing serum concentrations. Concentrations also fall rapidly in refeeding syndrome. Dietary sources include bananas, potatoes, and legumes. Symptoms of deficiency include fatigue and muscle weakness, while cardiac arrhythmias may also occur.

Sodium

Essential for regulation of fluid and electrolyte balance, muscle contraction, and nerve conduction. Dietary sources include processed meats, cheeses, and sauce. Hyponatraemia, a low serum sodium which may reflect either sodium deficiency or water excess, is discussed in Chapter 27.

Selenium

A trace element important for thyroid hormone synthesis, DNA production, and protection from oxidative damage. Dietary sources include bread and poultry. Clinical deficiency is rare, but seen in areas of China where Keshan disease, a selenium-responsive cardiomyopathy, occurs. Deficiency may also cause a skeletal myopathy.

Zinc

Involved in many metabolic pathways and is essential for the synthesis of RNA and DNA. Acrodermatitis enteropathica is an inherited disorder caused by malabsorption of zinc. Infants develop growth retardation, severe diarrhoea, hair loss, and a skin rash, which can occur anywhere on the body but is most often found around the mouth, genitalia, and hands (**Fig. 25.15**). A similar rash occurs in adults suffering from zinc deficiency due to other causes; see below. This condition provides a model for zinc deficiency. Zinc supplementation results in a complete cure. Zinc deficiency probably also plays a role in protein-energy under-nutrition and in many diseases in children in the developing world. Zinc supplementation has been demonstrated as being of some benefit in, for example, the prevention of diarrhoeal diseases and acute respiratory infections; it also improves growth. Levels of zinc have also been shown to be low in some patients with malabsorption or skin disease, and in patients with acquired immunodeficiency syndrome (AIDS), but its exact role in these situations is disputed. Excessive amounts of zinc carry a low risk of toxicity, but high levels can interfere with iron and copper absorption. Conversely, administration of copper or iron to treat deficiencies such as iron deficiency anaemia can precipitate zinc deficiency. Wound healing is impaired with moderate zinc deficiency and is improved by zinc supplements. Impaired taste and smell, hair loss, and night blindness are also features of severe zinc deficiency.

A list of common disorders and micronutrient deficiencies both predisposing to and resulting from these is found in **Box 25.12**.

Food fortification

Fortified food is a food product to which vitamins, minerals, energy, protein, or other nutrients, or a combination of them, have been added to increase energy or nutrient density. It can play an important role in improving micronutrient intake of the population as a whole, particularly when targeted appropriately.

As defined by the WHO and the Food and Agricultural Organization of the United Nations (FAO), fortification refers to 'the practice of deliberately increasing the content of an essential micronutrient, that is vitamins and minerals (including trace elements) in a food, to improve the nutritional quality of the food supply and to provide a public health benefit with minimal risk to health'.

Fortification of foods with specific nutrients is common. In the UK, margarine and milk are fortified with vitamins A and D, flour with calcium, iron, thiamine, and niacin, and breakfast cereals with several vitamins and iron.

NUTRITIONAL SUPPORT

Principles of nutritional support

The goals of nutritional support are to treat or prevent malnutrition and to improve patient-related outcomes. All patients should be screened for malnutrition on admission and the findings linked to a care plan, preferably under the supervision of a trained multidisciplinary team, including a dietician. There are many different means of providing nutritional support in both the community and hospital settings. Plans are discussed with patients and consent is taken for any invasive procedure (e.g., nasogastric tube, parenteral

nutrition). If the patient is unable to give consent, the healthcare team should act in the patient's best interest, considering any previously expressed wishes of the patient and views of the family.

The delivery of nutritional support can be described as either enteral or parenteral. Enteral nutrition refers to artificial feeding, which uses the gastrointestinal tract as a means of achieving calorie requirements. This incorporates oral nutritional supplements, nasogastric or percutaneous gastrostomy tubes, and post-pyloric feeding with nasojejunal or jejunostomy tubes.

Parenteral nutrition (PN) refers to intravenous nutrition and can be total or supplementary. PN is only indicated when it is not possible to supply nutrition using the gastrointestinal tract, that is due to intestinal failure or intestinal insufficiency (see later).

Nutritional requirements for adults

The exact nutrient requirements in many disease states are not clearly defined and vary with the stage and severity of disease, as well as nutritional status. There are different nutritional guidelines for patients with liver cirrhosis, cancer, chronic kidney disease, inflammatory bowel disease, obesity, and critical illness. However, generally, the following guidance applies to adults:

Fluid. Fluid requirements are generally calculated using 25 to 35 mL/kg/day (>60 years = 30 mL/kg, 18–60 years = 35 mL/kg). However, various other factors need to be taken into consideration. For instance, gastrointestinal losses (e.g., high-output jejunostomy or diarrhoea), fever and insensible losses, and also fluid-overloaded states such as renal failure, congestive cardiac failure, and oedema.

Energy. As previously discussed, typical energy requirements are approximately 7.5 to 10.0 MJ/day (1800–2400 kcal/day). When aiming for weight gain, an additional 400 to 600 kcal/day can be considered in metabolically stable patients. Disease increases resting energy expenditure but may also decrease physical activity. When energy requirements are calculated, other parameters affecting energy expenditure should also be considered. For example, fever, shivering, the work of breathing, and inflammation can all increase requirements. Conversely, muscle relaxants, analgesia, hypothermia, and adapted ventilation can all reduce requirements. Baseline energy requirements can be determined using a weight-based calculation, for example 25 to 35 kcal/kg/day. Predictive equations such as the Penn State equation are used to calculate energy requirements in critically ill patients who are ventilated on intensive care.

Carbohydrate as an energy source is provided in the form of glucose. It is generally provided in amounts of up to 50% to 70% of non-nitrogen energy. Glucose is essential for central nervous system functions, however exceeding the safe level can result in hyperglycaemia, hepatic steatosis, and impaired respiratory function with increased CO_2 production. The safe level can be determined using the glucose oxidation rate (4–7 mg/kg/min/day); when this has reached its maximum, excessive glucose can no longer be oxidized and it will be converted to fat or carbon dioxide.

Lipid in PN solutions provides a concentrated form of energy reducing the need for infusion of large amounts of glucose. It also prevents EFA deficiency. Lipid provides <50% of total non-nitrogen energy.

Protein. Protein is provided in the form of nitrogen, which is one of the main components of amino acids. Most stable patients require 0.8 to 1.4 g/kg/day of protein, where 1 g of nitrogen is equivalent to 6.25 g of protein. Requirements depend on the degree of stress and catabolism present. Most patients receive at least 11 to 15 g of nitrogen per day. Extra protein may be needed in severely catabolic conditions, such as extensive burns, sepsis, and major trauma.

Electrolyte requirements. The electrolyte requirements in an adult are outlined in **Box 25.13**.

Requirements are increased in patients with gastrointestinal effluents, for example high sodium and potassium losses from surgical drains, jejunostomies, ileostomies, and diarrhoea. The excretion of these minerals in various effluents can provide an indication of the additional requirements (see **Box 27.11**). Requirements may be lower in patients with fluid overload or if baseline levels are deranged (e.g., those with hypernatraemia or hyperkalaemia). The requirements for calcium and magnesium are higher in enteral than in parenteral nutrition because only a proportion of these minerals are absorbed by the gut.

Trace elements. For trace elements such as iodine, fluoride, and selenium, which are well absorbed, the requirements are similar in enteral and parenteral nutrition. For other trace elements, such as iron, zinc, manganese, and chromium, the requirements in parenteral nutrition are substantially lower than in enteral nutrition.

Vitamins. Many vitamins are given in greater quantities in patients receiving PN than in those receiving enteral nutrition. This is because patients on PN may have increased requirements, partly because of severe disease, partly because they may already have depleted pools of vitamins, and partly because some vitamins degrade during storage. Vitamin K is usually absent from parenteral nutrition regimens and therefore it may need to be administered separately.

Enteral nutrition

Enteral nutrition is indicated in patients who cannot meet their nutritional requirements by their standard oral dietary intake and have a functioning and accessible gastrointestinal tract. Clinical situations where enteral nutrition via a feeding tube may be indicated include a reduced conscious level such as in hepatic encephalopathy, when a patient has an unsafe swallow secondary to neurological disorders such as a stroke, or when a patient is critically ill in the intensive care unit.

