Clinical Medicine

Eleventh Edition

Edited by

David Randall, PhD, MRCP

Honorary Clinical Senior Lecturer, Barts and the London School of Medicine and Dentistry, QMUL;
Consultant Physician and Nephrologist, Barts Health NHS Trust, London, United Kingdom

John Booth, PhD, MRCP

Honorary Clinical Senior Lecturer, Barts and the London School of Medicine and Dentistry, QMUL;
Consultant Physician and Nephrologist, Barts Health NHS Trust, London, United Kingdom

Kate Wiles, PhD, MRCP

Honorary Senior Lecturer, Wolfson Institute of Population Health, Queen Mary University of London;
Consultant Obstetric Physician, Department of Women's Health, Barts Health NHS Trust, London, United Kingdom

Foreword by

Professor Dame Parveen J. Kumar, DBE, BSc, MD, DM(hc), DEd, DSc, FRCP, FRCPG, FRCPI, FRCPath

Emerita Professor of Medicine and Education, Barts and The London School of Medicine and Dentistry, Queen Mary University of London
Honorary Consultant Physician and Gastroenterologist, Barts Health NHS Trust and Homerton University Hospital NHS Foundation Trust, London, United Kingdom

Michael L. Clark, MD, FRCP

Honorary Senior Lecturer, Barts and The London School of Medicine and Dentistry, QMUL, and Princess Grace Hospital, London, United Kingdom

Foreword to the Eleventh Edition

Much has happened in the years since the last edition, not least the rapid spread of disease leading to the pandemic which stopped the world. We were all reminded that the world is intricately linked and that diseases can spread with great rapidity. Medicine is now viewed on a global landscape with the emergence of new diseases, and re-emergence of others. We live in a world with a changing and unpredictable climate, influencing the mass movement of populations due to, and leading to, difficult socioeconomic factors. This has led to a change in epidemiology and presentation of some diseases.

This book has always been written for students and doctors from around the world and each edition has kept up with the changes in diseases and technology. When the first edition of this book appeared on the market, it was said to have 'changed the face of medical publishing' by its clear format, accessibility, and the succinct way in which evidence-based facts were presented. The old turgid presentations with long unstructured prose were substituted by diagrams, algorithms, and tables to explain the scientific concepts and clinical aspects of diseases. Colour was introduced to help the reader find medicine fun and easy to learn. Subsequent editions of *Kumar & Clark's Clinical Medicine* have followed this basic structure but with added innovative ways of presentation, particularly in the online books. As new curricula evolve, new chapters have been added to keep up with the way that medicine is being taught.

This 11th edition is no exception. It has had to keep up with the extremely rapid pace of recent changes, some triggered by the pandemic, and others due to new discoveries in medicine. These include advances in technology, artificial intelligence, imaging for diagnostics, genomics, and personalised medicine. Modern physicians now have the difficult task of adapting their diagnostic skills and clinical acumen with the use of continually changing modern technology. They need to be compassionate, empathic, and adaptable, to face a new world of machines. With the advance of mechanical diagnostic aids, robots, and exciting new therapies, the role of the doctor often becomes blurred, making it ever important to keep the patient central.

In this edition, all the chapters have been carefully updated by the authors. David Randall has continued as editor, and John Booth and Kate Wiles have come on board as new editors. New authors have also been appointed with chapters added to follow the trends of modern medicine.

The multidisciplinary care of the patient is now the norm. This book continues to be used by pharmacists, nurses, and other allied professionals. We hope that they will find this useful for their respective roles as this book provides comprehensive knowledge for the practise of medicine.

We wish all our readers the very best in their chosen careers and hope they find medicine as exciting and enjoyable as we have. It has been an immense privilege to be a doctor.

Parveen J. Kumar and Michael L. Clark

Dr. Michael L. Clark and Professor Dame Parveen J. Kumar on the occasion of the publication of the first edition of *Clinical Medicine* in 1987.

This page intentionally left blank

Preface to the Eleventh Edition

First published in 1987, *Kumar & Clark's Clinical Medicine* has established itself as a core textbook for medical students, doctors in training, and allied health professionals worldwide. Born out of Professor Dame Parveen Kumar and Dr. Michael Clark's desire to transmit their passion for high-quality and evidence-based practice of medicine in an engaging and accessible format to the next generation of doctors, the editorial team for the eleventh edition of *Clinical Medicine* have worked hard to remain true to these fundamental aims. As ever, we are grateful for the extensive feedback and suggestions received on a regular basis, enabling us to revise and reshape the book with sensitivity to its most important stakeholder: yourself, the reader.

The practice of medicine continues to evolve at a staggering pace. Many hospitals are now 'paper free', with electronic records and real-time data transfer ushering in a new era of remote and 'virtual' consultation. Advances in clinical genomics are bringing next-generation genetic testing and gene therapies to the clinic, together with new ethical and moral responsibilities. Artificial intelligence and machine learning are no longer just the subject of science fiction but are already providing opportunities to collate, analyze, and interpret clinical data at a speed and scale previously considered unimaginable. Despite these breath-taking advances, the essence of being a doctor remains unchanged: to evaluate, diagnose, and treat each individual patient within their own unique clinical, social, and emotional context, to do so with empathy and compassion, and to navigate them through an increasingly complex and many-layered 21st-century healthcare system.

With this in mind, we have reshaped the book to resemble, as near as possible, a 'blueprint' for medical practice in the modern world. We have restructured the book into five sections, corresponding to core themes of medical knowledge and patient care, and introduced a number of new chapters to better reflect the structure of the contemporary hospital, and the knowledge and skills required by those working within it:

The practice of medicine: Drawing together the rudiments of medical practice—the 'Clinical Method' of information gathering and diagnosis, legal and ethical aspects of medicine, principles of evidence-based medicine, and relevant basic science applied to hands-on patient care. 'Evidence-based practice' (Chapter 4) includes an extensive new section on 'Medical statistics' to equip readers with the skills to analyze and appraise the medical literature. 'Radiology' (Chapter 8) is a new addition, covering the full spectrum of diagnostic imaging and interventional modalities.

Medicine and the world: 'Zooming out' to examine the determinants of health at the population level including chapters on 'Public health' (Chapter 9) and 'Global and planetary health' (Chapter 10).

Acute and emergency medicine: Pulling together key knowledge required for 'first contact' with patients in emergency and acute medical settings and management of the unwell or critically ill patient. 'Acute medicine' (Chapter 11) includes a 'ground up' approach to assessing patients presenting with 25 of the most common medical symptoms, concise pictorial guides to medical procedures and overviews of management of a broad range of medical emergencies. 'Anaesthesia and perioperative medicine' (Chapter 14) covers the contemporary approach to pre-, peri-, and postoperative management of the surgical patient. 'Environmental medicine' (Chapter 16) explores the interface between human health and extremes of the natural world.

Medical specialties: Covering the full spectrum of organ and system-based hospital specialty medicine. New standalone chapters include 'Stroke medicine' (Chapter 29), 'General hospital psychiatry' (Chapter 30), 'Obesity' (Chapter 37), and 'Human immunodeficiency virus' (Chapter 44), reflecting the growth and importance of these areas and better mapping to modern hospital teams and clinics.

Medicine throughout life: Focusing on the principles and practice of medicine contextualized to age, sex and gender. New chapters on 'Young adult medicine' (Chapter 46) and 'Sex and gender in medicine' including transgender health (Chapter 47) have been added to revised and updated chapters on 'Obstetric medicine' (Chapter 48), 'Medicine of the older adult' (Chapter 49), and 'Palliative care and symptom control' (Chapter 50).

Each chapter is formatted to include 'clinical skills' content at the beginning, providing a practical 'toolkit' for the reader, summaries of specialty-specific patient assessments, and a pictorial overview of key clinical examination findings. Online, readers will find additional resources, including self-assessment questions, clinical skills videos, and a table listing the location of conditions relevant to the Medical Licensing Assessment (MLA).

We hope you will find this edition helpful in your efforts to learn and practise medicine. Any suggestions you may wish to make are warmly welcomed and will help us to ensure that this book continues to meet the needs of its readers.

David Randall, John Booth, and Kate Wiles
2025

HOW TO USE THIS BOOK

The book is organized into five major sections (see 'Preface to the Eleventh Edition', previous page). Chapters focused on individual medical subspecialties begin by offering a tailored approach to basic clinical skills such as history-taking and examination. We have tried to encourage generic skills to be applied thoughtfully to the specialty in question: to encourage learners to adopt the approach taken by experts in the field, so that relevant questions are asked and key physical signs are carefully sought. Most chapters then cover basic sciences, including the anatomy and physiology of the relevant organs in question, before dealing with individual conditions in order. Within the text:

- **Pink subheadings** introduce individual conditions,
- **Green subheadings** introduce the scientific background to the condition (e.g., 'Aetiology' or 'Clinical features'), and
- **Orange subheadings** introduce clinical material, such as 'Investigations' or 'Management'.

Boxes have been classified by the type of information they provide and have the following symbols:

Emergency management

Clinical information

Differential diagnosis

Practical procedures

'Emergency' boxes are in red.

In the Index Medical Licensing Assessment (MLA) conditions have been highlighted in colour to make them easier to find. An MLA conditions contents table can also be found in the e-book.

E-Book extras

A selection of examination videos and assessment content are available online, accessible via the PIN page in the front of this book.

Prescribing

We have used the Recommended International Non-proprietary Names (rINNs) for all drugs. In some diseases where a particular formulation of a drug is required, the proprietary name is used. Drugs spellings follow international usage, e.g., bendroflumethiazide and not bendrofluazide, and amfetamine and not amphetamine. For adrenaline and noradrenaline, we have added epinephrine and norepinephrine in brackets, as these names are often used in emergency guidelines across the world.

Dosages have been given where appropriate, but we recommend that all readers check with their national formularies for the exact dosages.

Units of measurement

We have used the International System of Units (SI units) throughout the book. On occasion, if there is a possibility for confusion, we have also used non-SI units and given a conversion factor.

Also in the Kumar & Clark family of books:

- *Essentials of Kumar & Clark's Clinical Medicine,* 7e
- *Kumar & Clark's Cases in Clinical Medicine,* 5e
- *Clinical Surgery,* 4e

List of Contributors

The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

Wiaam Al-Hasani MBChB, MRCS, MSc
Specialist Registrar, Chemical Pathology, Guy's and St Thomas' Hospital, London, United Kingdom
Lipid and metabolic disorders

Jane Anderson BSc, MBBS, PhD, FRCP

Sepsis and the treatment of bacterial infection
Critical care medicine

Miles J. Levy MD, FRCP, MSc
Professor, Endocrinology, University Hospitals of Leicester, Leicester, United Kingdom
Endocrinology

Peter K. MacCallum MD, FRCP, FRCPath
Professor, Wolfson Institute of Population Health, Queen Mary University of London; Consultant, Haematology, Barts Health NHS Trust, London, United Kingdom
Venous thromboembolic disease

Ritwika Mallik MBBS, DNB, MRCP (London), SCOPE Certified
Clinical Research Fellow, Centre for Obesity Research, University College London, London, United Kingdom
Obesity

Peter Martin PhD, GradStat
Associate Professor, Department of Primary Care and Population Health, University College London, London, United Kingdom
Evidence-based practice

Beenish Masood MBBS, FCPS, MRCP, MSc
Clinical Teaching Fellow, Diabetes & Endocrinology, Royal Free NHS Foundation Trust; Clinical Research Fellow Diabetes and Metabolism, Diabetes, Barts Health NHS Trust, London, United Kingdom; Locum Specialty Registrar, Endocrinology, Mid and South Essex NHS Foundation Trust, Basildon, United Kingdom
Obesity

Kieran McCafferty MB BChir, MRCP, MD(Res)
Consultant Nephrologist, Barts Health NHS Trust; Honorary Senior Lecturer, Translational Medicine and Therapeutics, Queen Mary University London, London, United Kingdom
Water balance, fluids, and electrolytes

Shameer J. Mehta MBBS, BSc, MRCP, AFHEA, MD(Res)
Consultant Gastroenterologist, Department of Gastroenterology, Barts Health NHS Trust; Honorary Senior Lecturer, Centre for Immunobiology, Queen Mary University of London, London, United Kingdom
Nutrition

Mark Melzer FRCP, FRCPath
Consultant, Infection, Barts Health, London, United Kingdom
Sepsis and the treatment of bacterial infection

Catherine Moffat BSc(Hons) Physiotherapy
Specialist Physiotherapist, Palliative Care, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom
Palliative care and symptom control

Nicholas Robert Murch MB BCh, FRCP
Consultant Physician, Acute Medicine, Royal Free Hospital; Consultant Physician, Acute Admissions Unit, Cleveland Clinic London; Honorary Clinical Associate President, University College London Medical School, London, United Kingdom
Acute medicine

Michael F. Murphy MD, FRCP, FRCPath, FFPath
Consultant Haematologist, NHS Blood & Transplant; Consultant Haematologist, Department of Haematology, Oxford University Hospitals NHS Foundation Trust; Professor of Transfusion Medicine, Nuffield Department of Clinical and Laboratory Sciences, University of Oxford, Oxford, United Kingdom
Haematology

Arvind Nagra MBChB, MRCPCH (UK)
Consultant Paediatric Nephrologist, Paediatric Nephro-Urology Department, Southampton Children's Hospital, Southampton, United Kingdom
Young adult medicine

Melanie Nana MD, MRCP
Clinical Research Fellow, Department of Obstetric Medicine, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom
Obstetric medicine

Catherine Nelson-Piercy MD, FRCP, FRCOG
Professor, Department of Obstetric Medicine, Guy's and St Thomas' Foundation Trust; Consultant Obstetric Physician, Women's Health, Guy's and St Thomas' Foundation Trust, London, United Kingdom
Obstetric medicine

Lorraine M. Noble PhD, MPhil, Dip Clin Psychol, C Psychol, FBPsS, PFHEA
Professor, UCL Medical School, University College London, London, United Kingdom
Clinical communication

Alastair O'Brien MBBS, BSc, PhD
Professor, Institute of Liver Disease and Digestive Health, University College London, London, United Kingdom
Hepatology

Margaret O'Connor FRCPI, FRCP (UK)
Adjunct Associate Clinical Professor, Department of Ageing & Therapeutics, University of Limerick Hospital Group; Intern Network Programme Director, MidWest Intern Network, University of Limerick, Limerick, Ireland; BIASP Executive Lead for Ireland, British & Irish Association of Stroke Physicians, Ireland
Stroke medicine

Peter M. Odor BM BCh, PhD, MA, MSc, FRCA
Consultant, Department of Anaesthesia and Perioperative Medicine, University College London Hospital; Honorary Associate Professor, University College London, London, United Kingdom
Anaesthesia and perioperative medicine

Patrick O'Dwyer MCH, FRCSI, FRCS(Glas)
Emeritus Professor, School of Medicine, Dentistry and Medicine, University of Glasgow, Glasgow, United Kingdom
Radiology

Barbara Lachana Onen MBChB, MSc, MRCP, DTM&H
Acute & General Internal Medicine Consultant, Department of Acute Medicine, Royal London Hospital, Barts Health NHS Trust, London, United Kingdom
Acute medicine

Chloe M. Orkin MBBCh, MSc Infections Disease, LSHTM, FRCP
Professor of Infection and Inequities, SHARE Research Collaborative for Health Equity, Department of Immunobiology, Blizard Institute, Faculty of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom
Human immunodeficiency virus

K. John Pasi MBE, MBChB, PhD, FRCP, FRCPath, FRCPCH, FMedSci
Honorary Professor of Haemostasis and Thrombosis, Blizard Institute, Barts and the London School of Medicine and Dentistry, London, United Kingdom
Haematology
Venous thromboembolic disease

Hitesh C. Patel MBBS, PhD, MRCP, FRACP, CCDS
Deputy Director of Cardiology, Head Heart Failure and Cardiac Transplant, Cardiology, Alfred Hospital; Associate Professor, Monash University, Melbourne, Victoria, Australia
Cardiology

Piers Nicholas Plowman MA, MD, FRCR, FRCP
Consultant Oncologist, Department of Clinical Oncology, St Bartholomew's Hospital, London, United Kingdom
Malignant disease

Andrew A. Plumb BM, BCh, MRCP, PhD, FRCR (2010)
Consultant Radiologist, Department of Imaging, University College London Hospitals NHS Foundation Trust, London, United Kingdom
Radiology

Sotirios Posporelis MD, MRCPsych
Consultant Liaison Neuropsychiatrist, Psychological Medicine at King's College Hospital, South London and Maudsley NHS Foundation Trust; Honorary Senior Clinical Lecturer, Neuropsychiatry, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom
General hospital psychiatry

Joanna Preston MBBS, MRCP(Geris), MSc
Consultant Geriatrician, Senior Health, St George's NHS University Hospitals Foundation Trust, London, United Kingdom
Medicine of the older adult

Mark Pucci MBChB, MRCP
Consultant, Department of Clinical Toxicology, Sandwell and West Birmingham NHS Trust, Birmingham, United Kingdom
Toxicology

Mohammed Abbas Anisur Rahman PhD, FRCP
Professor of Rheumatology, Division of Medicine, University College London, Watford, United Kingdom
Rheumatology

Rosalind Ann Raine BSc, MBBS, MSc, PhD, FFPH, FMedSci
Professor, Department of Primary Care and Population Health, UCL, London, United Kingdom
Evidence-based practice

Neil Rajan MBBS, PhD
Professor, Translational and Clinical Research Institute, Newcastle University; Honorary Consultant Dermatologist, Department of Dermatology, Royal Victoria Infirmary, Newcastle upon Tyne, United Kingdom
Human genetics

Radha Ramachandran MBBS, FRCP, MSc, FRCPath, PhD
Consultant, Adult Inherited Metabolic Diseases, Guy's and St Thomas' Hospitals NHS Foundation Trust; Consultant, Chemical Pathology and Metabolic Medicine, Guy's and St Thomas' Hospitals NHS Foundation Trust; Honorary Clinical Senior Lecturer, School of Life Course and Population Sciences, King's College London, London, United Kingdom
Metabolic disease

David Randall PhD, MRCP
Honorary Clinical Senior Lecturer, Barts and the London School of Medicine and Dentistry, QMUL; Consultant Physician and Nephrologist, Barts Health NHS Trust, London, United Kingdom
The art of being a doctor

Robin Ray MB BS, MA(Oxon), FRCP, FHFA, PhD
Cardiology Consultant and Honorary Senior Lecturer, Cardiology Department, St George's University Hospitals NHS Foundation; Honorary Senior Lecturer, Molecular and Clinical Sciences Research Institute, St George's University, London, United Kingdom
Cardiology

Narendra L. Reddy MD, FRCP, CCT (Oxf)
Consultant Endocrinologist, Diabetes & Endocrinology, University Hospitals of Leicester; Honorary Senior Lecturer, University of Leicester, Leicester, United Kingdom
Endocrinology

Elliott Ridgeon BA, BMBCh, MSc, FRCA
Consultant, Department of Anaesthesia and Perioperative Medicine, Wexham Park Hospital, Slough, United Kingdom; Honorary Tutor in Physiology and Pharmacology, Magdalen College, University of Oxford, Oxford, United Kingdom
Anaesthesia and perioperative medicine

Noemi Roy MBChB, DPhil
Honorary Senior Clinical Lecturer, Weatherall Institute of Molecular Medicine, University of Oxford; Consultant Haematologist, Department of Haematology, Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom
Haematology

Hamoun Rozati MBBS, PGCert(HE), MSc, MD(Res), MRCP(UK), FRCR
Consultant Clinical Oncologist, Oncology, Barts Cancer Centre, London, United Kingdom
Malignant disease

Prina Ruparelia MBChB, MD, FRCP
Respiratory Consultant, Department of Respiratory Medicine, St Bartholomew's Hospital, London, United Kingdom
Respiratory medicine

Richella Ryan MB BCh, BAO, PhD, MRCPI
Consultant, Palliative Medicine, Arthur Rank Hospice Charity, Cambridge, United Kingdom
Palliative care and symptom control

Anshoo Sahota BSc, MBBS, FRCP
Consultant Dermatologist, Department of Dermatology, Barts Health NHS Trust, London, United Kingdom
Dermatology

Emily Scott BMBS, MRCP, FRCR
Specialty Doctor, Department of Oncology, Mount Vernon Cancer Centre, London, United Kingdom
Malignant disease

Leighton John Seal BSc, MBBS, PhD
Professor and Consultant in Endocrinology, Adult Gender Identity Clinic, Tavistock and Portman NHS Foundation Trust; Professor and Consultant in Diabetes and Endocrinology, Thomas Addison Unit, St George's University Hospitals NHS Foundation Trust; Professor, Institute of Biomedical Education, St George's Hospital Medical School University of London, London, United Kingdom
Sex and gender in medicine

Babulal Sethia FRCS, FRCP (Hon)
Past President, Royal Society of Medicine; Royal Society of Medicine, London, United Kingdom
Global and planetary health

Kay Seymour MB BChir, MA (Cantab), DOHNS, FRCS (ORL-HNS)
Consultant ENT Surgeon, Department of ENT, Royal London Hospital, Barts Health NHS Trust, London, United Kingdom
Ear, nose, and throat

Apeksha M. Shah MA (Cantab), FRCP
Consultant Neurologist, Neurology Department, Barts Health NHS Trust; Honorary Research Fellow, Centre for Preventive Neurology, Wolfson Institute of Population Health, Queen Mary University of London, London, United Kingdom
Neurology

Jonathan Shamash MBChB, MD, FRCP
Consultant, Department of Medical Oncology, St Bartholomew's Hospital, London, United Kingdom
Malignant disease

Stephen J. Shepherd MBBS, FRCP, FRCA, FFICM, EDIC, FEACVI
Consultant in Anaesthesia & Intensive Care Medicine, Department of Perioperative Medicine, St Bartholomew's Hospital; Consultant in Anaesthesia, Department of Perioperative Medicine, Royal London Hospital; Consultant in Transfer Medicine, Adult Critical Care Transfer Service, London, United Kingdom
Critical care medicine

Sridevi Siramahalingappa MBBS, FRCPsych, FRANZCP
Consultant Psychiatrist, Psychiatry, South London and Maudsley NHS Foundation Trust, London, United Kingdom
General hospital psychiatry

Suthesh Sivapalaratnam MD, PhD, FRCP, FRCPath
Clinical Senior Lecturer, PHURI, QMUL; Honorary Consultant, Clinical Haematology, Royal London Hospital, London, United Kingdom
Venous thromboembolic disease

Charlotte I. Skinner BM BCh, MD (Res)
Specialty Doctor, Department of Gastroenterology, Imperial Healthcare NHS Trust, London, United Kingdom
Gastroenterology

Sophie Michelle Strong MRCOG, MBBS, BSc(Hons)
Consultant Gynaecologist, Department of Women's Health, Barts Health NHS Trust; Obstetrics & Gynaecology, Women's Health, London, United Kingdom
Sex and gender in medicine

Ganesh Subramanian MBBS, FRCP, MEd (Med Ed), MRes (Med)
Consultant in Stroke Medicine, Department of Stroke Medicine, Nottingham University Hospitals NHS Trust, Newark, United Kingdom; Clinical Associate Professor, University of Nottingham, Nottingham, United Kingdom
Stroke medicine

Rebecca Swan MBChB, BSc (MedSci)
Specialty Doctor, Western General Hospital, Edinburgh, United Kingdom
Sex and gender in medicine

James Emmanuel Thaventhiran BSc, MBBS, PhD
MRC Investigator, MRC Toxicology Unit, University of Cambridge; Honorary Consultant Clinical Immunologist, Clinical Immunology, Cambridge University Hospitals, Cambridge, United Kingdom
Immunity

Yincent Tse MBChB, FRCPCH
Consultant Paediatric Nephrologist, Department of Paediatric Nephrology, Great North Children's Hospital; Honorary Senior Clinical Lecturer, Newcastle University, Newcastle upon Tyne, United Kingdom
Young adult medicine

Christopher Antony Wadsworth MBBS, PhD, FRCP
Clinical Director, Specialist Medicine, Department of Gastroenterology, Imperial College Healthcare NHS Trust, London, United Kingdom
Biliary tract and pancreatic disease

David W. Wareham MB BS, MSc, PhD, MRCP, FRCPath
Consultant Microbiologist, School of Medicine and Dentistry, Queen Mary University London, London, United Kingdom
Sepsis and the treatment of bacterial infection

Elinor Warner MBBS, MA(Oxon), FRCS (ENT)
Specialty Doctor, Department of ENT, University College London Hospitals, London, United Kingdom
Ear, nose, and throat

Veronica White BSc, MBBS, MSc, MD, FRCP
Respiratory Consultant, Department of Respiratory Medicine, Barts Health NHS Trust, London, United Kingdom
Respiratory medicine

Anthony S. Wierzbicki DM, DPhil, FRCPath
Consultant, Department of Metabolic Medicine, Guy's and St Thomas' Hospitals; Professor, Cardiometabolic Disease, King's College London, London, United Kingdom
Lipid and metabolic disorders

Kate Wiles PhD, MRCP
Honorary Senior Lecturer, Wolfson Institute of Population Health, Queen Mary University of London; Consultant Obstetric Physician, Department of Women's Health, Barts Health NHS Trust, London, United Kingdom
The art of being a doctor

Iain Stewart Ayrton Wilkinson MBBS, FRCP
Consultant Geriatrician, Medicine for the Elderly, Surrey and Sussex Healthcare NHS Trust, Redhill, United Kingdom; Honorary Senior Lecturer, Brighton and Sussex Medical School, Brighton, United Kingdom
Medicine of the older adult

Janet D. Wilson MBChB, FRCP
Consultant in Genitourinary Medicine and HIV, Genitourinary Medicine and HIV, Leeds Teaching Hospitals Trust, Leeds, United Kingdom
Sexually transmitted infections

Sarah Elizabeth Winchester MB BChir, MSc, MA (Cantab), FFPH
Consultant in Public Health Medicine, Public Health Team, Buckinghamshire Council, Aylesbury, United Kingdom
Public health

M. Magdi Yaqoob MD, FRCP
Professor, Renal Medicine and Transplantation, Barts Health NHS Trust and Queen Mary University of London, London, United Kingdom
Kidney and urinary tract disease
Water balance, fluids, and electrolytes

Anjali Zalin MBBS, BMedSci, FRCP, SCE (Diabetes and Endocrinology), PhD
Consultant Physician, Obesity Medicine/ Tier 3, Barts Health NHS Trust/ Bedfordshire Hospitals NHS Foundation Trust, London/Bedfordshire, United Kingdom
Obesity

Dominik Zenner MA, MSc, FHEA, MD, MRCGP, FFPH
Clinical Reader in Infectious Disease Epidemiology, Wolfson Institute of Population Health, Queen Mary University, London, United Kingdom
Global and planetary health

Parjam Zolfaghari MBBS, PhD, FRCA, FFICM, SFHEA
Consultant, Adult Critical Care Unit, The Royal London Hospital, Barts Health NHS Trust; Senior Lecturer, William Harvey Research Institute, Queen Mary University London, London, United Kingdom
Critical care medicine

International Advisory Board

The editors would like to acknowledge and thank all previous edition members of our International Advisory Board for their contributions.

AUSTRALIA

Clinical Associate Professor Peter Katelaris MB BS, MD (Lond), FRACP, FRCP (Lond), FGESA, AGAF
Director, Gastroenterology Department, Concord Hospital, University of Sydney, Sydney

BANGLADESH

Dr. A.B.M. Abdullah
Emeritus Professor, Bangabandhu Sheikh Mujib Medical University, Dhaka

CANADA

Dr. Bradley Little BSc, MD, CCFP
Family Physician, Spectrum Health; Clinical Instructor, University of British Columbia—Department of Family Practice; Medical Staff, Providence Health Care—Department of Family Practice, Vancouver, British Columbia

INDIA

Professor Richa Dewan
Ex Director, Professor, and Head, Department of Medicine, Maulana Azad Medical College, New Delhi

MALAYSIA

Dr. Anita Devi Krishnan Thantry
Manipal University College Malaysia (MUCM), Jalan Batu Hampar, Bukit Baru, Melaka

PAKISTAN

Prof. Dr. M. Akbar Chaudhry
Dean, Faculty of Medical Sciences, Azra Naheed Medical College, Superior University Lahore-Pakistan, Department of Medicine, Azra Naheed Medical College, Lahore

Dr. Nazish Imran
Professor of Child & Adolescent Psychiatry, King Edward Medical University, Lahore

Dr. Somia Iqtadar
Associate Professor Medicine, King Edward Medical University, Lahore; Secretary General, Pakistan Society of Internal Medicine and Dengue Expert Advisory Group, Punjab

SRI LANKA

Professor Christeine Ariaranee Gnanathasan
Senior Professor in Medicine and Consultant Physician, University of Colombo, Colombo

Professor Senaka Rajapakse
Senior Professor & Chair of Medicine Director, Postgraduate Institute of Medicine University of Colombo, Colombo

Professor Udaya K. Ranawaka
Department of Medicine, University of Kelaniya, Ragama

UNITED STATES OF AMERICA

Dr. Ahmed Abd Almalik Daak
Clinical Development-Immunohematology, Sanofi, Cambridge, Massachusetts

Acknowledgments for the Eleventh Edition

The editors would like to thank Parveen Kumar and Mike Clark for their innovation, inspiration, and longstanding commitment to medical education over nine previous editions of *Clinical Medicine*. We remain grateful to them for their ongoing guidance and wisdom. As training doctors, we were educated by them, and it is now our privilege to be able to contribute to the education of others. It is upon their shoulders that we stand.

This book would not exist without the chapter authors who have worked hard to ensure that the content is up to date and reflective of modern practice. We are very grateful to them for their efforts and expertise.

As well as welcoming new contributors to this edition, we would like to thank those who have stepped down, especially those who have had a long association with the book. The text of this edition continues to reflect the contributions made by them:

- Ajit Abraham (Surgery)
- Annie Cushing (Ethical practice and clinical communication)
- Damiete Harry (Male health)
- Deborah Bowman (Ethical practice and clinical communication)
- Edward Mullins (Female health)
- Francis Chinegwundoh (Male health)
- Francis Vaz (Ear, nose, and throat)
- Gavin Barlow (Infectious diseases)
- Helen Barratt (Public health)
- Jonathan Sive (Haematological oncology)
- Julius Bourke (Liaison psychiatry)
- Klaartje Bel Kok (Nutrition)
- Lesley Regan (Female health)
- Marinos Elia (Nutrition)
- Mark Peakman (Immunity)
- Michael Clark (Environmental medicine)
- Munir Pirmohamed (Prescribing, therapeutics, and toxicology)
- Nicholas Bunce (Cardiology)
- Nishchay Mehta (Ear, nose, and throat)
- Paul Jarman (Neurology)
- Peter Moss (Infectious diseases)
- Rachel Lewis (Oncology)
- Sara Booth (Palliative medicine)
- Sarah Wakelin (Dermatology)
- Silvie Cooper (Public health)
- Susan Lanham-New (Nutrition)
- Umesh Vivekananada (Neurology)

We would like to acknowledge the editorial contribution of Adam Feather and Mona Waterhouse to the 10th edition of *Kumar & Clark's Clinical Medicine*. Thank you for moving the book forward whilst keeping it relevant for modern medical practice. We wish you well in your new endeavours.

The team at Elsevier have worked extremely hard to bring this project to fruition. We are particularly grateful to Alex Mortimer, Susan Callahan, and Daniel Fitzgerald.

Finally, to our families including Abigail, Robbie, Thomas, Emily, Hayden, Nick, George, Fred, Meg, Ophelia, Amy, Oliver, and Timothy. This edition would not have been possible without your support. Thank you for allowing Kumar and Clark to live alongside you for a while.

Rapid MLA Conditions Contents Table

Conditions	Chapter	Page Number
Acid-base abnormality	13: Critical care medicine	307–308, 308b
Acne vulgaris	45: Dermatology	1570f
Acoustic neuroma	28: Neurology	946
Acute bronchitis	20: Respiratory medicine	545
Acute cholangitis	24: Biliary tract and pancreatic disease	741
Acute coronary syndromes	17: Cardiology	444–452
Acute glaucoma	31: Ophthalmology	1047b
Acute kidney injury	13: Critical care medicine	327–328, 228b, 228–231, 835–837
Acute pancreatitis	24: Biliary tract and pancreatic disease	749
Acute stress reaction	30: General hospital psychiatry	1023
Addison's disease	34: Endocrinology	1156, 1605
Adverse drug effects	7: Therapeutics and prescribing	114–115, 115b
Alcoholic hepatitis	23: Hepatology	724
Allergic disorder	6: Immunity	101b
Anaemia	38: Haematology	1277–1279
Anal fissure	22: Gastroenterology	667–668

CORE SKILLS AND KNOWLEDGE

Being a doctor is a privilege. Patients open their lives to us, sharing troubles and triumphs; for this they should be met with kindness, judgement, and skill. It is the interactions with others that make medicine the most humane of sciences and the most scientific of humanities.

In the 21st century, professional roles and responsibilities are changing and defining what it means to be a doctor can be challenging. Healthcare is often provided by teams of people from different professional backgrounds, with the potential to leave individual doctors unsure of their role and patients without a constant name and face to guide them: a state of dis-'ease' for both.

Artificial intelligence, which utilizes vast datasets to produce algorithms for diagnosis and management, challenges the traditional role of a doctor. However, human beings have not yet been replaced and remain key within a diagnostic and treatment partnership. The definition of a clinical problem and selection of the best treatment require more than assimilation of information, technical skills, data interpretation, and a standardized framework for decision-making; they require compassion, empathy, trust, respect, and humour: attributes that are exclusively human, at least for now.

THE CLINICAL CONSULTATION

A clinical consultation is a complex process including at least two unique individuals, with potentially very different knowledge and expectations. In simplistic terms, the clinical consultation is an interaction that achieves a diagnosis. Diagnosis forms the linchpin of the therapeutic journey, shifting the direction of travel from experience in the past (medical history) to the future (treatment plans). However, in practice, a clinical consultation is multifaceted, and in addition to diagnosis, it is enriched by a transfer of knowledge between individuals and the development of a complex shared understanding. No textbook can give you a complete understanding of the experience of disease for the individual in front of you.

The complexity of the medical consultation depends upon whether priorities are aligned between clinician and patient and the difficulty of the medical problem (Fig. 1.1).

- When diagnosis and/or treatment options are clear and priorities are shared, the clinician and patient work in ***coordination***.
- Where diagnosis and treatment options are clear, but patient and clinician priorities do not align despite best efforts (e.g., a request for antibiotics to treat a viral illness), ***competition*** occurs until one set of priorities prevails.
- When diagnoses are evolving or unclear, or when treatment options have unknowable or unintended consequences, or when definitions of success vary, the consultation is one of ***negotiation*** and ***evolution***.

Such models offer a guide as to why some consultations are more difficult than others. Negotiation is harder than coordination, and uncertainty and change are difficult for patient and clinician alike. A consultation includes both a person and a disease, the first being uniquely complex, and the latter potentially complex. Recognition of differences, adaptation, and skill are needed.

2 The art of being a doctor

This chapter describes the information-gathering steps of the medical consultation according to separate phases: history-taking, investigation, and diagnosis. Fig. 1.2 shows how diagnosis is an iterative process: information is gathered, interpreted, and integrated to form a diagnosis, which is communicated and acted upon. A diagnosis may be refined when there is new information including the patient's response to treatment. This structure is traditional and convenient and means that key aspects of doctoring are not forgotten. However, clinicians should be wary of the limitations of such a structured interaction designed by doctors for doctors. Although, for the clinician, this structure is everyday discourse, the consultation 'map' is not visible to patients. Patients may only become aware of this structure when it has progressed without them: the moment or opportunity to provide important information has gone with the doctor's focus shifting to the next step in their process.

Signpost and share your consultation agenda with your patients and change it when it does not work for your patient. At the end of the consultation, both patient and doctor should feel that they gave a full and honest account of themselves. If you are not sure whether your patient feels this, ask them. A successful consultation is more than the traditional ritual surmised in textbooks such as this.

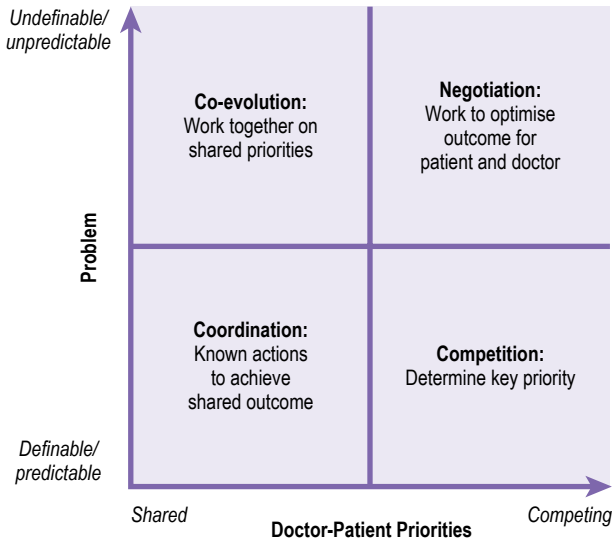

Fig. 1.1 The clinical consultation: variation according to doctor-patient priorities and the clinical problem.

THE INITIAL INTERACTION

Forming a rapport

First impressions matter. A clinical interaction that begins badly often leads to later problems. Patients need to be able to share intimate and worrying problems, which requires confidence and trust in clinicians. Though you may have consulted with many patients already that day, you may still have the privilege of being the first doctor that patient has met. Ask yourself, 'How would I wish my own doctor to behave?' Treat patients and their carers with respect. Ensure the physical environment supports interaction whilst also providing privacy, dignity, and comfort.

Introduce yourself (and any other health professionals present) and explain your role and the purpose of the encounter. A healthcare system can be busy and confusing, and it is important that patients understand where they are in their journey through it. The 'Hello, my name is…' campaign highlights the importance of introductions (Box 1.1). Appropriate expressions of empathy, support, and care can help establish rapport, allowing more successful subsequent discussion about the problem that led the patient to seek medical help. Non-medical discourse is the common language of both doctor and patient, often forgotten by those fluent in 'medicalese'. It may be safest to start first consultations with the assumption of no

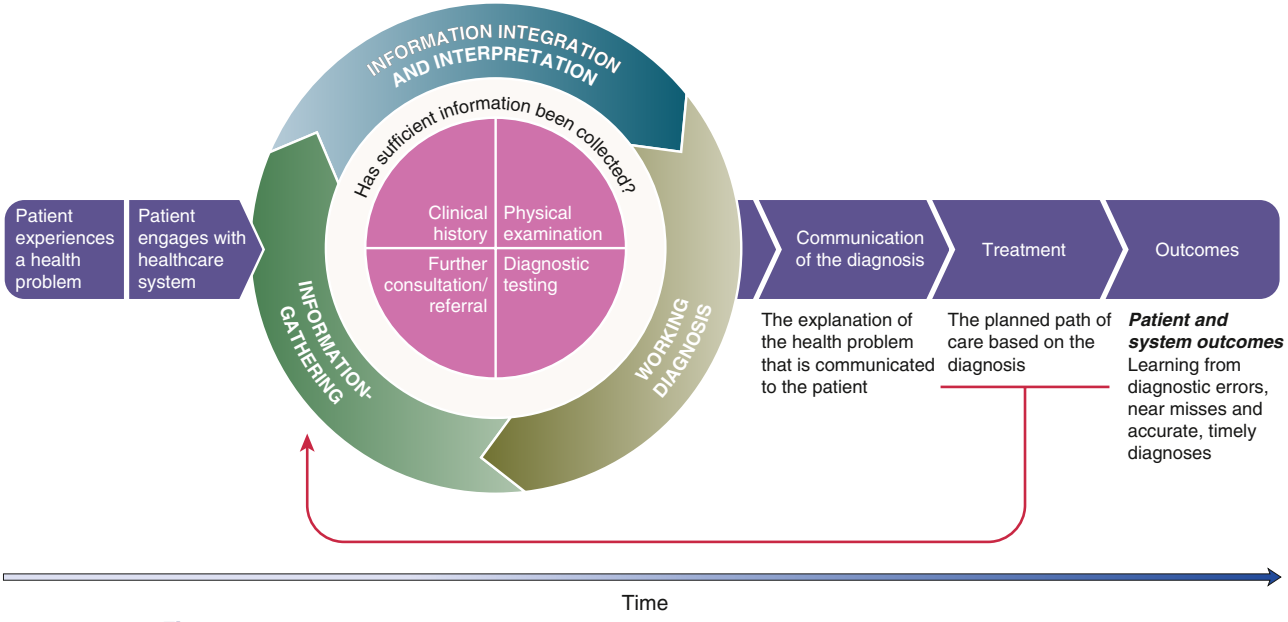

Fig. 1.2 A conceptualization of the diagnostic process. *(From National Academies of Sciences, Engineering, and Medicine.* Improving Diagnosis in Health Care. *Washington, DC: The National Academies Press; 2015. https://doi.org.10.17226/21794.)*

prior medical knowledge of disease (whilst remembering that the patient remains the expert on the impact of their disease on their life). The risk of impaired understanding contributing to dissatisfaction and poor engagement with care is far greater than the risk that lay descriptions of symptoms or disease processes will be considered offensive. Indeed, the expert patient may be very happy to help educate clinicians.

The worlds inhabited by doctors and patients have different cultures and different levels of power. The bridge between these worlds may be very wide, and you should be prepared to meet your patient beyond the middle to help them across.

Information-gathering

A full and detailed history from the patient is essential for accurate diagnosis. It is estimated that up to 80% of diagnoses can be made based on a careful history alone. In addition to information-gathering, eliciting the history forms a key part of the therapeutic relationship (**Box 1.2**). If it goes well, the patient feels listened to and has had an opportunity to convey their concerns. This builds mutual trust and respect.

The golden minute

At the start of the consultation the clinician should avoid interrupting the patient. An early interruption disrupts the patient's description of their symptoms and concerns, leaving the patient justifiably dissatisfied with the interaction and the doctor with less information about the presenting problem. The term '***the golden minute***' has been coined to encourage clinicians to allow patients to tell their story uninterrupted for at least 1 minute. This gives time for them to describe their symptoms as they have experienced them, including information that might be missed if the clinician jumps in too soon with closed, focused questions.

Allowing the patient freedom to relate their account of events also forms and reinforces the therapeutic relationship and increases both patient and clinician satisfaction. **Box 1.3** summarizes techniques that can be used to help patients share information.

A meeting of two experts

A medical consultation is a meeting of two experts: patient and doctor. A good consultation is based on mutual respect, rejecting a traditional paternalistic view of medicine that disempowers the patient ('doctor knows best'). The aim is shared understanding, where clinician and patient jointly grasp what is wrong, what impact it is having on the patient's life, what the patient expects from medical intervention, and which options might be best for investigating and treating the problem.

Box 1.1 The 'Hello, my name is…' campaign

In 2011, geriatrician Dr Kate Granger was diagnosed with metastatic sarcoma, from which she eventually died in 2016. Noticing that many of the healthcare staff treating her during her illness failed to introduce themselves, she created the 'Hello, my name is…' campaign. Describing why an initial introduction is so important, she said, 'I firmly believe it is not just about common courtesy, but it runs much deeper. Introductions are about making a human connection between one human being who is suffering and vulnerable, and another human being who wishes to help. They begin therapeutic relationships and can instantly build trust in difficult circumstances.'

The campaign encourages healthcare staff to greet and introduce themselves to patients and encourages the wearing of easy-to-read name badges like this one.

THE STRUCTURE OF HISTORY-TAKING

Over the last 150 years a formal structure for the recording of the patient's history has evolved. This has several subsections (**Box 1.4**). While facts may be recorded in this very stylized manner the patient will rarely, if ever, present them according to this structure. It is up to the interviewing clinician to assimilate and interpret information into a diagnostic narrative so that diagnostic reasoning and conclusions make sense.

The presenting symptom

What has prompted the patient to seek medical attention today? Although tempting to paraphrase a patient's presenting symptom using medical terms, it is preferable to record this in the patient's own words (e.g., 'vomiting blood' rather than 'haematemesis'). Care should be taken to understand exactly what the patient experienced. If a patient applies a medical term to their symptoms, it is important to ensure that term has the same meaning for both patient and clinician. For example, a patient reporting 'palpitations' may in fact be experiencing breathlessness or chest pain, and a patient with 'acute' symptoms may actually have severe symptoms that have been present for a long time.

Box 1.2 Good practice for using the medical history to build a therapeutic relationship

- Allow the patient to tell their story. Avoid jumping in prematurely with questions.
- Ask the patient specifically about their ideas, concerns, and expectations (ICE):
  - ***Ideas:*** What do they think might be going on? Have they done any reading about their symptoms? Do they know anyone who had similar symptoms?
  - ***Concerns:*** Are they feeling anxious or worried about their symptoms? What are they worried about? Are their symptoms causing any specific difficulties?
  - ***Expectations:*** What are they hoping for from this consultation?
- Try to develop an understanding of who the patient is as a person. Where, and with whom, do they live? What is their occupation? What things do they enjoy? Moments of human connection, such as a shared interest in a place or activity, can be powerful in building a relationship between clinician and patient.
- Try to convey empathy and concern. Reinforce to the patient that you are their advocate and will do your best to help them.

4 The art of being a doctor

Box 1.3 Strategies in history-taking

- ***Begin with open questions:*** 'Could you tell me more about the pain?' Do this before moving to closed questions that may help rule diagnoses in or out: 'Did the pain get worse after eating?'
- ***Active listening:*** Maintain eye contact, nod, acknowledge key points, respond to comments the patient might make that are humorous or sad.
- ***Respond to body language:*** Body language may reveal distress, anxiety, or embarrassment. Acknowledge this and address it.
- ***Empathize:*** Try to show the patient that you care about what they are going through. Put yourself in their shoes: how might they be feeling? Communicate this: 'Thank you for sharing this. It must be difficult not knowing what is going on.'
- ***Summarize:*** Run through what the patient has told you, to make sure nothing has been misunderstood or missed out.
- ***Signpost:*** Explain what you have covered, what happens next, and why.
- ***Use a common language:*** Avoid medical jargon or complicated vocabulary, unless it is clear that the patient is able to understand this.

Box 1.4 A structured approach to information-gathering in the medical history

- Presenting symptom: why has the patient sought medical advice?
- History of the presenting symptom: the information the patient wants to share, and the information needed to help make a diagnosis
- Medical and surgical history
- Drug history and allergies
- Family history
- Social history: information on the patient's present living arrangements and relevant risk factors

The patient's presenting symptom is the initial springboard towards diagnosis. For the experienced clinician a symptom will conjure a list of potential diagnoses, which will then be narrowed and refined (see 'Diagnostic reasoning' section later).

History of the presenting symptom

The aim is to provide a thorough account of symptoms. It is vital to listen closely and not to miss any clues that require follow-up or clarification. For each symptom, it should be possible to understand the following:

- ***Time course:*** When did the problem begin? Does it come and go? Is there anything that triggers it? Is there any variation e.g., time of day, eating, exertion? Has the patient ever had anything like this in the past? Symptom pattern is helpful for diagnosis (**Box 1.5**).
- ***Associated symptoms:*** What else has the patient noticed? Begin with an open question, then clarify the presence or absence of other symptoms that help with diagnosis.
- ***Pain:*** Severity, site, radiation, and character. How does the patient rate it on a scale from 1 to 10? How does the pain feel to them? Tight, dull, electric, and burning can be helpful when voiced by the patient. Is the pain getting worse, staying the same, or starting to improve?
- ***Responses:*** Have they sought medical advice or used medication that they have at home? Did it make things better or worse?

The 'Clinical skills' sections at the beginning of many of the chapters in this book present symptoms that are relevant to particular conditions within different medical specialties. However, most symptoms (at least at the start of the patient's story) do not tell you which chapter to go to. A review of systems may be valuable in eliciting additional symptoms that the patient may not have mentioned or thought relevant (**Box 1.6**).

Box 1.5 Using the time course of symptoms to suggest an underlying cause

Onset of symptoms	Possible causes
Immediate (seconds to minutes)	Vascular—thrombotic or embolic Anatomical—e.g., perforation of a viscus Electrical—e.g., dysrhythmias, seizures
Hours to days	Bacterial or viral infections Inflammatory and autoimmune diseases
Weeks to months	Malignant disease Inflammatory and autoimmune diseases Chronic infections, e.g., mycobacterial
Months to years	Degenerative conditions Fibrotic diseases

Medical history

This should include all significant conditions: hospital admissions, long-term conditions, important investigations, procedures, and therapeutic interventions (operations, endoscopies, chemo- or radiotherapy). If the patient has had surgery, an anaesthetic history should be sought and recorded. Five useful questions to ask about chronic conditions are listed in **Box 1.7**.

Drug history

Record all medications taken, including prescribed, over-the-counter, herbal, and traditional treatments. Record when each was started, the dose used, and adherence. Ask about side-effects. Medication error is a common cause of morbidity and mortality. Ask about and record ***drug allergies***, including the timing and nature of any reactions.

Family history

This is particularly relevant when the differential diagnosis includes genetic conditions or genetic risk. The medical history of first-degree relatives (parents, siblings, offspring) and consanguinity should be recorded. Diseases in the wider family are recorded in a pedigree.

Social history

The social history has two key purposes:

- Establishing whether ***environmental factors*** may be causative or exacerbating the patient's symptoms. Consider housing, occupation, smoking, alcohol, and illicit drugs. Where relevant, ask about travel history, animal exposure and insect bites, sexual history, and pregnancy history.
- Understanding more about ***the experience of the patient.*** Where and how do they live? How active are they? Are they limited in any daily activities, including mental health? Do they have informal or formal carers? If so, how often do carers attend and what do they do for the patient?

PHYSICAL EXAMINATION

Physical examination, including clinical observations, is used to confirm or refute the initial diagnosis/diagnoses suggested by the

Box 1.6 Review of systems

Conducting a brief but comprehensive 'review of systems' may be particularly useful when symptoms are non-specific and do not point to the diagnosis, for example, weight loss, tiredness, weakness, 'I just do not feel right'.

Respiratory
Cough: chronicity, nocturnal
Sputum: volume, frequency, consistency, colour, offensive taste or smell
Haemoptysis: volume, frequency, fresh or altered, clots
Shortness of breath: exercise tolerance, orthopnoea, wheeze
Chest pain: 'pleuritic' (with breathing)

Cardiovascular
Chest pain: character, precipitants, frequency, radiation
Shortness of breath: exercise tolerance, orthopnoea, paroxysmal nocturnal dyspnoea
Swelling: peripheral oedema, abdominal swelling (ascites)
Palpitations: precipitants, character (ask the patient to tap out what they feel)

Gastrointestinal (GI)
General: weight, appetite, oral intake
Upper GI:
Dyspepsia, early satiety
Nausea/vomiting: frequency, consistency (food/regurgitation)
Haematemesis: volume, frequency, consistency, fresh/altered, clots
Dysphagia: level (base of neck, mid or lower chest), consistency of food tolerated/not tolerated
Pain: odynophagia, upper abdominal pain
Lower GI:
Pain: lower abdominal pain, anal pain
Altered bowel habit: constipation, diarrhoea (volume, frequency, consistency, colour), blood per rectum, mucus per rectum
Hepatobiliary and pancreatic:
Jaundice, pain, pruritus, symptoms of encephalopathy, abdominal swelling (ascites)

Renal
Urine: frequency, volume, colour, offensive odour, dysuria
Haematuria: volume, frequency, colour, fresh/altered, clots
Bladder outflow tract obstruction: hesitancy, frequency, volume, dribbling

Musculoskeletal
Stiffness: timing during the day
Pain: acute/chronic, swelling, erythema, patterns of joints involved
Muscular: pain, weakness

Dermatological
Rashes, blisters, ulcers

Endocrine
Diabetes: thirst, vision, peripheral sensation
Thyroid: weight, tremor, cold/heat intolerance, palpitations, skin or eye changes
Sexual function, menstruation, pregnancy

Neurological
Movement: seizures, involuntary movements, loss of movement, altered gait, swallowing difficulties, fatigue
Sensation: increased or loss of sensation, balance
Higher neurological function: speech, vision, hearing

Ophthalmic
Eye pain, redness, dryness or grittiness, change in vision, flashing lights

Ear, nose, and throat
Pain, changes in smell, taste or hearing, pain in ears, discharge/crusting

Haematological
Easy bleeding or bruising, tiredness, lymph node swelling, abdominal fullness

Mental health
Mood: anxiety, depression, suicidality
Altered perceptions (hallucinations)
Abnormal beliefs (delusions)

Genitourinary
Discharge: urethral or vaginal, itch
Pain: abdominal, pelvic, testicular, anal, pain during sexual intercourse
Sexual function: menstrual cycle, contraception, pregnancy

Box 1.7 Five questions for the patient with a long-term condition

1. ***Diagnosis***—HOW, WHY, WHERE, and WHEN?
2. ***Progression***—How has it progressed since?
3. ***Control***—How do you monitor your condition? When did you last have a check-up? What medications do you take? What are your biggest challenges in managing your condition?
4. ***The good and the bad***—What is the BEST and WORST your condition has ever been? How does it impact your life?
5. ***Today/recently***—How are things today (compared to last week/year/last time you were unwell)? What happened last time you were unwell?

history. Extent and focus will be guided by the presenting problem. Even in the era of complex technological investigations, physical examination performs several key functions, including:

- Providing objective evidence (physical signs) to complement subjective evidence (symptoms). Rarely, diagnosis can be made with examination alone, e.g., skin disorders.
- Assessment of severity.
- Identification of unexpected findings that patients may have not noticed.
- Building rapport with patients. Physical examination can reinforce that assessment of their problem is thorough and compassionate.

An overall assessment is made as the history is elicited: does the patient look well or unwell? Are there any obvious clinical signs from the 'end of the bed?' Formal observations of physiological parameters are recorded routinely in the hospital setting: temperature, heart rate, blood pressure, oxygen saturation, respiratory rate, and level of consciousness.

A detailed assessment is then carried out, including:

- a general examination of the hands, face, and neck
- examination of the likely affected system or systems
- a wider examination of other relevant organ systems if indicated.

Fig. 1.3 outlines a typical general and systematic examination routine suitable for use in patients presenting with a wide range of medical conditions.

INVESTIGATION

There are a huge number of investigations available to the clinician, ranging from bedside tests including spirometry and urine dipstick analysis, to complex radiological imaging and invasive procedures. Some tests combine diagnostic and therapeutic potential, for example, endoscopy and angiography. A good test is appropriate, cost-effective, has high diagnostic value, and little burden to the patient or cost to providers. The following should be considered when investigations are requested:

- ***What question will this test help to answer?***
  It is helpful to have a clear diagnostic question in mind. Specialists can help select the most appropriate investigation to answer a relevant clinical question. Beware

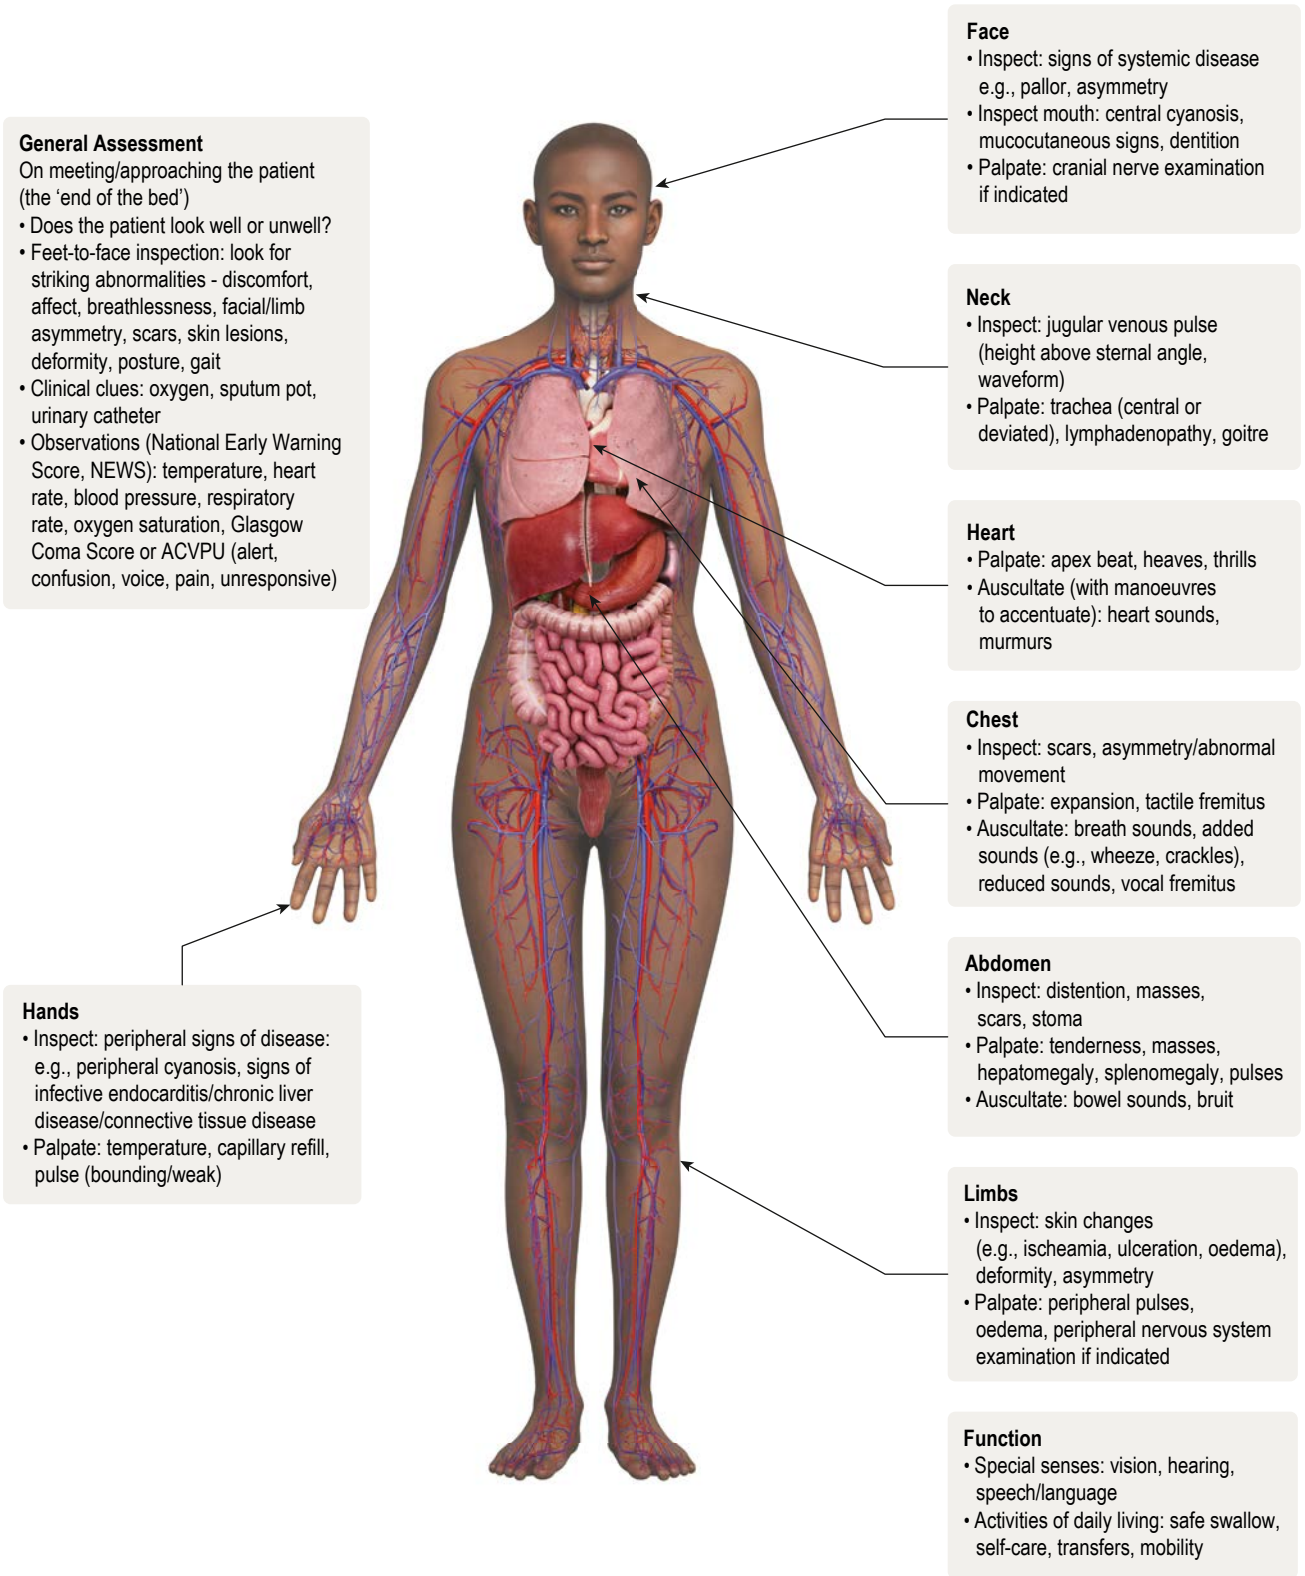

Fig. 1.3 **A basic approach to clinical examination.**

of requesting tests without a clinical reason: results may lead to more questions (and unnecessary further tests) than answers.

- ***What are the sensitivity and specificity of the test?***

A sensitive test correctly identifies patients with a disease and a negative result is useful in reassuring patients that they do not have the condition ('rule out'). For example, D-dimer is a highly sensitive test for thrombus: in patients with a low pre-test probability, a negative D-dimer test accurately excludes thrombus.

A specific test is accurate when the result is positive. For example, D-dimer is not a specific test for thrombus as

the result can also be positive in infection, autoimmune conditions, pregnancy, and following surgery. A specific test such as CT-pulmonary angiography is therefore needed to confirm ('rule-in') pulmonary embolus.

- ***What are the risks of the test to the patient?***
  Invasive procedures may cause bleeding, infection, or organ injury. Ionizing radiation carries a small risk of future malignant disease (<1 in a million for a chest X-ray). The risks of investigations and benefit of knowing the result need to be discussed and weighed with patients to allow them to make the best decision about proceeding with investigation.
- ***How much certainty is needed?***
  The need for certainty is often proportional to the burden of treatment: when treatment is complex or has significant risk of harm the need for certainty in the diagnosis is greater. For example, surgery or chemotherapy for cancer usually requires biopsy diagnosis.
- ***Will the test result make a difference?***
  If all treatment options have a greater risk of harm than benefit, undergoing investigation may not be appropriate.

Interpretation of test results

Diagnoses typically result from history and examination. However, diagnostic testing is often required to confirm a provisional clinical diagnosis and/or to rule out alternatives; at least 10% of all diagnoses are not considered final until testing is complete. Laboratory test results are also used to monitor disease progression and response to treatment.

Interpretation of test results is often undertaken by comparison to a reference interval. This reference interval may be erroneously termed the 'normal range', erroneous in that it does not define normal, and it is not a range. For example, a serum sodium concentration of 134 mmol/L (reference interval 135–145 mmol/L) may not be pathological, and the range of serum sodium is 10 mmol (the difference between highest and lowest reference limits).

A reference interval describes blood analyte concentrations in defined groups of individuals, estimating what can be expected in the population. It provides a reference point against which to interpret an individual patient's result. However, a reference interval may not encompass differences that can significantly impact an analyte, e.g., age, gender, pregnancy.

The decision to include 95% of results from a healthy population in a reference interval is purely pragmatic. It produces less false positives than the inclusion of 90% (when more people sit outside the reference interval) and less false negatives than the inclusion of 99% (when fewer people sit outside the reference interval). But if 95% are included, by default, 5% of people should be expected to be outside of all reference intervals in the absence of disease.

It is rare to request one test in isolation. In clinical practice it is common to request a series of tests on the same sample, for example, a 'metabolic' panel, a 'tired-all-the-time' screen. As, by pragmatic definition, 5% of test results sit outside the reference interval, the more tests that are requested, the greater the likelihood of an 'abnormal' result. If 20 (independent) test results are requested, there is a 38% chance that one result will be outside a 95% reference interval. It is therefore important that clinical suspicion guides test requests and not the appeal of tick box on a request form.

Reference intervals also do not consider intraindividual variation. For example, in a bleeding patient, a fall in haemoglobin from 170 g/L to 130 g/L may be significant even though both results sit within the reference interval. Repeated results may also conform to the phenomenon of 'regression to the mean'. This is a statistical tendency where extreme results tend to be followed by measurements that are closer to the mean when a test is repeated, meaning that the assumption that change is caused by disease or treatment may be flawed.

Reference intervals do not, and cannot, define normality. A result within the reference interval may occur with pathology and a result outside the interval can be seen in health.

When not to investigate

Decisions about whether and how to pursue a diagnosis are often complex and should be made in conjunction with the patient. Individuals differ in their willingness to tolerate uncertainty, with some wanting to seek a definitive diagnosis at all costs and others happy to accept a presumed diagnosis that may or may not be proven wrong. Clinicians can guide and help patients to understand likely and possible outcomes of different tests, offering 'best- and worst-case scenarios'. In general, investigations may not be undertaken when:

- the patient is too frail to derive any benefit from confirming a diagnosis, for example, if the burden is too great, or treatment is likely too ineffective.
- the patient agrees to have an initial investigation, but tests for definitive diagnosis are unacceptable. For example, the patient agrees to a myocardial perfusion scan but does not want to undergo subsequent coronary angiography.

Patients can make an informed decision to decline an investigation or intervention, but there is no entitlement to investigations or tests that are of no overall benefit.

DIAGNOSTIC REASONING

Making the correct diagnosis is key to safe and effective medical care. However, diagnosis is complex. Large amounts of information gathered from history, examination, and investigation results need to be assimilated and synthesized. Each piece of evidence should be weighed according to the confidence you have in its accuracy based on the information obtained. If significant findings remain unexplained, diagnosis should be re-evaluated. Each patient has a unique story and examination findings may vary, for example, with body mass index, posture, or the provision of analgesia. Diagnostic tests that are 100% sensitive and specific, with 100% positive predictive value do not exist (except for life ultimately predicting death). Be humble and insightful enough to seek help from others.

MODELS OF DIAGNOSIS

In a traditional model of medical diagnosis the clinician begins by considering all possible causes of a presenting symptom. Information gathered is then used to include and exclude causes, using probabilistic reasoning, until only one remains. This requires 'type 2 thinking', which is analytical and deductive. Type 2 thinking is the kind of thinking we would like to carry out all the time if only it were not so effortful and slow (**Fig. 1.4A**).

An alternative model is diagnosis by pattern recognition. This is 'type 1 thinking': automatic, intuitive, quick, and requiring little effort. It relies on ***heuristics:*** mental shortcuts or rules of thumb drawn from previous experiences and learned associations. These heuristics allow quick judgements of new situations by comparing

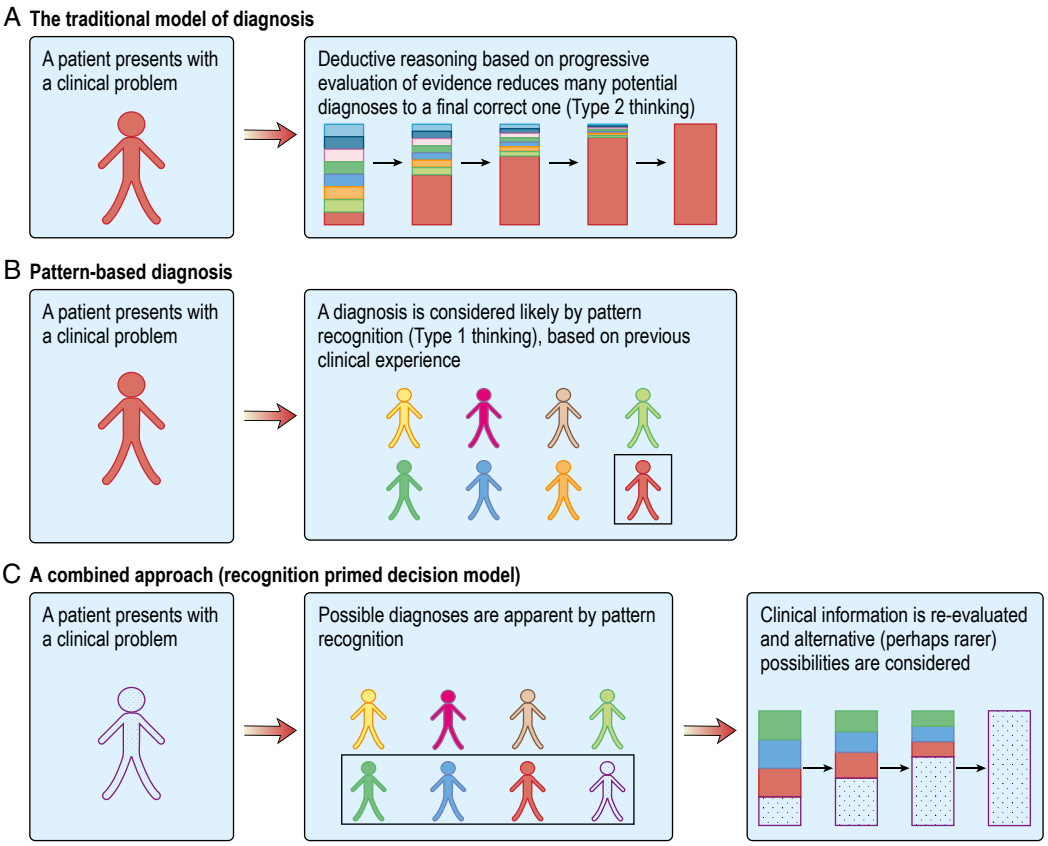

Fig. 1.4 Approaches to diagnosis. **(A)** The traditional model of diagnosis. **(B)** Pattern-based diagnosis. **(C)** A combined approach.

them with similar situations encountered in the past. In this form of diagnostic reasoning, clinicians rapidly compare the presenting patient with the many other patients they have seen, subconsciously drawing on similarities and differences that lead efficiently to a likely diagnosis (Fig. 1.4B).

The best model for efficient and safe diagnosis is likely to be a combination of these two approaches. This is a recognition-primed decision model: the rapid impression generated by type 1 thinking is revised by slower, reason-based type 2 thinking. This model draws on the strengths of both types of thinking (Fig. 1.4C).

CLINICAL INTUITION

Clinical intuition is often described, and aspired to, in medicine. It exists in the apparent 'magic' of the senior clinician to focus on a stable patient during a ward round due to apparent psychic knowledge that, by the end of the day, it will be that patient who will be most unwell. It occurs in their capacity to ask the single question that clinches the diagnosis, despite the extensive answers provided to the 50 questions asked by the trainee.

Yet there is no magic here, and to view clinical intuition as magic is to do a disservice to the complex scaffold of knowledge and expertise on which it is founded. The development of clinical intuition is like learning to read; a complex skill in which the letters and words of clinical information are suddenly read as whole sentences. This looks like a magic leap to those who are still learning letters or words. But with practice, and a degree of clinical predictability, complex analytical type 2 thinking can start to look as if it is type 1 thinking, with apparent near-instantaneous answers to clinical problems.

Clinical medicine is full of opportunities for diagnostic practice. Most clinicians will eventually learn to read in sentences, with a rare few going on to develop the expertise to devour a whole paragraph or even chapter at a time. Clinical medicine is, however, limited in predictability. Patients are unique. They present in different settings, with different experiences of disease, and at different time courses within their disease. This inherent unpredictability means that slower, effortful thinking will always be required. Although apparent 'intuition' looks easy, some cognitive effort is mandatory to keep it in check. Take comfort that on the days that you feel the burden of cognitive strain for it is likely to be protecting you from error.

BIAS AND ERROR

It has been estimated that 10% to 15% of medical diagnoses are wrong. Mis- or delayed diagnosis causes harm, including failure to receive timely intervention, and the adverse effects of unnecessary treatment. While misdiagnoses may occur because of inadequate knowledge or lack of diagnostic resources (particularly in resource-limited settings), they also arise as a result of cognitive bias. Box 1.8 lists cognitive biases which can lead to error.

Various strategies can be employed to reduce the chance of incorrect diagnosis:

- ***Working conditions:*** An environment with sufficient time, information, resources, and sleep is required for the cognitive load of analytical thought. Working conditions which promote reflex rather than analytical thinking should be addressed.
- ***Awareness of bias:*** Increasing clinicians' familiarity with cognitive biases may decrease bias-related errors. Guided reflection

Box 1.8 Cognitive biases leading to misdiagnosis

- ***The affect heuristic:*** A context or patient-specific response due to clinicians experiencing positive or negative feelings towards a patient, based on prior experiences. For example, the symptoms of someone viewed as a 'complainer' fail to trigger appropriate investigation.
- ***Anchoring:*** The tendency to rely on features in the patient's early presentation, with failure to adjust in the light of later information. It is a form of confirmation bias (see below). For example, a patient is sent to hospital by their GP with a suspected urinary tract infection; the doctor in the emergency department fails to consider other possible causes for the patient's confusion.
- ***Aggregate bias:*** The belief that conclusions drawn from aggregate data do not apply to the patient being evaluated due to the possibility of rare or atypical disease. For example, a clinician orders a CT scan despite decision-making tools showing it is not indicated.
- ***Ascertainment bias:*** A clinician's thinking is shaped by prior expectation. This includes stereotyping and race/ethnicity and gender biases. The routine use of race and ethnicity descriptors before the provision of clinical information in case presentations and medical assessments should be questioned.
- ***Availability:*** Explanations which spring easily to mind are presumed more likely to be correct. For example, a doctor assumes that acute kidney injury is due to dehydration (despite an absence of clinical signs) and administers intravenous fluids due to unfamiliarity with renal parenchymal disease.
- ***Confirmation bias:*** The tendency to look for confirming evidence to support a diagnosis rather than evidence that refutes a diagnosis. This occurs despite refuting evidence often being more definitive. For example, a mild neutrophilia is viewed as confirmation of a chest infection, and the clinical history consistent with pulmonary embolus is not sought.
- ***Framing:*** Making decisions in different ways, depending on whether a choice is presented in positive or negative terms. For example, a doctor may respond differently to an incidentally discovered adrenal mass that is reported to be 'probably benign', compared to a report reading 'unable to exclude malignancy'.
- ***Omission and commission biases:*** A tendency towards inaction (omission) or action (commission) depending on whether the clinician's focus is on harm arising from diagnosis/intervention, or conversely, a belief that active intervention is required to prevent harm. Omission bias is more common due to acceptance of the natural progression of disease over iatrogenic harm, for example, the unnecessary avoidance of chest X-rays in pregnancy.
- ***Optimism:*** The assumption that negative outcomes occur less often than they really do. For example, a junior doctor may fail to call for senior help with a clearly deteriorating patient because of an unrealistic expectation that the interventions they have instituted will improve the situation.
- ***Outcome bias:*** A belief that good or bad results are always attributable to prior decisions. Although a relationship between decisions and outcomes might seem logical, the outcome of a decision is not the only determinant of its quality; sometimes, a bad outcome can happen despite a good clinical decision. For example, a tissue biopsy is not requested because a previous biopsy resulted in a life-threatening bleed.
- ***Recency bias:*** Remembering most easily things that have happened most recently. For example, a doctor may be distracted away from a common diagnosis by a much rarer one, which was covered in a recent teaching session.
- ***Substitution:*** An easier (and related) question is solved in place of a more difficult one. For example, a patient with previous intravenous drug misuse presents with worsening headache and a CT scan of their head is normal. Rather than address a difficult question (why does this patient still have a headache?), a simpler question is solved (might they simply be seeking opiate analgesia?).
- ***The sunk-cost fallacy:*** Continuing to invest in a failing idea because of significant prior investment. For example, following an unsuccessful operation that resulted in significant complications, a clinician recommends a repeat procedure rather than conservative management to try to salvage something from the situation.

involves searching for and being open to alternative diagnoses. 'Cognitive forcing' involves conscious consideration of alternative diagnoses that do not come intuitively.

- ***Use language devoid of assumption:*** Patient's problems should be summarized succinctly and objectively. Do not assume previous diagnostic reasoning was correct.
- ***Awareness of the wider differential:*** Aides-mémoirs encourage consideration of the wide differential of any presenting problem. Diagnostic sieves remind clinicians of the spectrum of disease processes that can affect humans, for example, ***VITAMIN C DEF***iciency = **V**ascular, **I**nfective/**I**nflammatory, **T**rauma, **A**utoimmune, **M**etabolic, **I**atrogenic, **N**eoplastic, **C**ongenital, **D**rug related, **E**ndocrine/**E**nvironmental, **F**unctional.
- ***An iterative approach:*** All previous diagnoses are subjected to appropriate re-evaluation, looking specifically for evidence that brings them into question.
- ***Team discussion:*** All team members (including the patient) are empowered to challenge a diagnosis, including that of senior clinicians. Multidisciplinary team meetings bring together clinicians and allied healthcare professionals from different specialties so that relevant knowledge and expertise is shared in a collaborative environment. Healthcare leaders have a responsibility to flatten the authority gradient in team discussions.
- ***Diagnostic criteria:*** Evidence-based standards may be available to help guide diagnosis.

LEVELS OF DIAGNOSTIC DEPTH

Clinicians may assign an umbrella term that categorizes a collection of signs and symptoms into a clinical entity, for example, 'acute coronary syndrome', 'delirium', 'upper respiratory tract infection', or 'sepsis'. This umbrella term describes an initial impression; it is a step towards the final, specific diagnosis. Some patient presentations do not fall neatly under umbrella terminology and the initial impression remains a narrative description of the patient's problem.

The impression formed at the end of a clinical consultation may be confirmed, refined, or refuted by tests. For some conditions, complex, expensive, or potentially hazardous investigations are required for diagnosis. Tests might also be needed to demonstrate the extent, severity, or treatment responsiveness of the condition (Fig. 1.5).

It might be appropriate to stop at the level of a syndrome or clinical impression rather than continuing with investigations to define the histopathological or mechanistic cause if:

- the patient is satisfied with this level of explanation and declines further diagnostic work-up
- the problem is mild or self-limiting
- further investigation is unlikely to yield a specific cause, e.g., resolving diarrhoea due to likely viral gastroenteritis
- further investigation is unlikely to influence management as treatment will be the same (or not effective) regardless of further diagnostic clarification
- the risks of investigations and/or treatments are too great for the patient, for example, due to frailty or co-morbidity.

THE ROLE OF WATCHFUL WAITING

All diseases have a natural history: some are self-limiting, some progress, and some relapse and remit. Where there is diagnostic uncertainty, there can be a role for waiting to see how events

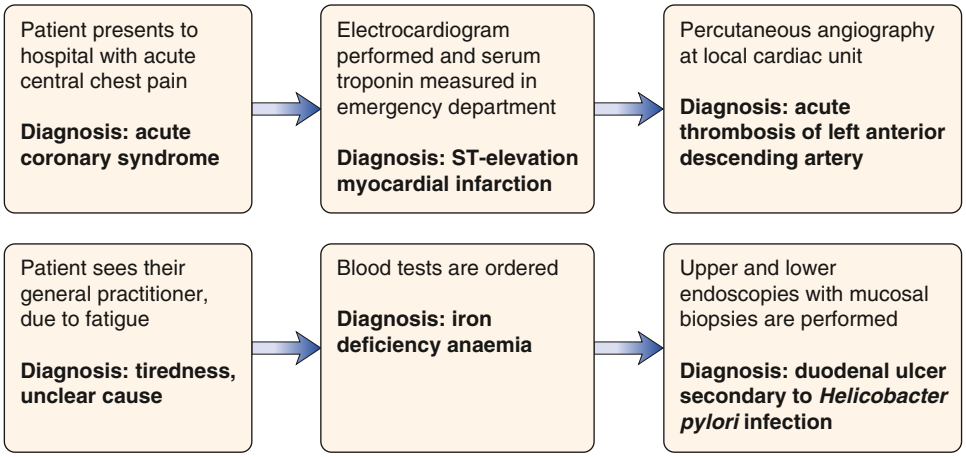

Fig. 1.5 **Examples of different levels of diagnosis.**

i Box 1.9 The role of watchful waiting in diagnosis

- **Incidental finding of a small pulmonary nodule.** A 77-year-old female undergoes CT scanning of the coronary arteries after an episode of chest pain. Incidentally, a small (<10 mm) pulmonary nodule is detected. She is at risk for lung cancer because of a long smoking history. In accordance with the British Thoracic Society's Guidelines for the Investigation and Management of Pulmonary Nodules, she is offered repeat computed tomography screening at 3 months and 1 year. These reveal stable appearances with no increase in size. She is discharged after 1 year.
- **Abnormal liver blood tests.** A 34-year-old male is found to have abnormal liver blood test results. Blood tests for viral hepatitis and autoantibodies associated with liver disease are negative. A liver biopsy is discussed with the patient, but because his liver blood tests are not rapidly deteriorating, a decision is made in favour of watchful waiting. Two months later, his liver blood tests are within the reference interval and remain normal. He is discharged without a diagnosis for his transient liver injury.
- **Relapse of nephrotic syndrome in adulthood.** An 18-year-old female with a history of presumed minimal change disease as a child presents with recurrent nephrotic syndrome. She is commenced on high-dose corticosteroids and her response to treatment is monitored. After 2 months, remission has not been achieved. No response to corticosteroids is atypical for minimal change disease so a kidney biopsy is done. This reveals a different but related kidney disorder: focal segmental glomerulosclerosis.

develop if it is safe to do so and when beneficial treatment is not inappropriately delayed (Box 1.9).

Watching and waiting are sometimes necessary for diagnosis when diagnostic criteria stipulate symptoms must have been present for a certain length of time. It may be wise to defer risky or burdensome investigations until the clinical course of the disease justifies investigation. Discussion with the patient is crucial.

DIAGNOSTIC CRITERIA

Some conditions are diagnosed with a single pathognomonic investigation. For example, the presence of urate crystals on microscopic examination of synovial fluid is diagnostic of gout. In other situations, confirming a diagnosis is more complex and based on a combination of symptoms, physical signs, and investigation results. For example, a diagnosis of systemic lupus erythematosus is based on evidence of autoimmunity plus additional symptoms, signs, or test results demonstrating constitutional, hematologic, neuropsychiatric, mucocutaneous, serosal, musculoskeletal, renal, or immunological involvement.

Diagnostic criteria are useful for:

- Patients: enabling correct diagnosis and treatment
- Epidemiology and public health: the compilation of accurate statistics for monitoring trends in the incidence and distribution of disease.
- Research: to allow study of defined diseases and their treatments
- Remuneration and service planning: adequate provision of care and payment to healthcare providers based on diagnostic codes.

OVERDIAGNOSIS: TOO MUCH MEDICINE

Overdiagnosis refers to the use of a diagnostic label that confers no benefit. It occurs due to:

- Overdetection: identification of diagnoses that will never cause harm
- Overdefinition: the medicalization of normality

Examples are shown in Box 1.10. Overtreatment is the use of treatments which do not provide benefit. Overtreatment can occur in the absence of overdiagnosis, but the two phenomena often go hand-in-hand.

UNCERTAINTY

Sometimes, it is not possible to make a definitive diagnosis. The reasons for this are varied:

- Available investigations are unable to confirm a definitive diagnosis. This can occur when diagnoses are more complex than the tests available or when medicine is delivered in a resource-limited setting without access to investigations.
- Definitive investigation is avoided due to risk of harm.
- Investigations are declined.
- There is a time-lag between investigations being sent and results becoming available.

Without a confirmed diagnosis, treatment and prognostication may be uncertain. Uncertainty is inherent to medical practice, as it is in all situations that encompass complex behaviours, dependent variables, and shifting coefficients. Osler (1849–1919) stated that medicine is the science of uncertainty and art of probability. R.C.

Box 1.10 Examples of overdiagnosis in medicine

Overdiagnosis	Mechanism
Chronic kidney disease (CKD)	Overdefinition: The absence of an age-adjusted CKD definition increases the diagnosis of CKD in elderly patients with an indolent decline in kidney function.
Subsegmental pulmonary embolus	Overdetection: Increasingly sensitive cross-sectional imaging may reveal emboli that do not cause harm.
Hypercholesterolaemia in the very elderly	Overdefinition: Reference intervals for the very elderly may differ from those derived from younger cohorts. Overdetection: Treatment may not confer long-term benefit.
Cancer screening	Overdetection: Screening for thyroid and prostate cancers reveal small indolent tumours that are unlikely to progress. Intervention does not change mortality, though morbidity from treatment may occur.
Incidental findings	Overdetection: The pulmonary nodule or small adrenal lesion found on imaging undertaken for other reasons leads to further tests or surveillance imaging.

Fox, a medical sociologist writing in 1980, stated that uncertainty derives from the limitations of medical knowledge, the limitations of personal knowledge, and the difficulty distinguishing between the two.

Uncertainty in medicine is a challenge, especially in a technologically advanced world in which the expectation of certainty is increasing. Clinicians who experience anxiety in response to uncertainty have higher levels of burnout and decreased job satisfaction. There may be more uncertainty when the traditional pathophysiological model of disease is insufficient; anxiety and discomfort may therefore be greater when patients present with psychological disease or when patients are dying.

Adherence to evidence-based or consensus clinical guidelines is a helpful response to uncertainty: knowing what other people do in similar or comparable circumstances can be useful. However, randomized controlled trial data deals with cohorts, not the individual patient in front of you. Research data also rarely measures the variance of humanity beyond the scientific, including levels of desire and interest in the outcome. This meta-uncertainty can be hard for both patients and clinicians.

Uncertainty requires acknowledgement and acceptance because it is inevitable in medicine. Talk to colleagues, for it is helpful to know that your peers are also uncertain and because uncertainty stimulates different ideas from different people. And talk to your patients; they are likely to have always been more uncertain than you. Empathetic common ground can be a comfortable place, and their unique perspective on their own life might bring some certainty about the right thing for them.

Some options are always available even when a diagnosis is uncertain:

- Symptomatic treatments, including pain relief and anti-sickness drugs, are always appropriate.
- Empirical treatment can be instituted based on suspected pathology, provided potential side-effects and the possibility of harm if the diagnosis is wrong are acceptable to the patient.
- Follow-up. Change or evolution of disease may lead to certainty, or diseases may remit, meaning certainty is no longer required.
- What is important to the patient? How can you help them live their lives according to their priorities, for example, time with family or friends, the achievement of an ambition or goal, or according to their faith.
- Compassion is 'to suffer with'. Walk and talk with your patient. Partner them on their health journey. Expertise and certainty may be less important than this.

COMMUNICATING A DIAGNOSIS

Towards the end of a clinical consultation the clinician will need to explain their diagnostic reasoning to the patient, with plans for further investigation and intervention. Effective clinical communication is an evidence-based, learnable, professional skill, which demonstrably improves the quality and safety of healthcare, and improves health outcomes. Clinical communication is addressed in Chapter 2.

INEQUALITIES IN MEDICINE

Race and ethnicity

The terms 'race' and 'ethnicity' attempt to describe highly complex concepts including phenotypic, genetic, geographic, and cultural factors, alongside an individual's perceived identity. However, aggregate categories are poor indicators of underlying biological and physiological variation; the assumption that a specific race or ethnicity equates to genetic or physiological distinction is unfounded.

Racism exists in every modern society, including in medicine. There is a shameful history of medicine being complicit in racist practices within society including forced sterilization, unethical research, and Nazi atrocities. Healthcare practitioners have an ethical duty to remove racial bias: look for it (especially in your subconscious), acknowledge it, and change things.

Treating patients differently based on a categorization of race or ethnicity can result in substandard care. For example, a race correction for estimated glomerular filtration rate (eGFR) *presumed* a higher muscle mass in those of Black ethnicity. This has now been abandoned in contemporary eGFR calculations; it is a flawed presumption that led to delayed care in those of Black ethnicity. The prescription of antihypertensives in the UK based on a binary definition of race may delay prescription of angiotensin blockade to those of Black ethnicities who may have much to gain from these drugs.

Although disease prevalence can vary with ethnicity, the inappropriate use of ethnicity as a proxy for disease or disease risk is pervasive throughout medical training. Race and ethnicity are commonly presented in case histories and exam questions before any clinical information is given, teaching clinicians that racial bias is helpful or necessary for diagnosis.

However, an understanding of differences in health and healthcare by ethnicity can identify and, therefore, help address inequalities. Ethnic differences in disease outcomes remain troublingly common. During the SARS-CoV-2 pandemic in 2020 to 2021, minority ethnic groups in the UK were more likely to develop severe infection with increased risk due predominantly to non-biological factors: increased exposure due to front-line work, overcrowded accommodation, barriers to health services, co-morbidity, and a life course that increases the risk of non-communicable disease. Distinction of health provision and outcomes by race and ethnicity to identify disparities requires accurate race and ethnicity data beyond umbrella definitions and binary or simplistic classifications, as well

as a wider reflection on the multifactorial nature of health outcomes (see 'Health inequality and intersectionality' section later).

Everyone has biases and, as clinicians, we are taught to stereotype. Awareness of this is the first step to correcting inequalities that arise from these on an individual level. On a wider level, the dismantling of systems that perpetuate intersecting and compounding inequities and action to address health inequalities between different ethnic groups are needed.

Sex and gender

Sex describes the biological differences between male and female: chromosomes, hormones, and reproductive anatomy. Gender refers to the socially and culturally constructed differences between males and females: normative roles and expectations in society. Gender identity is the person's sense of self: whether they see themselves as male, female, other, or no gender. Where distinction between sex is important for pathophysiology, terminology should describe sex and not presume gender; male or female is therefore preferentially used.

Sexism is the differential treatment of individuals (either more or less favourably) based on sex. Females and those who identify as females are disproportionately affected by sexism.