Nasogastric feeding is a generally well-tolerated and safe method of nutritional therapy. Some common problems include compliance and tube displacement (especially if a patient is confused or agitated), nausea/vomiting, diarrhoea, aspiration, and refeeding syndrome. Decisions regarding nasal versus percutaneous feeding tube will be determined by factors such as reversibility of acute pathology, prognosis, and patient choice. When long-term enteral nutrition greater than 4 to 6 weeks is anticipated, then

Box 25.13 Electrolyte requirements for adults

Electrolyte	Na^+	K^+	Ca^{2+}	Mg^{2+}	PO_4^{3-}	Cl^-
Requirement (mmol/kg/day)	1.0–1.5	1.0–1.5	0.1–0.15	0.1–0.2	0.5–0.7	1.0–1.5

Box 25.14 Indications for PEG insertion

Unsafe swallow	Failure of feeding
• Acute ischaemic or haemorrhagic stroke • Progressive neuromuscular disease e.g., motor neurone disease, Huntington's disease, Parkinson's disease, bulbar and pseudobulbar palsies	• Cystic fibrosis • Head and neck cancers

insertion of a percutaneous endoscopically placed gastrostomy (PEG) should be considered.

Percutaneous enteral feeding tube placement is performed to facilitate direct enteral feeding for patients whose oral intake is insufficient to meet their nutritional requirements or when anatomical abnormalities or neurological function precludes the normal process of swallowing. Common indications are outlined in **Box 25.14**. This list is not exhaustive and it should be noted that in clinical practice, there may be other situations where PEG placement is suitable after assessment by a wider multidisciplinary nutrition team.

The procedure takes place endoscopically (**Fig. 25.16**) and should be performed under full aseptic non-touch technique and with antibiotic prophylaxis to prevent skin site infection and clinically relevant bacteraemia. The surface marking for PEG placement requires endoscopic visualization with finger indentation and transillumination (when infrared light emitted from the endoscope into the gastric wall is visualized externally). Where endoscopic access is not possible, gastrostomies can be placed radiologically or surgically.

Complications arising from PEG insertion may be minor or major and can develop immediately after tube placement or later. Immediate and early risks from PEG placement include respiratory compromise, aspiration, bleeding, and peritonitis. Later complications include infection, leakage of gastric contents, and buried bumper syndrome, where the internal bumper of the PEG is pulled up too tightly against the gastric mucosa and over time erodes into it, becoming 'buried'. This can lead to obstruction of the tube with feed leaking back onto the skin. This should be suspected if the PEG tube does not push in easily. It can be prevented by regular rotation and gently pushing the tube in on a weekly basis.

Post-pyloric feeding

Post-pyloric feeding, that is feeding beyond the stomach, can be provided by a nasojejunal tube or jejunostomy. This method of feeding is indicated when there is pathology such as gastric outlet obstruction (GOO), or an anatomical reason that precludes gastric feeding such as large hiatus hernia or gastrectomy. GOO is a clinical syndrome characterized by abdominal pain and postprandial vomiting. Causes of GOO can be benign or malignant. Pancreatic cancer with local invasion and distal gastric cancer are common causes. Nasojejunal tubes require endoscopic placement, although bedside placement devices are also available. For long-term post-pyloric feeding, jejunostomies can be placed endoscopically, through an extension of an existing PEG, radiologically or surgically.

Feeding regimen

Enteral feeds are sterile nutritional liquids which are often nutritionally complete. Feeds are available in different preparations and volumes. Nutritional assessment helps to inform which type of feed is most suitable for the patient. The feeding regimen should be tailored to meet the patient's individual requirements and target goals of

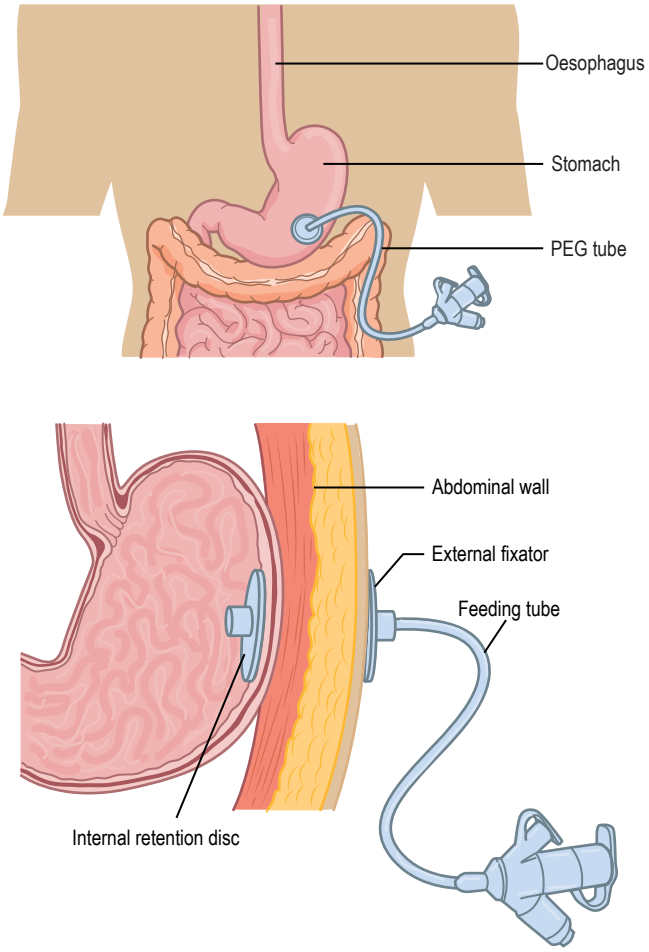

Fig. 25.16 Percutaneous endoscopic gastrostomy.

nutritional intervention. Most feeds provide 1 to 2 kcal/mL. Standard polymeric feeds contain whole protein and long-chain triglycerides (i.e., in the form in which they are within a normal diet), and are nutritionally complete. Some patients with severely impaired gastrointestinal function and malabsorption will require a pre-digested feed (i.e., semi-elemental/elemental). These feeds contain protein as low molecular weight short peptides or free amino acids. Carbohydrate provides the majority of the energy and energy is also provided from fat as either medium- or long-chain triglycerides. The aim is to improve absorption of nutrients. Choice of feed, rate, and volume will be guided by dietetic assessment, underlying clinical condition, and risk of re-feeding. Patients receiving enteral feeding require close monitoring to ensure nutritional requirements are being met, electrolyte and metabolic disturbances are reduced, and complications are avoided. Monitoring includes a food chart, fluid balance, weight, biochemistry, observations, bowel chart, nausea or vomiting, and gastric residual volumes to help determine tolerance of feeding and absorption.

Parenteral nutrition

Parenteral nutrition (PN) is the term to describe intravenous support provided to achieve normal fluid and nutritional balance and is indicated in the management of intestinal failure. PN can provide sufficient nitrogen for protein synthesis, calories for energy and electrolytes, vitamins, and trace elements to meet the patient's nutritional requirements. To establish a PN regimen, the patient

Box 25.15 Common types of vascular access for parenteral nutrition

Type of access	Disadvantages
Peripherally inserted central catheters (PICC)	Risk of infection, thrombosis Difficult to self-access if administering home PN (though mitigated by extension sets)
Tunnelled central venous catheters e.g., Hickman line	Risk of infection, thrombosis Requires surgical removal
Implanted port	Not commonly used therefore not all healthcare staff familiar with accessing Port infections generally cannot be treated with antibiotics alone and require port removal

needs to be assessed by a dietician and undergo a nutritional assessment. As discussed earlier, there are many factors that need to be considered as part of a nutritional assessment. These include anthropometry, weight, BMI, recent weight loss, biochemistry, and any changes to nutritional intake, which can indicate whether the patient is malnourished. Medical history is important as certain co-morbidities might influence patients' requirements.

Vascular access for parenteral nutrition

When it comes to delivery of PN, different types of venous catheters exist, some of which are more suitable in the short term and others in the long term (Box 25.15). Tunnelled lines are traditionally preferred for long-term PN administration. These are commonly known as Hickman lines, whereby catheters enter a central vein and are tunnelled through the skin to exit over the chest wall. Alternatively, peripherally inserted central catheters (PICCs) can be used for short- or medium-term PN. With either type of venous access, the risk of venous thrombosis is reduced when the catheter tip is located at the superior vena cava–right atrium junction. This can be useful when interpreting chest radiographs for venous line position.

Complications of parenteral nutrition

Complications can be related to vascular access or the parenteral nutrition itself. The most serious complication is infection, of which there are different types. An exit site infection refers to inflammation or purulence within 2 cm of an exit site. A tunnel infection refers to inflammation along a catheter greater than 2 cm from the exit site, and a pocket infection refers to inflammation or necrosis overlying a port, which is used to deliver PN in some centres.

Catheter-related bloodstream infection (CRBSI) refers to a bacteraemia that has originated from an intravenous catheter. Risk factors include the type of catheter used, the number of infusions per week, and whether patients are self-caring or nursed. Factors shown to reduce infection rates include strict asepsis during catheter handling, the use of 2% chlorhexidine during catheter insertion, the absence of a stoma, a single-lumen catheter (compared to a multi-lumen catheter), and the antimicrobial line lock agent taurolidine.

Initial diagnostic methods without catheter removal include paired quantitative blood cultures using pour plates. A CRBSI is diagnosed if the same organism is isolated from both blood obtained via the central catheter and a peripheral vein, and the colony count of microbes grown from blood obtained through the catheter hub is at least 3-fold greater than the colony count from blood obtained from a peripheral vein. This is considered gold standard but is not practiced universally. An alternative is paired *qualitative* blood cultures with a differential time to positivity of greater than 120 minutes. However, this requires standardization of factors such as volume of blood in each sample and delivery to labs within 30 minutes.

Other complications include thrombosis and intestinal failure-associated liver disease, or IFALD. IFALD is defined as abnormal liver function with evidence of radiological or histological liver abnormalities occurring in a patient with intestinal failure, in the absence of alternative liver pathology.

Box 25.16 Pathophysiological classification of intestinal failure

Mechanism	Potential causes
Reduced absorption	
Short bowel syndrome	Extensive intestinal resection after infarction Crohn's disease Volvulus Trauma
Intestinal fistula	Post-abdominal operation Crohn's disease Malignancy Radiation enteropathy
Extensive small bowel disease	Crohn's disease Radiation enteropathy Intestinal lymphangiectasia Chemotherapy-induced enteritits
Restriction of oral/enteral intake	
Intestinal dysmotility	Postoperative ileus Chronic intestinal pseudo-obstruction
Intestinal mechanical obstruction	Malignancy Crohn's disease Abdominal adhesions Desmoid tumours

INTESTINAL FAILURE

Intestinal failure (IF) is the rarest organ failure, although the prevalence is increasing. Intestinal failure is defined by the European Society for Clinical Nutrition and Metabolism (ESPEN) as the reduction of gut function below the minimum necessary for the absorption of macronutrients and/or water and electrolytes, such that intravenous supplementation is required to maintain health and/or growth. The reduction of gut absorptive function that does not require intravenous supplementation can be considered as intestinal insufficiency.

There are five major pathophysiological mechanisms that cause intestinal failure (Box 25.16).

Where short bowel syndrome, intestinal fistulae, and extensive small bowel disease are concerned, the primary mechanism

of intestinal failure is reduced intestinal absorptive capacity, either due to reduction of mucosal surface area or intestinal bypass. Conversely, with intestinal dysmotility and mechanical obstruction, the primary mechanism leading to IF is restricted oral or enteral nutrition. This can occur either as a result of feeding-related exacerbation of GI symptoms or due to mechanical intestinal obstruction.

Furthermore, there are many secondary pathophysiological mechanisms that can contribute to the development of IF. These include:

- Accelerated gastrointestinal transit time
- Increased intestinal secretion of fluids and electrolytes within dilated or obstructed bowel segments
- Loss of fluids/electrolytes through high output stomas, gastric drainage, vomiting
- Disease-related hypophagia
- Small bacterial overgrowth
- Increased metabolic demand due to concomitant infection, inflammation, or sepsis.

Functional classification of intestinal failure

The most useful classification in clinical practice is the functional classification, which describes types 1, 2, and 3 IF. In all IF types, a multidisciplinary and multispecialty approach is critical, ideally delivered by a team with expertise and in a centre with the correct infrastructure and services to deliver optimal care. Patient choice is clearly also vital and should underpin every decision made.

Type 1 intestinal failure

This describes an acute, and often self-limiting, type of IF diagnosed in approximately 15% of patients after abdominal surgery, or in association with critical illness. This usually resolves within days to weeks. Patients with type 1 IF generally have excellent outcomes with no long-term sequelae.

Type 2 intestinal failure

Type 2 IF is usually reversible but lasts for more than 28 days. It commonly arises as a consequence of abdominal sepsis and enterocutaneous fistula(e), bowel obstruction, or ileus and may be associated with metabolic consequences.

In type 2 IF, where PN or fluid is required for months and when patients are metabolically unstable in the initial period, the 'SNAP' mnemonic is useful to guide management. SNAP stands for Sepsis, Nutrition, Anatomy, and planned Procedure. Sepsis control is the first priority, as this is the leading cause of death in type 2 IF. It includes prompt diagnosis, radiological or surgical drainage of abdominal collections, and tailored antibiotic therapy. Alternative sources of sepsis should also be considered, such as urinary or central venous catheters. Fungal infection in prolonged sepsis and antibiotic exposure should also be borne in mind.

Normalization of hydration status, electrolyte levels, and acid–base balance are also critical during this period, after which delivery of appropriate PN is necessary. This can be challenging—this is a highly catabolic state and not only does protein balance need addressing but also optimization of tissue function while avoiding overfeeding, which can impair liver function. Enteral nutrition is rarely sufficient because of the loss of function of the gastrointestinal tract. Therefore, parenteral nutrition often represents the main option, alone or in combination with enteral nutrition. It is also crucial to take steps to prevent, monitor, and manage re-feeding syndrome where necessary.

Unfortunately, the abdominal cavity is hostile for several weeks or months after an initial laparotomy, meaning any reconstructive surgery would risk fistulation. Therefore, early surgery should be limited to sepsis control. Once the initial period of stabilization has been negotiated, delineation of intestinal anatomy should be undertaken with appropriate imaging modalities, which subsequently informs planning of definitive surgery. It is usual to wait for between 3 and 6 months, after sepsis has been cleared and the inflammatory response has subsided, before definitive surgery is undertaken.

The most frequent outcomes of patients with type 2 IF are full intestinal rehabilitation (about 40%) and long-term enteral tube nutrition or transition to type 3 IF status requiring prolonged home PN (together about 50%). In-hospital mortality of type 2 IF has been reported to be as high as over 10%.

Type 3 intestinal failure

Type 3 IF describes chronic and usually irreversible intestinal failure for which long-term parenteral nutrition delivered at home is the first-line treatment. These patients are usually metabolically stable. Lifelong dependence is typical, unless patients are considered for alternatives such as intestinal transplant, glucagon-like peptide (GLP) analogue therapy or bowel lengthening procedures (see later).

For type 3 IF, weaning from home PN (HPN) within 2 years of starting may occur in 20% to 50% of patients, due to intestinal adaptation. Patients with benign disease have a high probability of long-term survival on HPN: 1-, 5-, 10-, and 20-year survival has been reported as 93%, 71%, 59%, and 28%, respectively. However, type 3 IF may also be associated with life-threatening complications and the condition itself may be highly disabling and impair the patient's quality of life. A summary of the clinical features and management of the three types of intestinal failure can be found in **Box 25.17**.

Short bowel syndrome

Short bowel syndrome, or SBS, is defined as the combination of clinical features associated with a remaining small bowel length of less than 200 cm. The normal small intestinal length, measuring from the duodenal jejunal flexure, varies from about 275 to 850 cm depending on sex and height. SBS is a major cause of chronic intestinal failure—indeed it is responsible for three-quarters of IF due to benign causes in adults. Depending on the anatomy of the remnant bowel, four categories of short bowel are identified: end-jejunostomy with no colon in continuity, end-ileostomy with no colon in continuity, jejunocolic anastomosis with no ileocaecal valve and a part of the colon in continuity, and jejunoileal anastomosis with both the ileocaecal valve and the entire colon in continuity (**Fig. 25.17**).

Adaptation

During the acute phase following bowel resection, the absorptive capacity of the residual small bowel is limited by increased transit times, venous congestion, loss of surface area, and bacterial overgrowth.