Clinical practice and research have traditionally defaulted to the male patient. For example, females are less likely to be diagnosed with acute coronary syndrome and their chest pain is commonly described as 'atypical'. The fact that a presentation of pain which affects 50% of the population can be described as 'atypical' is striking in itself: for 'atypical', read 'not male'. Most medications used in pregnancy have insufficient safety information. Only six drugs are licensed for use in pregnancy in the UK, and in the last 30 years only a single medication has been specifically developed for use in pregnancy. Females are underrepresented in clinical trials, and pregnant and breastfeeding females are largely excluded from most research. Caution around medications in pregnancy leads to fear (in female patients and their healthcare providers) and undertreatment.

Conversely, males on average die younger than females, are less likely to access medical services, and tend to present later in the course of disease. Suicide is the leading cause of death in males under 50 in the UK, with societal perceptions of masculinity thought to be a contributor.

Examine your own gender biases and look for those that exist in healthcare and healthcare research. Was this female/male/gender-diverse patient represented in the published data for this disease? If not, highlight this and work to ensure inclusion in future research. Would you do or consider anything else if this patient were a different sex or gender? If so, make sure there is a very valid reason for not doing so now.

People living with disabilities

People living with physical or learning difficulties have poorer health outcomes compared to those with the same diseases without disability. They may struggle to access, understand, or adhere to care.

Healthcare facilities should be accessible, and appointment letters should be easy to read and understand. Resources should be made available in braille. Sign language should be included amongst the languages for which translation is made available. Specialist learning support services should be available for any for whom healthcare attendance is difficult. Individualized communication strategies may help patients that are neurodiverse to understand and engage with care. There should be a focus on barriers to care, as these may impact outcomes more than the disease. Ask service users what they think and how they would design their care.

Health inequality and intersectionality

Many groups in society experience worse health outcomes because of social, cultural, and demographic factors. As well as the differences according to ethnicity, gender, and ability, inequalities are also experienced by asylum seekers and other immigrant populations, those whose first language is not the main language of healthcare services, those with mental health problems or substance addiction, those living in poverty, older people and those with dementia, those with stigmatised conditions, those with low levels of educational attainment, and those without good social support networks.

Health inequalities are avoidable differences in health status or in the distribution of health resources that occur between different groups within society according to the conditions in which people are born, grow, live, work, and age. Health inequalities include differences in:

- health status, e.g., life expectancy, morbidity, mortality
- access to care, e.g., due to available health services (including contraception and safe termination), language, digital access
- quality and experience of care, e.g., patient satisfaction, understanding
- behavioural risks, e.g., smoking, sexual practices, alcohol/substance misuse
- wider determinants of health, e.g., income, housing, nutrition

Individuals may have multiple factors contributing to variation in health, for example, an unemployed female of Black ethnicity living with disability in a socially deprived area. The way in which these factors combine and interact is termed ***intersectionality***.

This is not an easy problem to solve. It requires attention, an intolerance of injustice, and a holistic policy-led approach that extends beyond healthcare providers. The individual clinician is not devolved of responsibility just because something is difficult; these are areas where a doctor's voice and advocacy can be powerful.

Clinicians have a responsibility to:

- pay attention to, measure, and talk loudly about inequality
- engage with public health colleagues and consider where there are opportunities to prevent disease, not just to diagnose and treat
- work with local communities to ensure equal access to services for all members of society
- empower and help all patients to be health literate.

ARTIFICIAL INTELLIGENCE AND MEDICINE

Artificial intelligence (AI) describes the ability of machines to perform tasks that require higher cognitive skills including natural language processing, perceiving, reasoning, problem-solving, creativity, executive planning, pattern recognition, and interacting with the environment. Although predictions are made about the development of self-aware technology and 'super' AI that out-performs humans, the only type of AI that currently exists is 'artificial narrow intelligence' (ANI): able to perform a single or narrow task (faster and better than a human) but with no capacity to function outside of this defined task. AI systems analyse and utilize trends in large datasets, 'seeing' structure and regularities, and 'learning' to perform tasks more efficiently than humans.

AI technologies have the potential to transform patient care. Several ANIs have been trialed:

- ***'Computer vision'.*** AI systems review large numbers of medical images with diagnostic labels supplied by experts. This produces algorithms that correlate image features with diagnosis.

Clinical utility has been shown in the analysis of electrocardiograms, diagnosis of skin cancers, interpretation of retinal screening images, and reporting of specific radiological images.

- ***Prediction.*** AI systems use large patient datasets and correlate demographics, physical signs, investigation results, and treatment responses with patient outcomes. This generates powerful predictors of outcomes including morbidity, mortality, long-term survival, and suicide risk. AI can reveal patterns overlooked by human researchers.
- ***Personalized treatment.*** AI systems identify genetic variants that predict responses to different treatments. These allow treatment regimens to be tailored to individual patients, maximizing efficacy and avoiding toxicity from treatments predicted to be ineffective.

All currently and imminently available AI presents clinicians with suggestions: the probability of a diagnosis, an assessment of risk, the identification of treatments most likely to be of benefit. AI requires training by expert humans, providing non-experts with a helpful, second opinion from which heuristics and biases are eliminated.

At present, AI that exceeds the intelligence of humans remains theoretical. But consider a future in which a patient tells a computer their symptoms, undergoes the investigations that a computer system determines to be most useful, receives an automated, algorithm-driven diagnosis, and is given a management plan based on a review of all available medical literature. Is this the perfect aspiration or a simplistic, mechanical representation of doctoring?

Whether AI will develop the capacity to read body language and verbal cues, be empathetic and compassionate, deal with uncertainty, hold a hand, share unique decision-making with every unique human, offer spiritual care to the dying, and raise its (automated) voice to try and address social determinants of health remains to be seen. For now, humans can take comfort in the predicted trajectory of AI that means doctors are not imminently likely to be replaced by AI. However, doctors that do not use AI may be replaced by those that do.

CORE SKILLS AND KNOWLEDGE

The goal of healthcare is to heal, save lives, and alleviate suffering. In contemporary healthcare, this is framed within the philosophy of patient-centred care. Patient-centred care places the person accessing healthcare at the centre of the health service they receive by:

- Providing care that is respectful of, and responsive to, individual patient preferences, needs, and values
- Ensuring that patient values guide clinical decisions.

Much of this is accomplished through communication. Effective clinical communication plays a critical role in enacting patient-centred care. It enables healthcare professionals to:

- Accurately identify problems
- Share information about the problem and options for intervention
- Learn the patient's perspective: values, needs, and concerns
- Understand the effects of the problem and its treatment on the patient, in their unique psychosocial context
- Empower the patient to make choices according to their values, needs, and circumstances
- Support the patient throughout the care process.

This chapter describes the core clinical communication skills that underpin these processes. Effective clinical communication is an evidence-based, learnable, professional skill that demonstrably improves the quality and safety of healthcare and affects health outcomes.

You are uneasy. You feel there is something wrong with your body. You navigate an unfamiliar website and receive a time and date for a phone call.

You are worried. Someone you don't know and can't see tells you that you need tests.

You are baffled. You try to orientate yourself in a strange building. It is cluttered with incomprehensible signs. You find your way to a corridor that looks the same as the others and are told to wait. You wait and wait. You are unsure if you are in the right place.

You are a body. You are passed through a series of rooms, where gowned figures and strange machines prod you, sample you, and take pictures. You answer the same questions again and again.

You are rebuffed. You are told to wait for results.

You are relieved. Another phone call, another voice you can't put a face to. You think you pick out, 'It's not cancer'. You hear yourself repeating those words. The voice repeats the words back and you appreciate its kindness.

You are alone. The conveyor belt you were on seems to have stopped. You wonder what will happen now.

PATIENT-CENTRED CARE

In patient-centred care, anyone accessing healthcare is treated as a person who makes autonomous choices based on their values and not as a bundle of symptoms or a disease. Values are what matters most to patients and are dependent on individual circumstances. In the United Kingdom, patient autonomy is enshrined in law. Enabling people accessing healthcare to make decisions that are right for them according to their unique circumstances often takes place during a medical consultation. A consultation can be defined as:

- the act of discussing something before deciding
- meeting with an expert to get advice

It can be helpful to understand the doctor–patient consultation as a 'meeting between experts'. Each participant brings expertise, working together to develop a feasible plan (**Box 2.1**).

WHAT IS CLINICAL COMMUNICATION?

Communication can be defined as the sharing of information, ideas, and feelings by speaking, writing, or other medium.

Emphasis is often placed on the importance of information exchange in healthcare, particularly verbal communication. But healthcare involves elements of cure (biomedical response) and

Box 2.1 Meetings between experts: what the patient and doctor bring to the consultation

Patient	Doctor
• Expert in their own life, values, and needs	• Expert in diagnosis and treatment
• Has autonomy: the right to make decisions about healthcare	• Must act in accordance with professional duties and responsibilities
• May have access to others' lived experiences relevant to this situation	• May have access to other patients' lived experiences relevant to this situation
• Has to integrate the agreed plan into their life	• Has to organize a feasible plan in the context of the healthcare system
• Has to live with the consequences of the healthcare decision	

care (impact on the person). A consultation to support a patient in deciding includes a discussion about:

- the evidence-based treatment options
- what matters to the patient according to individual circumstances.

Clinical communication is professional communication for and about patient care. This includes:

- direct communication between doctor and patient and those close to the patient: relatives, carers, and advocates
- communication about the patient's care: with colleagues and indirectly through record keeping.

This communication can be by any means: face to face, telephone, online, letter, and/or electronic patient record.

Clinical communication involves two key elements: tasks and process.

Tasks are the steps taken in the consultation to address the needs of the patient:

- Establish the nature of the problem: What is it? Is it serious?
- Gain information about available options: What is the treatment? What does it involve? Is there more than one option? How likely is it to work? What are the side-effects? What are the effects on other aspects of my life?
- Receive support in deciding: What does the doctor think based on their experience of others with this problem? How do I make the right decision for me?
- Devise a feasible plan: When, where, and how will this take place? What other information do I need?

Checklists, for example, for establishing medical history or breaking bad news, are universally written from a doctor's perspective, focusing primarily on the doctor's aims. This can marginalize or remove patient perspective and agency. Consider a meeting where the other person has set an agenda you do not have access to and the effect this has on your ability to prepare, participate meaningfully, and exercise control over decisions. Shared agenda setting is the key communicative strategy to facilitate patient agency.

Process is how communication is enacted to achieve the purpose of the meeting. This communication includes the following:

- Verbal: questioning, clarifying, summarizing, and explaining
- Para-verbal: tone, pauses, inflection, and volume
- Non-verbal: eye contact, facial expression, head movement, body posture, and gestures

The process facilitates the sharing of information, ideas, and feelings between the doctor and the patient. For example, a doctor may ask the patient about their concerns, while facing them and making eye contact. The doctor's verbal and non-verbal communication are congruent, signalling that they are listening. Alternatively, the doctor may ask the same question while looking away and typing at a computer. In this case, verbal and non-verbal incongruence signals a lack of interest in the answer.

A key principle of communication is that people understand the social rules of normal conversation. This means that people react not just to what is said (literal meaning) but also to what is communicated through the process of interaction (social function). This social function determines the effect of healthcare communication. It can empower, inform, comfort, and deliver patient-centred care, or do the opposite.

Medical encounters are a form of 'institutional communication': a conversation in an institutional setting with a professional, characterized by a format and language that may be unfamiliar to a lay person. Converting institutional communication to 'normal' effective communication requires the following:

- Orienting the patient to the care process: people need to know what is going to happen to have agency.
- Translation of technical language: people need comprehensible information.
- Compassion: health problems and receiving healthcare are worrying and people need support.

CLINICAL COMMUNICATION IS AN EVIDENCE-BASED SKILL

There is robust research literature, dating back nearly six decades, examining how doctor–patient communication affects care outcomes.

Clinical communication affects care outcomes

This includes outcomes that are:

- Immediate: accuracy of information, patient satisfaction, comprehension of information, medical error.
- Intermediate: follow-through of a treatment plan.
- Long term: health outcomes, litigation.

Communication is defined as 'effective' when it affects outcomes positively.

Clinical communication education is effective

This includes training in all aspects of clinical communication, from establishing a medical history to responding to difficult issues such as breaking bad news. There is evidence that communication deteriorates in the absence of training due to acculturation in healthcare systems that can depersonalize patients, prioritize targets that exclude patient agency, and use language saturated with medical jargon.

Key features of effective communication

- Experiential learning with feedback and reflection, e.g., simulated patients
- Observation of role models who communicate effectively
- Integration of clinical communication into summative assessments
- Valuing clinical communication and its education
- Revisiting skills through experiential learning (lifelong learning)
- Immersion in healthcare systems that value effective clinical communication

Silverman J, Kurtz S, and Draper J. *Skills for Communicating with Patients,* 3rd edn. Boca Raton, FL: CRC Press; 2013.

WHAT IS EFFECTIVE CLINICAL COMMUNICATION?

Across the diversity of people accessing healthcare, medical specialties, and settings, the fundamental elements of effective communication are constant (**Box 2.2**). People want and need to:

- be listened to
- be respected
- have a sense of control.

These three elements are the foundation on which the doctor–patient consultation is built. Research has shown that the elements of a consultation needed to achieve these are straightforward, predictable, and replicable across healthcare settings. Effective communication fosters self-efficacy: an ability to influence outcomes, which has a positive effect on physical and mental health outcomes.

Responsiveness, efficiency, patient-centredness, and appropriateness of language are key principles of effective clinical communication.

Responsive

The goals depend on the individual, with different ways of achieving them. For example, medical empathy can be defined as the ability to understand a patient's situation and emotional state and convey that understanding back to the patient. This is an important prerequisite to patient-centred care. Conveying understanding back to a patient shows that the doctor has listened and the patient has been heard; it expresses care and respect, which are bedrocks of effective doctor–patient communication. But empathy is needed in differing degrees in different consultations, and the ways in which empathy is expressed differ too. Empathy can be conveyed through the use of silence, a verbal statement, eye contact, facial expression, and touch. It is sometimes conveyed directly, for example, through the doctor explicitly stating awareness of the patient's perspective or emotion. At other times, it may be conveyed more subtly, such as demeanour when breaking bad news. The skill is to respond to the patient's need. While one patient might value the opportunity to discuss their emotions, another might want to focus on practical elements. There is no 'one-size-fits-all' approach to empathy, as it is contextually dependent and driven by the individual needs of the patient. Appropriate empathy is less about whether the doctor has displayed specific communicative behaviours and more about whether the patient feels understood and cared for.

The constituents of a 'good consultation' and 'good clinical communication' are dependent on context. A consultation with a patient in the emergency department with a suspected heart attack will be very different from an outpatient consultation with a patient with longstanding, stable ischaemic heart disease. As the role of clinical communication is to enact quality care that is appropriate to the setting, communication will inevitably differ in terms of aims, tasks, processes, and duration.

Box 2.2 What do patients want?

- Greet me in a way that makes me feel comfortable.
- Treat me with respect.
- Show interest in my ideas about my health.
- Understand my main health concerns.
- Pay attention to me (look at me, listen carefully).
- Let me talk without interruptions.
- Give me as much information as I want.
- Talk in terms I can understand.
- Check to be sure I understand everything.
- Encourage me to ask questions.
- Involve me in decisions as much as I want.
- Discuss next steps, including any follow-up plans.
- Show care and concern.
- Spend the right amount of time with me.

Makoul G, Krupat E, Chang CH. Measuring patient views of physician communication skills: development and testing of the Communication Assessment Tool. *Patient Educ Couns.* 2007;67:333–342.

Time efficient

Effective communication does not take longer than ineffective communication. Good communication is not an additional task, rather it is how the tasks required for quality care are enacted. A core task for the doctor is to establish relevant clinical details, and there are different ways to approach this. Evidence has shown that listening to the patient's reason for attendance (which generally takes less than a minute) and then checking that the patient has finished ('Is there anything else?') is the most effective way to gather full and accurate information, facilitating accurate diagnosis and appropriate management. In contrast, interrupting the patient after the first symptom to ask a series of questions leads to omissions and the possibility of time spent on low-priority symptoms. This results in poorer quality of information and care. Inaccuracy of diagnosis and the resultant inappropriate treatment plans are costly in terms of time and resources and can often be traced back to communication.

Efficiency relates to how information is gathered. A checklist of closed questions that limit answers to 'yes' or 'no' responses is less efficient than open questions, which provide space for the answer. Asking closed questions may seem time-efficient, as topics can be cycled through quickly and the patient spends less time talking. However, evidence shows otherwise. Using open questions increases the doctor's ability to obtain complete diagnostic information and target discussion to priority topics. A balance of types of questions is the most time-efficient. Communication is time-efficient when a clinician can:

- share comprehensible information
- work with the patient to develop a feasible plan that meets patient need
- coordinate with colleagues to share accurate information
- record information accurately.

Communication that is incomprehensible, jargon-laden, and inadequately recorded is costly in terms of time and resources and leads to poorer health outcomes.

Patient-centred

From the patient's perspective, a consultation may represent only a fragment of the care they experience. In contemporary healthcare, the patient's journey can involve multiple meetings with different, multidisciplinary healthcare professionals on different days and in different settings (see **Fig. 2.1**). This is an increasing trend as more people are living longer with multiple medical conditions. The patient is the only person present in all their consultations and must piece the jigsaw together in order to make informed decisions about their care.

Communication needs to:

- provide an overview of the process of care
- orient the patient as to where they are at each stage

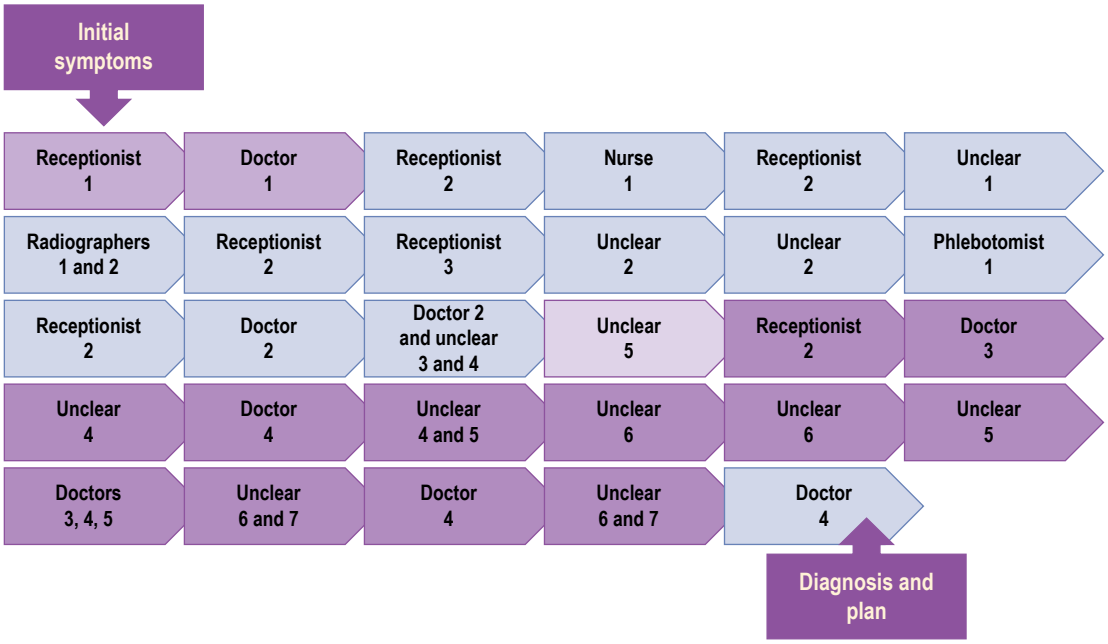

Fig. 2.1 An episode of care. This figure summarizes a patient's episode of care to establish *whether a symptom indicated that the patient had cancer.* It comprised 29 clinically relevant interactions between the patient and 18 different healthcare staff, of whom 4 were doctors. The episode comprised 5 events, on different days, with between 1 and 13 interactions per event. Three events were by phone (1st, 3rd, and 5th) and two (2nd and 4th) were in outpatient settings. The final event concluded the episode.

- foster self-efficacy and agency
- check that care meets need, which may change during the process
- empower the patient to engage in decision-making.

If the doctor's focus is on the immediate 'task at hand', with brief acknowledgement of previous and next steps, it can be unclear when, or whether, this necessary communication happens.

Language

From the first day at medical school, learners become immersed in a biomedical health service culture with its own language. This includes verbal communication (nouns, verbs, turns of phrase) and the way in which language is used to characterize the world and the people within it. This language is used both with and about patients and has a pervasive effect on doctor–patient communication. Traditional medical language, still used in contemporary healthcare, often relegates the patient to a passive role: the doctor **takes** a history, and the patient is expected to **comply** with treatment (Box 2.3). Such language reveals the underlying values of healthcare and reinforces these values in practice.

People accessing healthcare are confronted with strange medical language in all medical settings: on signs, on walls, and spoken by staff, rendering hospital visits akin to visiting a foreign country. This unfamiliar language is ubiquitous in medical settings: on signs, on walls, and spoken by staff, rendering hospital visits akin to visiting a foreign country. Language discordance is the difference between the patient's language and the language used in a consultation, and it applies equally to the language of health services as to discordance in national tongue. The language in medical consultations directly affects clarity and comprehensibility. Doctors' communication is imbued with medical jargon. There are words that the patient may have heard before but may not fully understand *('biopsy')*, phrases that have a different meaning in medicine *('the test results were positive')*, euphemisms that obscure meaning *('lesion')*, and language that is scary *('invasive procedure')* (Box 2.4).

Box 2.3 Examples of how traditional medical language can be rephrased to better represent patient-centred care

Traditional medical language	Patient-centred alternative
Doctor tasks	
Takes a history	Elicits a patient's medical history
Consents the patient	Records the patient's treatment choice
Deals with emotions	Responds to the patient's emotions
Manages the patient	Provides treatment
Discharges the patient	The patient leaves hospital
Patient tasks	
Gives consent	Makes a choice
Complies with treatment	Takes treatment
Tolerates treatment	Does not experience unacceptable side-effects
Description of patient	
This elderly primigravida	Mrs Olivia Leonard, who is pregnant for the first time
This multimorbid obese 42-year-old	Ms Rowena Rios, who is living with obesity and other long-term medical conditions
This poorly controlled diabetic	Mr Mason Harper, who is living with diabetes and has a high HbA1c

Box 2.4 Types of medical jargon

Type	Content	Examples
Technical terminology	Disease names, symptoms, anatomy, procedures, tests, treatments	*Adenocarcinoma, teratogenic, abdominal wall, endoscopy, stoma, radical prostatectomy, cholecystectomy*
Alphabet soup	Acronyms and abbreviations	*INR, CABG, BP, DNAR, DVT, PRN, U&E, TTA, PR, IM, AF, IV*
Medical vernacular	Words that seem familiar, but medical meaning may not be understood	*Biopsy, sepsis, sexually active, steroids, tumour, best interests, palliative, do your bloods, first-line treatment, conservative management*
Medicalized English	Words that have a different meaning in medicine	*Capacity, disease, chronic, drugs, theatre, occult, benign, F1* Includes 'accidental antonyms': *'positive' result, progress (tumour is progressing), advance (cancer is advanced)*
Unnecessary synonyms	Overcomplicating by replacing universally understood terms	*Upper/lower extremity, futile, take orally*
Euphemisms	Attempts to soften language that provide less clarity	*Shadow on X-ray, mass, lesion, growth, stool*
Judgmental jargon	Phrases appear derogatory or reflect bias	*Complains of, refuses treatment, denies, failure to progress, acopia*
Scary jargon	Words that imply violence or invoke troublesome imagery	*Strangulated, invasive treatment, organ harvesting, expose the abdomen*
Headings jargon	Tasks are presented without translation	*Does anything alleviate or exacerbate the pain? Is there anything associated with that? Does the pain radiate? We need to determine capacity.*
Depersonalizing jargon	Language that does not treat the patient as a person with agency	*You were diagnosed with, admit you, manage you, discharge you, send you for a procedure*
Official jargon	Presents the doctor as a detached professional, not in collaboration with the patient	*Most cases of, many patients with, upon further investigation, because of confidentiality issues, I must adhere to professional guidance*

Adapted from Pitt MB, Hendrickson MA. Eradicating jargon-oblivion: a proposed classification of medical jargon. *J Gen Intern Med.* 2020; 35(6):1861–1864.

The way doctors use medical jargon in the consultation can cause problems in communication. For example, a consultation that begins with, 'The biopsy showed non-Hodgkin lymphoma. Have you heard of that?' is foreign and does not provide the required information *('is it cancer?')*. The way the information is presented also implies that the patient should understand, and the preferred answer (following normal conversational rules) to such a closed question is: 'Yes'. The patient, already worried, now feels further disempowered. Explanations that inform and empower the patient start with what the patient already knows and take place in the language that they speak (lay language). This is termed 'given before new'. Providing the patient with the medical name of the condition/test/treatment is helpful (and empowering) in the right place in a consultation, such as following an explanation ('…this is called non-Hodgkin lymphoma'). When considering whether communication is respectful, clear, compassionate, and empowering, language must be considered in its entirety, not just according to the presence or absence of isolated jargon.

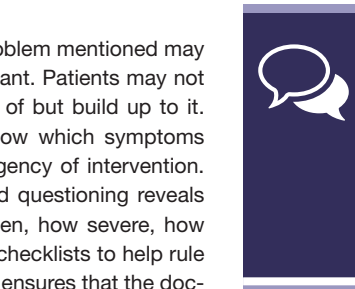
LEARNING CLINICAL COMMUNICATION

The development of effective clinical communication skills is a lifelong process, starting in medical school and ongoing throughout professional practice. It is iterative: building knowledge and skills and revisiting them over time. It draws on the learner's existing social and communication skills and emotional intelligence, as well as their lived experiences (e.g., cross-cultural communication, grief, parenthood, making difficult choices). The purpose of communication education is to enable the learner to use their natural skills to best effect in institutional communication. Clinical communication has a direct effect on healthcare outcomes with potentially long-lasting implications: consultations qualify as high-stakes interactions.

Key domains for learning include the following:

- *Core principles for an effective medical consultation.*
  Understanding the key features of effective communication and having the skills to achieve them. This includes building a working relationship, establishing the purpose of the meeting, developing a shared agenda, exchanging information effectively, supporting decision-making, and providing emotional care.
- *Responding to specific situations.*
  Having frameworks for conducting effective consultations in a variety of situations, including routine, sensitive, and difficult issues.
- *Being responsive.*
  Adapting communication style to meet the diverse needs of patients, relatives, and colleagues, in different settings and through different media (e.g., face to face, telephone, written, online).
- *Communicating beyond the patient.*



Communicating effectively with colleagues and healthcare systems.

Evidence-based core skills for some tasks are shown in Boxes 2.5–2.13.

Initiating a consultation

Investing in the beginning is important (**Box 2.5**). At the beginning of a consultation, the patient expresses their needs, helping the doctor understand what to address. A social greeting that includes introductions by name signals that the patient is a person (not just a body or medical condition). This is not the same as confirming the patient's name and date of birth. The successful *#hellomynameis* campaign, which encouraged all healthcare staff to introduce themselves, was initiated by a doctor who was also a patient who was terminally ill with cancer, who was shocked by the frequent absence of this basic component of communication.

Ending a consultation

The closing phase enables the patient and doctor to check that the purpose has been accomplished and confirm the decisions that have been agreed (**Box 2.6**). The time required will vary depending on the complexity of the content. Concise reiteration of important points (key information, decisions made, agreed next steps) capitalizes on the recency effect in memory, which aids recall. It also acts as a safety net to prevent misunderstanding. This is important for patients, often unfamiliar with medical settings, for whom information exchanged can be difficult to recall.

Gathering information

Gathering information to establish patient needs is best done in two stages: establishing the full problem list, followed by detailed questioning (**Box 2.7**). The first symptom or problem mentioned may not be the only problem, nor the most important. Patients may not start with the symptom they are most afraid of but build up to it. Furthermore, patients do not necessarily know which symptoms are diagnostically useful or determine the urgency of intervention. Once the problem list is established, detailed questioning reveals the comprehensive picture: what, where, when, how severe, how long, and how often. The doctor may deploy checklists to help rule in or out diagnoses. This two-stage approach ensures that the doctor captures the full problem, avoiding omissions through premature selective questioning. Sometimes called the 'open to closed question cone', this approach is reassuring to patients who feel listened to in the first stage and that the doctor is being thorough in the second stage. It is also effective in gathering information.

Sharing information

Patients generally expect information about (1) what is wrong, (2) what can be done, and (3) what the outcome will be. It helps to organize a consultation structure around these points. However, the patient may also have specific concerns; for example, whether the condition is serious or how soon they can get back to work, and more. Tailoring

Box 2.5 Core skills for initiating a consultation

- *Physical setting:* Ensure a suitable space with sufficient privacy to maintain confidentiality and dignity, with extraneous noise and distractions minimized.
- *Sit down:* Be at the same eye level, ideally both be sitting down. Do not stand over the patient talking down onto them.
- *Introductions:* Greet the person by their preferred name. Explain your name and role.
- *Agenda setting:* Ask the patient's aims for the consultation, explain your aim, and agree on joint aims. Clarify what will be covered and how (expected duration and format).
- *Establish rapport:* Begin to build a professional relationship, signal your curiosity, develop rapport, and use empathy.
- *Orient the patient:* Show consultation structure, e.g., when moving on to the next stage, signpost the transition.

Box 2.6 Core skills for ending a consultation

- *Orient the patient:* Signal transition to the closing stage; indicate that you have covered everything you need to and check whether there is anything more they need to add.
- *Revisit the purpose:* Check that the agenda has been addressed and note any aims not yet been accomplished.
- *Summarize:* Outline key information exchanged, decisions made, and plans agreed.
- *Next steps:* Ensure that what happens next is clear.
- *Close:* Thank the person and end the meeting.

Box 2.7 Core skills for gathering information

1. *Establish the full problem list*
   - Start with an open-ended question: ('Can you tell me why you've come to the clinic today?')
   - Listen in full to the person's opening statement.
   - Encourage a full description of the problem. Reflect back: ('…going on for a month', 'That's worrying you'). Use facilitative statements: ('Tell me more').
   - Listen actively and signal attention: eye contact, nodding head.
   - Encourage the person to hold the conversational floor. Use minimal encouragers: ('Mm-hmm.')
   - Focus on open-ended questions to achieve an overview.
   - Be careful about using the word 'symptom': ('Is there anything different that you have noticed about your health?', 'Are there any other problems you would like to mention?')
   - Note each problem to keep track without interrupting the flow.
   - Ask if there is anything else. Keep asking until the person says no.
   - Clarify the patient's goals.
   - Summarize key points.
2. *Detailed questioning*
   - Use signposting to orient the patient as to what you are going to ask about and when you are changing the topic.
   - Use a balance of open and closed questions.
   - Avoid jargon. Clarify jargon used by the patient or any part of their description that is not clear.
   - Adapt to the number of questions: different people require different numbers of questions to give you the same information.
   - Avoid leading questions *('You've never had this before?')* and multiple questions *('Have you ever had epilepsy, diabetes, rheumatic fever, stroke, heart attack, or any serious childhood illnesses?').*
   - Remember that people need time to digest each question and time to answer.
   - Listen to the answers.
   - Show receipt of information: acknowledging what the patient has said, reflecting it back, summarizing from time to time.
   - Before asking questions about sensitive issues or issues the patient might not expect to be asked about, give a brief explanation of why you need the information. Do not say that all patients are asked these questions unless it is true.
   - Identify the patient's perspective and goals and include worries and what they hope will be achieved by treatment.

information to the patient's starting point and responding to specific concerns are key. Sharing information is a process most effective as a dialogue, rather than a download (**Box 2.8**).

UK guidance states that doctors must:

- Give patients the information they want or need in a way they can understand.
- Work in partnership with patients, sharing the information they need to make decisions about their care.

It is helpful for the doctor to appreciate that:

- much of the information they are sharing (diagnosis, treatment, prognosis) will be new and unfamiliar to the patient
- medical information is often complex (new concepts and language used)
- the outlook may be uncertain and involve risk; there is rarely a straightforward route that provides a complete cure with no downsides
- being ill and navigating healthcare is stressful, generating fear, worry, and other emotions; this can make hearing and using information difficult

Box 2.8 Core skills for sharing information

Plan before the consultation:

- Know what information you need to share.
- Consider how to phrase it.
- Anticipate what information the patient may want and questions you might be asked.
- Identify a strategy to support the patient in recall, e.g., having a relative or friend present, recording the consultation, using a trusted resource.

During the consultation:

- Signpost the reason for the meeting and agree on shared aims for the consultation.
- Determine what the person knows at this point and what they want to know prior to any explanation.
- Give an overview of the agreed agenda, e.g., you are going to explain what the problem is, treatment options, and likely outcomes. Highlight if decisions are to be made in the consultation.
- Encourage the patient to guide the consultation by asking questions throughout (not just at the end).
- Given before new: start with what the person already knows and build up from there.
- Provide information about conditions, tests, procedures and treatments in lay terms first, then append with medical names. Write down or record medical names for them to take away.
- Ensure your language is understandable.
- Give information in small chunks and check that the information is clear and meets patient needs.
- Offer to repeat any or all information at key points, e.g., at the end of each segment and/or at the end.
- Check throughout that explanations are clear. Use non-verbal clues and ask directly: *('Would you like me to go over any of that again?')* Do not use loaded questions: *('Do you understand?')*
- Use signposting throughout to keep track of where you are in the consultation plan.
- Make sure the patient has all the information they need about the diagnosis before discussing treatment.
- Respect the patient's right to information; do not withhold information because you are worried it might upset the patient.
- Listen carefully to concerns and queries and respond fully to these.
- Towards the end, ask the patient to tell you what they have understood *('Would you like to go through how you will explain this to your partner/family when you get home?').*
- At the end, summarize the agreed plan including immediate next steps. If a plan has not been achieved, summarize to the point you have reached.

- the patient must make the right decision for themselves, often in an unfamiliar environment and sometimes under time pressure
- responding to patients' concerns and queries is integral to dialogue; a treatment plan requires understanding and agreement.

Discussing uncertainty and risk

Outcomes may be uncertain, and some treatments carry the risk of harm through side-effects or complications. Patients may therefore have to make decisions based on incomplete or probabilistic information including:

- a balance of likely benefits and risks for the individual
- the severity of any harmful effects.

There are different types of uncertainties that require different approaches:

1. Uncertainty that can be resolved.

   Explain what can be done to get the required information; for example, benign and malignant cancers distinguished by biopsy.
2. Uncertainty that cannot be resolved.

   It is not possible to know what will happen when the decision is made; for example, a choice of treatment options that may or may not provide a cure. It is important to acknowledge the stressful nature of uncertainty and to provide emotional support.

Uncertainty and potential harm are unsettling and can be distressing. People often hope for certain news of a positive outcome, and its absence is a form of bad news. Skills for discussing uncertainty and risk are required (**Box 2.9**).

Shared decision-making

Shared decision-making (**Box 2.10**) enables a person to develop an informed preference. People are often unused to making healthcare decisions. They may have expectations about what is to happen, and/or preferences about what they would like, but an informed decision cannot be made without the details of options and consequences. An informed preference is the patient's choice after being given the information they want and need, and the opportunity to consider implications in the context of their own circumstances and values. Depending on the complexity of the decision, this process may happen during a single consultation, across more than one

Box 2.9 Core skills for discussing uncertainty and risk

- State clearly that there is uncertainty and/or risk.
- Outline the decision clearly.
- Acknowledge that deciding in the face of uncertainty or risk is difficult and stressful.
- Offer partnership and support.
- Itemize options explaining likely benefits, harms, and uncertainties.
- Present information about risks and probabilities clearly:
  - Use natural frequencies not percentages, e.g., '3 out of 10 people' (not '30%').
  - Use small denominators where possible, e.g., '1 out of 10 people' (not '10 out of 100').
  - When comparing options, present 'like with like' comparisons, e.g., '2 out of 10 compared to 4 out of 10' (not '2 out of 10 compared to 2 out of 5').
  - Avoid relative risk (e.g., 'twice as big').
  - Be wary of describing risks only using words (such as usually, rarely, normally, or sometimes).
- Describe risk information about benefits and harms neutrally; avoid positive or negative bias.
- Supplement explanations with pictures such as icon arrays.
- Provide access to resources that the patient can take away.

consultation, or during blended care with access to decision aids either before, during, or after consultation. Decision aids/support tools are resources developed to support shared decision-making. They contain three components:

1. A clear statement of the decision to be made
2. Evidence-based information about options, benefits, harms, and uncertainties
3. Help to enable the person to clarify their values and preferences

Patient autonomy is facilitated by providing the required information about available options and supporting the patient in navigating options to make their choice. There can be a misalignment between a person's wish to decide and their confidence to do so, for example, due to an unfamiliar environment, new and complex information, worry about health, and worry about the 'right' decision. Doctors may query how to ensure autonomy when a patient is hesitant about deciding and wants to defer to a doctor's opinion. Most patients do want a professional opinion; the consultation is a meeting between experts (**Box 2.1**). If the patient concurs with the doctor's recommendation, it is not a failure of patient autonomy provided the patient has made an informed choice. Likewise, if the patient disagrees, it is not a failure of care provided when the patient has made an informed choice. More deliberation and support may be required if the choice is not straightforward. People may be more likely to defer to a clinician when seriously ill, but the patient must live with their decision in the long term, and it must be right for their needs. Uncertainty and fear reduce a person's confidence in decision-making; time and support increase confidence. Providing a support structure for decision-making (e.g., by using a decision aid and ensuring that the patient is not rushed) leads to better information and a choice that aligns with what matters most to the patient. Support is integral to this process; decision-making is not just about information. Patients appreciate reassurance that they do not have to make sense of options by themselves and decide on their own. When there is no treatment option that can deliver the goal the patient wishes, emotional support, acknowledgement, and empathy are essential.

Breaking bad news

Doctors have to share information that has a profound effect on patients, including many different forms of significant loss: news about death, serious illness, and life-changing injury. Patients and families need:

- information that is clear, personalized, and complete
- emotional support.

Box 2.10 Core skills for shared decision-making

Establish the decision-making team:
- Signpost: Explain the decision to be made.
- Support: State that you will work together to make a decision that is right for the patient.
- Explore: Find out what the patient knows and wants to achieve, and what questions or concerns they have.

Discuss the options:
- Share: Provide information about treatment options, potential benefits, potential harms, and uncertainties. Include the option of doing nothing.
- Supplement: Consider a written summary of information or decision support tool or decision aid.

Decision-making:
- Support: Ask the patient about their priorities and needs *('What matters most to you?')*, their thoughts and preferences based on the information provided, and their readiness to decide.

The principles of effective information sharing are amplified when the news is not good (**Box 2.11**). These consultations need more preparation, more attention to broaching the news, a slower delivery, continued vigilance about clarity, and a heightened sensitivity to emotions. The principle of patient autonomy applies; the patient has the right to be given information and to make decisions. Information should not be withheld because it might be upsetting (or because it is uncomfortable to deliver). In many consultations, including bad news consultations, patients and those close to them expect to be told key information without having to ask; it is important not to rely on the assumption that if a person has not asked about a particular topic (such as prognosis), they do not want to know about it.

Patients who receive bad news may remember little else about the rest of the consultation. The more serious the news, the less

Box 2.11 Core skills for breaking bad news

Prepare:
- What information do you have to give:
  - What is the bad news?
  - What are the implications for the person and their family?
  - What is the 'big picture', the overview that you need to convey?
  - What is the 'detail' that you will cover later?
- How will you phrase it?
- Anticipate questions.
- Prepare the setting: private, quiet, free from distractions and interruptions.

Broach:
- Establish the purpose of the consultation and signal its significance.
- Find out what the person already knows and what they want to know.
- Signal that there is bad news by using a warning shot *('The results of the tests are not good'; 'I'm afraid that it is serious')*.

Share:
- Given before new: start with what the patient already knows and provide new information one step at a time.
- Signpost each stage: bad news, implications, big picture, detail.
- 'Chunk, check, pause': give information in pieces, check that the pace and pitch of the explanation meet the person's needs, and pause after every segment leaving longer gaps than usual.
- Use clear words: *cancer, death, cannot be cured, not long to live.*
- Avoid jargon or euphemisms: *malignancy, tumour, lesion, shadow, not curative, palliative.*
- Check if a person is ready for a particular topic: *('There is more information I can give you about what will happen in the future. Would you like to talk about that now?')* Avoid vague questions: *('Are you the sort of person who would like to have all the information?').*
- Answer direct questions with direct answers.
- Be alert to cues that the person wants more information: indirect questions (which may be expressed as statements), expression of concern or other emotion, *('The doctor last time said that if it came back again it wouldn't be good news'); ('I'm worried about what this might be').*
- Give the person time to take the information in and time to be upset.
- Patients and relatives appreciate reassurance and hope, which must be honest.
- Sitting in silence with the person can be supportive.
- It is appropriate to say: *'I'm sorry'*. Do not say: *'I'm sorry to have to be the one to tell you'* (as this is about your needs, not theirs).

Plan:
- Offer time: ('We don't have to make a decision right now').
- Be responsive to cues about when to end the consultation; be flexible about what is covered.
- Keep any plans discussed clear and simple.
- Write information down.
- Provide contact information.

information a doctor will be able to provide in a single meeting. This impacts decision-making. Many patients are not in a position to make informed decisions immediately after receiving bad news. The patient may have heard the information but may not have fully processed it or be able to use it effectively. The doctor can provide support and reduce pressure by encouraging the person to take time and discuss the news with those close to them. However, this is not absolute; some patients may be immediately ready to make plans, either because they were expecting the news, or because the full emotional impact is delayed. Emotional reactions are not immediate and predictable but varied, including all kinds of emotions and none at all. The full emotional impact may come later, over time, rather than at a single point.

Other difficult conversations

Breaking bad news is typically viewed as the most difficult conversation a doctor may have, but other challenging topics include stigma, trauma, death, bereavement, and end-of-life care (**Box 2.12**).

These consultations can be difficult or sensitive due to the following:

- Topics that can elicit strong emotions, including shame, grief, fear, anger, and guilt. For example, sexual abuse, termination, terminal illness, addiction, sexual health, sexuality, domestic violence, suicide, obesity, and medical error (**Box 2.13**).
- Circumstances of the consultation. For example, absence of trust, worry about confidentiality, assumptions or judgment, or a doctor who is ill-equipped to respond to patient needs.

People can feel vulnerable when disclosing sensitive topics. The doctor may be the first person to whom the topic has been disclosed. In these conversations, it is particularly important to develop trust and rapport and to ensure that the patient feels safe, supported, and not judged. The basic elements of difficult conversations are the same as for any doctor–patient interaction: establish patient needs, listen, foster a respectful partnership, and work together to devise a plan. However, in these consultations, certain elements may be modified; for example, the patient may need more time for disclosure, or there may need to be a focus on listening and exploring to avoid premature solutions.

Remote consulting

Delivery of healthcare through remote means (telemedicine) has increased in recent years, in particular the number of doctor–patient consultations conducted at a distance, including video conferencing, phone, or written communication (email, messenger services, online platforms).

Remote consulting can be conducted:

- synchronously (in real time), e.g., by phone.
- asynchronously (not at the same time), e.g., by email.

Consultations can be conducted using one or more of the following methods:

- simple (single method), e.g., phone.
- augmented (more than one method), e.g., phone, with the patient sending a photo of a rash by email.

The question as to which is better, face-to-face or remote consulting, is a false dichotomy, as it depends on circumstances, including:

- the patient's clinical need
- whether physical examination is needed
- availability of medical records
- whether the care required can be provided through that method, e.g., sharing of information, tests, and treatments.

Box 2.12 Example framework: discussing end-of-life care

Before the consultation:	
Consider potential topics	Pain, dignity, the experience of dying, the effect of bereavement on loved ones.
During the consultation:	
Develop trust and rapport	Signal willingness to talk about issues that matter to the patient. Reassure about confidentiality. Spend time listening. e.g., *('You said you are anxious about what will happen nearer the time. Would you like to talk about that?')*
Pick up cues	Reflect back topics raised e.g., *('You said that you have never been there when someone has died. Are you worried about what dying will be like?')*
Explore	Ask about: • questions the patient has • worries • hopes • plans in the time left • who supports them • e.g., *('Have you talked with your family about who will be there with you?')*
Respond	• Listen and provide space for the patient to think things through (without providing advice) • Acknowledge difficulties or dilemmas • Provide/direct to information and/or practical support • e.g., *('You want to talk about dying, but you do not want to upset your family').*
Signal support	• Normalizing: signal that others have had the same experience. • Show that you are non-judgmental. • e.g., *('Many people worry that medication for the pain might affect their thinking'), ('You are angry that this has happened and that your life is being cut short.')*

Care may start with one method and then be augmented or switched. It may become apparent during a remote consultation that a physical examination is required, or care provided initially in a healthcare setting may be successfully followed up remotely. Neither face-to-face nor remote consultation is preferred by patients. Patients value choice, and what matters most will depend on the individual situation, including convenience, time off work, comfort in discussing sensitive issues, and privacy. Likewise, suitability varies, depending on the patient's digital access, sensory or cognitive impairments, and learning needs. Methods of remote consulting have advantages and disadvantages:

- Telephone is readily available, portable, and convenient but provides impoverished non-verbal communication.
- Video conferencing allows non-verbal communication, but it is more prone to technical and privacy issues and not everyone has access.

Box 2.13 Example of a framework for discussing medical error

Initiating the meeting
- Explain the purpose: to discuss a problem that has occurred with the patient's care.
- Listen to the patient's concerns about the care received.

Explanation
- Disclose clearly that a mistake or error has been made (not a 'complication', 'problem' or 'adverse event').
- Accept responsibility (do not be defensive, do not blame other staff or the patient's condition).
- Say sorry for the event; do not 'express regret' or say *'I am sorry to be the one to tell you.'*
- Provide a clear explanation of what happened.
- Explain the consequences of the mistake or error, both short term and long term.
- Explain what will be done to rectify the patient's situation.
- Provide reassurance about the steps being taken to ensure that the patient's future care will not be compromised.
- Explain what has been done to ensure the same mistake will not happen to anyone else.
- Provide clear information about complaint procedures and timescale.

Throughout the meeting
- Provide information that is honest, truthful, clear, and jargon-free.
- Answer questions honestly and in full.
- Empathize and acknowledge emotions that the patient expresses.
- Remain calm and professional.

Closing
- Check that the explanation has addressed the patient's needs.
- Summarize and agree on a plan.

- Written methods are convenient and give time to patients and doctors to prepare responses but may result in loss of nuance or focus or important omissions.

People communicate differently remotely, which is not inherently better or worse in terms of accomplishing the aims of doctor–patient communication. For example, phone consultations deprive the participants of eye contact and non-verbal cues. However, this may be compensated for by other means; for example, asking about the impact on the patient's life. Likewise, a patient may feel more comfortable discussing a sensitive issue in familiar surroundings. Remote conversations are often shorter than face-to-face equivalents due to natural differences in pacing and interaction style. This is not a problem in itself. However, shortcuts in care (e.g., a less thorough assessment of the patient's problem) do compromise quality. The key is to be vigilant to changes in communication and their impact (**Box 2.14**).

Electronic written communication tends to be used for:
- straightforward discussions: minor problems and reviewing existing treatment
- exchanging routine information: repeat prescriptions and routine results.

Written communication has the immediate advantage of being self-documented, so patients and doctors can refer back to the information. It can improve outcomes by enabling information exchange beyond the single 'event' of a consultation; for example, asking for additional information, confirming details and providing instructions. Helpful 'ground rules' include:
- an agreed turnaround time
- the types of topics it is to be used for, and when this mode of consulting is not appropriate
- how to seek help for urgent problems
- procedures to ensure confidentiality.

Box 2.14 Core skills for remote consulting

Before the consultation
- Check that the method selected is appropriate for the patient's needs, e.g., closed captioning for a patient with hearing loss.
- Ensure that the patient is given clear information about how to prepare including timing, duration, format, privacy and how to be 'called in'.

During the consultation
- Check technical quality: sound, picture, and time lag.
- Check confidentiality: does the patient have a private space? Is there anyone else in the room, e.g., a family member or children?
- Check consent: is the patient able to agree to a consultation in this format?
- Be aware of any differences in communication: pace, turn-taking, non-verbal communication, cues, and emotional tone that affect the achievement of the consultation aims.
- Consider how to support the patient to recall and use information in the absence of usual resources like information leaflets.

People also communicate differently in written form. Be mindful of the tone, clarity, level of language, and the way emotions may be expressed.

Communication with colleagues

Communication about patient care with colleagues is as important as communication with patients. It facilitates the exchange of the right information, ideas and plans at the right time with the right people. Healthcare relies on communication between healthcare staff and within healthcare systems. Both are needed for safe and effective care.

Communication in healthcare systems

Systems must meet requirements for accurate and timely information exchange and recording and retrieval of information across healthcare providers. Contemporary healthcare is multidisciplinary and delivered over time. Delays, omissions, and loss of information lead to unsafe care, medical errors, and complaints. The system may fail to meet its goals due to:
- system design: lack of clarity in how healthcare teams share information
- system operation: inadequate technology, staff shortages, and delays, leading to additional work to compensate for system failures.

24 Clinical communication

Communication between healthcare staff

The principles of effective communication apply to interprofessional communication. Colleagues want and need to be listened to, to be respected, and to have self-efficacy. Communication is most effective when there is:

- a clear shared agenda
- a common language
- orientation through signposting
- exploration that establishes a full problem list
- sharing of information by 'chunking and checking' and summarizing
- an agreed plan.

Communication problems between colleagues can be traced back to a failure of these principles. Similar to doctor–patient communication, communication with colleagues is a form of institutional communication. Structured protocols adopted for these interactions improve accuracy and efficiency.

SBAR communication tool

This provides a structure for colleagues to exchange information about patient care, which can be used within and between healthcare teams and with external agencies. Necessary information is shared in four domains:

S—Situation: the problem or concern
B—Background: significant information from the medical history/admission
A—Assessment: clinical impression and test results
R—Recommendation: what is needed

These domains can also be used to receive information by using questions to elicit each domain.

WHO Surgical Safety Checklist

A structure to ensure that key tasks are completed during surgery/procedures. It includes three stages:

- Before anaesthesia: confirmation of identity, site marking, machine and medication check, allergies, and airway and blood loss risks
- Before an incision: team members, patient name and procedure, antibiotics, anticipated critical events, and imaging
- Before the patient leaves the operating room: instrument count, specimens, and key concerns for recovery

These protocols work to improve the quality and safety of care by:

- providing a structure that is clear to all participants and
- ensuring that all participants are heard

which are important features of all healthcare communication.

CORE SKILLS AND KNOWLEDGE

The practice of medicine is a human and moral endeavour concerned with forming therapeutic relationships with patients. It is crucial for everyone practising medicine to understand the moral and legal framework that underpins and regulates their work. In clinical practising, ethical and legal decisions are made daily by clinical teams working with patients and, where appropriate, involving their families. Increasingly, hospitals have clinical ethics committees to discuss complex ethical cases. Hospitals may also seek a legal opinion for more challenging cases that involve a point of law. If situations are contested and disagreement seems intractable, the courts will occasionally be asked to give a decision about whether a planned course of action is lawful or unlawful. All clinicians need to understand key ethical and legal principles to ensure that their clinical practice meets the standards of the profession.

Key learning in ethical practice includes:

- Recognition of the need for ethical judgement
- Identification of ethical and legal issues in modern clinical practice
- Identification of the relevant ethical values and principles from the perspective of each stakeholder
- Application of ethical values and principles in clinical decision-making.

ETHICAL PRINCIPLES OF MEDICINE

The subject of ethics incorporates knowledge, cognitive skills such as reasoning, critique, and logical analysis, and skills for integrating and applying abstract ethical learning with clinical learning. Students and clinicians need skills and knowledge in ethics to enhance daily practice and better serve their patients.

The practice of medicine is inherently moral:

- Biomedical expertise and clinical science must be applied by and to people
- Clinical decisions are underpinned by values and principles
- Potential courses of action will have implications and consequences that are often uncertain
- Technological advancements sometimes have unintended or unforeseen consequences
- Patients and clinicians come from diverse backgrounds, creating potential for different moral values and divergent opinions

Ethical reasoning involves thinking through the available options and weighing the relative merits logically and thoroughly. Becoming, and practising as, a clinician demands an awareness of, and reflection on, ethical attitudes. Each of us has personal ***values*** and moral intuitions. In the field of ethics, a necessary part of learning is becoming aware of the assumptions on which these personal values are based, reflecting on them critically, and listening and responding to challenging or opposing beliefs. There are some key ethical concepts that can help with this process.

Duties

The General Medical Council (GMC) creates the moral framework for medicine in *Good Medical Practice*. It provides a list of duties a doctor registered with the GMC is expected to uphold. Although the list is pragmatic, the **duties** of a doctor describe ethical practice including truth-telling, maintaining confidentiality, and acting in a trustworthy way. These are duties that have traditionally been accepted as part of the core values of the profession, duties that all doctors ascribe to by virtue of taking up the role of being a doctor. We should be able to justify these duties independently of any good consequences that come from having such duties, for if we rely on consequential justification, and the consequences can be framed negatively, then duty dissolves. For instance, in the paternalistic practice of medicine, the duty to tell the truth was often set aside due to the consequences of truth-telling and a belief that the patient would be harmed by the truth of a terminal diagnosis. Justification for the duties of a doctor includes the fundamental need to respect patient autonomy and dignity. Doctors have absolute duties, such as refraining from killing patients. They also have context-specific duties, like giving appropriate clinical care in accordance with evidence-based practice. A focus on the moral duties of a doctor comes from a philosophical tradition known as deontology.

26 Medical ethics

Consequences

One key aspect of being a clinician is the ability to **calculate benefits, risks, and harms** and communicate them in such a way that patients and colleagues can understand and make decisions based on the information provided. Each patient interaction has the potential to bring about a range of outcomes, some foreseeable, some not so foreseeable. Prescribed medication, invasive procedures, research, prolonged waiting lists, and miscommunication between colleagues each have consequences that clinicians need to be able to calculate. In an ethical sense, consequences need to be weighed in terms of maximizing benefits for the patient and minimizing harm. It is recognized that the practice of medicine exposes patients to potential harm, but clinicians have an ethical duty to minimize harm and to explain when potential harm exists so that patients can make informed choices about the level of risk acceptable to them. Research ethics procedures formalize the process of calculating and minimizing risks by requiring researchers to complete ethical evaluations of their intended study and submitting these to research ethics committee scrutiny in order for permission to be granted for the research to take place. The principles of informal weighing of risks and benefits apply to all aspects of clinical practice. A focus on the consequences of healthcare comes from a philosophical tradition known as consequentialism.

Values

We expect clinicians to have a strong set of ethical values, even if there is debate about which values these should be. Contemporary discussions about professional values include the use of social media, remote consultations, and working under pressure. In whatever context we practice, the professional values of a clinician stem from characteristics that are seen as key to being the sort of clinician we would want to treat us and our family. The focus on duties and consequences centres on 'What should I do?', but the focus on values centres on 'What kind of person should I be?'. Generally, we desire clinicians who are trustworthy, compassionate, critically engaged, and good communicators. We want to work with colleagues who exemplify these values. We seek these qualities not because they are a clinician's duty, nor because they are seen to bring about the best consequences, but because these qualities exemplify who a clinician is. A clinician may or may not fail in their duty and negative consequences may or may not result, but excellent procedural skills without honesty, integrity, and compassion leave us with fundamental questions about what kind of person this clinician is. Values are not prescriptive, like duties and consequences. They exist on a spectrum, making room for the wide variety of personality types who make up the medical profession. Each clinician can have their own set of personal values that still conform to an agreed-upon set of expected values. Values that are not acceptable sit outside this spectrum. A focus on the values of a clinician comes from a philosophical tradition known as virtue ethics.

Frameworks and tools

Frameworks and tools can be useful in applying ethical theory to clinical practice. Perhaps the best known is the ***'Four Principles'*** approach:

- ***autonomy:*** 'self-rule', letting competent patients make their own choices and decisions about what happens to them
- ***beneficence:*** doing good, acting in a patient's best interests to benefit them
- ***non-maleficence:*** avoiding harm
- ***justice:*** treating people equitably and fairly

While this captures the key concepts that are important in clinical care, it offers no way of deciding which principle is most important when two or more principles are in conflict. It may be better to think of the four principles as providing an important linguistic framework for describing ethical concepts, rather than helping to resolve an ethical dilemma. Engaging with an ethical issue in clinical practice depends on a range of factors. We must discern the relevant moral questions and select the relevant ethical tools and theories for each clinical setting.

In clinical ethics, there are often three different dimensions, each interacting together:

Procedural ethics

Procedural ethics identifies which policies and procedures govern clinical situations in your local area. Hospitals have policies on consent, maintaining confidentiality, and following data protection regulations. Research ethics committees provide forms prepopulated with ethical questions for the clinician to answer. Procedural ethics relies on identifying and following appropriate ethical policies and procedures, which have been established in advance, often in response to legal cases and evidence-based practice.

Regulatory ethics

Regulatory ethics are produced by regulators such as the GMC. They set the framework and boundaries of the expectations of doctors and create ethical guidance in a regulatory capacity. This guidance is developed in response to legal cases, public consultation, and select committees. Where procedural ethics sits at a local level, regulatory ethics sits at a national level, providing specific guidance that is to be applied in the local setting. Regulatory ethical guidance can be found on the GMC website. Failure to follow regulatory requirements can lead to legal and professional consequences.

Aspirational ethics

Aspirational ethics focus on the factors that motivate a clinician, alongside the procedures and regulatory guidance that apply to the case. Aspirational ethics are the personal values we bring to our professional practice and want to actualize in ethical dilemmas. It is likened to our internal moral compass, which we would follow even if policies, procedures, and ethical guidance did not exist. Aspirational ethics are the fundamental values we aspire to as we practice medicine. They are formed through a variety of experiences:

- We may have a personal experience of healthcare (positive or negative) that has given us insight into what values we want to exhibit.
- We may have family members who have received healthcare that has left a lasting impression on us, shaping our moral character.
- We may have worked with senior clinicians who have become role models, exhibiting qualities we want to emulate or avoid.
- We may have a faith position that motivates how we see our role as a clinician, providing a framework for personal values that are important to foster.
- We may have sociopolitical beliefs that inform the values we believe should be important in resolving ethical dilemmas.

One or more of these experiences help us to develop aspirational ethics, which are likely to include values such as compassion, fairness, respect, truthfulness, kindness, and patience.

Moral injury and the ethics of self-care

Moral injury is defined as the profound psychological distress that results from actions, or the lack of actions, which violate one's personal moral code. Moral injury can be caused by a discrepancy between the care we want to provide and the care we are able to deliver, or by witnessing acts performed/not performed by others that go against our deeply held moral values. Resource allocation decisions must be made at local and national levels, but the impact these have on clinicians who must explain and justify them to patients and relatives is often overlooked. The daily stress experienced by many members of the healthcare team can lead to moral injury being more likely, as colleagues work under increasing pressure. Self-care in these working environments is an important moral duty for all clinicians. There is increasing awareness that moral injury has a serious impact on staff wellbeing, contributing to burnout. Regular debriefs, peer support and self-care are all important ethical requirements for working in increasingly pressured healthcare environments.

Professional guidance and codes of practice

Along with ethical theories and frameworks, there are professional guidelines and codes of practice. For example, in the UK, the standards set out by the GMC inform the regulation of doctors; if a doctor falls below these standards, disciplinary procedures may follow, irrespective of the harm caused or whether legal action ensues. In other countries, similar professional bodies license doctors and regulate healthcare. All clinicians should be aware of the regulatory framework and professional standards in the country within which they practice (**Box 3.1**).

Ethical practice and professionalism are significant requirements from the earliest days of medical study and training. In the UK, the GMC defines the standards expected of medical students, and all medical schools are required to have 'fitness to practice' procedures. Students should be aware of their professional obligations from the start of their training. Medical students commonly work with patients from the earliest days of their training and are privileged in the access they have to vulnerable people, confidential

Box 3.1 Vignette 1

A newly appointed consultant burns and plastics surgeon, specializing in breast reconstruction, is called to the emergency department to review Lisa, a 54-year-old patient. Lisa has returned to the UK from a European country where she had breast uplift and enlargement 5 days ago. She explains that after rapid weight loss, she was left with breast skin that had lost volume and sagged. She found this very distressing, losing her confidence, staying at home, and becoming withdrawn. A few of her family and friends contributed money so that she could have breast enlargements, but she couldn't afford it privately in the UK, so she went abroad to a clinic a friend had recommended. She reports that she had no immediate complications from the surgery, but on the flight home this morning she became 'uncomfortable'. When she arrived home, she took the dressings down and looked in the mirror. She was horrified to see 'bulging areas' under her breasts.

The clinician notes that Lisa has a temperature of 38.3°C and a heart rate of 124 beats per minute. Examination of the wound reveals that both suture lines are open, exposing the breast implants, which are protruding out of the wounds because they are too big for the pocket that was surgically created. The clinician has seen other patients who have arrived back from the same country with complications of breast enlargement procedures, where implants have been used that do not appear to meet UK safety standards.

The clinician explains to Lisa that the implants will need to be removed because they are causing significant health risks. Lisa is relieved that this will be done and asks that the replacement implants be as large as possible so that her body image will be close to what she was aiming for. The clinician now has the difficult task of explaining to Lisa that she can only remove the implants and she cannot replace them, as no NHS funding is available for enlargement surgery. Lisa becomes distraught. She cannot bear the thought of living without breast enlargement and cannot afford to have it done privately in the UK. The clinician knows that once the implants have been removed, future surgery might be more difficult if left for too long. While they are very sympathetic to Lisa's situation, they cannot comply with her request, as it is against hospital regulations. Lisa asks the clinician to recommend a private surgeon in the UK so that she can start the consultation process for enlargement surgery in the future and worry about finding the money later.

What ethical questions arise in this case?

- What **duties** does the clinician have, and to whom?
- What **consequences** should the clinician weigh, and for whom?
- What should the clinician communicate to Lisa to gain her **informed consent** for surgery?
- What **national and local policies and guidelines** apply to the management of this case?
- What guidelines about **conflicts of interest** apply to this case?
- What **professional values** should the clinician aim to display?
- What steps should the clinician take to deal with any **moral injury** they feel from dealing with this case?
- What principles of this case apply to your practice?

Commentary

This is a complex ethical dilemma. Leaving the implants in place will expose Lisa to risks of sepsis and death. Removing the implants without replacement will affect Lisa's mental health. The clinician consults NHS Trust policy and procedure to guide their decision-making. They access GMC guidance, including information on shared decision-making and conflicts of interest. They are particularly aware that when Lisa asks for a referral to a private surgeon, the clinician is in a difficult situation. Clinicians should not discuss private treatment during NHS consultations, but they can answer factual questions about the availability of private treatment and can inform the patient's GP about the request for information. Requests for second opinions in the private sector should be met unless refusal is clinically justified, which is not the case here.

They evaluate their duties and the consequences of each option they consider for Lisa. Each of those provides the clinician with the information they need to manage this consultation, but aspirational ethics play a deciding factor in how this consultation progresses. Their personal values of compassion, empathy, honesty, and respect for autonomy are expressed through their communication skills in this case. These personal values also help the clinician when they spend time reflecting on this case afterwards. They recognize the importance of using scarce resources appropriately and the need to prohibit breast enlargement on the NHS, but they would prefer to be able to make an exception in a case such as this. They experience moral injury as they reflect on the consultation with Lisa. They decide to refer the case to the hospital clinical ethics committee to ask whether an exception to hospital policy can be considered.

information, and sensitive situations. As such, medical schools have specific responsibilities to ensure that students behave professionally and are fit to study, as well as eventually practice, medicine.

ETHICS OF INEQUALITY

Principles of equality, diversity, and inclusion (EDI) are important in healthcare provision. There is a growing recognition that patients who come from minority communities have worse outcomes. Clinicians play an important role in reflecting on how healthcare can be delivered more fairly. While it is necessary to examine institutional responses to EDI principles, it is also necessary to reflect on choices made in individualized clinical care and research design.

Principles of equality, diversity, and inclusivity

The Equality Act 2010 lays out the legal framework that governs the duties healthcare providers have towards patients and colleagues. The Equality Act uses the concept of protected characteristics, identifying groups of people who are vulnerable to inequalities and need legal protection against discrimination. The protected characteristics are age, disability, gender reassignment, marriage and civil partnership, pregnancy and maternity, race, religion or belief, and sex and sexual orientation. While the law requires that healthcare provision addresses factors that are discriminatory, the ethical duty to consider EDI goes much further. It is not sufficient to avoid discriminatory practices; we need to embrace values that promote inclusivity. One way of doing this is to consider what the aims of healthcare ought to be.

We may assume that a goal of healthcare provision is to ensure that everyone has equal access to the same level of healthcare, no matter their background. In this assumption, we aim to treat everyone the same, without bias. **Equality of access** is an important ethical principle in the NHS. For instance, every person has access to a general practitioner and can attend an emergency department. Having equality of access does not ensure fairness. In some circumstances, patients may need to be treated differently to achieve **equality of outcome** rather than equality of access. Equality of outcome explores ways to assist patients and colleagues to reach the same goals as those who do not need additional support. This may include providing language services, offering 'out of hours' or longer appointments, ensuring correct pronouns are used, and ensuring diverse patient feedback is sought for service improvement. A focus on equality of outcome allows us to identify ways to respect and enhance patient autonomy and build better relationships that lead to better patient outcomes. It allows us to focus on inclusivity, where service provision improves for everyone, including patients with protected characteristics.

One key area that must be addressed to improve equality of outcome is research design, including a full diversity of patients to ensure better representation of participants. Data should be collected that truly represents patient/client groups to ensure that health improvements are experienced by all. If research is conducted with healthier participants who may have different responses to a therapy or service provision compared to groups most in need, the purpose of healthcare is undermined. NHS England has issued good practice guidance for researchers on how to engage with diverse participants and increase involvement with health research.

The concept of protected characteristics encourages us to think about categories of patients, but our true lived experiences rarely fit into a neat category. **Intersectionality** describes how a person's various identities combine to create experiences of discrimination and privilege, advantage and disadvantage (**Box 3.2**).

The NHS Race and Health Observatory has reported overwhelming evidence that racism affects healthcare. They identified five priority areas, namely mental health services, maternal and neonatal healthcare, digital inclusion and access to health services, genetic testing and genomic medicine studies, and ethnic inequalities in the NHS workforce, highlighting best quality evidence, and made recommendations for change. Among those making a substantial impact on inclusivity are medical students and junior doctors, who are raising awareness and providing resources to improve patient care and equality of outcome. *Mind the Gap: Online Clinical Handbook of Signs and Symptoms in Black and Brown Skin* is a collaboration between a medical

Box 3.2 Vignette 2

Monica consults her GP about back pain, which has been getting worse for around a week. Her GP takes a history, completes a physical examination, and reassures her it is nothing serious. They recommend a course of non-steroidal anti-inflammatory tablets taken regularly for 5 days and time off work to allow her back pain time to resolve.

Monica is a Somali refugee. She works as a cleaner. The other cleaners are male and earn more than her. She fears that if she takes time off work, she will be replaced. Her employer does not provide sick pay and she can't afford to take unpaid time off work to rest her back.

Monica lives in a flat with Jo. Monica's parents have recently learnt that Monica is in a relationship with Jo. They strongly disapprove of their daughter's same-sex relationship, as it is frowned upon in their community. They have become hostile to Monica and no longer speak to her.

What ethical questions arise in this case?

- What ethical **duties** does the GP have?
- What **consequences** should the GP weigh?
- What **national and local policies and guidelines** apply to the management of this case?
- What **professional values** should the GP aim to display?
- What factors should the GP consider with regards to **protected characteristics**?
- What issues of **intersectionality** does this case raise?
- What principles of this case apply to your practice?

Commentary

If the GP focuses on Monica's clinical presentation of back pain, without understanding her lived experience, Monica may have a worse outcome. Intersectionality enables us to understand Monica's situation beyond her initial presentation. In terms of protected characteristics, Monica's race, sex, and sexual orientation create multiple factors for discrimination and disadvantage. Being unaware of these can lead to Monica experiencing deteriorating mental health. While the GP cannot resolve each of the situations Monica faces, taking a broader social history can identify ways that Monica can talk about her lived experience and be referred for specific support at a local level. In this location, there was an active community voluntary sector support group for asylum seekers and refugees that ran social activities which Monica found interesting. She was keen to join a support group and talk with women who had similar experiences to her. This meets the ethical duty to respect patient autonomy and dignity more fully than solely concentrating on her presenting condition.

student and clinical skills teachers, which addresses the lack of diverse clinical images needed by clinicians to make accurate diagnoses in patients with darker skin tones. A new generation of medical students and junior doctors are being trained with a focus on inclusivity, with increasing access to inclusive resources. This will hopefully raise ethical standards of healthcare and improve patient outcomes.

LEGAL AND ETHICAL ISSUES IN MEDICAL PRACTICE

The law establishes boundaries for what is deemed to be acceptable medical professional practice. In the UK, along with other jurisdictions, both ***statutes and common law*** apply to the practice of medicine. Statutes are made by parliament, while common law is built up out of precedent set by judges in their rulings on previous cases. There are some legal differences between England and Wales, Scotland and Northern Ireland. Most cases involving healthcare arise in the civil system, where patients seek financial compensation for harm they have experienced. Occasionally a case is subject to criminal law, for example, when a patient dies in circumstances that could constitute manslaughter.

Respect for autonomy: capacity and consent

Capacity

Capacity is central to ethical decision-making because it is the gateway to self-determination (**Box 3.3**). People can make choices only if they have the capacity to do so. The presumption is that patients over the age of 16 have the capacity to make their own decisions unless evidence exists to the contrary. Assessing capacity is a significant ethical undertaking: a patient's freedom to choose depends on it. In England and Wales, the Mental Capacity Act 2005 sets out the criteria for evaluating whether a person has the capacity to make a decision. In Scotland, the Adults with Incapacity (Scotland) Act 2000 applies. In Northern Ireland, the Mental Capacity Act (Northern Ireland) 2016 applies.

Evaluating capacity is not a one-off judgement. Capacity can fluctuate and assessments should be reviewed regularly. Capacity is decision-specific, time-specific, and task-oriented. People may have the capacity to make some choices but not others, and capacity is not precluded by specific diagnoses or impairments such as dementia. The communication style of a clinician can enhance or diminish a patient's capacity, as can pain, fatigue, and the environment.

Box 3.3 Principles of self-determination[a]

- Every adult has the right to make their own decisions and is assumed to have capacity unless proved otherwise.
- Everyone should be encouraged and enabled to make their own decisions, or to participate as fully as possible in decision-making.
- Individuals have the right to make eccentric or unwise decisions.
- Proxy decisions should consider best interests, prioritizing what the patient would have wanted, and should be the least restrictive of basic rights and freedoms.

[a]Principles of self-determination underlying the Mental Capacity Act 2005 (England and Wales), which applies to patients over the age of 16 years.

Box 3.4 GMC guidance *Decision Making and Consent* 2020 lists seven principles involved in gaining informed consent

1. All patients have the right to be involved in decisions about their treatment and care and be supported to make informed decisions if they are able.
2. Decision-making is an ongoing process focused on meaningful dialogue: the exchange of relevant information specific to the individual patient.
3. All patients have the right to be listened to, to be given the information they need to decide, and the time and support they need to understand the decision.
4. Clinicians must try to find out what matters to patients so that they can share relevant information about the benefits and harms of proposed options and reasonable alternatives, including the option to take no action.
5. Clinicians must start from the presumption that all adult patients have the capacity to make decisions about their treatment and care. A patient can only be judged to lack the capacity to make a specific decision at a specific time, and only after assessment in line with legal requirements.
6. The choice of treatment or care for patients who lack capacity must be of overall benefit to them, and decisions should be made in consultation with those who are close to them or advocating for them.
7. Patients whose right to consent is affected by law (for instance, patients who are subject to compulsory treatment orders) should be supported to be involved in the decision-making process and to exercise choice if possible.

Informed consent

Informed consent is integral to ethical and lawful practice (**Box 3.4**). To act without, or in opposition to, a patient's valid informed consent is, in many jurisdictions, to commit assault or battery. Obtaining consent fosters choice and gives meaning to autonomy. Valid consent is:

- given by a patient with capacity
- voluntary: free from undue pressure, coercion, or persuasion
- sufficiently informed
- reversible: patients can change their minds at any time

The clinician seeking informed consent for a particular intervention must be competent in applying the procedure or treatment and be familiar with its problems. While it is good practice for written information to be provided, it does not remove the responsibility to talk to the patient.

Patients should be encouraged to ask questions and express their concerns, values, and preferences. Since it is the health and lives of patients that are at stake, the moral focus of information disclosure should be on what is acceptable to the individual patient rather than to the clinician.

Consent in educational settings

Medical education and training often happen in clinical environments where future clinicians learn new skills and apply their knowledge to patients. However, patients must be given a choice

as to whether they wish to participate in educational activities. The principles of seeking consent for education are identical to those applied to clinical situations. The rise in remote consultations has generated ethical issues in the education setting. Consent should be gained from the patient at the start of the remote consultation for students to be present in the consultation. Students should be introduced to the patient so that they know who is listening to the consultation. Being a silent and anonymous listener to a remote consultation is a breach of patient consent and confidentiality.

Advance decisions

Many countries have laws that allow people to make decisions about their future care. In the UK, these are called advance decisions. An advance decision enables someone to express their wishes about future care and is made in anticipation of someone losing capacity. An advance decision may refuse treatment but cannot lawfully request specific treatment. Where the treatment is lifesaving, the advance decision must be made in a specific way (**Box 3.5**). Countries have differing approaches to advance decision-making so the relevant local law must be understood. For example, the Mental Capacity Act 2005 applies in England and Wales, where a legally valid advance decision must be:

- made by someone with capacity
- made voluntarily
- based on appropriate information
- specific and applicable to the situation in which it is being considered.

In practice, it is often the specificity requirement that is difficult to satisfy because inevitable uncertainty surrounds future illness and potential treatments or interventions. For some people, the difficulty in anticipating the future and how they are likely to feel about that future informs an ethical objection to advance decision-making. Advance decisions can be made orally or in writing. However, decisions about withdrawing or withholding life-sustaining treatment must be in writing and witnessed. The decision should state explicitly that it is intended to include lifesaving situations. The list of lifesaving situations the patient can anticipate will be based on their diagnosis and prognosis, which will require sensitive discussion with the clinicians leading their care, to ensure that an appropriate range of scenarios have been explored and covered in the advanced decision. The more informal and non-specific an advance decision is, the more likely it is to be challenged or disregarded. When working in a country where advance decisions are recognized, clinicians should make reasonable attempts to establish whether a valid advance decision exists. Where there is ambiguity about either the existence or the content of an advance decision, the default is to preserve life. Advance decisions should be periodically reviewed and recorded; amendments, revocations, or additions are possible, provided an individual still has capacity.

The ethical rationale for advance decisions is respect for ***patient autonomy*** and extension of the right to make choices about healthcare in the future. Respect for autonomy includes supporting people to make choices that others might consider misguided. Advance decisions can foster trust and effective clinical relationships, but it is important to recognize that making decisions about future care can be difficult because the person we become when we are ill can differ from who we are when we are healthy.

Advance statements

Advance statements are broader than advance decisions and allow patients to express preferences and priorities without specifically ruling out an intervention or treatment. For example, a patient may wish to be more lucid than not towards the end of life or may like to retain the ability to eat with their family for as long as possible. A birth plan is often comprised of advance statements expressing wishes for labour and delivery. These preferences are not about choosing or ruling out specific treatments but are advance statements of wishes regarding the details of imminent future care. Advanced statements are not legally binding.

Box 3.5 Vignette 3

Mark is brought to the emergency department profoundly unwell, semi-conscious, and disorientated. He has Parkinson's disease and has an advanced decision on file, which states that he refuses antibiotics. Clinical investigations show that he has a urinary tract infection, which is sensitive to antibiotics. Mark has no relatives to consult about the context of his advanced decision refusing antibiotics. The clinicians discuss the likelihood that Mark anticipated antibiotics for a chest infection when he created the advanced decision. Clinicians decide to treat the urinary tract infection with intravenous antibiotics, as the advanced decision was not specific about the site of infection it covered.

Ethical questions

- What factors should clinicians weigh when deciding whether to uphold the advanced directive?
- What principles of the Mental Capacity Act apply to this case?
- What should Mark be told when he recovers sufficiently to discuss his treatment?
- What principles of this case apply to your practice?

Commentary

Mark is assessed not to have capacity, meaning that clinicians must make a judgement about whether to respect his advanced decision. They recognize that to override his stated refusal, they must have substantive reason to believe Mark had not considered the situation he is currently in. They hold a multidisciplinary team meeting to discuss options and seek advice from the hospital ethics committee. Four days after starting intravenous antibiotics, Mark is well enough to ask why clinicians ignored his advanced decision. He is angry and upset, as he had carefully planned refusal of treatments at the end of his life. Senior clinicians meet with Mark to explain the decision, providing him with information about the options they had considered, including abiding by his advanced decision. They offer Mark the opportunity to make a complaint about the care he received. The following day, Mark asks to speak with the clinicians again and enquires about how to make his advanced directive more specific.

Lasting power of attorney

Some countries allow for the appointment of a ***proxy:*** someone else to make decisions for patients lacking capacity. In England and Wales, consent to or refusal of treatment can be expressed by someone who has been lawfully granted lasting power of attorney (LPA) by a patient at a point when the patient still had the capacity to decide on this. For an LPA to be legally valid, it must be registered with the Public Guardian. The attorney then gains the power to represent the patient's interests only when the patient loses capacity. In jurisdictions that have LPA, the clinician should establish whether there is a valid LPA for a patient lacking capacity and adhere to the attorney's wishes. The only exception is where the attorney appears not to be acting in the patient's best interests, in which case the matter should be referred to the Court of Protection. Like advance decisions, the ethical rationale for LPAs is that prospective autonomy is desirable and facilitates informed care, rather than second-guessing patient wishes.

Best interests of patients who lack capacity

Where an adult lacks the capacity to give consent and there is no valid advance decision or LPA, clinicians must act in the patient's

best interests. This encompasses more than someone's best *medical* interests. In practice, determining best interests is likely to involve several people: relatives and carers, members of the healthcare team, professionals with whom the patient had a long-term relationship, and clinical ethicists. In England and Wales, an Independent Mental Capacity Advocacy Service advocates for patients without capacity who have no family or friends to represent their interests. In such a situation, people, including Independent Mental Capacity Advocates (IMCAs), are not making decisions; rather, they are giving an informed sense of the patient and their likely preferences.

Provision or cessation of life-sustaining treatment

For a patient who lacks capacity and has neither an advance decision nor an LPA, medical means to prolong life are not required when:

- the team believes, based on good evidence, that further treatment will not save the patient's life
- the patient is already imminently and irreversibly close to death
- the patient is so permanently or irreversibly brain-damaged that they will be incapable of any future self-directed activity or intentional social interaction.

Moral beliefs vary and, in general, decisions not to provide or continue life-sustaining treatment should be made with as much consensus as possible among the clinical team and those close to the patient. Where there is unresolvable conflict, hospital solicitors can apply for a court ruling. In the UK, judges are available in the relevant court, even in emergencies.

Where clinicians decide not to prolong the lives of imminently dying and/or extremely brain-damaged patients, the legal requirement is that they are acting in the patient's ***best interests*** by seeking to minimize suffering rather than intending to kill. Ethically, the significance of intention, along with the moral status of ***acts and omissions***, is integral to debates about assisted dying.

Assisted dying

In many countries assisted dying is illegal. In contrast, some jurisdictions, including New Zealand, Australia, Netherlands, Switzerland, Belgium, Portugal, and certain US states, allow assisted dying. England and Wales are in the process of implementing assisted dying following the House of Commons vote on the Terminally Ill Adults (End of Life) Bill. The Bill will go through committee and reading stages in the House of Commons and House of Lords before being implemented into practice in England and Wales. The timeframe for this is anticipated to be 2026. Prior to the legal change, assisted dying remains unlawful. Withholding and withdrawing treatment are usually acceptable in strictly defined circumstances, where the intention of the clinician is to minimize suffering, not to cause death. The ***doctrine of double effect*** remains in law, but its clinical application is limited because of improved practice and understanding in palliative and supportive care. Double effect is the legal doctrine that allows clinicians to prescribe medication that has, as its principal aim, the reduction of suffering but which may have side-effects that potentially shorten someone's life. Such prescribing is legally justifiable because the intention is benign and the side-effects, while foreseen, are not the primary aim. Once assisted dying is lawfully permitted in England and Wales, the doctrine of double effect will no longer apply to eligible patients, because it will become lawful for a doctor to intend to end a patient's life.

When assisted dying becomes lawful in England and Wales, no registered medical practitioner will be under a duty to participate in assistance. Conscientious objection will be protected. The Secretary of State will produce a Code of Practice along with guidance from the Chief Medical Officer. These will need to include:

- Whether doctors can initiate the discussion about assisted dying
- The scope of conscientious objection—who does it apply to and at what stage
- How to judge capacity if symptom control involves mediation which reduces consciousness
- What guidance to give Judges in the High Court about how to exercise their role
- Funding of assisted dying
- Likely numbers of patients
- Where assisted dying will be provided
- What medication will be used, in what quantity
- How to deal with complications of failed assisted dying
- Training and support for doctors/MDT

Whilst assisted dying is currently unlawful in the UK, ethical standards of clinical care requires that some questions are explored with the patient:

- What is most important to the patient at this point in their life?
- What symptoms are they experiencing and how effectively are these being managed?
- Has palliative care expertise been sought to support the patient journey?
- What involvement do the relatives/friends have in the patient journey?

Questions such as these allow clinicians to develop ethical relationships with patients which remain within legal boundaries and facilitate dignified care. Personal and professional moral values will inform how we relate to a patient asking for something currently unlawful but mindful that patients and relatives may be aware of the pending legal change. Once the change in law is implemented, doctors will need to be clear about whether they will take part in assisted dying or exercise their legal right to conscientiously object.

Further reading

General Medical Council. *Treatment and Care Towards the End of Life.* London: GMC; 2010, updated 2022. Terminally Ill Adults (End of Life) Bill. https://commonslibrary.parliament.uk/research-briefings/cbp-10123/.

Mental health and consent

Most people being treated for psychiatric illness have capacity. However, mental illness sometimes compromises an individual's capacity to make decisions. Many countries have specific legislation that enables people to be treated without consent on the basis that they pose a risk to themselves and/or to others.

People who have, or are suspected of having, a mental disorder may be detained for assessment and treatment in England and Wales under the ***Mental Health Act 2007***. The Act was reviewed in 2018, and a new Mental Health Bill 2022 is currently going through parliament. There are four principles that inform the Mental Health Bill 2022:

1. Choice and autonomy: ensuring service user's views and choices are respected.
2. Least restriction: ensuring the Mental Health Act powers are used in the least restrictive way.

3. Therapeutic benefit: ensuring patients are supported to get better so that they can be discharged from the Mental Health Act.
4. The person as an individual: ensuring patients are viewed and treated as individuals.

Implementation of the new Mental Health Act will be staggered over time, with the first duties to be introduced in 2024-2025. The first duties to be introduced include new detention criteria including for people with learning disabilities and autism, Nominated Person, and automatic referral to Independent Mental Health Advocacy (IMHA) services.

Consent and children

Where a child does not have the capacity to make decisions, treatment will usually depend on obtaining proxy consent. In the UK, consent is sought on behalf of the child from someone with parental responsibility. In the absence of someone with parental responsibility (e.g., in emergencies, where urgent treatment is indicated), clinicians proceed based on the child's best interests. Sometimes, parents and clinicians disagree about the care of a child who is too young to make their own decisions. Both national and international case law demonstrate that courts are prepared to override parental decisions if they are perceived to compromise the child's best interests. However, the courts have also emphasized that a child's best *medical* interests are not necessarily the same as a child's ***best overall interests or welfare***. Whenever the patient is a child, clinicians interact with a family unit. Sharing decisions and attending to the child as a member of a family are the most effective and ethical ways of practising.

As children mature, whether a young person has the capacity to make his or her own decisions is evaluated using principles derived from the case ***Gillick v. West Norfolk and Wisbech Area Health Authority***, which determined that a young person can make a choice about their own health where:

- the patient, although under 16, can understand medical information sufficiently
- the clinician cannot persuade the patient to inform, or give permission for the clinician to inform, the parents
- a young person is seeking contraception and is likely to have sexual intercourse with or without adequate contraception
- the patient's mental or physical health (or both) is likely to suffer if treatment is not provided
- it is in the patient's best interests for the clinician to treat without parental consent.

The *Gillick* case recognized that young people differ in their abilities to make decisions and established that decision-making capacity, not age, matters when considering whether a child can give consent. Situations should be approached on a case-by-case basis, considering the young person's level of understanding of a particular treatment. It is possible (and perhaps likely) that someone may be considered to have the capacity to consent to one treatment but not another. Even where a child does not have the capacity to make their own decision, clinicians should respect the child's dignity by discussing the proposed treatment with the child, even if parental consent must also be obtained. The Gillick principles now apply in a wide variety of paediatric settings. In the UK, once a child reaches the age of 16, the Mental Capacity Act 2005 states that they should be treated as an adult, except for the purposes of advance decision-making and appointing an LPA.

Confidentiality

Confidentiality is essential to therapeutic relationships. If clinicians violate the privacy of their patients, they disrespect autonomy, undermine trust, risk harm, and bring the medical profession into disrepute. Breaking the trust of a patient can lead to serious consequences for both the patient and the clinician. Within the UK, confidentiality is protected by common and statutory law. Some jurisdictions make legal provisions for privacy. Clinicians who breach confidentiality may face professional and legal sanctions.

Respecting confidentiality in practice

Patients should understand that information about them will be shared with other professionals involved in their treatment. Usually, by giving consent for investigations or treatment, patients are deemed to give their implied consent for information to be shared within the clinical team. Rarely, patients might object to information being shared, even within a team. In such situations, the advice is that the patient's wish should be respected, unless it compromises treatment. In almost all clinical circumstances, therefore, the confidentiality of patients must be respected. Confidentiality can be breached inadvertently by having clinical conversations in lifts, corridors, and cafés. Even on wards, confidentiality may be compromised by the proximity of beds and the visibility of whiteboards containing medical information. Everyone should be alert to incidental breaches of confidentiality and seek to minimize their role in unwittingly revealing sensitive information. In the UK, clinicians and trainee clinicians must ensure they practice in accordance with General Data Protection Regulations, which form part of hospital policy on handling and storing confidential data.

When confidentiality must or may be breached

Duty of confidence is not absolute. Sometimes, the law requires that clinicians reveal information about patients to others, even if the clinician is reluctant. Such instances include:

- Notifiable diseases, which, by virtue of public health legislation, must be notified to the relevant consultant in communicable disease control
- Court orders
- Road traffic accidents that lead to requests from the police
- Actual or suspected terrorist activity

There are also circumstances in which a clinician has the discretion to share confidential information within defined terms. For instance, not all communicable diseases are notifiable under law. A clinician could share confidential information about a communicable disease with colleagues who are directly involved in clinical care for that patient if they are at direct risk. It would be good practice to ask the patient's permission to share the information, but if the patient refuses permission, the clinician may judge that they have a duty to protect colleagues and other patients. In such a case, the clinician should inform the patient that they will share the information. Such

circumstances highlight the ethical tension between the rights of individuals and the public interest.

Aside from legal obligations, there are three situations in which information may be shared:

- The patient has given consent.
- It is in the patient's best interests to share the information, but it is impracticable or unreasonable to seek consent.
- It is in the public interest.

These three categories are a useful framework within which to think about the duty of confidentiality. They also require ethical judgement, particularly where sharing confidential information might be in the ***public interest***. In England and Wales, there is legal guidance on what constitutes sufficient 'public interest' to justify sharing confidential information, which is derived from the case of *W v. Egdell*. In that case, the Court of Appeal held that the 'most compelling circumstances' could justify a doctor acting contrary to the patient's perceived interest in the absence of consent. The court stated that it would be in the public interest to share confidential information where:

- there is a real and serious risk of harm
- the risk is of physical harm
- there is a risk to an identifiable individual or individuals.

Consent to disclose should be sought wherever possible, and disclosure based on 'public interest' should be a last resort. Each case must be weighed on its own merits, and a clinician who discloses confidential information on the grounds of 'public interest' must be able to justify their decision. Even where disclosure is justified, confidential information must be shared only with those who need to know.

Professional competence and mistakes

Clinicians must practice to an acceptable professional standard. There are essentially three sources that inform what it means to be a 'competent' clinician:

- the law
- professional guidance from bodies such as the GMC and Royal Colleges
- local policy

In practice, there is often overlap and interaction between the categories; for example, a doctor may be both a defendant in a negligence action and the subject of fitness to practice procedures. Professional bodies are established by, and work within, a legal framework. In order for professional bodies to implement policy, legislation is required, and interpretative case law will often follow. Professional bodies have diverse but often overlapping roles in developing, defining, and revising standards for clinicians. The principal publications in which the GMC sets out standards and obligations relating to competence and performance are *Duties of a Doctor* and *Good Medical Practice*.

Standards and the law

In most countries, the law provides the statutory framework within which the medical profession is regulated. For example, in the UK, it is the function of the GMC to maintain the register of medical practitioners, provide ethical guidance, and guide and quality-assure medical education. The GMC defines standards of professional practice and has responsibility for investigation when a doctor's standard of practice is questioned. Fitness to practice is assessed by the Medical Protection Tribunal Service, who provide tribunal services that are separate from the investigatory processes of the GMC. Clinicians have a responsibility not only to reflect on their own practice but also to be aware of and, if necessary, raise concerns about the practice of colleagues, even in the absence of formal 'line management' responsibilities.

Conscientious objection

Clinicians will have their own views about what is and is not acceptable ethically. All clinicians should feel able to express concerns, raise questions, and challenge constructively. However, the GMC is clear that doctors must not allow their own beliefs or judgements to compromise clinical care or discriminate against patients. Clinicians who are exercising a conscientious objection should usually ensure that the patient is referred to another clinician who does not have a conscientious objection. Conscientious objection should not be used to prevent patient autonomy and access to lawful treatment.

In the UK (apart from Northern Ireland), there is one situation in which the law provides for a right of conscientious objection: the provision of termination of pregnancy and some reproductive medicine that involves embryos. The right of conscientious objection allows clinicians to choose not to be involved in providing terminations, including making referrals to specialist services. However, clinicians must not convey their beliefs in a judgmental way to a patient and should arrange for a colleague to see the patient without delay. In an emergency, which is likely to be extremely rare in contemporary medical practice, a doctor would have to act if no one else was available. The law is silent on whether the provision applies to medical students, although most medical schools will offer guidance and accommodate students who have a conscientious objection to termination of pregnancy.

Clinical negligence

Negligence is a civil claim where damage or loss has arisen because of an alleged breach of professional duty, such that the standard of care was not, on balance, that which could be reasonably expected. To establish a case of negligence, the claimant must prove on the balance of probabilities that a doctor owed them a duty of care that breached the duty and that the breach caused them harm.

Of the components of negligence, duty is the simplest to establish: all doctors have a ***duty of care*** to their patients. Whether a doctor has discharged their professional duty adequately is determined by expert opinion based on standards that can reasonably be expected and an individual's conduct in relation to those standards. If doctors have acted in a way that is consistent with a reasonable body of their peers (the ***Bolam standard***) and their actions or omissions withstand logical analysis (the ***Bolitho standard***), they are likely to meet expected standards of care. Lack of experience is not considered a mitigating factor in legal determinations of negligence. The most common reason for a clinical negligence action to fail is ***causation***. For example, the alleged harm may have occurred against the background of a complex medical condition or course of treatment. In these cases, it can be very difficult to identify whether the alleged breach of duty caused the actual harm the

patient experienced, or whether disease progression played a role. Patients with chronic health conditions find it especially difficult to prove causation.

Clinical negligence remains relatively rare, but undue fear of litigation can lead to defensive medicine and poor practice. All clinicians make mistakes. Mistakes do not necessarily constitute negligence or indicate incompetence. Regulatory bodies and medical defence organizations require clinicians to be honest about their mistakes and to apologize, remembering that to do so is not an admission of negligence. Such honesty and humility, aside from its inherent moral value, have been shown to reduce the prospect of patient complaints or litigation. Patient complaints can be passed to *NHS Resolution*, who provide expertise to the NHS on resolving concerns and disputes fairly, share learning for improvements and preserve resources for patient care. They also administer the indemnity scheme for the NHS.

Professional accountability is important. The law, professional guidance, and policy documentation provide a starting point for clinicians. Complaints and possible litigation are often brought by patients who feel aggrieved for reasons that may be unconnected with the clinical care that they have received. When patients are asked about their decisions to complain or to sue clinicians, it is common for poor communication, insensitivity, administrative errors, and lack of responsiveness to be cited as motivation. Clinicians should offer an apology and explain fully and promptly what has happened, along with the likely short-term and long-term effects of any harm. Reluctance to say 'sorry' comes from a fear that it is an admission of fault, which later implies liability, but guidelines from medical defence organizations emphasize that this is not so. There is less to fear than clinicians sometimes believe. The courts and professional bodies are concerned neither with best practice nor with unfeasibly high standards of care. What is expected is that clinicians behave in a way that accords with the practice of a reasonable clinician, and the reasonable clinician is not perfect. Good habits begin in medical school. Effective communication is an important component in preventing and resolving complaints, reducing clinicians' stress, and developing the professional skills and reputation for handling difficult situations properly.

Challenges of implementing evidence 49
Improving the uptake of evidence 51

CORE SKILLS AND KNOWLEDGE

Estimates from various countries suggest that up to 40% of patients do not receive evidence-based healthcare. For example, despite the evidence for the effectiveness of prompt corticosteroids for Bell's palsy, almost half of patients (44%) do not receive this treatment, and provision is even lower for patients over the age of 60. Furthermore, 20% or more of healthcare is unnecessary or potentially harmful. For example, antibiotics continue to be widely prescribed for cough, despite being ineffective in the majority of cases.

Evidence-based practice offers a framework to assist clinicians in making efficient and appropriate use of the available literature and making informed decisions about its application.

All doctors need to develop key skills in applying this framework to clinical scenarios, including:

- Converting real-life clinical and population health problems into answerable questions
- Locating the best available evidence
- Appraising the evidence critically
- Applying the evidence in practice.

Opportunities for developing skills in evidence-based practice include attending (or setting up) a journal club where research papers are critically appraised, following the PICO approach—described later in this chapter—to apply evidence to particular dilemmas presenting in patients seen in clinical practice, visiting a local public health team to see how evidence is applied at a population level, or helping to write a local clinical guideline where evidence is applied at an institutional level.

BACKGROUND

The evidence-based medicine movement emerged over 30 years ago and is widely accepted as the gold standard for medical decision-making. It was defined in 1996 as 'the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients', with evidence in this case referring to peer-reviewed research literature. The focus has since expanded to include an emphasis on the importance of the patient and carer perspective in decision-making, alongside research evidence. We therefore refer in this chapter to evidence-based practice (EBP), which we define as '***an approach to decision-making in which the clinician uses the best scientific evidence available, in consultation with the patient, to decide upon the option that suits the patient best***'. This chapter will also embrace evidence-based public health practice, which applies evidence to wider populations, as well as individual patients.

The need for EBP

A number of factors have driven the rapid expansion of EBP. These include a growing awareness among health professionals of the gap between the large amount of good-quality research evidence available in the published literature and its often limited use in clinical practice. EBP also has a role in ensuring that treatments offered by healthcare providers are of high value and accrue the most benefits for patients and the public—especially where escalating demands for care result in constrained resources. For example, there is no national screening programme for pancreatic cancer in the UK, despite this disease often not being detected until a late stage and when already incurable. This is because pancreatic cancer is relatively uncommon and the population benefits are outweighed by costs (such as potential harms associated with follow-up invasive testing or surgeries in those with 'false positive' scan results, as well as financial costs).

Barriers to EBP

A multitude of barriers exist that lead to research evidence not being taken up into clinical practice, or to its being implemented in a delayed or patchy manner.

Knowledge barriers and the use of clinical guidelines

The most obvious barrier is lack of knowledge. It is estimated that general physicians would need to read 20 articles a day, all year round, to keep abreast of emerging knowledge in their specialist field. As research evidence continues to expand, clinical guidelines have become an important mechanism for informing day-to-day practice and helping clinicians keep up to date. Clinical guidelines identify, evaluate, and summarize the best available research evidence relating to the management of specific conditions. Consequently, they are a useful first port of call when seeking information on which to base decision-making. Guidelines are usually produced at the national or international level by medical associations or government bodies. In the UK, the National Institute for Health and Care Excellence (NICE) provides recommendations about care for patients with specific conditions. In the United States, the National Guideline Clearing House maintains a catalogue of guidelines published by various health and medical associations, including the Agency for Healthcare Research and Quality.

While clinical guidelines are not legally binding, doctors are expected to take them into account, and yet the extent to which this happens in practice varies. For example, UK clinical guidelines recommend that patients with high blood pressure and raised cholesterol receive antihypertensives, antiplatelet drugs, and lipid-lowering drugs for the secondary prevention of ischaemic stroke. However, one study demonstrated that only 25.6% of males and 20.8% of females receive appropriate treatment, and the likelihood of 80- to 89-year-olds receiving secondary prevention is nearly half that of 50- to 59-year-olds.

Other factors limiting the implementation of EBP

These include:

- doubts about the accuracy of the research evidence being promoted
- national and local political values
- priorities and pressures from industry, patients, the public, and clinicians
- cost.

These often interconnecting factors can lead to health policies being implemented *despite* contradictory or contested evidence. For example, a programme of 5-yearly preventative health checks for 40- to 74-year-olds was established in 2009 across the National Health Service in England. The programme aims to identify early signs of stroke, heart and kidney disease, type 2 diabetes, and certain types of dementia. However, findings of increased detection of heightened cardiovascular disease risk factors and diagnoses are inconsistent between studies, uptake varies between population subgroups, and the scientific evidence does not support the view that general health checks are effective in improving health outcomes. Some experts are concerned that universal assessment of risk could lead to unnecessary treatment and other harms, particularly in those known to be at low risk as they are less likely to benefit.

Consequently, this intervention could be considered inappropriate, as the potential harms outweigh the expected benefits.

A framework for applying evidence to clinical problems

EBP offers a framework to assist clinicians in making efficient and appropriate use of the available literature and in reaching considered decisions about its application. The goal of this chapter is to promote ways in which evidence can be used wisely, with a good understanding of its value and its limitations. In the following sections, we describe four essential steps:

- converting information needs into answerable questions
- locating the best available evidence
- appraising the evidence critically
- applying the evidence in practice.

ASKING ANSWERABLE QUESTIONS

Every day, doctors make multiple decisions that involve asking implicit and explicit questions. Evidence-based care protocols, pathways, and clinical guidelines are available that cover the management of a wide range of both common and rare conditions, and these should generally be a clinician's first port of call.

Sometimes, however, a literature search is required—perhaps where a patient does not fit well into the categories dealt with by clinical guidelines, or where a condition is rare and not covered by good evidence-based summaries. The first step is to turn the information need into a focused question. This must be directly relevant to the patient at hand and incorporate the key issues that need to be present in research articles to inform the decision-making process. Identification of these key issues will allow formulation of a focused literature search strategy.

The ***PICO approach*** facilitates this process (**Box 4.1**), where ***p***atient, ***i***ntervention, ***c***omparison, and ***o***utcome (PICO) are considered the four key parts of a well-built clinical question.

SEARCHING FOR THE EVIDENCE

The next step is to identify relevant research evidence that will provide an answer to the clinical question. There are two main sources of evidence available.

Primary sources of evidence

These are comprised of the thousands of original articles published every year in research journals. Research papers are catalogued in a variety of databases, which are searchable on the Internet. For many medical queries, Medline is the best-known database of health-related literature and makes a good starting place. The size and breadth of databases mean that a systematic searching approach is required to identify the best evidence available.

Box 4.1 Components of clinical questions structured using the PICO approach

Patient or problem (P)
- Who is the relevant patient?
- What is the condition or problem of interest?
- What are the most important characteristics of the patient?

Intervention (I)
- What is the management strategy of interest (e.g., diagnostic test, treatment)?

Comparison of interventions (C)
- What is the main alternative management strategy being considered, if any?

Outcome (O)
- What will the management strategy accomplish, measure, improve, or affect?
- What are the patient-relevant consequences?

Secondary sources of evidence

In order to deal with the growing volume of primary research, secondary sources of evidence are increasingly consulted. Secondary sources are summaries and analyses of evidence derived from and based on primary sources. The Cochrane Library (UK) was one of the first online collections of databases relevant to medicine and other healthcare specialties and includes the Cochrane Database of Systematic Reviews. Other organizations producing systematic reviews and other evidence syntheses to inform practice and policy include the Joanna Briggs Institute and the Campbell Collaboration.

How to conduct a search

Although biomedical databases vary in terms of their structure, the principles of using them apply to all. Using the PICO approach to generate a clinical question is helpful, as the components can then be employed to select search terms for conducting a search in Medline. Text-word searching involves seeking specific words or phrases, usually in the title or abstract of an article. The first step is to break the clinical question down into its individual components. **Box 4.2** contains a worked example, using the PICO approach.

Practical tips for searching databases include:

- Searching only for articles that include a full phrase, rather than individual words on their own, by putting double quotation marks around a group of words (e.g., "sore throat")
- Narrowing the search and reducing the number of citations identified by using AND in the database search function
- Avoiding narrowing too far. Using the example question in **Box 4.2**, entering "*sore throat*" AND *antibiotics* in the search function will identify articles that contain both terms, whereas including "*sore throat*" AND *antibiotics* AND "*symptom duration*", theoretically yielding the highest concentration of relevant articles, may also miss others. Consequently, for routine clinical queries, using two terms in a search strategy is usually sufficient to focus the search.
- Engaging the help of expert health sciences librarians. This may be valuable in developing search strategies for more complex queries.
- Remembering the dangers of publication bias (see also the section on 'Understanding statistical results' later in this chapter). Studies with negative results may not have made it as far as publication. On the other hand, studies may be in progress that could inform decision-making.

Box 4.2 Searching for evidence—worked example

Charlie is a 20-year-old student who has attended his GP practice and has a sore throat. You wonder whether antibiotics might help improve his symptoms.

Answerable clinical question
- Are antibiotics effective in reducing the duration of symptoms in patients with upper respiratory tract infections?

PICO
- ***Patient problem or population:*** Patients with a sore throat
- ***Intervention or exposure:*** Antibiotics
- ***Comparison or control:*** None
- ***Outcome measure:*** Duration of symptoms

Search terms in evidence/database (e.g., Medline)
- "sore throat" AND antibiotics—1032 articles
- "sore throat" AND antibiotics AND "symptom duration"—6 articles

Answer

Antibiotics shorten the duration of symptoms by about 16 hours overall

(Spinks A, Glasziou PP, Del Mar CB. Antibiotics for sore throat. *Cochrane Database of Systematic Reviews* 2013; 11. Art. No.: CD000023. https://doi.org/10.1002/14651858.CD000023.pub4.)

APPRAISING THE EVIDENCE

Once some potentially relevant research articles have been identified, the next step is to decide whether the studies described were undertaken in a way that makes their findings reliable and valid, and to consider the relevance of any articles to the clinical question identified. This process is known as critical appraisal.

The hierarchy of evidence

Ethically, patients should receive the best-evidenced treatment available, and the 'hierarchy of evidence' is a core principle of EBP that helps to ensure this. The hierarchy is formed by ***ranking study types based on the extent to which the reader can be confident that the results and estimates of a treatment effect are valid***. In most hierarchies, meta-analyses and systematic reviews are at the top of the pyramid, followed by experimental and observational studies, with case reports or case series at the bottom (**Fig. 4.1**). The hierarchy encourages a top-down approach to locate the best evidence, which involves first searching for evidence at the top (e.g., a recent meta-analysis) and, if that is not available, moving down to the next level of evidence.

Whatever the study design, when reading papers it is important to remain vigilant for poorly conducted research. Not all published research is of high quality, so it is necessary to critically appraise each study, as opposed to placing blind confidence in published results.

Systematic reviews and meta-analyses

Systematic reviews

These synthesize the results of all available studies in a particular area, identified via comprehensive, systematic literature searches. They therefore provide a summary of current evidence about a topic, including an analysis of study results, strengths, and weaknesses. Systematic reviews also highlight remaining gaps in knowledge or a lack of robust evidence. Data from all the included studies are combined to build up a broader picture of the evidence.

Systematic reviews aim to locate as much as possible of the research relevant to a particular research question. Clearly defined, methodical steps are then used to identify what can reliably be said

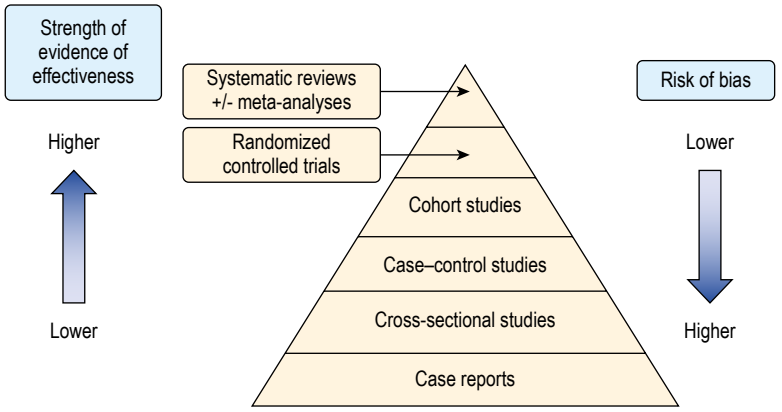

Fig. 4.1 **Hierarchy of evidence.**

about the topic, drawing on the findings of all the included studies. All study types can be included in a systematic review, including randomized controlled trials (RCTs) and observational studies, which are described later. A well-conducted review will assign a quality score to included studies so that the conclusions provide an overview of the status of the research field. For example, where there is a lot of robust evidence available to answer a question, clear recommendations can be made about patient care, or—in contrast—where there is a limited amount of low-quality evidence available, reliable recommendations cannot be made.

As systematic reviews draw together the findings of multiple studies, they lie at the top of the evidence hierarchy, though this position is not an absolute. For example, findings might quickly be superseded by evidence that is more recent. A large, well-conducted RCT may also provide more convincing evidence of effect than a systematic review of smaller RCTs.

Meta-analyses

A meta-analysis is an extension of a systematic review. Data from each of the included studies are combined statistically to give a single estimate of effect. To conduct a meta-analysis, the included studies must address the same research question and make use of the same outcome measure. Individual research papers can be included only when they report relevant numerical data in sufficient detail.

As meta-analyses pool findings from all the included studies, and therefore draw on data from a larger number of patients, they provide a stronger and more accurate estimate of a treatment effect than individual studies on their own.

Interventional studies

Randomized controlled trials (RCTs)

RCTs are generally considered to provide the most reliable evidence of whether an intervention is effective. A range of different types of intervention can be tested in an RCT, including therapeutic and prophylactic agents (e.g., drugs, vaccines), surgical and medical procedures, or health service and public health strategies.

Randomization

The strength of the RCT lies in the process of randomization, which is characteristic of this type of study design. Typically, study participants are randomly assigned to one of two study groups: the experimental group, who will receive the intervention being tested, and a comparison group (known as controls), who may receive:

- a conventional treatment (sometimes referred to as usual care)
- no intervention
- a placebo—a substance that resembles the intervention in all respects, except that it contains no active ingredients.

In the most common RCT design, every participant has an equal chance of being in the treatment group or the control group. The two groups are then followed up prospectively over time, to assess the effectiveness of the intervention compared with the conventional or placebo treatment.

The goal of randomization is to ensure that the two study groups are as similar as possible in all respects, apart from the treatment or intervention they receive. Randomization ensures that other factors that might also have an impact on the outcome, known as confounders, do not differ systematically between the two groups. Consequently, any observed differences between the study group outcomes are more likely to be caused by the treatment.

Those responsible for recruiting participants into a study must not influence the process of allocation to treatment groups. A common method of achieving this is randomization by Internet, where the investigator accesses a web-based randomization service to obtain information about which study arm the participant should be allocated to.

Confounding factors

A confounding factor is a variable that influences both the exposure and the outcome in a study. Failure to control for confounders can lead to biased results. For example, observational studies found that the proportion of people with coronary heart disease (CHD) was lower among those who take vitamin C supplements, compared to those who do not. This suggested that vitamin C may protect against CHD. However, randomized controlled trials that allocated participants randomly to taking or not taking vitamin C supplements found no evidence of a benefit of vitamin C. It is likely that socioeconomic position is a confounding factor: affluent people are more likely to take vitamin supplements and also have a lower risk of CHD than the less well-off (see *Lawlor DA et al. Those confounded vitamins: what can we learn from the differences between observational versus randomised trial evidence?* The Lancet *2004 363; 9422:1724–1727)*. This induces a spurious association between vitamin C and risk of CHD, and thus the observational studies which concluded a benefit of vitamin C were likely biased due to their failure to adequately control for confounding. In an RCT, randomization ensures that potential confounding factors are randomly distributed among the treatment and control groups. In sufficiently large trials, randomization ensures approximate balance between the groups with respect to any confounding factors, thus eliminating confounding bias.

Blinding

When a participant has been randomized, the investigator may or may not be aware of which group the participant has been allocated to. If they know which treatment the participant is receiving, this might influence (intentionally or unintentionally) the way in which they measure or interpret the outcome data, introducing bias into the study. For example, they may interpret information more favourably if it comes from participants who they know to be receiving the drug under investigation. Similarly, if a participant knows that they have been allocated to the placebo group, this may influence the way in which they participate in the trial. Therefore, blinding can be seen as a way to avoid potential bias.

- In a double-blind study, neither the patients nor the investigators know the study group allocation.
- In a single-blind study, patients do not know their study group allocation.

Blinding also involves ensuring that, as far as possible, the intervention and standard or placebo treatment both appear the same, although this may not be possible for non-drug interventions. For example, if the intervention involves physiotherapy exercises or a new way of delivering a service, it is often not feasible to conceal which group participants have been allocated to.

Intention-to-treat analysis

During an RCT, participants may be lost to follow-up for a range of reasons. Individuals may be unable to continue participating or may stop taking their allocated treatment—perhaps because of adverse side-effects or because they felt it was not working. If these individuals are subsequently excluded from the analysis of the results, the effectiveness of the drug may be overestimated. In the real world, patients do not always take their medication as prescribed, so RCT data are often examined using intention-to-treat analysis. This means that the final results are analysed based on the treatment arm to which participants were initially allocated, and not on the treatment they actually received.

Adaptive platform trials

Adaptive platform trials (APTs) are emerging RCT designs which use innovations in statistics and computing to enable trial protocols to be adapted and updated as evidence is generated. The design allows multiple treatments to be studied simultaneously in a continuous fashion, with therapies entering and leaving the platform on the basis of a predefined decision algorithm. The COVID-19 pandemic stimulated a rise in APTs because they are particularly appropriate for rapid evidence generation at a time of unprecedented pressures on healthcare systems worldwide (see Vanderbeek et al. in Further Reading). Their advantages are that they can be more time efficient and require fewer participants than standard RCTs. However, they can be logistically complicated and have varying adaptive designs and analytical approaches, in contrast to standard RCTs where design consensus is well established.

Limitations of RCTs

Although RCTs are considered to provide the most reliable evidence of effectiveness, they are not without their limitations.

Patient populations to whom the results might subsequently be applied in real clinical practice may often be excluded from RCTs in order to minimize differences between experimental groups. For example, strict inclusion and exclusion criteria may mean that patients with co-morbidities are excluded, as the presence of other conditions might affect their response to the intervention. This means, however, that the results of the RCT may not apply to patients with multiple morbidities, of which there are many in the real world.

Patients recruited to trials are also more likely to be receiving care in teaching hospitals, where care may differ from that provided in district general hospitals. This reduces the external validity or generalizability of the trial or the extent to which the findings can be applied in other settings. Adaptive platform trials may be able to overcome these limitations by widening inclusion criteria and by using routine healthcare data systems to identify eligible patients admitted to any hospital.

Additionally, although RCTs are the gold standard for evaluating the effectiveness of interventions, randomization may not always be required. For example, an RCT may be unnecessary when the effect of an intervention is dramatic (e.g., vaccination for smallpox or penicillin for bacterial infections). In these cases, the likelihood of unknown confounding factors affecting the outcome is so small that they can be ignored.

An RCT may be unfeasible when the outcome of greatest interest occurs rarely (e.g., death) and may be too costly if the outcome of greatest interest occurs far in the future (e.g., loosening of artificial hip joints). Observational methods, such as cohort studies, may be the only practical means of obtaining such information in these cases.

Finally, the use of RCTs raises several ethical issues. RCTs are based on the premise that there is sufficient doubt about the particular intervention being tested to justify not giving it to half of the participants. At the same time, there must be sufficient belief in its potential benefit to justify exposing the remaining half of the patients. This is known as ***clinical equipoise*** and requires careful consideration to be given to the intervention that is received by the control group. If an effective treatment already exists, participants in the control group should have this rather than a placebo in order to make a transparent assessment of the novel intervention in comparison to usual care. Informed consent is required in all study designs, but particularly so in RCTs. Participants need to understand that they are participating in an experiment and, consequently, may not receive the treatment under investigation.

Observational studies

Cohort studies

Cohort studies follow a group of individuals over a period of time (often years) to examine whether they benefit from a healthcare or public health intervention or develop a disease or other outcome of interest. A cohort is a group of individuals who have a common characteristic. Cohorts are selected on the basis that individuals share similar, relevant characteristics, such as receiving cancer screening or being exposed to cigarette smoking. For example, the British Doctors Study, which ran from 1951 to 2001, was a cohort made up of doctors, including both smokers and non-smokers. It provided convincing proof of the association between smoking and lung cancer and led to a dramatic decline in smoking from the 1970s onwards.

Cohort studies are a type of observational study, meaning that no interventions are made to influence participants' treatments or lifestyle. However, detailed information is collected about the treatments they receive in the ordinary course of living their lives, their sociodemographic characteristics, lifestyles and behaviours, and their outcomes, using questionnaires, interviews, physical examinations, and investigations such as blood tests, as well as taking information from existing sources such as medical records. Cohort studies can therefore be prospective, involving the collection of new data, or retrospective, looking back in time and using existing data

such as medical records. Retrospective studies are cheaper and faster to conduct because the data have already been collected and stored. However, because it was not collected for research purposes, information in patients' medical records may be incomplete, inaccurate, and inconsistently recorded.

Cohort studies can also vary significantly in terms of their size and complexity. At one extreme, a large population may be studied over decades. For example, the Millennium Cohort Study (MCS) follows the lives of around 19,000 young people born across England, Scotland, Wales, and Northern Ireland in 2000–2001. Families were first assessed when children were 9 months old and have been followed up at regular intervals. Interviews are carried out with the main parent and the child, and a range of information is collected, including employment and income, housing, family structure, ethnicity, parenting activities such as reading to the child, developmental indicators, and both parental and child mental health. At the other extreme, some cohort studies follow up in relatively small groups for a few days or weeks.

Cohort studies are particularly valuable in situations where RCTs cannot be performed because randomization is either unethical or impractical. They also allow rare or long-term outcomes to be assessed: for example, in the UK, the National Joint Registry collects information on a nationwide cohort of patients who have undergone joint replacement operations. Implants that fail earlier than expected can be identified and the information acted on. External validity (also referred to as generalizability) will be higher in large cohort studies such as this because a broad range of patients, from different settings, are included, without the restrictive inclusion criteria that are often applied in RCTs.

A limitation of the cohort method is losses of follow-up. Cohort members may decline to continue participation in the study or fail to maintain contact. Loss to follow-up may (or may not) be related to the exposure, the outcome, or both. For example, a study looking at the effect of high-impact exercise on risk factors for osteoporosis had a greater loss of follow-up in the group assigned to exercise. Females who dropped out may have had inherently lower bone strength, which made the exercise less tolerable for them. If so, this would have produced selective loss of females more likely to develop osteoporosis from the active treatment group, and this would cause a biased estimate: specifically, an overestimate of the benefit of exercise.

Case-control studies

In a case-control study, patients who have received a healthcare intervention or developed a disease are identified. Their past history is then compared with that of individuals—called controls—who did not receive the intervention or do not have the disease. For example, participants with a disease of interest (e.g., lung cancer) may be tracked back in time, sometimes for many years, to determine whether they were exposed to a risk factor of interest (e.g., secondhand tobacco smoke). In another example, a study used primary healthcare records to look at service use in the previous year, in order to identify factors associated with frequent attendance at hospital emergency departments.

Researchers try to ensure that the cases and controls are as similar as possible with respect to other factors. This can be done either on an individual basis (e.g., by pairing each case with a control of the same age and sex) or in groups (e.g., choosing a control group with an overall age and sex distribution similar to that of the cases). Unknown differences may still exist between the cases and controls, however, which could influence the results.

A particular limitation of case-control studies is the risk of recall bias. Case participants are usually keen to find out what caused their illness or may ascribe their positive and adverse outcomes to an intervention. As a result, they may be better motivated to remember details of their past than controls with no special interest in the study question. Assessing the exposure of controls may therefore be challenging, especially if this relies only on their personal recall. This risk can be lessened by using data from electronic medical records.

Since the assessment is retrospective and the risk of recall bias is high, case-control studies lie towards the bottom of the evidence hierarchy. However, they can provide interesting insights. For example, case-control studies start with people who are known to have a disease of interest, rather than looking at a population free of disease and waiting to see who develops it. This approach therefore lends itself to studying groups of patients with rare conditions. For example, in 1955, Richard Doll published a case-control study demonstrating a significant excess of the rare lung cancer mesothelioma among asbestos workers. This study was the first to identify asbestos as one of the world's most dangerous industrial carcinogens.

Cross-sectional surveys

These observational studies provide a snapshot of a particular group of patients or people at a single point in time and can be used to assess the prevalence of illness or a risk factor, or the range of perceived symptoms in a given population. Examples include the proportion of patients with bladder cancer who smoke, or patient-reported outcomes on discharge from hospital.

As cross-sectional data describe only what is happening at a single moment in time, they cannot be used to answer questions about the causes of disease or the impact of treatment. They also do not provide information about changes over time, unless they are repeated. Consequently, they are ranked low in the hierarchy of evidence.

Nevertheless, cross-sectional surveys can provide key information, for example, in planning services and ensuring that they are equipped to meet the needs of the local population. They may also be used to draw inferences about possible relationships between factors or outcomes, or to gather preliminary data to support further research and experimentation.

Case series or case reports

These describe a group of patients or a single individual with an outcome of interest, or novel and unusual features. Due to their descriptive nature, they provide little evidence of causality. Their small size and lack of representativeness also mean that they cannot be assumed to have relevance for the wider population of patients with the same condition. Therefore, they are regarded as the weakest form of evidence in the hierarchy.

Nevertheless, they can still provide useful information, particularly in the very early stages of research into a disease area. For example, in 1985, the Centers for Disease Control and Prevention in the United States published a report describing five cases of *Pneumocystis* pneumonia in previously healthy, gay males in Los Angeles. This was the first official reporting of what became known as the AIDS epidemic. However, case reports can also be misused: an important example is the now discredited case series published in *The Lancet* in 1998 (retracted in 2010), which falsely claimed to provide evidence for a link between the measles, mumps, and rubella vaccine; colitis; and autism.

Problems with the 'hierarchy of evidence'

Although the evidence hierarchy has become widely accepted, concerns have been raised about ranking evidence in this way. As

has been outlined, study designs traditionally ranked lower down the hierarchy may be more appropriate if, for example, outcomes of interest are rare or occur far into the future. Some observational studies also produce results with higher external validity than some RCTs, because inclusion and exclusion criteria are usually less restrictive. Additional concerns, including the extent to which the findings of RCTs can be applied to patients in other settings, are explored in the final section of this chapter.

The hierarchy focuses only on research addressing the question of the effectiveness of interventions. Other questions are equally salient, however, such as:

- prognosis (what is likely to happen?)
- harm (is this substance likely to have adverse effects?)
- experience (what is it like to receive this intervention?)
- implications for services (staff workload, the need for additional monitoring, and so on).

Different types of questions require different study designs (**Box 4.3**):

- Determining the number of patients living with a condition at a given point in time (a ***prevalence question***) may be best achieved using a cross-sectional survey. However, because it provides only a snapshot of that single time point, it cannot estimate the likely duration between diagnosis and death.
- The design needed for a ***prognosis question*** is a cohort study—a study that follows up on recently diagnosed patients and records what happens to them.
- To answer ***experience questions*** (what it is like to live with a particular condition, or whether a certain intervention is acceptable to patients), qualitative approaches, such as interviews or focus groups, are often also needed.

Combined approaches

The most comprehensive, generalizable, and useful research is that which combines quantitative and qualitative data. For example, qualitative approaches can helpfully be used within an RCT to explore how an intervention was implemented and what was actually delivered, compared with what was intended. This is known as a ***process evaluation***, as it documents the process that took place. Process evaluation can explain discrepancies between expected and observed outcomes, help us to understand how local context influences outcomes, and provide insights to aid implementation in other settings.

Critical appraisal

Critical appraisal aims to:

- identify the methodological strengths and weaknesses of a piece of research
- assess whether the researchers used the right design for their study
- make informed decisions about the quality of the evidence being appraised
- establish how useful the piece of research is for wider decision-making.

A range of tools and checklists exist to help assess the quality of each design (see 'Further reading'). However, these checklists should be regarded as an aid to careful thought, rather than a substitute for it. Regardless of the study type, critical appraisal involves some overarching questions (**Box 4.4**); the three main steps involved are described below.

Question 1: Are the results of the study valid?

Validity refers to the soundness or methodological rigour of a study. A study is considered valid if the way it has been designed and carried out means that the results provide a trustworthy estimate of clinical effectiveness. A study that is ***sufficiently free from bias*** has internal validity.

Bias is a systematic error that causes a study to produce an invalid estimate. For example, in a case-control study, recall bias may occur because a patient with an outcome of interest (e.g., lung cancer) may report their exposure experience (e.g., smoking) differently to a control without the outcome. This would then lead to an invalid estimate of the association between smoking and lung cancer.

No study is perfect and free from all bias. A systematic check should be carried out to ensure that the researchers have done all

Box 4.3 Key messages about study design

Randomized controlled trials (RCTs)

- ***Randomization*** aims to ensure that the study groups are as similar as possible, apart from whether or not they receive the treatment being studied. Consequently, observed differences are more likely to be due to differences in the treatment alone.
- ***Blinding*** ensures that there are no differences in the way in which participants in each study arm are managed or in which their progress and outcome are measured. In a double-blind study, neither patients nor investigators know the study arm to which the participant has been allocated.
- In an ***intention-to-treat analysis***, RCT findings are analysed based on the treatment arm to which participants were initially allocated, regardless of whether they dropped out of the study.
- Ensuring that RCT participants are as similar as possible enhances the ***internal validity*** of the results (i.e., their accuracy in the study context) but may reduce their ***external validity*** (i.e., their generalizability to the diverse range of patients with the condition under study).
- RCTs are a form of ***experimental study.*** The researcher manipulates exposure to the intervention (e.g., a new drug treatment) by allocating participants to the intervention or control group.

Observational studies

- In an ***observational study***, the researcher measures exposures (e.g., new surgical procedures) that the participants are already receiving. Outcomes (e.g., postoperative complications) are then observed as they occur.
- In a ***cohort study***, a group of participants (the cohort) is followed over time. Researchers observe which individuals develop outcomes of interest (e.g., breast cancer) and collect information about factors that might be relevant to the development of the outcome (e.g., smoking, alcohol consumption). Cohort studies can provide valuable evidence when conducting an RCT is unfeasible. The findings may have greater generalizability because inclusion and exclusion criteria are usually less restrictive.
- In a ***case-control study***, patients who have an outcome of interest are identified (i.e., cases). Their past history is then compared with that of individuals—or controls—who do not. Cases and controls should be as similar as possible with respect to other factors. A particular limitation of case-control studies is the risk of recall bias because cases may be better motivated to remember details of their past than controls.

Box 4.4 Key questions in critical appraisal

Why was the study done?
- A clearly focused question should address population, intervention, and outcomes.

What type of study was done?
- The study design must match the question asked.

What are the study characteristics?
- Use the PICO question format to help answer this question.

Are the results of the study valid?
- Was the assignment of patients to treatments in a controlled trial (RCT) randomized? If another design was used, how were participants allocated?
- Were patients, health workers, and study personnel 'blind' to treatment allocation?
- Were all the patients who entered the study properly accounted for at its conclusion? Look for follow-up tables and whether patients in an RCT were analysed in the groups to which they were randomized.
- Were the groups similar at the start of the study?
- Aside from the experimental intervention, were the groups treated equally?

What were the results?
- How large was the treatment effect? How precise was the estimate of the treatment effect?
- Look for confidence limits and p-values.

Will the results help?
- Can these results be applied locally? Are these findings applicable to other patients?
- Were all relevant outcomes considered, including those relevant to patients?
- Are the benefits worth the harms and costs?

they can to minimize it. Different study designs are prone to different types of bias, but observational studies (and especially case-control studies) are particularly susceptible. More than 50 types of research bias have been identified but, for simplicity, they can be broadly grouped into two categories:

- ***Information bias.*** This results from systematic differences in the way in which data are collected from the various study groups, including data relating to either the exposure (i.e., factors that may be associated with an outcome of interest, such as weight) or the outcome (e.g., type 2 diabetes). For example, participants' weights may have been recorded when they visited a GP complaining of symptoms (which may be indicative of type 2 diabetes), or the study may rely on information collected at the time the participants registered in primary care. In the former case, information might be systematically more accurate for patients with diabetes than for patients without weight-related conditions, leading to an incorrect estimate of the association between exposure and outcome.
- ***Selection bias.*** This occurs when there is a systematic difference between either:
  - those who participate in the study and those who do not, *or*
  - those in the treatment arm of a study and those in the control group.

Patients and clinicians who have strong treatment preferences are often excluded from RCTs. While these steps increase the internal validity of an RCT, they often lead to selection bias and an overestimation of the benefits of treatment, especially for patient-centred outcomes. For example, some people with early breast cancer have a strong preference for less invasive lumpectomy, whereas others prefer the reassurance of knowing that all potentially cancerous tissue has been removed by a mastectomy. In one series of RCTs, only people without a strong preference for a particular treatment were recruited. However, as few as 10% subsequently agreed to have their treatment chosen at random, significantly reducing the extent to which the findings could be generalized to the wider population.

Similarly, telehealth interventions are becoming a prominent part of healthcare delivery, with examples including online cognitive behavioural therapy or home monitoring of health parameters such as blood pressure. There is some evidence of their effectiveness from RCTs. However, in several trials a large number of eligible individuals (over 75% in some cases) have declined to take part. As well as compromising external validity (i.e., generalizability of findings to other populations outside the setting of the trial), this may also indicate problems with the acceptability of the intervention, which may have a negative impact on uptake if it is later introduced into routine practice. In the case of telehealth, issues might include physical barriers in terms of accessing technology, as well as psychological barriers such as low confidence in using it.

Question 2: What are the results?

The second step of critical appraisal is to consider the results. In any study reporting quantitative data, these should be presented using statistical methods, including statistical measures of the uncertainty around study estimates. The particular methods employed will, and should, depend on the study design and the types of data that are being analysed. The section 'Understanding statistical results' (see below) gives a short introduction to the critical appraisal of statistical reports.

Question 3: Will the results help?

The final step of critical appraisal is considering whether the study is applicable to the decision being made for a particular patient. There are three issues to consider here.

First, are there any ***important differences*** between the participants in the study and the patient in question? These must be identified, as they could have an impact on the effectiveness of an intervention. Check the study inclusion and exclusion criteria, which are usually reported in the methods section. Would the patient in your care have been eligible for inclusion in the study? Identify any characteristics that the patient has that were not considered in the study.

Second, many interventions and processes used in everyday clinical practice have both benefits and ***adverse consequences***, and these should be weighed against each other. For example, breast cancer screening programmes in the UK currently invite females aged 50 to 70 years to undergo mammography every 3 years. Breast screening helps identify breast cancer early. The earlier the condition is found, the better the chances of surviving it, and the less likely patients are to need a mastectomy or adjuvant therapy (chemotherapy and/or radiotherapy). However, all screening can lead to overdiagnosis. Overdiagnosis refers to the detection of cancers through screening that would not have become clinically apparent in the person's lifetime. Although their cancer would not have caused them ill health, these people will undergo treatment, such as surgery, which may result in side-effects and complications, as well as psychological, social, and financial consequences. Of the 470,000 UK females aged 50 years who are invited to begin screening every year, it is estimated that just over 3 per 1000 will be overdiagnosed with cancer in the next 20 years. Although most public health bodies internationally recommend screening, there remains some debate as to the balance of benefits and harms. Finally,

cost-effectiveness is often not reported in the analysis of clinical trials. If a treatment is effective but provides only a small benefit and is very expensive, it may not be a good use of resources. Equally, even if a treatment is shown to be cost-effective, it may not be affordable. In the UK, NICE uses the cost per quality-adjusted life-year (QALY) to judge the cost-effectiveness of new technologies. This is the estimated cost of each additional year of life gained by a treatment or procedure, measured not just in terms of extra months or years of life but also in terms of the quality of that life. This is defined, for example, as freedom from or reduction in pain, or the ability to carry out the basic activities of daily living. Currently, NICE uses a threshold of £20,000–£30,000 per QALY. Treatments that come in at or below the threshold are usually approved. Those that come in above tend not to be judged cost-effective and so are not recommended for adoption by the NHS. Again, however, affordability of the healthcare system is not taken into account by this approach. For example, a treatment may result in significant quality-of-life gains but be very expensive and applicable only to a small subset of patients with a particular condition.

UNDERSTANDING STATISTICAL RESULTS

Statistics is the science of learning from data. It has two branches: descriptive and inferential. Descriptive statistics is the art of describing and visualizing the information contained in a given dataset. Inferential statistics is the art of drawing inferences from a particular dataset to the real-world process that is being studied. Reports of statistical results in medicine should contain both descriptive and inferential statistics.

Descriptive statistics

Descriptive statistics may be presented in the form of tables, graphs, and numbers included in a text. A description of the dataset is an important part of a statistical report. Descriptive statistics provide context and allow the reader to judge the representativeness of the data and how likely it is that biases are present. For example, descriptive statistics may show that all patients studied were aged 65 or younger. It is then clear that the study's conclusions may not be generalizable to patients who are older.

Inferential statistics

Description of a particular dataset in itself does not enable us to draw conclusions about the real-world process we wish to study. To do so, we need to employ inferential statistics. Inferential statistics are based on mathematical models that account for the influence of randomness on the data that we happen to observe in a particular study. In general, inferential statistics account for randomness only and do not account for other aspects that may affect the validity or reliability of a study's results, such as poor data quality or selection bias. For the reader of research reports, the two most important techniques of inferential statistics to understand are confidence intervals and hypothesis tests.

Confidence intervals

To understand confidence intervals, consider the following example. During the COVID-19 pandemic, the UK Office for National Statistics (ONS) conducted regular surveys to estimate the SARS-CoV-2 infection rate. In the last week of September 2021, the ONS estimated that 1.6% of the population of Scotland had a SARS-CoV-2 infection (https://www.beta.ons.gov.uk/peoplepopulationandcommunity/healthandsocialcare/conditionsanddiseases/bulletins/coronaviruscovid19infectionsurveypilot/8october2021). Since this estimate was based on testing a random sample of people, rather than testing everyone in the population, there is statistical uncertainty around this estimate.

A confidence interval is used to quantify the uncertainty around an estimate. For example, the ONS reported a confidence interval of 1.3% to 1.9% around its estimate of the SARS-CoV-2 infection rate in Scotland. Such a confidence interval is often written as [1.3%, 1.9%]. Informally, this confidence interval can be interpreted to mean that the true infection rate is probably somewhere between 1.3% and 1.9%.

A confidence interval is specified by a confidence level. Typically in medical research, 95% confidence intervals (95% CIs) are reported, although other confidence levels (such as 99% or 90%) are sometimes used. A 95% CI has a 95% probability of containing the true value that we are trying to estimate, but that we do not know. Another way to understand this statement is: if I conducted 100 studies to estimate the infection rate and calculated a 95% confidence interval from each study, on average, 95 of these 100 confidence intervals would contain the true infection rate.

The importance of confidence intervals lies in the fact that they tell us something about the uncertainty around an estimate. A wider confidence interval indicates more uncertainty. For example, consider **Box 4.5** below, which contrasts two hypothetical studies: one large and one small. Both studies estimate the SARS-CoV-2 infection rate in Scotland to be 1.6%, but their confidence intervals differ. The 95% CI from the smaller study is 0.7% to 3.1%. This confidence interval is relatively wide, reflecting a high statistical uncertainty.

Generally, a published study should report confidence intervals around all important estimates. These may be estimates of percentages or proportions (as in the example above), or of other quantities, such as the size of a treatment effect. Confidence intervals are important because they indicate the statistical uncertainty around an estimate. To say that 'this study shows that the infection rate in Scotland is 1.6%' is not justified, because the true infection rate remains unknown. A better way to interpret the study's results acknowledges the uncertainty, for example, 'From this study, we estimate that the infection rate is probably somewhere between 1.3% and 1.9%'.

Hypothesis tests and p-values

Hypothesis tests are used to formally evaluate the statistical evidence for the existence of treatment effects or other effects of interest. There are many different types of hypothesis tests, but the basic logic is the same, regardless of which particular test is used.

As an example, consider a study of the effect of dietary salt intake on systolic blood pressure (SBP). Patients with chronic kidney disease (CKD) were randomized to either of two groups: 38 patients followed a diet with normal salt intake, and 38 different patients had low salt intake for 1 week. SBP was measured at the end of the week.

Box 4.5 Estimates and confidence intervals of the SARS-CoV-2 infection rate from two hypothetical studies

Study size	Estimated percentage of infected people	Estimated number of infected people (in a population of 5.3 million)	95% confidence interval for the percentage	Confidence interval for the number of infected people	The estimate is…
Large sample	1.6%	85,000	[1.3%, 1.9%]	[69,000, 101,000]	…relatively precise
Small sample	1.6%	85,000	[0.7%, 3.1%]	[37,000, 164,000]	…relatively imprecise

The mean (average) SBP in the low salt group was 115.0 mmHg, while in the normal salt group the mean was 121.6 mmHg. A measure of the effect of a low salt diet on SBP is the difference between these means. The mean difference observed in this study is 115.0 mmHg – 121.6 mmHg = –6.6 mmHg. So the 'low salt' group, on average, had a lower SBP, by 6.6 mmHg.

This mean difference in the sample (–6.6 mmHg) is a descriptive statistic. It applies to our particular sample of 38 patients. To draw conclusions about the effect of a low salt diet in patients with CKD generally, we need to use inferential statistics.

Statistical hypothesis tests assess the compatibility of a statistic with a pre-specified hypothesis about the world outside our sample. This hypothesis is formally called the *null hypothesis*. The null hypothesis in our example may be: 'Salt intake has no effect on SBP'. Is the result from our sample (mean difference of –6.6 mmHg) compatible with the absence of a real effect of salt intake on SBP in patients generally? This is the question a hypothesis test would aim to answer in this example.

The results of a hypothesis test may be reported as something like this:

$$\text{Mean}_{\text{normal_salt}} - \text{Mean}_{\text{low_salt}} = -6.6\,\text{mmHg},\ p = 0.021$$

Other numbers relevant to the test may be reported, but to explain them in detail is beyond this short introduction. For our purposes, it is important to understand the quantity p, which is commonly called the p-value. Here, the p-value is 0.021.

The p-value is a probability and can take values between 0 and 1. It indicates the probability of seeing a difference as large as the one we did see (or a larger one), if the null hypothesis was in fact true. In this example, the p-value is the probability of seeing a difference of 6.6 mmHg (or larger) between the two groups if in reality salt intake had no effect on SBP. Here, p = 0.021, or about 2%. This means that, if in reality salt intake had no effect, and we conducted our study 100 times on different patients, on average we would see a difference of 6.6 mmHg in SBP or larger in 2 out of our 100 studies. So if the null hypothesis was true (if salt intake had no effect), our observed difference would be unlikely. This is interpreted as evidence that the null hypothesis may be false, which in our example means: the small p-value is evidence that salt intake does in fact have an effect on SBP.

The null hypothesis to which a particular p-value refers may not always be explicitly stated in a publication. Usually, the null hypothesis has the form 'the treatment has no effect' or 'the exposure has no effect', although this is not necessarily so. When trying to understand the meaning of a p-value in a published study, ask yourself which null hypothesis it assesses, as this must be clearly understood in order to interpret the p-value correctly.

Statistical significance

A customary threshold of $p<0.05$ is often used to make a binary decision whether the evidence against the null hypothesis is strong enough to 'reject' it, or not. According to this method, if $p<0.05$, the result is called 'statistically significant' and is taken as evidence against the null hypothesis. For example, when a research report states that 'the treatment group had a lower blood pressure than the control group, and this difference was statistically significant', this is usually a way of saying that $p<0.05$ for the null hypothesis of 'no difference' in blood pressure between the groups.

The threshold '$p<0.05$' is arbitrary, and there is no statistical or scientific reason why it should be preferred over other possible thresholds. It is an unfortunate fact that in much medical research today, complex statistical results are often reduced to a binary judgement regarding whether some result is 'statistically significant' or not. Good publications should report precise p-values (e.g., p = 0.021, as in the example above), rather than merely stating if a result is 'statistically significant' or not. However, p-values smaller than 0.001 are often legitimately reported as '$p<0.001$' in research publications.

Many misconceptions exist about the concept of 'statistical significance' among researchers, and these misconceptions are often reflected in erroneous interpretations of study results. Three points are especially worth emphasizing:

Statistical significance does not mean strong scientific evidence. If $p<0.05$, this is often misinterpreted to mean that a finding is scientifically robust. In fact, all aspects of the study need to be considered to judge the scientific robustness of a finding, including the study design, the quality of the data, the likelihood of biases, the plausibility of the causal mechanism hypothesized to explain the finding, etc. None of these other aspects are measured by the p-value.

Statistical significance does not mean clinical relevance. If $p<0.05$, this is often misinterpreted to mean that a finding is clinically important, or important to patients. In fact, a treatment may have a very small effect (e.g., it may very slightly reduce blood pressure) that is 'statistically significant' but clinically irrelevant (e.g., the small reduction in blood pressure may not be sufficient to help prevent heart disease).

Absence of evidence is not evidence of absence. If $p>0.05$, this is often misinterpreted to mean that the null hypothesis is true. In fact, a large p-value means that this particular study has not produced strong evidence *against* the null hypothesis. But a large p-value does *not* constitute evidence in favour of the null hypothesis. For example, you may read a sentence like: 'There was no difference between the treatment and control groups (p = 0.38).' This is a misleading statement. A better report should state what the descriptive difference between treatment and control group actually was, should give the confidence interval for the estimated treatment effect, and might interpret the large p-value as indicating 'weak statistical evidence for an effect of the treatment' or 'insufficient statistical evidence to conclude that the treatment has an effect'. Just because a particular study did not find strong evidence for an effect does not mean that the study has established that no effect exists in reality. In hypothesis testing, absence of evidence for an effect is not evidence of absence of an effect.

Worked examples

We will now turn to worked examples that illustrate the use of descriptive statistics, confidence intervals, and hypothesis tests in real research studies. The four examples differ by study design and the type of outcome that is being measured. We consider, in turn:

- Treatment effects on numeric measurements
- Treatment effects on dichotomous (binary) outcomes
- Treatment effects on the time it takes for an event to occur
- Meta-analyses of studies of treatment effects.

Numeric outcomes: differences between means

When the outcome is a numeric measurement, such as blood pressure, body weight, or serum creatinine, the measure of the treatment effect is often defined to be the difference in means between the treatment group and the control group. Consider again the hypothetical study of the effect of dietary salt intake on systolic blood pressure (SBP). We saw that the mean difference in the sample was –6.6 mmHg, such that the low salt group had lower SBP on average, and that this may be reported as:

$$\text{Mean}_{\text{normal_salt}} - \text{Mean}_{\text{low_salt}} = -6.6\text{mmHg},\ p = 0.021.$$

The small p-value indicates statistical evidence that a low salt diet results in lower average SBP than a normal salt diet. Conversely, if the p-value had been large (e.g., p = 0.32), this would be taken to indicate that there is weak statistical evidence from this study for an effect of salt intake on blood pressure.

A confidence interval (CI) of the treatment effect should always be considered alongside the p-value. Here, the 95% CI for the mean difference is [–1.0 mmHg, –12.2 mmHg]. This indicates that, according to this study, a low salt diet reduces SBP by probably somewhere between 1.0 and 12.2 mmHg. It is thus possible, judging from this study alone, that the effect of the low salt diet is very small: a reduction of only 1 mmHg is unlikely to be clinically relevant. On the other hand, this study's data are also compatible with a rather large effect (a reduction of 12.2 mmHg). Larger studies, or a meta-analysis of small studies, may be needed to obtain a more precise estimate of the effect of a low salt diet on SBP.

There is a mathematical correspondence between confidence intervals and p-values. When a 95% CI contains the test value of the null hypothesis (here: 0 mmHg difference due to low salt intake compared to normal salt intake), then the p-value for that null hypothesis will always be 0.05 or larger. Conversely, when a 95% CI does *not* contain the test value, the p-value will always be smaller than 0.05.

(This example is inspired by *Konishi Y et al. Sodium sensitivity of blood pressure appearing before hypertension and related to histological damage in immunoglobulin A nephropathy.* Hypertension *2001 38; 1:81–85*, although Konishi et al. used a different study design and hence different tests.)

Dichotomous (binary) outcomes

An outcome is dichotomous when there are exactly two possibilities: either an event occurs or it does not. Examples of dichotomous outcomes are patient death (death or survival), recovery from illness (recovered or not), and hospital readmission after surgery (readmitted within 12 months or not readmitted).

Consider the following example. A randomized placebo-controlled trial was conducted in South Africa and Malawi to evaluate the efficacy of a rotavirus vaccine in preventing severe gastroenteritis in infants; 4417 infants were included in the analysis, and of these, 2974 were randomly allocated to receive the vaccine, while 1443 received a placebo. The primary outcome was gastroenteritis caused by rotavirus in the period from 2 weeks to 1 year after the last dose of the vaccine (or placebo) was given. In the vaccine group, rotavirus infection was detected in 56 infants (1.88%); the same was true for 70 infants in the placebo group (4.85%); *Madhi SA et al. Effect of human rotavirus vaccine on severe diarrhoea in African infants.* New England Journal of Medicine *2010; 362:289–298.*

A good paper should report all these descriptive statistics. They are summarized in **Box 4.6**. The results might then be further analysed in several ways.

Odds and the odds ratio

The odds ratio is a measure of the relative effect of a treatment on the odds of an effect of interest. The odds of an event are calculated as the number of people who experience the event divided by the number who do not experience the event. In our example, the odds of disease for the vaccine (intervention) group are:

$$Odds_{\text{int}} = D_{\text{int}} / H_{\text{int}} = 56/2918 = 0.0192$$

By the analogous calculation, the odds of disease in the control group are $Odds_{cont} = 0.0510$.

The odds ratio (*OR*) is calculated as the odds in the intervention group divided by the odds in the control group:

$$OR = \frac{Odds_{\text{int}}}{Odds_{cont}} = \frac{0.0192}{0.0510} = 0.38$$

This result means that the vaccine group had lower odds than the placebo group by a factor of 0.38. The same result is sometimes expressed by stating that *the vaccine group had 62% lower odds than the placebo group*, since (1 – 0.38) × 100% = 62%.

Generally, an odds ratio of 1 would indicate that there is no difference between the two groups. In our example, if *OR* = 1, this would indicate that the vaccine had no effect on the odds of disease. An odds ratio smaller than 1 indicates that the treatment group has lower odds of the event compared to the control group, while an odds ratio larger than 1 indicates that the treatment group has higher odds of the event.

Turning now to inferential statistics, the odds ratio observed in the sample (here: 0.38) is taken as an estimate of the odds ratio in the population (here: the reduction of disease odds that would result if all infants were vaccinated). A good publication should report a confidence interval around the odds ratio estimate. In the rotavirus

Box 4.6 Results from an RCT of rotavirus vaccine in Malawi and South Africa

	Event: Rotavirus gastroenteritis	Non-event: No rotavirus detected	Total
Intervention Arm: Vaccine	D_{int} 56	H_{int} 2918	N_{int} 2974
Control Arm: Placebo	D_{cont} 70	H_{cont} 1373	N_{cont} 1443

D denotes patients experiencing gastroenteritis (***D***iseased), H patients who did not (***H***ealthy), and N the total ***N***umber of patients studied. The 'int' suffix denotes patients in the '***int***ervention' (vaccine) group and 'cont' patients in the ***cont***rol group.

vaccine study, the 95% CI for the odds ratio is [0.23, 0.54]. So the data from this study suggest that the vaccine reduces the odds of severe rotavirus gastroenteritis by probably somewhere between a factor of 0.23 and 0.54. We can see that there is considerable uncertainty around the estimate—the confidence interval indicates that the data are compatible with a wide range of effect sizes, which include a halving of the odds (*OR* = 0.5) as well as a fourfold reduction of the odds (*OR* = 0.25).

Risk and the risk ratio

The risk ratio is another measure of the relative effect of two treatments. The risk of an event is estimated as the proportion of people who experience the event (i.e., the number of people who experience the event divided by the total number of people under investigation). The estimated risk of disease in the vaccine group is:

$$Risk_{int} = D_{int} / N_{int} = 56/2974 = 0.0188$$

By the analogous calculation, the estimated risk of disease in the control group is $Risk_{cont}$ = 0.0485. Risks are also sometimes expressed as percentages. Here, the estimated risk is 1.88% in the treatment group and 4.85% in the control group.

The risk ratio (*RR*) is calculated as the risk in the intervention group divided by the risk in the control group:

$$RR = \frac{Risk_{int}}{Risk_{cont}} = \frac{0.0188}{0.0485} = 0.39$$

This result means that the vaccine group had a lower proportion of diseased infants than the placebo group, by a factor of 0.39. The same result is sometimes expressed by stating that the vaccine group had a 61% lower estimated risk than the placebo group.

Generally, a risk ratio of 1 would indicate that there is no difference between the two groups. A risk ratio smaller than 1 indicates that the treatment group has a lower risk of the event compared to the control group, while a risk ratio larger than 1 indicates that the treatment group has a higher risk of the event.

The risk ratio calculated from the study data is taken as an estimate of the risk ratio in the population. A 95% confidence interval for the risk ratio is [0.27, 0.55]. So the data from this study allow us to estimate that the vaccine reduces the risk of severe rotavirus gastroenteritis by probably somewhere between a factor of 0.27 and 0.55 (approximately quartering to halving the risk). This indicates considerable statistical uncertainty.

In the case of vaccination studies, the quantity (1 – *RR*) × 100% is called the vaccine efficacy. Here, the vaccine efficacy is estimated as (1 – 0.39) × 100% = 61%. This means that a vaccinated person has a 61% lower estimated risk of contracting the disease compared to an unvaccinated person. A 95% confidence interval for the vaccine efficacy should also be reported (in our example this is [45%; 73%]).

More generally, when a treatment or exposure reduces the risk of the outcome event, a relative risk reduction (RRR) can be calculated, such that *RRR* = 1 – *RR*. In our example, the relative risk reduction is as follows: *RRR* = 1 – 0.39 = 0.61, or 61%. Conversely, if a treatment or exposure increases the risk of the outcome event, such that the risk ratio is larger than 1, a relative risk increase (RRI) can be calculated as *RRI* = *RR* – 1.

Absolute risk reduction

The *risk difference* associated with a treatment is calculated by subtracting the risk of disease in the treated group from the risk in the control group. Since usually a treatment is hypothesized to reduce the risk of the outcome event, the risk difference is often referred to as the *absolute risk reduction* (*ARR*). Should a treatment or exposure increase the risk of an outcome event, the term *absolute risk increase* would be more appropriate.

Using the estimates from the vaccination study, the *ARR* is calculated thus:

$$ARR = Risk_{cont} - Risk_{int} = 0.0485 - 0.0188 = 0.0297$$

$$= 2.97 \textit{ percentage points}$$

This result means that the proportion of diseased infants in the vaccine group was 2.97 percentage points lower than in the control group.

A 95% confidence interval for the *ARR* is [0.018, 0.042]. So the data from this study allow us to estimate that the vaccine reduces the risk of severe rotavirus gastroenteritis by probably somewhere between 1.8 and 4.2 percentage points.

About odds ratios, risk ratios, and absolute risk reduction

The odds ratio and the risk ratio are common effect size measures in clinical trials as well as observational studies. They are useful because they can be compared across studies with different baseline odds, or baseline risks. For example, suppose the risk of death from some disease is 10% in Country A, and a study finds that a new drug has the effect of halving that risk (*RR* = 0.5) so that the risk of death among patients who take the drug is 5%. A different study may investigate the same drug in a different country, Country B, where the risk of death from the disease may be only 4%. If the effect of the drug is the same in both countries (*RR* = 0.5), the risk of death among patients in Country B who take the drug is 2%. Note that, despite the risk ratio being the same in both studies, the ARR would be 5 percentage points in the first study, but 2 percentage points in the second study. So the drug, given to 100 patients in each country, would, on average, save 5 lives in Country A, but only 2 lives in Country B.

The risk ratio and the odds ratio can encourage misleading interpretations, if the baseline risk is small. For example, an epidemiological study may find that taking a certain food supplement is associated with halving the risk of some disease (*RR* = 0.5). This sounds like a large effect: 50% less risk! However, suppose the baseline risk is 0.001% (1 in 100,000 people get the disease without the food supplement). Then *RR* = 0.5 means that the risk with the food supplement is 0.0005% (1 in 200,000 people). So the absolute risk reduction is 0.0005 percentage points, which does not sound quite as impressive as a 50% risk ratio. A good research publication will report both a measure of relative effect and a measure of absolute effect. If only a relative effect measure is reported, it is often useful, as a reader, to use the descriptive statistics that have been reported to calculate an absolute effect measure oneself, in order to get a fuller picture of the size of the effect.

Number needed to treat

The number needed to treat is another measure of absolute effect size, which is popular due to its intuitive interpretation: the number of people who need to receive the treatment in order for one person to benefit. The number needed to treat (*NNT*) is calculated thus (again using the rotavirus vaccine study as an example):

$$NNT = \frac{1}{ARR} = \frac{1}{0.0297} = 33.7$$

This means that 33.7 infants would need to be vaccinated for 1 infant not to get rotavirus gastroenteritis, who would have got it without the vaccine. A 95% CI for the *NNT* is [23.9, 56.9]. So the data from this study allow us to estimate that the number needed to treat with the vaccine to avoid one case of the disease is probably somewhere between 23.9 and 56.9.

Hypothesis tests for dichotomous outcomes

The primary effect size measure for dichotomous outcomes is usually either the risk ratio or the odds ratio. To gauge the evidence for an effect of the treatment, a hypothesis test is usually conducted. The null hypothesis is then usually that *RR* = 1, or that *OR* = 1, which would indicate the absence of an effect of the treatment. In the rotavirus vaccine study, a test for the null hypothesis '*RR* = 1' yields p = 0.00000008. This very small p-value is strong statistical evidence that the vaccine has an effect. Conversely, a large p-value would be taken to indicate that there is weak statistical evidence for an effect of the vaccine from this study.

Time-to-event data (survival analysis)

Some studies follow participants over long periods of time and record the occurrence of events during that time. For example, the Scandinavian Simvastatin Survival Study (4S study) was a randomized controlled trial of 4444 patients with angina pectoris or previous myocardial infarction, who also had high serum cholesterol. Patients were randomized to receive either simvastatin or a placebo. One of the outcomes studied was death from any cause. Patients were followed up for 5 to 6 years from randomization. (See: *Scandinavian Simvastatin Survival Study Group. Randomised trial of cholesterol lowering in 4444 patients with coronary heart disease: the Scandinavian Simvastatin Survival Study [4S].* The Lancet *1994 344; 8934:1383–1389.*)

Survival analysis considers the outcome to be the time until a specific event occurs (here: the time until the participant dies, called 'time to death'). When analysing time-to-event data, it is important to consider unequal follow-up times. These come about because patients are usually not all randomized at the same time and also because some patients drop out of the study or are lost to follow-up before they experience the event. For example, if a patient moved out of the country 2 years after randomization, the investigators know that the patient was alive for the first 2 years of the study duration, but no information is available for the remainder of the intended follow-up time. This patient's follow-up is said to be 'censored at 2 years'. Survival analytic methods can account for censored data and obtain valid estimates of the survival chances of patients even in the presence of unequal follow-up times, while using all available data.

In the 4S study, death was recorded among 256 out of 2223 patients (11.5%) in the placebo group and 182 out of 2221 patients (8.2%) in the simvastatin group. This is important information, but since follow-up times varied between patients, these percentages cannot straightforwardly be used to compare the effects of treatment and placebo on the risk of death.

Kaplan-Meier plot

Time-to-event data are often visualized using a so-called Kaplan-Meier survival plot (K-M plot, **Fig. 4.2**). A K-M plot estimates the proportion of patients who have not yet experienced the event ('survived') over time and takes into account censoring. In this example, the K-M plot indicates that deaths occurred at a slower rate in the simvastatin group compared to the placebo group.

Cox regression and the hazard ratio

Several statistical methods may be used to make inferences about treatment effects from survival curves. A common method is Cox regression (also called 'Cox model' or 'proportional hazards model'). Cox regression can be used to model the effect of a treatment on the *hazard* of the outcome event (e.g., death) from time-to-event data. The hazard is the rate of events at one moment in time. The hazard may change over time, but the Cox model assumes that the ratio of the hazards of the two treatment groups remains constant over time. This is known as the 'proportional hazards assumption'.

The measure of the treatment effect provided by Cox regression is the hazard ratio (*HR*). A hazard ratio of 1 indicates that the treatments confer the same hazard of the outcome event. Hazard ratios that differ from 1 (are smaller or larger) indicate differences between the treatments.

Using the hypothetical data displayed in **Fig. 4.2**, Cox regression estimates *HR* = 0.78, for simvastatin versus placebo, indicating that the simvastatin group is estimated to have a 22% lower hazard of death than the placebo group.

A 95% confidence interval for the hazard ratio is [0.64, 0.95], and a p-value for the hypothesis of no difference between the groups is p = 0.014. Thus there would be strong statistical evidence from these hypothetical data that simvastatin reduces the hazard of mortality, and the confidence interval suggests that simvastatin reduces the hazard of death by probably somewhere between 5% and 36%, compared to a placebo.

Meta-analysis

Suppose that you would like to know if exercise can reduce cardiovascular deaths in patients with coronary heart disease. Suppose, further, that you find two high-quality studies on this topic, and that one study reports 'statistically significant' evidence for a benefit of exercise, while the other reports a 'non-significant' result. It would be tempting to conclude from this that the published evidence is inconclusive. To do so is a form of what's called *vote counting*, the logic of which goes: one study shows a benefit of exercise, one study does not, so no side wins. However, vote counting is not the best way to combine information from several studies and can, in fact, lead to erroneous conclusions, which ultimately may mean that patients miss out on the best treatments or advice. A better way to make sense of data from multiple studies is meta-analysis.

Meta-analysis pools information from several studies that assess the same research question. The studies should investigate the same treatment or exposure (e.g., exercise-based rehabilitation), the same control (e.g., passive control), and the same outcome (e.g., death from cardiovascular causes). The population studied (e.g., patients with cardiovascular disease) should also be the same or similar across studies, and reports of meta-analyses should carefully document variations in populations (e.g., if studies differ in the age distribution of included patients or differ in their inclusion criteria).

Meta-analysis is typically conducted based on published information only, without access to the original data. The effect sizes and their statistical variability, which were either reported in the original studies or can be inferred from the study reports, are collated and combined statistically. The measure of effect size (such as risk ratio, hazard ratio, mean difference, etc.) should be the same in all studies. If it is not, the meta-analyst can sometimes use the information from the study report to convert one effect size into another, for example, to convert an odds ratio into a risk ratio.

In simple terms, meta-analysis works as follows:

- Take the effect size estimate from each study.
- Weight each study by the precision with which it has measured the effect, with more precise studies getting more weight (a more precise study has a smaller confidence interval).

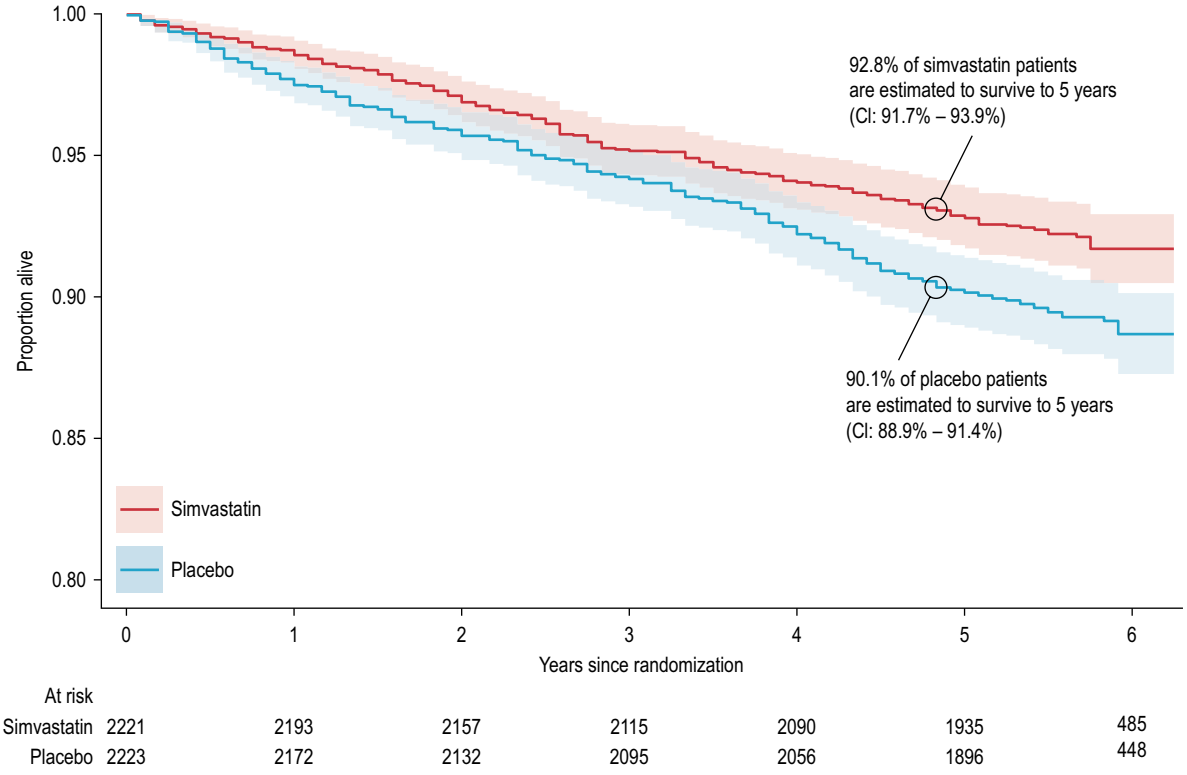

Fig. 4.2 Kaplan-Meier survival plot: Simvastatin vs placebo (hypothetical data). This plot is based on hypothetical data designed to be similar to the data from the 4S study but does not report the original data from that study. CI: 95% confidence interval (shaded areas around the survival curves). At Risk: Number of patients still alive and in the study at each time point. This is an indication of the size of the sample on which survival estimates from that point onwards are based. The number 'at risk' reduces over time for two reasons: because some patients die, and because some patients' follow-up is censored while they are still alive. *(Based on Spinks A, Glasziou PP, Del Mar CB. Antibiotics for sore throat. Cochrane Database of Systematic Reviews 2013; 11. Art. No.: CD000023.* https://doi.org/10.1002/14651858.*CD000023.pub4.)*

- Calculate a pooled effect size estimate as the weighted average of the estimates from all studies.

The details of these calculations are sometimes more complicated, but the above is the general logic. Generally, studies with larger sample sizes tend to produce more precise estimates and hence receive more weight, although factors other than the sample size can also influence the precision of a study. The results of a meta-analysis are typically displayed in a forest plot (**Fig. 4.3**), which displays a summary of the results from all studies included in the meta-analysis, as well as the result of the meta-analysis itself. The bottom row ('Common effect model') shows a risk ratio estimate of 0.56 (95% CI: 0.42, 0.76) from the meta-analysis, suggesting strong statistical evidence that exercise-based rehabilitation reduces the risk of cardiovascular death. In this special case, all eight study confidence intervals include the value 1 for the RR, which indicates no effect (lines for 95% CI cross the centre line). Therefore naïve *vote counting* would have led to the conclusion that no study has produced evidence for a benefit of exercise—but the meta-analysis shows that properly combined, the eight studies provide strong statistical evidence in favour of a benefit of exercise.

Publication bias

A good meta-analysis should assess publication bias. Publication bias comes about when the result of a study influences the likelihood of its publication. In many fields, studies with 'positive' results (e.g., that show evidence for an effect of a treatment) are more likely to be published than studies with 'negative' results (i.e., with statistically 'non-significant' findings). A naïve meta-analysis, which fails to account for publication bias, would then overestimate the efficacy of a treatment and indeed may conclude that a treatment is effective if, in reality, it is not. Therefore, many meta-analytic studies include a funnel plot that charts the study estimates around their pooled average and allows the meta-analyst to infer the presence or absence of bias (**Fig. 4.4**). Statistical methods exist to detect publication bias and adjust the analysis to remove the bias from the pooled estimate.

Summary and outlook

This section has discussed the concepts of descriptive and inferential statistics and has introduced two inferential procedures: confidence intervals and hypothesis tests. We have then illustrated how to apply these concepts in two-group randomized controlled trials with three types of outcomes (numeric, binary, and time-to-event), as well as in meta-analysis.

Of course, many more statistical procedures are found in published medical studies. Different methods and different tests are appropriate for different research designs and different types of data. A good introductory statistics textbook will introduce the reader to the technical vocabulary that is necessary to understand the rationale underlying statistical techniques, as well as to some of

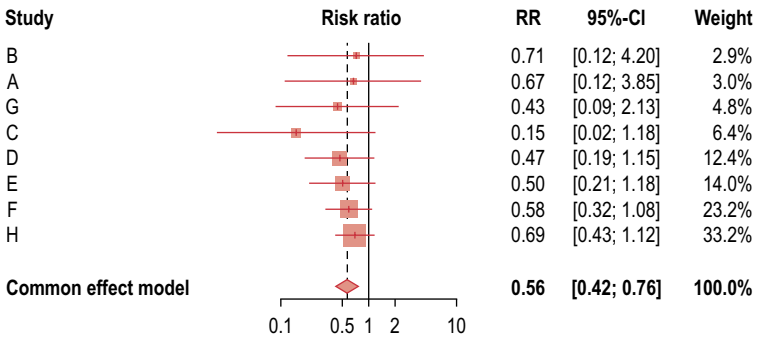

Fig. 4.3 Forest plot: risk ratios of eight studies on cardiovascular mortality: Exercise-based rehabilitation versus control. This forest plot, including some of the results, is based on Analysis 1.2.3 (p. 221) in: Dibben G et al. Exercise-based cardiac rehabilitation for coronary heart disease. Cochrane Database of Systematic Reviews 11 2021. Studies with narrower confidence intervals, and thus greater precision, are given larger weight in the analysis, represented by the size of the square. The location of the square indicates the study's effect size estimate, while lines extending to the left and right of the square indicate the 95% CI. The bottom row (diamond) is the result of the meta-analysis, with the diamond's centre indicating the pooled effect size estimate and its width the 95% CI. *CI,* Confidence interval; *RR,* risk ratio estimate.

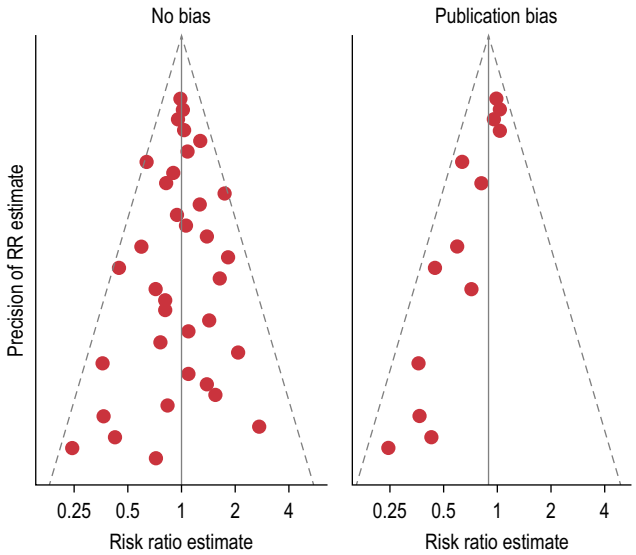

Fig. 4.4 Funnel plots illustrating two hypothetical meta-analyses. Each dot represents a study. The vertical axis represents the precision of the study, with more precise studies located towards the top. If there is no publication bias, a funnel plot should look something like the left panel: a symmetrical distribution scattered around the true effect size (in this example RR = 1, i.e., no effect), with more variation in estimates as study precision decreases towards the bottom of the plot. In the presence of publication bias, a funnel plot might look something like the right panel: the absence of symmetry suggests that small studies with 'non-significant' results or whose results indicate that the treatment may do harm (RR > 1) have been withheld from publication, while studies showing a benefit of the treatment (RR < 1, and 'statistically significant') were more likely to be published.

the most common analytic methods and when they are appropriate to use.

APPLYING THE EVIDENCE

The medical literature is continuously expanding, with new information published every day that could help to improve care for patients and population health. However, there are often major challenges involved in implementing the findings of research in clinical practice, with some estimates suggesting that the process takes an average of 17 years. The gap leads not only to the under-use of effective interventions but also to the incorrect use of others, as well as the over-use of unhelpful or unproven interventions. All of this means negative outcomes for patients and for population health. It is also a waste of health service resources and of costly and time-consuming research. Consequently, considerable effort has been put into improving the routine use of research findings.

Challenges of implementing evidence

Trial design

RCTs are designed to minimize the risk of bias, so differences between randomized groups can be interpreted as estimates of the causal effect of the treatment. RCTs may achieve this internal validity at the expense of external validity or generalizability. There are three reasons why RCTs in many areas of healthcare may have low external validity:

- ***The provider.*** The healthcare professionals who participate may be unrepresentative. They may have a particular interest in the topic or be enthusiasts and innovators.
- ***The setting.*** This also may be atypical: a teaching hospital, for example.
- ***The patients.*** All trials exclude certain categories of patients: for example, older patients or those with more than one illness. Often the exclusion criteria are so restrictive that the patients who are eligible for inclusion represent only a small proportion of the patients being treated in normal practice.

The outcome of drug treatment is likely to be unaffected by the characteristics of the prescribing doctor or the setting in which it is administered. On the other hand, the outcome of activities such as surgery and physiotherapy may be highly dependent on the characteristics of the provider, setting, and patients. Thus findings from

RCTs often need to be interpreted as indications of the *efficacy* of an intervention rather than its actual *effectiveness* in everyday practice. For successful implementation, however, both external validity and effectiveness are required if the findings are to be generalized to different patients and different settings.

Pragmatic RCTs

In a conventional RCT, the principal aim is to establish whether a treatment works. As outlined, because of the emphasis placed on internal validity, these 'explanatory' RCTs generally provide evidence of efficacy or what can be achieved in ideal circumstances.

However, the ultimate goal is to improve the health of real people in real settings, so it is crucial also to know whether an intervention is going to be effective in the real world. In contrast to explanatory trials, pragmatic RCTs place the emphasis on effectiveness rather than efficacy and seek to measure the benefit that the treatment produces in routine clinical practice; they therefore provide better evidence for decision-making.

There are some key differences between explanatory and pragmatic trials:

- Explanatory trials recruit a population that is as homogeneous as possible. In contrast, the design of a pragmatic trial reflects variations between patients that occur in real clinical practice.
- It may not be possible to blind participants and investigators to the treatment that is being given. Such biases are not necessarily viewed as detrimental in a pragmatic trial.
- In pragmatic trials, outcome measures should represent the full range of health gains relevant to patients and clinicians, for example, both a reduction in mortality after stroke and an improvement in quality of life.
- The two approaches to trial design will sometimes arrive at different conclusions about the benefit of a treatment, because a treatment that works in an ideal setting may not work in real life. The difference could also stem from the fact that improvement in a biomedical end-point does not produce the expected health gain. For example, although fluoride treatment for osteoporosis increases a commonly measured biomedical end-point (non-vertebral bone density), it actually raises fracture rates (an important clinical end-point) because it increases skeletal fragility. Consequently, it is not an effective treatment for postmenopausal osteoporosis.

The Pragmatic RCT design demonstrated its value early in the COVID-19 pandemic when the 'RECOVERY' trial was established in the UK to rapidly examine treatment effectiveness (see Pessoa-Amorim G et al., in 'Further Reading'). Key characteristics of the pragmatic RECOVERY design were as follows: simple recruitment of hospitalized patients using national routine datasets, allowing all hospital admissions to be quickly considered for recruitment, rapid randomization, and high follow-up rate; wide inclusion criteria allowing a diverse, representative population to be included; a platform design which allowed treatment arms to be added and removed as evidence emerged; and integration into the healthcare system allowing rapid translation into clinical practice. Within 100 days, RECOVERY demonstrated the survival benefit of dexamethasone in severe disease and enabled the swift cessation of other commonly used treatments which were ineffective, potentially harmful, and costly. Dexamethasone was promptly implemented worldwide, saving hundreds of thousands of lives.

Patient-centred outcome measures

Research only has external validity if it reflects the wider priorities of patients and, for population health research, the public. For this reason, the outcomes of most relevance to patients must be included in trials. In one study, for example, patients with multiple sclerosis and their doctors were independently asked to select the three aspects of the disease that had the greatest effect on quality of life. Doctors focused mainly on the physical effects of the disease, whereas patients were more concerned about mental health, emotional wellbeing, general health, and vitality, which are often not measured in RCTs. Similarly, in RCTs of anticonvulsants, individuals with epilepsy are much more interested in the proportion of patients rendered free of seizures than they are in changes in mean seizure frequency (a commonly used measure of benefit in RCTs).

Barriers and facilitators to change

Almost all healthcare interventions are complex and involve several interacting components. For example, a new drug therapy may superficially seem simple to implement, but the process might actually require additional patient monitoring or allow management to move from an inpatient to a community setting, requiring a change in care pathways. Other new interventions may necessitate amendments to referral processes (e.g., by allowing direct access to hospital care) or involve care provision by different staff (e.g., allied health professionals rather than doctors). These changes may involve modification of working practices, equipment, and care setting and entail additional unforeseen costs. It is often not clear which of the specific components of these complex interventions represent the 'active ingredient' for bringing about the intervention's effect.

If interventions are to be rolled out in other settings, careful consideration should be given to ensuring that interventions are designed in such a way as to be easily and successfully replicated. This involves trying to identify not only the key 'ingredients' that must be included but also whether the intervention might be sensitive to particular features of the local setting.

Intervention context

Barriers to change can arise at different levels in the healthcare system: the patient, their carer and family, the individual care professional, the healthcare team, the healthcare organization (e.g., its resources, capabilities, structure, culture, and politics), and wider society (e.g., the economic, social and political environment). Each of these components makes up the context of the intervention (**Fig. 4.5**). When a new intervention is being implemented, consideration should be given to what will happen when these individual contextual factors interact. Because of the complexity and diversity of each of these factors, the effect is likely to differ in different settings.

For example, reduction in hospital-acquired infections is a healthcare priority in many countries. Handwashing plays a key role. However, concordance on the part of healthcare workers in general, and doctors in particular, is known to be poor. Doctors are generally aware of the evidence but overestimate their own handwashing practices. Most countries and many hospitals have guidelines on the prevention of infections but they are frequently not followed. This means that, despite well-established evidence that has been properly disseminated, performance remains poor.

What is the problem? Research has shown that a range of competing demands reduce the likelihood of doctors washing their hands. These include a high workload, organization of the ward and access to facilities, concerns about skin irritation, lack of knowledge of the evidence, a lack of leadership to encourage change and mutual accountability, and an absence of institutional policies. Even if doctors are aware of the evidence and are willing to change, altering well-established patterns of care is difficult if the clinical environment is not conducive to change. These factors will be present to

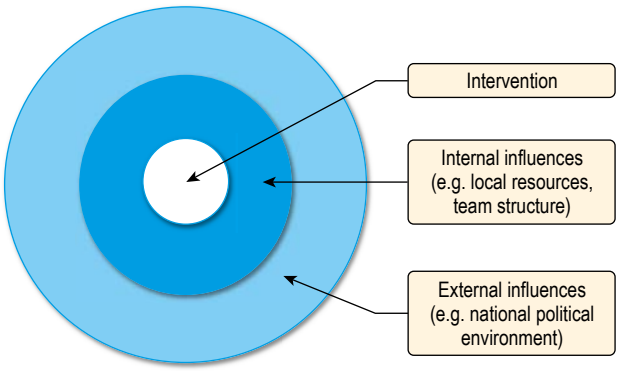

Fig. 4.5 Contextual factors that influence the implementation of evidence.

differing extents in different settings. The key ones should be identified in each location to ensure that change comes about.

Leadership

Local leadership has been identified as key to ensuring that evidence is used in practice. Leadership includes the actions taken by formal leaders in an organization to influence change. The attributes and qualities of leaders that appear to facilitate the use of research evidence to change practice include:

- valuing research
- being knowledgeable about research
- role-modelling evidence-based practice
- involving other staff in decision-making
- supporting changes in practice
- ensuring that policy and procedures are evidence based and up to date.

Resistant leadership that fails to support change reduces the likelihood that evidence will be applied in practice.

Improving the uptake of evidence

There is a growing body of evidence relating to the effectiveness of different interventions to improve the uptake of evidence and change clinical and public health practice, which includes synthesizing and disseminating evidence in more accessible formats. For example, information graphics (or 'infographics') utilize images and data visualizations (pie charts, bar graphs, line graphs) to present research in an engaging way. Infographics add value by enhancing understanding and the reach of research. Information is more likely to be retained if it has been learned from an infographic than from text alone. However, although this may help ensure the uptake of some simple changes, it is insufficient for most innovations. Instead, multifaceted approaches are required, including a combination of the following:

- ***Educational strategies.*** Large conferences and courses have limited effects; small group interactive education sessions with active participation have more positive results. Educational outreach by experts may be especially effective for improving prescribing behaviour.
- ***Audit and feedback.*** These seem to be most effective when targeting diagnostic test ordering and prevention interventions. The effect size depends on the type of feedback, its source and format, and the frequency or intensity of presentation. Feedback is recommended in combination with education, outreach visits, or reminders.
- ***Use of reminders and computers.*** Computer prompts, for example, may be one of the most effective interventions. They have been shown to be particularly effective in increasing the use of prevention interventions, For example, vaccination and cancer screening reminders.

All of these interventions have the potential to help facilitate the effective transfer of evidence to practice, although the evidence base for them is still emerging. More than one approach may be needed. Further research is ongoing to increase understanding of the processes and elements behind successful change.

Online material at Elsevier eBooks+ includes a significant amount of additional content, including practical exercises based on published clinical evidence, to help readers put into practice the principles described in this chapter.

Questions for this chapter can be found on Elsevier eBooks+.

SECTION 1: ASKING ANSWERABLE QUESTIONS AND SEARCHING FOR THE EVIDENCE

Q1: Sarah is a 37-year-old female who asks for your advice about managing her mild depression. She is reluctant to take medication and wonders if regular exercise might improve her mental health.

For the vignette above, please set out:

a. An answerable clinical question
b. PICO terms

Question 1b

Patient Problem or Population	Intervention or Exposure	Comparison or Control	Outcome Measure

c. Search terms for use in an online database (e.g., Medline)

Model answer:

a. Answerable clinical question: Is exercise as effective as drug therapy in reducing symptoms of mild depression?
b. PICO terms

Answer 1b

Patient Problem or Population	Intervention or Exposure	Comparison or Control	Outcome Measure
Mild depression	Exercise	Drug therapy	Reducing symptoms of depression

c. Search terms for use in an online database (e.g., Medline)
depression AND exercise
depression AND exercise AND drug AND symptoms

Q2: Elizabeth is 62 years old and suffers from chronic obstructive pulmonary disease, for which she takes regular medication. You wonder whether she might also benefit from pulmonary rehabilitation.

For the vignette above, please set out:

a. An answerable clinical question
b. PICO terms

Question 2b

Patient Problem or Population	Intervention or Exposure	Comparison or Control	Outcome Measure

c. Search terms for use in an online database (e.g., Medline)

Model answer:

a. Answerable clinical question: In patients under the age of 65 years who suffer from chronic obstructive pulmonary disease, does pulmonary rehabilitation in conjunction with pharmacological treatment significantly improve quality of life?
b. PICO terms

Answer 2b

Patient Problem or Population	Intervention or Exposure	Comparison or Control	Outcome Measure
Patients <65 years old suffering from COPD	Pulmonary rehabilitation in conjunction with current pharmacological treatment	Standard pharmacological treatment without pulmonary rehabilitation	Improved quality of life

c. Search terms for use in an online database (e.g., Medline)
COPD AND "pulmonary rehabilitation"
COPD AND "pulmonary rehabilitation" AND "quality of life"

Q3: David is 67 years old and has had four episodes of cellulitis affecting his lower leg. You wonder whether he might benefit from prophylactic antibiotics.

For the vignette above, please set out:

a. An answerable clinical question
b. PICO terms

Question 3b

Patient Problem or Population	Intervention or Exposure	Comparison or Control	Outcome Measure

c. Search terms for use in an online database (e.g., Medline)

Model answer:

a. Answerable clinical question: In patients with recurrent cellulitis, do prophylactic antibiotics reduce the risk of the infection recurring, compared with no treatment?
b. PICO terms

Answer 3b

Patient Problem or Population	Intervention or Exposure	Comparison or Control	Outcome Measure
Patients with recurrent cellulitis	Prophylactic antibiotics	No treatment	Repeat infection

c. Search terms for use in an online database (e.g., Medline)
"recurrent cellulitis" AND "prophylactic antibiotics"
"recurrent cellulitis" AND "prophylactic antibiotics" AND infection

SECTION 2: CRITICAL APPRAISAL

In this section, you should read and critically appraise the following papers:

Lamb SE, Sheehan B, Atherton N et al. Dementia and Physical Activity (DAPA) trial of moderate to high intensity exercise training for people with dementia: randomised controlled trial. BMJ 2018;361:k1675.

CASP checklists can be downloaded at https://casp-uk.net/casp-tools-checklists/. Specimen answers are provided for your reference at https://coursewareobjects.elsevier.com/objects/elr/Kumar/clinicalmedicine10e/PDF/.