Intestinal adaptation is a natural and spontaneous compensatory mechanism following bowel resection whereby structural and functional changes in the remnant bowel attempt to maximize nutrient and fluid absorption. The ileum has greater adaptive potential than the jejunum. Adaptation usually takes place over 1 to 2 years post resection and occurs partly by increasing the absorptive area but also the slowing of gut transit. The process is promoted by the

Box 25.17 Summary of functional classification of intestinal failure (IF)

	Type 1 IF	Type 2 IF	Type 3 IF
Features	Acute, self-limiting Often post operative	Prolonged condition (>28 days) Potentially reversible Metabolically unstable Sepsis is common Often related to complex abdominal surgery and its complications e.g., fistula development	Chronic condition Usually irreversible Stable patient
Management	Short-term PN and i.v. fluid Consider and treat reversible causes e.g., ileus	PN/i.v. fluid for months SNAP approach	Home PN/i.v. fluid GLP2 analogues Bowel lengthening surgery Intestinal transplant
Prognosis	Excellent	Intestinal rehabilitation 40% Long-term enteral or parenteral nutrition 50% Inpatient mortality 10%	5-year survival 71% 10-year survival 59%

presence of nutrients in the gastrointestinal lumen, gut hormones, and pancreatico-biliary secretions.

Causes of short bowel syndrome

The causes of SBS can be thought of as being anatomical or functional (**Box 25.18**). Congenital causes or paediatric short bowel syndrome will not be discussed here.

Anatomical causes include extensive bowel resection, a proximal jejunostomy, a proximal fistula (e.g., enterocutaneous, entero-enteric, or entero-colic), or multiple bowel resections over time. Functional causes include extensive mucosal disease impairing normal function, due to inflammation (e.g., Crohn's disease), following abdomino-pelvic radiation or, less commonly, small intestinal bacterial overgrowth. Causes may coexist, for example a patient with Crohn's disease and previous bowel resections but also active current inflammation, or a patient with a previous irradiated bowel, malignant bowel obstruction, and a proximal jejunostomy.

Pathophysiology of short bowel syndrome

The total normal daily volumes of gastrointestinal secretions in a healthy adult are as follows:

- Food and drink intake 1500 mL
- Saliva 750 mL
- Gastric secretions 1250 mL
- Biliary secretions 1000 mL
- Pancreatic secretions 1000 mL
- Jejunal secretions 2500 mL

This totals approximately 8 L per day. However, normal daily stool volumes are around 150 mL. Therefore, in short bowel syndrome, where the distal intestine is lost or out of continuity, intestinal effluent volumes will be much higher.

All fluid entering the gut originates proximal to the ileum, and reabsorption occurs distal to the ileum. A healthy individual is considered to be a 'net absorber', meaning that increased fluid consumption will lead to greater absolute intestinal absorption. The proximal intestinal secretory response occurs up to a sodium level of 90 to 100 mmol/L. Given that the sodium content of almost all drinks is below this, drinking will lead to a further secretory effect. This is overcome in a healthy individual by the absorptive capacity of the distal small bowel and colon to ensure net absorption. However, in a patient with SBS, their absorptive capacity is lost, meaning that additional drinking drives secretion but without reabsorption, resulting in paradoxical further dehydration.

Management of short bowel syndrome

Given the above underlying mechanism of dehydration in SBS, the aims of management are to reduce gastrointestinal secretions, slow gut transit, correct fluid and electrolyte abnormalities, optimize nutritional status, and manage symptoms of thirst. One such management strategy is fluid restriction of hypotonic fluid with intake of hypertonic drinks. Hypertonic drinks should have a sodium content of greater than 90 mmol/L, such as St Mark's solution (**Box 25.19**). Other medical treatments include acid suppression with proton pump inhibitors such as omeprazole, to reduce gastric secretions. Loperamide and codeine can be used as antimotility agents.

With regards to nutrition, enteral nutrition is important for the integrity of the gut barrier and immune function. The need for parenteral support in the form of intravenous fluids and/or nutrition is determined largely by the underlying anatomy and bowel length (**Box 25.20**).

Complications of short bowel syndrome

The following complications are usually seen in patients with SBS and presence of colon in continuity.

D-lactic acidosis

Short bowel syndrome is a risk factor for D-lactic acidosis. This is a rare clinical condition and patients typically present with clinical features of confusion, ataxia, and slurred speech. Blood gas analysis classically demonstrates a raised anion gap metabolic acidosis with a normal L-lactate level. A D-lactate level of above 3 mmol/L is considered to be significant. In SBS, there is an absence or reduction of small bowel area, which is usually responsible for the absorption of simple carbohydrates. The unabsorbed carbohydrate then passes into the colon, where it is fermented by colonic microbiota to form D-lactate. Treatment of D-lactic acidosis is with intravenous fluids and sodium bicarbonate. Patients should be advised to reduce the amount of carbohydrates in their diet.

Renal stones

Oxalates are natural compounds found within the diet (spinach, almonds, beetroot, blackberries, blueberries, and raspberries) and are also produced within the body as a waste product. Oxalate is absorbed in the colon and precipitates within the renal tubule, leading to damage. In a healthy individual, calcium binds to oxalate within the intestinal lumen reducing the amount available for absorption and therefore preventing renal damage. However, in a

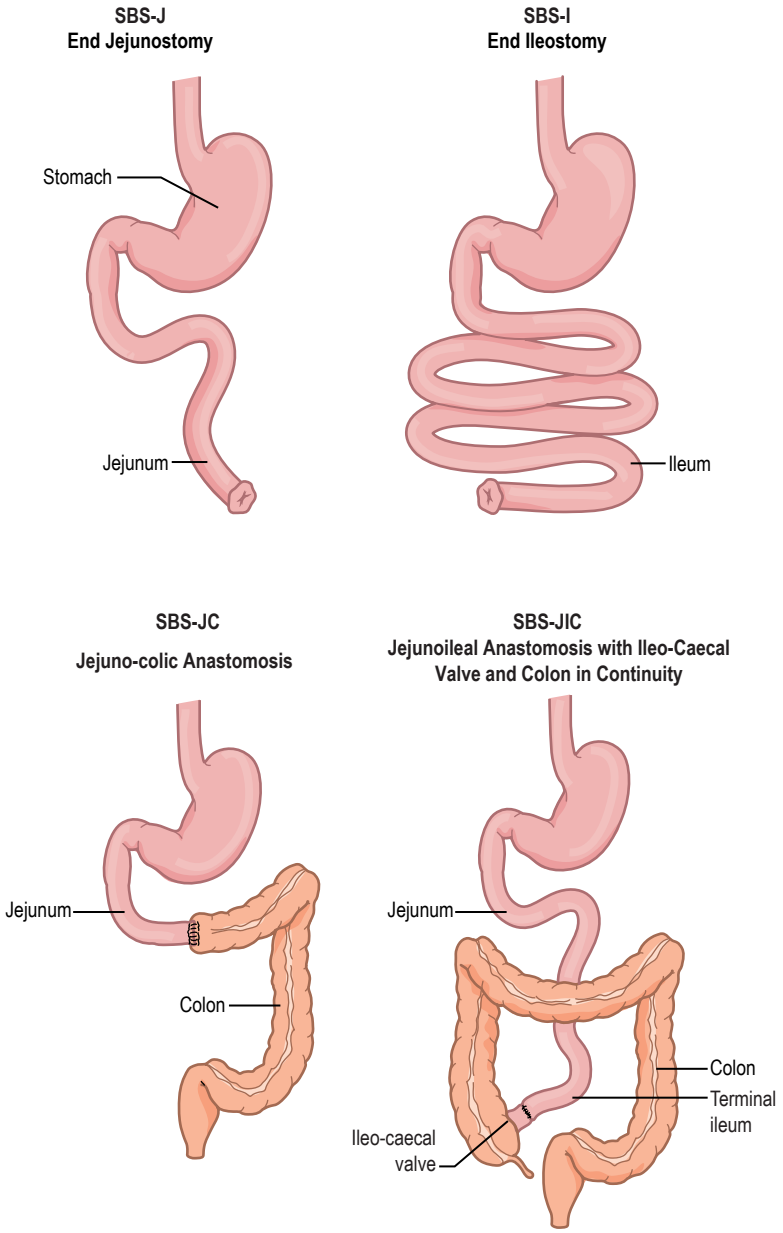

Fig. 25.17 **Short bowel syndrome.**

Box 25.18 Causes of short bowel syndrome

Anatomical causes	Functional causes
• Extensive bowel resection e.g., mesenteric ischaemia • Proximal jejunostomy • Proximal fistula • Multiple bowel resections	• Mucosal inflammation e.g., Crohn's disease • Radiation enteropathy • Small intestinal bacterial overgrowth

Box 25.19 St Mark's solution

Ingredients for 1 L batch of St Mark's solution
Glucose powder 20 g (6 teaspoons) Table salt (sodium chloride) 3.5 g (1 level 5 mL teaspoon) Sodium bicarbonate 2.5 g (heaped 2.5 mL teaspoon)

patient with SBS, unabsorbed long-chain fatty acids compete for calcium binding. The resultant effect is more free oxalate available for absorption and an increased risk of oxalate renal stone formation. This problem occurs in up to a quarter of patients with SBS and colon in continuity. General measures to reduce this risk include adequate hydration, reduced dietary fat, increased dietary calcium, and to adopt a low oxalate diet.

Chronic intestinal failure: alternatives to home parenteral nutrition

Chronic intestinal failure should be managed by a multidisciplinary team at a specialist IF centre. The goals of care should be to maximize enteral function, while attempting to wean PN requirements, avoid or minimize any PN-related complications, and improve quality of life.

Box 25.20 Nutritional and fluid support in short bowel syndrome

Small bowel length(from DJ flexure)	Jejunostomy	Jejunocolic anastomosis
0–50 cm	Parenteral nutrition + intravenous fluids	Parenteral nutrition
51–100 cm	Parenteral nutrition +/– intravenous fluids	Oral nutritional support
101–150 cm	Oral nutrition + oral glucose solution	No support required
151–200 cm	Oral glucose solution	No support required

Intestinal transplant

An alternative to home parenteral nutrition (HPN) is intestinal transplantation. This is a rare procedure and only occurs at specialist centres. There are three different types of intestinal transplantation—isolated small bowel transplants, liver-containing grafts, and multi-visceral transplants, which include the stomach and/or pancreas.

The indications for intestinal transplant are outlined in **Box 25.21**. The main indications are due to complications related to PN: progressive IFALD, recurrent life-threatening catheter-related sepsis, and loss of central venous access. Referral for consideration of transplant should be considered before life-threatening complications develop. Poor quality of life and acceptance of PN can be considered alongside other factors, and this could be an emerging indication over the next decades as post-transplant outcomes continue to improve. There are also non-intestinal failure-related indications for transplant. Multi-visceral transplant can be considered in patients who require surgical evisceration for treatment of invasive desmoid tumours or pseudomyxoma peritonei. Another emergency indication is mesenteric vascular catastrophe.

The survival rates for post-transplant patients are improving but remain inferior to those on HPN, with 1- and 5-year figures of 88.2% and 72.6%, respectively. Outcomes are better with non–liver-containing grafts versus liver-containing grafts. Complications of intestinal transplant include rejection, graft versus host disease, infection, and post-transplant lymphoproliferative disorder. Currently, intestinal transplantation remains a rescue procedure for life-threatening complications because of the superior survival figures with HPN. However, as outcomes improve, transplantation may start to be considered earlier for patients on HPN.

Bowel lengthening procedures

A variety of surgical techniques to improve bowel length have been described. These procedures are not performed routinely and require specialist centres. The Bianchi procedure involves a longitudinal incision of dilated bowel and an end-to-end anastomosis, resulting in increased intestinal length. The serial transverse enteroplasty, or STEP procedure, involves diagonal breaks in dilated bowel to increase length and slow transit time. Lastly, in the spiral intestinal lengthening and tailoring (SILT) procedure, a spiral incision is made in dilated bowel, which then allows resewing and intestinal extension.

GLP2 analogues

Endogenous glucagon-like peptide 2 (GLP2) is a gut hormone produced by the L cells in the small intestine in response to carbohydrate ingestion. The recombinant GLP2 analogue teduglutide, containing a substitution of the amino acid alanine with glycine at position 2 of the polypeptide chain, is used in clinical practice to promote intestinal absorption, having been originally found to increase mesenteric blood supply and mucosal growth, while reducing gastric emptying and gastric secretions in animal studies.

FOOD INTOLERANCES

Many people ascribe various gastrointestinal symptoms to food, and many such sufferers are seen and started on exclusion diets. Adverse reactions to food do exist. These can be divided into food allergy and food intolerance. Food allergy incorporates immunological reactions—both IgE and non-IgE mediated. Common triggers of food allergies include cows' milk, eggs, peanuts, tree nuts, wheat, and shellfish. These should be managed by an immunologist. Food intolerance describes the occurrence of similar symptoms on a non-immune basis and will be the focus of this section.

Lactose intolerance

This is probably the most common form of food intolerance, with lactose malabsorption reported as affecting up to 60% to 70% of the world's population. Loss of intestinal lactase expression in the first two decades of life (lactase non-persistence) is the dominant phenotype worldwide, with highest rates found in East Asia and West Africa (70%–100%). Lactase persistence is the dominant phenotype in Western countries, with Northern Europeans least likely to be affected (rates of <5%). Patients develop symptoms of abdominal bloating and diarrhoea following ingestion of lactose, which is a sugar present in dairy products such as milk, butter, and cheese. It is defined as symptoms on lactose exposure in individuals with lactose malabsorption. Tests for lactose intolerance are usually not necessary. Most patients are advised to trial a lactose elimination diet, where lactose-containing foods are avoided and symptoms reassessed. Alternatively, a hydrogen breath test can be performed although this is not routinely done and there is variable reliability of these tests.

For quality of life, patients are often advised that they may continue to eat lactose up to their individual point of tolerance, rather than completely eliminating lactose from the diet. Harder cheeses contain less lactose than soft cheeses as the lactose sugar is spent

Box 25.21 Indications for intestinal transplant

Complications or failure of PN	Treatment of underlying condition	Poor patient acceptance
• Liver failure • Central venous thrombosis of two or more central veins • Frequent catheter-related bloodstream infections • Frequent episodes of severe dehydration	• Invasive desmoid tumours • Congenital mucosal disorders • Ultra-short bowel syndrome	• Frequent hospitalizations • Inability to function • Unwillingness to accept long-term home PN

during the fermentation of cheese. Lactose-free or alternative milks tend to be fortified with calcium. Most individuals with lactose malabsorption can tolerate up to 12 g of lactose, which is equivalent to a large glass of milk, without experiencing symptoms.

FODMAPs

FODMAPS (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) are fermentable carbohydrates which are found in many food groups and can trigger symptoms of irritable bowel syndrome (IBS); such as abdominal cramping, bloating, and loose stool. Unlike other carbohydrates, FODMAPs are not easily absorbed within the small intestine and therefore pass into the colon where they get fermented by bacteria. This leads to production of gas and fluid shifts within the large bowel resulting in the symptoms mentioned above. Therefore, it is sometimes recommended to follow a low FODMAP diet under the guidance of a specialist dietician for a limited period for symptom relief and identification of specific triggers.

Non-coeliac gluten sensitivity

Non-coeliac gluten sensitivity (NCGS) describes a syndrome of symptomatic response to gluten ingestion in patients with no serologic or histologic evidence of coeliac disease (see Chapter 22). Common symptoms include abdominal pain, bloating, and diarrhoea. Extraintestinal manifestations such as headache and 'brain fog' have also been reported. In patients presenting with symptoms that they attribute to gluten, it is important to exclude coeliac disease and IgE-mediated wheat allergy. However, there are no tests that distinguish NCGS from IBS. The clinical response to a gluten-free diet may be caused by a variety of mechanisms, including placebo effect and reduction in FODMAPs (particularly fructans), as well as by true gluten sensitivity. Patients should see a specialist dietician before embarking on a gluten-elimination diet and counselled on potential nutritional deficiencies such as calcium, vitamin D, iron, and zinc.

CORE SKILLS AND KNOWLEDGE

Kidney disease is common: acute kidney injury (AKI) affects around 20% of hospitalized patients, and 10% to 15% of the general population meet diagnostic criteria for chronic kidney disease (CKD). The kidney is involved in systemic conditions including diabetes, hypertension, autoimmune disorders, haematological malignancies, and infections including human immunodeficiency virus (HIV) and viral hepatitis.