SECTION 3: INTERPRETING ODDS RATIOS, CONFIDENCE INTERVALS, AND P-VALUES

Paper 1

If tuberculosis treatment is not taken regularly, there may be risks to the patient and the public through the generation of drug resistance, relapse, and transmission of infection. Consequently, directly observed treatment (DOT) is currently recommended by the World Health Organization for patients at high risk of poor adherence (e.g., those with a history of homelessness, imprisonment, or drug use). Although DOT can be administered in clinic, community, or home settings, it still entails substantial inconvenience to patients and service providers. Developments in video technology have raised the possibility of remote video-observed treatment (VOT) as an alternative approach.

This study was carried out to test whether or not levels of treatment observation were improved with VOT. Patients who were at least 16 years old, with active pulmonary or non-pulmonary tuberculosis, and eligible for DOT were identified from 22 clinics in England. Individuals were then randomly assigned to either VOT (daily remote observation using a smartphone app) or DOT (observations done three to five times per week in the home, community, or clinic settings). The primary outcome was the completion of 80% or more scheduled treatment observations over the first 2 months following enrolment.

A total of 226 patients were randomly assigned, namely 112 to VOT and 114 to DOT; 78 (70%) of 112 patients on VOT successfully completed ≥80% of the scheduled observations during the first 2 months, compared with 35 (31%) of 114 on DOT. Odds ratio (OR) 5.18; 95% CI 2.94–9.12; p<0.0001.

Adapted from Story A et al. Smartphone-enabled video-observed versus directly observed treatment for tuberculosis: a multicentre, analyst-blinded, randomised, controlled superiority trial. Lancet *2019; 393(10177):1216–1224.*

Q1: What type of study is this?

Answer

A randomized controlled trial. Participants were randomly assigned to receive either the intervention, VOT (daily remote observation using a smartphone app), or the usual treatment/control, DOT (observations done three to five times per week in the home, community, or clinic settings).

Q2: What is the estimated odds ratio in this study?

Answer

5.18.

Q3: What does this mean in practice?

Answer

An odds ratio is a relative measure of the effectiveness of the intervention being studied, which allows the comparison of the intervention group of a study to the comparison or placebo group.

The trial above compared participants who had received video-observed therapy (VOT, intervention arm) with participants who had received directly observed therapy (DOT, control arm). The outcome—or event—of interest was ≥80% of the scheduled observations successfully completed during the first 2 months.

An odds ratio of 5.18 means that patients in the VOT group (intervention arm) had more than 5 times higher estimated odds of the successful completion of ≥80% of the scheduled treatment observations compared with the DOT group (control arm).

Here, the outcome is a desirable one (successful completion of treatment).

The OR is >1, so the intervention is better than the control—the odds of the outcome occurring is greater in the intervention group.

If the OR were <1, the control would be better than the intervention—the odds of the outcome occurring would be lower in the intervention group.

If the OR were = 1, there would be no difference between the two study groups, as the outcome is the same in both.

Q4: What is the confidence interval?

Answer

95% CI 2.94–9.12.

Q5: What does this mean in practice?

Answer

The confidence interval indicates the amount of statistical uncertainty around the measure of the efficacy of the intervention being studied. In other words, the confidence interval indicates how precise the effect estimate is. Confidence intervals are used because a study recruits only a small sample of the overall population, so the treatment effect (odds ratio) observed in the particular study is an imprecise estimate of the true treatment effect (true odds ratio in the population). Most studies report the 95% confidence interval (95% CI).

If the 95% confidence interval for an odds ratio includes the value 1 (e.g., if 95% CI 0.9–1.1), this implies that there is weak evidence for an effect of the treatment. If it does not (e.g., 95% CI 0.7–0.8), this is equivalent to a p-value smaller than 0.05 and suggests some statistical evidence for an effect of the treatment.

In the trial comparing VOT to DOT, the confidence interval is reported as 95% CI = 2.94–9.12, or approximately 3 to 9. This can be interpreted as follows: From this study, we estimate that the treatment probably increases the odds of completing ≥80% of the scheduled observations by somewhere between 3 and 9 times.

Q6: What is the p-value?

Answer

p<0.0001.

Q7: What does this mean in practice?

Answer

The p-value in this study is <0.0001. This means that if VOT actually had no effect, compared to DOT, the probability to observe an odds ratio of 5.18, or a larger one, was smaller than 0.0001 (or smaller than 0.01%).

This very small p-value is interpreted as strong statistical evidence that the treatment does have an effect.

Q8: How would you summarize the findings of this study?

Answer

This trial was carried out to examine whether or not levels of treatment observation were improved with video-observed therapy (VOT), compared with conventional directly observed therapy

(DOT). The results were presented as an odds ratio = 5.18; 95% CI 2.94–9.12; p<0.0001. This means that the odds of patients successfully completing ≥80% of the scheduled treatment observations were more than 5 times greater in the VOT arm, compared with the DOT arm, and we can be 95% confident that the treatment effect lies between 2.94 times and 9.12 times greater.

As a consequence, the authors concluded that VOT was a more effective approach to observation of tuberculosis treatment than DOT. They note that VOT is likely to be preferable to DOT for many patients across a broad range of settings, providing a more acceptable, effective, and cheaper option for supervision of daily and multiple daily doses than DOT.

CORE SKILLS AND KNOWLEDGE

The clinical practice of diagnosing and managing genetic disease is an expanding and evolving field. Increasingly, this is carried out by experts in organ-based subspecialties (e.g., neurologists and dermatologists), in partnership with clinical genetics teams. Hence, a working knowledge of skills such as documenting a family history and understanding basic genetic investigations is relevant across a range of disciplines. Typically, clinical geneticists are qualified adult or paediatric physicians who undertake postgraduate training in the specialty, often including a period of laboratory-based research. Genetics services are usually delivered in specialist centres in the outpatient setting.

Key skills in clinical genetics include:

- Obtaining a comprehensive history. A careful family history is essential.
- Drawing and interpreting a family tree.
- Estimating the risk of a future pregnancy being affected or carrying a disorder, based on common patterns of inheritance.
- Understanding the principles of genetic testing and the ethical challenges this may entail.

Exposure to genetics multidisciplinary team meetings and genetics clinics represent opportunities for medical students and training clinicians to gain insights into how to ask relevant questions when taking a history from a patient with genetic disease. This has to be coupled with thorough clinical examination, which may lead to the selection of appropriate radiological imaging tests and invasive tests such as tissue biopsies.

CLINICAL SKILLS

Taking a genetic family history

A genetic family history consists of information describing how family members are related to each other (their biological relationships) and any medical conditions they may have.

Establishing such a family history can:

- reveal patterns of inheritance
- help make or refine a diagnosis
- help assess the likelihood of genetic disease in relatives
- affect testing, treatment and management strategies
- highlight the need for referral to specialist services
- help in building rapport with patients.

Box 5.1 How to take a genetic family history

Immediate family

In adult patients, information is typically obtained first on which members of the immediate family are affected by a disorder. Begin drawing a pedigree with the patient towards the bottom of the page (allowing space below for any children).

- Ask about their spouse or partner.
- Ask about any children the patient may have.
- Enquire sensitively about stillbirths and miscarriages.

Where any individual is affected, try to determine the age at which they were diagnosed and the severity of their disease.

Patients' siblings and parents

Siblings are drawn alongside the patient and the parents are placed above, with lines indicating family relationships (which can be complex):

- Ask whether the patient's parents are alive, and about any illnesses they have at present or have been diagnosed with in the past. If the parents are deceased, record the stated cause of death and the age at which this happened.
- Ask how many siblings and half-siblings the patient has, and their ages. Enquire about their health.

Sometimes, patients may not know the family members' cause of death, which may, in some cases, reflect medical uncertainty (e.g., in conditions that cause sudden death); this uncertainty should be recorded.

Father's side of the family

Typically, these family members will be drawn above and to the left of the patient and include the father's siblings and parents. Information on a minimum of three generations should be obtained.

Mother's side of the family

Typically, these family members will be drawn above and to the right of the patient and include the mother's siblings and parents. Information on a minimum of three generations should be obtained.

Family history questionnaire

Sometimes, patients may find it difficult to recall information in a clinical consultation. A family history questionnaire can aid information-gathering, as the patient can fill this in at home, with the help of family. These questionnaires can be verified against cancer registry data, which is important as patients sometimes may not know which specific cancers affected their relatives. Increasingly, online forms are being piloted, which can be filled in electronically.

Information is usually gathered by asking a series of questions about each member of the family in a systematic order (**Box 5.1**) and recording the information pictorially as a family tree (a pedigree; see opposite). Family history can be an important risk factor for cancer and a wide range of conditions with monogenic or complex polygenic aetiology. Some national clinical guidelines therefore highlight the importance of taking and recording a genetic family history.

Drawing a pedigree

A set of agreed symbols is used when drawing a pedigree (**Fig. 5.1**). In order to show how individuals are related to each other, lines are drawn between symbols. The correct placement of these lines is a key skill to ensure that the pedigree gives an accurate picture of family relationships.

A dominantly inherited example is presented in **Fig. 5.2**. Affected males and females are filled in with black, and unaffected are left white. Males and females are equally affected, and both can transmit the disease to their offspring, who carry a 50% chance of inheriting the 'faulty' gene. More examples of patterns of inheritance are shown in the later section entitled 'Patterns of inheritance of single-gene diseases'.

BACKGROUND

The genetic code that forms the instruction manual for humans can now be sequenced in less than a day. From a clinical perspective, this brings an enormous range of new possibilities and challenges to the practice of medicine. In this chapter, we aim to provide an overview of key concepts in deoxyribonucleic acid (DNA), when we can use it to predict with confidence and the caveats that apply.

DNA is an efficient means of storing information. Three billion base-pairs (bp) sit in the nucleus of each cell and carry the instructions to make all the parts of any cell in the human body. When a cell divides, all of this information is duplicated, with systems designed to prevent mistakes from occurring during this process. Nonetheless, errors do arise, which can either be harmless or cause disease, depending on the nature and the timing of the change. The discovery that the genetic code could be 'read' or sequenced allowed changes in parts of this instruction manual to be sought as an explanation for inherited diseases. In addition the study of how the genetic code is altered in malignant cells has provided new insights into cancer biology (see Chapter 41). Progressive advances in DNA sequencing technology have meant that we are able to look at the human genome of an individual at multiple time points from conception to the grave (**Fig. 5.3**). This information can have a range of implications, from pre-implantation genetic diagnosis to predicting and stratifying disease, selecting treatments and assessing drug response and the risk of adverse side-effects. An understanding of how this new information fits into clinical medicine is immensely relevant for patient care. As the cost of DNA sequencing drops, adoption of this technology is likely to become more widespread and indeed is now implemented in the National Health Service (UK) (NHS) for rare disorders and cancer. Commercially available testing is accessible simply by supplying a saliva sample in the post.

However, while we are able to sequence DNA rapidly, much bigger challenges lie ahead. For example, it can be difficult to interpret changes in DNA found in apparently healthy individuals. Until recently, genetic changes in rare diseases were studied in the context of affected individuals and their families. A genetic change that can cause disease within such families may not have the same effect on other people. This is thought to be due to the genetic context in which the change presents. It is hoped that when careful phenotyping and long-term follow-up are combined with genomics, we can advise appropriately on the implications of a broad range of such genetic changes. Currently, in some areas there is consensus on 'actionable' incidental findings in genomics, such as when preventative mastectomy should be discussed with patients when a genetic change is found that may predict early-onset breast cancer. Work remains to be done, however, to capture how the human genotype predicts phenotype, and large consortia efforts such as the Human Phenotype Ontology project aim to achieve this across all diseases.

Gene editing

In addition to reading the human genome, we can now also edit and change the genetic code, using very precise molecular tools such as CRISPR (see **Fig. 5.19**). By 2018, reports had been verified of gene editing in humans, which can be transmitted to the next generation. There is much discussion about how gene-editing technologies should and should not be used.

Here we aim to highlight selected genetic advances that exemplify concepts of genetic disease and to describe cases where genetic information has been clinically relevant to patients, either in routine care or in the context of clinical trials. The ability to interpret and contextualize genetic information in clinical care is becoming increasingly relevant as genomics is mainstreamed across clinical specialties.

Fig. 5.1 **Symbols used in drawing a genetic pedigree.**

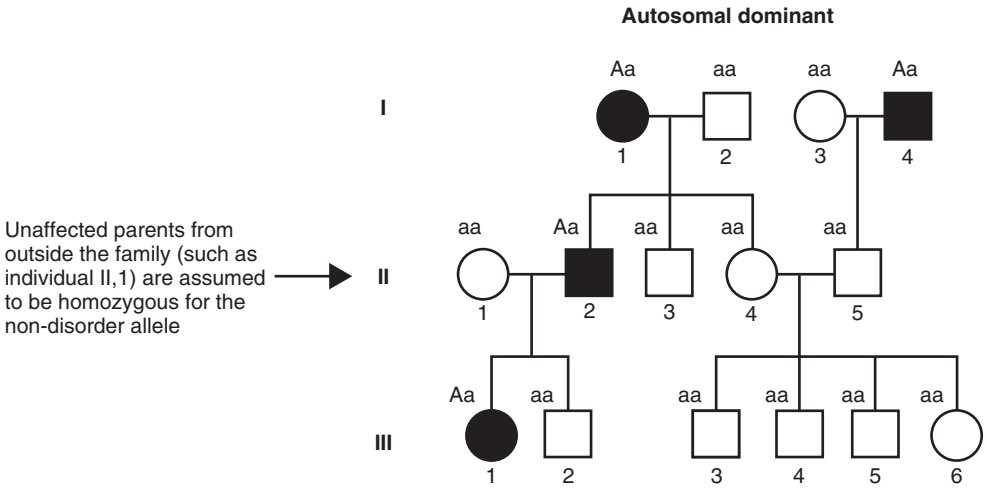

Fig. 5.2 **An autosomal dominant pattern of inheritance.** Affected males and females are shown in *black*. Capital 'A' indicates the allele associated with the disorder in question and lowercase 'a' the non-disorder allele.

CLINICAL GENETICS

Genetic disorders pose considerable health and economic problems, and early diagnosis is crucial. While individual diseases are rare, it is estimated that almost 6000 genetic disorders are recognized, and as a collective, 1 in 25 children may be affected with a genetic disorder. In any pregnancy the risk of a serious developmental abnormality is approximately 1 in 50 pregnancies, and around 15% of paediatric inpatients have a multifactorial disorder with a predominantly genetic element. In addition, 50% of clinical genetics referrals are adults with late-onset disease, including neurological, endocrine and gastrointestinal conditions, along with cancer.

Approach to the patient with a suspected genetic disease

Genetic services routinely coordinate clinical diagnosis, genetic testing, information-giving, family planning and targeted screening

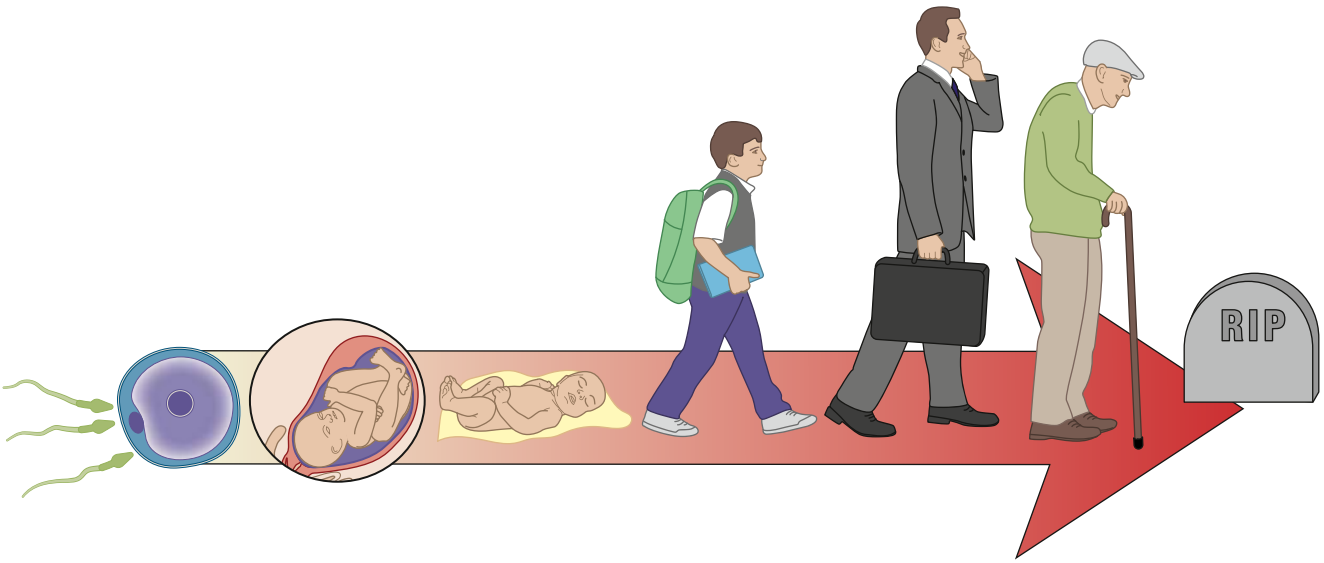

Fig. 5.3 Genotype and phenotype. Sequencing the human genome throughout our lifetime can give insights into disease susceptibility and healthcare management.

for a range of genetic disorders. Clinicians assessing a patient with a genetic disorder should keep in mind the following aims:

- ***Obtaining a full history.*** The pregnancy history, drug and alcohol ingestion during pregnancy, and maternal illnesses (e.g., diabetes) should be detailed.
- ***Establishing an accurate diagnosis.*** Examination may help in diagnosing a genetically abnormal child with characteristic features (e.g., trisomy 21) or ascertaining whether a genetically normal fetus was damaged *in utero.*
- ***Drawing a family tree.*** This is essential. Questions should be asked about abortions, stillbirths, deaths, marriages, consanguinity, and medical history of family members. Diagnoses may need verification from other hospital reports.
- ***Estimating the risk of a future pregnancy being affected or carrying a disorder.*** Estimation of risk should be based on the pattern of inheritance. Disorders caused by pathogenic variants in single genes carry a high risk; chromosomal abnormalities other than translocations typically carry a low risk. Empirical risks may be obtained from population or family studies.
- ***Information-giving.*** Information on prognosis and management should be supplied, with adequate time allowed for it to be discussed openly and freely and repeated as necessary.
- ***Continued support and follow-up.*** An explanation should be provided of the implications for other siblings and family members.
- ***Genetic screening.*** This includes prenatal diagnosis or preimplantation genetic diagnosis (*in vitro* fertilization followed by testing of embryos before implantation) and, if requested, carrier detection. A large number of molecular genetic tests are available.

Genetic counselling should be non-directive, with the couple making their own decisions on the basis of an accurate presentation of the facts and risks in a way they can understand.

Further details on taking a genetic history and drawing a family tree can be found in the 'Clinical skills' section (see earlier).

Ethical considerations

Ethical considerations must be taken into account in any discussion of clinical genetics. For example, prenatal diagnosis with the option of termination may be unacceptable on moral or religious grounds. In the case of diseases for which there is no cure and currently no treatment (e.g., Huntington's chorea), genetic tests can accurately predict which family members will be affected; many people, however, would rather not have this information. One very serious outcome of new genetic information is that disease susceptibility may be predictable—for example, in Alzheimer's disease—and so medical insurance companies can decline to issue policies for individuals at high risk. In some countries a moratorium is in place to prevent insurers from using such data against patients in this way. It remains to be decided who should have access to an individual's genetic information and to what extent privacy should be preserved.

Testing for genetic disease

Genetic testing is extremely powerful, as it can reveal changes in DNA that explain why a patient has a clinical disease. Once such information is acquired, it can, for example, guide the selection of screening tests, aid prognostication, and influence treatment. In some instances, it can elegantly replace the multiple biochemical, pathological and radiological tests that were previously required to make a diagnosis of a genetic disease. Patients with rare disease often report a 'diagnostic odyssey', which may be attenuated by genetic testing. In some situations, where the diagnosis is unknown and a strong clinical suspicion of genetic disease exists, genetic tests can provide the necessary clues to exclude certain differentials and aid the process of making and refining a diagnosis.

There will increasingly be a temptation simply to order whole-genome sequencing (see 'Techniques for studying the genetic code') for any genetic disease but this may have negative outcomes. For example, it may reveal unexpected findings that patients may not necessarily have wanted to know, such as a predisposition to early-onset dementia or cancer. Changes in disease genes may also be detected and cause anxiety, yet the genetic changes may not give rise to the expected disease in that patient. In some situations, incomplete knowledge may make any form of prognostication or reassurance impossible. The individual responses of each patient to such uncertainty can be difficult to predict, and more dialogue is needed to understand how to make better decisions for comprehensive testing in partnership with patients.

REFERRAL REASON:
Multiple monogenic benign skin tumours
Diagnostic testing for a panel of genes associated with multiple monogenic benign skin tumours John Smith who is clinically affected.

Result summary
A molecular diagnosis has not been confirmed or excluded.

Result
Next generation sequencing detected no clearly pathogenic variant John Smith see technical information below.

Further testing
Please contact the laboratory if further analysis is required.

Reported John Smith clinical scientist	Date: 12/05/23
Authorised by: John Smith principal clinical scientist	Date: 14/05/23

Technical information

Variant details
No reportable variants have been detected in the analysed genes.
Only variants that are considered likely to be relevant to this patient's clinical phenotype are reported. Variants classified as benign, likely benign or uncertain significance, where further testing would not alter classification, or monoallelic variants in recessive genes are not reported.

Panel and coverage information

Test directory indication:	R230 Multiple monogenic benign skin tumours
Panel ID:	MMBST_v1.3_R230_Green
Target bases >20x:	100.0%
Average depth across target:	1228

MMBST_v1.3_R230_Green panel:
CYLD, FLCN, LEMD3, MLH1, MSH2

For details of the sequence coverage for individual gene(s) please contact the laboratory.

Fig. 5.4 A sample clinical genetic test report.

In the UK, genetic tests accessible by NHS clinicians are now catalogued in the Genetic Test Directory and updated every 6 months. This directory has been developed as part of an agenda of 'mainstreaming' genetic testing, where clinicians across a range of specialties can order genetic tests for certain conditions. The test directory lists a range of types of tests, relevant for specific clinical indications. Based on existing data on the types of genetic changes that cause specific conditions, bespoke tests are designed that are drawn from more than 30 types of tests. These can include targeted panels, whole exome, and whole genome sequencing. Where it is more efficient, established tests that can detect single nucleotide variants, small insertions or deletions, or copy number changes are offered in place of whole genome sequencing. For the non-genetic specialists, access to such testing will need to be supported with training and education on how to counsel and choose tests.

The importance of taking a comprehensive personal and family history and performing a clinical examination is paramount. This information may identify a single gene that needs to be tested if a particular disorder is suspected. In some conditions, where a selection of genes may account for a phenotype, a panel of 10 to 20 relevant genes can be tested. Some genomic medicine centres favour this approach, in which only clinically relevant genes are analysed in a tiered manner, with further testing carried out only in cases that are negative. There will still be unsolved cases despite these approaches, and this should be one of the outcomes made aware to the patient.

Interpreting a genetic test report

Genetic test reports are written by clinical scientists who have designed and analysed specific genetic tests for specific conditions. Their knowledge of the known genetic variants linked with a clinical phenotype gives important context to the report. Genetic test reports will feed back clinically relevant changes, which are categorized according to the American College of Medical Genetics (ACMG) criteria. These utilize standardized terminology to describe any genetic variants found; 'pathogenic', 'likely pathogenic', 'uncertain significance', 'likely benign', and 'benign'. For clinical purposes, 'pathogenic and likely pathogenic' changes are useful for counselling patients. Variants of uncertain significance (VUS) may need to be investigated further across additional members of the family to determine their importance, and clinicians need to note that these can be reclassified in the future as new information becomes available in clinical variant databases and the published literature. 'Likely benign and benign' variants in relevant genes for the clinical diagnosis being tested for are unlikely to impact genetic counselling and are not routinely reported in test reports from UK Genomic Medicine Services.

In addition to stating the ACMG status of a detected variant, genetic test reports will report the change of the sequence to standardized criteria, established by the Human Genome Variant Society (HGVS). In the example of a single nucleotide variant, this will indicate the reference nucleotide and the detected nucleotide in the patient, as well as its location in the gene of interest. For example, a change in the gene causing tuberous sclerosis *(TSC1)* will be reported as 'a heterozygous pathogenic variant in TSC1 has been detected (c.1525C>T)', where the nucleotide cytosine (C) has been replaced by a thymine (T) at position 1525 within the coding sequence of the *TSC1* gene.

Genetic test reports will include details of the test type used to test the DNA sample, the genes covered, the performance of this test and the limitations of the test strategy. A sample test report is shown (Fig. 5.4).

Genetic testing is a rapidly changing field and exposure to clinical genetics clinics and multidisciplinary meetings will be crucial in training clinicians to select and implement the 'right' test.

THE CELLULAR BASIS OF GENETICS

DNA and the genetic code

Hereditary information is contained in the sequence of the building blocks of double-stranded DNA (Fig. 5.5). Each strand of DNA is made up of a deoxyribose–phosphate backbone and a series of purine (adenine [A] and guanine [G]) and pyrimidine (thymine [T] and cytosine [C]) bases. Because of the way in which the sugar–phosphate backbone is chemically coupled, each strand has a polarity, with a phosphate at one end (the 5′ end) and a hydroxyl at the other (the 3′ end). The two strands of DNA are held together by hydrogen bonds between the bases. T can pair only with A, and G can pair only with C; therefore each strand is the antiparallel complement of the other (see Fig. 5.5). This is key to DNA replication because each strand can be used as a template to synthesize the other.

The two strands twist to form a double helix with a major and a minor groove, and the large stretches of helical DNA are coiled around histone proteins to form nucleosomes (see Fig. 5.5). They can be condensed further into the chromosomes that can be visualized by light microscopy at metaphase (see Figs. 5.5 and 5.12).

Human chromosomes

Chromosomes are complex structures containing one linear molecule of DNA that is wound around histone proteins into small units called nucleosomes, and these are further wound to make up the structure of the chromosome itself.

Diploid human cells have 46 chromosomes, 23 inherited from each parent; thus there are 23 'homologous' pairs of chromosomes (22 pairs of '***autosomes***' and 2 '***sex chromosomes***'). The sex chromosomes, called X and Y, are not homologous but are different in size and shape. Males have an X and a Y chromosome; females have two X chromosomes. (Primary male sexual characteristics are determined by the *SRY* gene—sex-determining region on the Y chromosome.)

The chromosomes are classified according to their size and shape, the largest being chromosome 1. The constriction in the chromosome is the ***centromere***, which can be in the middle of the chromosome (metacentric) or at one extreme end (acrocentric). The centromere divides the chromosome into a short arm and a

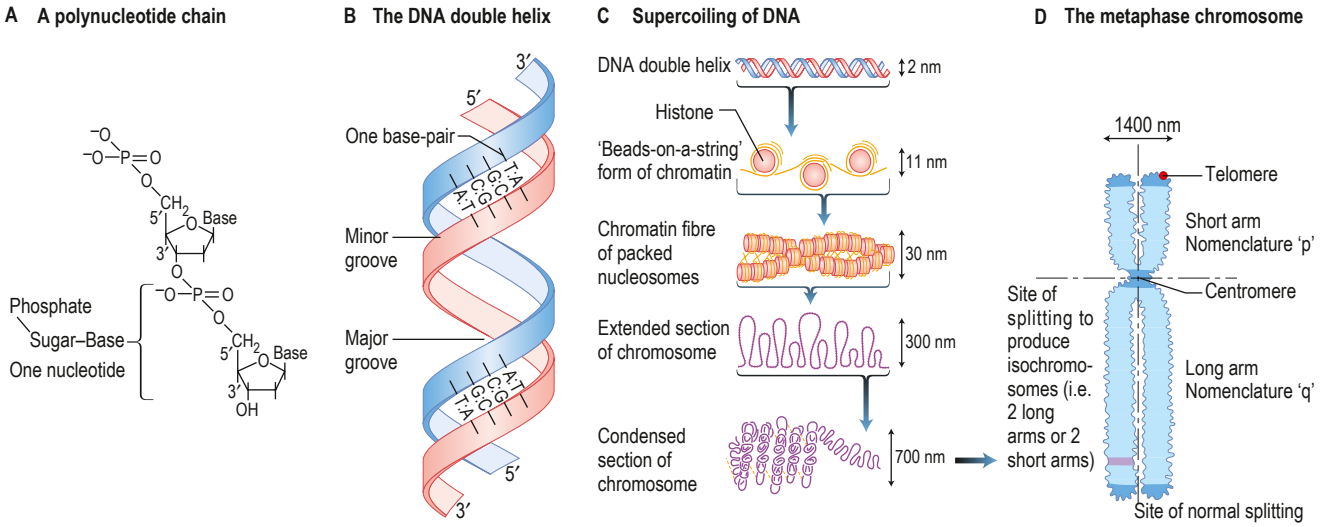

Fig. 5.5 DNA and its relationship to human chromosomes. (A) Individual nucleotides form a ***polymer*** linked via the deoxyribose sugars to form an ssDNA. The 5′ carbon of the sugar is covalently joined to phosphate. The 3′ carbon links the phosphate on the 5′ carbon of the ribose of the next nucleotide, forming the sugar–phosphate backbone of the nucleic acid. The 5′ to 3′ linkage gives orientation to a sequence of DNA. **(B)** ***Double-stranded DNA***. The two strands of DNA are held together by hydrogen bonds between the bases. T pairs with A, and G with C. The orientation of the complementary ssDNA is thus complementary and antiparallel. The helical three-dimensional structure has major and minor grooves, and a complete turn of the helix contains 12 base-pairs. The grooves are structurally important; DNA-binding proteins predominantly interact with the major grooves. **(C)** ***Supercoiling of DNA***. The large helical DNA is coiled into nucleosomes by winding around nuclear proteins (histones) and further condensed by coiling and supercoiling into the chromosomes that are visible at metaphase. **(D)** ***At the end of the metaphase, DNA replication*** results in a twin chromosome joined at the centromere. Chromosomes are assigned a number (or the letter X or Y for the sex chromosomes), plus short arm (p) or long arm (q). The region or subregion is defined by the transverse light and dark bands observed when staining with Giemsa (see Fig. 5.18) (hence G-banding) or quinacrine, and numbered from the centromere outwards. ***Chromosome constitution = chromosome number + sex chromosomes + abnormality***; for example, 46XX = normal female; 47XX + 21 = Down's syndrome (trisomy 21); 46XYt (2;19) (p21;p12) = male with a normal number of chromosomes but a translocation between chromosome 2 and 19 with breakages at short-arm bands 21 and 12 of the respective chromosomes. *DNA,* Deoxyribonucleic acid; *ssDNA,* single-strand DNA.

long arm, referred to as the ***p arm*** and the ***q arm***, respectively (see Fig. 5.5).

Chromosomes can be stained when they are in the metaphase stage of the cell cycle and are very condensed. The stain gives a different pattern of light and dark ***bands*** that is diagnostic for each chromosome. Each band is given a number, and gene-mapping techniques allow genes to be positioned within a band within an arm of a chromosome. For example, the *CFTR* gene (a pathogenic variant that gives rise to cystic fibrosis) maps to 7q21; that is, on chromosome 7 in the long arm in band 21.

During cell division (mitosis), each chromosome divides into two so that each daughter nucleus has the same number of chromosomes as its parent cell. During gametogenesis, however, the number of chromosomes is halved by meiosis so that, after conception, the number of chromosomes remains the same and is not doubled. In the female each ovum contains one or other X chromosome, but in the male the sperm bears either an X or a Y chromosome.

Chromosomes can be seen easily only in actively dividing cells. Typically, lymphocytes from the peripheral blood are stimulated to divide and are processed to allow the chromosomes to be examined. Cells from other tissues can also be used for chromosomal analysis; for example, amniotic fluid, placental cells from chorionic villus sampling, or bone marrow and skin cells (Box 5.2).

The mitochondrial chromosome

In addition to the 23 pairs of chromosomes in the nucleus of every diploid cell, the mitochondria in the cytoplasm of the cell also have their own genome. The mitochondrial chromosome is a circular DNA (mtDNA) molecule of approximately 16 500 bp, and every base-pair makes up part of the coding sequence. These genes principally encode proteins or RNA molecules involved in mitochondrial function. These proteins are components of the mitochondrial respiratory chain involved in oxidative phosphorylation, producing adenosine triphosphate (ATP). They also have a critical role in apoptotic cell death. Every cell contains several hundred mitochondria, and therefore several hundred mitochondrial chromosomes. Virtually all mitochondria are inherited from the mother, as the sperm head contains no (or very few) mitochondria. Disorders mapped to the mitochondrial chromosome are shown in Fig. 5.6.

Box 5.2 Examples of clinical indications for genetic testing

Antenatal
- Positive maternal serum screening test for aneuploid pregnancy
- Ultrasound features consistent with an aneuploid fetus or genetic syndrome (e.g., skeletal dysplasia)
- Severe fetal growth retardation
- Sexing of fetus in X-linked disorders

In the neonate
- Congenital malformations
- Suspicion of trisomy or monosomy
- Suspicion of microdeletion syndrome
- Ambiguous genitalia

In children and adolescents
- Primary amenorrhoea or failure of pubertal development
- Growth retardation
- Malignant disorders (e.g., haematological malignancies, Wilms' tumour, neuroblastoma)

In the adult
- Screening of parents of a child with a chromosomal abnormality for further genetic counselling
- Learning difficulties
- Certain malignant disorders (e.g., haematological malignancies)

DNA transcription

To express the information in the genome, cells transcribe the code into the single-stranded ribonucleic acid (RNA). RNA is similar to DNA in that it comprises four bases—A, G, and C but with uracil (U) instead of T—and a sugar–phosphate backbone with ribose instead of deoxyribose. Several types of RNA are made by the cell. Messenger RNA (mRNA) codes for proteins that are translated on ribosomes. Ribosomal RNA (rRNA) is a key catalytic component of the ribosome, and amino acids are delivered to the nascent peptide chain on transfer RNA (tRNA) molecules.

A gene is usually 20 to 40 kilobases of DNA that contains the code for a polypeptide sequence (but lengths vary—the muscle protein dystrophin is 2.4 megabases long). Three adjacent nucleotides (a codon) specify a particular amino acid, such as AGA for arginine. There are only 20 common amino acids, but 64 possible codon combinations make up the genetic code (see Fig. 5.8). This redundancy means that most amino acids are encoded by more than one triplet, and additional codons are used to signal initiation or termination of polypeptide-chain synthesis.

Human protein-coding sequences (exons) are interrupted by intervening sequences that are non-coding (introns) at multiple positions (see Fig. 5.7). These are spliced from the nascent message in the nucleus by an RNA/protein complex called a spliceosome. Differential splicing can cause exons to be spliced alongside their intervening introns. This contributes significantly to the complexity of the human transcriptome, as proteins translated from these messages lack particular domains and therefore have different activity.

There are also a variety of RNAs that regulate gene expression or RNA processing. The non-coding RNAs (ncRNAs) include a group that regulates gene expression. These include microRNA (miRNA) and small interfering RNA (siRNA), which typically bind to a subset of mRNAs and inhibit their translation and/or initiate their degradation (siRNA only initiates degradation). miRNAs and siRNAs are short ncRNAs (19–29 bp) that together regulate the expression of approximately 30% of genes by degradation of transcripts or repression of protein synthesis. A growing range of additional regulatory ncRNA classes are being identified, many of which control gene expression by epigenetic mechanisms (see below).

Control of gene expression

The genome of all cells in the body encodes the same genetic information, yet different cell types express very different subsets of proteins. Gene expression is controlled at many steps, from transcription to protein degradation. However, for many genes, transcription is the key point of regulation. This is controlled primarily by proteins, which bind to short sequences within the promoter regions that either repress or activate transcription, or to more distant sequences where proteins bind to enhance expression. These transcription factors and enhancers are often the end-points of signalling pathways that transduce extracellular signals to change gene expression. This level of regulation often involves the translocation of an activated factor from the cytoplasm to the nucleus. In the nucleus, these DNA-binding proteins recognize the shape and position of hydrogen bond acceptor and donor groups within the major and minor grooves of the double helix (i.e., the double helix

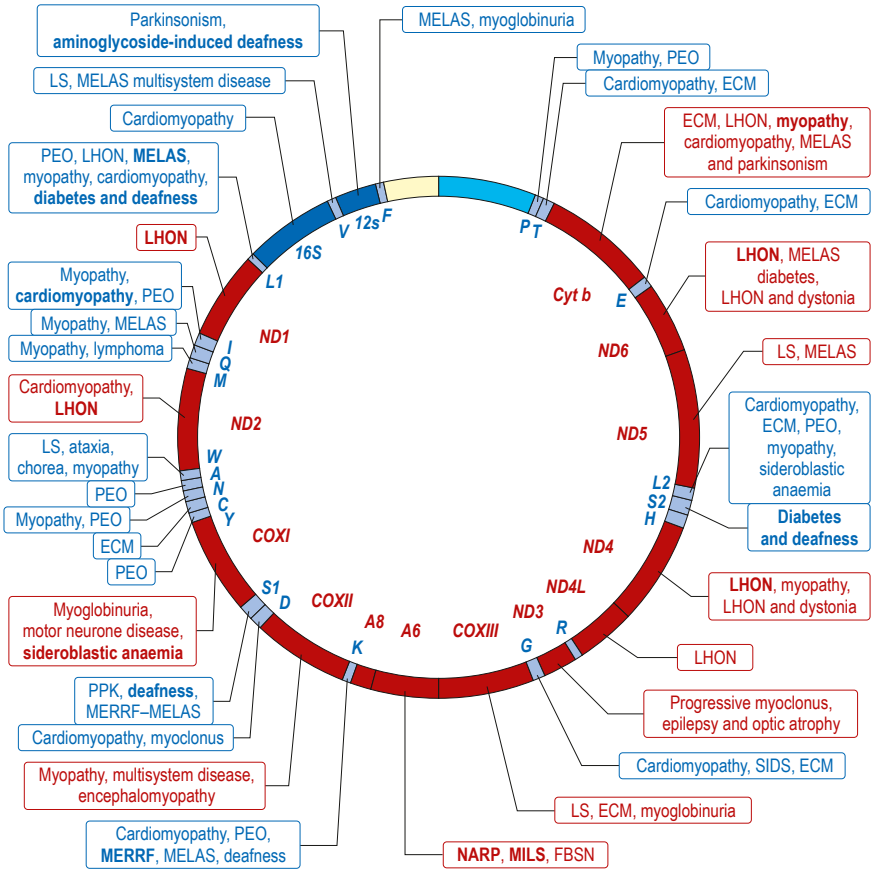

Fig. 5.6 Mitochondrial chromosome abnormalities. Disorders that are frequently or prominently associated with pathogenic variants in a particular gene are shown in bold. does not need to unwind). There are several classes of DNA-binding protein that differ in the protein structural motif, which allows them to interact with the double helix. More permanent control of gene expression patterns can be achieved epigenetically.

Epigenetics

Although the importance of the genetic code has been emphasized, normal function and disease can occur, despite a particular DNA sequence being exactly the same. The term '***epigenetics***' is used to explain changes that arise due to differing gene expression but do not involve changes in the underlying DNA sequence. Despite not altering the genetic sequence the effects of epigenetic changes are stable over rounds of cell division. A number of systems initiate and sustain these changes:

- ***Modifications to DNA's surface structure*** but not its base-pair sequence: DNA methylation. Enzymes called methyltransferases modify cytosine to 5-methylcytosine. This 'tag' occurs mainly in sites where a cytosine molecule is next to a guanidine nucleotide, a CpG site. When CpG islands (groups of CpG sites) in the promoter region are methylated, gene expression is repressed.
- ***Modification of chromatin proteins*** (in particular, acetylation of histones), which not only support DNA but also bind it so tightly as to regulate gene expression. At the extreme, such binding can permanently prevent the DNA sequences from being exposed to, let alone acted on by, gene transcription (DNA-binding) proteins.

Some epigenetic modifications are also 'transmissible', meaning that a dividing liver cell, for example, can give rise to two daughter cells with the same epigenetic signals, such that they express the appropriate transcriptome for a liver cell. Epigenetic change forms the basis of genomic imprinting (see later). Epigenetic changes in gene expression also occur in cancer. An example is DNA methylation repressing tumour suppressor genes.

The X chromosome and inactivation

Although females have two X chromosomes (XX), they do not have two doses of X-linked genes (compared with just one dose for a male XY) because of the phenomenon of X inactivation or ***lyonization*** (after its discoverer, Dr Mary Lyon). In this process, one of the two X chromosomes in the cells of females is epigenetically (see earlier) silenced through the action of a regulatory ncRNA, so the cell has only one dose of the X-linked genes. Inactivation is random and can affect either X chromosome.

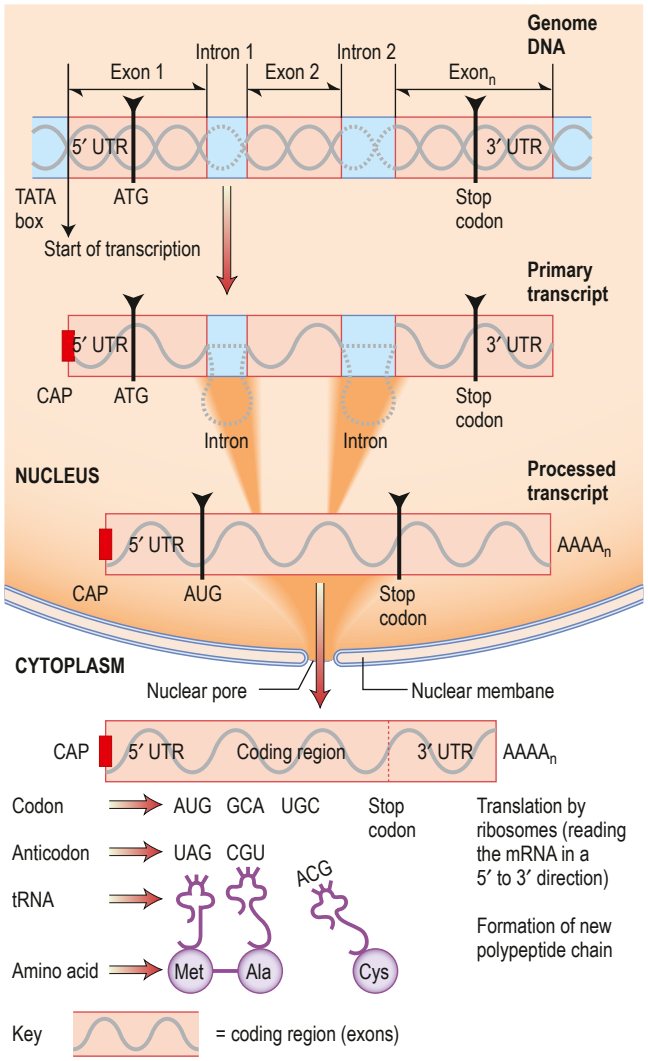

Fig. 5.7 Transcription and translation (DNA to RNA to protein). ***RNA polymerase*** transcribes an RNA copy of the DNA gene sequence. The ***transcript*** is capped at the 5′ end by the addition of an inverted guanine residue, which is then methylated to form 7-methylguanosine. At the 3′ end the sequence AAUAAA is recognized by endonuclease, and the transcript is then cleaved 20 base-pairs further downstream. ***Poly-A polymerase*** then adds adenosine residues to the 3′ end, forming a poly-A tail (polyadenylation). The ***introns*** are then spliced to produce the mature mRNA, which is trafficked to the cytosol via nuclear pores. ***Ribosomal subunits*** assemble on the 5′ end of the mRNA to translate the message into protein, for which tRNAs deliver the amino acid building blocks (see also **Fig. 5.8**). *DNA,* Deoxyribonucleic acid; *mRNA,* messenger RNA; *RNA,* ribonucleic acid; *tRNAs,* transfer RNAs; *UTR,* untranslated region.

Protein synthesis and secretion

While the instructions are essentially the same in every cell, in different tissues the regions that are transcribed are cell specific, and so are the ensuing proteins. For example, in skeletal muscle the RNA transcripts involve the generation of proteins that are needed for muscle, such as myosin. Conversely, in the cells of the cornea, specific keratins that are transparent are expressed. The actual working parts of the cell are protein, and the translation of the nucleic acid sequence to protein involves the ribosome.

Protein translation

Mature mRNA is transported through the nuclear pore into the cytoplasm for translation into protein by ribosomes (**Fig. 5.8A**).

- In the cytoplasm the two ribosomal subunits interact on an mRNA molecule, usually via ribosome-binding sites encoded in the untranslated 5′ region of the message. The mRNA is then pulled through the ribosome until a translation initiation codon is encountered (usually an AUG).
- As the mRNA is pulled through the ribosome in the 5′ to 3′ direction, codons distal to the AUG are recognized by complementary sequences, or anticodons, in tRNA molecules that dock on the ribosome. Each tRNA molecule carries an amino acid specific to the anticodon (**Fig. 5.8B**). The amino acids are transferred from tRNA molecules and sequentially linked to the carboxy-terminus of the growing polypeptide by the peptidyl transferase activity of the ribosome. The poly-A tail of the mRNA is not translated (3′ untranslated region [UTR]) and is preceded by a translational stop codon; UAA, UAG, or UGA.

Protein structure

The amino acid sequence of a polypeptide chain (its ***primary structure***) ultimately determines its shape. The weak bonds (hydrogen bonds, electrostatic and van der Waals interactions) formed between the side-chains of the different amino acids and/or the peptide backbone provide the ***secondary structure*** (α-helices, β-strands, loops). These, in turn, are folded into a three-dimensional, ***tertiary structure*** to provide functional protein

domains of 40 to 350 amino acids. The modular nature of domains allows their functionality to be combined in protein complexes of different proteins. This final level of organization is the ***quaternary structure***.

The folding of polypeptides into fully functional proteins is facilitated by an assortment of molecular chaperones, which bind to partially folded polypeptides and prevent the formation of inappropriate bonds.

Genetics and the cell

The nucleus is the most prominent cellular organelle (Fig. 5.9) and has a double membrane enclosing the human genome (the outer membrane is continuous with the endoplasmic reticulum). The double membrane contains nuclear pores, through which gene regulatory proteins, transcription factors and mRNA that has been transcribed from DNA are transported. The nuclear matrix is highly organized. Microscopically dense regions of heterochromatin represent highly compacted chromosomal DNA, which tends to be transcriptionally repressed. Lighter regions of euchromatin contain extended chromosomes, which tend to be transcriptionally active. Outside the nucleus, mRNA is translated into amino acid chains in the endoplasmic reticulum.

Embryonic development and stem cells

It is critical to recognize that all of the estimated 37 trillion cells that form a person are derived from a single cell. Genetic changes that involve this first cell, whether due to natural variation or artificial manipulation via gene-editing techniques like CRISPR (clusters of regularly interspaced short palindromic repeats), are carried forward to every subsequent cell. These changes are also passed on to future generations. The gravity of intervening at this moment is captured in the ethical debates around interventions such as preimplantation genetic diagnosis and mitochondrial replacement therapy (see 'Genomic medicine').

Following fertilization the newly formed zygote and the cells it forms following the first few divisions are totipotent, meaning that they can differentiate into any cell type in the adult body (Fig. 5.10A). At the blastula stage of embryonic development, these cells undergo a primary differentiation event to become either the trophectoderm or the inner cell mass (ICM) (see Fig. 5.10A). The trophectoderm gives rise to the fetal cells of the placenta, while the ICM cells are pluripotent and give rise to all other cell types of the body (except those of the placenta); they are more commonly called embryonic stem (ES) cells. Stem cells have two properties:

- ***self-renewal:*** the ability to divide indefinitely without differentiating
- ***pluripotency*** or ***totipotency:*** the capability to differentiate, given the appropriate signals, into any cell type (except fetal placental cells).

During embryogenesis a carefully orchestrated programme ensues, with this ball of cells ultimately forming the early embryo, recognizable as human with the formation of organs such as the heart and the development of limbs (Fig. 5.10B).

As they begin to differentiate, adult progenitor cells (sometimes referred to erroneously as stem cells) retain their ability to self-renew, but their potency is reduced; with this limited ability to self-renew they can differentiate into multiple related lineages (multipotent, like haemopoietic 'progenitor cells') or single lineages (unipotent, like muscle satellite cells). The body uses these partially differentiated progenitor cells to replace or repair damaged cells and tissues, even into adulthood.

Stem cells have great therapeutic potential and can be obtained from blood from the umbilical cord, which contains embryo-like stem cells (which are not as primitive as ES cells but can differentiate into many more cell types than adult progenitor cells). Alternatively, adult cells, such as skin fibroblast cells, can be reprogrammed to regain stem-like properties (induced pluripotent stem cells, IPSCs).

Review of cellular genetics

According to the fundamental paradigm in genetics, information to create a human is stored in the genetic code in a cell. This code is identically replicated in every cell from conception onwards. In different cells, different parts of the code are needed, specific to that cell type, to make proteins required for the functioning of that cell; this control of gene expression is achieved through a number of

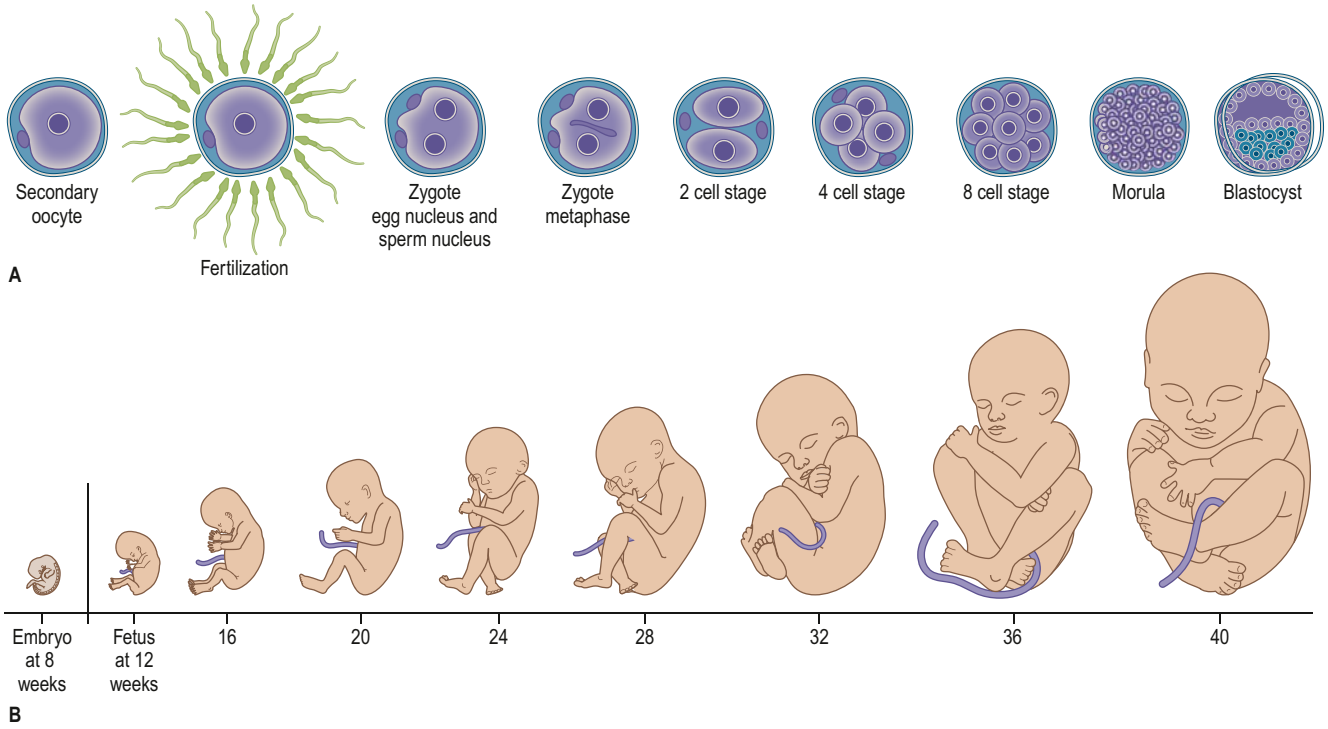

Fig. 5.10 Cell division, embryogenesis, and fetal development. **(A)** Early stages of cell division leading to the formation of the blastocyst. **(B)** Stages of fetal development.

mechanisms affecting gene transcription, processing of RNA and translation of mRNA into protein.

In the next section, we describe examples of what happens when there are specific changes in the genetic code that have been associated with the presentation of specific genetic disorders.

GENETIC DISORDERS

Inherited genetic disorders occur due to pathogenic variants in the genetic code; their prevalence is indicated in **Box 5.3**. They can arise because of new mutations in sperm or ova, or as a result of an inherited pathogenic variant passed down a family line. These disorders can stem from a single base-pair change, alteration of a region of a chromosome, or even duplication or omission of an entire chromosome (**Box 5.4**). The pattern of inheritance in a family tree depends on which chromosome the pathogenic variant occurs in, and whether both copies need to be affected to cause the disease. Somatic mutations typically occurring after birth can be responsible for benign and malignant tumours (see 'The genetic basis of cancer').

To start, we will consider conditions for which chromosomal changes are responsible. These were among the first to be studied, as the technique known as karyotyping allowed for the visualization of differences in chromosomes using a light microscope.

Chromosomal disorders

Chromosomal abnormalities are much more common than is generally appreciated (see **Box 5.3**). Over half of spontaneous abortions have chromosomal abnormalities, compared with only 4 to 6 abnormalities per 1000 live births. Specific chromosomal abnormalities can lead to well-recognized and severe clinical syndromes; autosomal aneuploidy (a differing from the normal diploid number) is

Box 5.3 Prevalence of genetic disease[a]

Genetic disease
- 0.5% of all newborns have a chromosomal abnormality
- 7% of all stillborns have a chromosomal abnormality
- 20% to 30% of all infant deaths are due to genetic disorders
- 11% of paediatric hospital admissions are for children with genetic disorders
- 12% of adult hospital admissions are due to genetic causes
- 15% of all cancers have an inherited susceptibility
- 10% of chronic diseases in the adult population (heart, diabetes, arthritis) have a significant genetic component

Congenital malformation
- 3% to 5% of all births result in congenital malformations
- 30% to 50% of post-neonatal deaths are due to congenital malformations
- 18% of paediatric hospital admissions are for children with congenital malformations

European incidences per 1000 births

Single-gene disorders: 10
- Dominant: 7.0
- Recessive: 1.66
- X-linked: 1.33

Chromosomal disorders: 3.5
- Autosomes: 1.69
- Sex chromosomes: 1.80

Congenital malformations: 31
- Genetically determined: 0.6
- Multifactorial: 30
- Non-genetic: ~0.4

[a]Although individual genetic diseases are rare, regional variation is enormous; the incidence of Down's syndrome varies from 1/1000 to 1/100 worldwide. Single-gene diseases collectively comprise over 15 500 recognized genetic disorders. The global prevalence of all single-gene diseases at birth is approximately 10/1000.

Box 5.4 Some inherited genetic conditions that exemplify different genetic mechanisms

Condition	Mechanism responsible
Down's syndrome	Trisomy 21
Cystic fibrosis	Recessive
Haemophilia	Dominant or recessive
BRCA	Dominant
Xeroderma pigmentosum	Recessive
Huntington's disease	Anticipation
Angelman's syndrome	Imprinting
Myoclonic epilepsy with ragged-red fibres (MERRFs)	Mitochondrial

usually more severe than the sex chromosome aneuploidies (Box 5.5). Abnormalities may occur in either the number or the structure of the chromosomes.

Abnormal chromosome numbers

If a chromosome or chromatids fail to separate ('non-disjunction') in either meiosis or mitosis, one daughter cell will receive two copies of that chromosome, and one daughter cell will receive no copies of the chromosome. If this non-disjunction occurs during meiosis, it can lead to an ovum or sperm having:

- ***an extra chromosome***, resulting in a fetus that is 'trisomic' and has three instead of two copies of the chromosome
- ***one less chromosome***, resulting in a fetus that is 'monosomic' and has one instead of two copies of the chromosome.

Non-disjunction can occur with autosomes or sex chromosomes. However, only individuals with trisomy 13, 18 and 21 survive to birth, and most children with trisomy 13 and trisomy 18 die in early childhood. ***Trisomy 21 (Down's syndrome)*** is observed with a frequency of 1 in 650 live births, regardless of geography or ethnic background. This rate is reduced with widespread screening and selective termination of pregnancy (see 'Prenatal diagnosis of congenital anomalies'). Full ***autosomal monosomies*** are extremely rare and generally incompatible with survival to full gestation. ***Sex chromosome trisomies*** (e.g., Klinefelter's syndrome, XXY) are relatively common. The ***sex chromosome monosomy*** in which the individual has one X chromosome only and no second X or Y chromosome (i.e., X0) is known as ***Turner's syndrome*** and is estimated to occur in 1 in 2500 live-born females.

Occasionally, non-disjunction can occur during mitosis shortly after two gametes have fused. It will then result in the formation of two cell lines, each with a different chromosome complement; the person is termed a 'mosaic' as only some of their cells carry an incorrect number of chromosomes (see later).

Very rarely the entire chromosome set will be present in more than two copies, so the individual may be triploid rather than diploid and have a chromosome number of 69. Triploidy and tetraploidy (four sets) is not usually compatible with life and results in spontaneous abortion.

Abnormal chromosome structures

Along with abnormal numbers of chromosomes, chromosomes can have abnormal structures, and the disruption to the DNA and gene sequences may give rise to a genetic disease.

- ***Deletions*** of a portion of a chromosome may give rise to a disease syndrome if two copies of the genes in the deleted region are necessary, and with just the one normal copy remaining on the non-deleted homologous chromosome the individual will not be normal. Many deletion syndromes have been well described. For example, ***Prader–Willi syndrome*** is the result of deletion of part of the long arm of chromosome 15; ***Wilms' tumour*** is characterized by deletion of part of the short arm of chromosome 11; and microdeletions in the long arm of chromosome 22 give rise to ***DiGeorge's syndrome*** (see Chapter 6).
- ***Duplications*** occur when a portion of the chromosome is present on the chromosome in two copies, so the genes in that chromosome portion are present in an extra dose. A form of neuropathy, ***Charcot–Marie–Tooth disease*** (see Chapter 28), is due to a small duplication of a region of chromosome 17.
- ***Inversions*** involve an end-to-end reversal of a segment within a chromosome, for example, 'abcdefgh' becomes 'abcfedgh', as in ***haemophilia*** (see Chapter 38).
- ***Translocations*** occur if two chromosome regions join together, when they would not do so normally. Chromosome translocations in somatic cells may be associated with tumorigenesis (see 'The genetic basis of cancer') and Fig. 5.24).

Translocations can be very complex, involving more than two chromosomes, but most are simple and fall into one of two categories:

- ***Reciprocal translocations*** occur when any two non-homologous chromosomes break simultaneously and rejoin, swapping ends. In this case the cell still has 46 chromosomes but two of them are rearranged. Someone with a balanced translocation is likely to be normal (unless a translocation breakpoint interrupts a gene); however, at meiosis, when the chromosomes separate into different daughter cells, the translocated chromosomes will enter the gametes, and any resulting fetus may inherit one abnormal chromosome and have an unbalanced translocation with physical manifestations.
- ***Robertsonian translocations*** occur when two acrocentric chromosomes join and the short arm is lost, leaving only 45 chromosomes. This translocation is balanced, and the individual is healthy. However, any offspring have a risk of inheriting an unbalanced arrangement. This risk depends on which acrocentric chromosome is involved. The 14/21 Robertsonian translocation is clinically relevant. A female with this karyotype has a 1 in 8 risk of having a baby with Down's syndrome (a male carrier has a 1 in 50 risk). However, they have a 50% risk of producing a carrier like themselves, hence the necessity for genetic family studies. Relatives should be alerted to the increased risk of Down's syndrome in their offspring and should have appropriate genetic counselling.

Mitochondrial chromosome disorders

The mitochondrial chromosome (see Fig. 5.6) carries its genetic information in a very compact form; for example, there are no introns in the genes. Therefore any mutation has a high chance of having an effect. However, as every cell contains hundreds of mitochondria, a single altered mitochondrial genome will not be noticed. As mitochondria divide, there is a statistical likelihood that there will be more mutated mitochondria, and, at some point, this will give rise to a mitochondrial disease.

Most mitochondrial diseases are myopathies and neuropathies with a maternal pattern of inheritance. Other abnormalities include retinal degeneration, diabetes mellitus, and hearing loss. ***Myopathies*** include chronic progressive external ophthalmoplegia (CPEO); encephalomyopathies include myoclonic epilepsy with ragged-red fibres (MERRFs) and mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) (see Chapter 28).

Box 5.5 Chromosomal abnormalities: examples of a few syndromes

Syndrome	Chromosome karyotype	Incidence and risks	Clinical features	Mortality
Autosomal abnormalities				
Trisomy 21 (Down's syndrome)	47,+21 (95%) Mosaicism translocation 5%	1:650 (overall) (risk with a 20- to 29-year-old mother 1:1000; >45-year-old mother 1:30)	Flat face, slanting eyes, epicanthic folds, small ears, single palmar crease, short and stubby fingers, hypotonia, variable learning difficulties, congenital heart disease (up to 50%)	High in first year but many survive to adulthood
Trisomy 13 (Patau's syndrome)	47,+13	1:5000	Low-set ears, cleft lip and palate, polydactyly, micro-ophthalmia, learning difficulties	Rarely survive for more than a few weeks
Trisomy 18 (Edwards' syndrome)	47,+18	1:3000	Low-set ears, micrognathia, rocker-bottom feet, learning difficulties	Rarely survive for more than a few weeks
Sex chromosome abnormalities				
Fragile X syndrome	46,XX, fra (X) 46,XY, fra (X)	1:2000	Most common inherited cause of learning difficulties, predominantly in males Macro-orchidism	Typically survive to adulthood
Female				
Turner's syndrome	45,XO	1:2500	Infantilism, primary amenorrhoea, short stature, webbed neck, cubitus valgus, normal IQ	Typically survive to adulthood
Triple X syndrome	47,XXX	1:1000	No distinctive somatic features, learning difficulties	Typically survive to adulthood
Male				
Klinefelter's syndrome	47,XXY (or XXYY)	1:1000 (more in sons of older mothers)	Decreased crown–pubis:pubis–heel ratio, eunuchoid, testicular atrophy, infertility, gynaecomastia, learning difficulties (20%; related to number of X chromosomes)	Typically survive to adulthood
Double Y syndrome	47,XYY	1:800 High incidence in tall criminals	Tall, fertile, minor mental and psychiatric illness	Typically survive to adulthood

- ***Kearns–Sayre syndrome*** includes ophthalmoplegia, heart block, cerebellar ataxia, deafness and learning difficulties due to long deletions and rearrangements.
- ***Leber's hereditary optic neuropathy*** (LHON) is the most common cause of blindness in young males, with bilateral loss of central vision and cardiac arrhythmias, and is an example of a mitochondrial disease caused by a point mutation in one gene.
- ***Multisystem disorders*** include ***Pearson's syndrome*** (sideroblastic anaemia, pancytopenia, exocrine pancreatic failure, subtotal villous atrophy, diabetes mellitus, and renal tubular dysfunction). In some families, hearing loss is the only symptom, and one of the mitochondrial genes implicated may predispose patients to aminoglycoside cytotoxicity.

Analysis of chromosomal disorders

Historically, karyotyping involved growing cells from patient samples and studying the chromosomes. The cell cycle (Fig. 5.11) can be arrested at mitosis with the use of colchicine and, following staining, the chromosomes with their characteristic banding can be seen and any abnormalities identified. This is an automated process with computer scanning software searching for metaphase spreads and then automatic binning of each chromosome to allow easy scoring of chromosome number and banding patterns.

Current approaches utilize genome-wide array-based platforms (called single nucleotide polymorphism [SNP] arrays) to identify changes in chromosome copy number and can identify very small interstitial deletions and insertions. The presence of translocations cannot be detected using SNP arrays but instead is studied in a targeted way using fluorescence *in situ* hybridization (FISH). Large, region-specific probes are labelled with fluorescently tagged nucleotides and used to allow rapid identification of metaphase chromosomes (Fig. 5.12). As whole-genome sequencing is becoming more accessible and coverage increases, it will increasingly be used to identify deletions, insertions, and translocation breakpoints.

Point mutations, insertions, and deletions

The advent of Sanger sequencing rapidly accelerated the discovery of base-pair level changes. These pathogenic variants can have various effects on the expression of the gene, and many cause a dysfunction of the protein product. In contrast to the previous section, where changes were described that affect millions of base-pairs in a cell, point mutations can involve just one critical base-pair. These are small but important changes.

Mutations

Although DNA replication is a very accurate process, mistakes occasionally occur and produce changes or mutations. These changes can also arise because of other factors, such as radiation, ultraviolet light, or chemicals. Mutations in gene sequences or in the sequences that regulate gene expression (transcription and translation) may alter the amino acid sequence in the protein encoded by that gene. In some cases, protein function will be maintained; in

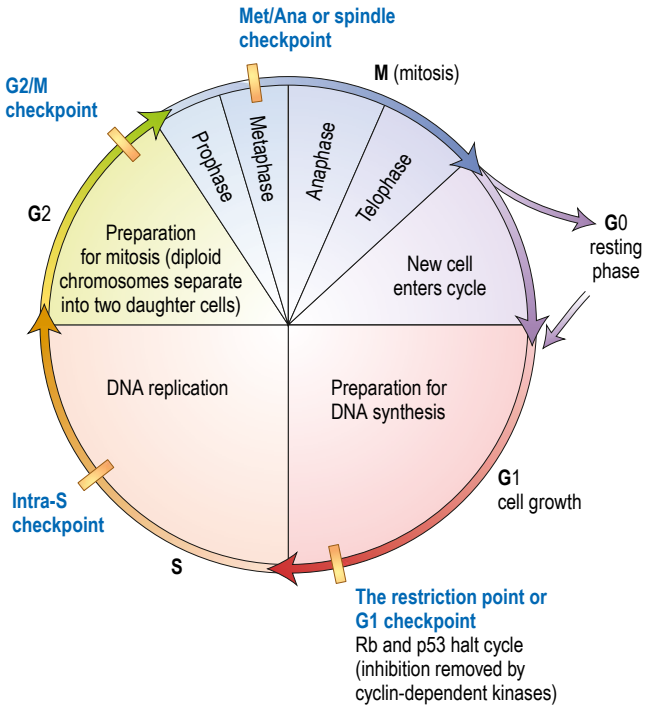

Fig. 5.11 The cell cycle. Cells are stimulated by growth factors to leave non-cycle ***G0*** to enter G1 phase. ***During G1***, transcription of the DNA synthesis molecules occurs. Rb is a 'checkpoint' (inhibition molecule) between G1 and S phases and must be removed for the cycle to continue. This is achieved by the action of the cyclin-dependent kinase produced during G1. During the ***S phase***, any DNA defects will be detected and p53 will halt the cycle. Following DNA synthesis (S phase), cells enter ***G2***, a preparation phase for cell division. Mitosis takes place in the ***M phase***. The new daughter cells can now either enter ***G0*** and differentiate into specialized cells, or re-enter the cell cycle. *DNA*, Deoxyribonucleic acid.

other cases, it will change or cease, perhaps producing a clinical disorder. Many different types of mutation occur.

Point mutation

This is the simplest type of change and involves the substitution of one nucleotide for another, thus changing the codon in a coding sequence and leading to an amino acid substitution (assuming the new sequence is non-synonymous with the former). For example, in ***sickle cell disease*** a pathogenic variant within the globin gene changes one codon from GAG to GTG so that, instead of glutamic acid, valine is incorporated into the polypeptide chain, which radically alters its properties. However, substitutions may have no effect on the function or stability of the proteins produced, as several codons code for the same amino acid (synonymous—see Fig. 5.8).

Insertion or deletion

Insertion or deletion of one or more bases is a more serious change, particularly if the inserted or deleted DNA is not a multiple of three bases, as this will cause the following sequence to be out of the reading frame and can result in a premature stop codon.

Splicing mutations

If the DNA sequences that direct the splicing of introns from mRNA are mutated, then abnormal splicing may occur. In this case the processed mRNA that is translated into protein by the ribosomes

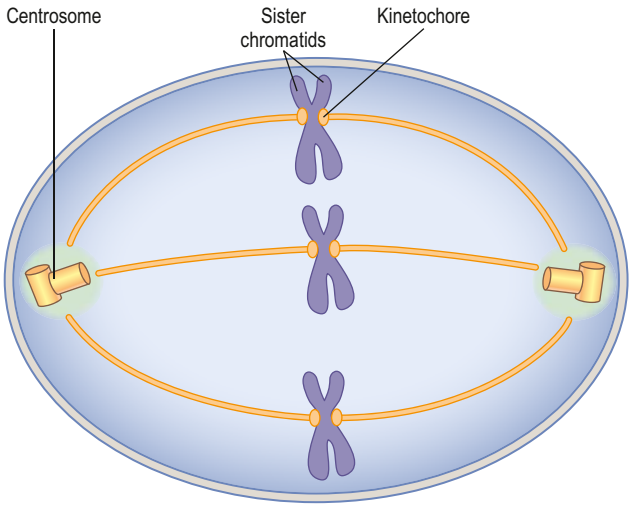

Fig. 5.12 The mitotic spindle at metaphase.

may carry intron sequences or miss exons, thus altering amino acid sequence and affecting protein function.

Nonsense mutations

A nonsense mutation is a point mutation in a sequence of DNA that results in a premature stop codon.

Prenatal diagnosis of congenital anomalies

Prenatal screening should be offered to *all* pregnant females. In England, screening for the three most common trisomies (Down's, Edwards' and Patau's) is offered universally. The risk increases disproportionately for children born to mothers older than 35 years. Infants born to mothers with a history or family history of other conditions due to chromosomal abnormalities may also be at increased risk.

Personal choice

There should be a detailed discussion with all mothers about the possible consequences of each screening test before they are offered it. In particular, they should have an understanding of the failure rates, detection rates, and false-positive and false-negative rates of each test so that they can exercise choice properly.

Screening

10–14 weeks (combined test)

A screening test for Down's syndrome, Edwards' syndrome and Patau's syndrome is available between weeks 10 and 14 of pregnancy and is called a combined test. Mothers may choose to have screening for Down's syndrome alone if they prefer.

The combined test comprises:

- ultrasound for nuchal translucency measurement
- testing of maternal serum for pregnancy-associated plasma protein-A (PAPP-A from the syncytial trophoblast) and β-human chorionic gonadotrophin.

All serum marker measurements are corrected for gestational ages, a multiple of the median value for the appropriate week of gestation. It is possible to sequence cell-free placental DNA in the maternal bloodstream to measure the copies of chromosomes that inform the risk of the fetus having a common chromosomal disorder. Known as non-invasive prenatal testing (NIPT), it is offered as a second test in females where a high-risk result (likelihood greater than 1

in 150) is returned from the combined test. In the event of an abnormal NIPT test, it may be necessary to consider a formal and more invasive diagnostic test (chorionic villus sampling or amniocentesis).

14–20 weeks (serum quadruple test)

A serum quadruple test is done if the pregnancy is too advanced for the earlier tests or if the combined test was not offered.

The quadruple test for chromosomal abnormalities consists of testing maternal serum for levels of:

- α-fetoprotein (low in Down's syndrome pregnancies).
- unconjugated oestradiol (low in Down's syndrome pregnancies)
- human chorionic gonadotrophin (raised in Down's syndrome pregnancies)
- inhibin A (raised in Down's syndrome pregnancies).

Again, a high-risk result is followed by NIPT and/or a diagnostic test.

18–20 weeks (ultrasound)

Ultrasound detects structural abnormalities (e.g., neural tube defects and congenital heart defects). Reported detection rates for congenital anomalies vary; for example, from 14% to 61% for hypoplastic ventricles to 97% to 100% for anencephaly.

Newborn screening

In the UK and other countries, there has been a longstanding program of screening normal newborns for a handful of genetic conditions where knowledge of the result will influence care of the newborn. The newborn blood spot test ('Guthrie test') relies on biochemical testing to detect nine rare but serious health conditions in neonates, including sickle cell anaemia, cystic fibrosis and phenylketonuria. Genomics England, which led the 100 000 Genomes Project, is about to embark on the whole genome screening of 100 000 apparently normal newborns in the UK. The aim is to detect a range of conditions, including inborn errors of metabolism, immunodeficiencies, and other conditions where knowledge of the genetic change within the first 2 weeks of life can make a difference to the life course of the affected child. This may be by modifications to lifestyle (e.g., avoidance of sun exposure in patients with xeroderma pigmentosum), dietary changes (patients with inborn errors), enzyme supplementation, and implanting cochlear devices in patients with some forms of congenital hearing.

Patterns of inheritance of single-gene diseases

Monogenetic disorders involving single genes can be inherited in a dominant, recessive or sex-linked manner.

Autosomal dominant disorders

Each diploid cell contains two copies of all the autosomes. An autosomal dominant disorder (Fig. 5.13A) occurs when one of the two copies has a pathogenic variant, and the protein produced by the normal form of the gene cannot compensate. In this case a heterozygous individual who has two different forms (or alleles) of the same gene will manifest the disease. The offspring of heterozygotes have a 50% chance of inheriting the chromosome carrying the disease allele and therefore also of having the disease. However, estimation of risk to offspring for counselling families can be difficult because of three factors:

- Some disorders have great variability in their manifestation. 'Incomplete penetrance' may occur if patients have a dominant disorder, but it does not manifest itself clinically in them. This gives the appearance of the gene having 'skipped' a generation.
- Dominant traits are extremely variable in severity (variable expression), and a mildly affected parent may have a severely affected child.
- New cases in a previously unaffected family may be the result of a new pathogenic variant. In this case the risk of a further affected child is negligible. Most cases of achondroplasia, for example, are due to new pathogenic variants.

Autosomal recessive disorders

These disorders (Fig. 5.13B) manifest themselves only when an individual is homozygous or a compound heterozygote for the disease allele; that is, both chromosomes carry the same gene pathogenic variant (homozygous) or two different pathogenic variants in the same gene (compound heterozygote). The parents are unaffected carriers (heterozygous for the disease allele). If carriers marry the offspring have a 1 in 4 chance of carrying both mutant copies of the gene and being affected, a 1 in 2 chance of being a carrier, and a 1 in 4 chance of being genetically normal. Parental relatedness increases the risk.

Sex-linked disorders

Genes carried on the X chromosome are said to be 'X-linked' and can be dominant or recessive in the same way as autosomal genes (Fig. 5.13C and D).

X-linked recessive disorders

These disorders present in males and only in homozygous females (usually rare). X-linked recessive diseases are transmitted by healthy female carriers or affected males if they survive to reproduce. An example of an X-linked recessive disorder is ***haemophilia A*** (see Chapter 38), which is caused by a pathogenic variant in the X-linked gene for factor VIII. It has been shown that in 50% of cases there is an intrachromosomal rearrangement (inversion) of the tip of the long arm of the X chromosome (one breakpoint being within intron 22 of the factor VIII gene).

Of the offspring from a carrier female and a normal male:

- 50% of the girls will be carriers, as they inherit a mutant allele from their mother and the normal allele from their father; the other 50% of the girls inherit two normal alleles and are themselves normal.
- 50% of the boys will have haemophilia, as they inherit the mutant allele from their mother (and the Y chromosome from their father); the other 50% of the boys will be normal, as they inherit the normal allele from their mother (and the Y chromosome from their father).

The male offspring of a male with haemophilia and a normal female will not have the disease, as they do not inherit his X chromosome. However, all the female offspring will be carriers, as they all inherit his X chromosome.

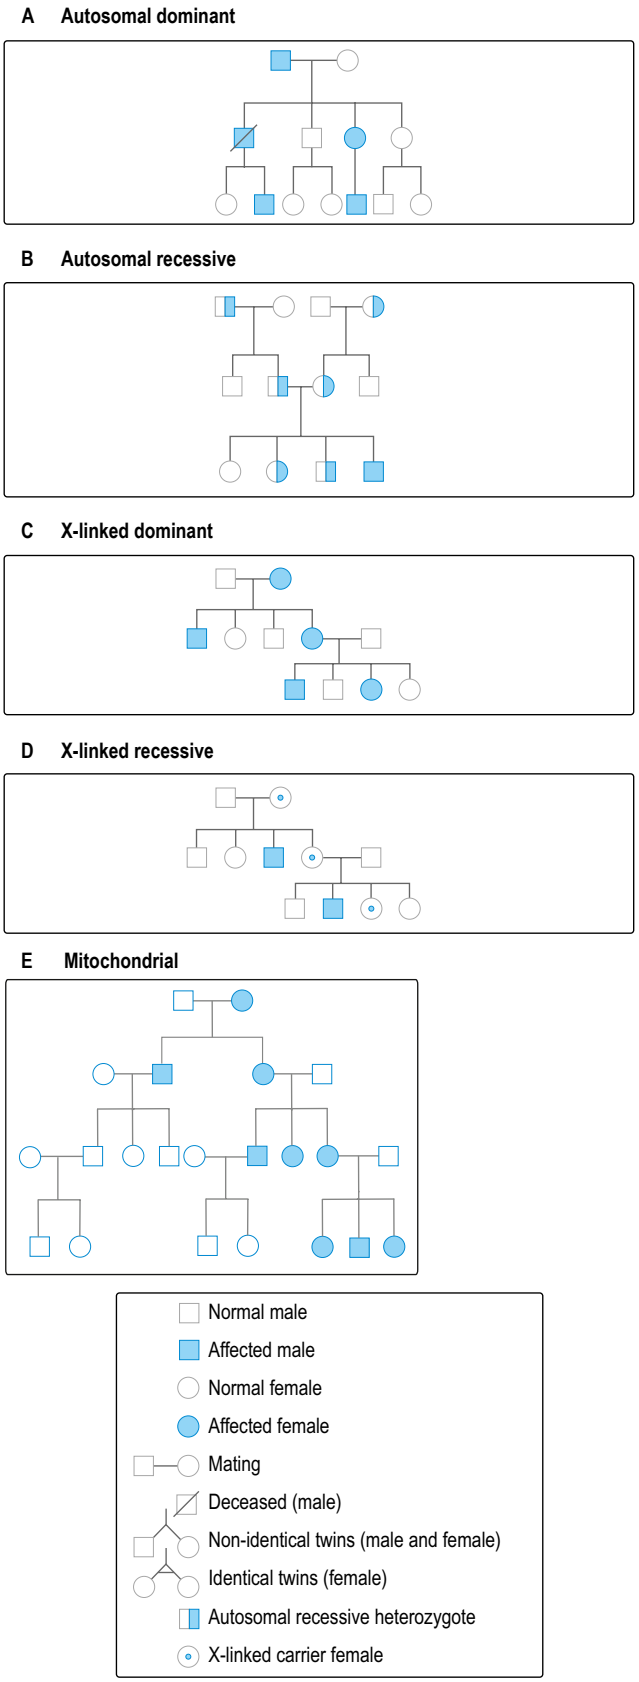

Fig. 5.13 **Modes of inheritance of simple gene disorders and mitochondrial inheritance.**

X-linked dominant disorders

These are rare. Females who are heterozygous for the mutant gene and males who have one copy of the mutant gene on their single X chromosome will manifest the disease. Half the male or female offspring of an affected mother and all the female offspring of an affected male will have the disease. Affected males tend to have the disease more severely than the heterozygous female.

Mitochondrial inheritance

The pattern of inheritance associated with alterations in the mtDNA involves both males and females, but always with the condition passed on through the female line (maternal inheritance). Since many mitochondria are passed into the egg from the cells in the ovary, all the offspring of an affected female would be expected to inherit the condition. An affected male does not pass his mitochondria on to his children, so his children will be unaffected (see **Fig. 5.13E**). Note that not all mitochondrial diseases will show this pattern of inheritance. As these conditions arise due to incorrectly functioning mitochondria, they may also be caused by an alteration in the nuclear DNA that has an impact on mitochondrial function, and not just be caused directly by a mitochondrial pathogenic variant. Hence, some mitochondrial diseases may demonstrate dominant patterns of inheritance.

Special presentations of genetic disease

These are disorders that may be due to pathogenic variants in single genes but which do not manifest as simple monogenic disorders. They can arise from a variety of mechanisms.

Mosaicism

Genetic mosaicism arises when a mutation occurs in a cell during embryonic development. This cell and its progeny are then genetically distinct from the rest of the fetus. This can give rise to a less severe form of recognized genetic disease, sometimes referred to historically as a 'forme fruste'. Equally, some mutations are not compatible with life if every cell in the fetus is affected but may be rescued if the fetus is mosaic. Schimmelpenning's syndrome is an example, where patients carry a mosaic *HRAS* gene pathogenic variant.

Triplet repeat mutations and genetic anticipation

In the gene responsible for myotonic dystrophy (see Chapter 28) the mutated allele was found to have an expanded 3′ UTR region in which three nucleotides, CTG, were repeated up to about 200 times. In families with myotonic dystrophy, people with the late-onset form of the disease had 20 to 40 copies of the repeat, but their children and grandchildren who presented with the disease from birth had vast increases in the number of repeats—up to 2000 copies. It is thought that some mechanism during meiosis causes this 'triplet repeat expansion' so that the offspring inherit an increased number of triplets. The number of triplets affects mRNA and protein function, and patients with more repeats present earlier (**Box 5.6**). The phenomenon has also been recognized with Huntington's chorea, where patients with more repeats present earlier and with progressively worse symptoms. This 'anticipation' is due to unstable mutations occurring within the disease gene. Trinucleotide repeats, such as CTG (dystrophia myotonica) and CAG (Huntington's disease), expand within the disease gene with each generation, and somatic expansion with cellular replication is also observed. This type of genetic mutation can occur within the translated region or untranslated (and presumably

regulatory) regions of the target genes. This genetic distinction has been used to subclassify a number of genetic diseases that have now been shown to be caused by trinucleotide repeat expansion and display phenotypic 'anticipation' (see Box 5.6).

Imprinting

Normal humans need a diploid number of chromosomes; that is, 46, with 23 inherited from each parent. For the majority of genes both maternally and paternally inherited alleles are functional; however, in some cases the gene from one parent is silenced. The mechanism that regulates the differential expression of two alleles of the same gene is termed ***genetic imprinting***, an epigenetic change brought about through DNA methylation.

Imprinting is relevant to human genetic disease because different phenotypes may result, depending on whether the mutant chromosome is maternally or paternally inherited. A deletion of part of the long arm of chromosome 15 (15q11–q13) will give rise to ***Prader–Willi syndrome***, if it is paternally inherited. A deletion of a similar region of the chromosome gives rise to ***Angelman's syndrome*** if it is maternally inherited. The affected gene has been identified as ubiquitin *(UBE3A)*.

Different genes that cause the same disease

Although classically divided into autosomal dominant, recessive or X-linked disorders, many syndromes show multiple forms of inheritance pattern. For example, in ***Ehlers–Danlos syndrome***, there is autosomal dominant, recessive and X-linked inheritance. This has now been explained by the finding that pathogenic variants in different genes that contribute to a common function can have the same clinical presentation. In addition, in some recessive disorders, even having just one defective allele gives a mild form of the disease (semi-dominant), while having both alleles with the pathogenic variant results in a more severe form of the syndrome.

Different diseases caused by the same gene

The following are two examples of how different pathogenic variants in a gene can cause different diseases, referred to as genotype–phenotype correlation.

CYLD

Patients with CYLD cutaneous syndrome carry germline pathogenic variants in *CYLD*, where two strikingly different phenotypes may be seen. Patients can develop tumours on the head or on the face, previously categorized as two separate diseases. It is now known that these different presentations can occur within a family where the same pathogenic variant has been documented. It is thought that the distinct phenotypes are due to yet undefined changes present in the genetic background of patients who carry *CYLD* pathogenic variants (Fig. 5.14).

Box 5.6 Examples of trinucleotide repeat genetic disorders

Syndrome inheritance pattern	Disease prevalence	Gene, product, location, and disorder	Genetic test detection rate (%)
Friedreich's ataxia—AR	2–4/100 000	*FRDA* (frataxin) 9q13—GAA trinucleotide repeat expansion disorder in intron 1 of *FRDA*	96
Fragile X syndrome—X-linked	16–25/100 000	*FMR1* (fragile X mental retardation 1 protein) Xq27.3—CGG trinucleotide repeat expansion and methylation changes in the 5′ untranslated region of *FMR1* exon 1	99
Huntington's disease—AD	3–15/100 000	*HD* (Huntingtin protein) 4p16.3—CAG trinucleotide repeat expansion within the translated protein, giving rise to long tracts of repeat glutamine residues in *HD*	98
Myotonic dystrophy—AD	1/20 000	*DMPK* (myotonin–protein kinase) 19q13.2–13.3—CTG trinucleotide repeat expansion in the 3′ untranslated region of the *DMPK* gene (dystrophia myotonica 1, DM1). Less common form—expanded. CCTG repeat in zinc finger protein 9 *(ZNF9)* gene (DM2)	100

Box 5.7 Examples of disorders that may have a polygenic inheritance

Disorder	Frequency (%)	Heritability (%)[a]
Hypertension	5	62
Asthma	4	80
Schizophrenia	1	85
Congenital heart disease	0.5	35
Neural tube defects	0.5	60
Congenital pyloric stenosis	0.3	75
Ankylosing spondylitis	0.2	70
Cleft palate	0.1	76

[a]Percentage of the total variation of a trait that can be attributed to genetic factors.

STAT3

The transcription factor signal transducer and activator of transcription 3 *(STAT3)* is a critical regulator of multiple and diverse cellular processes. Heterozygous, germline, loss-of-function pathogenic variants in *STAT3* lead to the primary immune deficiency hyper-IgE syndrome. Recently, germline, heterozygous pathogenic variants in *STAT3* that confer a gain of function have been discovered and result in early-onset, multiorgan autoimmunity.

Complex traits: multifactorial and polygenic inheritance

Characteristics resulting from a combination of genetic and environmental factors are said to be multifactorial; those involving multiple genes are said to be polygenic. There has been an explosion in genetic discoveries about these complex traits with the development of high-throughput genome-wide SNP arrays, which has allowed cost-effective and unbiased screening of large case–control cohorts (in excess of 1000 cases). These studies are known as genome-wide association studies (GWASs) and are discussed later. They have permitted unequivocal identification of SNPs associated with a variety of traits and diseases. For example, over 30 SNPs in immune-related gene loci have been associated with coeliac disease, with over half also associated with other immune-mediated or inflammatory diseases. This indicates that there are many low-risk genetic risk factors associated with complex traits, and common pathways are implicated in different diseases.

Most human diseases, such as heart disease, diabetes, and common mental disorders, are multifactorial traits (**Box 5.7**).

TECHNIQUES FOR STUDYING THE GENETIC CODE

Polymerase chain reaction

Polymerase chain reaction (PCR) is a core technique in genetics, which has revolutionized genetic research because small regions of interest in a sample of DNA—for example, the *BRCA1* gene—can be amplified over a million times within a few hours. The DNA is amplified between two short (generally 17–25 bases) single-stranded DNA fragments ('oligonucleotide primers') that are complementary to the sequences on different strands at each end of the DNA of interest (**Fig. 5.15**). These short lengths of amplified DNA can then be sequenced to obtain identification of the exact nucleotide sequence using Sanger sequencing (named after its inventor).

Sanger sequencing

This involves a chemical process known as dideoxy-sequencing. Once the sequence of interest is amplified, this is used as a template for the Sanger sequencing reaction. An oligonucleotide primer is designed to anneal adjacent to the region of interest. This

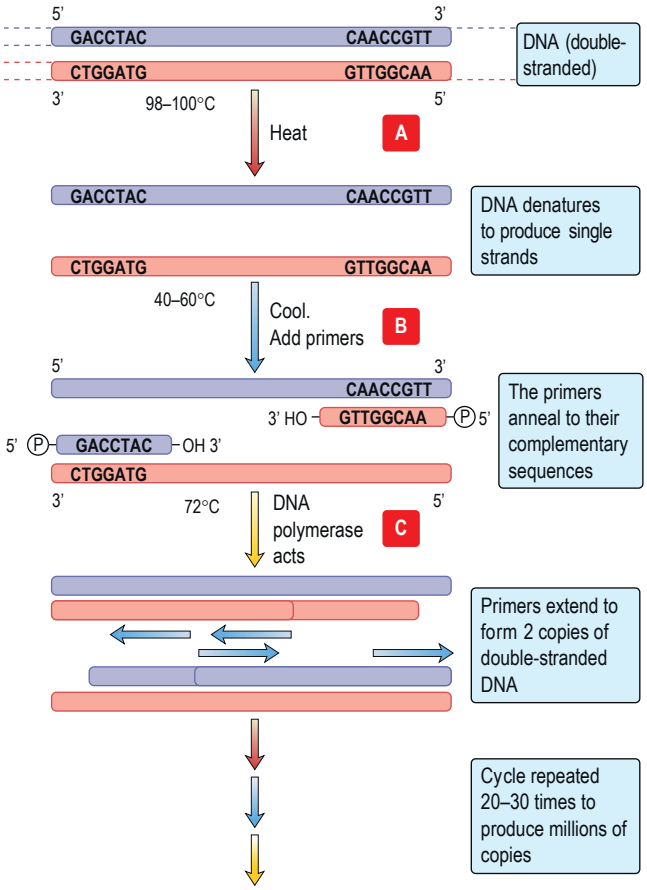

Fig. 5.15 Polymerase chain reaction. The technique is based on thermal cycling and has three basic steps. **(A)** The double-stranded genomic DNA is heat-denatured into single-stranded DNA. **(B)** The sample is cooled to favour annealing of the primers to their target DNA. **(C)** A thermostable DNA polymerase extends the primers over the target DNA. After one cycle, there are two copies of double-stranded DNA, after two cycles there are four copies, and so on. *DNA,* Deoxyribonucleic acid; *PRC,* polymerase chain reaction.

primer acts as the starting point for a DNA polymerase to build a new DNA chain that is complementary to the sequence under investigation. Chain extension is prematurely interrupted when a fluorescently labelled dideoxynucleotide becomes incorporated (this happens because it lacks the necessary 3′-hydroxyl group needed for extension). Each base dideoxynucleotide (G, C, T, A) has a different fluorochrome attached, and thus each termination base can be identified by its fluorescent colour. As each strand can be separated efficiently by capillary electrophoresis according to its size or length, simply monitoring the fluorescence as the reaction products elute from the capillary tube will give the gene sequence (Fig. 5.16). This is a widely used but relatively low-throughput method, which is increasingly being replaced with high-throughput methods.

Next-generation sequencing

Sequencing technology has developed such that it is now possible to sequence DNA molecules in a high-throughput manner ('next-generation sequencing' [NGS]), and new, faster, and cheaper methods are being developed. It is possible to sequence all the coding genes in an individual's human genome (termed the 'exome') to catalogue all possible disease-associated and non-disease-associated variants in every human gene at a low cost. If necessary, whole genomes (including non-coding regions) can also be sequenced in this way, although this involves a greater cost. The sequences are typically generated as short runs of sequences between 75 and 200 bp long, known as reads, which are aligned to the reference human genome (Fig. 5.17).

Differences from the reference genome are called 'variants' and are catalogued for each sample. The computational requirements for processing data from NGS experiments are significant and are usually performed on dedicated computer clusters. Whole-genome sequencing has the advantage over whole-exome sequencing of being able to detect intronic changes, structural variants, and changes in DNA copy number.

Transcriptomics

Along with sequencing genomic DNA, NGS technology can be used to sequence RNA (termed 'RNAseq') to assess gene expression levels accurately, in addition to determining all splice variations and allelic copy number. Analysis of all the RNA transcripts in a sample, or 'transcriptomics', allows for the comprehensive study of disease states. A limitation of this approach is that there may be a difference between levels of RNA transcripts and corresponding proteins that are encoded, warranting validation using additional techniques. It can be useful in some cases to look at affected tissue for non-coding variants such as splice site mutations. Note that, in addition to carrying out such work on whole-tissue samples, such as liver or skin, it is now possible to sequence single cells. This represents an opportunity to investigate disease states at unprecedented resolution; the Human Cell Atlas is one such project that aims to capture representative transcriptomes of human cells from all tissues. It is now possible to also study entire transcriptomes from sections of tissue, giving spatial context to transcriptomic data in health and disease.

Epigenetic techniques

NGS can also be used to study epigenetic changes. Changes in methylation can be studied using a technique that converts the unmethylated cytosines across the whole genome using a chemical process called bisulphite conversion, allowing for the absence and presence of methylation to be comprehensively detected. In addition to methylation, it is possible to determine the accessibility of chromatin using additional techniques such as assay for transposase-accessible chromatin sequencing (ATAC-seq).

Genome databases

Information arising from human genome sequencing is publicly available, providing biological information on every gene in the human genome. Information on any gene describing its protein product, function, tissue-specific expression, disease association and sequence variation can be easily obtained by searching and manipulating computer databases. In addition to genotype, it is necessary to consider databases that couple genotype with phenotype, such as DECIPHER. Some databases such as the UK BIOBANK have allowed extensive studies where genetic data can be analysed with clinical data, allowing for a range of research questions to be addressed. Phenotyping is difficult to do, although frameworks to aid this have been developed, such as the Human Phenotype Ontology (HPO).

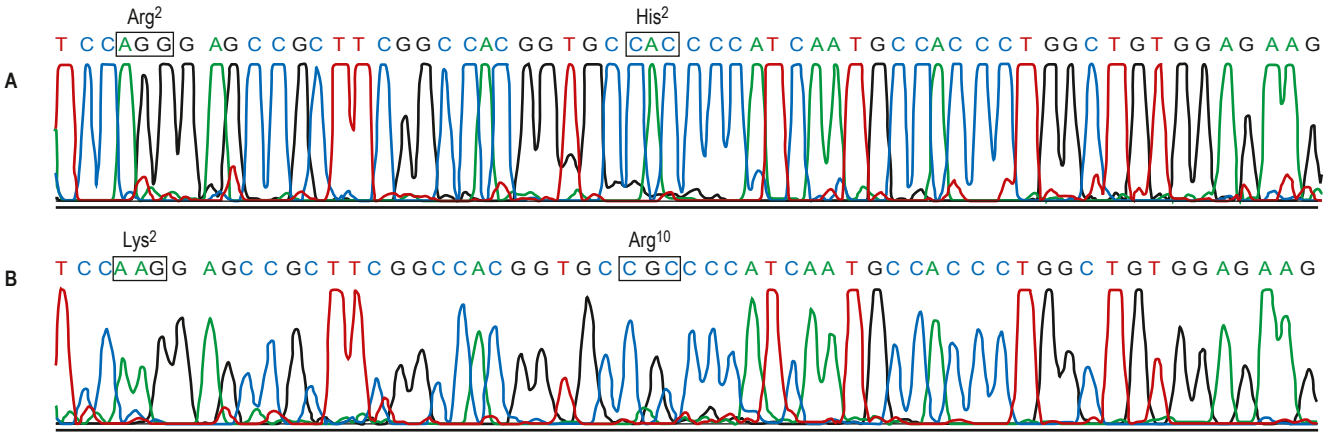

Fig. 5.16 Sanger sequencing. **(A)** Part of the normal luteinizing hormone beta chain gene. **(B)** Two polymorphic variants. The base changes and consequential alterations from arginine to lysine, and histidine to arginine amino acid residues are indicated.

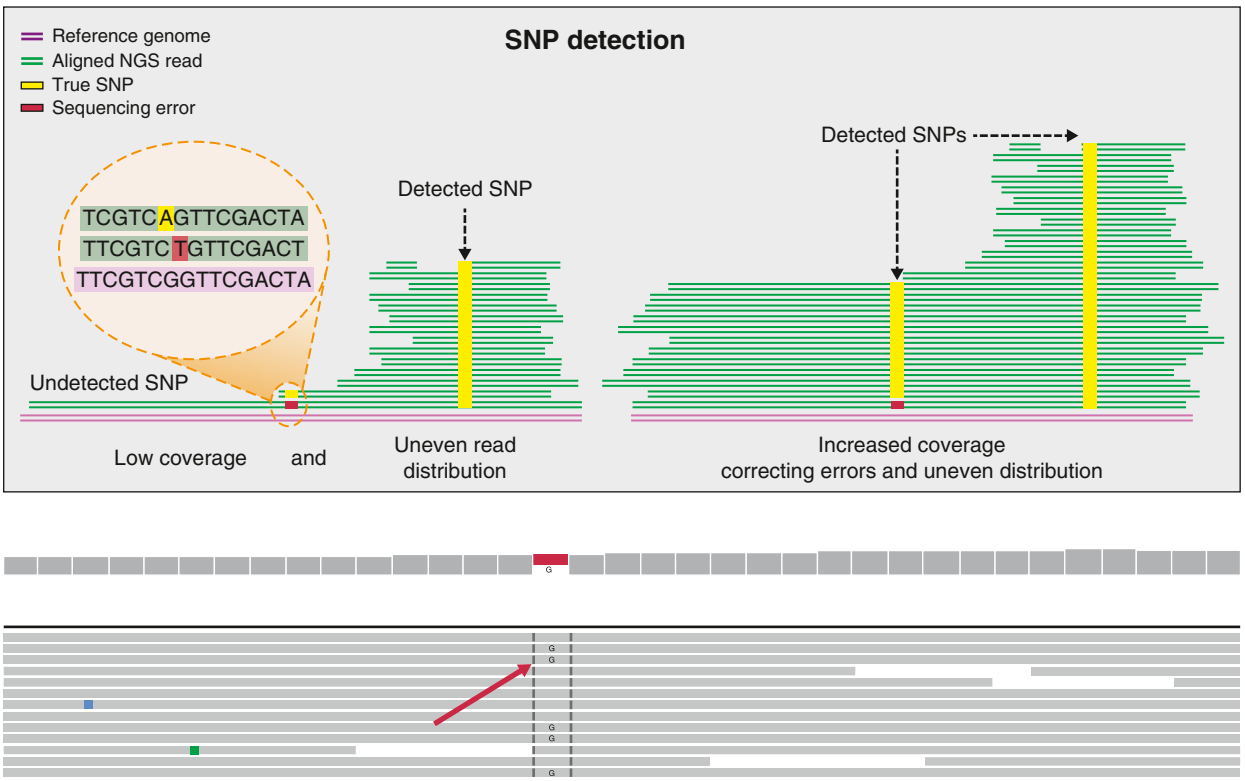

Fig. 5.17 Next-generation sequencing. The ability to detect genetic changes depends on good coverage of the region of interest, and the depth allows for true calls of variants over sequencing artefacts. *NGS,* Next-generation sequencing; *SNP,* single-nucleotide polymorphism.

Research techniques

Discovery of disease-causing genes

Genetic polymorphisms and linkage studies

Linkage analysis has provided many breakthroughs in mapping the positions of genes that cause genetic diseases, such as the gene for cystic fibrosis, which was found to be tightly linked to a marker on chromosome 7.

These studies relied on finding markers that segregate with the disease in large families and are typically used in rare monogenic disease. Techniques that identify and quantitate genetic polymorphisms, such as SNPs (see earlier), microsatellites, and copy number variants (CNVs), are essential, as these serve as markers. Polymorphisms that are closer together are more likely to have alleles that move together in a block during meiosis than those further apart. This phenomenon is called 'linkage disequilibrium' and enables, for example, one SNP variant (tag SNP) in this block to act as a marker for the presence of other SNP variants.

Sequencing trios using whole-exome and whole-genome sequencing (WES/WGS)

The ability to study whole genomes is being used in work such as the 100,000 Genomes Project to discover new disease-causing genes. The aims of gene discovery include diagnosis, genetic counselling, and targeted screening. Typically, affected and unaffected individuals are studied, and variants that segregate with the disease are filtered. The DNA from both parents and the affected individual, known as a 'trio', is the minimum, and usually, the suspected gene in the affected individual will be found in other families with the same disease, strengthening the association. These advances have made it possible to find novel disease-causing genes in smaller pedigrees without needing to use the linkage approach.

Genome-wide association studies

Breakthroughs in complex polygenic disease are increasingly being achieved by studying large numbers (typically several thousands) of affected and unaffected patients. Many of these studies use SNP arrays, which provide informative data on hundreds of thousands of SNPs across the entire genome of an individual. Using these markers, statistical testing of association is applied, and changes that are linked with disease are typically plotted on a Manhattan plot (so called because the graph can look like the skyline of Manhattan; **Fig. 5.18**). This plot has genomic coordinates on the x-axis, and a measure of the statistical likelihood that the association detected has occurred by chance on the y-axis. SNPs that are likely to be associated with the disease have a low p-value, and as the y-axis values are plotted as negative logarithmic transformations of these p-values, a peak is displayed for such changes. These SNPs may not necessarily sit within the causative gene but may, for example, lie nearby, such as in the promoter of the gene affecting expression. GWAS can highlight regions of interest for polygenic diseases, which can then be studied in more detail, with the aim of gaining genetic insights into disease pathogenesis.

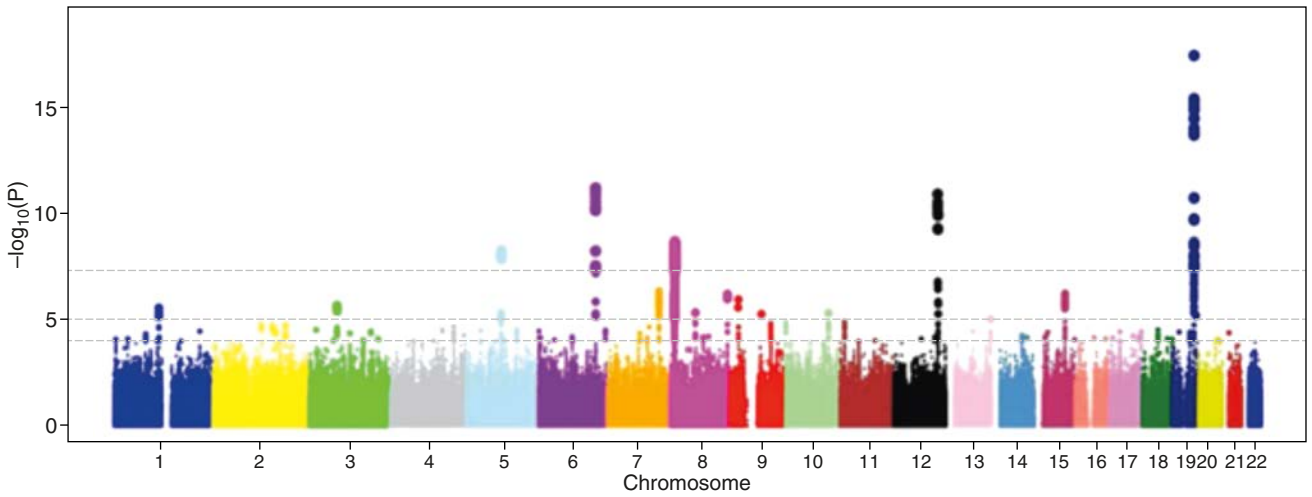

Fig. 5.18 A Manhattan plot of a genome-wide association study. SNPs at genetic loci that associate with the disease being studied are indicated; in this case, regions of interest lie in chromosomes 5, 6, 8, 12 and, most strongly, 19. Such regions can then be studied further. *SNPs,* Single-nucleotide polymorphisms.

Identification of gene function

Following the finding of genes of interest in either rare or common disease the challenge is to understand the function of these protein-coding genes. To gain insights into gene function the genetic changes found in disease can be modelled in cells or in animals. Most studies rely on the comparison of a cell's or an animal's phenotype in the presence or absence of the genetic change in question. Each approach has its respective merits and faults.

Cell culture models

DNA transfection

Human cells can be grown in cell culture flasks in the laboratory and their behaviour (growth rate, morphology, motility, gene expression profile, and biochemistry) characterized. A specific gene can then be introduced in a small plasmid (a circle of DNA from which the gene of interest can be expressed) or incorporated into a virus, and the change in cell behaviour can be assessed to provide an indication of gene function.

A recent advance is the use of genome editing, for example, CRISPR (clusters of regularly interspaced short palindromic repeats) gene editing to introduce the genetic change found in humans into cell lines (Fig. 5.19). This has the advantage of achieving physiological levels of gene expression over plasmids, where genes may be expressed at higher levels due to the presence of viral promoters in plasmid DNA. CRISPR can be used to introduce patient pathogenic variants into cells or to knock out genes completely to study their function.

RNA interference

Alternatively, if the cell line in question already expresses the gene of interest, its expression can be knocked down by RNA interference (RNAi). RNAi takes advantage of the cellular machinery that allows miRNAs encoded by the genome to regulate the expression of many genes at the level of mRNA stability and translation. This phenomenon has been exploited in the laboratory to study the function of a gene of interest or, on a much larger scale, the function of each gene in the genome. In such an RNAi screen an siRNA specific for each gene in the genome is introduced into cells grown *in vitro*, in effect knocking down expression of each gene in approximately 20 000 separate experiments. The phenotype of the cells in each experiment is then monitored to test the effect of loss of gene expression.

Animal models

The effect of a gene at the organism level can also be tested by misexpression/over-expression or knockout of a particular gene in a model animal. Nematode worms *(Caenorhabditis)*, fruit flies *(Drosophila)*, zebrafish, and rodents have all been genetically engineered to identify the function of a gene of interest. Knockout models of the higher organisms can be particularly helpful for medical research in providing a model of disease for the exploration of therapeutic intervention. Large-scale mutagenesis programmes are knocking out every gene or regulatory element in the mouse genome. However, note that the physiology of rodents and humans can differ.

GENOMIC MEDICINE

Gene therapy

A clinical aim of genetics has been to correct the disease-causing pathogenic variant and to treat the disease.

There are many technical problems to overcome in gene therapy, particularly in finding delivery systems to introduce DNA into a mammalian cell. Very careful control and supervision of gene manipulation is necessary because of its potential hazards and the attendant ethical issues.

Two major factors are involved in gene therapy:

- the introduction of the functional gene sequence into target cells
- the expression and permanent integration of the transfected gene into the host cell genome.

Haemophilia

These approaches have been gaining ground with conditions such as haemophilia, where recent trials of gene therapy have

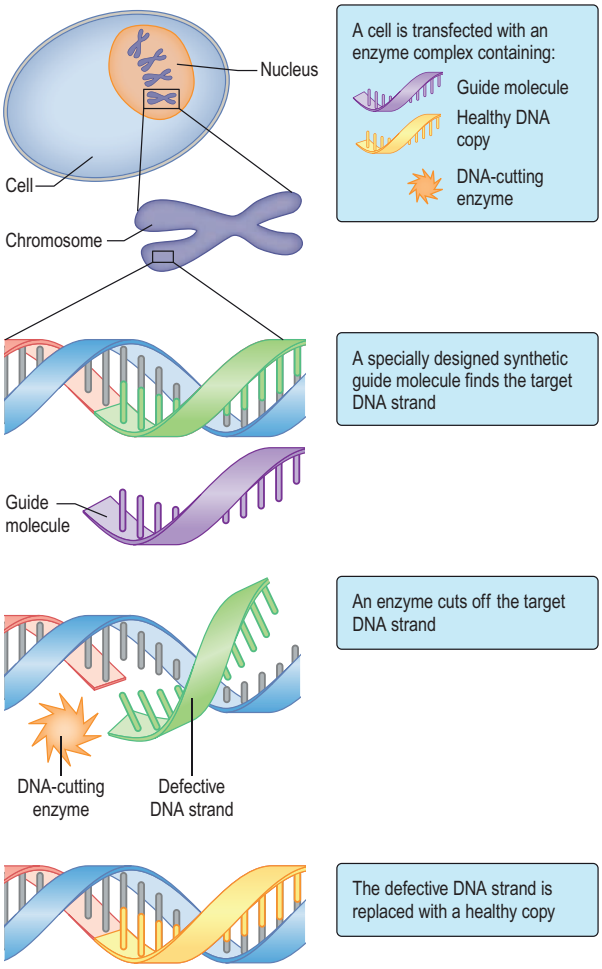

Fig. 5.19 Gene editing using technologies such as CRISPR (clusters of regularly interspaced short palindromic repeats).

meant that some patients no longer need transfusions to maintain normal clotting function. This approach involves using a virus to deliver a DNA construct with a normal sequence of factor VIII (haemophilia A) or factor IX (haemophilia B) to cells in the patient, administered as an infusion. Due to the design of this DNA construct, liver cells selectively express and produce functional clotting factors, with clinical improvement measured as reduction of bleeding episodes in the absence of regular transfusions of coagulation factors (Fig. 5.20).

Cystic fibrosis

Restoring function in diseases affecting solid organs rather than blood poses different challenges. In cystic fibrosis (CF), rather than trying to restore the altered sequence of the gene in every affected cell, a different approach is used. *CFTR*, the cystic fibrosis transmembrane regulator (see also Chapter 20), is an unusual ABC transporter in that it does not function as a primary active transporter but as a ligand-gated chloride channel (Fig. 5.21). The common CF pathogenic variant is a 3 bp deletion in exon 10 that results in the removal of a codon specifying phenylalanine (F508del). In this pathogenic variant the CFTR protein is misfolded, thereby causing ineffective biosynthesis and consequently disrupting the delivery of the protein to the cell surface. This pathogenic variant has recently been targeted with a combination of therapies (lumacaftor–ivacaftor) in phase 3 clinical trials and is now approved for clinical use. Lumacaftor brings more mutant CF channel proteins to the cell surface, and ivacaftor aids by prolonging the opening of the chloride ion channel, which restores partial function to the mutated protein. Early clinical results are encouraging, with patients demonstrating increased pulmonary function as measured by improved forced expiratory volume. More recent trials are being carried out to determine whether early intervention in childhood may modify the course of the disease.

Mitochondrial replacement therapy

In mitochondrial diseases arising due to pathogenic variants in the mitochondrial DNA, it is possible to avoid transmission of these maternally transmitted mitochondria using a technique known as pro-nuclear transfer. This involves transferring the nucleus from a fertilized cell from an affected patient with mitochondrial disease to a fertilized cell from a healthy donor, from which the nucleus has been removed. By doing this the developing embryo will have mitochondria only from the healthy donor while retaining nuclear DNA from the biological parents. In the UK, this process is underway in a small number of families (Fig. 5.22).

Stem cell therapy

Stem cell therapy has the potential to change the treatment of human disease radically. A number of adult stem cell therapies already exist, particularly bone marrow transplants for immune deficiencies. In this context a patient with a genetic immune deficiency receives a transplant from a healthy donor, and these normally functioning cells confer immunity. It is currently anticipated that technologies derived from stem cell research can be used to treat a wider variety of diseases in which replacement of destroyed specialist tissues is required, such as in Parkinson's disease, spinal cord injuries, and muscle damage.

In the era of gene editing the possibility of restoring genetically corrected cells has become a reality in some genetic blistering skin disorders. A male child with junctional epidermolysis bullosa developed blisters, with epidermal loss affecting 80% of his total body surface area. Skin cells were taken from this patient and transduced with a DNA construct that resulted in the production of the necessary protein, laminin 332. These corrected stem cells were grown in the laboratory before being transplanted back onto the patient's skin. Therapy resulted in complete coverage of the patient's skin, with genetic testing of the skin confirming the presence of the corrected cells.

These examples are indicative of the potential for using genetic information for clinical benefit and also of the length of time it takes to achieve meaningful outcomes.

Pre-implantation genetic diagnosis

Genetic diagnosis in a family can also be used to prevent transmission of a disease. This process requires knowledge of the genetic pathogenic variant that runs in the family. Early stage 8 cell embryos can have a cell removed and continue to form into a normal baby (Fig. 5.23A). It is possible to take such a cell and use it to genotype an embryo. Only embryos that do not carry the pathogenic variant are taken forward for implantation (Fig. 5.23B). This approach has been used to prevent transmission of cancer genes such as *BRCA*.

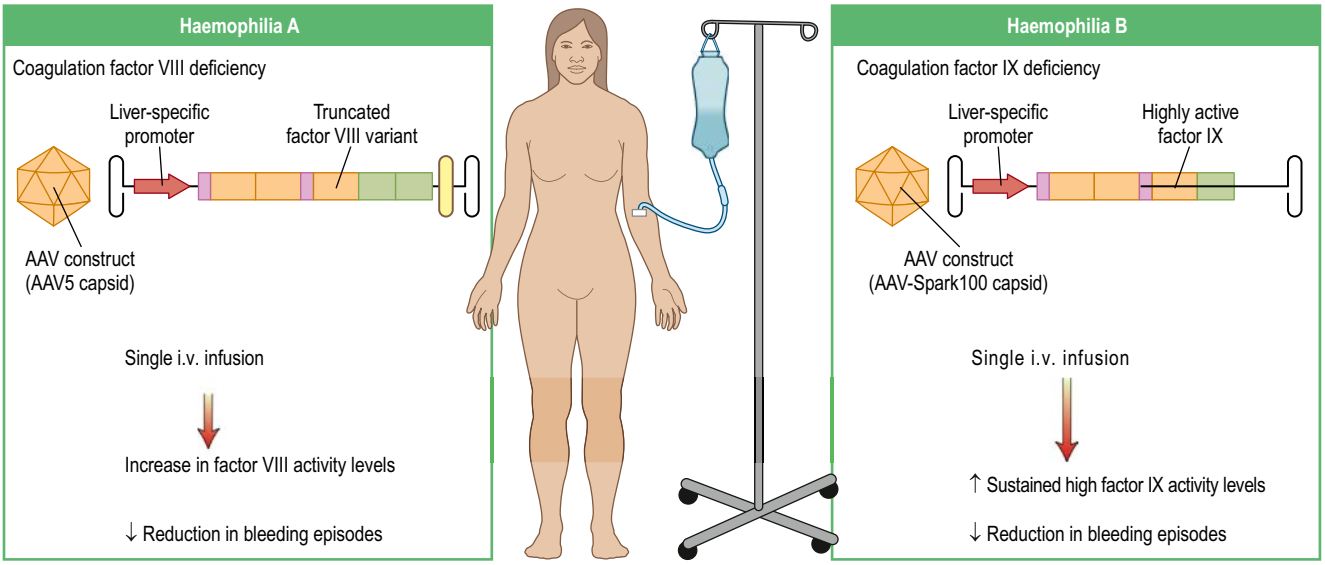

Fig. 5.20 Haemophilia targeted with gene therapy. THE GENETIC BASIS OF CANCER

The preceding sections have given an outline of how the genetic code gives rise to human health and disease. Cancers are genetic diseases and involve changes to the genetic code that result in abnormal function of cellular genes. The Cancer Genome Project set out to map the variety of pathogenic variants seen across human cancers, and these changes are detailed in online repositories (the Catalogue of Somatic Mutations in Cancer, COSMIC). Multiple gene pathogenic variants interact during oncogenesis and a progression of genetic defects gives a cancer cell a survival advantage over surrounding normal cells, famously termed the 'hallmarks of cancer' (see Fig. 41.2). These hallmarks include processes like increased proliferation, avoidance of control mechanisms such as apoptosis (programmed cell death) and the ability to evade immune detection. In the vast majority of cancer cases (especially those arising later in life) the multiple genetic changes that occur are somatic; that is, they occur *de novo* and are not inherited. In the next section the impact of inheriting pathogenic variants in cancer predisposition genes, such as early-onset and multiple cancers, is exemplified.

Inherited cancer syndromes

In some cancers (normally those that occur at an earlier age) an inherited single-gene defect can give rise to an almost Mendelian trend with lifetime risks of nearly 90%.

Autosomal dominant inheritance of cancer syndromes

The development of cancers at an earlier age and the occurrence of multiple tumours in these individuals highlight how genetic pathogenic variants facilitate the development of cancer. The following are examples of cancer syndromes that exhibit dominant inheritance:

- ***Retinoblastoma.*** This eye tumour is found in young children. It occurs in both hereditary (40%) and non-hereditary (60%)

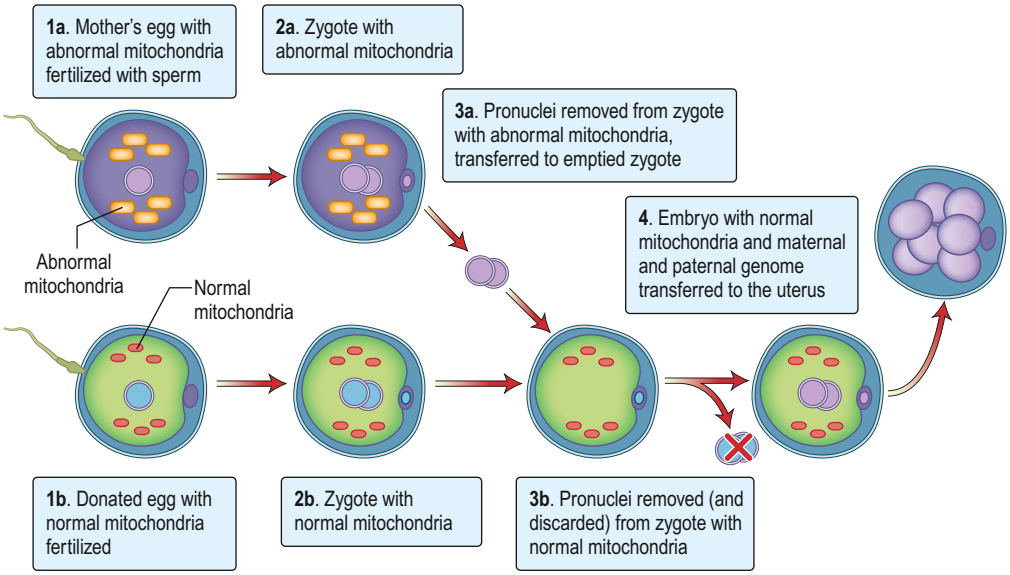

Fig. 5.22 Mitochondrial replacement therapy. Parents with transmissible mitochondrial disease provide fertilized eggs that carry abnormal mitochondria (1a, 2a). A healthy donor produces a fertilized egg, with normal mitochondria (1b, 2b). The nucleus from the affected parents' egg is transferred to the donor egg (3) and this is then transferred to the uterus to develop (4).

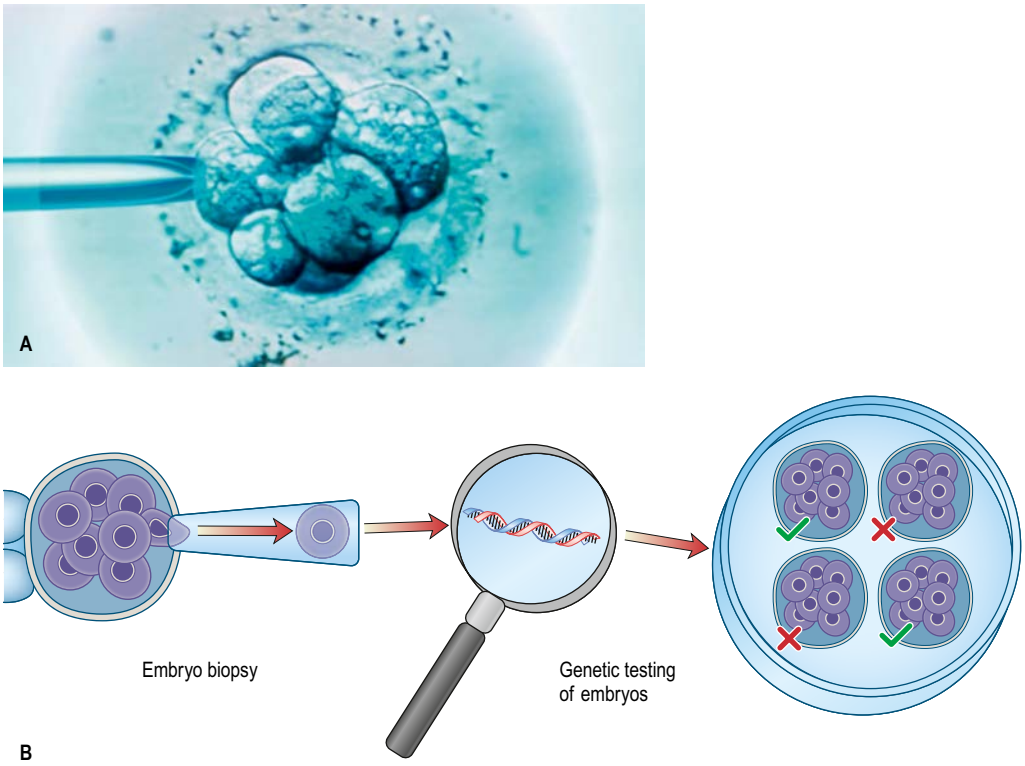

Fig. 5.23 Pre-implantation genetic diagnosis. (A) An early-stage blastocyst being sampled for genetic testing. **(B)** Each cell is tested, and only embryos without the screened pathogenic variant are selected for implantation.

forms. In the hereditary form, there is a germline pathogenic variant in the retinoblastoma gene *(RB1)* and people are also at risk of developing other tumours, particularly osteosarcoma. Knudson studied these patients, and this led to the 'two-hit hypothesis' (see later).

- ***Breast and ovarian cancer.*** Two major genes have been identified: *BRCA1* and *BRCA2*. A strong family history along with germline pathogenic variant of these genes accounts for most cases of familial breast cancer and over half of familial ovarian cancers. BRCA1 and BRCA2 proteins bind to the DNA repair

enzyme Rad51 to make it functional in repairing DNA breaks. Pathogenic variants in the *BRCA* genes will lead to the accumulation of unrepaired mutations in tumour suppressor genes and crucial oncogenes. Treatments that block the remaining repair mechanism of double-stranded breaks in these cells, a process called 'non-homologous end joining', have been used to treat *BRCA*-deficient cancers. This paradoxically increases the mutational load in these cells, resulting in cell death. The process is described as synthetic lethality and, in the case of *BRCA*-deficient tumours, is achieved by inhibitors of an enzyme called poly-ADP ribose polymerase (PARP).

- ***Neurofibromatosis.*** Inactivation of the *NF1* gene will lead to constitutive activation of Ras proteins and the development of multiple tumours in the nervous system (see Chapter 28).
- ***Lynch syndrome*** (see Chapter 22). Patients with defects in a group of genes that encode proteins involved in DNA mismatch repair are at increased risk of colorectal cancer. This syndrome has recently been highlighted as one instance where chemoprevention with aspirin can reduce the development of colorectal cancer by as much as 63%.

Autosomal recessive inheritance of cancer syndromes

Some relatively rare autosomal recessive diseases associated with abnormalities of DNA repair predispose to the development of cancer:

- ***Xeroderma pigmentosum.*** There is an inability to repair DNA damage caused by ultraviolet light and by some chemicals, leading to a high incidence of skin cancer.
- ***Ataxia telangiectasia.*** Increased sensitivity to ionizing radiation and a higher incidence of lymphoid tumours is seen.
- ***Bloom's syndrome and Fanconi's anaemia.*** An increased susceptibility to lymphoid malignancy is seen.

The majority of individuals who develop cancer do not have a genetic predisposition. In these people, somatic changes in DNA drive cancer. Studies of cancer where such changes are amplified have led to the discovery of selected genes that repeatedly cause cancer when mutated. These include oncogenes and tumour suppressor genes.

Oncogenes

The genes coding for growth factors, growth factor receptors, secondary messengers or even DNA-binding proteins would act as promoters of abnormal cell growth if mutated. This concept was verified when viruses were found to carry genes that promoted oncogenesis when integrated into the host cell. These were originally termed viral or 'v-oncogenes'; later, their normal cellular counterparts, c-oncogenes, were found. Thus oncogenes encode proteins that are known to participate in the regulation of normal cellular proliferation; for example, *erb-A* on chromosome 17q11–q12 encodes for the thyroid hormone receptor.

Activation of oncogenes

Non-activated oncogenes, which are functioning normally, have been referred to as 'proto-oncogenes' (Box 5.8). Their transformation to oncogenes can occur by mutation. A range of patterns of genetic mutations have been shown to cause cancer, and additional mechanisms such as 'chromothripsis', or chromosomal shattering, have been recently described.

Mutation

Carcinogens, such as those found in cigarette smoke, ionizing radiation and ultraviolet light, can cause point mutations in genomic DNA encoding tumour suppressor genes or oncogenes.

Box 5.8 Examples of acquired/somatic mutations and proto-oncogenes

Point mutation
- *K-RAS:* colorectal and pancreatic cancer
- *B-RAF:* melanoma, thyroid cancer
- *ALK:* lung cancer

DNA amplification
- *MYC:* neuroblastoma
- *HER2*-neu: breast cancer

Chromosome translocation
- *BCR/ABL:* chronic myeloid leukaemia, acute lymphoblastic leukaemia
- *PML/RARA:* acute promyelocytic leukaemia
- *BCL2/IGH:* follicular lymphoma
- *IGH/CCND1:* mantle cell lymphoma
- *MYC/IgH:* Burkitt lymphoma

Chromosomal translocation

If an error occurs during cell division and two chromosomes translocate so that a portion swaps over, the translocation breakpoint may occur in the middle of two genes, resulting in a mutation. If this happens, then the end of one gene is translocated onto the beginning of another gene, giving rise to a 'fusion gene'. Therefore sequences of one part of the fusion gene are inappropriately expressed because they are under the control of the other part of the gene. An example of such a fusion gene (the Philadelphia chromosome) occurs in *chronic myeloid leukaemia* (Fig. 5.24).

Viral activation

There are different ways in which viruses can cause cancer. When viral RNA is transcribed by reverse transcriptase into viral cDNA and, in turn, is spliced into the cellular DNA, the viral DNA may integrate within an oncogene and activate it. Alternatively, the virus may pick up cellular oncogene DNA and incorporate it into its own viral genome. Subsequent infection of another host cell might result in expression of this viral oncogene. For example, the Rous sarcoma virus of chickens was found to induce cancer because it carried the *Ras* oncogene.

Tumour suppressor genes

These genes restrict undue cell proliferation (in contrast to oncogenes) and induce the repair or self-destruction (apoptosis) of cells containing damaged DNA. Therefore mutations in these genes, which disable their function, lead to uncontrolled cell growth in cells with active oncogenes.

The ***RB gene*** was the first tumour suppressor gene to be described. In inherited retinoblastoma the first pathogenic variant in the *RB* gene is inherited; by chance, a second somatic mutation in the remaining normal copy of the *RB* gene then occurs, with the formation of a tumour. In the sporadic variety, mutations occur in both of the *RB* genes in a single cell. Knudson described this phenomenon as the 'two-hit' hypothesis, which accounts for the earlier and bilateral presentation of tumours in patients with germline *RB* pathogenic variants. *RB* is involved in the normal regulation of the cell cycle, and loss of control of the cell cycle in *RB*-deficient retinal cells contributes to tumour formation.

Since the finding of *RB*, other tumour suppressor genes have been described, including the gene ***p53***, known as the 'guardian of the genome'. Rarely, patients are born with an inherited change in *p53*, giving rise to Li–Fraumeni syndrome. These patients have an increased predisposition to a range of types of cancer, including

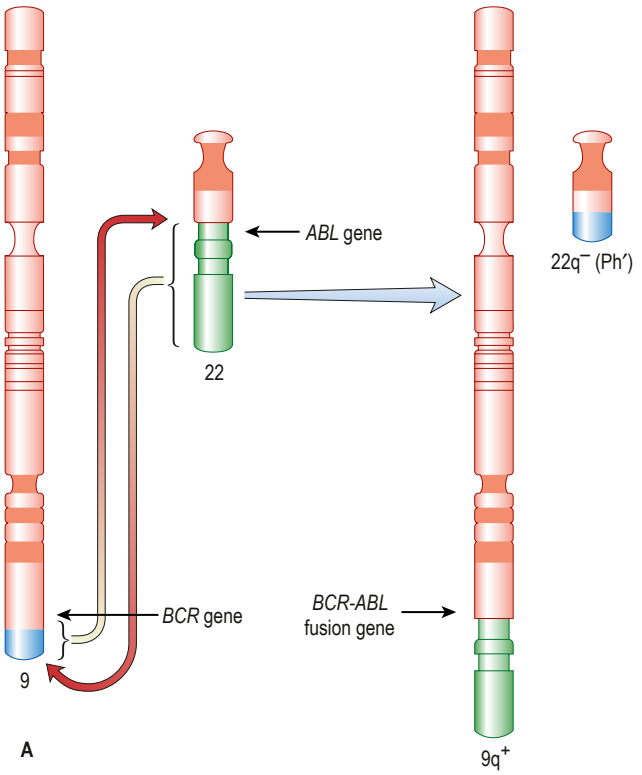

Fig. 5.24 The Philadelphia chromosome (Ph). **(A)** The long arm (q) of chromosome 22 has been shortened by a reciprocal translocation with chromosome 9. **(B)** The Philadelphia chromosome is formed by a reciprocal translocation of part of the long arm (q) of chromosome 22 to chromosome 9. It is seen in 90%–95% of patients with chronic myeloid leukaemia. The karyotype is expressed as 46XX, (9;22)(q34;q11).

breast cancer, soft tissue sarcomas, brain tumours, and leukaemia. Pathogenic variants in *p53* have also been found in almost all sporadic human cancers, suggesting that somatic mutations in *p53* are driver mutations. The protein encoded by *p53* plays a role in DNA repair and synthesis, in the control of the cell cycle, cell differentiation, and apoptosis. Four p53 protein molecules assemble into a tetramer that is functionally active.

p53 is a DNA-binding protein that activates many gene expression pathways, but it is normally only short lived. In some cancers, there is loss of *p53* from both chromosomes, accounting for loss of normal function of *p53* and ensuing tumour formation. In many tumours, mutations that disable *p53* function also prevent its cellular catabolism. Thus even a mutation in a single copy of the gene can promote tumour formation because a heterotetramer of mutated and normal *p53* subunits would still be dysfunctional.

Many other genes have been identified that function as tumour suppressor genes, including those found in Lynch syndrome, which are responsible for repairing DNA mismatches (see Chapter 22).

Genetic diagnostics for cancer

The ability to detect cancer-specific DNA sequences has led to the development of monitoring tests that can detect levels of circulating cell-free DNA in the blood. In addition, cancer cells can circulate in the bloodstream, and tests are being developed to detect these and monitor response to therapy.

Targeted treatments for cancer

The ability to sequence cancers rapidly has supported the development of targeted treatments. These aim to be selective and ideally have few side-effects compared to conventional chemotherapy. Tyrosine kinase inhibitors, such as imatinib, are examples of targeted treatments in selected haematological malignancies that carry the Philadelphia chromosome and even some solid cancers such as gastrointestinal stromal tumours. A shift heralded by cancer sequencing is the concept of orphan molecular entities. Rather than treating cancer of a tissue such as breast or lung, sequencing allows the detection of drivers in a cancer, for which a selected cocktail of treatments may apply. This may lead to the increased personalization of cancer therapy. Resistance to such treatments is well recognized, however, as cancers mutate further to become resistant to these drugs. An example is seen in metastatic melanoma, where drugs that target mutant *BRAF* in melanoma cells offer temporary but non-sustained remission for patients.

Precision (or personalized) medicine

There is a huge shift in healthcare research and delivery towards developing strategies that treat the individual patient using a combination of genetics and metabolic biomarkers with lifestyle and environmental modifications. These studies are driven by the observations that not all medical treatments including drugs will work the same or even have efficacy in every patient with a particular condition. The goal is to deliver the right drug to each patient together with appropriate lifestyle changes such as diet and exercise. Towards this ambition of 'personalized' medicine, large-scale population-based studies with ethnic diversity are being conducted to identify new drug targets and biomarkers to stratify patients into subgroups for specific disease management strategies and also to design more robust clinical trials with more defined patient recruitment. This will lead to improved individual patient diagnosis, treatment, and even disease prevention. Examples of these approaches are being employed in inflammatory conditions like psoriasis and rheumatoid arthritis and for targeted cancer therapy such as in mutant *BRAF*-positive melanoma and in mutant *BRCA*-breast cancer with the use of PARP inhibitors. In parallel, and linked to these approaches for precision medicine, there are new diagnostic tools being developed and implemented in clinical practice. These include wearable devices, for example, for monitoring heart rhythm and blood pressure, as well as the implementation of artificial intelligence (AI), for

example, in radiology and pathology. In cancer, there is also the use of liquid biopsy from blood or urine to detect cancer-associated cells, DNA, or other biomarkers to monitor cancer and metastasis.

CORE SKILLS AND KNOWLEDGE

Aspects of immunity have an impact on all areas of medicine, from diagnosis and treatment to diseases that arise when the immune system goes wrong. Allergic disorders affect at least 1 in 10 individuals and autoimmune diseases will affect 1 in 20 individuals at some point in their life. The number of people living with secondary immune deficiency is rising as survival of malignancy and disorders treated with immune-modulating therapy improves.

The role of a clinical immunologist is to manage immune-mediated diseases and provide specialist advice and guidance to primary care physicians and hospital practitioners on diagnostic testing, interpretation, and treatment of organ-specific disorders. Clinical immunologists run clinics for severe or complex allergy and inborn errors of immunity that can lead to severe immunodeficiency and manage patients with immunodeficiency secondary to immune-modulating therapies.

Key skills in clinical immunology include:

- Recognizing the possibility of an immunodeficiency syndrome in patients presenting with recurrent or severe infections such as meningitis or pneumonia, and understanding appropriate ways to investigate and manage this.
- Assessing patients with complex allergy, including food and drug allergy, and undertaking provocation testing and desensitization including immunotherapy when appropriate.

Opportunities to learn clinical immunology in general medical contexts include seeking to apply basic immunological principles to understand patients with autoimmune conditions or those receiving immunosuppressant medications. Attending specialist immunology and allergy clinics gives insight into how patients live with chronic disease, how parenteral therapies such as immunoglobulins are administered, and how immunologically mediated conditions, including urticaria, angioedema, allergic rhinitis, and anaphylaxis, can be managed.

INTRODUCING THE TISSUES, CELLS, AND MOLECULES OF THE IMMUNE SYSTEM

Immunity can be defined as protection from infection, whether this is bacterial, viral, fungal or due to multicellular parasites. The immune system can also distinguish ***altered self*** and prevents the development of malignancy by destroying cancerous cells. The immune system is composed of cells and molecules organized into specialized tissues and acts in concert to orchestrate an immune response (Fig. 6.1).

The ***primary lymphoid organs*** (thymus and bone marrow) are where the cells originate. Cells and molecules of the immune system circulate in the blood; immune responses do not take place there but are initiated at the site of infection (typically the mucosa or skin). Immunity is then propagated and refined in the ***secondary***

Non-immune host defence mechanisms

Normal barriers	Events that compromise barrier function
Physical barriers	
Cough reflex	Suppression, e.g., by opiates, neurological disease
Skin and mucous membranes	Trauma, burns, i.v. cannulae
Mucosal function	Ciliary paralysis (e.g., smoking) Increased mucus production (e.g., asthma) Abnormally viscid secretions (e.g., cystic fibrosis) Decreased secretions (e.g., sicca syndrome)
Urine flow	Stasis (e.g., prostatic hypertrophy)
Chemical barriers	High gastric pH (gastric acid secretion inhibitors)
Resistance to pathogens provided by commensal skin and gut organisms	Changes in flora (e.g., broad-spectrum antibiotics)

A

Cells involved in the immune response

Category	Cells	Main functions	Origin	Special features
Myeloid	Neutrophils	Immunity to bacteria and fungi	Bone marrow	Major first-line defence against pathogens
	Eosinophils, mast cells, and basophils	Immunity to parasites	Bone marrow	Role in allergy
	Monocytes and macrophages	Immunity to bacteria, fungi, parasites	Bone marrow	Specialized phagocytes; cytokine secretion
Lymphoid	Dendritic cells	Antigen presentation to T lymphocytes	Bone marrow	Key role in activating T lymphocytes
	B lymphocytes	Antibody production	Bone marrow	Have specific receptor for antigen (called 'antibody'). Mature into plasma cells that are 'antibody factories'
	T lymphocytes	Orchestration of immune response against bacteria, fungi, parasites, and viruses	Precursors come from bone marrow and undergo selection process in the thymus to avoid self-reactivity	Have specific receptor for antigen (called T-cell receptor). Two major subsets: CD4 ('helper' and 'regulatory') and CD8 ('cytotoxic')

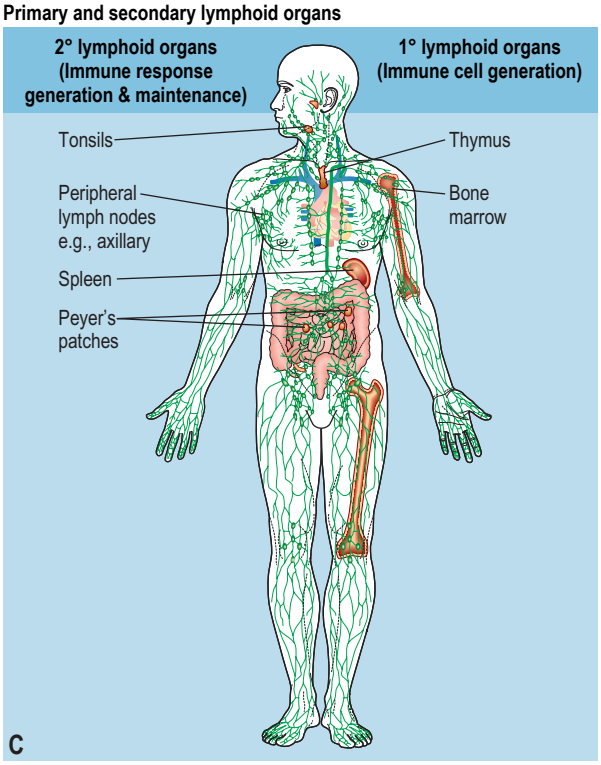
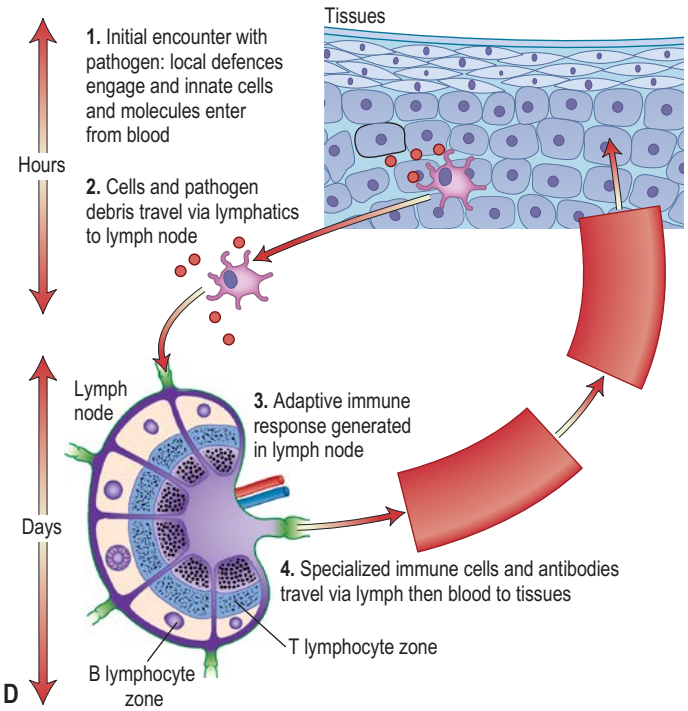
Primary and secondary lymphoid organs



C

Immune response: locations and dynamics



D

Fig. 6.1 Overview of the cells, molecules, and tissues of the immune system. The barrier to invasive infection includes both **(A)** non-immune and **(B)** cellular immune defences. **(C)** Lymphocytes are generated as precursors in the bone marrow and differentiate into T (thymus) or B (bone marrow) lymphocytes in the primary lymphoid tissue. Once differentiated, 98% of lymphocytes reside in the secondary lymphoid tissue, where the adaptive immune response takes place. **(D)** The immune response to infection involves a variety of local and regional responses: **(1)** There are rapid local responses that include ingress of cells (e.g., neutrophils) from the blood. **(2)** Immune cells and pathogen debris migrate via lymphatics to the local lymph node. **(3)** An adaptive immune response is generated in the regional lymph node. **(4)** Effector cells travel by lymph and then blood to the infected tissue.

lymphoid organs (e.g., lymph nodes). Following resolution of the infection, immunological memory specific for the pathogen is generated and resides in cells (lymphocytes) in the spleen and lymph nodes, as well as being widely secreted in a molecular form (antibodies). Secondary lymphoid organs include adenoids, tonsils, spleen, Peyer's patches in the small intestine, peripheral lymph nodes (cervical, axillary, inguinal), and the thoracic duct, which drains the lymph (containing immune cells) into the right subclavian vein.

Cells involved in immune responses: origin and function

All immune cells derive from pluripotent stem cells generated in the bone marrow. They have diverse functions (see **Fig. 6.1**). ***T lymphocytes*** undergo 'education' in the thymus to avoid self-recognition and populate the peripheral lymphoid tissue, where B lymphocytes also reside. Both sets of lymphocytes undergo activation in the peripheral tissue to become mature effector cells. ***B lymphocytes*** may further differentiate into antibody-secreting ***plasma cells***. Lymphoid tissue is frequently found at mucosal surfaces in non-encapsulated patches, termed ***mucosa-associated lymphoid tissue (MALT)***.

The immune system

Cells and molecules involved in immune responses are classified into innate and adaptive systems:

- The ***innate immune system*** is inborn and operates throughout life (see 'Innate immune system' section).
- The ***adaptive immune system*** changes in response to the pathogens it encounters (see 'Adaptive immune system' section).

There are also non-immunological barriers that are involved in host protection, and lowering of these may allow a pathogen to gain a foothold (see **Fig. 6.1**).

The immune system is immensely powerful, in terms of its ability to inflame, damage, and kill, and it has a capacity to recognize multiple molecular patterns in the microbial world. However, immune responses are not always beneficial. They can give rise to a range of autoimmune and inflammatory diseases, known as ***immunopathologies***. Conversely, the immune system may fail, giving rise to immune deficiency states. These conditions are grouped under the umbrella of clinical immunology.

A major feature of the immune system is the complexity of its surface-bound, intracellular, and soluble mediators. In particular, it is necessary to be aware of the clusters of differentiation classification (**Box 6.1**) and the functions of cytokines and chemokines. The clusters of differentiation classification is like a barcode for defining a cell.

Cytokines

Cytokines are small polypeptides released by a cell in order to change the function of the same or another cell. These chemical messengers are found in many organ systems but especially the immune system. Cytokines have become markers in the investigation of disease pathogenesis; they are also therapeutic agents in their own right, as well as the targets of therapeutic agents. The key features of a cytokine are:

- ***pleiotropy:*** has different effects on different cells
- ***autocrine function:*** modulates the cell secreting it
- ***paracrine function:*** modulates adjacent cells
- ***endocrine effects:*** modulates cells and organs at remote sites
- ***synergistic activity:*** acts in concert with other cytokines to achieve effects greater than the summation of their individual actions.

The main immune cytokines are the ***interferons*** (IFNs) and the ***interleukins*** (ILs). The IFNs are limited to a few major types (α, β, and γ), whereas there are 40 ILs.

i Box 6.1 The CD classification

- Immune cells are distinguished by the surface receptors and proteins that they express in order to mediate their particular range of immunological functions, for example cell–cell signalling, cell activation.
- The surfaces are covered with such proteins and indicate the cell lineage or differentiation pathway. The discovery of monoclonal antibodies (proteins tailor-made to bind to a specific target) made this feasible.
- Surface molecules defining the origin and function of selected groups of cells are known as clusters of differentiation (CD). Over 360 CD numbers exist.
- CD markers can be detected within histologic specimens of tissues by immunohistochemistry or by the use of flow cytometry.
- In clinical use CD markers are used to analyse peripheral blood lymphocytes by the use of:
  - CD3 (all T-cells)
  - CD4 (Helper T-cells)
  - CD8 (Cytotoxic T-cells)
  - CD19 (B-cells)
  - CD16/56 (NK-cells).
- These may be used to diagnose SCID ('Severe combined immunodeficiencies' section), monitor B-cell depletion therapy (see IgG4-RD, 'IgG4 disease' section), and response to HIV therapy (see Chapter 44).
- The same technique can be used to monitor or diagnose haematologic malignancy using different markers (Chapter 39).

An updated listing is available at: http://www.hcdm.org/.

Chemokines

The defining feature of chemokines is their function as chemotactic molecules: that is, they attract cells along a gradient of low to high chemical concentration, particularly from the blood into the tissues and from the tissues into lymphatics. They also have the ability to activate immune cells. All chemokines have a similar structure relating to the configuration of cysteine residues, which gives rise to four families (**Box 6.2**).

Cell-surface receptors for chemokines are denoted by 'R'. CCR5 is a co-receptor for the human immunodeficiency virus (HIV; see Chapter 39), and drugs to block this and other chemokine receptors are under active development to combat inflammation.

INNATE IMMUNE SYSTEM

Innate immunity provides immediate, first-line host defence. The key features of this system (as well as the adaptive system, 'Adaptive immune system' section) are shown in **Box 6.3**. It is present at birth and remains operative at comparable intensity into old age. Innate immunity is mediated by a variety of cells and molecules (**Box 6.4**). Activation of innate immune responses is mediated through interaction between:

- the ***pathogen side***, comprising a relatively limited array of molecules (pathogen-associated molecular patterns [PAMPs])
- the ***host side***, comprising a limited portfolio of receptors (pattern recognition receptors [PRRs]).

Activation of certain cells in the innate immune system leads, in turn, to activation of the ***adaptive immune response*** (see 'Adaptive immune system' section). The ***dendritic cell*** is especially involved in this process and forms a bridge between innate and adaptive systems.

i Box 6.2 Features of chemokine mediators and receptors

Chemokine family	Structure	Receptor family	Pathological or therapeutic target
CXC	Two cysteines (C) separated by any other amino acid residue (X)	CXCR	CXCR4—co-receptor for late HIV infection
CC	Two cysteines next to each other	CCR	CCR5—co-receptor for early HIV infection and blocked by 'entry inhibitors'
C	One cysteine	CR	XCR1—target of Kaposi's sarcoma human virus protein
CX3C	Two cysteines separated by any three amino acids	CX3CR	Possible survival factor in myeloma

R, Receptor.

i Box 6.3 Features of the innate and adaptive immune responses

Innate	Adaptive
No memory: quality and intensity of response invariant	Memory: response adapts with each exposure
Recognition of limited number of non-varying, generic molecular patterns on, or made by, pathogens	Recognition of vast array of specific antigens[a] on, or made by, pathogens
Pattern recognition mediated by a limited array of receptors	Antigen recognition mediated by a vast array of antigen-specific receptors
Response immediate on first encounter	Response on first encounter takes 1 to 2 weeks; on second encounter, 3 to 7 days

[a]Antigen is a molecular structure (protein, peptide, lipid, carbohydrate) that generates an immune response.

Complement

Complement proteins are produced in the liver and circulate in an inactive form. When triggered, complement molecules become enzymatically active and trigger several molecules of the next stage in a series. This ***complement cascade*** is initiated via three distinct pathways: alternative, classical, and lectin (Fig. 6.2). Each pathway culminates in the cleavage of C3 and C5. Cleavage of C3 has a number of biological consequences; breakdown of C5 achieves the same and, in addition, provides the triggering stimulus to the final common ('membrane attack') pathway, which provides most of the biological activity (see Fig. 6.2).

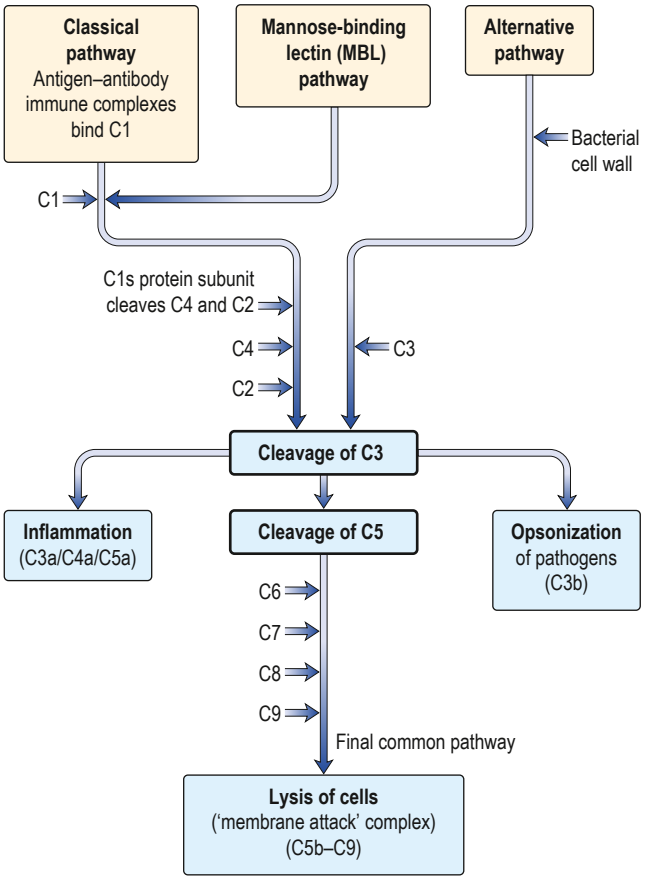


Fig. 6.2 The complement pathways and their effector functions.

i Box 6.4 Soluble components of innate immunity

Molecules	Name (examples)	Function	Provide immunity against
Complement	Cascade of >50 proteins	Lyse bacteria; opsonize[a] bacteria; promote inflammation; recruit and activate immune cells	Bacteria, viruses
Collectins	Mannose-binding lectin	Bind bacteria; activate complement	Bacteria
Pentraxins	C-reactive protein[b]	Opsonize bacteria	Bacteria
Enzymes	Lysozyme	Present in secretions; cleave bacterial cell wall	Bacteria

[a]Opsonize means to coat bacteria to enhance phagocytosis by granulocytes and monocytes/macrophages.
[b]C-reactive protein (CRP) is an acute phase protein. Blood level rises 10- to 100-fold within hours of the start of an infective or inflammatory process, making it extremely useful in monitoring infective or inflammatory diseases and their response to treatment.

The main functions of complement activation are to:

- promote inflammation (e.g., through the actions of the anaphylatoxins C3a, C4a, and C5a)
- recruit cells (e.g., through chemoattractants)
- kill targeted cells, such as bacteria
- solubilize antigen–antibody ('immune') complexes and remove them from the circulation.

During an immune response, removal of immune complexes protects unaffected tissues from the deposition of these large, insoluble composites, which could result in unwanted inflammation. Failure of this protective mechanism can result in 'immune complex' pathology, where immune complexes lodge in organs such as the joints, kidney, and eye. This can complicate infectious diseases such as infective endocarditis or result in some of the clinical manifestations of autoimmune disease such as systemic lupus erythematosus (SLE).

Neutrophils

Neutrophils phagocytose and kill microorganisms by releasing antimicrobial compounds (e.g., defensins). They are derived from the bone marrow, which can produce between 10^{11} (healthy state) and 10^{12} (during infection) new cells per day. In health, neutrophils are rarely seen in the tissues.

Neutrophil phagocytosis is activated by interaction with bacteria, either directly or after bacteria have been coated (opsonized) to make them more ingestible (Fig. 6.3). The contents of neutrophil granules are released both intracellularly (predominantly azurophilic granules) and extracellularly (specific granules) following fusion with the plasma membrane. Approximately 100 different molecules in neutrophil granules (Box 6.5) kill and digest microorganisms, for example:

- ***Myeloperoxidase and cytochrome b_{558}*** are key components of major oxygen-dependent bactericidal systems.
- ***Cathepsins, proteinase-3, and elastase*** are deadly to Gram-positive and Gram-negative organisms, as well as some *Candida* species.
- ***Defensins*** are naturally occurring cysteine-rich antibacterial and antifungal polypeptides (29–35 amino acids).
- ***Collagenase and elastase*** break down fibrous structures in the extracellular matrix, facilitating progress of the neutrophil through the tissues.

Granule release is initiated by the products of bacterial cell walls, certain complement proteins, leukotrienes (LTB_4) and chemokines (e.g., CXCL8), and cytokines such as tumour necrosis factor-alpha (TNF-α). A further defence mechanism is the formation of ***neutrophil extracellular traps*** from DNA, which bind pathogens to facilitate killing.

Eosinophils

Eosinophils release pro-inflammatory mediators to provide immunity against parasites. In contrast to neutrophils, several hundred times more eosinophils are present in the tissues than in the blood, particularly at epithelial surfaces, where they survive for several weeks. The main role of eosinophils is protection against multicellular parasites such as worms (helminths). This is achieved by the release of pro-inflammatory mediators, which are toxic, cationic proteins. In populations and societies in which such parasites are rare, eosinophils contribute mainly to allergic disease, particularly asthma (see Chapter 20). Eosinophils have two types of granules:

- ***Specific granules*** (95%) contain the cationic proteins, of which there are four main types: ***major basic protein, eosinophil***

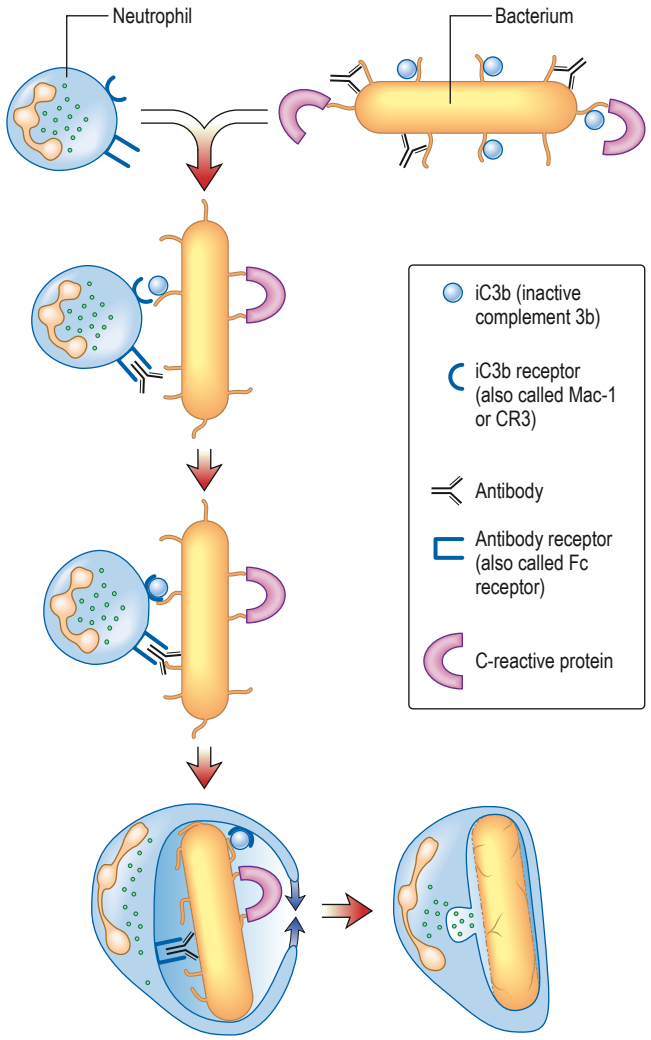

Fig. 6.3 Opsonization. Bacteria are coated with a variety of soluble factors from the innate immune system (opsonins), which enhance phagocytosis. This leads to engulfment of the bacteria into phagosomes and fusion with granules to release antibacterial agents.

Box 6.5 Contents and function of key neutrophil granules

Function	Primary or azurophilic granules	Secondary or specific granules
Antibacterial	Lysozyme Defensins Myeloperoxidase (MPO) Proteinase-3 Elastase Cathepsins Bactericidal/permeability-increasing protein (BPI)	Respiratory burst components (e.g., cytochrome b_{558}) producing reactive oxygen metabolites, such as hydrogen peroxide, hydroxyl radicals, and singlet oxygen Lysozyme Lactoferrin
Cell movement		Collagenase CD11b/CD18 (adhesion molecule) *N*-formyl-methionyl-leucylphenylalanine receptor (FMLP-R)

cationic protein, and ***eosinophil neurotoxin***, which are all potently toxic to helminths, and ***eosinophil peroxidase***, similar to neutrophil myeloperoxidase.

- ***Primary granules*** (5%) synthesize and release ***leukotrienes C_4 and D_4*** and ***platelet-activating factor***, which alter airway smooth muscle and vasculature.

Eosinophils are activated and recruited by a variety of mediators via specific surface receptors, including complement factors and LTB_4. In addition, the chemokines eotaxin-1 (CCL11) and eotaxin-2 (CCL24) are highly selective in eosinophil recruitment. There are surface receptors for the cytokines interleukin-3 (IL-3) and interleukin-5 (IL-5), which promote the development and differentiation of eosinophils.

Mast cells and basophils

Mast cells release pro-inflammatory and vasoactive mediators and have a role in allergy. Mast cells and ***basophils*** share features in common, especially in that they contain:

- histamine-containing granules
- high-affinity receptors for immunoglobulin E (IgE, an antibody type that is involved in allergic disease, see **Box 6.9**).

Mast cells are found in tissues (especially skin and mucosae) and basophils in the blood. Both mast cells and basophils release pro-inflammatory mediators, which are either pre-formed or synthesized *de novo* (**Box 6.6**).

Histamine is a low-molecular-weight amine (111 Da) with a blood half-life of less than 5 minutes; it constitutes 10% of the mast cell's weight. When injected into the skin, histamine induces the typical 'weal and flare' or 'triple' response: reddening (erythema) due to increased blood flow, swelling (weal) due to increased vascular permeability, and distal vascular changes (flare) due to effects on local axons.

The ***complement-derived anaphylatoxins*** C3a, C4a, and C5a activate basophils and mast cells, as does IgE. The mast cell also has a role in the early response to bacteria through release of TNF-α, in cell recruitment to inflammatory sites such as arthritic joints, in promotion of tumour growth by enhancing neovascularization and in allograft tolerance.

Box 6.6 Mast cell and basophil mediators

Mediators	Effects
Pre-formed	
Histamine	Vasodilation Vascular permeability ↑ Smooth muscle contraction in airways
Proteases	Digestion of basement membrane causes ↑ vascular permeability and aids migration
Proteoglycans (e.g., heparan)	Anticoagulant activity
Synthesized *de novo*	
Platelet-activating factor (PAF)	Vasodilation
Leukotriene B_4 (LTB_4), LTC_4, LTD_4	Neutrophil and eosinophil activation and chemoattraction Vascular permeability ↑ Bronchoconstriction
Prostaglandins (mainly PGD_2)	Vascular permeability ↑ Bronchoconstriction Vasodilation

Monocytes and macrophages

Monocytes (in blood) and macrophages (in tissue) ingest and kill bacteria, release pro-inflammatory molecules, present antigen to T lymphocytes, and are necessary in immunity to intracellular pathogens such as mycobacteria.

Cells of the monocyte/macrophage lineage are highly sophisticated phagocytes. ***Monocytes*** are the blood form of a cell that spends a few days in the circulation before entering into the tissues to differentiate into ***macrophages***, and some types of dendritic cell. Blood monocytes can be divided into subsets according to expression of CD14 (a receptor for lipopolysaccharide, a bacterial cell wall component) and CD16 (a receptor for IgG antibodies).

A key role of tissue macrophages is the maintenance of tissue homeostasis through clearance of cellular debris, especially following infection or inflammation. They are responsive to a range of pro-inflammatory stimuli, using their PRRs to recognize PAMPs. Once activated, they engulf and kill microorganisms, especially bacteria and fungi, and release a range of pro-inflammatory cytokines. Evidence suggests that evolutionarily conserved molecular patterns in mitochondria (organelles that were originally derived from bacteria) can also activate monocytes. These damage-associated molecular patterns could play a major role in the systemic inflammatory response that follows extensive tissue damage (e.g., following ischaemic injury).

It has been observed that some PAMPs induce the cytoplasmic assembly of large oligomeric structures of PRRs termed ***inflammasomes***. There are numerous examples: members of the Nod-like receptor family can be activated by stimuli such as viruses, bacterial toxins, and, interestingly, crystallized endogenous molecules, including urate causing inflammatory arthritis in gout. Inflammasomes have potent effects in activating caspases, leading to processing and secretion of pro-inflammatory cytokines such as IL-1β and IL-18.

Macrophages have pro-inflammatory and microbicidal capabilities similar to those of neutrophils. Under activation conditions, macrophages present antigen to T-lymphocytes (see 'T lymphocyte development and activation' section) and secrete a range of cytokines, notably TNF-α, IL-1, and interferon-gamma (IFN-γ). These are necessary for the removal of certain pathogens that live within mononuclear phagocytes (e.g., mycobacteria). Macrophages and related cells may also undergo a process termed ***autophagy***. Autophagy is a lysosomal degradative process that removes abnormal organelles, protein aggregates, and intracellular pathogens. The autophagy machinery targets an autophagosome with the relevant material to fuse with lysosomes, which then causes degradation of the contents. This self-cannibalization is used by the immune system to destroy intracellular pathogens such as *Mycobacterium tuberculosis*, which otherwise persist within cells and block normal antibacterial processes. Autophagy is also a means of enhancing antigen presentation pathways. Dysregulation of the autophagic pathway has been associated with a number of diseases, including cancer, inflammatory disease, and infections.

Tissue macrophages involved in chronic inflammatory foci may undergo terminal differentiation into multinucleated giant cells, typically found at the site of the granulomata characteristic of tuberculosis and sarcoidosis (see Chapter 20).

Dendritic cells

The function of dendritic cells (DCs) is activation of naive T lymphocytes to initiate adaptive immune responses (see 'Adaptive immune

system' section); they are the only cells capable of this. The definition of a dendritic cell is one that has:

- dendritic morphology (Fig. 6.4)
- machinery for sensing pathogens
- the ability to process and present antigens to CD4 and CD8 T lymphocytes, coupled with the ability to activate these T lymphocytes from a naive state
- the ability to dictate the T lymphocyte's future function and differentiation.

This is a powerful cell type that functions as a critical bridge between the innate and adaptive immune systems.

Types of dendritic cell

The major types are the ***conventional DC (cDC)***, the ***plasmacytoid DC***, and a variety of ***specialized DCs*** found in tissues that resemble cDCs (e.g., the Langerhans cell in the skin). DCs have several distinctive cell surface molecules, some of which have pathogen-sensing activity (e.g., the antigen uptake receptor DEC205 on cDCs), while others are involved in interaction with T lymphocytes such as Human Leucocyte Antigen (HLA) molecules. Immature cDCs and pDCs are present in the blood but at very low levels (<0.5% of lymphocyte/monocyte cells).

Pathogen sensing is a key component of the function of immature DCs, as well as monocytes/macrophages, and is achieved through expression of a limited array of specialized PRR molecules capable of binding to structures common to pathogens, aided by long cell dendrites and pinocytosis (constant ingestion of soluble material).

Pattern recognition receptors may induce opsonization (see Fig. 6.3), or act as ***signalling receptors***, such as the PRR known as Toll-like receptors (Box 6.7).

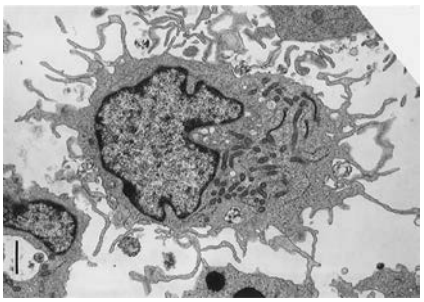

Fig. 6.4 Mature dendritic cell. The cell ingests pathogens, migrates to lymph nodes, and presents pathogen-derived antigen to T lymphocytes to enable adaptive immunity.

Box 6.7 Toll-like receptors (TLRs)

Pattern recognition receptor (PRR)	Pathogen-associated molecular pattern (PAMP)	Pathogen	PRR expressed by
TLR2	Peptidoglycan	Gram-positive bacteria	cDC
TLR3	Double-stranded RNA	Viruses	cDC
TLR4	Lipopolysaccharide	Gram-negative bacteria	cDC
TLR7	Single-stranded RNA	Viruses	pDC
TLR9	Double-stranded DNA	Viruses	pDC

cDC, Conventional dendritic cell; *pDC,* plasmacytoid dendritic cell.

The key principle is that the immune system has devised a means of identifying most types of invading microorganisms by using a limited number of PRRs recognizing common molecular patterns, or PAMPs. This recognition event has been termed a '***danger signal***'; it alerts the immune system to the presence of a pathogen.

Dendritic cells and T-cell activation

In a sequence of events that spans 1 to 2 days, immature DCs are activated by PAMPs or damage-associated molecular patterns in the tissues binding to PRRs. During maturation and migration, the cDC matures, changing its shape, gene and molecular profile, and function within a matter of hours to take on a mature form, with altered capabilities (Fig. 6.5), the most important of which is upregulating the machinery required to activate T lymphocytes. Once in the lymph node, the mature cDC interacts with naive T lymphocytes (antigen presentation), resulting in two key outcomes:

- activation of T cells with the ability to recognize peptide fragments (termed epitopes) of the pathogen
- polarization of the T-cell towards a functional phenotype (see below) that is tailored to the particular pathogen.

The mature cDC provides three major signals to naive T cells (see Fig. 6.5):

- ***signal 1:*** presentation of peptide fragments from the pathogen bound to surface HLA molecules
- ***signal 2:*** co-stimulation through CD80 and CD86 interacting with CD28 on T cells
- ***signal 3:*** secretion of cytokines, notably IL-12.

Innate lymphoid cells

Innate lymphoid cells (ILCs) are a group of immune cells that play a crucial role in the innate immune response. They are distinct from adaptive immune cells, such as T and B cells, as they lack antigen-specific receptors. ILCs are primarily involved in early immune defence against pathogens, tissue homeostasis, and regulation of immune responses at barrier surfaces, such as the skin, lungs, and intestines.

Innate lymphoid cells are classified into three major subsets based on their cytokine production profiles and transcription factor expression: ILC1, ILC2, and ILC3. Each subset has unique functions and contributes to various aspects of immune defence.

The study of ILCs is relatively recent, and ongoing research continues to uncover their diverse functions and regulatory mechanisms.

ADAPTIVE IMMUNE SYSTEM

The information gained by cDCs that interact with a pathogen is passed on, in the form of signals 1 to 3 (see Fig. 6.5B). These activate T lymphocytes in the adaptive immune system, which recognize the same pathogen. T lymphocytes may be involved in pathogen removal directly (e.g., by killing) or indirectly (e.g., by recruiting B lymphocytes to make specific antibody). Lymphocytes

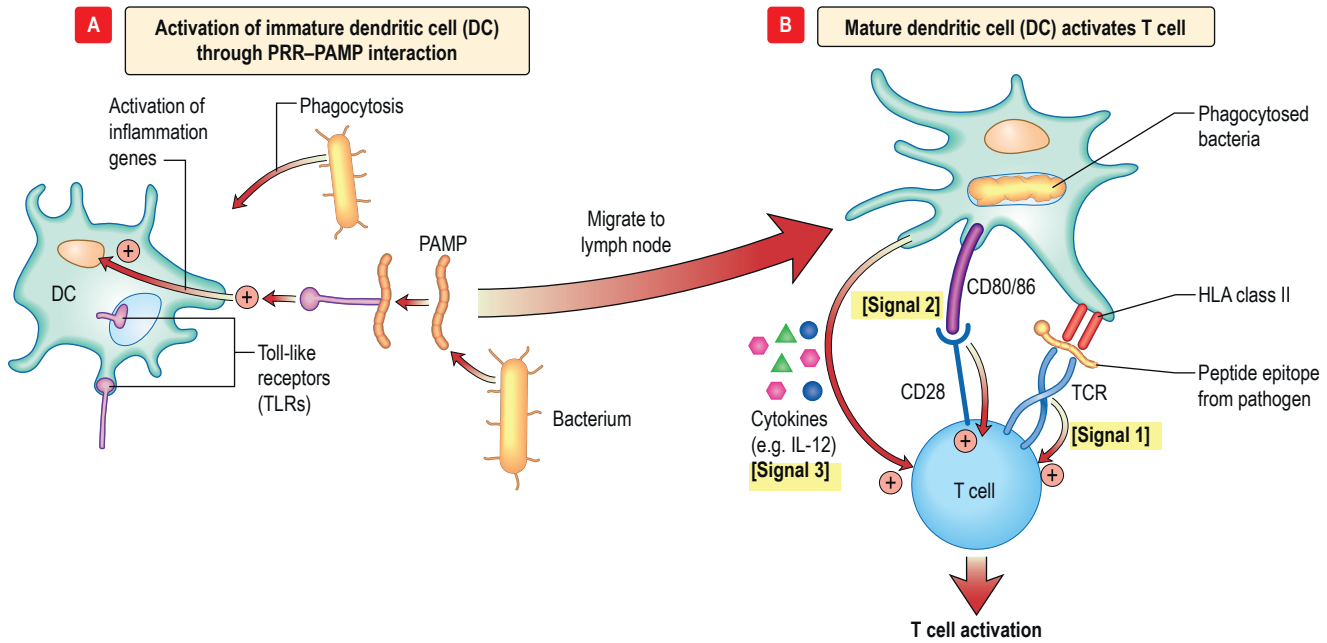

Fig. 6.5 Dendritic cell activation of T lymphocytes. **(A)** Immature dendritic cells (DCs) in the tissues are activated by pathogens through pathogen-associated molecular pattern–pattern recognition receptor (PAMP–PRR) interaction. **(B)** Multiple rapid changes in gene expression lead to migration to the lymph node as the DC takes on the mature phenotype. During migration, there is synthesis of the machinery required for activation of T lymphocytes, shown here in response to ***signals 1 to 3***. *CD,* Cluster of differentiation; *HLA,* human leucocyte antigen; *IL-12,* interleukin 12; *TCR,* T-cell receptor.

orchestrate immune responses via cell-to-cell interactions and cytokine release.

Antigen receptors on T and B lymphocytes

One of the key features of the adaptive immune system is specificity for antigen. For example, if a person is immunized against the measles virus, that person does not have immunity to hepatitis B, and vice versa. This specificity is conferred by two types of receptor: the T-cell receptor (TCR) on T lymphocytes and an equivalent on B lymphocytes, the B-cell receptor. B-cell receptors are also termed surface immunoglobulin; they differ from TCRs in also being secreted in large quantities by end-stage B lymphocytes (plasma cells) as soluble immunoglobulins, also known as antibodies.

To maintain protection against the multiplicity of pathogens in our environment, each of us generates great diversity among TCRs and antibodies. This is achieved through a mechanism shared by both TCR and antibody, in which distinct families of genes are encoded in the germline, each family (called constant, variable, diversity, and joining) contributing a sequence to part of the receptor. Recombination between randomly selected members of each family ensures diversity in the end product. Recombination frequently involves base deletions and additions, adding to the diversity. In the case of antibodies, the result is a potential capacity of more than 10^{14} different antibody molecules; for TCRs, it may be as high as 10^{18}.

Immunoglobulins

In structural terms, antibodies have four chains: two identical heavy and two identical light chains (Fig. 6.6). Each chain contains both highly variable and essentially constant regions. The variable parts of the heavy and light chains pair to form the potentially diverse part of the antibody molecule that binds antigen. The constant region of

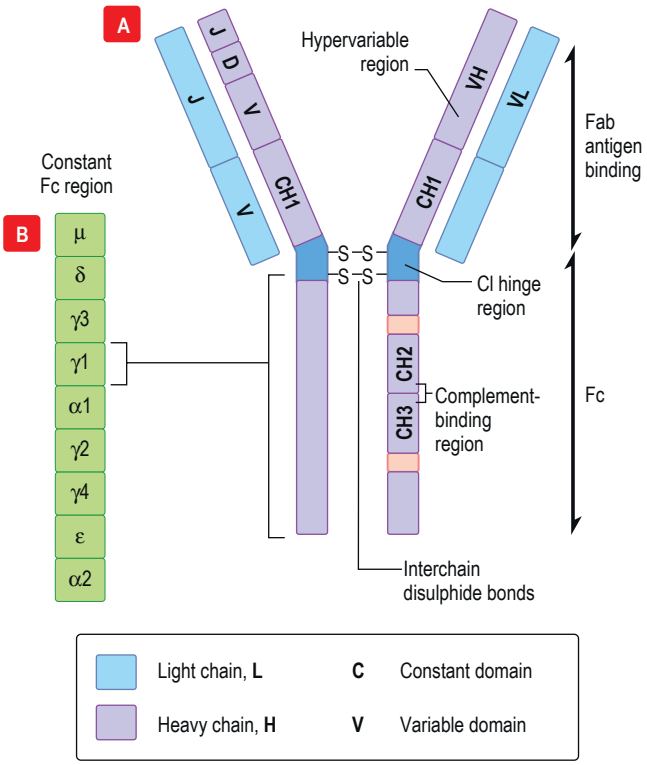

Fig. 6.6 Immunoglobulin structure. Basic subunit consisting of two heavy and two light chains **(A)**. Genes on the Fab and Fc regions of an immunoglobulin **(B)**. The chain is made up of a V (variable) gene, which is translocated to the J (joining) chain. The VJ segment is then spliced to the C (constant) gene. Heavy chains have an additional D (diversity) segment, which forms the VDJ segment that bears the antigen-binding site determinants.

the heavy chain dictates the function of the antibody and belongs to one of the classes of M, G1–4, A1–2, D, and E, giving rise to antibodies called IgM, IgG1–4, IgA1–2, IgD, and IgE, respectively. The characteristics of these different isotypes are shown in **Box 6.8**. As it matures, and under the instruction of T lymphocytes, a B lymphocyte may change the class (class switching), but never the specificity, of the antibody it makes; minor changes in antibody gene sequence can take place (somatic mutation), potentially allowing antibodies with higher affinity to arise and be selected for the effector response (affinity maturation).

Antibody function

In host defence, antibodies target, neutralize, and remove infectious organisms and toxins from the circulation and tissues, often through recruitment of innate host effector mechanisms such as complement, phagocytes, and mast cells (by binding to specific surface receptors on these cells).

In clinical medicine, specific anti-pathogen antibody levels are used in diagnosing/monitoring infectious disease and may also be administered as serum pools to provide host protection passively.

Antibodies can be raised in animals to generate monoclonal antibodies, which are commonly used in diagnostic immunology tests and increasingly employed as therapeutics (***immunotherapy***; e.g., to target cancer cells or to target immune cells and molecules to suppress or activate immune responses), often after 'humanization' (see later).

T-cell receptor genes and receptor diversity

The genomic organization of TCR genes and principles of generation of receptor diversity are similar to those of immunoglobulin genes. The TCR exists as a heterodimer, with a similar overall structure to that of the antibody molecule. There are two TCR types:

- ***α and β chains*** (αβ TCR). These are expressed on all CD4 T lymphocytes and approximately 90% of CD8 T lymphocytes; they play a role in adaptive immune responses.
- ***γ and δ chains*** (γδ TCR). These are fewer in number and are expressed mainly on intraepithelial lymphocytes; they are involved in epithelial defence.

The chains of each type of TCR are divided into variable and constant domains, each domain being encoded by separate gene pools. Like the B lymphocyte producing a single clone of immunoglobulin molecules, the T lymphocyte expresses only one form of TCR once the genes have been rearranged. Unlike antibodies, TCRs do not undergo somatic hypermutation and are not secreted.

T lymphocyte development and activation

T lymphocytes are generated from precursors in the bone marrow, which migrate to the thymus (**Fig. 6.7**). Only 1% of the cells that enter the thymus will leave it as naive T lymphocytes to populate the lymph nodes. This process (termed thymic selection) leads to a cohort of cells (**Box 6.9**) with:

- functionally rearranged genes allowing surface expression of a receptor for antigen (the TCR) alongside the CD3 accessory molecule involved in transducing the antigen-specific signal
- selection of a co-receptor, either CD4 or CD8, to stabilize the interaction between TCR and peptide-HLA:
  - CD4 T-cell responses require presentation of peptide antigens by *self* HLA class II molecules
  - CD8 T-cell responses require presentation of peptide antigens by *self* HLA class I molecules
- a reduced tendency of the selected TCR to recognize self antigens (thus avoiding autoimmunity).

Thus, during thymic education, most TCRs are rejected for further use (negative selection), either because they are unable to bind self HLA molecules or because they bind with too strong an affinity, which would run the risk of self-reactivity and autoimmune disease. The chosen TCRs (positive selection) have low/intermediate affinity for self HLA molecules. During post-thymic activation of T lymphocytes in the lymph node, TCR interaction with HLA has to be bolstered by additional signals (called co-stimulation) provided by cDCs. This ensures that T lymphocytes are activated by a mature cDC; this happens only in the presence of pathogens.

Co-stimulation of T cells is such a critical event in immune responses that it is tightly regulated. One level of control relies on molecular interactions that are termed ***immune checkpoints***. An example is cytotoxic T-lymphocyte-associated antigen 4, which is expressed shortly after T-cell activation and competes with CD80 and CD86 for CD28, at the same time providing a negative signal, reducing T-cell activation which is exploited in a rheumatoid arthritis

Box 6.8 Characteristics of the immunoglobulins (Igs)

	IgG	IgM	IgA	IgE	IgD
Description	Dominant class of antibody	Produced first in immune response	Found in mucous membrane secretions	Responsible for symptoms of allergy: used in defence against nematode parasites	Found almost solely on B lymphocyte surface membranes
Heavy chain	γ	μ	α	ε	δ
Mean adult serum levels (g/L)	IgG (total) = 8–16 G1 = 6.5 G2 = 2.5 G3 = 0.7 G4 = 0.3	0.5–2	IgA (total) = 1.4–4 A1 = 1.5 A2 = 0.2	17–450 ng/mL	0–0.4

Box 6.9 Identification of T lymphocytes

T-cell population	Marker	Typical percentages in blood	Additional information
T lymphocytes	T-cell receptor CD3	100% of T cells (70% of lymphocytes)	All T cells are thymus-derived
Helper T lymphocytes (Th)	CD4	66% of T cells	Th interact with antigen presented by MHC class II molecules
Cytotoxic T lymphocytes (CTL)	CD8	33% of T cells	CTL interact with antigen presented by MHC class I molecules

CD, Cluster of differentiation; *MHC,* major histocompatibility complex.

treatment with a soluble fusion protein (Fig. 6.8A). A further example is the immune checkpoint involving programmed cell death protein-1 (PD-1) and its ligands (PD-L1/L2). Like cytotoxic T-lymphocyte-associated antigen 4, PD-1 is upregulated after T lymphocyte activation, and interaction with PD-L1/L2 leads to inhibition of T lymphocyte function. PD-L1/L2 may be expressed on a variety of cells, including cDCs but also many non-immune cells, most notably tumour cells. *Immune checkpoint blockade* (see Fig. 6.8B) using monoclonal antibodies focused on PD-1/PD-L interactions releases the brakes on the immune system and is at the heart of the recent revolution in cancer immunotherapy (see Chapter 41).

Most naive T lymphocytes are resident in the lymph nodes or spleen. Naive T lymphocytes are activated for the first time in the lymph node by antigens presented to their TCRs as short peptides bound to major histocompatibility complex (MHC) molecules on the surface of DCs (see Fig. 6.5). Provision of signals 1 to 3 sets off an intracellular cascade of signalling molecule activation, leading to induction of gene transcription in T lymphocytes.

The outcome is T lymphocyte activation, cell division, and functional polarization, which is the acquired ability to promote a selected type of adaptive immune response. These processes take several days to achieve and through specific ***transcriptional regulation*** defined subsets of T cells are generated. The major functional polarities of T-cell responses (Box 6.10) are:

- $CD4^+$ pro-inflammatory T lymphocytes; T helper 1 (Th1), Th2, and Th17
- $CD8^+$ cytotoxic T lymphocytes (CTLs)
- $CD4^+$ regulatory responses (Treg).