Kidney physicians work in lifetime partnership with patients, their families, and a multidisciplinary team including nurses, therapists, counsellors, nutritionists, technicians, and pharmacists. Most patients with kidney disease are managed in outpatient settings, although patients with AKI may require inpatient investigation and management. Specialist kidney expertise including transplantation and dialysis are offered in tertiary units. Kidney physicians manage immunosuppression during and after kidney transplantation, and supervise peritoneal and haemodialysis. Nephrologists need to be general physicians, comfortable with complexity and co-morbidity.

Key skills in kidney medicine include:

- Diagnosing AKI and managing its complications
- Understanding CKD causes, complications, and progression
- The principles of dialysis and kidney transplantation.

Opportunities for learning kidney medicine include attending outpatient clinics, assessing patients with AKI presenting to emergency or acute admissions departments, and spending time in specialist centres with patients receiving kidney replacement therapies.

CLINICAL SKILLS

History

In its early stages, kidney disease may be asymptomatic and diagnosed incidentally on blood or urine tests. History-taking in kidney medicine (Box 26.1) is tailored to the clinical context of the individual patient.

Quantification of proteinuria

Quantifying the concentration of urinary protein is necessary in kidney disease. Testing is done initially using a urine dipstick and then quantified using one of the measures shown in Box 26.2. There is a rough equivalence between methods if proteinuria is non-selective (i.e., if protein is excreted in the urine in the same proportions as in the blood). In healthy people there should be virtually no urinary albumin (uACR <2.5 mg/mmol for males, <3.5 mg/mmol for females); even very low concentrations above this threshold (not detectable by dipstick testing) confer increased cardiovascular risk. High concentrations of proteinuria generally indicate glomerular disease, and uPCR > 350 mg/mmol indicates nephrotic syndrome if hypoalbuminuria and oedema are also present.

Examination

Except for palpable polycystic kidneys, there may be few physical signs specific to kidney disease. Signs of systemic disease with kidney involvement may be evident, for example, systemic lupus erythematosus, systemic sclerosis, diabetic microvascular disease, cardiovascular disease. The figure on the next page shows potential signs of kidney disease in the **grey boxes**. The **yellow boxes** indicate signs related to renal replacement in patients with kidney failure or due to previous treatment including physical signs of peritoneal dialysis, haemodialysis, and transplantation.

A diagnostic approach to new kidney disease

A diagnostic approach to kidney dysfunction is presented in Box 26.3. This is relevant in AKI and CKD with superimposed AKI or a rapid deterioration in kidney function.

Box 26.2 Quantifying the concentration of urinary protein

24-hour urine protein collection (g/24 h)	Urine protein:creatinine ratio (uPCR, mg/mmol)	Urinary albumin:creatinine ratio (uACR, mg/mmol)
1	100	70
2	200	150
3	300	200
4+	400+	300+

Box 26.1 History-taking in kidney and urinary tract disease

Assessing the likely duration of kidney dysfunction

- Duration of symptoms
- Previous occasions on which urinalysis or measurement of serum creatinine might have been performed, e.g., pre-employment health check, new patient check, pregnancy.
- Urine volume:
  - Oliguria is a symptom of acute kidney injury
  - Slowly progressive kidney disease can cause an increase in urine volume when a reduction in tubular function leads to a salt- and water-wasting. Urine volume increases as tubular concentrating ability reduces meaning that polyuria/nocturia may suggest the length of time for which CKD has been present.

Symptoms of uraemia

Symptoms are common when the serum urea concentration exceeds 40 mmol/L, though many patients develop uraemic symptoms at lower concentrations. Symptoms are generally non-specific but may include:

- malaise, loss of energy
- loss of appetite and weight loss
- insomnia
- nocturia/polyuria
- itch
- nausea/vomiting
- 'restless legs' syndrome
- bone pain
- peripheral oedema
- symptoms due to anaemia
- amenorrhoea
- erectile dysfunction
- CNS symptoms in advanced uraemia: mental slowing, clouding of consciousness, myoclonic twitching, seizures

History that may reveal the aetiology of kidney disease:

- ***Medical history*** focusing on diseases that commonly affect the kidney: diabetes, hypertension, systemic inflammatory diseases, blood-borne viruses, myeloma
- ***Recent ill health***—e.g., sepsis or dehydration causing kidney hypoperfusion and pre-renal AKI
- Symptoms of ***urinary tract obstruction*** (see Chapter 47)
- Symptoms of ***systemic inflammatory or malignant conditions:*** fever, malaise, joint pain, rash, eye inflammation, hair fall, nasal discharge, haemoptysis
- ***Medications*** use now and in the past. Remember known nephrotoxic agents (such as non-steroidal anti-inflammatory drugs, which the patient may have obtained over-the-counter and therefore may forget to disclose), and traditional and herbal remedies, which are implicated in kidney disease
- ***Family history*** of kidney disease or kidney replacement therapy

In advanced CKD

- Do they understand their diagnosis?
- What form of renal replacement offers the best quality/quantity of life?
- Do they wish to consider dialysis or prefer a supportive/palliative approach?

In patients receiving dialysis

- How are they managing their treatment?
- Are there any symptoms relating to anaemia or bone disease?
- Is transplantation medically achievable and feasible?

Kidney transplant recipients

- Any there any symptoms to suggest opportunistic infections?
- How are they managing with their immunosuppressant medications? Are strategies needed to aid adherence?
- Have they noticed any skin lesions/changes?
- Can their lifestyle be optimized to increase the survival of their transplant?

SIGNS OF KIDNEY DISEASE

General features
Short stature (childhood kidney disease)
Pallor (anaemia)
Photosensitive pigmentation
Yellowish complexion

Observation chart
Hypoxia and hypertension suggest fluid overload

Fundoscopy
Signs of diabetic or hypertensive eye disease

Mouth
Dry mouth suggests intravascular fluid depletion

Neck
Jugular venous pressure reflects fluid status

Chest
Basal crackles suggest fluid overload

Heart
Pericardial friction rub (uraemia)

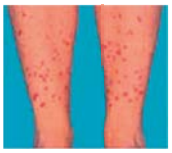
Skin
Scratch marks due to uraemic pruritus

Abdomen
Grossly enlarged kidneys may be palpated in polycystic kidney disease

Peripheral pulses
Reduced in atherosclerotic disease

Hands
Brown discoloration of the nails

Legs
Signs of fluid overload
Purpuric rash suggests an underlying vasculitis with potential kidney involvement



EVIDENCE OF RENAL REPLACEMENT THERAPY

General features
Tremor may suggest toxicity from calcineurin inhibitor immunosuppression

Skin
Basal cell carcinomas and other malignant or pre-malignant change with long-term immunosuppressant use

Mouth
Gingival hypertrophy with some immunosuppressant medications

Neck
Scars from previous venous dialysis catheters

Chest
Tunnelled dialysis catheter

Forearms
Evidence of arteriovenous fistulae – check for a thrill to confirm patency

Abdomen
Tenckhoff peritoneal dialysis catheter
Kidney transplant: mass with overlying scar in the iliac fossa

Box 26.3 Causes of kidney dysfunction

Pre-renal:
- Intercurrent illness including systemic infection or sepsis
- Vomiting, diarrhoea, and dehydration
- Concurrent use of antihypertensives or diuretics in intercurrent illness, e.g., angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers

Intrarenal:
- Disease with kidney involvement, e.g., cast nephropathy in myeloma
- Nephrotoxic medication
- Symptoms suggestive of systemic inflammatory disease
- Proteinuria/haematuria

Post-renal:
- Symptoms of urinary tract obstruction
- Anuria
- A condition associated with urinary tract obstruction: prostate disease, bladder or pelvic cancer
- Bladder distension or hydronephrosis on ultrasound

BACKGROUND

Nephrology is a major medical specialty; over 10% of the world's population are thought to be living with kidney disease.

The kidneys maintain our internal environment and influence other systems when they fail. Glomerular pathology, an array of local and systemic diseases causing kidney injury, and the complex consequences of fluid and electrolyte shifts make nephrology broad and challenging. Chronic kidney disease is often a life-long journey, encompassing different treatment modalities and necessitating an appreciation of and support for the physical, psychological social adaptations required when living with CKD.