Through cell division, a proportion of the T lymphocytes that are activated in response to a pathogen undertake these effector or regulatory functions, while a proportion is assigned to a memory pool.

CD4 T lymphocyte functions

As the pivotal cell in immune responses, the CD4 T lymphocyte influences most aspects of immunity, either through the release of cytokines or via direct cell–cell interaction, a process often termed 'licensing'. Licensing critically involves the pairing of CD40 on a specialized subset of cDC (cDC1) with CD40 ligand (CD40L, CD154) on the CD4 T lymphocyte; defects in this process result in antibody deficiency (see later).

Major functions of CD4 T lymphocytes are:

- ***licensing of cDCs*** during antigen presentation to activate CD8 T lymphocytes and generate cytotoxic cells
- ***licensing of B lymphocytes*** to initiate and mature antibody responses, leading to class switching, affinity maturation of antibodies, and generation of plasma cells or memory cells
- ***secretion of cytokines*** responsible for growth and differentiation of a range of cell types, especially other T lymphocytes, macrophages, and eosinophils
- ***regulation of immune reactions.***

T helper 1 cells

T helper 1 cells are the main effector subtype of CD4 T lymphocytes. In physiology, they drive activation of monocytes/macrophages and CTLs. In pathology, they have a key role in protection against intracellular pathogens such as viruses and mycobacteria. Th1 cells are recognized by secretion of the pro-inflammatory cytokines IFN-γ and TNF-α (Box 6.11).

T helper 2 cells

In physiology, Th2 cells drive antibody responses, especially IgE, and also promote eosinophil granulocyte functions. In pathology, they have a key role in protection from extracellular parasites (helminths) and also in the immune responses that underlie allergic disease. Th2 cells are recognized by secretion of IL-4, IL-5, and IL-13.

T helper 17 cells

In physiology, Th17 cells drive inflammatory responses, especially via recruitment of neutrophil granulocytes. In pathology, they are necessary for protection from fungal infections and are increasingly

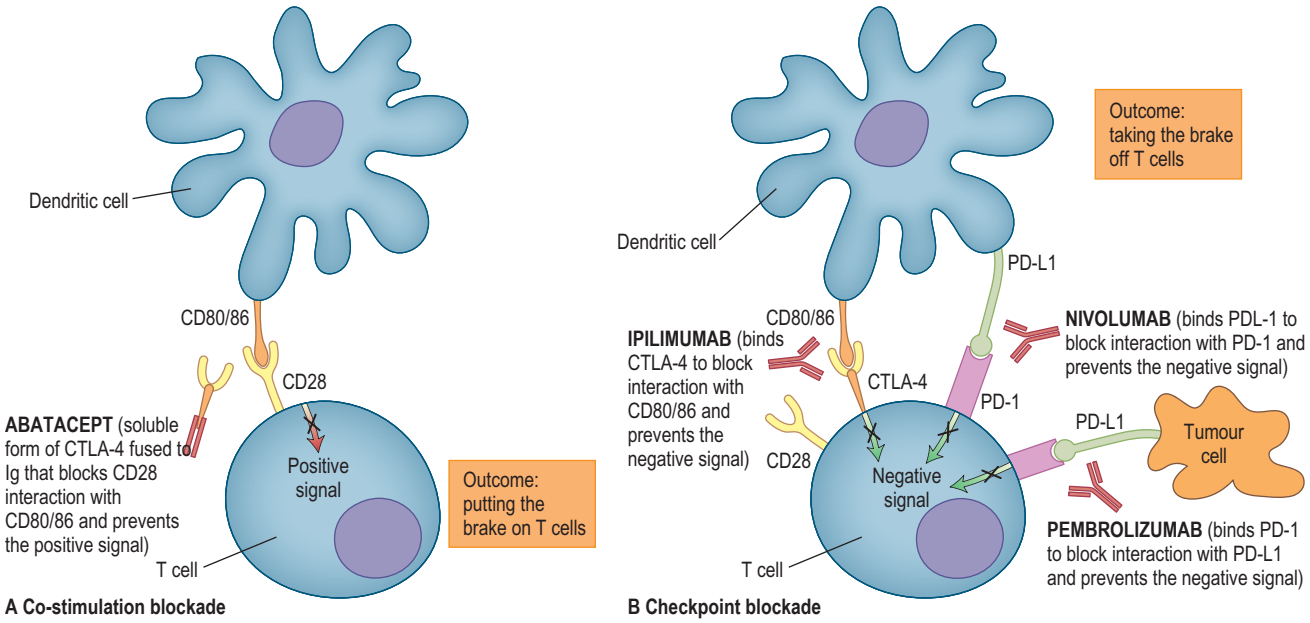

Fig. 6.8 Understanding immune checkpoints for immunotherapy. **(A)** T cells require co-stimulation, as well as recognition of antigen, to undergo full activation (see also **Fig. 6.5B**). CD80/86 on the dendritic cell binds CD28 on the T-cell receptor, providing a positive co-stimulatory signal. The drug abatacept is a soluble fusion of the cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) molecule with an immunoglobulin stalk. Since CTLA-4 has a higher affinity for CD80/86 than CD28, abatacept blockades co-stimulation and suppresses T-cell responses. **(B)** Soon after activation, T cells express CTLA-4 and programmed cell death protein-1 (PD-1), which deliver negative signals. Monoclonal antibodies aimed at blocking the interactions of these receptor/ligand pairs are thus able to take the brakes off the T-cell response. This can be critical for promoting anti-tumour responses.

Box 6.10 Identification of T lymphocyte subsets by function

T-cell type	Major CD marker	Main transcriptional regulators	Main cytokines causing polarization	Main cytokines produced	Functions	Major role in physiological immune response
T helper 1 (Th1) cells	CD4	T-bet	IL-12	IFN-γ, IL-2, TNF-α	Pro-inflammatory	Organize killing of bacteria, fungi, and viruses; activate macrophages to kill intracellular pathogens; instruct cytotoxic T-cell responses
T helper 2 (Th2) cells	CD4	GATA3	IL-4	IL-4, IL-5, IL-13	Pro-inflammatory	Organize killing of parasites by recruiting eosinophils; promote antibody responses, especially switching to IgE so play a role in allergic disease
T helper 17 (Th17) cells	CD4	RORγt	IL-6, IL-23, TGF-β	IL-17	Pro-inflammatory	Essential in preventing fungal infection, control of viral infection such as molluscum and warts, contribute to autoimmunity when dysregulated
Regulatory T cells (Treg)	CD4	FOXP3	IL-10, TGF-β	IL-10, TGF-β	Regulatory	Regulation of inflammation
Cytotoxic lymphocyte	CD8	T-bet/ Eomesodermin	IL-12, IFNa, IL-2	IFN-γ, TNF-α	Cytotoxic	Kill target cells via recognition of HLA class I+ peptide Protect from viruses

recognized as having a role in chronic inflammatory diseases such as multiple sclerosis, rheumatoid arthritis, and inflammatory bowel disease. They are recognized by secretion of IL-17.

T follicular helper cells

T follicular helper cells express CXCR5, the inducible T-cell co-stimulator molecule (ICOS), and secrete IL-21. They are responsible for licensing B lymphocytes for antibody production (see earlier).

Regulatory T lymphocytes

The generation of B and T lymphocytes provides a potentially vast array of rearranged antigen receptors. Although there are selection processes to remove lymphocytes with 'dangerous' avidity for 'self', these are not foolproof and the potential for autoreactivity remains. The fact that there is no self-destruction in the vast majority of people implies that the norm is a state of immunological self-tolerance: the controlled inability to respond to self. Several mechanisms operate to maintain this state, including CD4 T lymphocytes that respond to antigenic stimulation by suppressing ongoing immune responses. These regulatory T lymphocytes (Treg) express high levels of CD25, the receptor for IL-2; regulate other T lymphocytes by cell–cell contact; and also secrete the immune-suppressive cytokines IL-10 and TGF-β. They can be generated in the thymus or post-thymically in the periphery. Their key feature is high expression of the transcription factor Foxp3.

Evidence that Tregs are clinically relevant is provided by rare cases of genetic defects in the *Foxp3* gene, leading to IPEX (***i***mmune dysregulation, ***p***olyendocrinopathy, ***e***nteropathy, ***X***-linked) syndrome. Patients with this rare syndrome have defective Tregs and develop a range of conditions soon after birth, including organ-specific autoimmune disease such as type 1 diabetes.

CD8 T lymphocyte functions

Cytotoxic CD8 T lymphocytes are involved in defence against viruses. CTLs kill virus-infected cells following recognition of viral peptide-HLA class I complexes. CTLs must be activated first in the lymph node by a specialized cDC subset (called cDC1) that cross-presents the *same* viral peptide that is seen on infected cells and is licensed by a CD4 T lymphocyte recognizing viral peptide-HLA class II complexes. The same defence mechanism may also apply in tumour surveillance. This is a checkpoint that ensures that CTL responses, which have great destructive power, are activated only against a target for which there is also a CD4 T-cell response. CTLs kill via three mechanisms:

- cytotoxic granule proteins (cytolysins such as perforin, granzyme B)
- toxic cytokines (e.g., IFN-γ, TNF-α)
- death-inducing surface molecules (e.g., Fas ligand binds Fas on target cells mediating apoptosis via caspase activation, Fig. 6.9).

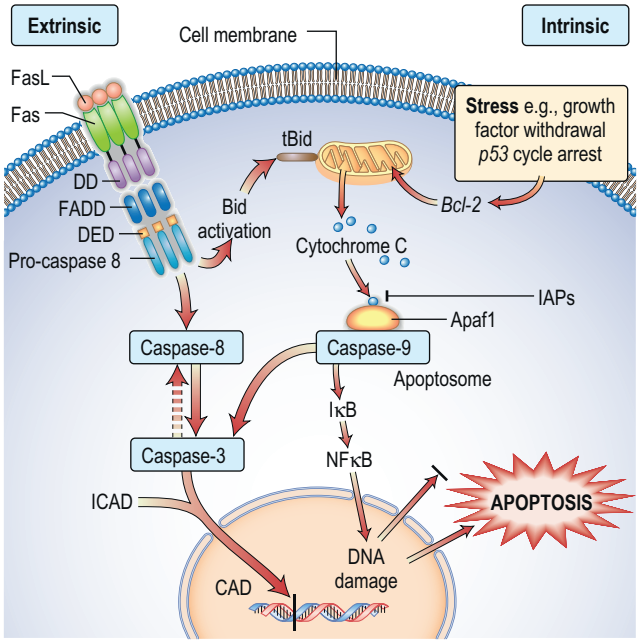

Fig. 6.9 Extrinsic and intrinsic apoptotic signalling network. The **Fas protein** and **Fas ligand (FasL)** are two proteins that interact to activate an apoptotic pathway: that is, a process of programmed cell death that removes cells that are infected or contain damaged DNA. Fas and FasL are both members of the tumour necrosis factor family. When FasL binds to Fas, it causes Fas to trimerize and brings together the death domains on the cytoplasmic tails of the protein. The **adaptor protein FADD** (Fas-associating protein with death domain) binds to these activated death domains and they bind to pro-caspase 8 through a set of death effector domains. **Pro-caspase 8s** then release caspase 8, in turn cleaving and activating other caspases, including caspase 3. **Caspase 3** cleaves ICAD, the inhibitor of caspase-activated DNase, which frees caspase-activated DNase to enter the nucleus and cleave DNA. *Apaf1,* Apoptotic protease-activating factor 1; *Bid,* family member of Bcl-2 protein; *IAPs,* inhibitor of apoptosis proteins; *IκB,* inhibitor of kappa B; *NFκB,* nuclear factor kappa B.

Natural killer cells

Natural killer cells are bone marrow derived, present in the blood and lymph nodes, and represent 5% to 10% of lymphoid cells. The name reflects two features. Unlike B and T lymphocytes, NK cells are able to:

- mediate their effector function *spontaneously* (i.e., *killing* of target cells through release of perforin, a pore-forming protein) in the absence of previous known sensitization to that target
- achieve this with a very limited repertoire of germline-encoded receptors that do not undergo somatic recombination.

For identification purposes, the main surface molecules associated with NK cells are CD16 (see later) and CD56 (note that NK cells are CD3- and TCR-negative). The role of NK cells is to kill 'abnormal' host cells, typically cells that are virus infected, or

tumour cells. Killing is achieved in similar ways to CTLs. NK cells also secrete copious amounts of IFN-γ and TNF-α, through which they can mediate cytotoxic effects and activate other components of the innate and adaptive immune systems. To become activated, NK cells integrate the signal from a potential target cell through a series of receptor–ligand pairings (**Box 6.12**). These pairings provide activating and inhibitory signals, and it is the overall balance of these that determines the outcome for the NK cell. The balance can be abnormal on a virus-infected or tumour cell, which might have altered expression of HLA molecules, for example, that mark them out for NK cytotoxicity.

CELL MIGRATION

For the immune system to function effectively, its cells must be able to access all areas of the body. Immune cells are highly mobile, allowing recirculation through the bloodstream, tissues, and lymphatics to provide systemic pathogen surveillance. For example, migration of a DC into a regional lymph node from the tissues via the lymphatics (**Fig. 6.10**) is highly dependent on expression of the chemokine receptor CCR7 by the migrating cell and of its ligand (CCL21) by the target tissue. In addition, naive lymphocytes express L-selectin, which binds a glycoprotein cell adhesion molecule-1, found on the high endothelial venules of lymph nodes. This system can be upregulated in an inflamed lymph node, leading to an influx of naive lymphocytes and the typical symptom of a swollen node. The ability of CCR7 to retain lymphocytes in the lymph nodes is balanced by the activity of sphingosine-1-phosphatase (S1P) and its receptors. High levels of S1P allow activated immune cells to recirculate back into the tissues. Modulation of S1P can be used to retain lymphocytes in the lymph node in the treatment of multiple sclerosis (see Chapter 28).

Migration into inflamed tissue requires:

- an affected organ or tissue to signal that there is a focus of injury/infection *and*
- responding immune cells to bind and adhere specifically to that tissue.

This process is highly organized and has a similar basis for all immune cells, involving three basic steps: rolling, adhesion, and transmigration. Each of these is dependent on specialized adhesion molecules (**Fig. 6.11**).

The expression of these molecules (e.g., leucocyte function associated antigen-1) is upregulated on T lymphocytes after activation in the lymph node. Intercellular cell adhesion molecule 1 (ICAM-1) expression on tissue endothelium is sensitive to numerous pro-inflammatory molecules and allows immune cells to be guided from the blood into the tissues. Once there, cells move along a gradient of increasing concentration of mediators such as chemokines in the process of chemotaxis.

HLA MOLECULES AND ANTIGEN PRESENTATION

On the short arm of chromosome 6 is a collection of genes termed the major histocompatibility complex (MHC; known as the human leucocyte antigens, or HLA, in humans), which plays a critical role in immune function. MHC genes code for proteins expressed on the surface of a variety of cell types that are involved in antigen recognition by T lymphocytes. The T lymphocyte receptor for antigen recognizes its ligand as a short antigenic peptide embedded within a physical groove at the extremity of the HLA molecule (Fig. 6.12).

Differences in HLA molecules between individuals are responsible for tissue and organ graft rejection (hence the name 'histo' [*tissue*]-compatibility). Possession of certain HLA genes is linked to susceptibility to particular diseases (Box 6.13).

The human major histocompatibility complex

The human MHC comprises three major classes (I, II, and III) of genes involved in the immune response (Fig. 6.13).

HLA classes

Classical HLA class I genes

Classical HLA class I genes (also termed Ia) are designated *HLA-A*, *HLA-B*, and *HLA-C*. Each encodes a class I α chain, which combines with a β chain to form the class I HLA molecule (see Fig. 6.12). While there are several types of α chain, there is only one type of β chain: β_2 microglobulin. The HLA class I molecule has the role of presenting short (8–10 amino acid) antigenic peptides to the TCR on the subset of T lymphocytes that bear the co-receptor CD8. As an example of HLA polymorphism, there are nearly 200 allelic forms at the *A* gene locus. Class I HLA molecules are expressed on all nucleated cells.

Non-classical HLA class I genes

Non-classical HLA class I genes are less polymorphic, have a more restricted expression on specialized cell types, and present a restricted type of peptide or none at all. These are the *HLA-E*, *F*, and *G* (Ib genes) and MHC class I–related (MIC, or class Ic) genes, *A* and *B*. The products of these genes are predominantly found on epithelial cells, signal cellular stress, and interact with lymphoid cells, especially natural killer cells (see 'Natural killer cells' section).

HLA class II genes

The class II genes have three major subregions: *DP*, *DQ*, and *DR*. In these subregions are genes encoding *A* and *B* genes that combine to form dimeric $\alpha\beta$ molecules that present short (12–15 amino acid) peptides to T lymphocytes that bear the CD4 co-receptor. Class II HLA genes (apart from *DRA*) are highly polymorphic. Other genes in this region encode proteins with key roles in antigen presentation (e.g., TAP, HLA-DM, HLA-DO, proteasome subunits; see later). Class II HLA genes are expressed on a restricted cohort of cells that go by the general term of antigen-presenting cells ([APCs]; DCs, monocyte/macrophages, B lymphocytes).

HLA class III genes

HLA class III genes encode proteins that can regulate or modify immune responses; they include tumour necrosis factor (TNF), heat shock protein, and complement protein (C2, C4).

HLA genotypes and the range of their protein products

HLA genotype is denoted first by the letters that designate the locus (e.g., *HLA-A*, *HLA-DR*, *HLA-DQ*). For class I alleles, this is followed by an asterisk and then a two- to four-digit number defining the allelic variant at that locus, often called the HLA type (e.g., *HLA-A*02* is the 02 variant of the *HLA-A* gene). The class II nomenclature is the same, except that both *A* and *B* genes are named.

Some general principles apply to the HLA genes and their protein products:

- The presence of multiple genes on each chromosome, and the fact that both maternal and paternal genes are co-dominantly

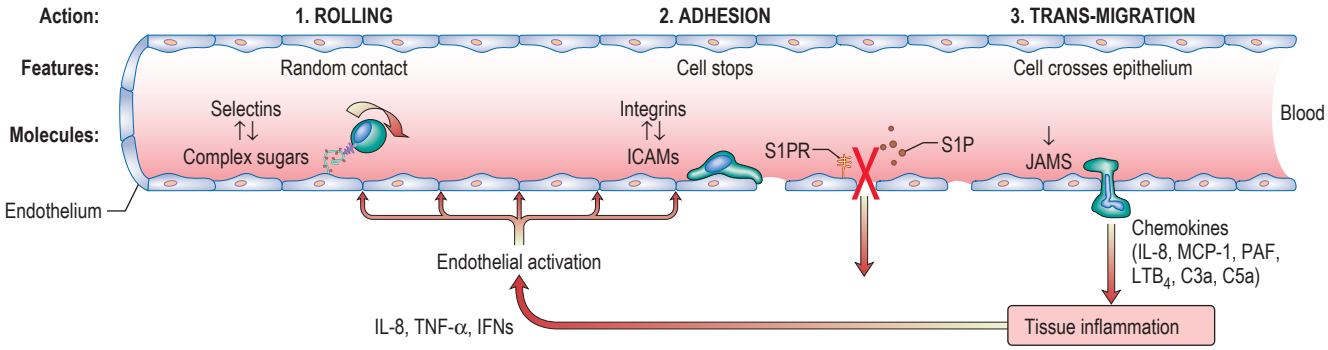

Fig. 6.11 Neutrophil migration. Neutrophils arrive at the site of the inflammation, attracted by various chemoattractants. **(1)** They roll along the blood vessel wall through interaction between L-selectin, on their surface, binding to a carbohydrate structure (e.g., sialyl-Lewis^X) on the endothelium. E-selectin on the endothelium mediates a similar effect. P-, E- and L-selectin (***p***latelet, ***e***ndothelium, and ***l***eucocyte, respectively) are named after the predominant cell type that expresses them and bind to carbohydrate moieties such as sialyl-Lewis^X (CD15s) on immune cells, inducing them to slow and roll along the vessel lumen. **(2)** ***Firm adhesion*** is then mediated via interaction between integrins on the neutrophil and intercellular and vascular cell adhesion molecules (ICAM-1 and VCAM-1) on the endothelium. The best-known integrin is the heterodimer of CD11a/CD18 (leucocyte function associated antigen-1—LFA-1), which binds ICAM-1. **(3)** ***Trans-migration*** (diapedesis) then occurs: this is a complex process that involves platelet-endothelial cell adhesion molecule-1 and junctional adhesion molecules. Following transmigration (diapedesis), mediators such as interleukin-8 (IL-8) and tumour necrosis factor alpha attract and activate the neutrophil to the infected tissue, where it phagocytoses and destroys the C3b-coated bacteria. *IFNs,* Interferons; *LTB_4,* leukotriene B_4; *MCP-1,* monocyte chemoattractant protein-1 (CCL2); *PAF,* platelet-activating factor.

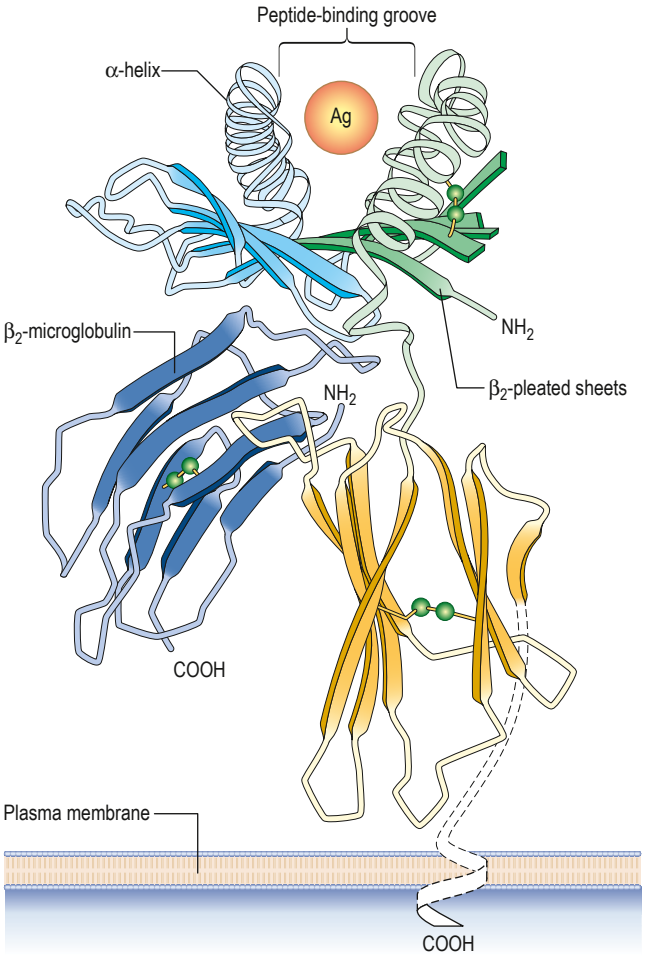

Fig. 6.12 Structure of human leucocyte antigen (HLA) class I molecule. The peptide-binding groove is used to present antigen (Ag) to T lymphocytes.

expressed, allow considerable breadth in the number of HLA molecules that an individual expresses.

- The existence of polymorphisms at each locus provides great breadth in the number of HLA molecules expressed at a population level. The polymorphic forms of HLA molecules differ predominantly in the peptide-binding groove (see Fig. 6.12).

Overall, then, each human can bind a range of peptide epitopes from pathogens to enhance individual protection; similarly, the population has an even greater range of protection to ensure population survival.

Antigen presentation

HLA molecules bind short peptide fragments that are processed ('chopped up') from larger proteins (antigens) derived from pathogens. The peptide–HLA complex is presented on APCs for recognition by TCRs on T lymphocytes. There are three major routes to antigen processing and presentation:

- *The endogenous route* (Fig. 6.14) is a property of all nucleated cells; the internal milieu is sampled to generate peptide–HLA class I complexes for display ('presentation') on the cell surface. In a healthy cell, the peptides are derived from self proteins in the cytoplasm (see Fig. 6.14) and are ignored by the immune system. In a virus-infected cell, viral proteins are processed and presented. The resulting viral peptide–HLA class I complex is presented to CD8 T lymphocytes that have cytotoxic (killer) function. In an immune response against a virus infection, CD8 T lymphocytes recognizing viral peptide–HLA complexes on the surface of an infected cell will kill it as a means to limit and eradicate infection.
- *The exogenous route* (Fig. 6.15) is a property of APCs; the external milieu is sampled. Antigens are internalized, either in the process of phagocytosis of a pathogen, through pinocytosis, or through specialized surface receptors (e.g., for antigen/antibody/complement complexes). The antigen is broken down by a combination of low pH and proteolytic enzymes for 'loading' into HLA class II molecules. At the APC surface, the pathogen peptide–HLA

Box 6.13 Examining the immune system in the clinical immunology laboratory

	Measurement	Interpretation
Proteins	C-reactive protein	Raised levels indicate infection or inflammation
	Total immunoglobulins	Low levels indicate antibody deficiency, usually a result of underlying disease or primary immunodeficiency. High levels, for example ↑ IgM, are seen in acute viral infection (e.g., hepatitis A), or may be present in plasma cell disorders such as myeloma
	IgG subclasses	Specific reductions in IgG subclasses (1–4) may indicate immune deficiency. High levels of IgG4 are observed in IgG4 disease
	Complement level and function	Low levels indicate consumption of complement in immune complex disease or primary complement deficiency, which can be confirmed with testing of the alternative or classical pathway function
	IgE	Raised levels are seen in allergy; allergen-specific IgE is useful to pinpoint the inciting stimulus (e.g., pollen, grass), component allergens may be useful in assessing anaphylaxis risk or cross-reactivity between allergens
Cells	Neutrophils	High levels are seen in bacterial infection; low levels in secondary immune deficiency
	Eosinophils	High levels are seen in allergic or parasitic disease
	CD4 T lymphocytes	Low levels are seen in HIV infection
Function (these are specialist tests and not available in routine clinical practice)	Neutrophil respiratory burst	Absent in immune deficiency chronic granulomatous disease
	T lymphocyte proliferation	Abnormally low in primary T-cell immune deficiency disease
Autoantibodies (see also Box 6.18)	Rheumatoid factor, anti-citrullinated peptide antibodies (ACPA)	Rheumatoid arthritis
	Double-stranded DNA autoantibodies	Systemic lupus erythematosus
	Acetylcholine receptor antibodies	Myasthenia gravis
	Anti-neutrophil cytoplasmic antibodies (ANCA)	Vasculitis
	Mitochondrial	Primary biliary cholangitis

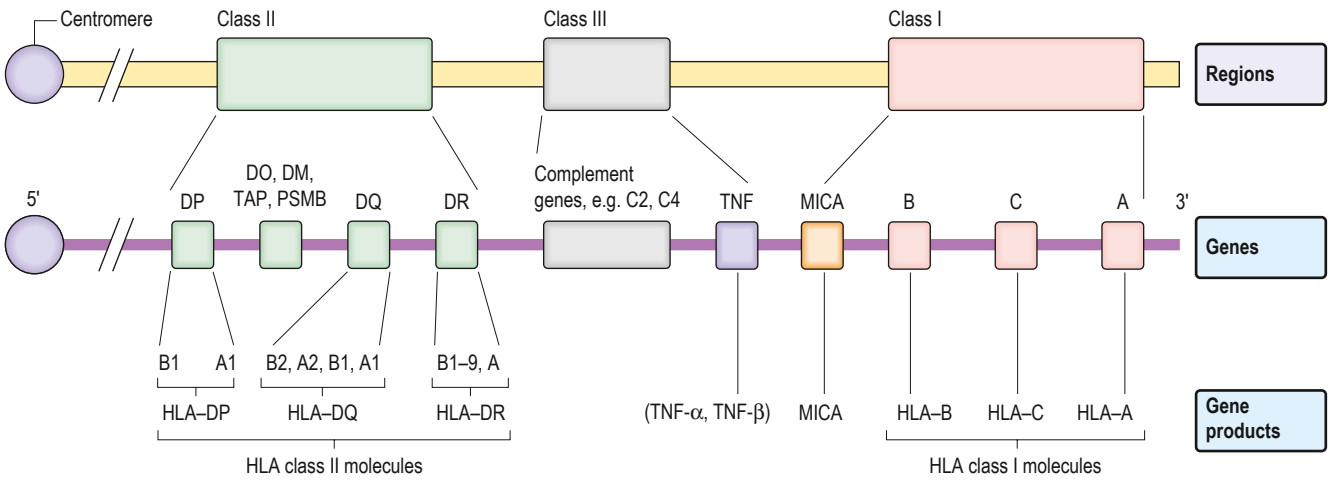

Fig. 6.13 The human leucocyte antigen (HLA) system in humans. On chromosome 6 are three major HLA regions (classes I–III), including genes that encode the HLA class I and II molecules, complement genes, the cytokine tumour necrosis factor, and other genes involved in antigen presentation (HLA-DO, HLA-DM; transporter associated with processing, TAP; proteasome subunit beta, PSMB; and the non-classical HLA class Ic molecule, MICA).

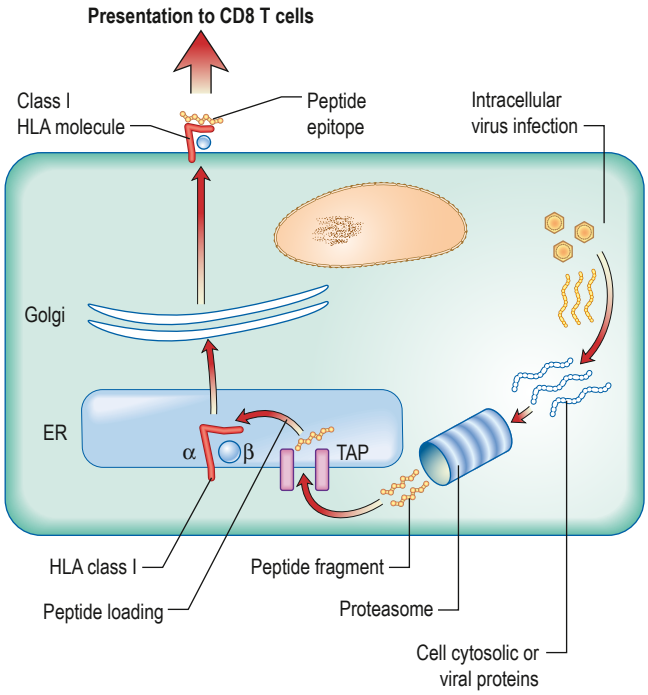

Fig. 6.14 The endogenous route of antigen presentation. Antigen is presented to CD8 T lymphocytes. Cytosolic proteins derived from self (resting cells) or viruses (virus-infected cells) are broken down by the proteasome (a sort of 'protein recycler') into fragments 2–25 amino acids long. Some of these are taken into the endoplasmic reticulum by a transporter (TAP), trimmed, and loaded into empty human leucocyte antigen (HLA) class I molecules. These are exported to the surface membrane for presentation to CD8 T lymphocytes.

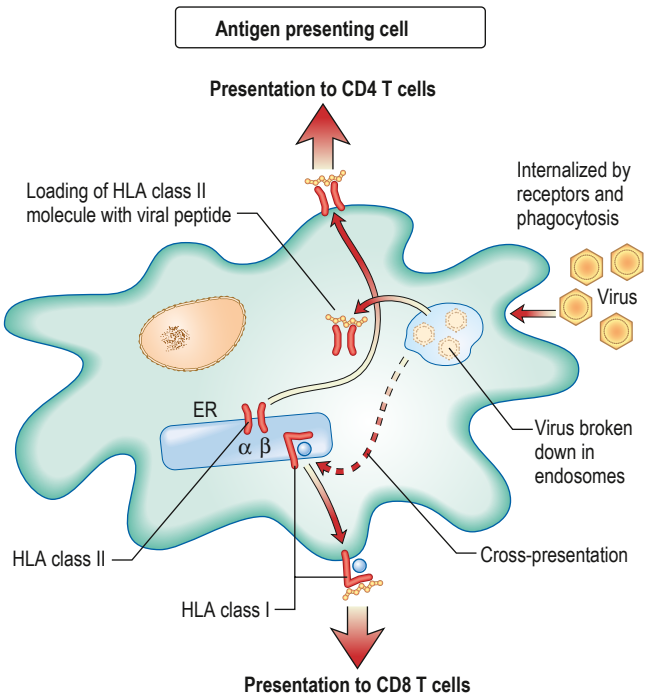

Fig. 6.15 The exogenous route of antigen presentation and cross-presentation. External material (e.g., virus particles) is taken into an antigen-presenting cell and broken down into specialized compartments by a combination of low pH and proteolysis. Peptides are then loaded into human leucocyte antigen (HLA) class II molecules for presentation to CD4 T lymphocytes. Material may also be transferred across the cell so that it is loaded on to HLA class I molecules for presentation to CD8 T lymphocytes. This process of cross-presentation is restricted to specialized antigen-presenting cells such as dendritic cells. *ER,* Endoplasmic reticulum.

class II complex is presented to, and able to interact with, CD4 T lymphocytes. Presentation by DCs can initiate an adaptive immune response by activating a naive, pathogen-specific CD4 T lymphocyte. Presentation by monocyte/macrophages and B lymphocytes can maintain and enhance this response by activating effector and memory pathogen-specific CD4 T lymphocytes.

- ***Cross-presentation*** refers to the ability of some APCs (mainly cDC1s) to internalize exogenous antigens and process them through the endogenous route (see Fig. 6.14). This is an essential component in the activation of CD8 cytotoxic T-cell responses against a virus.

THE IMMUNE SYSTEM IN CONCERT

Acute inflammation: events and symptoms

This is the early and rapid host response to tissue injury. To take a bacterial soft tissue infection and abscess formation as a classic example:

- Local expansion of pathogen numbers leads to direct activation of complement in the tissues, with ensuing degranulation of mast cells.
- Inflammatory mediators (from mast cells and complement) change the blood flow and attract and activate granulocytes (neutrophils).
- Concomitantly, there are the local symptoms of heat, pain, swelling, and redness, and perhaps more systemic symptoms such as fever due to the effect of circulating cytokines (IL-1, IL-6, TNF-α) on the hypothalamus. Indeed, gene mutations that lead to excessive actions of IL-1 (e.g., mutation of the *IL1RN* gene, which encodes a natural IL-1 antagonist) give rise to rare disease with just these symptoms, as well as bone erosion and skin rashes, which are treatable with IL-1 blockade using soluble IL-1 receptor antagonist (anakinra) or monoclonal anti-IL-1β antibody.
- Systemically active mediators (especially IL-6) also initiate the production of C-reactive protein in the liver.
- Bacterial lysis follows through the actions of complement and neutrophils, leading to formation of fluid in the tissue space containing dead and dying bacteria and host granulocytes ('pus').
- At the site of pathogen entry, there is often relative tissue hypoxia. The low oxygen tension has the effect of amplifying the responses of innate immune cells and suppressing the response of adaptive immune cells. This is probably an effective means of preventing excessive immune activation, which can result in collateral damage (Fig. 6.16).
- The inflammation may become organized and walled off through local fibrin deposition to protect the host.
- Antigens from the pathogen travel via the lymphatics (which may become visible as red tracks in the superficial

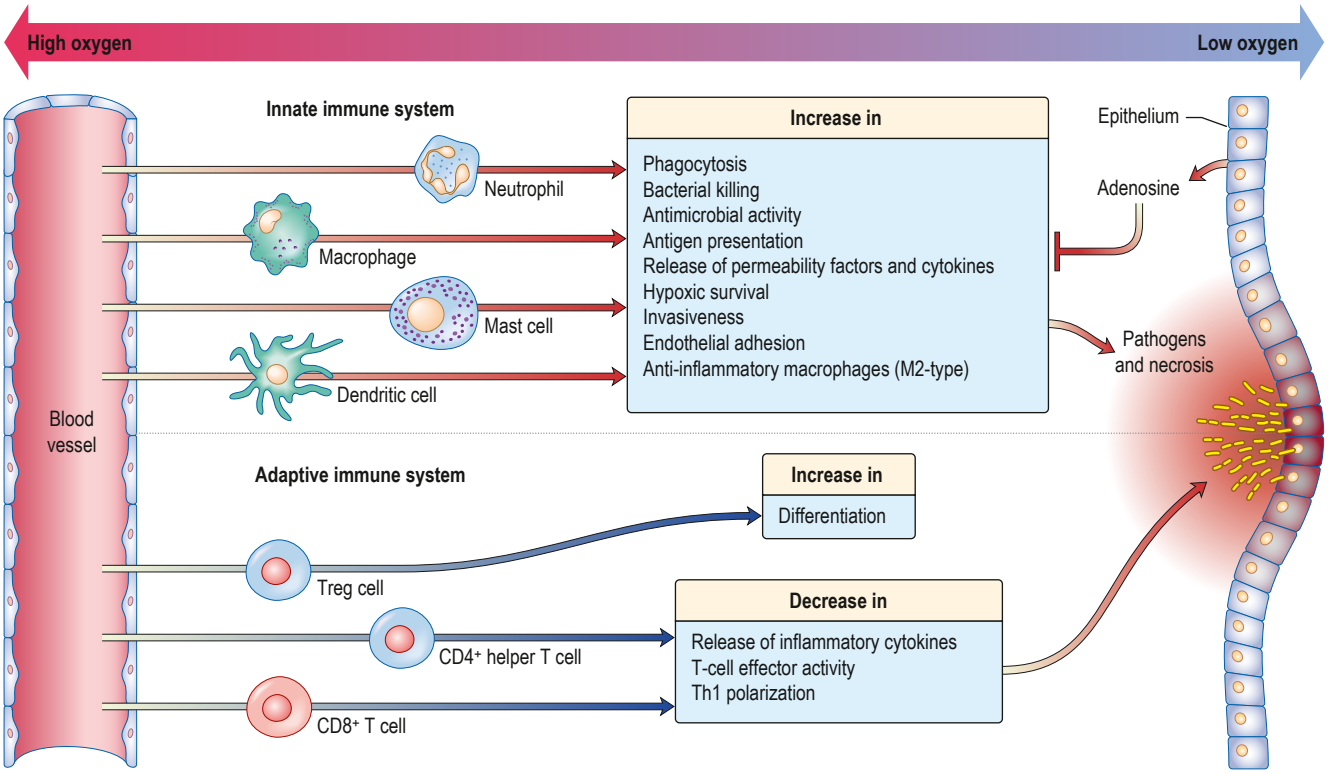

Fig. 6.16 Hypoxia and inflammation. At the site of pathogen invasion and necrosis, the oxygen tension is low *(right)*. Hypoxia acts on the inflammatory process by amplifying innate immune cell responses and dampening down the adaptive response. Overall, this benefits the host by avoiding an excessive, uncontrolled immune response.

tissues—lymphangitis) in soluble form or are carried by DCs to establish an adaptive immune response, which, at the first host–pathogen encounter, takes approximately 7 to 14 days. DCs are activated via the PRR–PAMP system (see Fig. 6.5).

- The adaptive immune response leads to activation of pathogen-specific T lymphocytes and of B lymphocytes and production of pathogen-specific antibody, initially of the IgM class and of low to moderate affinity, and subsequently of the IgG class (or IgA if the infection is mucosal) and of high affinity.
- Resolution of the infection is aided by the scavenging activity of tissue macrophages.

Chronic inflammation: events and symptoms

Inflammation arising in response to immunological insults that cannot be resolved in days or weeks gives rise to chronic inflammation. Examples include infectious agents (viruses that cause chronic infections such as hepatitis B and C or intracellular bacteria such as mycobacteria) and environmental toxins (such as asbestos and silicon). At the intracellular level, key processes of inflammasome generation and autophagy serve to enhance the chronic inflammatory process. Chronic inflammation is also a hallmark of some forms of allergic disease, autoimmune disease, and organ graft rejection.

The common feature of these pathological processes is the difficulty of removing the inciting stimulus. For example, some viruses and mycobacteria remain hidden intracellularly. In many ways, the pathology that results is inadvertent: the immune system is caught between the repercussions of not dealing with the infection or insult and the tissue damage that is caused by chronic activation of lymphoid and mononuclear cells.

Mycobacterium leprae

Leprosy, also known as Hansen's disease, is a chronic infectious disease caused by the bacterium *Mycobacterium leprae*. The immune responses that lead to different clinical manifestations of leprosy, specifically lepromatous and tuberculous leprosy, are primarily determined by the interactions between the immune system and the bacteria, so that the efficacy of cell mediated immunity determines the clinical manifestation of infection (see leprosy, Chapter 42):

- ***Lepromatous leprosy*** is characterized by a weak cellular immune response and a robust humoral immune response. In this form of the disease, the immune system fails to mount an effective defence against *M. leprae*, allowing the bacteria to multiply and spread extensively. Key features of lepromatous leprosy include:
  - Humoral Response: Antibodies, particularly IgG and IgM, are produced against *M. leprae*, leading to the formation of immune complexes. However, these immune complexes are not efficient at eliminating the bacteria.
  - Th2 Dominance: There is a predominance of Th2-type immune responses, leading to the production of cytokines such as IL-4 and IL-10. Th2 responses are associated with the production of antibodies and a weak cellular immune response.
  - Macrophage Dysfunction: Macrophages, which are immune cells responsible for engulfing and destroying pathogens, are not effectively activated in lepromatous leprosy. This allows

the mycobacteria to replicate within the macrophages and leads to the characteristic skin lesions and nodules observed in this form of the disease.

- ***Tuberculous leprosy***, also known as paucibacillary leprosy, is characterized by a stronger cellular immune response compared to lepromatous leprosy. The immune system is better equipped to control the growth of *M. leprae*, resulting in milder clinical manifestations. Key features of tuberculous leprosy include:
  - Cellular Response: There is a more effective cellular immune response, involving T cells, particularly $CD4^+$ and $CD8^+$ T cells. These T cells release cytokines such as IFN-γ, which activate macrophages to destroy the bacteria.
  - Th1 Dominance: Tuberculous leprosy is associated with Th1-type immune responses, characterized by the production of IFN-γ and other pro-inflammatory cytokines. Th1 responses are crucial for controlling intracellular pathogens.
  - Granuloma Formation: Granulomas, which are organized collections of immune cells, form around infected cells to contain the infection and limit bacterial spread. In tuberculous leprosy, granulomas are more likely to form and contribute to disease containment.

Recall responses as diagnostic markers

The cell-mediated immune response can be measured as a **recall response**. This forms the basis of diagnostic testing for mycobacterial infection and more commonly for **mycobacterium tuberculosis** (see Chapter 20):

- The measurement of the recall response can be *in vivo* as a skin test or ***Mantoux test***, where antigen is injected under the skin and primed T-cells migrate to and recognize the TB antigens causing local inflammation on the skin as a hallmark of current or previous infection.
- An alternative approach is to take blood, incubate the cells with TB antigens, and measure any interferon gamma released by previously activated T-cells. This is known as an ***interferon gamma release assay*** (IGRA).

Neither IGRA nor Mantoux tests are reliable in severe T-cell immunodeficiency diseases (e.g., advanced HIV infection), and neither can distinguish between latent or active infection. Other clinical disciplines use recall responses to determine if someone is sensitized to a specific antigen to a point that it would cause clinical symptoms; for example, in dermatology patch testing applies antigens to the skin to determine possible causes of contact dermatitis.

Crohn's disease

While in leprosy the cause of chronic inflammation is known, in several immune-mediated and autoimmune diseases (such as Crohn's disease) it is unclear what kick-starts or maintains the inflammatory process. When inflammation is sufficiently chronic, it may take on the appearance of organized lymphoid tissue resembling a lymph node germinal centre (e.g., in the joints in rheumatoid arthritis, Chapter 32). Alternatively, massive cytokine production by T lymphocytes and APCs, which contributes to local tissue damage, may give rise to the same sort of granulomata that are observed in mycobacterial disease. The granulomata 'wall off' the inciting stimulus but may also result in fibrosis and calcification. Symptoms typically relate to the site of the inflammation, so in Crohn's disease there is gut inflammation, bleeding, and fibrosis. The immune response may also be responsible for systemic effects such as fever and weight loss.

Genome-wide association studies (GWAS, Chapter 5) can help reveal the genetic basis for such chronic inflammatory disorders. Several of the polymorphisms associated with Crohn's disease reside in genes known to be involved in inflammasome induction, such as *NOD2*. Cytokine regulation has also emerged as a critical disease pathway in GWAS studies on Crohn's disease: most notably, *IL-23R* (the IL-23 receptor gene), which influences Th17 cell differentiation. Clues like these point to patients with Crohn's disease having impaired ability to control or terminate inflammasome activity, as well as a predisposition to make polarized pro-inflammatory cytokine responses.

LABORATORY INVESTIGATIONS OF THE IMMUNE SYSTEM

In the clinical immunology laboratory, proteins and cells can be measured to ascertain the status of the immune system. The results may reveal non-specific evidence of inflammatory or infectious disease (e.g., high C-reactive protein level); a state of immune deficiency (e.g., low concentration of IgG); or a state of immune pathology (e.g., the presence of autoantibodies or allergen-specific IgE).

Examples of the more common tests and their interpretation are shown in **Box 6.13**.

DISORDERS OF IMMUNODEFICIENCY

Secondary (acquired) versus primary immunodeficiency

Most forms of immunodeficiency that are encountered in clinical practice are secondary to infection (mainly HIV) or therapy (e.g., corticosteroids, monoclonal antibody [MAb] therapy, cytotoxic anticancer drugs, bone marrow ablation pre-transplant). Examples of other secondary immunodeficiencies are:

- ***Acquired neutropenias***, which are common (e.g., due to myelosuppression by disease or drugs or the increased rate of destruction in hypersplenism or autoimmune neutropenia) and carry a high risk of infection once the neutrophil count falls below 0.5×10^9/L.
- ***Acquired reductions in levels of immunoglobulins*** (hypogammaglobulinaemia), which are seen in patients with myeloma and chronic lymphocytic leukaemia or lymphoma. The use of chimeric antigen receptor (CAR)-T-cell therapy and B lymphocyte targeting monoclonal antibodies (e.g., rituximab) can cause significant depletion of B-cell numbers which has significantly added to the burden of secondary antibody deficiency.
- ***Impairment of defence against capsulated bacteria***, especially pneumococcus, following splenectomy; such patients should receive pneumococcal, meningococcal, and Hib vaccinations as a matter of course and antibiotic prophylaxis (see Box 38.17).

Primary immunodeficiencies are individually rare, but with now over 400 single gene entities recognized, collectively they are sufficiently common that most doctors will treat some of these patients.

Box 6.14 Classification of immunodeficiencies and the main diseases in each category[a]

Immune component	Examples of diseases
T lymphocyte deficiency	DiGeorge's syndrome
	Acquired immunodeficiency syndrome (AIDS)/human immunodeficiency virus (HIV) infection
	T-cell activation defects (e.g., CD3γ chain mutation)
	X-linked hyper-IgM syndrome (XHIM; CD40L deficiency)
B lymphocyte deficiency	X-linked agammaglobulinaemia (XLA)
	Common variable immunodeficiency (CVID)
	Selective IgA deficiency (IgAD)
Combined T- and B-cell defects	Severe combined immunodeficiency (SCID) (e.g., due to defects in common γ chain receptor for IL-2, 4, 7, 9, 15)
T-cell antigen–presenting cell interactions	IFN-γ receptor deficiency
	IL-12 deficiency and IL-12 receptor deficiency
Neutrophil defects	Chronic granulomatous disease (CGD)
	Leucocyte adhesion deficiency (LAD)
Deficiency of complement components	Classical pathway
	Alternative pathway
	Common pathway
	Regulatory proteins
	Mannose-binding lectin

[a]Apart from HIV infection, all the diseases shown here are primary immunodeficiencies.

Box 6.15 Immune defects and associated infections

Neutropenia and defective neutrophil function
- *Staphylococcus aureus*
- *Staphylococcus epidermidis*
- *Escherichia coli*
- *Klebsiella pneumoniae*
- *Proteus mirabilis*
- *Pseudomonas aeruginosa*
- *Serratia marcescens*
- *Bacteroides* spp.
- *Aspergillus fumigatus*
- *Candida* spp. (systemic)

Opsonin defects (antibody/complement deficiency)
- Pneumococcus
- *Haemophilus influenzae*
- Meningococcus
- *Streptococcus* spp. (capsulated)

Antibody deficiency only
- *Campylobacter* spp.
- *Mycoplasma* spp.
- *Ureaplasma* spp.
- Echovirus
- *Pseudomonas* spp.

Complement lytic pathway defects (C5–9)
- Meningococcus
- Gonococcus (disseminated)

Defect in T-cell or T-cell antigen–presenting cell responses
- *Listeria monocytogenes*
- *Legionella pneumophilae*
- *Salmonella* spp. (non-typhi)
- *Nocardia asteroides*
- *Mycobacterium tuberculosis*
- Atypical mycobacteria, especially *Mycobacterium avium-intracellulare*
- *Candida* spp. (mucocutaneous)
- *Cryptococcus neoformans*
- *Histoplasma capsulatum*
- *Pneumocystis jirovecii*
- *Toxoplasma gondii*
- Herpes simplex
- Herpes zoster
- Cytomegalovirus
- Epstein–Barr virus

They arise at birth as the congenital effect of a developmental defect or as a result of a genetic abnormality (Box 6.14). Gene defects may not manifest until later in infancy or childhood, and some forms of immunodeficiency typically present in adolescence or adulthood as a combined effect of genetics and environment.

Clinical features of immunodeficiency

The infections associated with immunodeficiency have several typical features:
- They are often chronic, severe, or recurrent.
- They resolve only partially with antibiotic therapy or return soon after cessation of therapy.
- The organisms involved are often unusual ('opportunistic' or 'atypical').

The pattern of infection, in terms of the type of organism involved, is indicative (Box 6.15):
- ***'Opportunistic' organisms*** are of low virulence but become invasive in immunodeficient states, for example atypical mycobacteria, *Pneumocystis jirovecii*, *Staphylococcus epidermidis.*
- ***Phagocyte defects*** cause deep skin infections, abscesses, and osteomyelitis.
- ***Defective antibody*** production is associated with infections with pyogenic ('pus-forming') bacteria.
- ***T lymphocyte deficiency*** causes infection with fungi, protozoa, and intracellular microorganisms or persistent viral infection.
- ***Congenital deficiencies*** of antibody production are not revealed for several months after birth, due to the 28-day half-life of maternal IgG.

The family history may reveal unexplained sibling death, the fact that only males of the family are affected (X-linked), or consanguinity; each of these makes a primary genetic syndrome more likely. In babies with severe combined immunodeficiencies (SCID) it is possible for high numbers of memory T-cells to be detected. The source of these cells is either engraftment of maternal cells ***(materno-fetal engraftment)***, an expansion of a few viable clones of the babies' own cells, known as ***Omenn syndrome***, or the inadvertent transfusion of cells as part of healthcare intervention.

Primary immunodeficiency

T lymphocyte deficiency

Complete DiGeorge's syndrome

DiGeorge's syndrome arises in 1 to 5 per 100 000 of the population due to deletions on the long arm of chromosome 22. It has a highly variable presentation, including ***c***ardiac abnormalities, ***a***bnormal

facies, ***t***hymic dysfunction, ***c***left deformities, and ***h***ypocalcaemia/hypoparathyroidism, remembered by the acronym 'CATCH-22'. In those DiGeorge individuals born without a thymus, the lack of a location for T lymphocyte development means that they have reduced or absent T lymphocyte number and proliferation responses. Apart from calcium supplementation, correction of cardiac abnormalities, and prophylactic antibiotics, cure has been reported with thymic transplantation using fetal tissue or stem cell transplant (SCT) from HLA identical siblings. Other athymic conditions include Foxn1 deficiency and CHARGE syndrome (***c***oloboma, ***h***eart defects, choanal ***a***tresia, ***r***etardation of ***g***rowth and development, ***e***ar abnormalities) caused by CHD7 mutations.

Other T lymphocyte deficiencies

Other T lymphocyte deficiencies caused by single-gene defects have been characterized and typically present from the age of 3 months with candidal infections of the mouth and skin, protracted diarrhoea, fever, and failure to thrive. These disorders are similar in presentation and management to the combined (T and B lymphocyte) immunodeficiencies.

T and B lymphocyte deficiency

Severe combined immunodeficiencies

Severe combined immunodeficiencies are a heterogeneous group of rare (1–2 live births per 100 000), genetically determined disorders resulting from impaired T, NK, and B lymphocyte immunity. The most common form of SCID is an X-linked defect in the IL-2 receptor γ chain, interfering with the function not just of IL-2 but also of IL-4, IL-7, IL-9, and IL-15, which share this component in their receptors. Clinical features are similar to those of pure T lymphocyte deficiency and, in the blood, T and NK cells are lacking while B lymphocyte numbers may be normal. The most successful treatment for all forms of SCID is SCT, preferably from HLA-identical donors such as siblings. For a few disorders, such as ADA (adenosine deaminase) and γ chain-deficient SCID, gene therapy is possible if no appropriate HLA-matched donor can be found.

Hyper-IgM syndrome

This mixed or combined immunodeficiency may not be diagnosed until later in life. It usually results from an X-linked defect in the gene encoding CD40 ligand (CD40L, also called CD154). Signalling between CD40 on B cells and CD40L on T cells is necessary for the generation of class-switched B cells bearing high-affinity immunoglobulin and for mature T-cell responses. In CD40L deficiency, B lymphocytes are unable to class-switch, producing only IgM. Levels of other types of immunoglobulin, IgG and IgA, are absent or low and there are mild defects in T-cell function. Autosomal forms are also seen with defects in CD40, activation-induced cytidine deaminase (AID), and uracil-DNA glycosylase (UNG).

Opportunistic infections occur: for example, with *Pneumocystis*, *Cryptosporidium*, *Candida*, *Cryptococcus* and herpes viral infections. Treatment is with replacement immunoglobulin, antifungals, antibiotics, and avoidance of *Cryptosporidium* by boiling water. SCT is used in some patients.

Wiskott–Aldrich syndrome

This is an X-linked defect (at Xp11–23) in a gene involved in signal transduction and cytoskeletal function. It is associated with eczema and thrombocytopenia; a mainly cell-mediated defect with falling immunoglobulins is seen, and autoimmune manifestations and lymphoreticular malignancy may develop. Activating mutations in the same gene have been described that cause severe congenital neutropenia, highlighting the key role of Wiskott–Aldrich serine protease in immune regulation.

Ataxia telangiectasia

Patients with this disease have defective DNA repair mechanisms and have cell-mediated defects with low IgA and IgG_2. Lymphoid malignancy is common and a shortened life expectancy often results from the neurological disease.

Epstein–Barr virus-associated immunodeficiencies

Apparently normal but genetically predisposed individuals develop overwhelming Epstein–Barr virus (EBV) infection, polyclonal EBV-driven lymphoproliferation, combined immunodeficiency, aplastic anaemia, and lymphoid malignancy. EBV appears to act as a trigger for the expression of a hitherto silent immunodeficiency. Many genetic susceptibilities to EBV have now been described, including X-linked lymphoproliferative disease 1 and 2 (XLP1 and XLP2), which demonstrate defects in the *SH2D1A* and *XIAP* genes, respectively, and may also present with Crohn's-like gut inflammation (see Chapter 22). Other genetic causes include mutations in *CD70*, *CD27*, *ITK*, and *CARD11*.

Antibody deficiencies

Antibody deficiency syndromes may be caused by intrinsic defects in B lymphocyte development, resulting in absence of B lymphocytes or specific subsets. Antibody deficiency due to inborn errors of immunity also occurs when normal antibody production is not well sustained. Intrinsic developmental defects tend to present 6 months after birth when transplacentally transferred maternal IgG has declined, while other syndromes may present variably throughout childhood and adult life. The clinical features of antibody deficiency are severe, recurrent sinopulmonary infection leading to bronchiectasis and persistence of gut pathogens (e.g., *Giardia*) with resultant chronic diarrhoea and malabsorption. Morbidity and mortality are high if the conditions are untreated, mainly due to chronic lung disease and central nervous system infections with enteroviruses.

X-linked agammaglobulinaemia

X-linked agammaglobulinaemia is an intrinsic defect in B lymphocyte maturation. The cause is a loss-of-function mutation of Bruton's tyrosine kinase, which is involved in cell activation and maturation. B lymphocyte development is arrested at the pre-B stage, and B lymphocytes are absent in the blood. Clinical presentation follows the fall in protective maternal IgG.

Common variable immunodeficiencies

Common variable immunodeficiencies are a heterogeneous group of disorders arising during late childhood and early adulthood, with very low IgG levels. Although rare (1/50 000), it is the most common severe primary immune deficiency and carries a significant risk of morbidity and mortality. Autoimmunity and granulomatous disease are found in up to 15% of cases. Genetic defects underlying the condition have revealed mutations in multiple genes: in Europe the most common is haploinsufficiency of *NFKB1*. In most patients, the underlying defect remains unknown.

Selective IgA deficiency

Selective IgA deficiency (IgAD; serum IgA <0.05 g/L), with normal levels of IgG and IgM, is found in approximately 1/600 Northern

Europeans. Most individuals are asymptomatic but numerically this is the most common primary immunodeficiency. The underlying defect is unknown. Patients may present at any age with recurrent infections caused by pyogenic organisms, particularly affecting mucosal sites.

Treatment of antibody deficiencies

Treatment of IgAD is not usually required; when it is, antibiotics are used. Some IgAD patients produce anti-IgA antibodies of the IgG and IgE classes, and so infusion of exogenous IgA (e.g., during a blood transfusion) could result in anaphylaxis. IgAD patients should therefore be screened for anti-IgA antibodies if there is a history of transfusion reaction and transfused with appropriate precautions if positive.

For patients with X-linked agammaglobulinaemia, common variable immunodeficiencies, or another major antibody deficiency, treatment is with replacement immunoglobulins (intravenous or subcutaneous, intravenous immunoglobulin [IVIg] or SCIg) to a level that controls infections. Trough IgG concentrations should remain well within normal limits (i.e., >6 g/L), and infections should be treated promptly and aggressively with antibiotics. Prognosis has improved in recent years as more patients survive into adulthood, but chronic lung disease and lymphomas remain life-threatening complications.

Defects in antigen-presenting cell function

A series of rare genetic defects have been uncovered in which APCs demonstrate an inability to mount protective responses to intracellular bacteria, particularly low-virulence mycobacteria and salmonella. The axis affected is the interplay between CD4 T lymphocytes and APCs that drives Th1 responses and therefore, in turn, activates mononuclear cells such as macrophages to kill and eradicate intracellular pathogens.

Neutrophil defects

Chronic granulomatous disease

Chronic granulomatous disease is a rare (1/250 000) immunodeficiency that is caused by a defect in neutrophil killing; it is characterized by deep-seated infections. The functional defect is an inability to generate antibacterial metabolites through the respiratory burst (see **Box 6.5**). X-linked and autosomal forms are described. Typical onset is at toddler age. Neutrophil numbers are normal or increased. A simple respiratory burst test of neutrophil function is diagnostic. The dysfunctional neutrophils' inability to clear infection adequately and frustrated apoptosis lead to granulomatous inflammation, and CGD may also present with a Crohn's-like gut disease (see Chapter 22).

Treatment of infections and prophylactic antibiotic and antifungal therapy are required. In many cases, SCT is necessary. For the X-linked form, gene therapy is a treatment option when a suitably matched donor cannot be found.

Leucocyte adhesion deficiency

Leucocyte adhesion deficiency results from defects in integrins (see **Fig. 6.11**). Numerous underlying defects in the genes encoding one of the component chains, *CD18*, have been described in LAD-1. LAD-1 has an autosomal recessive inheritance, presenting almost immediately after birth with delayed umbilical cord separation. In later life, there is a characteristic failure to lose primary dentition and severe gingivitis. Recurrent infections appear during the first decade of life. Blood neutrophil levels are high but cells are absent from the sites of infection, which require aggressive antimicrobial and antifungal treatment and SCT for cure.

Hyper-IgE syndrome (Job's syndrome)

This is an autosomal dominant (occasionally sporadic) immune disorder with high serum IgE levels, dermatitis, boils, pneumonias with cyst formation, and bone and dental abnormalities. Mutations in *STAT3*, *DOCK8*, and *ZNF341* have been found.

Shwachman–Diamond syndrome

This can resemble cystic fibrosis clinically, with exocrine pancreatic insufficiency and pyogenic infections. A mild neutropenia is associated with a defect of neutrophil migration.

Chédiak–Higashi syndrome

This rare recessive disorder is caused by a mutation in the lysosomal trafficking regulator gene *(LYST)* on chromosome 1q42–45. There are defects in neutrophil function with defective phagolysosome fusion, and large lysosome vesicles are seen in phagocytes. Patients have recurrent infections, neutropenia, anaemia, and hepatomegaly. As with Shwachman–Diamond syndrome, tissue infiltration with histiocytes is usually seen, including in bone marrow, and Chédiak–Higashi syndrome is one of several genetic causes of primary haemophagocytic lymphohistiocytosis.

Complement deficiency

The consequences of deficiency of complement proteins can be predicted from their functions (see **Fig. 6.2**):

- Failures in innate response components (e.g., the alternative pathway) lead to impaired non-specific immunity with an increase in bacterial infections.
- Failure of the classical pathway results in a tendency towards infection and also towards diseases in which immune complex deposition causes inflammation, such as SLE (e.g., C1 and C4 deficiency), vasculitis, and glomerulonephritis.

Neisserial infections (e.g., meningitis due to *N. meningitidis*) are often encountered in patients with complement defects of the membrane attack complex (C6–9). Lectin pathway deficiency in isolation rarely causes major ill health.

Complement regulatory proteins

Deficiency of C1 inhibitor ***(C1 esterase deficiency)*** is relatively rare. Since this enzyme is involved in regulation of several plasma enzyme systems (e.g., the kinin system) and is continuously consumed, a single parental chromosome defect resulting in 50% of normal production barely copes with the demand and fails under stress (hence has an autosomal dominant effect). As a result, uncontrolled activation of low-molecular-weight kinins may occur, leading to oedema of the deep tissues affecting the face, trunk, viscera, and airway, and explaining the alternative name of hereditary angio-oedema (HAE). Treatment is with C1 inhibitor concentrate or a selective bradykinin-2 receptor antagonist (icatibant). Steroids and antihistamines are not useful in this form of angio-oedema. Prophylaxis may be with specific kallikrein pathway inhibitors such as berotralstat (an oral kallikrein inhibitor) or lanadelumab. (MAb to Kallikrein). New genetic causes of HAE are now recognized, all with defects in the contact-kinin pathway. An acquired form of C1 esterase inhibitor deficiency (acquired angio-oedema, AAE) may be seen in lymphoproliferative disease or complicating autoimmunity. The treatment is largely for HAE.

DISORDERS OF EXAGGERATED IMMUNE RESPONSE

ALLERGIC DISEASE (IMMEDIATE HYPERSENSITIVITY)

Normally, host defence can cope with potentially harmful cells and molecules. Under some circumstances, a harmless molecule can initiate an immune response that can lead to tissue damage and death. Such exaggerated, inappropriate responses are termed hypersensitivity reactions or allergic disease.

In ***allergic hypersensitivity***, the binding of an antigen to specific IgE bound to its high-affinity receptor on a mast cell surface results in massive and rapid cell degranulation and the inflammatory response outlined in Chapter 11 ('Anaphylaxis' section). The antigens involved are typically inert molecules present in the environment.

The immediate effects of allergen exposure are often very florid ***(early phase response)***. Allergic disorders also have a second phase, occurring a few hours after exposure and lasting up to several days. These '***late phase responses***' are mediated by Th2 cells recognizing peptide epitopes of the allergen. Recruitment of eosinophils is often a prominent feature.

From a pathological and therapeutic viewpoint, the LPR gives rise to chronic inflammation, which is difficult to control. In ***asthma***, the LPR causes prolonged wheezing, which can be fatal. Immediate hypersensitivity is usually responsive to antihistamines but the LPR is not, requiring powerful immune modulators such as corticosteroids.

In immunopathological terms, in the LPR:

- Neutrophils and eosinophils are prominent in the first 6 to 18 hours and may persist for 2 to 3 days.
- Th2 cells accumulate around small blood vessels and persist for 1 to 2 days.
- Mediators responsible for the cellular infiltrate include platelet-activating factor and leukotrienes (**Box 6.16**).
- Th2 cytokines IL-4 and IL-5 and chemokines such as eotaxin act as growth and activation stimuli for eosinophils, which are capable of extensive tissue damage. Th2 cytokines are also responsible for the class switch of Ig production towards IgE, maintaining the cycle of immediate and late responses.

What makes an allergen so powerful?

Several allergens are proteolytic enzymes, allowing them to cross skin and mucosal barriers. They are often contained within small, aerodynamic particles (e.g., pollen grains) that gain access to nasal and bronchial mucosa.

Box 6.16 Mediators involved in the allergic response

Pre-formed mediators

- Histamine and serotonin:
  - Bronchoconstriction
  - Increased vascular permeability
- Neutrophil chemotactic factor (NCF) and eosinophil chemotactic factor (ECF):
  - Induction of inflammatory cell infiltration

Newly formed mediators (membrane derived)

- Leukotriene (LT) B_4:
  - Chemoattractant
- LTC_4, LTD_4, LTE_4 (slow-reacting substance of anaphylaxis, SRS-A):
  - Sustained bronchoconstriction and oedema
- Prostaglandins and thromboxanes:
  - Platelet-activating factor (PAF)
  - Prolonged airway hyperactivity

Why do some people react and others do not?

The tendency to develop allergic responses (known as atopy) shows strong heritability. Between 20% and 30% of the UK population is atopic, and two, one, or no atopic parents pass on the atopic trait to their children with a risk of 75%, 50%, and 15%, respectively. In developing nations, the tendency to allergy is estimated at one-tenth of the rate in industrialized countries. Among the predisposing genes are those encoding the β chain of the high-affinity receptor for IgE and IL-4, both strongly associated with Th2 pathways. The presence of Th2 cells recognizing allergens is the pathological hallmark of allergy.

What environmental factors are involved?

Early exposure to allergens (even *in utero*) may be a factor in developing atopy. Over-zealous attention to cleanliness (the hygiene hypothesis) in developed societies (use of antibiotics, reduced exposure to pathogens that might favour a Th1-like environment) may favour a reduction in Treg activity. This environmental factor is demonstrated by the rapid increase of allergy in the eastern part of Germany following reunification in 1990.

In clinical terms, approximately two-thirds of atopic individuals (who can be identified as those with circulating allergen-specific IgE) have ***clinical allergic disease*** (equating to 15%–20% of the UK population). Allergy accounts for up to one-third of school absences because of chronic illness. Allergic disorders include allergic rhinitis (hay fever), allergic eczema, bee and Wiskott–Aldrich serine protease venom allergy, some forms of food allergy, urticaria, and angio-oedema.

Diagnosis

Diagnosis of allergic disease is usually made on the history and backed up by skin-prick testing (insertion of a tiny quantity of allergen under the skin and measurement of the size of the weal) and/or measurement of serum allergen-specific IgE. Mast cell tryptase serum levels peak 1 to 2 hours after an event, remaining high for 24 hours.

Treatment

Avoidance is the first line of therapy. Other measures are as follows:

- ***Antihistamines*** are effective for many immediate hypersensitivity reactions (but have no role in the treatment of asthma).
- ***Corticosteroids*** have several well-identified modifying actions in the allergic process: production of prostaglandin and leukotriene mediators is suppressed, inflammatory cell recruitment and migration are inhibited, and vasoconstriction leads to reduced cell and fluid leakage from the vasculature.
- ***Cysteinyl leukotriene receptor antagonists*** inhibit leukotrienes (LTs) by blocking the type I receptor (e.g., montelukast, used in asthma, particularly the aspirin-induced type).
- ***Omalizumab*** is a MAb that binds IgE. It is used in severe asthma (see Chapter 20) that cannot be controlled with a corticosteroid plus a long-acting β_2 agonist. Treatment must be initiated in a specialist centre where staff have experience of treating severe, persistent asthma.
- ***Dupilumab*** is a MAb that inhibits the biological activity of both IL-4 and IL-13. It has been shown to be beneficial in severe atopic eczema and asthma.
- ***Desensitization (allergen immunotherapy)*** works on the principle that allergy can be prevented by inoculation if the allergen is given in a controlled way. Desensitization is indicated for disorders in which the hypersensitivity is IgE mediated, for example life-threatening allergy to insect stings, drug allergy, and allergic rhinitis. An induction course of subcutaneous injections of increasing doses of the allergen extract, given once every 1 to 2 weeks, is followed by maintenance injections monthly for

Box 6.17 Mechanism of action of desensitization for allergy

Probable mechanism	Effect
IgG blocking antibodies	During repeated exposure to desensitizing allergen, IgG class antibodies develop (especially IgG4 subclass); these compete with the pathogenic IgE for allergen binding and/or prevent IgE–allergen complexes from binding to mast cell high-affinity IgE receptors
Regulation	Exposure to repeated desensitizing allergen induces Treg cells, which recognize allergen but invoke regulatory immune responses, dampening down migration, infiltration, and inflammation
Immune deviation	A shift away from Th2- to Th1-producing CD4 cells results in the generation of cytokines (e.g., interferon-gamma) that are inhibitory to IgE production

2 to 3 years. A systematic review of 51 published randomized, placebo-controlled clinical trials, enrolling a total of nearly 3000 participants, showed a low risk of adverse events with consistent clinical benefit. From an immunological viewpoint, desensitization seems capable of modifying the allergic response at several levels (**Box 6.17**). Sublingual allergen immunotherapy (using grass pollen extract tablets of Phl p 5 from timothy grass) is used in hay fever that has not responded to anti-allergic drugs (the first dose is given under medical supervision) (see Chapter 21).

Anaphylaxis

This is a severe and life-threatening form of allergic reaction. The immediate management of a patient with an allergic reaction is covered in Chapter 11 ('Anaphylaxis' section).

In patients who experience anaphylaxis, the best treatment is prevention. Avoidance of triggering foods, particularly nuts and shellfish, may require almost obsessive self-discipline. Patient education is necessary and many are instructed in the self-administration of adrenaline (epinephrine) and carry pre-loaded syringes. Recent changes in UK law oblige retailers to list all allergens and ingredients in freshly prepared and pre-prepared food that they sell. Desensitization has a well-established place in the management of this disorder, particularly if exposure is unavoidable or unpredictable, as in insect stings. In peanut allergy, it has been shown that early introduction of peanuts in children modulates the response in later life, and this benefit extends to high-risk children with atopic eczema or allergy to another food. Further studies have shown that it is possible to give graded peanut exposure to those already sensitized and that oral desensitization can reduce the risk of anaphylaxis associated with inadvertent exposure in children with a history of peanut allergy. The addition of modified peanut peptides further enhances the success and tolerability of this approach.

AUTOIMMUNE DISEASE

Autoimmunity is when the immune response turns against self, that is recognizes 'self' antigens. The vast array of possible TCRs and antibodies that can be generated by the host make it highly probable that at least a small proportion can recognize self (i.e., are autoreactive). Moreover, a degree of autoreactivity is physiological: the TCR has evolved to interact both with the peptide epitope in the HLA molecule binding groove *and* with the HLA molecule itself.

The critical event in the development of autoimmune disease is when T and B lymphocytes bearing these receptors for 'self' become activated: this leads to loss of immunological tolerance. The major checkpoints that the immune system has in place to prevent this are:

1. removal of TCRs with very strong affinity for 'self' in the thymus
2. the presence of naturally arising regulatory T lymphocytes (Tregs)
3. the requirement for a danger signal to license DCs to activate CD4 T lymphocytes.

Failure of immune tolerance checkpoint 1: thymic education

During thymic education, TCRs with a dangerously high affinity for self are deleted. It has become apparent that this process relies on the thymic expression of self antigens. Situations that compromise the expression of a self protein would be expected to favour the development of autoimmunity. Indeed, in a rare group of patients who develop multiple autoimmune disorders affecting the adrenal and parathyroid glands (autoimmune polyglandular syndrome type 1, Chapter 34), there is a defect in the autoimmune regulator *(AIRE)* gene, which controls thymic expression of a host of self genes. When the gene malfunctions, there is reduced expression of self proteins in the thymus and autoimmune disease is a consequence.

Failure of immune tolerance checkpoint 2: regulatory T lymphocytes

An example of Treg failure is the defect in the gene encoding Foxp3, a critical transcription factor in Tregs, which leads to IPEX (see 'Regulatory T lymphocytes' section). IPEX is very rare but it serves to indicate how Treg defects can lead to autoimmune disease. Laboratory studies in this area are revealing subtle Treg defects in several autoimmune diseases (e.g., type 1 diabetes, multiple sclerosis, rheumatoid arthritis). The role of FoxP3 in regulating peripheral immune responses highlights the control of immune expansion and regulation of immunological 'space'. Another component of this process is the contraction of an immune response once the infection has been dealt with. Autoimmune lymphoproliferative syndrome is a disorder with defects in either Fas, its ligand (FasL or CD95), or the associated intracellular signalling pathway, which in healthy individuals allows immune cells to induce apoptosis in cells displaying abnormal DNA, for example, because of viral infection (**Fig. 6.9**). Individuals develop multiple cytopenias, organ-specific autoimmunity, and lymphoproliferation that may mimic lymphoma. The common problem is the inability to 'switch off' activated T cells. Treatment is with haemopoietic SCT if the disorder is severe. Many patients with multiple cytopenias, including Evans' syndrome (autoimmune thrombocytopenia and haemolytic anaemia), are revealed to have autoimmune lymphoproliferative syndrome defects when appropriately tested.

Failure of immune tolerance checkpoint 3: CD4 T lymphocyte activation against an autoantigen (or its mimic)

For an autoimmune disease to develop, there must be presentation of autoantigens to a naive, potentially autoreactive CD4 T lymphocyte by activated cDCs. Several theories exist to explain this:

- Tissue damage due to infection leads to both the release of hidden self antigens and the provision of sufficient danger signals

to activate cDCs, which in turn activate autoreactive CD4 T lymphocytes, as well as pathogen-specific ones. This is often termed 'bystander activation'.

- A pathogen mimics a self antigen. In the process of mounting an entirely appropriate immune response against the pathogen, T or B lymphocytes are generated that also have the capacity to recognize self. This is termed molecular mimicry.
- Post-translational modification. Self proteins and peptides are modified in such a way that they appear foreign. A good example is an antibody found in patients with rheumatoid arthritis, which recognizes citrulline-modified forms of self peptides.

It is unlikely that, for the common autoimmune diseases (**Box 6.18**), there is a 'single tolerance checkpoint' explanation. Rather, it is likely that multiple subtle defects, at various checkpoints, are at play.

Mechanisms of tissue damage in autoimmune disease

Fig. 6.17 illustrates potential mechanisms of immune damage in autoimmune disease.

Tissue damage via chronic inflammation

In a number of autoimmune diseases (e.g., type 1 diabetes, multiple sclerosis), autoreactive T lymphocytes are likely to be the main drivers of disease and tissue damage. Th1 cells, CTLs, and Th17 cells induce chronic inflammation and release cytokines that recruit other effector cells (macrophages) or are directly toxic (e.g., insulin-producing β cells are susceptible to the combined effects of IL-1β, IFN-γ, and IL-17 in type 1 diabetes).

Box 6.18 Some autoimmune diseases and their autoantigens

Disease	Antigens
Addison's disease	21 α-hydroxylase
Goodpasture's syndrome	Alpha-3 chain of type IV collagen
Granulomatosis with polyangiitis	Neutrophil proteinase 3
Graves' thyroiditis	Thyroid-stimulating hormone receptor
Hashimoto's thyroiditis	Thyroid peroxidase, thyroglobulin
Multiple sclerosis	Myelin basic protein Myelin oligodendrocyte glycoprotein
Myasthenia gravis	Acetylcholine receptor, muscle-specific kinase (MuSK)
Pemphigus vulgaris	Desmoglein-3
Pernicious anaemia	H^+/K^+-ATPase, intrinsic factor
Polymyositis/ dermatomyositis	Transfer RNA synthases (e.g., Jo-1, PL7, PL12)
Primary biliary cholangitis	Pyruvate dehydrogenase complex
Rheumatoid arthritis	Citrullinated cyclic peptide, IgM
Scleroderma	Topoisomerase
Sjögren's syndrome	Ro/La ribonuclear proteins
Systemic lupus erythematosus	Sm/RNP, Ro/La (SS-A/SS-B), histone and native double-stranded DNA
Type 1 diabetes	Pro-insulin, glutamic acid decarboxylase, IA-2, ZNT8
Vitiligo	Pigment cell antigens

IgG4 disease

Pathophysiology

IgG4-related disease (IgG4-RD) is characterized by chronic inflammation, fibrosis, and the infiltration of IgG4-positive plasma cells into a wide range of target tissues (**Box 6.19**). These include the pancreas, salivary glands, lacrimal glands, bile ducts, kidneys, lymph nodes, and others, with the specific clinical manifestations depending on the organs involved and varying widely between individuals. The exact cause of IgG4-RD is not fully understood; however, class-switched B-cells producing IgG4 are central to the pathogenesis and appear to respond to multiple auto-antigens.

IgG4 antibodies are a subclass of immunoglobulins with anti-inflammatory properties. However, their excessive production can lead to immune complex formation and tissue damage associated with dysregulated T-cell responses. An imbalance in cytokine signalling (with ILs 4 and 10 promoting IgG4 production and regulatory T-cell responses) promotes inflammation and fibrosis, and activation of fibroblasts can result in fibrosis or scarring of affected organs, which impairs their normal function. No unifying genetic predisposition has yet been identified.

Clinical features

IgG4-related disease is usually insidious in onset, consistent with the slow accumulation of inflammatory foci in tissues. At the time of diagnosis, there is often significant dysfunction, for example, in autoimmune pancreatitis there is loss of both exocrine and endocrine function (see 'Autoimmune chronic pancreatitis' section in Chapter 24). Clinical presentations may include pseudotumours with local anatomical disturbance (e.g., proptosis from retrobulbar lesions) to metabolic complications such as thyroiditis or pancreatitis. In some presentations, such as retroperitoneal fibrosis or pulmonary lesions, the diagnosis may only be considered following incidental imaging findings. The salivary glands and pancreas are the most commonly affected sites, with multiple organ involvement in the majority of cases.

The estimated incidence is 0.3–1 per 100 000 of population with a prevalence of 62 per million. There is equal sex distribution.

Diagnosis

The diagnosis is usually established by appropriate imaging findings of an affected site, and there are no universally accepted consensus criteria. A definite diagnosis requires:

- multiple affected sites with characteristic swelling or nodules (diagnosed clinically or radiologically)
- a significant rise in serum IgG4 (>135 mg/dL)
- the presence of classical histopathological findings with storiform fibrosis, high percentage of IgG4 positive plasma cells, or dense lymphocytic infiltrate with plasma cells and fibrosis.

Management

Glucocorticoids are usually seen as first-line management, although 40% may not achieve remission with steroids alone and their use is compounded by the high rate of pre-existing pancreatic endocrine insufficiency with pancreatic disease involvement. Remission rates are higher (and relapse rates lower) in individuals treated concomitantly with either low-dose cyclophosphamide (50–100 mg/day) or mycophenolate mofetil (1000–1500 mg daily). The use of B-cell depleting therapy (e.g., the anti-CD20 MAb rituximab) is often associated with rapid reduction in active lesions, although no therapy has any major impact on significantly fibrotic tissue. A single course of anti-CD20 therapy can induce remission for 6 to 18 months. Based

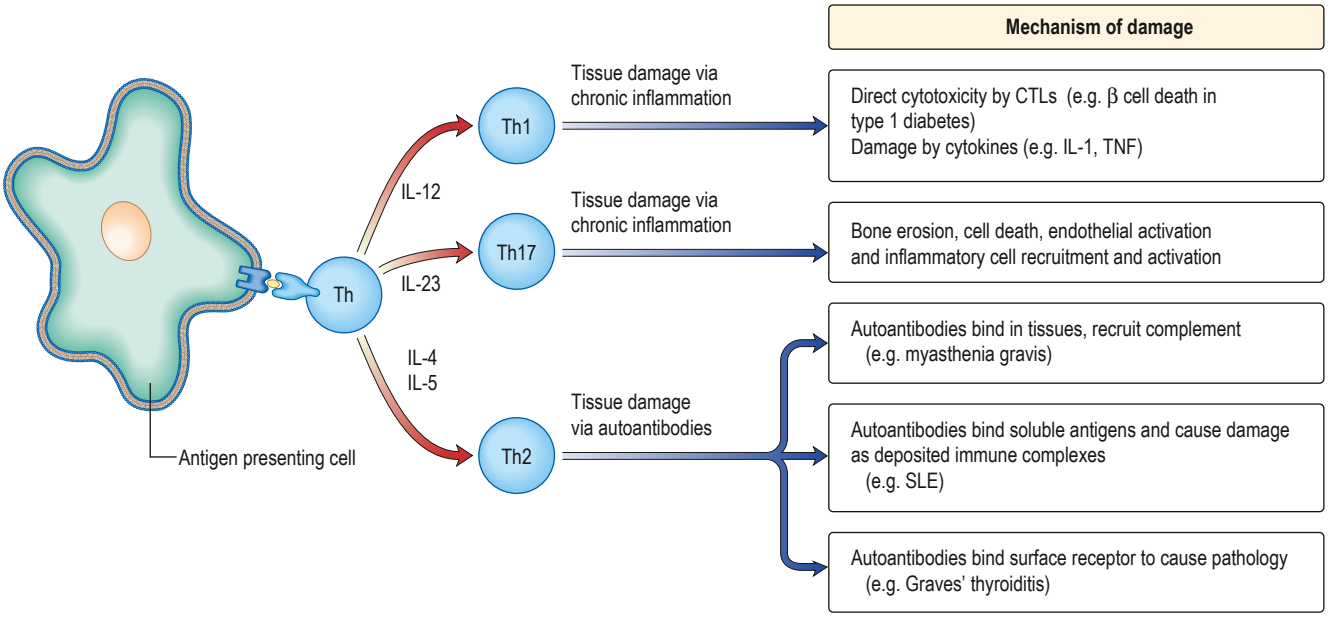

Fig. 6.17 Potential mechanisms of immune damage in autoimmune disease. *CTL,* Cytotoxic T lymphocyte; *IL,* interleukin; *SLE,* systemic lupus erythematosus; *Th,* helper T lymphocyte; *TNF,* tumour necrosis factor.

Box 6.19 IgG4-related disease

Disease	Affected Organs
Autoimmune pancreatitis	Pancreas
IgG4-related cholangitis	Bile ducts, liver
Mikulicz's syndrome	Salivary glands
IgG4-related dacryoadenitis	Lacrimal glands
Eosinophilic angiocentric fibrosis	Eye, orbit
Retroperitoneal fibrosis	Retroperitoneum
IgG4-related tubulointerstitial nephritis	Kidneys
IgG4-related lung disease including inflammatory pseudotumours	Lungs
IgG4-related lymphadenopathy	Lymph nodes
IgG4-related aortitis	Aorta and other blood vessels
Riedel's thyroiditis	Thyroid gland
Hypertrophic pachymeningitis	Brain and spinal cord meninges (rare)
IgG4-related dermatopathy	Skin (rare)
IgG4-related cardiovascular disease	Heart and blood vessels (rare)
IgG4-related prostatitis	Prostate gland (rare)

on these findings, other experimental B cell-depleting approaches are in current clinical trials.

Prognosis

The long-term prognosis in IgG4-related disease is highly dependent on the extent of the tissue fibrosis and organ dysfunction at presentation, much of which can be irreversible. Relapse is common and so maintenance therapy is usually advised until there is no clinical or radiologic evidence of relapse for 1 to 3 years. Some patients will have relapses many years after their initial presentation, so long-term follow-up is advised.

Tissue damage via autoantibodies

Examples of damage through direct binding to a target cell or structure, with recruitment of complement and other destructive processes, include:

- ***myasthenia gravis*** (autoantibodies against the acetylcholine receptor cause damage to the neuromuscular junction)
- ***autoimmune haemolytic anaemia*** (autoantibody targets red blood cell autoantigens, leading to lysis)
- ***Goodpasture's syndrome*** (anti-glomerular basement membrane autoantibodies damage glomerular integrity).

Autoantibodies can also bind their antigen in the circulation to form immune complexes. When these are deposited in the tissues, complement- and cell-mediated immune reactions are initiated. Immune complexes preferentially deposit in sites such as the kidney glomerulus, leading to chronic kidney disease. This is a feature of SLE, in which the autoantigen within the immune complexes is host-derived double-stranded DNA.

Autoantibody binding may act by binding to surface receptors. In Graves' thyroiditis, for example, the anti-thyroid stimulating hormone receptor antibody stimulates follicular cells to produce thyroid hormones, leading to hyperthyroidism.

Common autoimmune diseases

Over 80 diseases are now classified as autoimmune. The autoimmune origin of some of these diseases is very clear-cut but that is not so for others, and both major and minor factors must be defined.

Major criteria

- There is evidence of autoreactivity (e.g., activated or memory autoreactive T lymphocytes or autoantibodies).
- A clinical response to immune suppression can be demonstrated.
- Passive transfer of the putative immune effector (e.g., autoreactive T lymphocyte or autoantibody) causes the disease (this is the hardest criterion to satisfy in humans but is the most stringent).

Minor criteria

- An animal model exists that resembles the human condition, and in which there is a similar loss of immunological tolerance to self.
- There is evidence that, in the animal model, passive transfer of the putative immune effectors reproduces the disease in a naive animal.
- There is an HLA association (a frequent indicator that a disease is autoimmune).

ORGAN REJECTION IN CLINICAL TRANSPLANTATION

The outcome of an allograft (i.e., a graft between genetically non-identical members of the same species) in the absence of adequate immunosuppressive therapy is ***immunological rejection***. Histological analysis of rejected solid organs shows a range of immunological processes in action (**Box 6.20**). With modern tissue-matching approaches, hyperacute rejection should never occur and acute rejection can usually be prevented or treated with immunosuppression. The process of chronic rejection typically takes place over several years and is the main reason for organ graft failure.

The antigens recognized in acute and chronic graft responses are donor HLA molecules (alloantigens):

- In acute rejection, it is thought that the predominant response is against intact HLA molecules ***(direct allorecognition)*** and is mediated by $CD4^+$ and $CD8^+$ T lymphocytes.
- As the rejection process becomes more chronic, peptides from donor HLA molecules are processed and presented to T lymphocytes by host HLA molecules ***(indirect allorecognition)*.**

In haematopoietic stem cell transplantation the recipient may be recognized by the donor immune system as 'foreign' giving rise to GVHD. For GVHD to occur, there must be impaired T lymphocyte function in the recipient and the transfer of immunocompetent T lymphocytes from an HLA non-identical donor.

IMMUNE-BASED THERAPIES

Manipulation of the immune response in a therapeutic setting has seen many successes, as evidenced by the control of organ rejection in clinical transplantation through targeted immunosuppression (**Box 6.20**). Monoclonal antibodies offer the opportunity to neutralize the unwanted effects of cytokines or to direct immune responses, drugs, toxins, or irradiation against a specific target, whether it be a tumour cell or an immune cell involved in a damaging autoimmune response. Natural antiviral mediators, such as the IFNs, are already in the clinic as therapies for chronic viral infection, among other things. Genetic manipulation of T lymphocytes has generated a new class of cellular therapies.

Monoclonal antibody therapy (targeted therapy)

The combined power of MAb and recombinant DNA technology has led to a series of 'designer' drugs, which have been engineered so that they:

- are exquisitely targeted
- have optimal effector function
- do not carry antigenic segments that may incite a neutralizing response in the host.

In general, this has meant a process of 'humanizing' antibodies of mouse origin and selecting an appropriate effector function. For example, a MAb designed to remove a subpopulation of lymphocytes from the patient should have good complement-fixing ability or bind well to receptors on phagocytes, whereas a MAb designed to 'modulate' a cell without depletion should have these functions removed. Many examples of MAbs in current use are described in individual chapters. Therapeutic MAbs are potent modifiers of essential components of immune responses and therefore carry both predictable and unpredictable risks. For example, anti-TNF therapies increase the risk of invasive viral and mycobacterial infection. The new inhibitors of integrins, such as natalizumab, have been associated with JC virus reactivation in patients, leading to progressive multifocal leukoencephalopathy. Since integrins are essential for the migration of T cells into tissues, the blockade prevents egress into inflammatory sites but also reduces immune surveillance of infection.

Immunotherapy, including most monoclonal antibodies, brings unique challenges for drug safety as both efficacy and toxicity is difficult to predict for individual patients. The side-effects of immunotherapy can be life-threatening with severe immunodeficiency being a risk

Box 6.20 Classification of rejection

Description	Timing of response	Immunological mechanism	Management
Hyperacute	Minutes to hours	Pre-formed antibodies (e.g., anti-blood group, anti-HLA)	Prevention with typing to avoid mismatch, or depleting antibodies for 'high-risk' transplants
Accelerated acute	1–5 days	T lymphocytes	Combinations of immune suppression used prophylactically and as required, for example corticosteroids, ciclosporin, tacrolimus, sirolimus, polyclonal antibodies (e.g., against all T lymphocytes) and monoclonal antibodies (e.g., against activated T lymphocytes expressing CD25)
Acute	7–14 days onwards	T lymphocytes	
Chronic	Months to years	Antibodies, complement, endothelial cell changes	Chronic oral immunosuppression

HLA, Human leucocyte antigen.

of immunotherapy use in autoimmune disease, and severe autoimmunity being a risk of immune checkpoint targeting in cancer treatment.

Chimeric antigen receptor T-cell therapy

Chimeric antigen receptor T-cell therapy is an exciting new approach to the treatment of haematological malignancy. In the first licensed product of its kind (tisagenlecleucel) for B lymphocyte leukaemia and lymphoma, blood is taken from the patient and T lymphocytes are separated out. Using a retrovirus, the T lymphocytes are modified to express the CAR (which comprises a receptor for CD19 coupled to a powerful intracellular co-stimulation molecule). The CD19 target is expressed on all B lymphocytes (including lymphomas and B-cell leukaemias). The CAR-modified T lymphocytes are infused back into the patient and will then kill all target B lymphocytes. The main risk of this therapy is massive cytokine release from CAR T lymphocyte activation. Since all B lymphocytes (and not just the tumour cells) are removed, the patients develop antibody deficiency and require life-long immunoglobulin replacement. Specific co-stimulation domains in the CAR T cells have been shown to aid long-term persistence, correlating with prolonged protection against disease relapse. Further targets and approaches are now in clinical trials.

Immunosuppressive drugs

- ***Glucocorticosteroids*** (cortisone, hydrocortisone, prednisone, and prednisolone) are the most commonly used steroids and have a variety of effects on immune function, including:
  1. potent effects on monocyte production of the pro-inflammatory cytokines IL-1 and TNF-α
  2. blockade of T lymphocyte production of IL-2 and IFN-γ
  3. reduced activation and migration of a range of innate and adaptive immune cells.
- ***Ciclosporin, tacrolimus, and sirolimus (rapamycin)*** have similar effects on T lymphocyte function. Ciclosporin and tacrolimus are calcineurin inhibitors and inhibit Ca^{2+}-dependent second messenger signals in T lymphocytes following activation via TCRs. By contrast, sirolimus achieves a similar effect but acts at the level of post-activation events in the nucleus.
- ***Purine analogues*** such as azathioprine are also frequently used as anti-inflammatory drugs in conjunction with steroids and act by inhibiting DNA synthesis in dividing adaptive immune cells. Similar in mode of action, but more powerful, is mycophenolate mofetil.
- ***Alkylating agents*** that interfere with DNA synthesis, such as cyclophosphamide, are also used for immunosuppression.
- ***Tyrosine kinase inhibitors*** have profoundly improved the treatment of some malignancies with previously very poor outcomes. Tyrosine kinases are ubiquitous regulators of cell activation, promoting cell division and proliferation in response to growth factors and cytokines. Inhibition of the signalling pathways can lead to immune suppression. In immune cells, the relevant kinases include the Janus kinases (JAK) that signal through the STAT pathway. Inherited mutations in JAK-STAT pathway molecules can lead to immunodeficiency or, if the mutation causes constant (constitutive) activation, can give rise to uncontrolled cell division independent of growth factors: that is, cancer. Specific tyrosine kinase inhibitors have been developed for a range of cancers and as T- and B-cell immune suppressants.

Cytokines and anticytokines

Cytokines are pleiotropic agents with powerful pro-inflammatory and immunosuppressive effects and are attractive targets for therapies that inhibit or enhance their function. TNF-α targeting agents (cytokine modulators) have been tested in rheumatoid arthritis, as has the recombinant IL-1 receptor antagonist anakinra, although with much less success. Nonetheless, the good safety profile of anakinra has prompted its use in other diseases, and a beneficial effect has been shown in haemophagocytic lymphohistiocytosis, which may have an innate inflammatory component. IL-2 and its receptor (CD25) are also obvious candidates for immune therapies, and basiliximab which targets CD25 is used to induce immunosuppression during organ transplantation. IFNs are successfully used to boost pro-inflammatory immunity in chronic virus infection.

Restoring tolerance in autoimmune diseases and allergy

One of the goals of immune-based therapies for autoimmune disease is not simply to achieve immunosuppression but also to restore immunological tolerance against the relevant autoantigens. In animal models, an effective means of achieving this is to administer the autoantigen itself, or key peptide epitopes from it. This is known as antigen-specific or peptide immunotherapy and is under trial for several autoimmune diseases, where it appears to induce Tregs. The diseases that have the most advanced clinical data are in the field of allergy. For example, administration of cocktails of peptides of the cat allergen Fel d 1 has led to a reduction in detectable skin-prick responses and improved clinical scores.

Intravenous immunoglobulin

Intravenous immunoglobulin is a preparation of polyspecific IgG chemically purified from the plasma of large numbers (>20 000) of healthy donors. IVIg is used as a replacement therapy in patients with primary and secondary antibody deficiencies. When it is used for inflammatory conditions, however, there is also a therapeutic benefit, although randomized, placebo-controlled studies are few. In the USA, IVIg is recommended only for a small number of diseases in addition to antibody deficiency. These include immune-mediated thrombocytopenia, Kawasaki's disease, chronic inflammatory demyelinating polyneuropathy, and post-transfusion purpura.

The mechanism of action is not known, but may include:

- blockade of Fc receptors to prevent pathogenic antibodies binding to phagocytes
- inhibition of autoantibody synthesis by B lymphocytes
- modulation of dendritic cell function
- inhibition of complement activation
- inhibition of specific cytokines
- induction of T-cell regulation.

CORE SKILLS AND KNOWLEDGE

All prescribers need to learn how to use medications safely and effectively. This requires mastery of the principles in the first half of this chapter, which cover key concepts including pharmacokinetics, pharmacodynamics, drug interactions, and adverse drug reactions to apply in the specific clinical situations and related scenarios described in the second half of the chapter. Pharmacists, whether independent prescribers themselves or not, play a critical role in helping doctors make safe and effective choices when prescribing.

Key skills related to prescribing and therapeutics include:

- Developing a systematic approach to prescribing
- Using key pharmacological principles to select and administer an appropriate drug
- Learning parameters to monitor patients for both efficacy of treatment and unintended adverse reactions/toxicity
- Using information sources to assist in safe prescribing, including avoiding drug–drug interactions (DDIs).

There are many practical ways to learn prescribing skills: reviewing patients' medication charts on ward rounds, rewriting medication charts under supervision, observing annual medication reviews in primary care, reporting adverse drug reactions (e.g., using the 'Yellow Card' scheme in the UK), or working with pharmacists reviewing inpatient or outpatient prescriptions. Providing evidence of competence in these domains is increasingly required in modern healthcare. In the UK all new doctors must pass the Prescribing Safety Assessment (PSA) exam before they qualify, which covers the principles covered in this chapter.

BACKGROUND

Prescribing a medicine is the most common healthcare intervention performed by doctors and hence the correct choice of medication and the act of prescribing are key skills required by all doctors. The 1984 'Nairobi Declaration' emphasized that prescribing should be to the ***right patient*** with the ***right drug*** at the ***right dose*** and at an ***affordable cost***. Thus the prescription of a medicine needs to take into account the potential benefits and harms of that medicine and ensure that every step is taken to maximize the therapeutic benefit:harm ratio. The key principles of therapeutics and prescribing are described in **Box 7.1**.

WHY DO PATIENTS NEED DRUGS?

There are many reasons for prescribing drugs to patients:

- ***Disease treatment.*** A reliable diagnosis is usually secured before starting treatment to ensure that a patient is not exposed unnecessarily to the hazards of a particular intervention. However, a prior diagnosis may not be possible in every circumstance. For example, in sepsis the initiation of ***blind*** (empirical) antimicrobial therapy is justified, as delay would expose a patient to serious hazards (see Chapter 12).
- ***Symptom relief.*** Drugs are frequently used in the relief of symptoms, for example, in the treatment of severe pain, constipation, or pruritus. It is important to monitor for effectiveness and to consider stopping the medication if it is no longer indicated.
- ***Prevention.*** Medicines are also given to otherwise healthy individuals. In such circumstances, there must be a very clear imperative to ensure that the benefits to the individual outweigh the harm. Examples include:
  - primary cardiovascular prevention with lipid-lowering therapy (i.e., statins)
  - oral contraceptives for prevention of pregnancy

THERAPEUTIC CHOICE

The choice of the drug (**planned management** or therapeutic choice) depends on clinical factors (such as age of the patient,

Box 7.1 Key principles of prescribing

- ***Be clear about the reasons for prescribing.*** Secure, where appropriate an accurate diagnosis and have clear aims of what the benefits will be from prescribing the drug.
- ***Obtain an accurate drug history.*** Patients should be asked about their current medications, over-the-counter herbal medicines, and illicit drug usage. A past history of intolerances, including true allergic reactions, is also required.
- ***Obtain an accurate history of other factors that might affect the benefit:harm ratio of drugs.*** Take note of liver and renal impairment, age, whether patient is pregnant or breast-feeding, and co-morbidities.
- ***Establish what the patient expects from the drug, and deal with any concerns.*** Provide good information for the patient and answer any questions clearly.
- ***Select the most clinically effective, cost-effective, and safe medicine for the patient, based on an assessment of the individual.*** Optimize the benefit:harm balance by choosing the right dose and frequency and the right drug, in the best formulation, route of administration, and duration of treatment. Prescribe within the licence of the medicine, except when no alternative is available.
- ***Adhere to guidelines and local and national formularies.*** Based on the needs of the individual patient, use the most reliable information to identify the medicine most suited to the patient.
- ***Write prescriptions legibly using the correct documents, or prescribe electronically, depending on availability.*** Take care to avoid medication errors.
- ***Monitor the patient for both efficacy and safety after starting the drug.*** This is essential to optimize dose, identify adverse reactions, and determine when to stop the medicine. Report adverse reactions using spontaneous reporting schemes, if appropriate.
- ***Communicate clearly with other healthcare professionals and patients about the reasons for prescribing decisions.*** Communication is essential to optimize the benefit:harm ratio of drugs, particularly when there are multiple prescribers for a single patient.
- ***Prescribe within your competencies.*** Prescribing should be within the limits of your knowledge and experience. Do not be afraid to ask for advice and ensure that complex prescriptions are checked (e.g., when calculating doses).

Adapted from British Pharmacological Society; https://www.bps.ac.uk/education-engagement/teaching-pharmacology/ten-principles-of-good-prescribing.

concomitant disease, and concurrent therapy), pharmaceutical factors (the availability of other medicines and relative cost-effectiveness), and, increasingly, individual (host) factors.

Selecting the right drug (therapeutics) involves three elements:

- the drug's clinical efficacy for the proposed use
- the balance between the drug's efficacy and safety
- patient preference.

The most common approach to assessing a drug's efficacy is the randomized controlled trial (RCT) (**Box 7.2**), although other approaches can be informative (see Chapter 4). Although common adverse reactions are usually identified in early-phase drug development studies and RCTs, rare (often serious) adverse reactions are often only discovered after drugs are licensed by post-marketing surveillance studies (pharmacovigilance) (see **Box 7.2**). All patients should be offered the opportunity to be involved in making decisions about their medical treatment, including those about medications, by employing a ***shared decision-making*** approach (see Chapter 1). Patients' own preferences should be discussed to enable them to be equal partners in decision-making about whether, and how, they wish to be treated. This approach improves 'concordance' with treatment regimens.

Box 7.2 Evaluation of new drugs

Phase I: Healthy human subjects

- First use in humans
- Evaluation of safety and toxicity
- Pharmacokinetic assessment
- Sometimes pharmacodynamic assessment
- Approximately 100 subjects

Phase II: First assessment in patients

- Safety and toxicity evaluated
- Dose range identified
- Pharmacokinetic and pharmacodynamic monitoring
- Approximately 500 subjects

Phase III: Use in wider patient population

- Efficacy main objective
- Safety and toxicity also monitored
- Often multicentre trials
- Approximately 2000 patients involved

Phase IV: Post-marketing surveillance

- All patients prescribed drug monitored
- Efficacy, safety, and toxicity measured
- Quantification of unusual drug adverse effects
- Yellow Card and spontaneous reports of adverse reactions
- Often very large numbers of patients observed

THE DOSE

The dose administered to the patient is crucial in determining both efficacy and safety of medicines. Appropriate drug dosages will usually have been determined from the results of so-called '***dose-ranging***' studies during the drug development programme (see **Box 7.2**).

In some cases, drug doses are ***fixed***, with all patients being given the same dose, for example, levonorgestrel for emergency contraception (see Chapter 47). However, these situations are unusual. Medications used for blood pressure, diabetes, pain control, and anaesthesia, to name a few examples, have an initial dose selected based on patient parameters and then the dose is titrated to response or other indicators.

More commonly, doses are ***titrated***. For many drugs, there are wide inter-individual variations in response. As a consequence, while a particular dose may, in one person, lack any therapeutic effect, the same dose in another may cause serious toxicity. This is because the concentration of drug reaching the systemic circulation ('exposure') varies between individuals even for the same dose, and it is exposure that determines the response to drugs, both in terms of both efficacy and safety. Pharmacokinetic factors (including differences in the rates of drug absorption, metabolism, and excretion) are the main determinants of such variability in exposure between individuals.

Variability in response, at an equivalent exposure, can also be due to ***pharmacodynamic factors***, where there are differences in the sensitivity of the drug target (typically due to differences in expression or biological activity of different receptors, enzymes, ion channels, transporters, DNA, or transcription factors).

Because it is not easy to measure exposure, we use the dose as a proxy. Furthermore, it is not always possible to predict

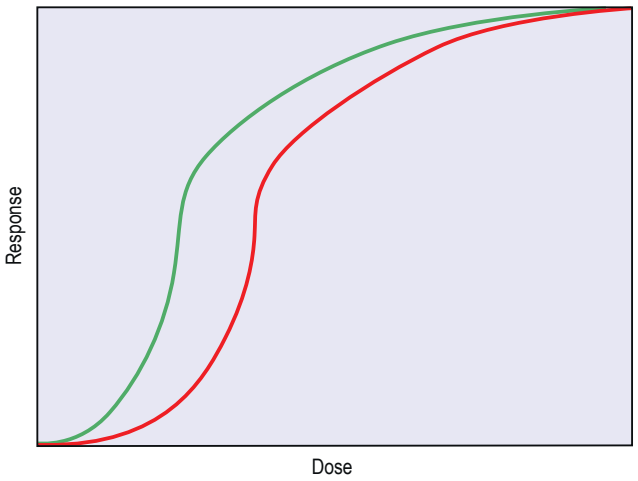

Fig. 7.1 Dose–response curve, showing the variable response of the same dose in different patients. The patient represented by the red line requires a higher dose to achieve the same desired effect than the patient represented by the green line and may therefore be at risk of experiencing more adverse effects.

pharmacodynamic variability. For these two reasons, prescribers should start most drugs at a low dose and titrate to the ***lowest effective dose***. This can help overcome the inter-individual variability in the dose–response curve, whereby there is an increase in response with an increase in dose, until a plateau effect is reached (Fig. 7.1).

Pharmacokinetics

Pharmacokinetics is the study of ***what the body does to a drug***. This can be divided into four different processes: absorption, distribution, metabolism, and excretion. Age, body weight, renal and hepatic function, concomitant drugs, co-morbidities, diet, smoking and alcohol, and genetic factors are all known to affect pharmacokinetics and so increase the inter-individual variation in required drug dose.

Absorption

Drugs can be administered by various different routes (Box 7.3) but oral administration is the most common. The main determinants of a drug's plasma concentration after oral administration are its bioavailability (Box 7.4) and its rate of systemic clearance (by hepatic metabolism or renal excretion). A drug's oral bioavailability depends on the extent to which it is:

- Destroyed in the gastrointestinal tract, especially by gastric acid.
- Unable to cross the gastrointestinal epithelium. Drugs can cross either by passive diffusion or by active uptake by gut epithelial transporters. Transporters can generally be divided into influx transporters, which increase uptake of drug (e.g., the PEPT1 influx transporter is required for the uptake of penicillins), and efflux transporters, which limit the absorption of a drug (e.g., P-glycoprotein is an efflux transporter that limits digoxin absorption).
- Metabolized by the liver before reaching the systemic circulation ('first-pass' metabolism). First-pass metabolism can be avoided by non-enteral routes.

Distribution

This is the process by which drugs are distributed from the bloodstream to organs and cells. Most drugs will circulate in the bloodstream bound to plasma proteins, most commonly albumin. Free drug, which is the active drug, is usually in dynamic equilibrium with protein-bound drug, with the latter being released as the free drug concentration decreases. The volume of distribution described the amount of body tissue into which a drug redistributes and is calculated by dividing the total amount of drug in the body (mg) by the plasma concentration (mg/L). Drugs with small volumes of

Box 7.3 Routes of drug administration

Route	Description	Example
Buccal	Rapid absorption, avoids first-pass metabolism	Midazolam for status epilepticus
Epidural	Administration of drug into epidural space around the spinal cord	Epidural anaesthetic for pain relief during labour
Inhaled	Achieves high concentrations at site of disease with limited systemic absorption	Salbutamol for acute asthma relief
Intramuscular	Easier than intravenous route but absorption is less predictable	Adrenaline (epinephrine) in anaphylaxis
Intranasal	Often used for local delivery	Intranasal corticosteroids in allergic conditions
Intrathecal	Used to achieve high local levels	Methotrexate in acute lymphoblastic leukaemia
Intravenous	100% of dose enters systemic circulation but invasive and inconvenient	Intravenous teicoplanin for treatment of invasive MRSA infections
Oral	Most common route, convenient, but subject to first-pass metabolism for certain drugs	Ramipril for hypertension
Per rectum	For local administration: for rectal/colonic disorders For systemic absorption: when oral or intravenous routes not possible	Prednisolone enema for rectal inflammatory bowel disease Diazepam for seizures
Subcutaneous	Good absorption, can be self-administered	Insulin for diabetes
Sublingual	Rapid absorption, avoids first-pass metabolism	GTN for acute relief of angina chest pain
Topical	Used for local application of cutaneous or joint diseases	Corticosteroids for eczema
Transdermal	Absorption through the skin via a patch	Nicotine replacement therapy for smoking cessation

Box 7.4 Key pharmacokinetic parameters

- ***Area under the curve:*** a plasma concentration time curve and a measure of the actual body exposure to a drug after administration of a dose of the drug; expressed in mg/L × h.
- ***Bioavailability:*** the fraction or proportion of a drug that enters the systemic circulation. Thus while intravenous formulations have 100% bioavailability, administration via other routes will have <100% bioavailability.
- ***Clearance:*** the volume of plasma cleared of the drug per unit time.
- **C_{max}:** peak plasma concentration after drug administration.
- ***Concentration:*** the amount of drug in a given volume. Even when the dose is similar, concentrations (and thus exposure) will vary between individuals.
- ***Dose:*** the amount of drug administered. This may be micrograms, milligrams, or grams. Occasionally, drugs are administered per body weight or body surface area.
- ***Loading dose:*** an initial larger dose to achieve immediate therapeutic plasma or tissue drug concentration. It is usually reserved for medical emergencies but can also be used for drugs with long half-lives, which would otherwise take a long time to reach desired therapeutic steady-state concentration.
- ***Elimination half-life:*** the time required for the drug concentration to reach half its original value. With repeat dosing, for most drugs, it takes four to five half-lives to approach steady state.
- ***Steady state:*** the situation for most drugs where drug intake is in dynamic equilibrium with drug elimination.
- **T_{max}:** time to reach C_{max}.
- **V_d:** volume of distribution—the apparent volume in which a drug is distributed. Drugs with low V_d are predominantly in the circulation, while drugs with a high V_d have diffused into the peripheral tissue compartment, such as body fat. Drugs with a low V_d are amenable to removal by haemodialysis in overdose, while drugs that have a high V_d are not.

distribution stay in the plasma, while those with larger volumes of distribution move freely into other body tissues such as adipose tissue.

Metabolism

Metabolism takes place in many different organs the liver being the most common site. Drug metabolism converts lipid-soluble drugs to water-soluble metabolites for excretion by the kidneys. Metabolism usually inactivates a drug, but in some cases, it can convert a prodrug into an active drug (e.g., enalapril to enalaprilat) or lead to the formation of metabolites that are toxic (N-acetyl-para-benzoquinoneimine in paracetamol overdose). Drug metabolism occurs in two stages:

- ***Phase I:*** oxidation, reduction, or hydrolysis. This is largely undertaken by a family of isoenzymes known as the cytochrome P450 system. Inhibition or induction of cytochrome P450 isoenzymes is a major cause of drug–drug interactions (DDIs) (see Chapter 7).
- ***Phase II:*** conjugation with glucuronate, sulphate, or other substances. This renders drugs more water soluble.

Variability in the genes that encode drug-metabolizing enzymes (**Box 7.5**) is a major determinant of the inter-individual differences in the therapeutic and adverse responses to drug treatment. One-quarter of all licensed medicines are substrates for a single P450 isoenzyme, CYP2D6. The poor metabolizer (reduced function) CYP2D6 phenotype leads to accumulation of drugs when used at conventional doses, increasing the risk of toxicity with drugs such as selective serotonin reuptake inhibitors or antipsychotics (e.g., risperidone) that undergo CYP2D6 metabolism.

Reduced conversion of a prodrug to active metabolite may also compromise efficacy in some patients; for example, poor metabolizers of CYP2D6 do not experience analgesic benefit with codeine, which is a prodrug converted to morphine by CYP2D6. Conversely, some individuals have multiple copies of the normal *CYP2D6* gene and are described as ultra-rapid metabolizers. These patients display increased drug metabolism and therapeutic failure at conventional doses for most drugs, although ultra-rapid metabolism can also lead to increased toxicity for prodrugs such as codeine, because there is increased conversion to morphine.

Understanding the role of genetic differences in drug metabolism can allow prescribing to be tailored to individual patients:

- Warfarin: variation in CYP2C9 activity and vitamin K epoxide reductase complex *(VKORC1)* genes affect warfarin pharmacodynamics. Determining the genotype before prescribing can improve anticoagulation control.

Mercaptopurine/Azathioprine: patients with reduced or absent activity of the enzyme thiopurine methyltransferase (TPMT) are at high risk of bone marrow suppression at conventional doses of thiopurine drugs such as mercaptopurine or azathioprine. Pre-treatment activity determination allows appropriate dose selection.

Excretion

Excretion of drugs and their metabolites occurs most commonly via the kidneys, although faeces, breath, and sweat represent other routes of excretion. In the kidney, free drug is filtered through the glomerulus and excreted in the urine as long as it is water soluble. Lipid-soluble drugs are usually reabsorbed into the circulation in the renal tubules. Some drugs, such as benzylpenicillin, are actively excreted by cells in the proximal convoluted tubule. Renal impairment reduces the elimination of water-soluble drugs, and thus reduction of the maintenance dose is usually undertaken to avoid toxicity.

Pharmacodynamics

Pharmacodynamics is the study of ***what the drug does to the body***. Pharmacodynamic sources of variation in drug action can be due to changes in the expression of the drug target, their affinity or their selectivity. This can be caused by genetic factors and also by disease. For example, in hepatic impairment, pharmacodynamic factors can determine the sensitivity to a drug, adding to changes in pharmacokinetics.

Genetic factors affecting drug pharmacodynamics also play a role in determining how individuals respond to drugs. For example, variation in the β_2-adrenoceptor gene can affect response to the most common bronchodilator (salbutamol) in asthma. Glucose-6-phosphate dehydrogenase deficiency the most common enzyme deficiency, can predispose patients to acute red cell haemolysis with certain drugs such as primaquine, dapsone, sulphonamides, and rasburicase.

The biggest clinical advances in this area have occurred in two therapeutic areas: targeted cancer therapies and drug safety:

- Sequencing cancer genomes has identified novel driver mutations, leading to the development of targeted therapies. These have seen remarkable success: for instance, trastuzumab is only of value in women with breast cancer whose malignant cells express the HER2 epidermal growth factor receptor.
- Some immune-mediated adverse drug reactions involving the skin and liver can now be predicted by genotyping for certain human leucocyte antigen (HLA) polymorphisms. For example, pre-prescription genotyping for *HLA-B*57:01* has largely

Box 7.5 Genetic polymorphisms affecting drug response

Organ or system involved	Associated gene/allele	Drug/drug response phenotype	Pharmacokinetic/pharmacodynamic
Blood			
Red blood cells	*G6PD* *TPMT*2*	Primaquine and others Azathioprine/6MP-induced neutropenia	Pharmacodynamic Pharmacokinetic
Neutrophils	*UGT1A1*28*	Irinotecan-induced neutropenia	Pharmacokinetic
Platelets	*CYP2C19*2*	Stent thrombosis	Pharmacokinetic
Coagulation	*CYP2C9*2, *3, VKORC1*	Warfarin dose requirement	Mixed
Brain and peripheral nervous system			
CNS depression	*CYP2D6*N*	Codeine-related sedation and respiratory depression	Pharmacokinetic
Anaesthesia	Butyrylcholinesterase	Prolonged apnoea	Pharmacokinetic
Peripheral nerves	*NAT-2*	Isoniazid-induced peripheral neuropathy	Pharmacokinetic
Drug hypersensitivity and liver injury			
	*HLA-B*57:01*	Abacavir hypersensitivity	Pharmacodynamic
	*HLA-B*15:02*	Carbamazepine-induced Stevens–Johnson syndrome (in some Asian groups)	Pharmacodynamic
	*HLA-A*31:01*	Carbamazepine-induced hypersensitivity in Caucasians and Japanese	Pharmacodynamic
	*HLA-B*58:01*	Allopurinol-induced serious cutaneous reactions	Pharmacodynamic
	*HLA-B*57:01*	Flucloxacillin hepatotoxicity	Pharmacodynamic
Malignancy			
Breast cancer	*CYP2D6*	Response to tamoxifen	Pharmacokinetic
Chronic myeloid leukaemia	*BCR-ABL*	Imatinib and other tyrosine kinase inhibitors	Pharmacodynamic
Colon cancer	*KRAS*	Cetuximab efficacy	Pharmacodynamic
Gastrointestinal stromal tumours	*c-kit*	Imatinib efficacy	Pharmacodynamic
Lung cancer	*EGFR*	Gefitinib efficacy	Pharmacodynamic
	EML4-ALK	Crizotinib efficacy	Pharmacodynamic
Malignant melanoma	*BRAF V600E*	Vemurafenib efficacy	Pharmacodynamic
Muscle			
General anaesthetics	Ryanodine receptor	Malignant hyperthermia	Pharmacodynamic
Statins	*SLCO1B1*	Myopathy/rhabdomyolysis	Pharmacokinetic

eliminated hypersensitivity to the anti-retroviral drug abacavir. Similarly, *HLA-B*15:02* predisposes patients from South-East Asia to Stevens–Johnson syndrome with carbamazepine.

Although not generally available yet in routine clinical practice, whole genome sequencing (see Chapter 5) may in the future be used to personalize drug therapy to improve both efficacy and safety of drugs, a key component of the drive towards ***personalized medicine***.

THERAPEUTICS IN SPECIAL POPULATIONS

Most medications are evaluated in clinical trials and therefore licensed for use, in adult, non-pregnant patients, usually without multimorbidity. Trial data may therefore not easily generalize to real-life patient populations, and healthcare professionals need to consider specific issues relating to prescribing in other special populations.

Pregnancy

Four in five females who are pregnant use an over-the-counter or prescribed medicine while pregnant. There is little published evidence for the safety of most drugs in pregnancy. Clinicians should be cautious about prescribing drugs to pregnant females and only essential treatments should be given, though equally necessary and effective medications should not be unduly withheld. There are significant changes in maternal physiology that have consequences for the prescribing of medications.

Pharmacokinetics

- ***Absorption:*** decreased intestinal motility and gastric emptying, increased gastric reflux and emesis.
- ***Distribution:*** increased total plasma volume (up to 40% higher), increased total body fat, decreased albumin.
- ***Metabolism:*** no major changes.

- ***Excretion:*** increased glomerular filtration rate (GFR) (up to 50% higher).

There is also significant drug transfer to the fetal circulation. Blood flow to the placenta increases 1000% over the last 6 months of gestation. Total placental surface (and therefore drug transfer) is greatest at term. Drugs that are small (<1 kDa) can cross the placenta and the main determinant of fetal drug concentration is maternal drug concentration.

Up to 1% of fetal malformations may be due to *in utero* drug exposure. Many drugs are known to cause developmental abnormality (teratogenesis) (**Box 7.6**). Furthermore, there is increased exposure to drugs that are renally excreted into the amniotic fluid as this is reswallowed and recirculated in the fetus *in utero*. Organ structure and function is most susceptible to perturbation during organogenesis between 2 and 14 weeks' gestation, which may include a period where the female is unaware of being pregnant.

When a known or potential teratogen is required during pregnancy (e.g., an anticonvulsant drug or lithium), the potential adverse effects should be discussed with the patient, preferably before conception (pre-conception counselling). The relevant drug literature should be consulted when prescribing for pregnant females.

Breast-feeding

Although most drugs can be detected in breast milk the quantity is generally small, as for most drugs, the concentration in milk is in equilibrium with plasma water (i.e., the non-protein-bound fraction). A few drugs (e.g., aspirin, carbimazole, methotrexate) may, however, cause harm to the infant if ingested in breast milk. This is especially the case for drugs that cause idiosyncratic reactions where there is little or no concentration–effect relationship (type B adverse events; see Chapter 7). The relevant drug literature should be consulted when prescribing for women who are breast-feeding.

Old age

Prescribing in old age has additional considerations. Old age alters drug pharmacokinetics:

- ***Absorption:*** diminished due to reductions in intestinal motility and blood flow.
- ***Distribution:*** reduced total body-water and increased body-fat affects the volume of distribution for water-soluble and fat-soluble drugs, respectively.
- ***Metabolism:*** decreased hepatic blood flow and enzyme function.
- ***Excretion:*** renal function declines with age at the rate of approximately 1 mL/min after the age of 40 years.

Old age also alters pharmacodynamics and exaggerated pharmacodynamic effects of drugs acting on the central nervous, cardiovascular, and gastrointestinal systems are common.

Examples of common problems encountered in the use of drugs among older people are shown in **Box 7.7**. ***Extrapolation of drug dosages*** from those appropriate in younger adults may therefore lead to toxic plasma levels in older patients.

Additional considerations include:

- ***Multimorbidity***, often associated with polypharmacy, leads to increased opportunities for disease–drug and DDIs.
- ***Concordance with treatment regimens*** diminishes as the number of prescribed drugs increases and is especially poor in the face of cognitive impairment (see Chapter 49).

Kidney disease

Prescribing drugs that require renal excretion as a major form of drug clearance can be problematic in patients with coexisting chronic kidney disease.

In chronic kidney disease there is less glomerular filtration of drugs leading to reduced renal clearance, enhanced drug half-life, and potential for drug accumulation. Patients with chronic kidney disease appear to be more susceptible and sensitive to adverse drug effects. Some medications, such as thiazide and thiazide-like diuretics, work from the luminal side of the collecting duct and therefore are ineffective in advanced chronic kidney disease.

The level of kidney function below which the dose of a drug must be reduced depends on the proportion of the drug eliminated by renal excretion and its toxicity. For many drugs with only minor or no dose-related side-effects, very precise modification of the dose regimen is unnecessary and a simple scheme for dose reduction is sufficient. For more toxic drugs with a small safety margin or in patients at extremes of weight, dose regimens based on kidney function should be used. When both efficacy and toxicity are closely related

Box 7.6 Some human teratogens

Drug or drug class	Effect
ACE inhibitors	Oligohydramnios
Retinoids, e.g., isotretinoin	Multiple abnormalities
Carbimazole	Neonatal hypothyroidism Abnormalities of bone growth
Fluconazole	Fallot's tetralogy
Antiepileptics: carbamazepine, lamotrigine, phenytoin, valproate	Cleft palate, facial abnormalities, neural tube defect, neurodevelopmental delay
NSAIDs	Delayed closure of the ductus arteriosus
Cytotoxic drugs	Most are presumed teratogens
Lithium	Ebstein's anomaly
Misoprostol	Moebius' syndrome (rare neurological condition)
Thalidomide (and possibly lenalidomide)	Phocomelia

Box 7.7 Common adverse reactions to drugs in older people

Drug or drug class	Effect
Nitrates **α-Adrenoceptor-blockers** **Loop diuretics**	Postural hypotension
Diuretics (thiazides)	Glucose intolerance, gout
Antimuscarinic drugs **Tricyclic antidepressants** **Neuroleptics** **Anticonvulsants** **Hypnotics** **Opioids**	Confusion, cognitive dysfunction
Non-steroidal anti-inflammatory drugs (NSAIDs)	Gastric erosions Small bowel and colonic lesions (less frequently than gastric) Upper gastrointestinal bleeding Perforated peptic ulcer Salt and water retention Acute kidney injury

to plasma drug concentration, dosage must be adjusted according to clinical response and plasma drug concentration.

Most drug adjustments are recommended to use estimated GFR (eGFR) or creatinine clearance (usually calculated by the Cockcroft–Gault formula). Although there is a good correlation between these two measures, at the extremes of weight there can be significant differences and so the relevant drug literature should be checked when prescribing for patients with chronic kidney disease to be sure which measure is recommended.

Various patterns of drug-induced nephrotoxicity can occur, with the commonest being:

- ***Pre-renal effects*** of diuretics (volume), angiotensin-converting enzyme (ACE) inhibitors (renal perfusion), antihypertensive medications (hypotension), and non-steroidal anti-inflammatory drugs (NSAIDs) affect autoregulation of renal perfusion.
- ***Tubulointerstitial nephritis*** caused by immune reactions to commonly used medications such as penicillin antibiotics and proton-pump inhibitors.
- ***Direct toxic effects***, typically to renal tubular cells where drugs reach high intracellular levels due to reabsorption, caused by medications including cisplatin, lithium, and aminoglycoside antibiotics.
- ***Other mechanisms***, including crystal nephropathy (e.g., some older anti-retroviral protease inhibitors), drug-induced thrombotic microangiopathy (e.g., calcineurin inhibitors), or direct glomerular effects (e.g., NSAIDs).

It is good practice to advise avoidance where possible of nephrotoxic drugs, especially over-the-counter drugs such as NSAIDs, in patients with chronic kidney disease.

Liver disease

Prescribing drugs that require hepatic metabolism as a major form of drug clearance can be problematic in patients with coexisting chronic liver disease.

In chronic liver disease, there is less first-pass metabolism and often portosystemic shunts. These combine to increase the proportion of drug that enters the systemic circulation, increasing drug exposure for a fixed-given oral dose.

However, some drugs require hepatic metabolism for efficacy (prodrugs, such as clopidogrel). For prodrugs the presence of chronic liver disease and/or portosystemic shunts reduces the proportion of orally ingested drug that undergoes hepatic activation and therefore there is relatively less circulating active drug per oral dose.

The assessment of severity of chronic liver disease that requires dose-adjustment is more nebulous than when dose adjusting in chronic kidney disease. Although there are validated scoring systems for predicting outcomes in chronic liver disease, such as Child–Pugh and MELD (see Chapter 23), these have not been routinely used to make decisions on drug-dose adjustment. Holistic clinical assessment is preferred and the relevant drug literature and specialist advice should be consulted when prescribing for patients with chronic liver disease if there is clinical uncertainty.

Drugs can cause liver injury in various patterns, for example:

- ***hepatitis:*** paracetamol, amiodarone, azathioprine
- ***fatty change:*** tetracyclines
- ***cholestasis:*** co-amoxiclav, nifedipine

Therefore in patients with chronic liver disease, avoid hepatotoxins if possible or reduce doses. For example, it is common to restrict paracetamol dosing to 2 g/day in chronic liver disease, compared with 4 g/day in patients without liver injury.

PRESCRIBING

Once the most appropriate therapeutic choice has been made taking into account of the issue above, then the medications should be safely **prescribed**. It is worth pointing out that medical gases (e.g., supplemental oxygen), intravenous fluids, and some devices (such as anti-embolic stockings) should also be prescribed routinely.

Act of prescribing

Essentials of a valid prescription include drug name (the generic unless there is a specific reason to include brand name), dose, route, frequency (or duration of administration), start date (and end date if appropriate), name and contact details of prescriber, and signature. There may be additional regulatory requirements for prescribing of certain drugs such as strong analgesics, narcotics and hypnotics (termed 'controlled drugs' in the UK), and cytotoxic chemotherapeutic agents.

Electronic prescribing

Although prescribing has been traditionally a pen-to-paper activity, there is increasing reliance on proprietary electronic prescribing systems linked to electronic health records. There are clear advantages of electronic prescribing relating to legibility, clinical audit, and linking to pharmacy dispensing and stock systems. There is additionally the possibility of building in checks for allergies, interactions, and other inappropriate therapeutic choices, though these depend on human creation of these specific rules and their integration into the systems.

Calculation skills

For certain medications that are used based on a weight or time, then basic **calculation skills** may be required to be certain of the dose. Calculation errors are common when changing units (i.e., between minutes to hours, concentration from % to mg per mL, etc.), and it is good practice to check calculations with a colleague to ensure they have been done correctly.

Ethical issues relating to therapeutics and prescribing

The use of medications in humans involves a range of considerations that are critical to both the wellbeing of patients and trust in healthcare systems. Important ethical issues include:

- ***Informed consent:*** patients should have adequate information about the medication, alternative options, the benefits, risks, and potential adverse reactions, to allow them to make an informed decision with their healthcare provider about the best course of action: this is termed ***shared decision-making*****.**
- ***Benefit/Risk:*** Use of medicines should aim to maximize benefit (beneficence) and minimize harm (non-maleficence) by selecting the most appropriate medication for the individual patient. This requires continuing professional development for prescribers to keep up to date with latest evidence—for example, if safety alerts are issued based on post-marketing surveillance of a new drug. There are important implications for end-of-life care where the shift of priorities may change from extending life to symptom management if aligned to patient wishes, so drugs with

long-term preventative effects may be discontinued in favour of those with immediate symptomatic benefits.

- ***Justice:*** medicines should be used based on equity of access and need. Affordability is included in this equation, though this is usually dealt with at formulary level rather than on an individual patient level. Confidentiality applies to medicines use as it does to any other healthcare information. Just use of medicines also relates to preserving antibiotic efficiency by preventing overuse of antibiotics and to prevent medication misuse or abuse of medicines with addictive potential.
- ***Conflict of interest:*** prescribers must disclose issues that may influence prescribing decisions, such as financial relationships with pharmaceutical producers or personal research in the area.

MEDICATION REVIEW

Timely intermittent medication review is an essential component to lifelong care of patients on medications. Reviews may occur multiple times per day for critically ill patients or once per year or opportunistically for stable patients in primary care.

The purpose of medication review is to:

- ensure all medications prescribed still have a positive benefit/risk profile with changing clinical status (there should be ***active de-prescribing*** where appropriate)
- identify and manage potential DDIs
- identify and manage (or avoid) adverse drug effects
- ensure required monitoring is in place—for instance, monitoring for toxicity to liver, kidney, or bone marrow is required for some medications.

MONITORING DRUG THERAPY

Pharmacokinetic and pharmacodynamic variability makes monitoring of the effects of many medications essential. While there are generally agreed upon principles for certain medicines (i.e., intermittent renal function monitoring for diuretics or renin-angiotensin system inhibitors), some drugs have strict recommendations in the licensing agreements for timed parameters (i.e., leucocyte and prolactin levels for clozapine).

Three approaches for monitoring are generally used:

- ***Pre-treatment dose selection.*** In patients who have known, or suspected, impaired renal or liver function, it is usually possible to predict dose requirements from their eGFR or clinical assessment of severity of chronic liver disease (see Chapter 23).
- ***Measuring plasma drug concentrations.*** For a few drugs, dosages can be effectively monitored by reference to their plasma concentrations (**Box 7.8**). This technique is useful only if both of the following criteria are fulfilled:
  1. There is a reliable and available drug assay.
  2. Plasma concentrations correlate well with both therapeutic efficacy and toxicity.

Therapeutic drug monitoring refers to the individualization of dosage by maintaining plasma or blood drug concentrations within a target range (the 'therapeutic range' or 'therapeutic window'). Using this pharmacokinetic approach, therapeutic drug monitoring is used in two major situations:

1. when drugs are used prophylactically to maintain the ***absence*** of a condition, to ensure doses are high enough to be effective but low enough to avoid toxicity. Examples include drugs to prevent seizures (many anti-epileptic drugs), depressive or manic episodes (lithium), or organ rejection (calcineurin inhibitors such as tacrolimus).
2. to avoid serious toxicity, as with the aminoglycoside antibiotics which, unlike most antibiotics, have a narrow therapeutic range.
   - Data and measuring drug effects

For many drugs, dosage adjustments are made in line with patients' responses (a pharmacodynamics-based approach). Monitoring can involve dose titration against a therapeutic endpoint or a toxic effect. Objective **data interpretation** (such as monitoring antihypertensive therapy by measuring blood pressure, glycated haemoglobin in diabetes mellitus, or cytotoxic therapy with serial white blood cell counts) is most helpful, but subjective assessments are necessary in many instances (as with antipsychotic therapy in people with schizophrenia). Pharmacodynamic tests can be used in clinical practice to target therapy or to avoid undue sensitivity. Examples are use of the INR or prothrombin time to titrate warfarin dosage to find the targeted level of anticoagulation.

Box 7.8 Some drugs for which therapeutic drug monitoring is used

Drug	Therapeutic plasma concentration range	Toxic level	Optimum post-dose sampling time (h)
Carbamazepine	20–50 μmol/L	>50 μmol/L	>8
Ciclosporin	50–200 μg/L	>200 μg/L	Pre-dose
Digoxin	1.3–2.6 nmol/L	>2.6 nmol/L	>8
Gentamicin	Trough <2 mg/L	>2 mg/L	Pre-dose
	Peak 5–10 mg/L	>12 mg/L	>1
Lithium	0.6–1.0 mmol/L	>1.5 mmol/L	>10
Phenytoin	40–80 μmol/L	>80 μmol/L	>10
Tacrolimus	4–12 μg/L	>12 μg/L	Pre-dose
Theophylline	55–110 μmol/L	>110 μmol/L	>4
Vancomycin	15–20 mg/L	>20 mg/L	Pre-dose

ADVERSE DRUG REACTIONS

Adverse drug reactions (ADRs), defined as 'the unwanted effects of drugs occurring under normal conditions of use', are a significant cause of morbidity and mortality. The burden of ADRs is huge in both adults and children: ADRs account for about 6.5% of hospital admissions and affect 15% of adult inpatients. In addition, about one in four patients in primary care will have an adverse reaction, but fortunately these are mild in most cases. Unwanted effects of drugs are five to six times more likely in the elderly than in young adults, and the risk of an adverse drug reaction (ADR) rises sharply with the number of drugs administered.

Classification

Two types of ADR are recognized: type A (augmented) reactions and type B (idiosyncratic) reactions (**Box 7.9**).

Box 7.9 Classification and examples of adverse drug reactions

Type A (augmented)	
• Common but only occasionally serious • Qualitatively normal, but quantitatively abnormal, manifestations of known pharmacology • Show a clear dose–response relationship • May occur after a single dose (hypotension with atenolol), or may develop after months (dependence with opioids), or years (second malignancies with anticancer drugs) • Usually reproducible in animal models	
Type of drug (or drug class)	*Type A adverse reaction*
Anticoagulants, e.g., warfarin	Gastrointestinal bleeding Intracerebral haemorrhage
Antipsychotics, e.g., haloperidol	Acute dystonia/dyskinesia Parkinsonian symptoms Tardive dyskinesia
Cytotoxic agents, e.g., 5-fluorouracil	Bone marrow dyscrasias Cancer
Diuretics, e.g., furosemide	Dehydration, renal impairment
Insulin	Hypoglycaemia
Type B (idiosyncratic)	
• Usually rare and are often serious • Qualitatively abnormal responses to the drug (not predictable from its known pharmacology) • Show a dose–response relationship that is complex and not easily discernible • Not reproducible in animal models	
Type of drug (or drug class)	*Type B adverse reaction*
Benzylpenicillin Radiological contrast media	Anaphylaxis
Broad-spectrum penicillins, e.g., co-amoxiclav	Maculopapular rash
Phenytoin Sulphonamides	Toxic epidermal necrolysis Stevens–Johnson syndrome
Diclofenac Isoniazid	Hepatotoxicity
Isotretinoin	Depression, suicidal ideation

Diagnosis

All ADRs mimic some naturally occurring disease, and drawing a distinction between an iatrogenic aetiology and an event unrelated to the drug is often difficult. The patient should be asked not only about prescription drugs but also about over-the-counter medicines, herbal medicines, and illicit drugs. Although some effects are obviously iatrogenic (e.g., acute anaphylaxis occurring a few minutes after intravenous penicillin), many are less so.

Causality assessment of a suspected ADR can be difficult, particularly in patients on multiple drugs. The temporal relationship between drug exposure and suspected adverse events should be appropriate, and other causes of the suspected adverse events should be excluded. Rechallenge with the suspected drug and dechallenge (i.e., stopping the suspected drug to see if the adverse effect disappears) may be appropriate in certain circumstances. Some ADRs are so typical, such as cough or angio-oedema following initiation of ACE inhibitors, that identification of such an ADR is likely.

Management

As a general rule, type A reactions can usually be managed by a reduction in dosage, while type B reactions almost invariably require the drug to be withdrawn (and never re-instituted). Most ADRs resolve spontaneously when the drug is withdrawn, but specific therapy is sometimes required for ADRs that cause acute patient harm. For example, bleeding with anticoagulants is actively reversed (vitamin K and prothrombin complex can be used for warfarin) and drug-induced anaphylaxis is a medical emergency.

When a patient suffers an ADR, this should be reported to the regulatory agency, for example, through the UK's ***Yellow Card reporting*** scheme to the Medicines Healthcare Products Regulatory Agency. The criteria for reporting vary across the world but, in general, all ADRs to new drugs or drugs used outside their licence should be reported, while only the serious ADRs to established drugs (i.e., those that have been on the market for usually more than 2 years) should be reported.

Coleman JJ, Pontefract SK. Adverse drug reactions. *Clin Med* 2016; 16:481–485.

DRUG INTERACTIONS

Drugs can interact with each other DDIs, with food (drug–food interactions) and with herbal medicines (drug–herbal interactions) (**Box 7.10**). These interactions, in general, can be either pharmacokinetic (affecting the processes of absorption, distribution, metabolism, and excretion), pharmacodynamic (synergistic or antagonistic), or mixed. Approximately 1% of all ADRs that lead to hospital admission are due to DDIs. A major risk factor for DDIs is polypharmacy, which is becoming more common because of the co-morbidities associated with an ageing population (see Chapter 49). About 57% of patients above the age of 65 years are on more than five drugs, with 12% being on more than ten drugs.

Food–drug interactions are also becoming increasingly recognized. A common example is grapefruit juice that inhibits CYP3A4 in the intestinal wall, increasing the bioavailability of drugs metabolized by CYP3A4 (see **Box 7.10**), resulting in higher exposure and toxicity.

Herbal medicines are taken by almost 20% of the population but are rarely asked about when a patient's clinical history is taken. Many different herbal–drug interactions have been described the best recognized of which is with St John's Wort (SJW), which is an inducer of P450 enzymes and drug transporters, such as P-glycoprotein. SJW can lead to increased drug metabolism, reduction in drug concentration, and failure of therapeutic effect. An example is interaction with immunosuppressants such as prednisolone and ciclosporin, where the use of SJW has led to allograft rejection.

Reliable sources of information (see next section) must be used when prescribing new drugs to patients who already are taking other medications to ensure that no significant DDI exists.

Box 7.10 Some examples of drug interactions

Implicated drug(s)	Affected drug(s)	Mechanism	Clinical effect
Pharmacokinetic: absorption			
Colestyramine	Digoxin	Binding of colestyramine to digoxin	Reduced digoxin plasma concentration and reduced efficacy
Pharmacokinetic: enzyme induction			
Carbamazepine Phenytoin Rifampicin	Oral contraceptive Warfarin Ciclosporin	CYP3A4 induction CYP2C9 induction CYP3A4 and P-glycoprotein induction	Contraceptive failure Thrombosis Allograft rejection
Pharmacokinetic: enzyme inhibition			
Amiodarone Ciprofloxacin Grapefruit juice Ritonavir	Warfarin Theophylline Simvastatin Inhaled fluticasone	CYP2C9 inhibition CYP1A2 inhibition CYP3A4 inhibition CYP3A4 inhibition	Haemorrhage Arrhythmias Myopathy Cushing's syndrome
Pharmacokinetic: excretion			
Naproxen Bendroflumethiazide	Methotrexate Lithium	Inhibition of methotrexate excretion Inhibition of lithium excretion	Methotrexate toxicity Lithium toxicity
Pharmacodynamic: synergistic interaction			
Verapamil Ramipril	Atenolol Spironolactone	Atrioventricular node block Reduced excretion of potassium	Bradycardia, heart block Hyperkalaemia
Pharmacodynamic: antagonistic interaction			
Salbutamol Furosemide	Atenolol Digoxin	Opposing effects at the β-receptor Hypokalaemia	Lack of bronchodilation Digoxin toxicity

INFORMATION SOURCES

Pharmacotherapy moves at a very rapid pace and it is impossible for anyone to keep up with contemporary advances. Critical information relating to essential contraindications, interactions, and monitoring, as well as treatment pathways, can be found in reliable prescribing literature:

- The ***Summary of product characteristics (SmPCs)*** for individual drugs is produced by manufacturers and vetted by drug regulatory authorities.
- The relevant ***national formulary***. Many countries have their own formularies, for example, the UK has the *British National Formulary* (BNF).
- ***Guidance*** produced by national health technology agencies such as the UK's *National Institute for Health and Care Excellence (NICE).*

CORE SKILLS AND KNOWLEDGE

Radiological examinations are part of every 21st-century patient's medical journey—in the outpatient clinic and community setting as well as emergency and inpatient services and across almost every clinical specialty.

From ubiquitous X-ray to complex CT and MRI, imaging is central to diagnosis, treatment planning, and therapy evaluation or simply to reassure the patient all is well. More recently, Interventional Radiology provides indispensable, often lifesaving treatment options for patients across a range of conditions.

Key learning outcomes in this chapter include:

- Learning the different imaging modalities available, the underpinning principles of physics and which modality is best suited to particular clinical questions and conditions
- Becoming familiar with the concept of radiation safety
- Learning the fundamentals of how to interpret common imaging examinations.

Opportunities for learning include spending time in radiology departments, observing how radiographers/imaging technicians acquire images and navigate concerns relating to patient comfort and safety; sitting with radiologists as they report diagnostic imaging; attending multidisciplinary imaging meetings; talking with and examining patients undergoing radiological examinations, then correlating the clinical presentations with subsequent imaging appearances and reports.

BACKGROUND

Radiology is one of the physician's most powerful investigative tools. Clinical imaging is ubiquitous in every 21st-century patient's medical journey—from disease screening and diagnosis to reassuring the patient all is well. Radiology and the radiologist are central to treatment planning, therapy evaluation, and delivering treatment through interventional radiology.

The effective use of the radiology department requires an understanding of the strengths and limitations of myriad radiological examinations to answer the clinical question (**Box 8.1**). More than mere hypothesis testing, a firm grasp of how pre-test probability impacts interpretation of imaging findings is crucial. Consideration should also be given to examination availability, patient suitability, radiation dose, and cost. Inappropriate or over-investigation harms patients, not least from issues arising from incidental imaging findings (in up to 30% of all diagnostic imaging).

Box 8.1 Categories of radiological investigation modalities

Non-ionizing radiation	Ionizing radiation
Ultrasound	Plain X-ray/radiography
Magnetic resonance imaging (MRI)	Computed tomography (CT)
	Fluoroscopy
	Nuclear medicine, e.g., bone scan
	Positron emission tomography (PET)
	Interventional radiology (IR) procedures

Box 8.2 Ionising Radiation (Medical Exposure) Regulations [IR(ME)R]—UK

The Ionising Radiation (Medical Exposure) Regulations 2017 are accessible on legislation.gov.uk. Medical ionizing radiation is used to help diagnose and treat conditions. The regulations aim to make sure that it is used safely to protect patients from the risk of harm when being exposed to ionizing radiation.

They set out the responsibilities of duty holders (the employer, referrer, practitioner, and operator) for radiation protection and the basic safety standards that duty holders must meet.

Responsibilities include:

- minimizing unintended, excessive, or incorrect medical exposures
- justifying each exposure to ensure the benefits outweigh the risks
- optimizing diagnostic doses to keep them 'as low as reasonably practicable' for their intended use.

Good communication between the clinical and radiology team is essential. While in person discussions are ideal, providing all relevant clinical information in clinical requests, most commonly via the radiology request form, helps the radiologist decide the best radiological investigations and greatly increases the likelihood of answering the clinical question and helping the patient.

Referring clinicians are bound by legal responsibilities when requesting imaging examinations (IRMER in the UK, when requesting tests using ionizing radiation, see **Box 8.2**) and to take the appropriate action(s) after reading each radiology report. Many clinical and therapeutic management decisions are made today in multidisciplinary meetings (MDTs). The radiologist, presenting each patient's imaging findings, is an indispensable presence at these discussions.

Radiology is involved in ever-increasing therapeutic procedures. These range from lifesaving haemostatic procedures (e.g., to treat bleeding aneurysms or postpartum haemorrhage) to oncologic interventions (e.g., ablating tumours) to organ-saving revascularization (e.g., thrombectomy for ischaemic limb or brain).

This chapter aims to:

- Introduce the reader to a variety of radiological examinations and interventional procedures
- Briefly describe the basic science underpinning each radiology modality
- Introduce common clinical imaging and principles of interpretation
- Discuss issues relating to the radiology patient including selection, preparation, contraindications, safety, and potential complications

PLAIN RADIOGRAPHY/X-RAYS

Plain radiographs are the most commonly performed radiological examination (**Box 8.3**). They are relatively quick to perform, well tolerated by patients, and are the investigation of choice in many conditions.

Box 8.3 Principles of plain radiography and fluoroscopy

- Image is produced when X-rays from the source pass through the body onto the detector
- Involves ionizing radiation
- Radiation dose is small (one chest X-ray = 10 days of background radiation exposure)
- Common body parts examined include chest (CXR), abdomen (AXR), spine, and limb bones
- Images produced correspond to how much X-rays are absorbed by the body: for example, bones appear 'white' or 'dense' because most of the X-rays have been absorbed. Lungs filled with air absorb little X-ray—hence they appear 'dark'
- Fluoroscopy uses the same principles but produces a continuous 'moving' X-ray image
- No special patient preparation required usually

Chest radiography (chest X-ray)

Chest X-ray (CXR) is an important first-line investigation for a broad range of symptoms including breathlessness, chest pain, and cough and is often requested and interpreted at the 'point of care' by clinicians in the emergency department and acute medical unit. Careful, systematic, and structured examination of a CXR may yield a wealth of information about a patient's health above and beyond the basic diagnostic indication for requesting the X-ray. A suggested structured approach to reporting and interpretation of the CXR can be found in the online edition of this chapter at Elsevier eBooks+ (see Box E8.1).

Many examples can be found within Chapter 17 ('Cardiology') and Chapter 20 ('Respiratory medicine'). This section will illustrate some common conditions and principles of interpretation.

Normal CXR

Fig. 8.1 shows an example of a normal CXR. Familiarity with the normal X-ray is the essential first step in confidently identifying and diagnosing pathology.

Pulmonary oedema

Pulmonary oedema results in accumulation of fluid within the alveolar, interstitial, or pleural lung spaces; common causes include left ventricular failure and renal failure. A spectrum of radiographic changes may be seen (**Fig. 8.2**): in milder cases, these may be confined to central venous prominence with engorgement of the upper lobe pulmonary veins; more severe acute pulmonary oedema leads to loss of clarity of the lung bases and air space opacification which is typically bilateral with a 'batwing' distribution. Kerley-B lines, fine horizontal lines perpendicular to the pleural surface and representing oedema of the interlobular septae, may be visible at the peripheries. Bilateral pleural effusions, often larger on the right, dominate in more chronic cases. Cardiomegaly is common and careful inspection of the X-ray may reveal pointers towards the underlying cause of cardiac disease (e.g., a mechanical heart valve); see **Fig. 8.1**.

Infection

CXR can be helpful to diagnose pneumonia (**Fig. 8.3**). Patchy or confluent air space opacities ('white areas') can be demonstrated in the normally black-appearing lungs, where secretions fill the alveolar spaces. 'Consolidation' is said to be present if aerated airways (black, branching tubes known as 'air bronchograms') can be seen against white secretion-filled alveolar spaces. The normal

Box E8.1 Stepwise approach to reporting a CXR

1. Preliminaries		• **Patient details:** - Which patient, how old, when was this image taken? • **X-ray details:** - Is it a posteroanterior or anteroposterior projection? - Is the patient rotated? - Is there adequate penetration? - Has the patient taken an adequate breath?	• Compare where available to previous radiograph images • The distance between each clavicular head and the spinal processes should be equal • In a CXR at maximal inspiration, 8-10 posterior and 5-6 anterior ribs should be visible • With modern digital imaging systems, under- or over-penetration can usually be corrected by 're-windowing' the image
2. Trachea		• The trachea should be widely patent and should be central in the chest	• The trachea may be pulled towards areas of fibrosis or collapse • It may be pushed away by masses, a goitre, lymphadenopathy, large pleural effusion or a tension pneumothorax
3. Mediastinum		• The aortic notch should be just visible • The left hilum should be slightly higher than the right • The hila should be symmetrical in size	• The mediastinum is widened by lymphadenopathy, masses such as thymoma, and aortic aneurysm • The hila may be pulled up or down by collapsed lobes, or enlarged by the presence of a tumour
4. Heart size		• Heart size should be less than 50% of the thoracic width on a PA chest film • Assess heart borders	• Cardiomegaly may be caused by hypertension, valvular disease, heart failure or cardiomyopathy • Loss of right heart border may suggest right middle lobe pathology • Loss of left heart border suggests lingular pathology
5. Diaphragm		• The right hemidiaphragm is usually higher than the left • Look for air/gas under the diaphragm and for elevation of the diaphragm on either side	• Air or gas under the diaphragm indicates a perforated abdominal viscus • A hemidiaphragm may be pulled up from above by lobar collapse, or pushed up from below by a large mass
6. Pleura		• The costophrenic angles should be clearly visible • Look for lung markings extending to the chest wall • Look for evidence of a lung edge	• Loss of the costophrenic angle is usually due to the presence of pleural effusions • Larger pleural effusions may cause a 'white out' on one side • Loss of lung markings or a visible lung edge suggests a pneumothorax
7. Lungs		• Is there consolidation of the upper lobe (stops at horizontal fissure), middle lobe/lingula (heart edge unclear) or lower lobe (diaphragm unclear)? • Inspect each part of the lung looking for round shadows • Inspect the lung parenchyma for interstitial changes • Remember to examine the apices, behind the heart and lung peripheries for subtle tumour or pneumothorax	• Areas of consolidation may often be restricted to a lobe and are usually caused by pneumonia. An air bronchogram (airways outlined) or evidence of cavitation may be seen • Rounded shadows may be caused by cancer, inflammatory lesions, such as tuberculosis or fungal disease • Interstitial changes may be caused by pulmonary oedema or fibrosis
8. Bones		• Inspect all ribs for evidence of fractures • Faint bones imply osteopenia • Are there lytic lesions?	• Think of systemic diseases: - Osteoporosis may cause osteopenia or fractures - Solid organ cancers or myeloma can cause lytic lesions
9. Soft tissue		• Observe the soft tissue around the rib cage	• Air within the skin suggests surgical emphysema
10. Miscellaneous		• Look for any externally applied devices	• Nasogastric tubes should bisect the carina and cross the diaphragm • Chest drains should terminate in the pleural space • Central venous catheters should end just above the right atrium • Pacemaker wires, and sternotomy wires imply cardiac disease

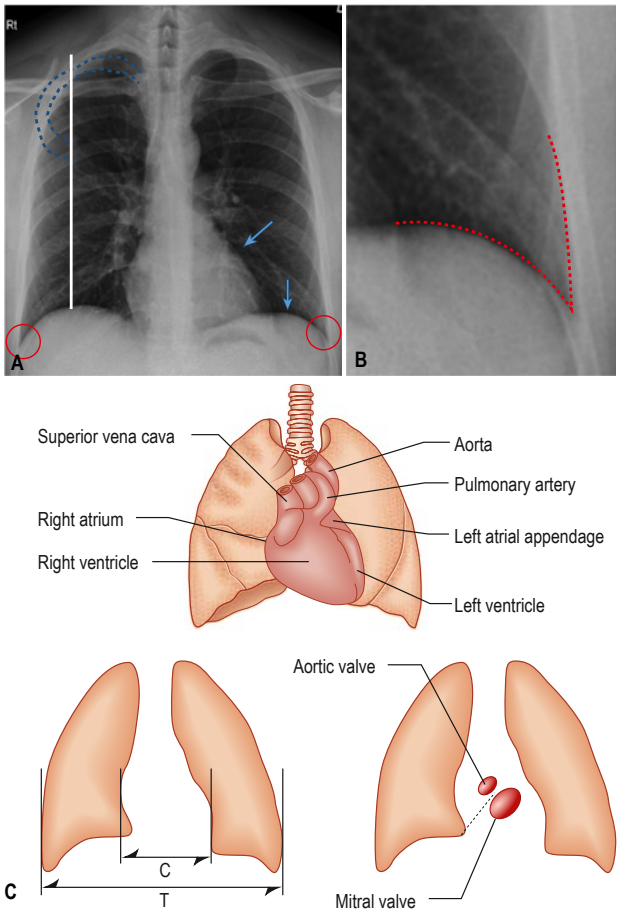

Fig. 8.1 An exemplar normal CXR. **(A)** The lungs are both well inflated—with approximately 6 anterior ribs or 9 posterior ribs *(dotted lines)* visible at the mid-clavicular line *(white)*. Notice the crisp and distinct outline of the heart and diaphragm *(arrows)*—both juxtaposed against aerated ('black') lungs. Notice the sharp costophrenic angles bilaterally *(red circles)*. **(B)** Magnified view of sharp left costophrenic angle: *red dots* outline the lateral thoracic pleural surface and left hemidiaphragm. **(C)** The cardiac silhouette as it is seen on the CXR. The heart (measurement C) should measure half the width of the thorax (T). The *dotted line* is an arbitrary line from the left hilum to the right cardiophrenic angle; a calcified aortic valve is seen above this line and mitral valve below.

sharp outlines of the heart or diaphragm may be lost in CXRs—this is a subtle clue that infection is present, also known as the 'silhoutte sign'. Consolidation may be 'lobar' (occupying an area on the CXR corresponding to an anatomical lung lobe) or 'bronchopneumonia' (usually patchy, separated by areas of normal lung, and often bilateral).

Viral pneumonitis often results in bilateral changes on CXR, and infiltrates may be either 'interstitial' (involving the connective tissues surrounding the alveoli and bronchioles, resulting in a reticulonodular pattern on X-ray) or 'alveolar' (resulting in a hazy 'ground-glass' appearance).

Pleural effusion

Pleural effusion indicates a collection of fluid within the pleural cavity and is recognized by a homogeneous 'white' opacity to lower zones of the lung on CXR, obliterating the normal sharp costophrenic angle (Fig. 8.4). The upper border is typically curved ('meniscus'). A large effusion will exert mass effect, pushing normal midline structures (trachea, heart) towards the opposite side. A careful review of other structures in the X-ray may reveal clues to the underlying diagnosis (e.g., sclerotic rib metastases secondary to a bronchogenic carcinoma; pleural plaques indicating asbestos exposure and thus risk of mesothelioma). Blunting of the costophrenic angle (the earliest radiographic evidence of effusion) implies at least 500 mL of fluid sequestered within the pleural space.

Pneumothorax

A pneumothorax is where air, often leaked from the lung, is present in the pleural cavity. On a CXR the periphery of the thoracic cavity will appear black, lacking the usual fine network of vascular markings (Fig. 8.5). Careful inspection will reveal the edge of aerated lung 'fallen away' from the chest wall; this may be difficult to spot, particularly if the pneumothorax is localized or small, and rotating the X-ray 90 degrees can sometimes be helpful.

Nasogastric tube

Nasogastric (NG) tubes allow for delivery of medications and nutrition directly to the stomach, for instance in those unable to safely swallow. Risks of a misplaced tube are significant and include inadvertent delivery of feed into the lung if mis-sited in the bronchus,

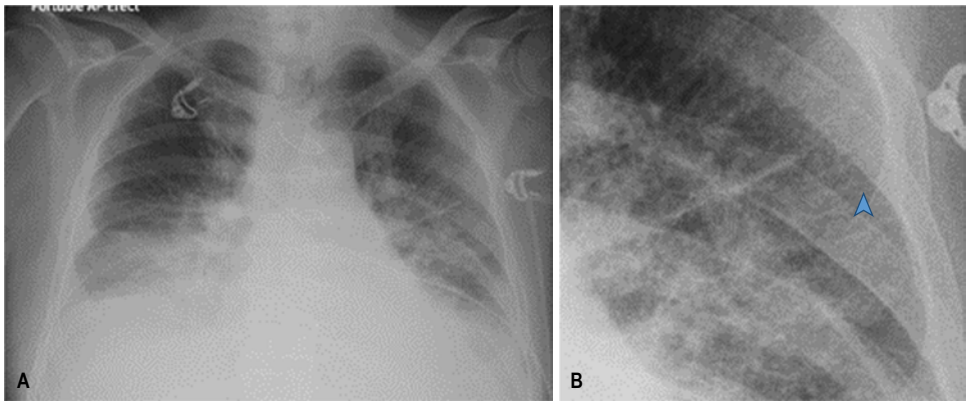

Fig. 8.2 Pulmonary oedema. **(A)** Notice the presence of median sternotomy wires which may indicate previous cardiac surgery. **(B)** Magnified image. The *blue arrowhead* points to a Kerley-B line.

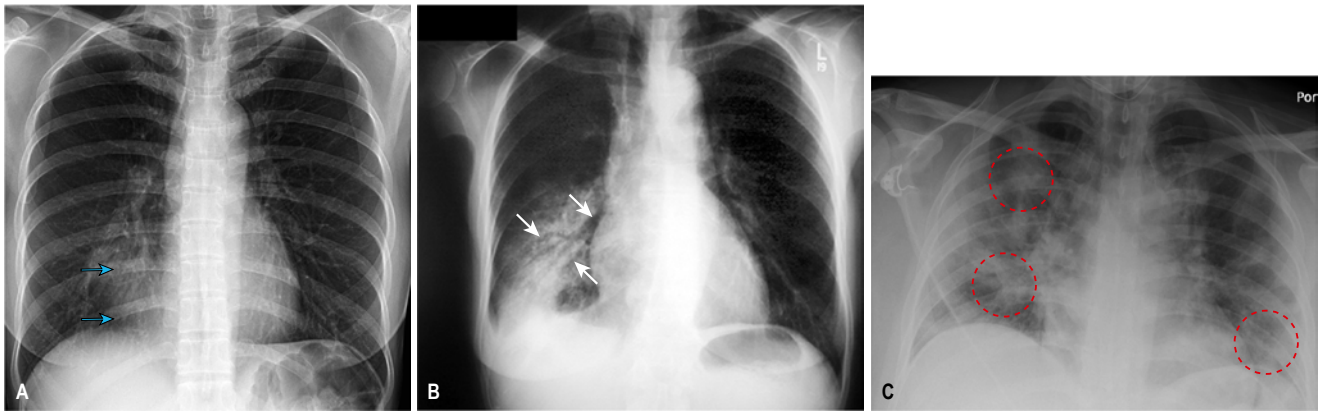

Fig. 8.3 Infection on CXR. **(A)** Right middle lobe pneumonia. The right heart border is indistinct ('silhouette sign'), localizing the consolidation to the anatomical right middle lobe *(arrows)*. **(B)** Right lower lobe pneumonia. In this instance the right diaphragmatic contour is indistinct, localizing to the anatomical right lower lob. Air bronchograms *(white arrows)* can be clearly seen coursing through the consolidated lung. **(C)** Viral pneumonitis (in this instance due to SARS-CoV-2). Notice the patchy bilateral ground-glass opacities (a few of these areas are highlighted by *red circles*). *(Panel A reproduced with permission from* ExpertDDX: Chest, *Second Edition, Elsevier; panel B reproduced from* Respiratory physiotherapy: an on call survival guide, *Elsevier.)*

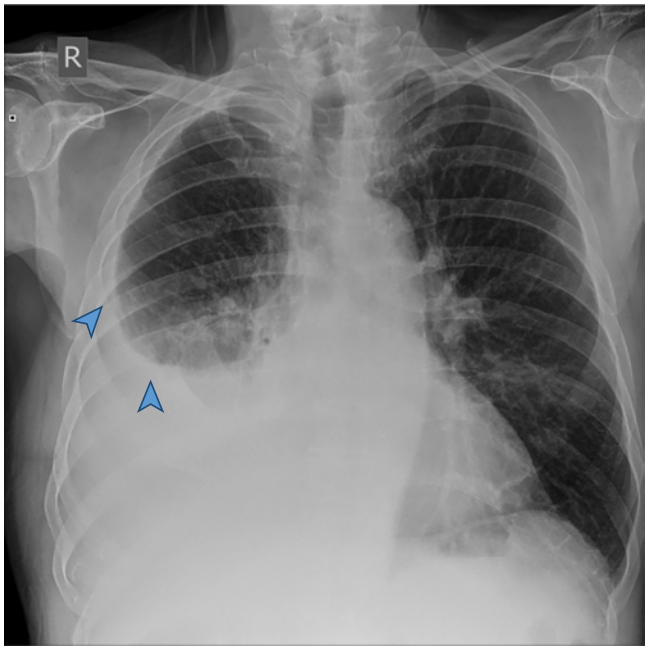

Fig. 8.4 Right pleural effusion. Notice the meniscus *(blue arrowhead)*.

which may be fatal. CXR is one means by which to confirm correct position prior to use (Fig. 8.6).

Free gas

Subdiaphragmatic free gas implies perforation of an abdominal viscus (e.g., perforated duodenal ulcer) (Fig. 8.7). Similar appearances may be seen if an X-ray is taken after recent laparoscopic surgery (where CO_2 is insufflated into the abdominal cavity to aid vision). To detect free gas, the X-ray should be taken after at least 10 minutes with patient in erect or lateral decubitus position.

Lung collapse

Lung collapse implies loss of normal aeration of a lung segment, lobe, or entire lung usually due to a blockage within the lumen of a bronchus (e.g., tumour, retained secretions, or foreign body). Collapse of a significant volume of lung tissue will result in an area of opacification (white) on CXR accompanied by signs of 'volume loss' within the corresponding hemithorax (e.g., deviation of the trachea *towards* the collapsed lung, crowding of ribs or elevated hemidiaphragm on the affected side) (Fig. 8.8).

The lung lobes collapse in characteristic directions:

- The ***lower lobes*** collapse downwards and towards the mediastinum.
- The ***left upper lobe*** collapses forwards against the anterior chest wall. This produces a 'hazy' appearance, or a 'veil-like' opacity, to the entire/much of the left hemithorax.
- The ***right upper lobe*** collapses upwards and inwards, giving the appearance of an arch over the remaining lung.
- The ***right middle lobe*** collapses anteriorly and inwards, obscuring the right heart border.
- If a ***whole lung*** collapses, that hemithorax will appear white, and the mediastinal structures will shift towards the side of the collapse.

Pulmonary fibrosis

Pulmonary fibrosis implies scarring of the interstitial scaffold of the lung tissue and may have numerous causes including connective tissue or granulomatous diseases, drug toxicity, occupational exposures, infection, or rarer idiopathic pneumonitides. Fibrosis produces a reticular pattern of shadowing on CXR accompanied by signs of volume loss in more advanced cases (Fig. 8.9). More generalized fibrosis can lead to a honeycomb appearance (see Chapter 20), seen as diffuse shadows containing multiple circular translucencies a few millimetres in diameter.

Round opacities

Lung cancer is the most common cause of large round shadows but many other aetiologies are recognized (Box 8.4).

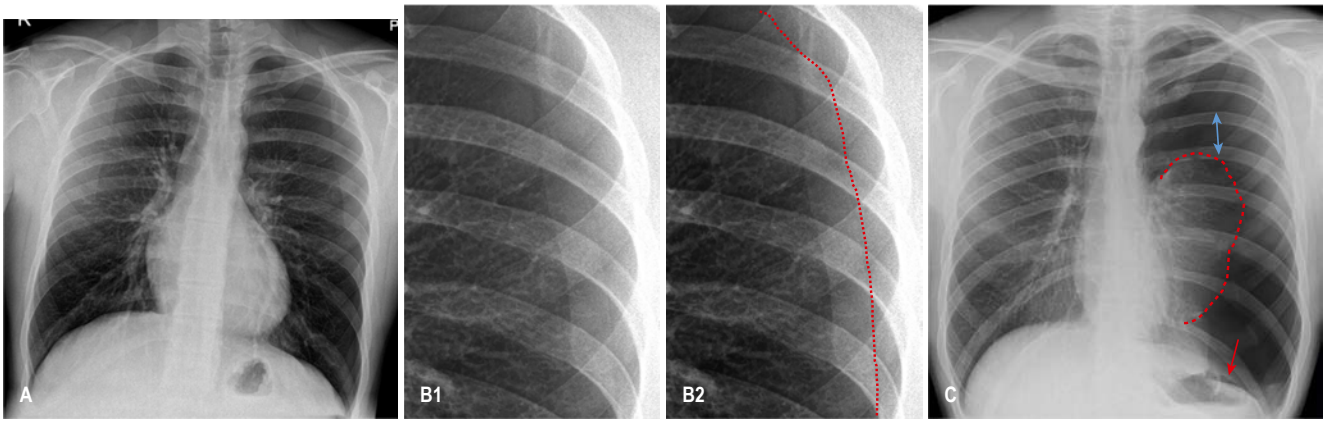

Fig. 8.5 Pneumothorax. **(A)** The left lung has 'deflated' away from the chest wall. To diagnose a pneumothorax confidently, you must see both a lung edge and an absence of lung markings peripherally. **(B)** Enlarged image with lung edge marked by *red outline*. Do not confuse the lung edge with the adjacent scapular edge. **(C)** This is a tension pneumothorax. Notice deflated lung *(red outline)*. Air is in the pleural space. Ribs are splayed apart *(double-headed arrow)*. Diaphragm is depressed downwards into the abdomen by the intrathoracic pressure *(red arrow)*. The heart is pushed towards the right. Without emergency treatment a tension pneumothorax will be fatal; ideally a tension pneumothorax is diagnosed clinically and without delaying treatment to obtain a CXR and so this image is rarely seen.

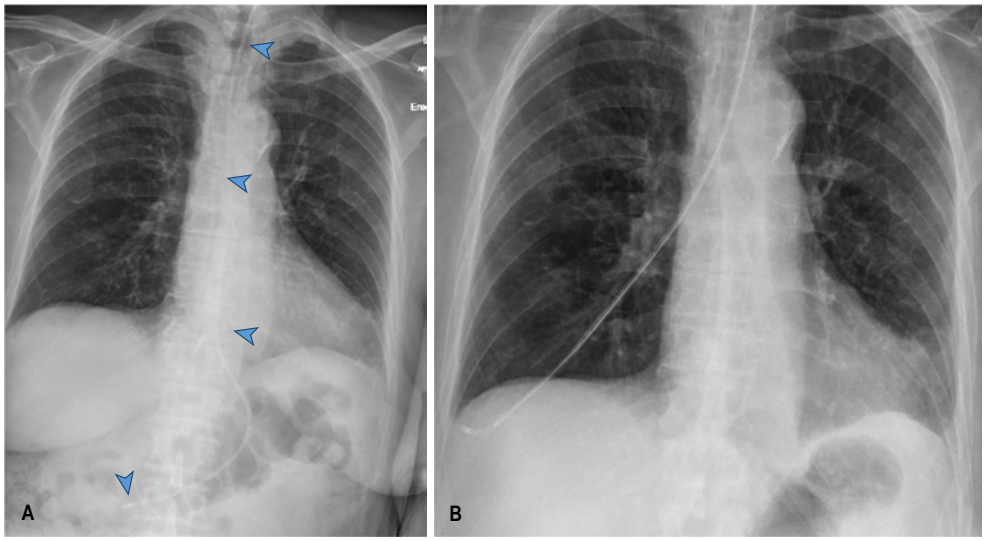

Fig. 8.6 NG tube. **(A)** The NG tube is correctly sited: (1) Tube in midline; (2) bisects carina; (3) crosses diaphragm in the midline and then deviates to the left; (4) tip is clearly seen under the diaphragm (>5 cm) *(blue arrowheads)*. **(B)** In contrast, the tube in this image is sited in the right lung.

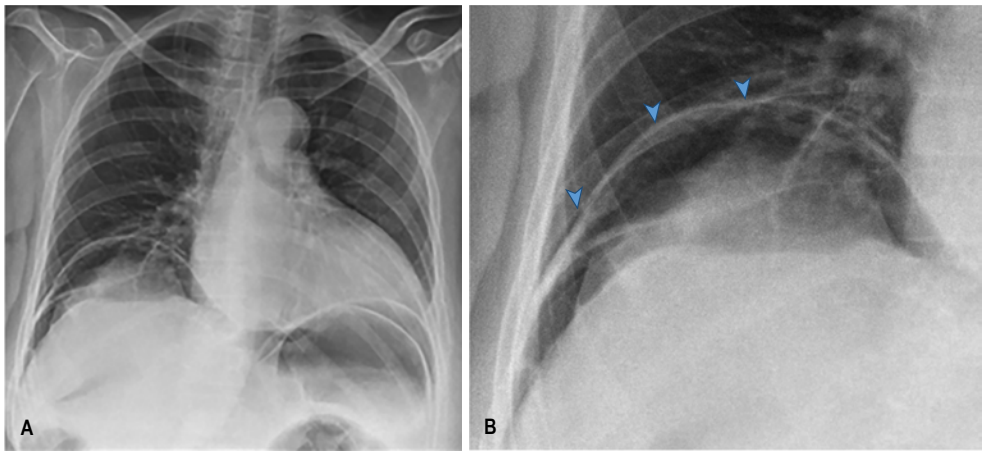

Fig. 8.7 Free gas under both diaphragms. The outline of diaphragm *(blue arrowheads)* can be clearly seen, sandwiched between air above and below it. This patient with inflammatory bowel disease came with severe generalized abdominal pain and vomiting. At operation, there was a duodenal perforation.

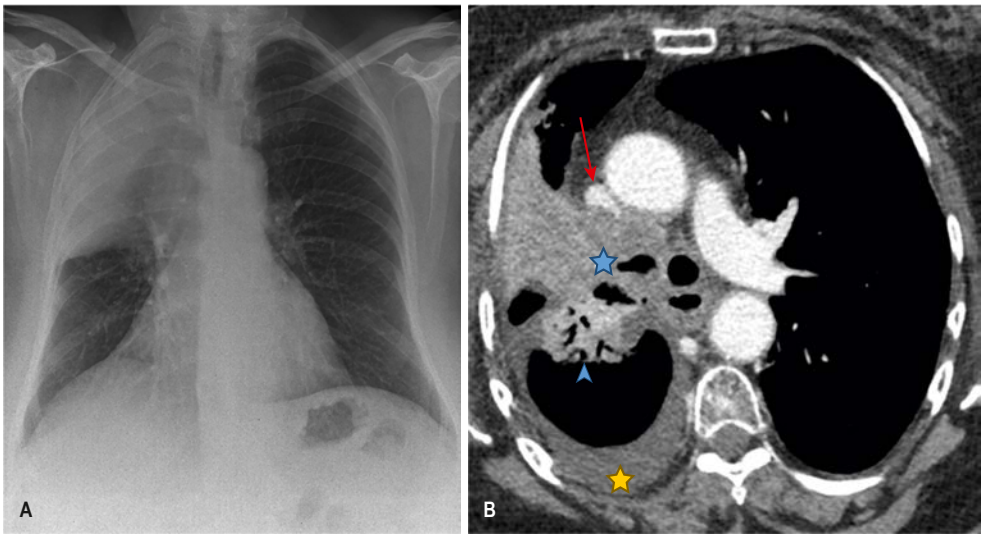

Fig. 8.8 Lobar lung collapse. This patient was a smoker and presented with lethargy and hypercalcaemia. **(A)** CXR demonstrated a collapsed right upper lobe. **(B)** CT demonstrated a large bronchial tumour *(blue star)* causing the lung collapse *(blue arrowhead)* with invasion of superior vena cava *(red arrow)* and a right pleural effusion, not visible on CXR *(yellow star)*. This is a reminder that by the time an effusion is visible on CXR, it is moderately large.

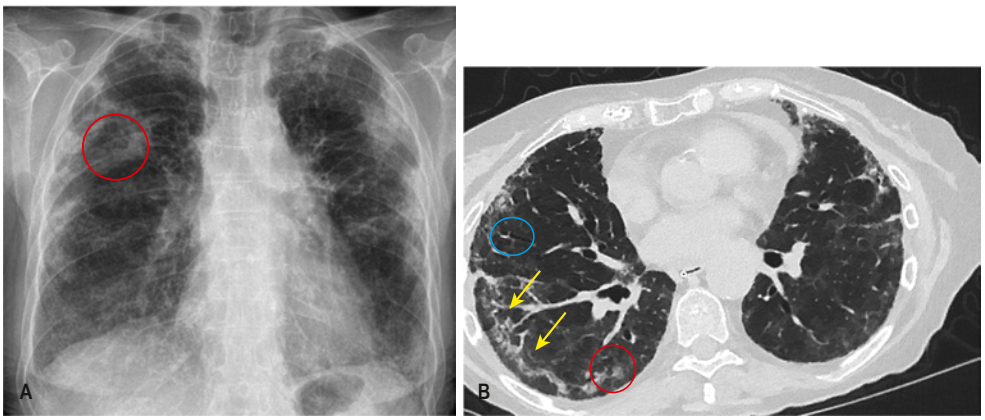

Fig. 8.9 Pulmonary fibrosis. Increased interstitial lung marking, scarring *(yellow arrows)*, ground-glass pulmonary opacity *(red circles)*, and (traction) bronchiectasis *(blue circle)* are visible on CXR **(A)** but better appreciated on CT **(B)**.

? Box 8.4 Causes of round opacities (>3 cm) in the lung

- Carcinoma
- Metastatic tumours (usually multiple shadows)
- Lung abscess (usually with fluid level)
- Encysted interlobar effusion (usually in horizontal fissure)
- Hydatid cysts (often with a fluid level)
- Arteriovenous malformations (usually adjacent to a vascular shadow)
- Aspergilloma
- Rheumatoid nodules
- Tuberculoma (may be calcification within the lesion)
- Bronchial carcinoid
- Cylindroma
- Chondroma
- Lipoma

Other shadows related to mediastinum

- Pericardium
- Oesophagus can be characterized by performing a lateral chest X-ray
- Spinal cord

Abdominal radiography (abdominal X-ray)

Abdominal radiographs are often the first examinations performed for patients with abdominal symptoms. They can be helpful in the diagnosis of ***bowel obstruction*** (Figs. 8.10 and 8.11). AXR has low sensitivity (~15%) for detection of bowel perforation (presence of 'Rigler's sign' where both sides of a bowel wall are outlined distinctly by intra- and extraluminal gas, Fig. 8.12) but may be helpful in neonates.

Skeletal radiography

Since the first X-ray image taken by Röntgen of his wife Anna's hand in December 1895, skeletal radiography continues to be the modality to investigate the skeletal system today. X-rays can diagnose ***fractures*** (Fig. 8.13), ***arthritis*** (Figs. 8.14 and 8.15), and ***bone destruction from infection*** (Fig. 8.16) or ***cancer*** (Fig. 8.17). This is because of the excellent contrast between bones (which absorb a lot of X-rays) and adjacent soft tissues (which absorb less X-rays).

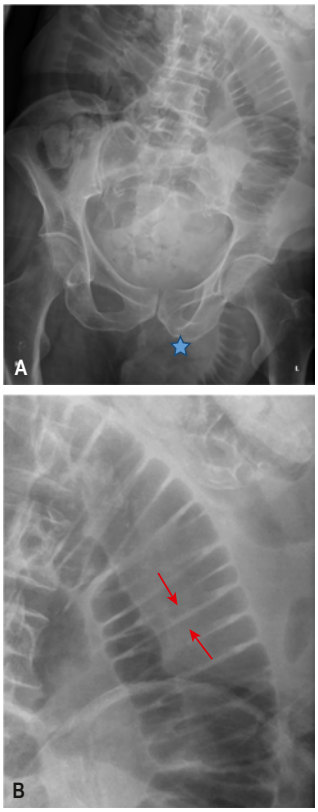

Fig. 8.10 Small bowel obstruction. This patient presented with abdominal pain, distension, and vomiting. AXR demonstrates small bowel obstruction. Notice dilated (>2.5 cm) loops of centrally positioned small bowel (recognized by valvulae conniventes which span across the whole width of the bowel, *red arrows*). The left inguinal hernia is the cause *(blue star)*.

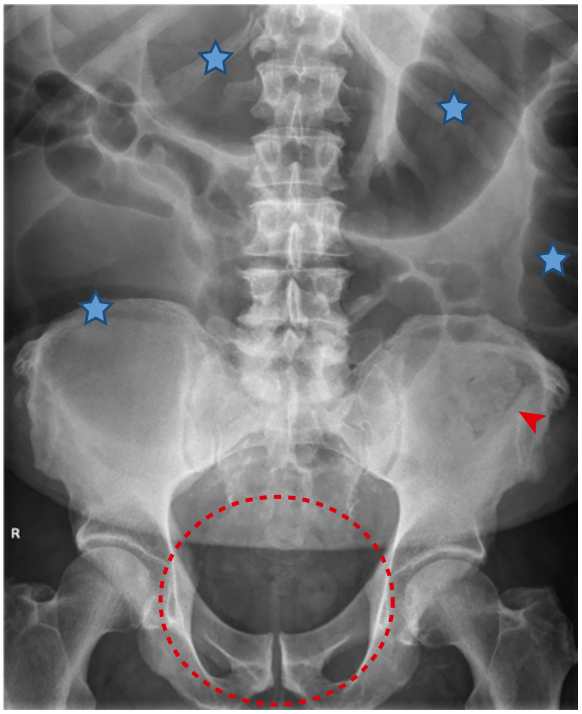

Fig. 8.11 Large bowel obstruction. This patient presented with abdominal pain and no bowel movement for 2 days. They were tender on abdominal examination. AXR demonstrated dilated peripherally placed large bowel *(blue stars)*, stopping abruptly in the descending colon *(red arrowhead)*. There is no visible rectal gas *(red outline)*. This patient had an obstructing descending colon tumour.

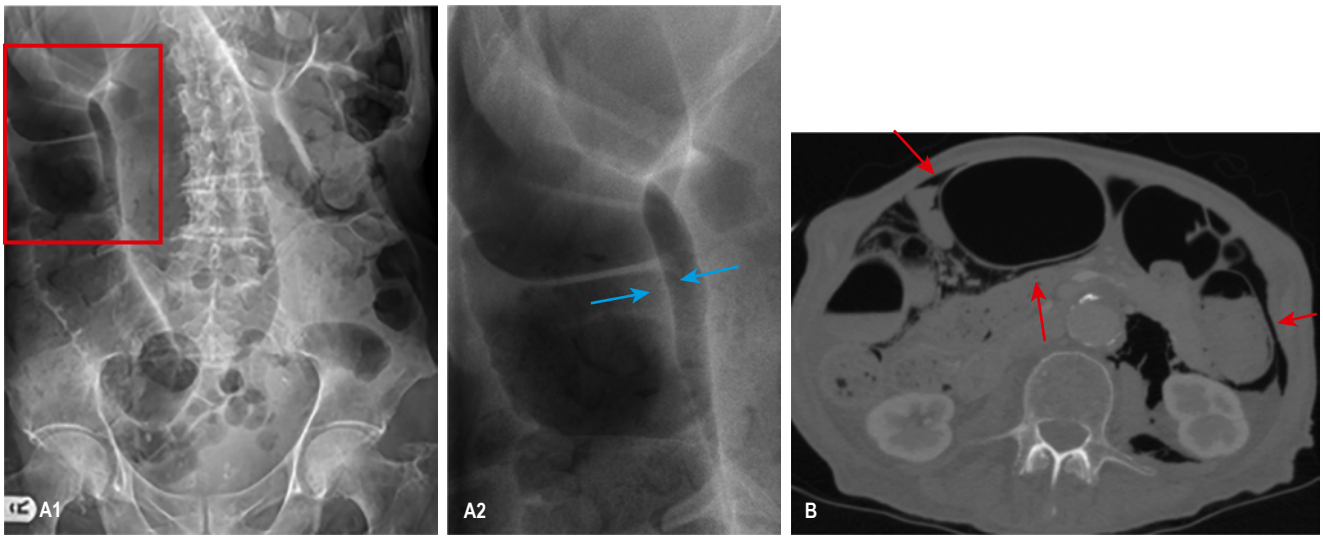

Fig. 8.12 Perforation: This patient with known sigmoid volvulus complained of severe abdominal pain. (A) AXR demonstrates the sigmoid volvulus and Rigler's sign *(blue arrows)*. **(B)** CT demonstrates large amount of free extraluminal gas *(red arrows)*, indicating perforation.

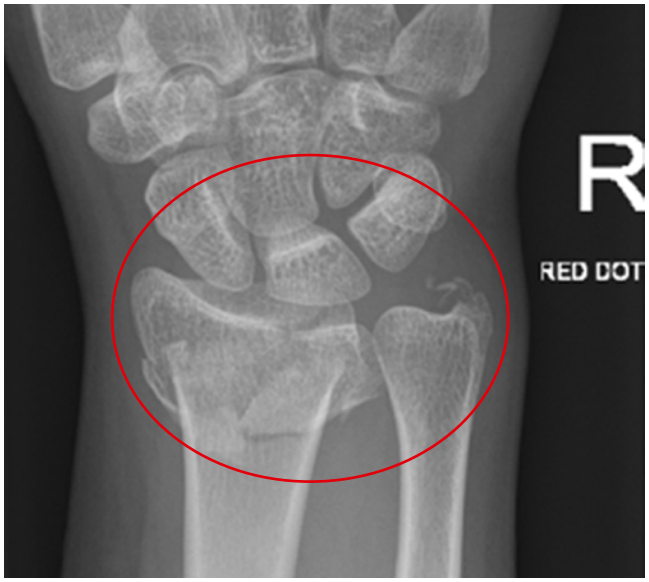

Fig. 8.13 Fractures of distal radius and ulna *(red circle)*. When reviewing an X-ray for possible fracture, trace the margin of a bone looking for disruption of the normal smooth contour and consequent loss of internal trabecular continuity. In this instance the emergency radiographer has noted an abnormality and marked the X-ray with a 'Red dot'.