ANATOMY AND PHYSIOLOGY

Functional anatomy

The ***kidneys*** are paired organs, which in adults are 11 to 14 cm in length, 5 to 6 cm in width and 3 to 4 cm in depth. They lie in the retroperitoneum, on either side of the vertebral column at the level of T12–L3 (the right kidney lies lower than the left, pushed down by the liver), enclosed in a fibrous capsule. Kidneys have an outer cortex and an inner medulla (Fig. 26.1). There are about 1 million ***nephrons*** in each kidney. Each nephron contains a glomerulus, proximal tubule, loop of Henle, distal tubule, and collecting duct. All glomeruli lie in the cortex. The tubules dip in and out of the medulla, where the collecting ducts merge to form the ducts of Bellini, emptying at a papilla at the apex of the renal pyramid into a calyx. Urine flows through merging calyces into the renal pelvis, ureters, and bladder.

The renal arteries branch off the abdominal aorta, dividing until arterial blood reaches the glomerulus. About 25% of people have dual or multiple renal arteries on one or both sides. ***Afferent glomerular arterioles*** arise from interlobular branch arteries to supply the glomerular capillary tuft, which drains into an ***efferent glomerular arteriole***. Efferent arterioles from (outer) cortical glomeruli drain into a peritubular capillary network within the cortex and then into increasingly large proximal branches of the renal vein. In contrast, blood from the (inner) juxtamedullary glomeruli passes via vasa recta in the medulla and returns via the cortex to renal veins that drain into the inferior vena cava.

The capsule and ureters are innervated via T10–12 and L1 nerve roots, and pain related to the kidney is felt over the corresponding dermatomes.

Nephron

The glomerular tuft is a ball of capillaries enclosed by Bowman's capsule, a chamber lined with specialized ***parietal epithelial cells*** that marks the origin of the tubule. The tuft, held together and regulated by ***mesangial cells*** serves as a filtration barrier, allowing filtrate from plasma to move into the urinary (Bowman's) space (Fig. 26.2). The rate of glomerular filtration is influenced by changes in the contractile tone of either afferent or efferent arterioles; for example, efferent vasoconstriction increases transglomerular capillary pressure and filtration. Glomerular capillaries are lined with ***endothelial cells***, fenestrated with 60 to 80 nm pores and covered with charged glycocalyx. The glomerular basement membrane (GBM), about 300 nm thick and made of type IV collagen, laminin, and heparin sulphate, separates the endothelium from podocytes. Podocytes anchor to the GBM by an extensive trabecular network of foot processes, and hang into Bowman's space. The interdigitating foot processes of podocytes form the 40 nm filtration slit, a narrow potential space traversed by a protein 'zipper' that may prevent the passage of larger molecules (such as albumin) into the urinary space, and regulates the architecture and function of podocytes.

Mesangial cells (thought to be related to macrophages) sit within the tuft, able to contract and relax to control blood flow and the filtration surface area along the glomerular capillaries in response to a host of mediators. They also secrete the ***mesangial matrix***, which provides the scaffold for glomerular capillaries.

The ***kidney tubules*** are lined by epithelial cells, which alter the composition of filtrate that eventually forms urine. Proximal tubular cells have a luminal brush border to increase (by thirtyfold) the surface area exposed to filtrate, rich in transporters and channels. The loop of Henle is lined with squamous cells, which are more permeable to water than solute, and cuboidal epithelium, which is more permeable to solute. The distal tubule regulates electrolytes and pH through cuboidal epithelium, and the cortical portion of the collecting ducts contains two cell types with different functions: principal cells (sodium, potassium, and water homeostasis) and intercalated cells (acid–base homeostasis). Finally, interstitial fibroblast-like cells in the cortex produce erythropoietin in response to hypoxia.

Juxtaglomerular apparatus

The juxtaglomerular apparatus sits between the afferent arteriole and the distal convoluted tubule of the same nephron (Fig. 26.3). It is critical to regulation of blood flow and glomerular filtration rate via tubuloglomerular feedback. It includes the macula densa: modified epithelial cells in the distal convoluted tubule. Columnar epithelial cells in the macula densa sense the concentration of tubular fluid sodium (higher filtrate flow means more delivered sodium), triggering adenosine-mediated vasoconstriction of the afferent arteriole to reduce glomerular filtration. Juxtaglomerular cells secrete renin, able to induce aldosterone release, allowing retention of salt to maintain fluid balance in response to decreased glomerular filtration when needed.

It contains the macula densa. **(B)** The countercurrent system (i) Vasa recta: vessels descend from the cortex into the medulla and then turn back towards the cortex. (ii) The descending limb of the cortical nephron extends into the outer medulla. (iii) Juxtamedullary nephron: the descending limb dips into the hypertonic inner medulla. Numbers indicate approximate osmolalities.

Physiology

A ***hydrostatic pressure gradient*** of approximately 10 mmHg (capillary pressure of 45 mmHg minus 10 mmHg of pressure within Bowman's space and 25 mmHg of plasma oncotic pressure) provides the driving force for ultrafiltration of virtually protein-free and fat-free fluid across the glomerular filter into Bowman's space and the renal tubule (Fig. 26.4).

The ***glomerular filtration rate*** (GFR) varies with age and sex but is approximately 120 to 130 mL/min/1.73 m^2 surface area in adults. This means that ultrafiltration of 170 to 180 L of water and unbound small-molecular-weight constituents of blood occurs each day. If these volumes of ultrafiltrate were excreted unchanged as urine, it would be necessary to drink huge amounts of water and salts to maintain balance. Instead, reabsorption occurs.

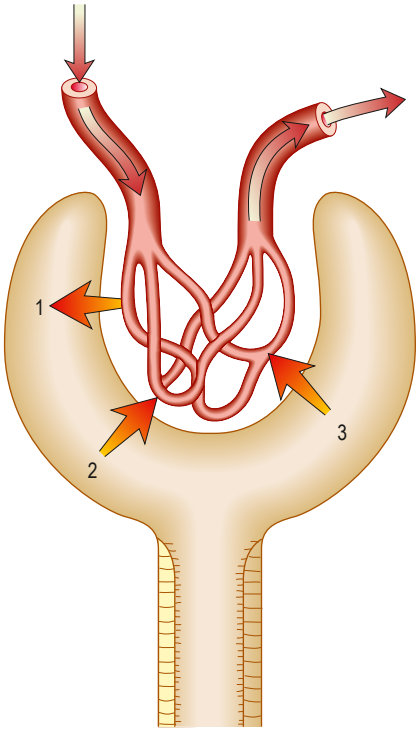

Fig. 26.4 Pressures controlling glomerular filtration. (1) Capillary hydrostatic pressure (45 mmHg). (2) Hydrostatic pressure in Bowman's space (10 mmHg). (3) Plasma protein oncotic pressure (25 mmHg). *Arrows* (1, 2, 3) indicate the direction of the pressure gradient.

Absorption of solutes

Essential electrolytes and other blood constituents, such as glucose and amino acids, are absorbed from filtrate along the course of the nephron (see Fig. 26.3).

Sodium filters freely, and 60% to 80% of filtered sodium (and water) is reabsorbed in the late proximal tubule, where the apical membrane Na^+/H^+ exchanger (NHE3) trades hydrogen ions into the lumen for absorbed sodium, with anionic chloride (Cl^-) accompanying sodium to maintain electric neutrality. Secreted H^+ allows bicarbonate (HCO_3^-), formed from water and CO_2 by cellular and luminal carbonic anhydrase, to exit the basolateral membrane with absorbed Na^+. Recently, sodium–glucose co-transporters 1 and 2 (SGLT-1 and -2) have generated a lot of interest because of the use of SGLT-2 inhibitors in the treatment of diabetes. SGLT-2 is a predominant proximal tubular transporter that absorbs glucose and sodium. SGLT-2 inhibitors promote glycosuria and natriuresis.

Around 25% of Na^+ is absorbed in the thick ascending limb of the loop of Henle, as NaCl by the $Na^+/K^+/2Cl^-$ co-transporter (NKCC). The remaining 5% is absorbed by the thiazide-sensitive NaCl co-transporter and the epithelial sodium channel (ENaC) in the principal cell of the collecting duct. Of the recommended daily intake of up to 6 g per day of ***salt*** (equivalent to around 2 g Na^+), only around 5% to 10% is excreted in urine, stool, and sweat.

Potassium is freely filtered at the glomerulus, largely reabsorbed in the proximal tubule, and secreted in the distal tubule and collecting ducts. A clinical consequence of this is that elimination of unwanted potassium is less dependent on GFR than elimination of urea or creatinine.

Virtually all bicarbonate, glucose, and amino acids are absorbed in the proximal tubule though there is a maximal absorptive capacity for many compounds. For example, if blood glucose concentrations are above the upper reference limit, the amount filtered (filtered load = GFR × plasma concentration) may exceed maximal absorptive capacity and glucose will 'spill over' as glycosuria. Inherited or acquired defects in tubular function may lead to incomplete absorption of a *normal* filtered load, and substances such as glucose, amino acids, phosphate, sodium, potassium, and calcium appear in the urine, either singly or in combination. Examples include cystinuria (a defect of a specific amino acid transporter) or Fanconi's syndrome (a proximal tubule disorder leading to phosphaturia, aminoaciduria, and glycosuria). Other compounds filtered and reabsorbed or secreted to a variable extent include urate, many organic acids, and many drugs or their metabolic breakdown products. The more tubular secretion of a compound that occurs, the less dependent elimination is on GFR.

Absorption of water

Urine is concentrated by the countercurrent multiplier mechanism in the loop of Henle, the medullary interstitium, medullary blood vessels (vasa recta), and the collecting ducts (Fig. 26.3). Sodium and urea in water flow as filtrate into the descending loop, which is permeable to water and impermeable to sodium. In the thick ascending limb, which is impermeable to water, active absorption of sodium by the $Na^+/K^+/2Cl^-$ co-transporter into the interstitium increases tissue osmolarity. Because of the hairpin nature of the loop, water from the permeable descending limb enters the interstitium by osmosis, where the vasa recta return fluid to the circulation. Constant active absorption of sodium in the ascending loop multiplies this process over time, and the solute concentration at the tip of the loop is fourfold that of extracellular fluid (Fig. 26.3B). By this mechanism, salt and water are returned to the circulation. Filtrate entering the collecting duct is increasingly concentrated by the action of arginine vasopressin (AVP, or vasopressin), leading to the release of intracellular aquaporin water channels, which insert themselves across the apical membrane allowing water to be absorbed along an osmotic gradient. When the effect of AVP wears off, water channels return to the cell cytoplasm. The final urine volume is 1 to 2 L daily.

Glomerular filtration rate

In health, the GFR remains constant owing to intrarenal regulatory mechanisms. In disease (e.g., a reduction in intrarenal blood flow, damage to or loss of glomeruli, obstruction to the free flow of ultrafiltrate along the tubule), the GFR will decrease and the ability to eliminate waste and regulate the volume and composition of body fluid declines. This is measured as a rise in the plasma urea or creatinine, or as a reduction in measured GFR.

The concentration of urea or creatinine in serum represents the dynamic equilibrium between production and elimination. In healthy subjects there is an enormous reserve of excretory function, and serum urea and creatinine do not rise above the normal range until there is a reduction of 50% to 60% in the GFR (Fig. 26.5). Thereafter, the concentration of urea depends on both the GFR and urea production rate (Box 26.4). The latter is heavily influenced by protein intake and tissue catabolism. The concentration of creatinine is much less dependent on diet but can vary with age, sex, and muscle mass. Once it is elevated, serum creatinine is a better guide to GFR than urea and is widely used to monitor further deterioration in the GFR.

Measuring or estimating the GFR

If a substance is filtered and unmodified by the tubules as it passes along the nephron, the concentration of that substance per mL will

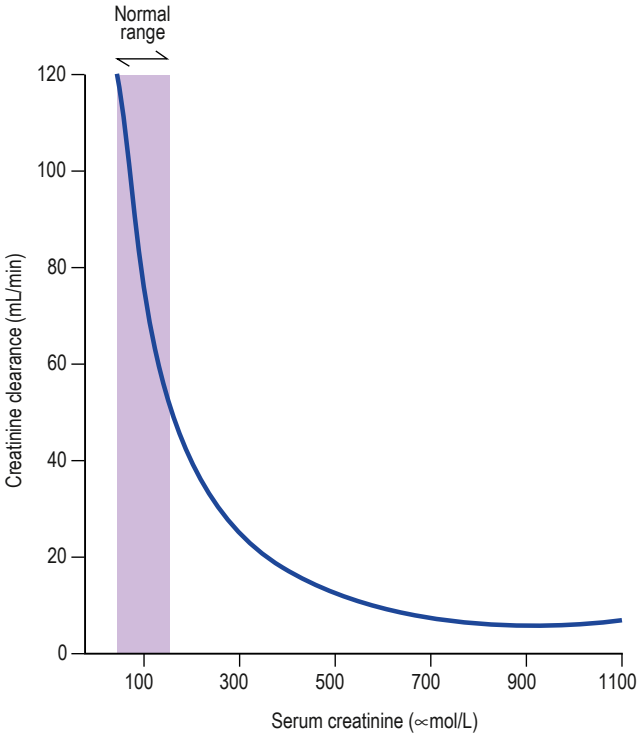

Fig. 26.5 Creatinine clearance versus serum creatinine. Serum creatinine does not rise above the upper reference limit until there is a 50%–60% reduction in glomerular filtration (creatinine clearance).

Box 26.4 Factors influencing serum urea concentrations

Increased serum urea	Increased production: • High-protein diet • Increased catabolism • Surgery • Infection • Trauma • Corticosteroid therapy • Upper gastrointestinal bleeding • Cancer	Reduced elimination: • Glomerular disease • Reduced renal blood flow • Hypotension • Dehydration • Urinary obstruction • Tubulointerstitial nephritis
Decreased serum urea	Decreased production: • Low-protein diet • Reduced catabolism, e.g., old age • Liver failure	Increased elimination • Pregnancy

be the same in blood and urine. Accurate assessment of GFR, particularly when urea and creatinine may be in the normal range or near normal, can be done via cystatin C, which is a freely filtered low-molecular-weight protein and more accurate marker of kidney function than creatinine, though measurement has not widely entered clinical practice.

Daily production of creatinine (principally from muscle cells) is fairly constant and little affected by protein intake. Serum creatinine and excreted (urinary) creatinine vary little throughout the day, allowing measurement of ***creatinine clearance***. Urine is collected over 24 hours for measurement of total urinary creatinine, paired with a single plasma creatinine measured during the 24-hour period. Creatinine clearance is calculated as $U \times VP$, where U = urine concentration of creatinine, V = rate of urine flow in mL/min, and P = plasma concentration of creatinine. Normal ranges are 90 to 140 mL/min in males and 80 to 125 mL/min in females.

Alternatives for quantifying true GFR include measuring iohexol or inulin clearance, or radio-isotope (^{51}Cr-EDTA) GFR. Neither is practical for clinical practice.

Estimated GFR (eGFR)

Measurement of GFR is cumbersome, time-consuming, and may be inaccurate if 24-hour urine collections are incomplete. Several formulae estimate GFR from serum creatinine and patient characteristics, often derived from large trials. Variables include age, weight, and sex. For patients with chronic kidney disease, the convenience and ease of eGFR monitoring led to its widespread adoption. Commonly used equations have their shortcomings and are less accurate the closer GFR is to normal. CKD-EPI is most reliable for predicting eGFR above 60 mL/min/1.73 m^2. Race adjustment of equations has been abandoned due to overestimation compared to measured GFR and the systemic disadvantage of patients of black ethnicity. A new equation using cystatin C (eGFRcys) does not include adjustment for race. Race-free eGFR equations represent an important step forwards, and validation across the full range of kidney disease, body mass index (BMI), and ethnicities continues.

Drugs, toxins, proteins, and the kidney

A substantial fraction of prescription drugs is handled and eliminated by the kidney. Many medications (e.g., penicillins, cephalosporins, diuretics, NSAIDs, antivirals) circulate in the plasma as small organic anions, and are eliminated in the proximal tubule by a specific organic anion transporter (OAT) system. The kidney is also a major site for the catabolism (and therefore elimination) of many small-molecular-weight proteins and polypeptides, including hormones such as insulin, parathyroid hormone (PTH), and calcitonin, by endocytosis carried out by the megalin–cubilin complex in the brush border of proximal tubular cells. In CKD, clearance is reduced and half-life is prolonged. This accounts, for example, for the reduced insulin requirements of patients with diabetes as kidney function declines.

Endocrine function

Renin–angiotensin system

Pro-renin, synthesized by specialized arteriolar smooth muscle cells in the JGA, is cleaved into the active proteolytic enzyme, renin. Active renin is stored in the JGA and released in response to a falling intravascular volume, pressure, or increased fluid losses via the kidney. These are 'sensed' as:

- pressure changes in the afferent arteriole or changes in sympathetic tone
- chloride and osmotic concentration in the distal tubule via the macula densa