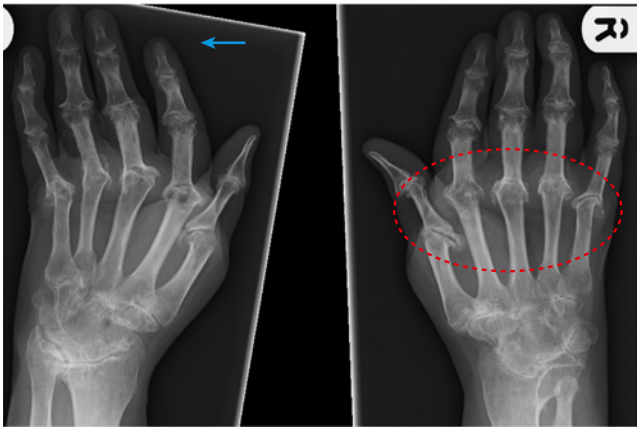

Fig. 8.14 X-rays of a patient's hands with rheumatoid arthritis. Notice the ulnar deviation (fingers deviating towards ulna: *blue arrow* demonstrating the direction) and symmetrical para-articular erosions affecting the metacarpals *(red circle)*, proximal interphalangeal joints, and wrists.

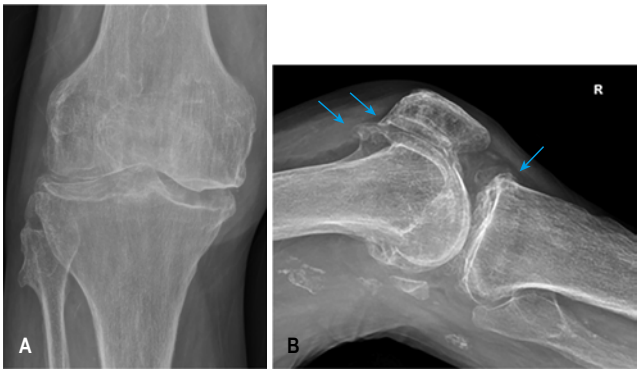

Fig. 8.15 Joint space narrowing, subchondral sclerosis, and osteophytes in a knee with marked degenerative change. *Blue arrows* pointing to visible exophytic osteophytes extending from the articulating surfaces of femur, patella, and tibia.

Fig. 8.16 Digital osteomyelitis. This patient with diabetes had a chronic ulcer on their great toe. Note the marked vascular calcification *(arrow)*. The tuft of the distal phalanx is ill-defined, in keeping with osteomyelitis. Note: normal X-rays do not exclude osteomyelitis. X-ray has a low sensitivity (5% at presentation; 33% at 1 week). If there is concern regarding osteomyelitis, bone scan or MRI should be performed.

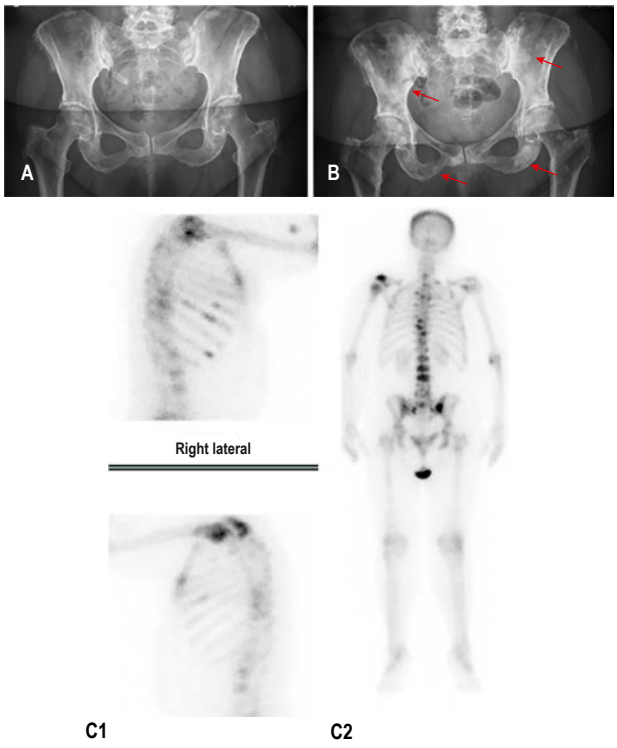

Fig. 8.17 Sclerotic bone metastases. This patient with breast cancer developed bone metastases. Notice the multiple new sclerotic bone metastases *(red arrows)* on the pelvic X-ray **(B)**, new from 8 months previous **(A)**. Bone scan (**C**, showing widespread skeletal 'hot spots' in the same patient) and MRI are much more sensitive at detecting bone metastasis and should be performed if clinical management is dependent on their identification.

Mammography

Breast imaging by mammography is used either as part of the assessment of female patients presenting with breast symptoms or as screening to detect ***early breast cancer*** (Fig. 8.18; see also Chapter 47). It uses X-rays to detect calcifications (e.g., ductal carcinoma in situ) or masses within the breast. Each breast is compressed during the procedure to acquire the best

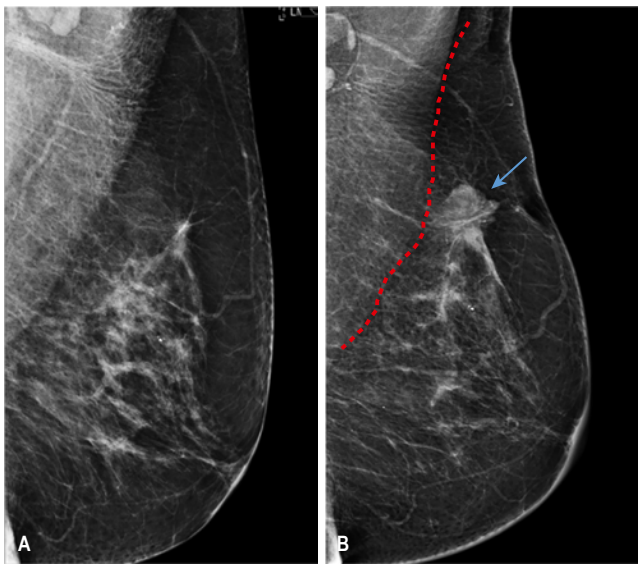

Fig. 8.18 Mammogram. This patient presented with a 2 cm palpable left breast lump. Mammography **(B)** demonstrates the mass *(blue arrow)* and tenting of the pectoralis muscle *(red dotted line)* from this tumour. These were not present on the previous examination **(A)**.

quality images. Some women may find this uncomfortable. Two (sometimes three) views are taken. Radiation-related carcinogenic risk is considered small in relation to the potential benefits of screening. Individuals who are known to be carriers of risk-increasing genetic variations and/or have an inherited predisposition to breast cancer, as well as those who suffer from hyper-susceptibility to ionizing radiation should avoid ionizing radiation as much as possible, however, and should instead be referred for ultrasound or MRI.

FLUOROSCOPY

Fluoroscopy uses X-rays to acquire images of a patient, usually during live, 'dynamic' examinations to demonstrate anatomy and interrogate function after administration of a radio-opaque contrast, for example barium or Gastrografin (an iodine-based contrast medium).

This section focuses on barium swallow and voiding micturating cystourethrogram (VMCUG) as examples of common fluoroscopic investigations. Other applications of fluoroscopy include barium defecography/proctography (imaging the patient's ability to evacuate their rectum) and hysterosalpingography (helpful in fertility investigation). Small bowel barium follow-through and intravenous pyelogram are less frequently/no longer performed in a modern radiology department and have been superseded by MRI enterography/enteroclysis and CT intravenous urogram, respectively, where superior images are obtained with similar or no (in the case of MRI) radiation.

Barium swallow

Common indications: High (cervical) dysphagia; suspicion of disordered swallowing (neurological or muscular); aspiration. (Upper GI endoscopy, rather than barium studies, is the preferred examination to investigate patients with dyspepsia and suspected gastro-oesophageal reflux or gastric ulcer disease.)

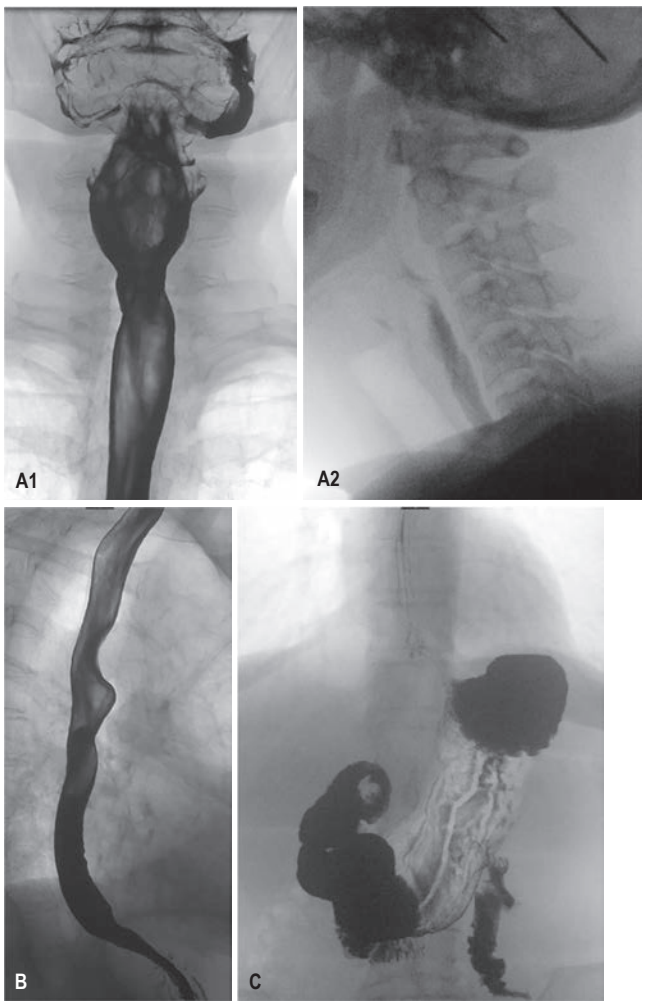

Fig. 8.19 Normal barium swallow. **(A)** Frontal and lateral view of cervical oesophagus; **(B)** oblique view of thoracic oesophagus; **(C)** frontal view of the stomach.

Patient preparation: Fasting, usually 4 to 6 hours—occasionally overnight.

Procedure: The patient is given a cup of liquid barium which can be mixed with an effervescent agent (Carbex®) to drink from. When instructed by the radiologist/fluoroscopist, the patient takes a mouthful of barium and swallows. Simultaneously the radiologist times the acquisition of 'cine'-images—much like a video—to demonstrate precisely the passage of barium from the mouth down the oesophagus.

Fig. 8.19 shows images from a normal barium swallow. Figs. 8.20 and 8.21 show findings from patients with achalasia and a pharyngeal pouch, respectively.

Voiding micturating cystourethrogram

Common indications: Urinary tract infection(s), dysuria, dysfunctional voiding, bladder outlet obstruction, trauma, neurogenic dysfunction of the bladder, congenital anomalies of the genitourinary tract, and postoperative evaluation of the urinary tract.

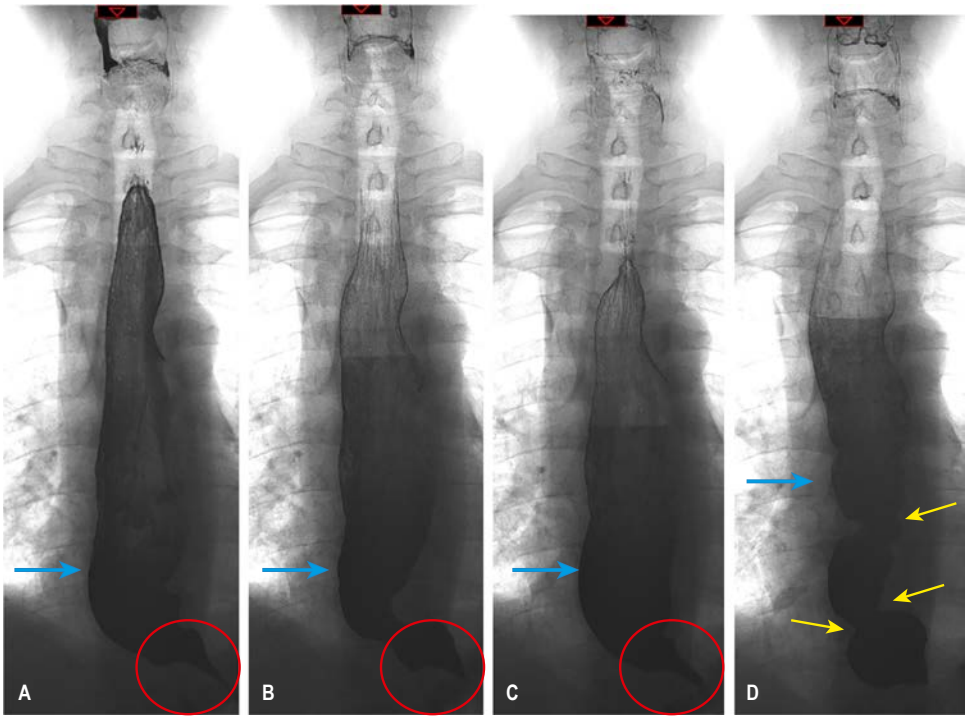

Fig. 8.20 Barium swallow: Achalasia. **(A–C)** There is a persistent narrowing at the end of the oesophagus (*red circles*, the lower oesophageal sphincter, LOS), with a dilated oesophagus *(blue arrows)* above the narrowed region. **(D)** Spastic contractions in the oesophagus above the LOS, are also visible *(amber arrows)*.

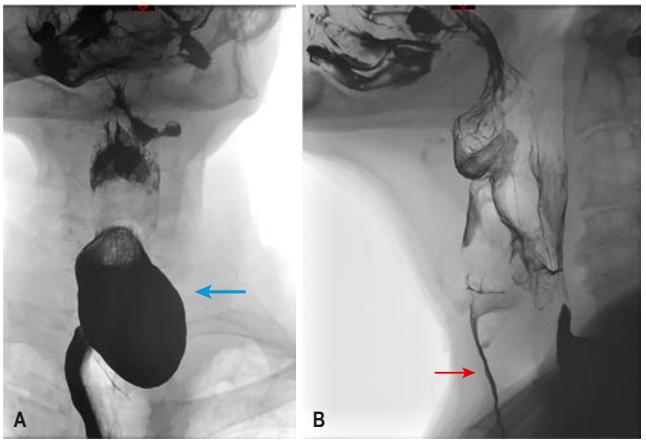

Fig. 8.21 Barium swallow: Pharyngeal pouch. This patient has a large pharyngeal pouch *(blue arrow)*. Aspiration of barium can be seen in the trachea *(red arrow)*.

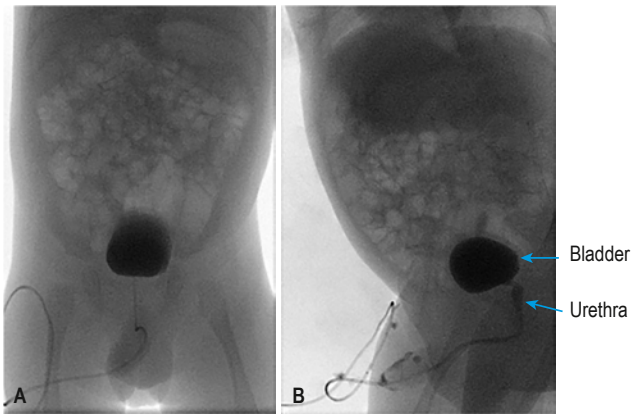

Fig. 8.22 Normal VMCUG. **(A)** Anteroposterior and **(B)** lateral views. Contrast is seen in the urinary bladder, urethra, and catheter.

Patient preparation: Patients often require antibiotics to 'cover' the procedure (this could be pre- and post-examination or doubling any usual prophylactic dosage for a few days, depending on agreed local protocols). Patients (adults or children who are able to cooperate) usually empty their bladders prior to the procedure. If the patient is an infant, an adult accompanies the infant to support them in remaining still for the examination.

Procedure: The patient having the examination lies on the fluoroscopy table. A urinary catheter is placed into the bladder through the urethra, under aseptic conditions. Contrast is then infused through the catheter to fill the bladder.

Babies and young children will naturally pass urine when the bladder is full. Older children/adults will be given a receptacle to void while lying on the table, when they feel ready. The radiologist/fluoroscopist will take cine-images/videos using X-rays while the patient voids.

A normal VMCUG is shown in Fig. 8.22 and images from a patient with reflux nephropathy in Fig. 8.23.

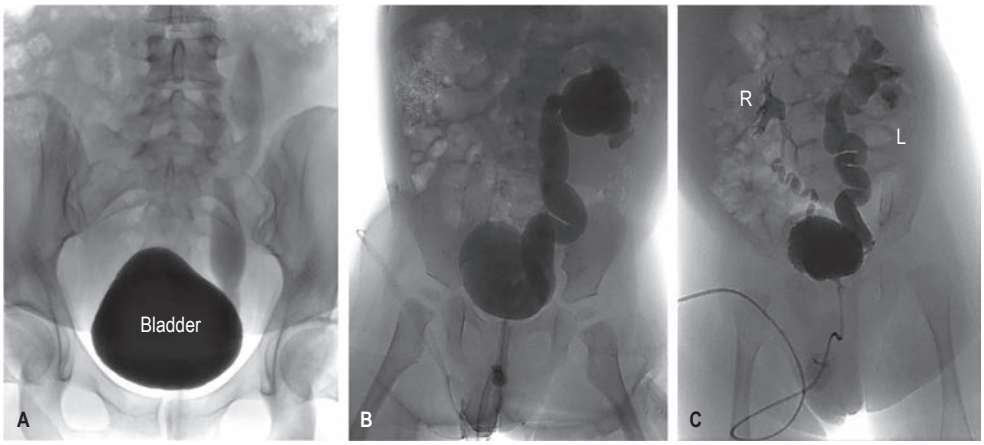

Fig. 8.23 VMCUG: Reflux nephropathy. **(A)** This study shows contrast in the urinary bladder. **(B)** Contrast can be seen refluxing into a dilated left ureter (with left hydronephrosis) and **(C)** non-dilated right ureter.

Box 8.5 Principles of ultrasound (US) imaging

- The ultrasound transducer contains piezoelectric crystals. These produce high-frequency sound waves when an electrical current is applied. They also act in reverse—producing an electric field when sound waves are applied to them. The transducer therefore both emits ultrasound waves into and detects waves reflected back ('echo') from the body. These electrical currents are converted by a computer into images by calculating the distance between the transducer and the body (using the speed of sound and the time of each echo's return).
- Minimizing the distance between the transducer and organ of interest reduces the energy lost in the body tissue, thereby improving the image quality.
- Gel applied between the transducer and body improves image quality by minimizing air pockets. Air blocks ultrasound waves and prevents images from being generated.
- Does not involve ionizing radiation.
- Relatively low cost and accessible modality; well tolerated by patients.
- Almost all parts of the body can be imaged. It is particularly useful in evaluating pelvic and intra-abdominal organs.
- Endoscopic ultrasound produces high-resolution images of many internal organs such as the oesophagus, heart (transoesophageal US), and the reproductive organs (transvaginal US).
- Ultrasound is occasionally performed with intravenous contrast agents e.g., to evaluate or treat liver or kidney tumours.
- Patient preparation is sometimes required (e.g., fasting when evaluating gallbladder or a full bladder when examining pelvic organs).

ULTRASONOGRAPHY

Ultrasound (US) is an excellent modality for evaluating many organs (**Box 8.5**). It is the modality of choice for evaluating superficially placed organs such as the thyroid gland, testes, and leg veins for venous thrombosis. US is also often used as the first-line test for the solid upper abdominal and pelvic organs with common indications including abdominal pain, deranged liver function, renal impairment, haematuria, and sepsis. US can even be used to evaluate a neonate's brain through the soft fontanelles. The use of US and Doppler to evaluate cardiac function by echocardiography is discussed in Chapter 17.

The kidney

US is frequently used as a first-line modality to image the urinary tract (**Fig. 8.24**). Common diagnoses visible on US include ***renal tract obstruction*** (**Fig. 8.25**) (resulting in hydronephrosis, a potential

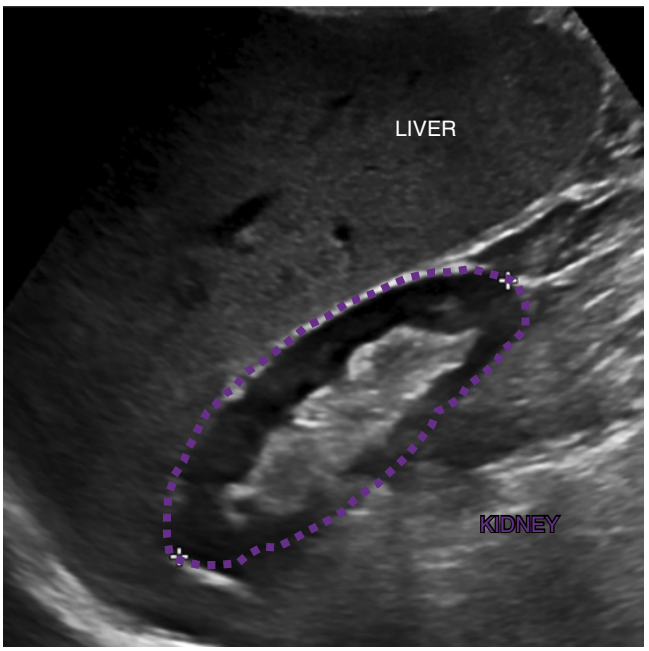

Fig. 8.24 The normal kidney on US. This US image demonstrates a normal right kidney *(purple outline)*, adjacent to a normal liver. Note normal renal cortex and medulla are distinct from the echo-bright renal sinus fat.

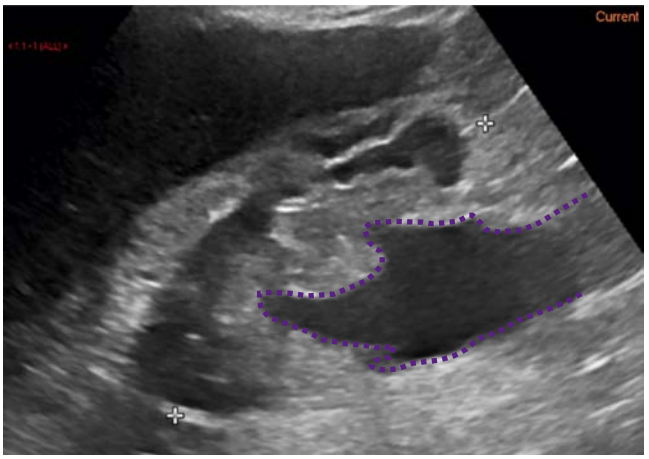

Fig. 8.25 Hydronephrosis on US. This kidney is obstructed. Notice the dilated renal pelvis and calyces *(purple outline)* extending from the renal medulla into the dilated ureter. Cortical thinning is also evident, particularly towards the lower pole, suggesting the obstruction may be long-standing.

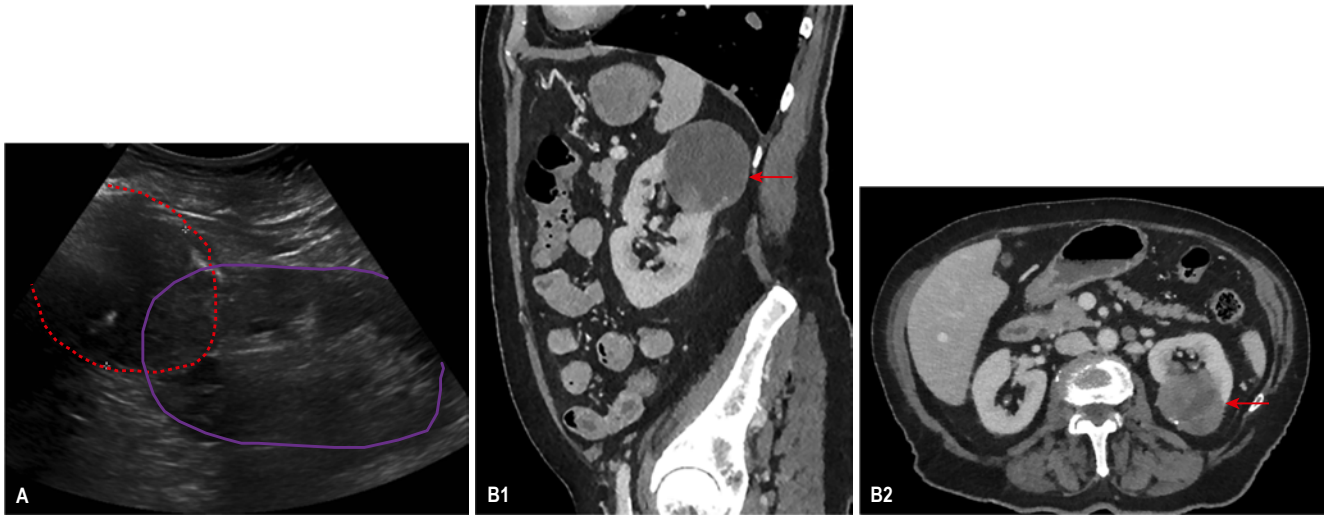

Fig. 8.26 Renal mass lesion on US. **(A)** US shows a large mass *(red outline)* at the superior pole of right kidney *(purple outline)*. **(B)** CT images of the renal tumour *(red arrow)* in the same patient.

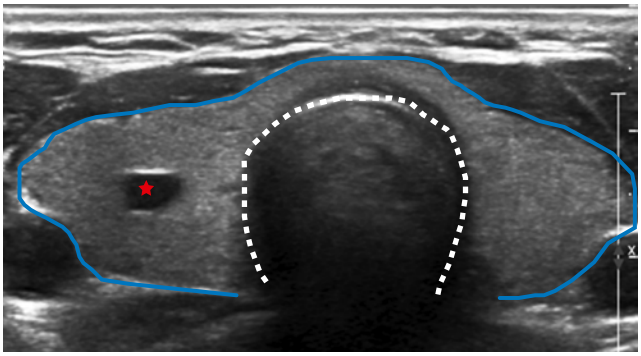

Fig. 8.27 US of normal thyroid gland. A normal thyroid *(outlined in blue)* wrapping around the air-filled trachea *(white dotted outline)*. Incidental cyst *(red star)* of no clinical significance.

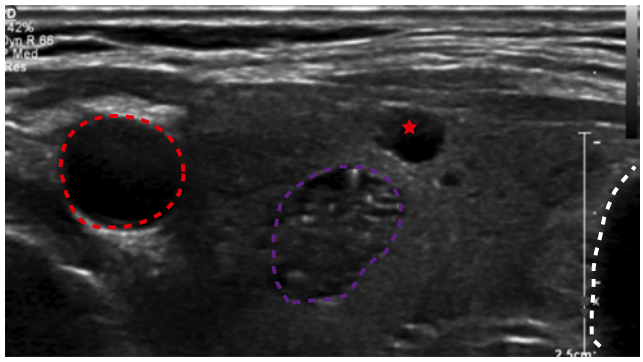

Fig. 8.28 Thyroid colloid cyst on US. This thyroid has a small colloid cyst *(purple outline)*, a common benign thyroid nodule. Trachea *(white outline)*, cyst *(red star)*, and jugular vein *(red outline)*.

cause of renal impairment or sepsis) and ***renal masses*** (Fig. 8.26; potential cause of haematuria or anaemia).

Thyroid gland

The thyroid gland lies superficially in the neck, on either side of the centrally placed trachea (Fig. 8.27). Imaging may be required if a neck swelling is palpable, to evaluate thyroid dysfunction or to further investigate abnormalities detected incidentally by other examinations such as CT or PET-CT (Figs. 8.28 and 8.29).

Pelvic organs: uterus and ovary

US is the first-line modality and investigation of choice when imaging the gynaecological pelvic organs (Fig. 8.30). These examinations require patients to have a full bladder; the urine-filled bladder allows transmission of ultrasound waves from the transducer on the abdominal wall to the pelvic organs, which would otherwise be interrupted by the gas-containing bowel, obscuring the view. Alternatively, a transducer placed internally—a transvaginal US (TVUS)—may be used, which gives much higher resolution images as the probe is now located much closer to the organs of interest (Fig. 8.31).

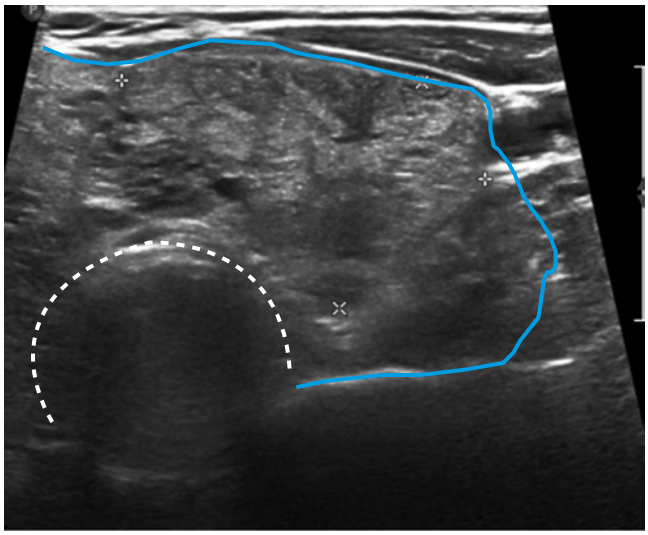

Fig. 8.29 Multinodular goitre on US. This thyroid is enlarged and contains multiple nodules—a multinodular goitre *(blue outline)*. The trachea is outlined in *white*.

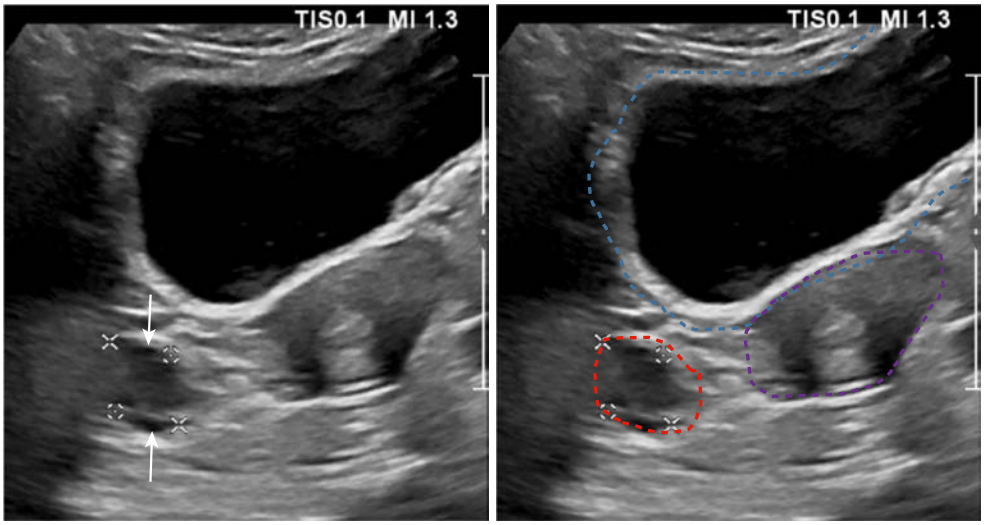

Fig. 8.30 Transabdominal US of the pelvic organs. This is a transabdominal US image of the right ovary *(red outline)* and uterus *(purple outline)*. Note the full bladder *(blue outline)* and the small cysts contained within the ovary *(white arrows)*.

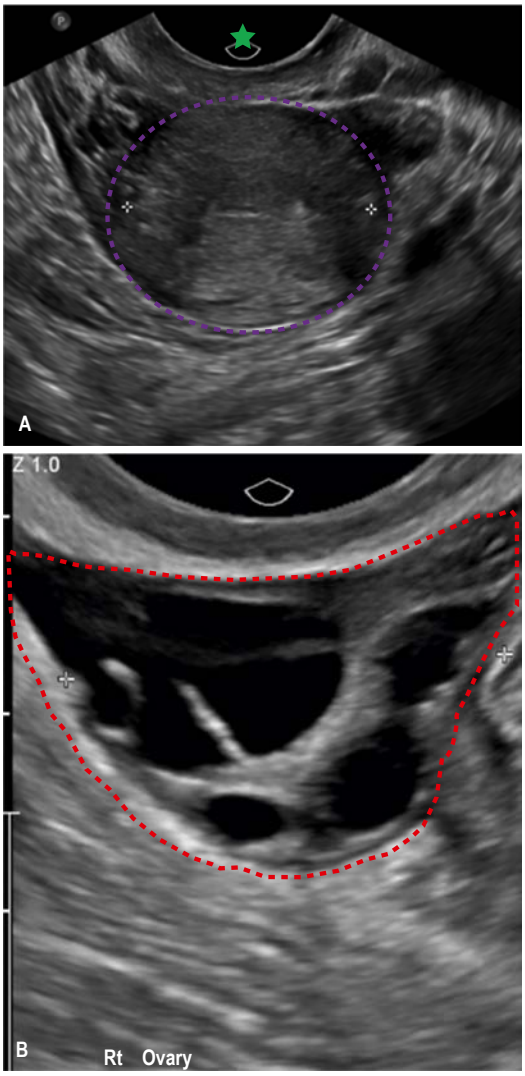

Fig. 8.31 Transvaginal US of the pelvic organs. TVUS images from the same patient as **Fig. 8.30**. The transducer *(green star)* is in much closer proximity to the uterus (**A**, *purple outline*) and right ovary (**B**, *red outline*), therefore the images obtained are of a superior quality.

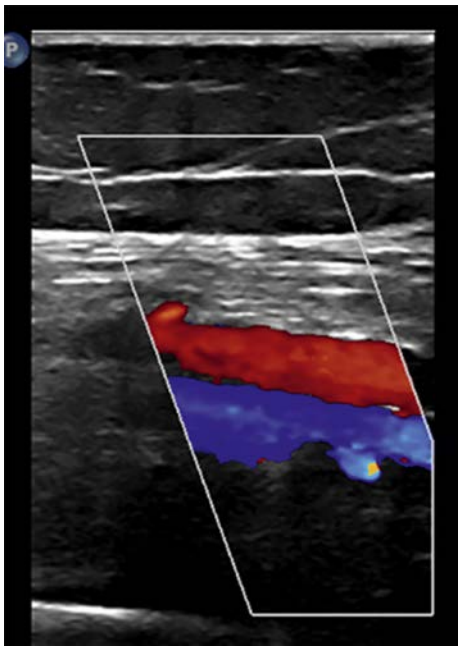

Fig. 8.32 US of femoral vein and artery. Doppler colour flow is demonstrated in the normal patent femoral vein *(blue)* and adjacent femoral artery *(red)*. Notice the colour block extends wall-to-wall within each vessel. The colour *(blue/red)* denotes the direction of flow of blood corpuscles: *blue* for blood flowing towards and *red* for blood flowing away from the transducer *(white angled box)*.

TVUS, however, may be uncomfortable for some patients, while others may find it too intrusive.

Venous ultrasound

Despite their name, the deep leg veins are readily seen on US (**Fig. 8.32**). Patent veins are easily compressible, completely anechoic ('black') internally within the lumen and when colour Doppler sound waves are applied, wall-to-wall colour can be seen inside the vessel. Venous US is commonly employed in the patient presenting with a swollen leg, where it can aid in discriminating between venous thrombosis, cellulitis, and 'simple' oedema (**Fig. 8.33**).

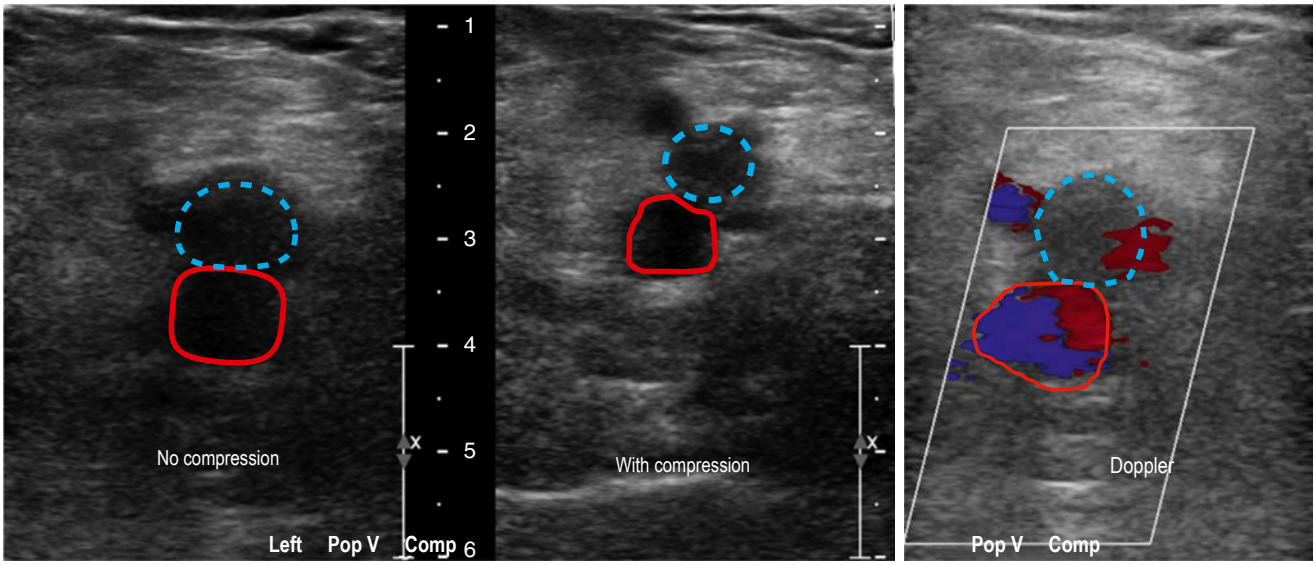

Fig. 8.33 Popliteal vein thrombosis. This patient has a thrombus in their popliteal vein. Notice the echogenic ('bright') thrombus lying within the lumen of the popliteal vein *(blue outline)*, in contrast to the patent popliteal artery *(red outline)*, which appears black. Notice too that the calibre of the popliteal vein does not change with external compression as the thrombus prevents the vein from completely flattening—as would be observed in a patent vein. No flow (colour) is seen in the vein when Doppler is applied. Wall-to-wall Doppler flow is visible within the patent artery.

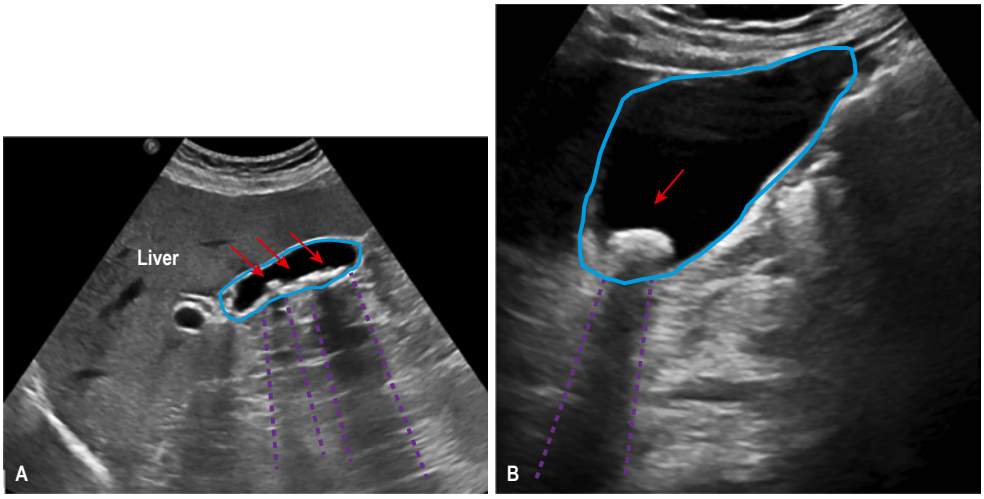

Fig. 8.34 US of liver and gallbladder. (A) There are multiple echogenic ('bright') gallstones *(red arrows)* within a normal thin-walled gallbladder *(blue outline)*. Notice the acoustic shadows cast by the gallstones *(purple lines)*. **(B)** Another example of an echogenic gallstone *(red arrow)* within a normal gallbladder *(blue outline)*, casting an acoustic shadow *(purple)*.

Hepatobiliary disease

The liver and gallbladder are easily visualized and well evaluated by US. Indeed, US is the most sensitive test for detecting the presence of ***gallstones*** (Fig. 8.34). Gallstones are best seen when the gallbladder is maximally distended—this requires the patient to be adequately fasted prior to the examination. US is also used as a first-line tool to evaluate a patient with ***deranged liver function tests***, a screening tool to detect ***hepatocellular carcinoma*** in patients with chronic liver disease and can be used to evaluate liver stiffness/fibrosis using a technique called elastography (see also Chapter 23).

Testis

Just like the thyroid gland, the testes are readily accessible to US, lying immediately under the skin (Fig. 8.35). Abnormalities within the testes are often palpable and easily visualized by US (Fig. 8.36).

Special ultrasound procedures

High-intensity focused ultrasound (HIFU): Therapeutic ultrasound which uses high levels of acoustic output to focus on specific targets for the purpose of heating, ablating, or

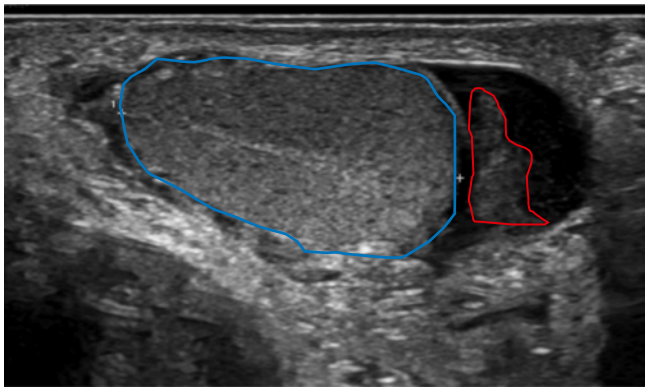

Fig. 8.35 US of the normal testis. A normal testis *(blue outline)* lying superficially under the scrotal skin. Epididymis is outlined in *red*.

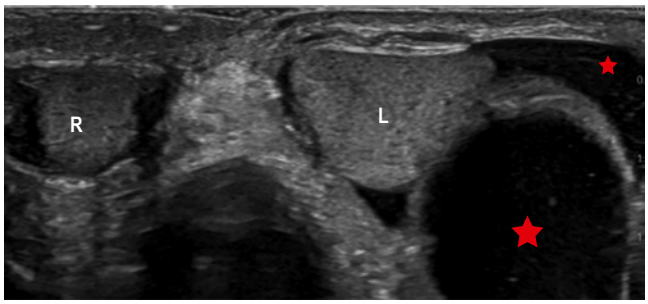

Fig. 8.36 Hydrocoele. Both testes are seen in this image (R and L). A left-sided hydrocele (dark excess fluid around the testis, *red stars*) is present.

breaking up tissue. Examples include treatment of uterine fibroids, to alleviate pain from bone metastases, and ablation of prostate tissue.

Ultrasound contrast: Intravenous injection of a highly echo-reflective substance, usually microbubbles filled with gas, allows assessment of vascularization of target structures—commonly used for focal masses in the liver or kidneys.

COMPUTED TOMOGRAPHY

Computed tomography (CT) is the 'workhorse' of the modern radiology department (Box 8.6). It is the modality of choice for evaluating many acute or emergency presentations on account of the excellent diagnostic images, ready availability, and speed of image acquisition—ideal for the unwell patient. It is also used for routine diagnostic or follow-up indications.

Examinations may be performed with or without iodinated intravenous contrast agents (Box 8.7), depending on the clinical indication. This section will discuss the common examinations under each anatomic system.

It should be emphasized that CTs are complex examinations. Interpretation of these large datasets of images requires years of training and (uninterrupted) time. By providing the reporting radiologist with as much salient information as possible, you will help improve the accuracy of the report—and patient outcome—greatly.

Tip: when viewing a CT scan in the axial plane, imagine you are viewing the image from the perspective of the patient's feet—structures on the right of the patient's body (e.g., liver) will be seen on the left side of the image.

Box 8.6 Computed tomography (CT)

- Images are produced with the same principles as X-rays.
- The scanner contains one or two X-ray sources and multiple detectors spin rapidly around the patient as they move through the scanner on the table.
- Images are produced by a computer from the information received by the detectors. Images can be reconstructed in multiple planes (axial, sagittal, and coronal) and even in three-dimension.
- Just like X-rays, images relate to how much X-ray energy is absorbed by the body: for example, bones appear 'white' or 'dense' on a CT because most of the X-rays have been absorbed. Lungs filled with air absorb little X-ray so appear 'dark'.
- Density of images is described using 'Hounsfield Units' (HU). Water is assigned as having 0 HU. Bones are dense with high HU (often >1000), air is low density (<–500 HU), and soft tissue is around 50 HU.
- Involves ionizing radiation.
- Radiation dose is higher than X-ray.
- All parts of the body can be imaged.
- Patient preparation is sometimes required (e.g., venous access may be required for intravenous contrast).

Box 8.7 Iodinated intravenous contrast: patient considerations

- Require venous access—large bore if angiogram is being performed.
- ALLERGY: Some patients may be allergic to iodinated contrast. It is important to alert the Radiology Department if the patient has had a previous contrast-related reaction.
- RENAL IMPAIRMENT: Patients with renal impairment should receive intravenous contrast if its use is deemed necessary to answer the clinical question with monitoring of renal function following the exposure.
- HYPERTHYROIDISM: Patients with a history of hyperthyroidism rarely develop thyrotoxicosis. However, iodinated contrast should be avoided in patients with acute thyroid storm or those considering/undergoing radioactive iodine therapy.

The brain

CT brain is often the first imaging examination for patients presenting with neurological impairment, confusion, headache, or trauma. It demonstrates the cerebral soft tissues, ventricles, and cerebrospinal fluid spaces as well as the cranium with exquisite clarity—allowing the diagnosis of ***infarction*** (Fig. 8.37), ***haemorrhage*** (Figs. 8.38 and 8.39), or ***tumour*** (Fig. 8.40).

Thorax

Common indications for performing CT of the thorax include further assessment of an abnormal CXR (Fig. 8.41); unexplained weight loss in a smoker (Fig. 8.42) or if there is clinical concern of an underlying pulmonary embolus (CT pulmonary angiography [CTPA], see Fig. 8.49). With the exception of pulmonary nodule follow-up and CT for diagnosing interstitial lung disease, most CT thorax examinations are performed with intravenous contrast. Low-dose CT scans of the thorax are used to screen for lung cancer in patients with elevated risks of developing lung cancer (i.e., those with significant smoking history).

Abdomen and pelvis

The patient presenting acutely with abdominal pain or trauma is frequently sent for a CT of abdomen and pelvis. Common diagnoses

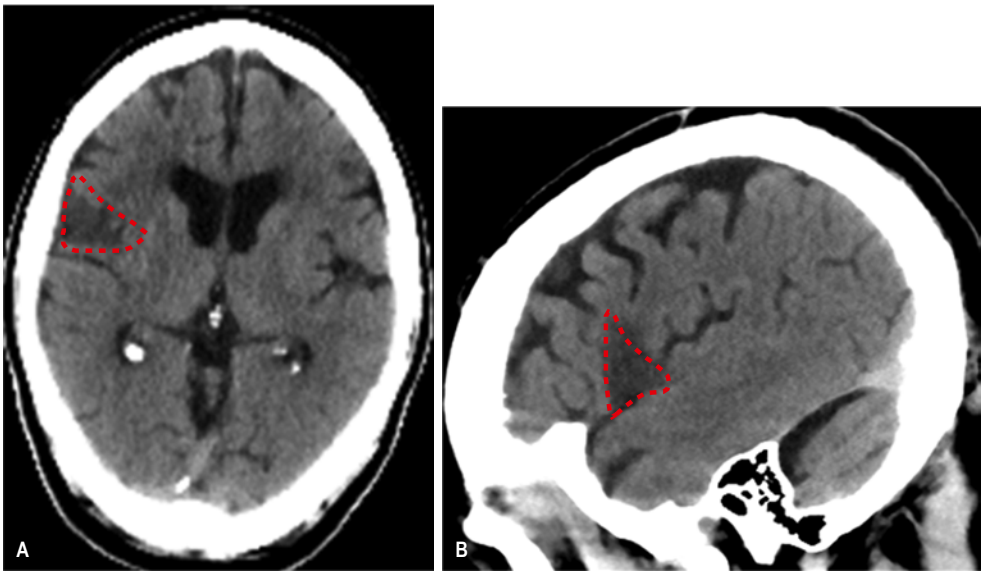

Fig. 8.37 Cerebral infarction on CT. This patient presented with a sudden onset of frontal headache, slurred speech, and facial droop. A wedge-shaped low-density zone is apparent in the right frontal lobe *(red outline)*: an area of infarction consistent with an ischaemic stroke. **(A)** Axial view; **(B)** saggital view.

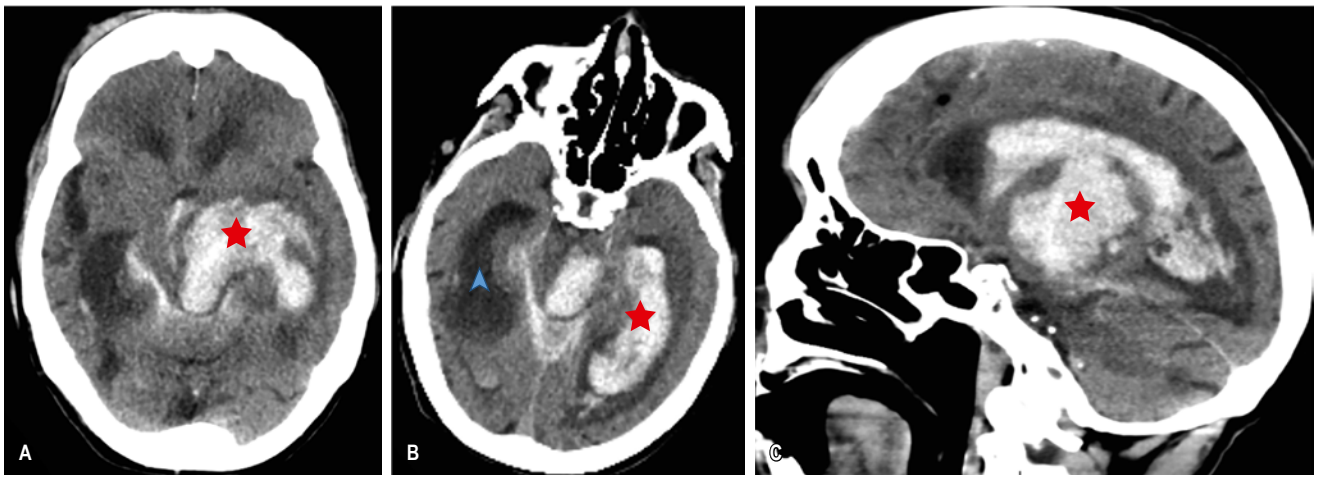

Fig. 8.38 Intraventricular haemorrhage on CT. This patient was found collapsed on the floor at home having last been seen the night before. There were signs of external head injury and GCS was 3. CT demonstrates blood in all ventricles *(red star)*, causing obstructed hydrocephalus *(blue triangle)* and left to right midline shift. **(A)** and **(B)** Axial views; **(C)** saggital view.

include ***renal calculi*** (Fig. 8.43), ***hernias*** (Fig. 8.44), ***bowel obstruction*** (Figs. 8.45 and 8.46), intra-abdominal causes of sepsis, ischaemia, haemorrhage, and complications of severe pancreatitis.

CT allows for optimized preoperative surgical planning and may prevent unnecessary exploratory laparotomies.

CT angiography

CT angiography is performed with high-flow contrast injected intravenously through a wide-bore catheter. Typically, the scan is triggered when the Hounsfield index (density) within the target vessel (aorta or pulmonary artery) reaches the predetermined level to allow maximal contrast opacification of the arterial system being studied (so-called 'bolus-tracking'). The catheter is usually placed in the arm. Specially manufactured central venous catheters able to withstand the injection pressures (without splitting or embolizing) may also be used.

Common applications of CT angiography include to diagnose ***aortic dissection*** (Fig. 8.47), investigate ***internal bleeding*** (Fig. 8.48), and to diagnose ***pulmonary embolism*** (PE; Fig. 8.49).

CT urography

CT urography is performed approximately 5 to 10 minutes after injection of intravenous iodinated contrast medium, when the iodine is excreted into and opacifies the urinary tract. A second dose of intravenous contrast is often given at the time of scan to allow better evaluation of the solid upper abdominal organs including the kidneys and liver. CT urography is most commonly requested in the investigation of ***haematuria*** (Fig. 8.50).

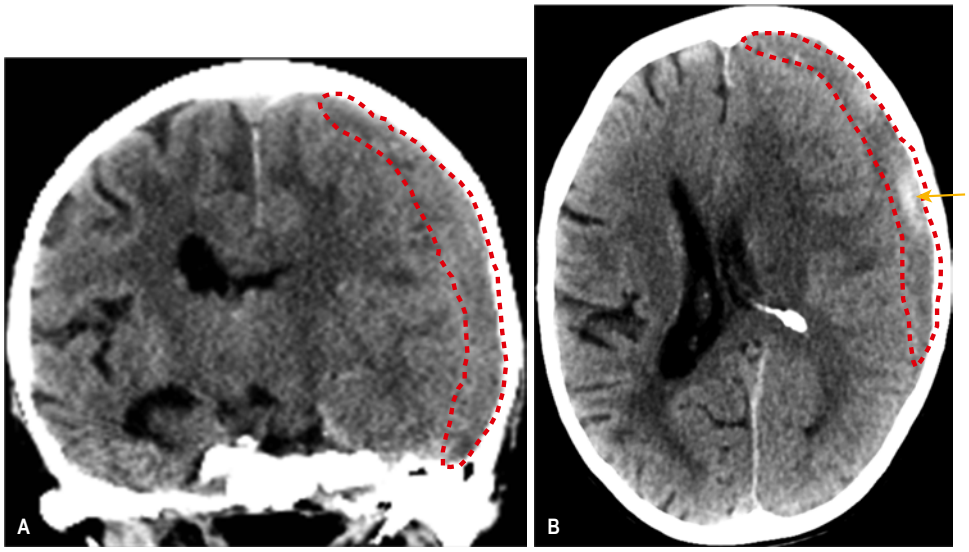

Fig. 8.39 Subdural haematoma on CT. This patient, taking regular apixaban, presented with a fall and head injury followed by nausea, vomiting, and headache. CT demonstrates a crescent-shaped left extra-axial acute-on-chronic subdural haematoma *(red outline)*. Acute bleeding appears of high density *(amber arrow)*. There is cerebral oedema (visible as low-density change in the white matter) and left-to-right midline shift due to the brain swelling and the mass effect of the haematoma itself. This patient needs an urgent neurosurgical opinion. **(A)** Coronal view; **(B)** axial view.

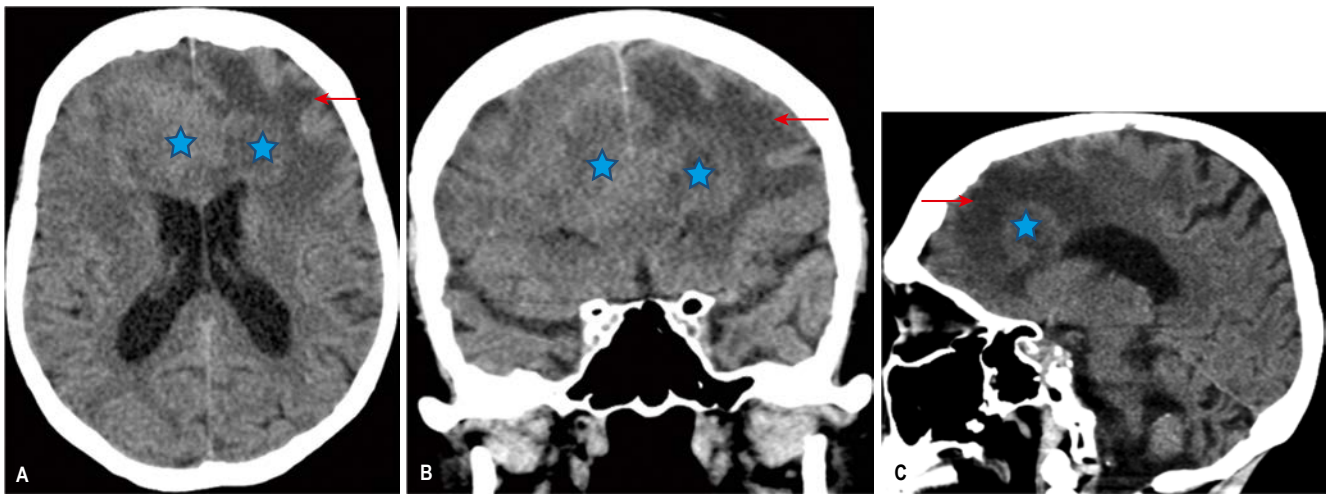

Fig. 8.40 Brain tumour on CT. This patient has a 3-month history of worsening confusion, agitation, and falls. CT demonstrates bilateral frontal masses *(blue stars)* with adjacent cerebral white matter oedema *(red arrows)*, consistent with metastatic cerebral deposits. **(A)** Axial view; **(B)** coronal view; **(C)** saggital view.

Special CT procedures

CT colonography (CTC) and CT coronary angiography (CTCA) are specialized examinations evaluated by subspecialist radiologists.

CT colonography (colloquially known as 'virtual colonoscopy') has been shown to be almost as sensitive as colonoscopy at detecting colonic cancer and larger (over 6 mm) polyps. It is a good alternative to investigate the large bowel, particularly for frailer or elderly patients. A big advantage of CTC over colonoscopy is the ability to provide information on abdominal organs outwith the bowel, which may be causing the patient's symptoms (e.g., anaemia secondary to renal tumour).

Patients are given oral laxatives to cleanse the bowel and oral iodinated contrast or barium to 'tag' residual colonic content with high-density material—meaning stool can be distinguished from colonic polyps or cancers. The colon is then inflated with carbon dioxide (via a pressure-sensitive catheter inserted per rectum) and CT of the abdomen is performed twice, in the supine and prone positions. Antispasmodic medication is usually given intravenously if there is no contraindication (e.g., significant cardiac disease such as heart failure, poorly controlled coronary heart disease, or cardiac tachyarrhythmia). It is important to inform the radiologist if the patient has these conditions. Risk of complication (e.g., perforation) is extremely low (1–2 per 10 000 examinations). CTC should be

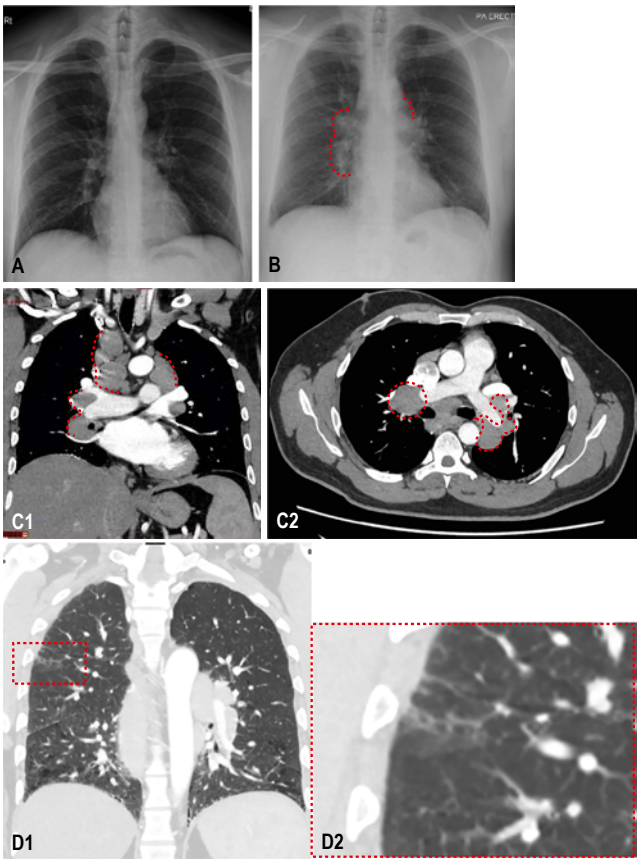

Fig. 8.41 Sarcoid lung disease. An abnormal CXR (**A** from 2 years ago; **B** current). CT demonstrates the extensive enlarged mediastinal lymph nodes *(red dotted lines)* with pulmonary ground-glass opacity and bronchovascular nodularity visible **(C, D)**.

Fig. 8.43 Renal calculi on CT. This patient presented with bilateral flank pain, haematuria, reduced renal function, a high serum calcium, and elevated PTH. Unenhanced, non-contrast CT kidneys, ureter, and bladder (KUB) demonstrate bilateral renal calculi *(red arrows)* and left renal pelvis calculi with mild left hydronephrosis (*blue arrow*; compared to normal renal collecting system on the right, *gold arrow*). The patient was subsequently diagnosed with primary hyperparathyroidism. **(A)** Coronal view; **(B)** axial view..

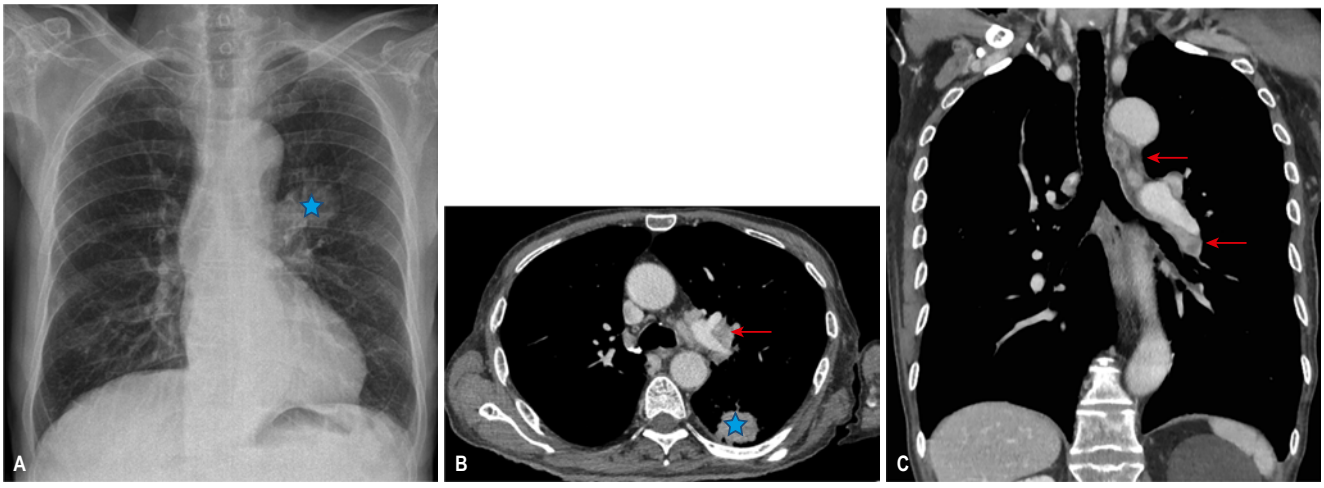

Fig. 8.42 Lung cancer. This patient was a smoker and presented with left shoulder pain and weight loss. CXR **(A)** was abnormal. CT demonstrates left pulmonary mass *(blue star)* and left hilar abnormal lymph nodes *(red arrow)*. **(B)** Axial view; **(C)** coronal view.

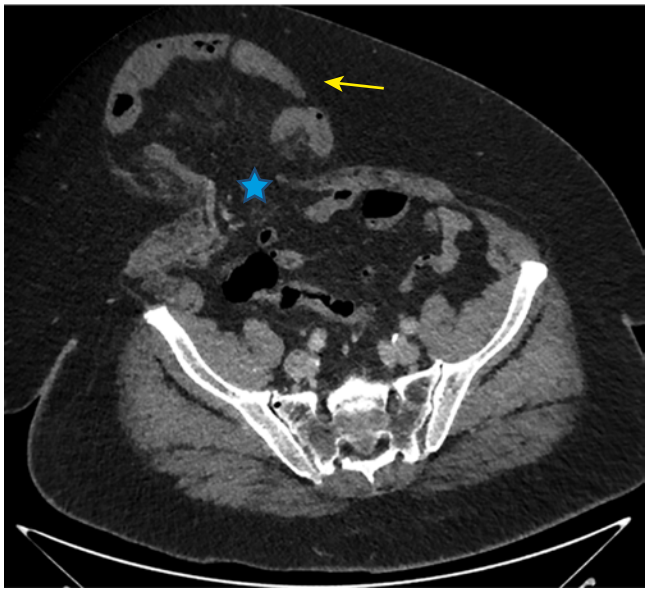

Fig. 8.44 Incarcerated umbilical hernia. This patient with a history of severe obesity described a 5-day history of central abdominal pain. On examination, there was a large 20 × 20 cm firm tender swelling in the mid-upper abdomen, consistent with an incarcerated umbilical hernia. The patient was not vomiting and was opening bowels normally, but white blood cell count was elevated. CT (axial view) demonstrates the large anterior abdominal wall hernia *(blue star)* containing small bowel *(amber arrow)*. No obstruction nor bowel ischaemia was evident on CT, but operative small bowel resection was later performed for infarcted bowel.

Fig. 8.46 Small bowel obstruction. This patient with a past history of abdominal surgery presents with abdominal pain, distension, and vomiting. CT (coronal view) demonstrates dilated loops of small bowel with a transition point at an abrupt calibre change *(green arrow)*. Appearance is in keeping with small bowel obstruction from adhesions.

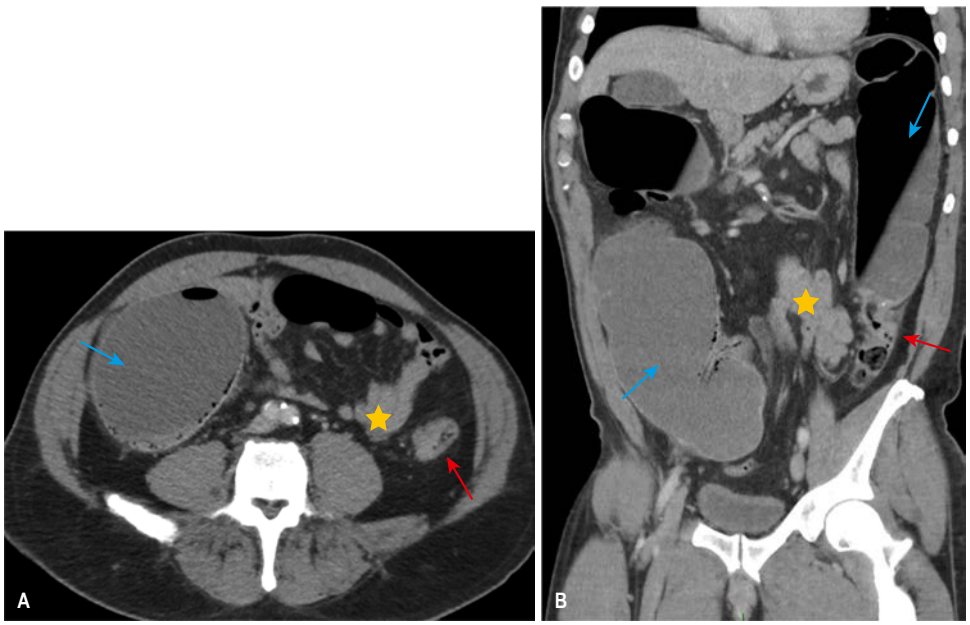

Fig. 8.45 Large bowel obstruction. This patient presented with abdominal pain, constipation, and distended abdomen. CT demonstrated large bowel obstruction with a competent ileocaecal valve (non-dilated small bowel, *amber star*; dilated right and left colon, *blue arrows*) from a descending colon tumour *(red arrow)*—a surgical emergency due to the high risk of colonic perforation. No metastases were evident on CT, so subtotal colectomy was performed. **(A)** Axial view; **(B)** coronal view.

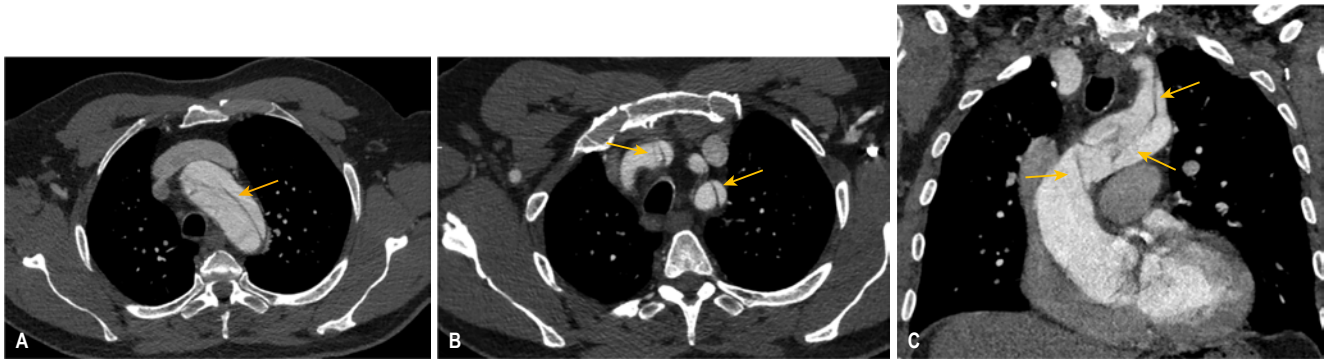

Fig. 8.47 CT angiogram showing aortic dissection. This patient presented with sudden onset neck pain and syncope. On examination, there was 50 mmHg difference in systolic blood pressure between the arms and a loud aortic regurgitant murmur. CT angiography demonstrated type A aortic dissection, extending into the carotid and brachiocephalic arteries *(amber arrows)*. Aortic arch and tissue aortic valve replacement were performed. **(A)** and **(B)** Axial views; **(C)** coronal view.

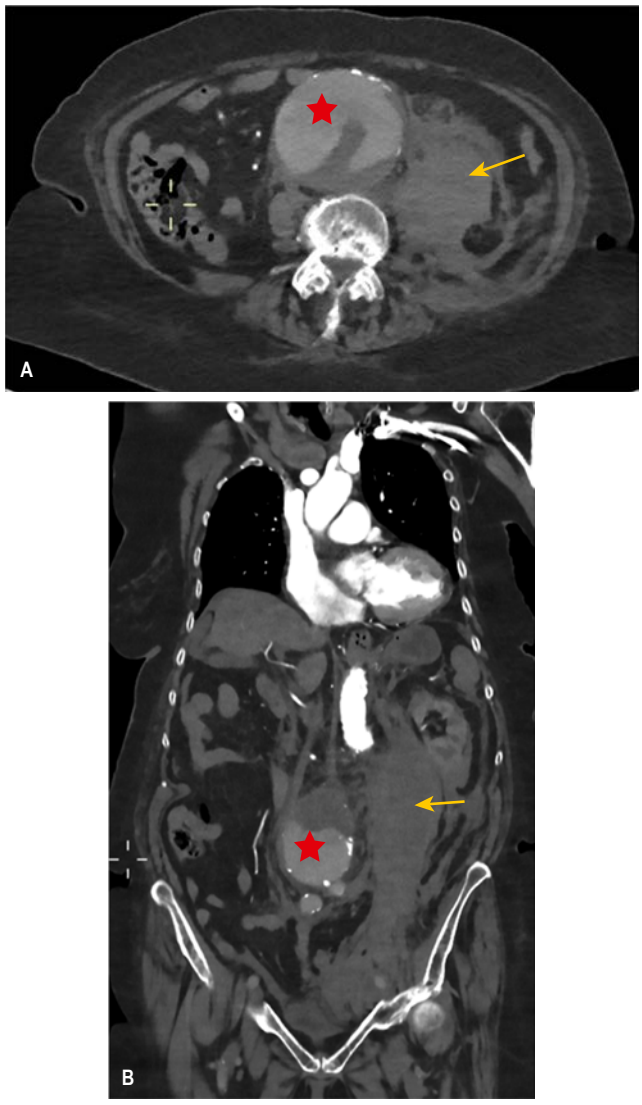

Fig. 8.48 CT angiogram showing aortic aneurysm rupture. This patient presented with severe back pain, radiating to the front of the abdomen. CT angiogram demonstrated a large aortic aneurysm *(red star)*, which was leaking into the left retroperitoneal/para-psoas space *(amber arrow)*. **(A)** Axial view; **(B)** coronal view.

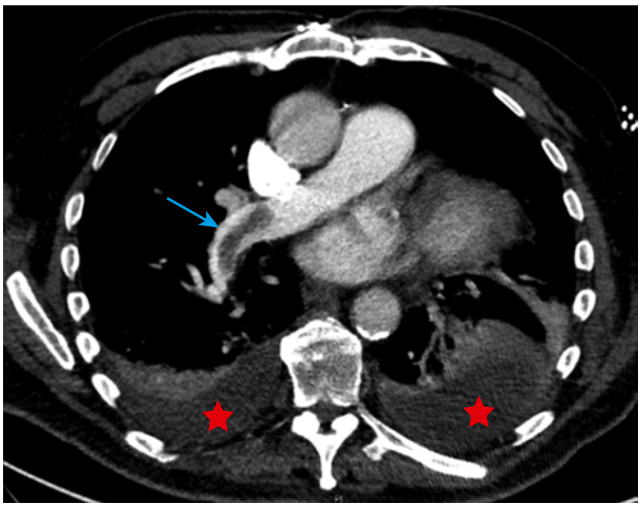

Fig. 8.49 CT pulmonary angiogram showing pulmonary embolism. This patient presented with severe sudden-onset chest pain and tachycardia. They had undergone recent surgery. CT pulmonary angiogram (axial view) demonstrates a right pulmonary artery embolus *(blue arrow)* and bilateral effusions *(red stars)*. No pulmonary trunk enlargement or ventricular septal right to left deviation (signs of right ventricular dysfunction indicative of sub-massive PE) are evident.

deferred if there has been recent large colonic biopsy. It is contraindicated in patients with large bowel obstruction or active inflammatory bowel disease.

CT coronary angiography is recommended as the first-line test for evaluation of stable coronary artery disease in chest pain pathways, allowing invasive percutaneous angiography to be reserved for therapy. CT, performed with intravenous contrast, beta-blockers to slow the heart rate and occasionally nitroglycerin produces exquisite images to identify narrowed or blocked arteries in the heart. The patient is connected to an electrocardiogram (ECG) monitor during the test, and the CT scanner is synchronized with the heartbeat to ensure imaging occurs when the heart is most likely to be still.

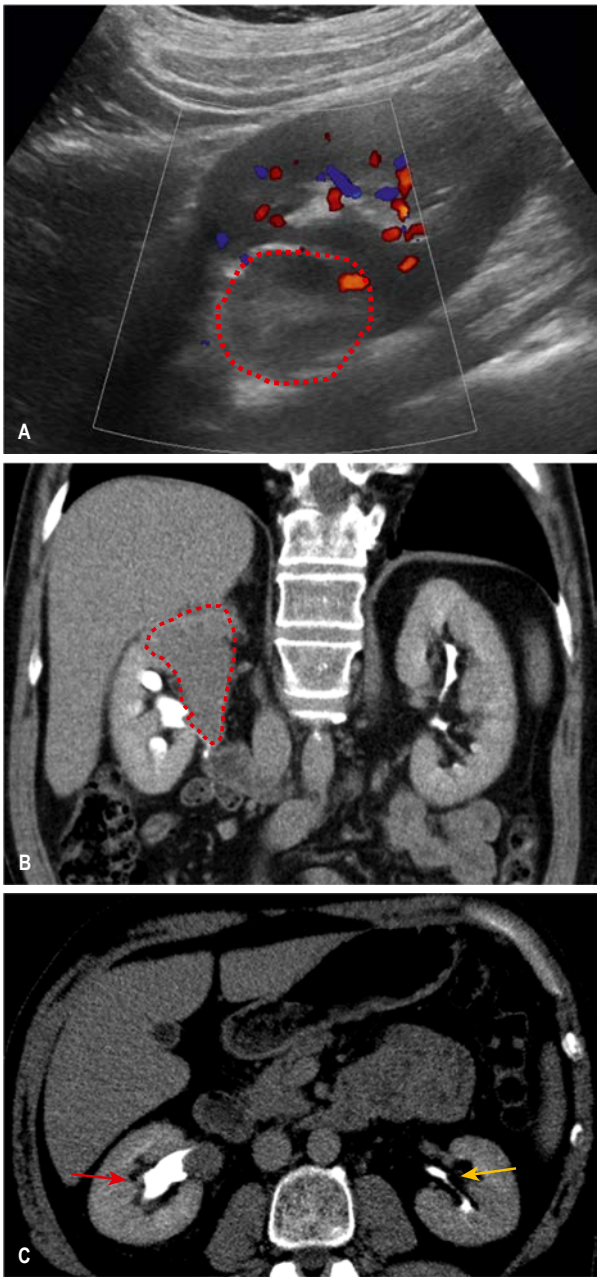

Fig. 8.50 CT urogram showing renal tumour. This patient presented with visible haematuria. **(A)** An initial US was abnormal. **(B)** CT urogram (coronal view) demonstrates a mass *(red dotted line)* arising from the upper pole of the right kidney, extending into the renal pelvis. **(C)** The mass is causing a degree of hydronephrosis, seen well on axial view (*red arrow*; compared to normal left system, *amber arrow*).

The patient should fast and avoid caffeinated beverages 12 hours before the test. Even though the actual scan is over in seconds, the whole process of preparation can take up to an hour with the patient on the scanner table.

While the risk of serious complications from CTCA is lower than percutaneous coronary angiography, subsequent percutaneous coronary angiography or cardiac surgery may still be required if CTCA demonstrates a treatable lesion.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) excels in delineating soft tissues, making it well suited to the investigation of musculoskeletal tissues, brain, liver, and pelvic organs (**Box 8.8**). Factors limiting its use include scanner availability and length of time required for image acquisition—not ideal for the unwell patient. Examinations may be performed with or without intravenous gadolinium-based contrast agents (**Box 8.9**). The use of powerful medical magnets has important safety implications requiring strict protocols, including the completion of detailed checklists to ensure that patients with MRI contraindications are not exposed to the magnetic field (**Fig. 8.51** and **Box 8.10**).

i Box 8.8 Magnetic resonance imaging (MRI)

- MRI scanners create powerful magnetic fields to align protons that exist in body tissues that contain water. The applied radio waves interact with these protons to produce signals that are picked up by a receiver within the MRI scanner. The signals are specially characterized using the rapidly changing magnetic fields. Computer processing converts these signals into images, which like CT images, can be viewed in any orientation.
- Intravenous contrast agents used in MRI are gadolinium based.
- Does not involve ionizing radiation.
- All parts of the body can be imaged. It is particularly helpful in evaluating soft tissues, brain, liver, and pelvic organs such as rectum, prostate, uterus, cervix, and ovary.
- Patient preparation is sometimes required (e.g., venous access may be required for intravenous contrast). Patients would routinely be dressed in a hospital gown. They should be warned they may hear a loud sound while the scanner is operating. Ear plugs/headphones may be provided for their comfort. Some examinations may require the patient to lie still for an extended period of time.
- Special considerations may be required for some patients, for example patients who experience claustrophobia, are pregnant or breast-feeding.
- MRI and patient safety are important considerations; see **Box 8.10**.

i Box 8.9 MRI contrast agent: gadolinium chelates

Gadolinium is a paramagnetic heavy metal and is toxic when a free ion; to ensure safety it is administered as a chelate, with the gadolinium safely locked away inside a larger molecule. However, post-contrast gadolinium retention in the brain as well as in extracranial tissues such as the liver and bone is documented and the long-term impact of this is unknown. Gadolinium-based contrast medium can rarely cause allergic reactions in patients. Care should be taken before administering gadolinium in patients with the following:

- Renal impairment or history of renal disease requiring dialysis
- Received a dose of gadolinium-based contrast medium in the last 24 h
- Patients who had a previous allergic or anaphylactic reaction to gadolinium-based contrast medium
- Patients who have risk factors for nephrogenic systemic fibrosis (NSF)
- Patients who are pregnant: The administration of contrast during pregnancy is predicated on a risk-benefit assessment.

Gadolinium-based contrast is excreted into breast milk in less than 0.04% of the dose injected to a mother. Also, of that tiny amount excreted into the milk, only 0.8% is absorbed by the baby. Thus, while there should be no concern about continuing breast-feeding after contrast administration, you may wish to keep the patient informed.

Fig. 8.51 MRI safety warning sign. *(Produced by the Institute of Physics and Engineering in Medicine [www.ipem.ac.uk].)*

Box 8.10 MRI safety considerations

- The magnetic field used for MRI is never switched off. The MRI room is under strong magnetic fields at all times.
- Free ferromagnetic (iron-based) material could get heated or become attracted by the strong magnetic field, becoming hazardous flying projectiles. These are not allowed into the scanner room.
- Examples of patient implants which are contraindicated:
  - Older implanted pacemakers (newer pacemakers may be conditionally safe)
  - Intracranial aneurysm clips
  - Cochlear implants
  - Implanted drug infusion pumps
  - Internal metallic objects such as bullets, shrapnel, and occupational iron embedded in the eyes
- Examples of relative contraindications:
  - Coronary stents
  - Recently placed surgical clips, pins, plates, screws, metal sutures, or wire mesh
  - Pregnancy

Box 8.11 Common MRI sequences

T1: Fluid appears dark. Useful when looking at anatomy and the soft tissues.
T2: Fluid appears bright. Useful when evaluating inflammation or oedema.
DWI (diffusion-weighted imaging): Areas where proton diffusion is restricted appear bright. It is useful for evaluating for ischaemic strokes, abscesses, and most tumours.
FLAIR (fluid-attenuated inversion recovery): Essentially T2, but fluid is suppressed, so it appears dark. It is useful for evaluating multiple sclerosis in the brain.
STIR (short tau inversion recovery): Essentially T2, but fat is suppressed so it appears dark. It is useful for evaluating oedema in soft tissues e.g., perianal abscesses.
MRA (magnetic resonance angiography): Intravenous contrast is administered, so vessels appear bright. It is useful for evaluating vascular anomalies such as arteriovenous malformations or aneurysms.

The magnetic field can be manipulated to produce differing radiofrequency pulses and gradients referred to as 'sequences', allowing the scan to be tailored to optimize assessment of different tissues and disorders (Box 8.11).

MRI, like CT, are complex examinations, for which accurate interpretation critically depends on salient clinical information. Providing relevant clinical background and potential diagnoses under consideration will greatly help to improve the quality of the radiology reports you receive.

The brain

MRI brain is usually performed when either CT has not provided the information required for patient management, or if CT is not as sensitive for the suspected clinical diagnosis. Indications include evaluation for ***demyelinating disorders*** (Fig. 8.52), diagnosis of ***stroke*** (Fig. 8.53), and characterization of ***intracranial mass lesions*** (Fig. 8.54) including pituitary tumours and lesions of the cerebellopontine angle.

The abdomen and pelvis

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) utilizes heavily T2-weighted sequences to evaluate the gallbladder and biliary tree. Common indications include the work-up of obstructive (cholestatic) jaundice, or ***further investigation of dilated bile ducts*** identified on US (Fig. 8.55).

Liver MRI

MRI is very helpful in the evaluation of liver lesions. Besides standard T1, T2 weighted, and contrast-enhanced dynamic sequences, using hepatocyte-specific contrast agents and diffusion-weighted sequences can help ***distinguish benign from malignant liver lesions*** (Fig. 8.56).

Pelvic malignancies

MRI is a frontline modality for diagnosis and staging of pelvic malignancies including ***rectal cancer*** (Fig. 8.57) and ***cervical cancer*** (Fig. 8.58) and in characterization of ***ovarian masses*** (Fig. 8.59).

Bones, soft tissues, and joints

Common indications to request MRI include ***evaluation of the spinal cord and canal*** (Fig. 8.60) including in patients with possible spinal cord compression or cauda equina syndrome, ***characterization of bone lesions*** (Figs. 8.61 and 8.62) including tumour, osteomyelitis, and osteonecrosis and diagnosis of the painful or swollen joint.

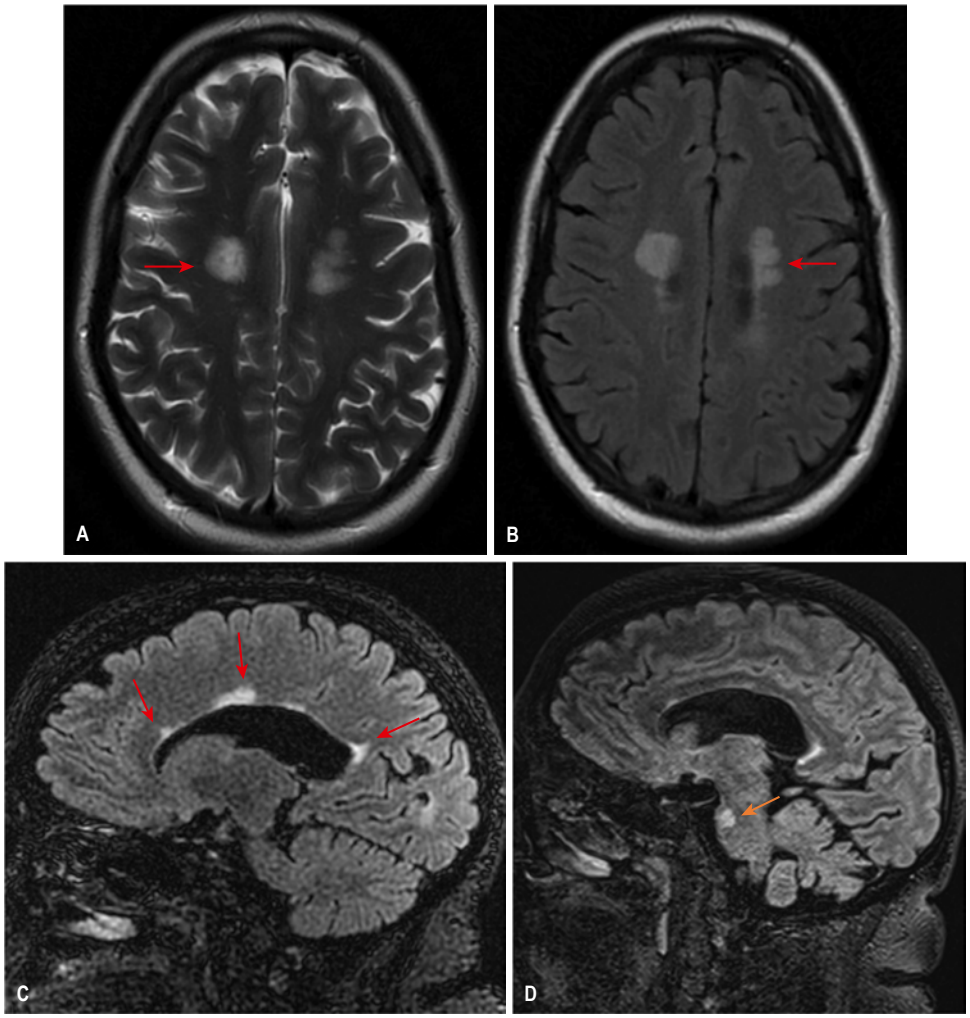

Fig. 8.52 MRI brain in a patient with multiple sclerosis. This patient has relapsing multiple sclerosis on disease-modifying medication. T2W **(A)** and FLAIR **(B–D)** MRI images demonstrate white matter changes *(red arrows)* in the periventricular white matter consistent with zones of demyelination, with a further lesion within the pons *(orange arrow)*. Occasionally, clinical decision-making may be helped by the use of contrast to determine if such plaques enhance.

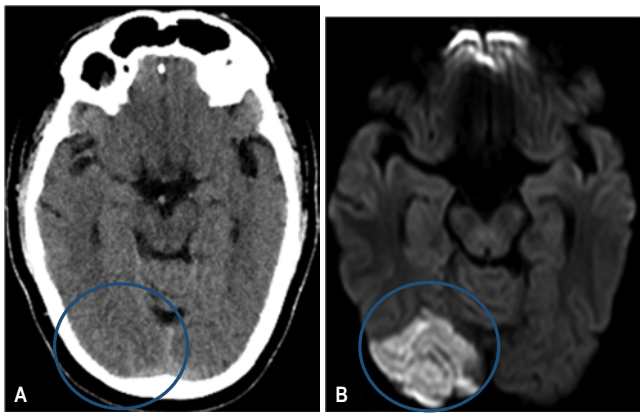

Fig. 8.53 MRI brain in a patient with ischaemic stroke. This 65-year-old male presented with sudden onset loss of coordination down his left side, unsteady on feet with left facial droop and dysaesthesia in left upper and lower limbs. CT brain **(A)** was normal. Subsequent MRI **(B)** demonstrated a large right occipital infarct *(blue circles)* visible on diffusion-weighted imaging.

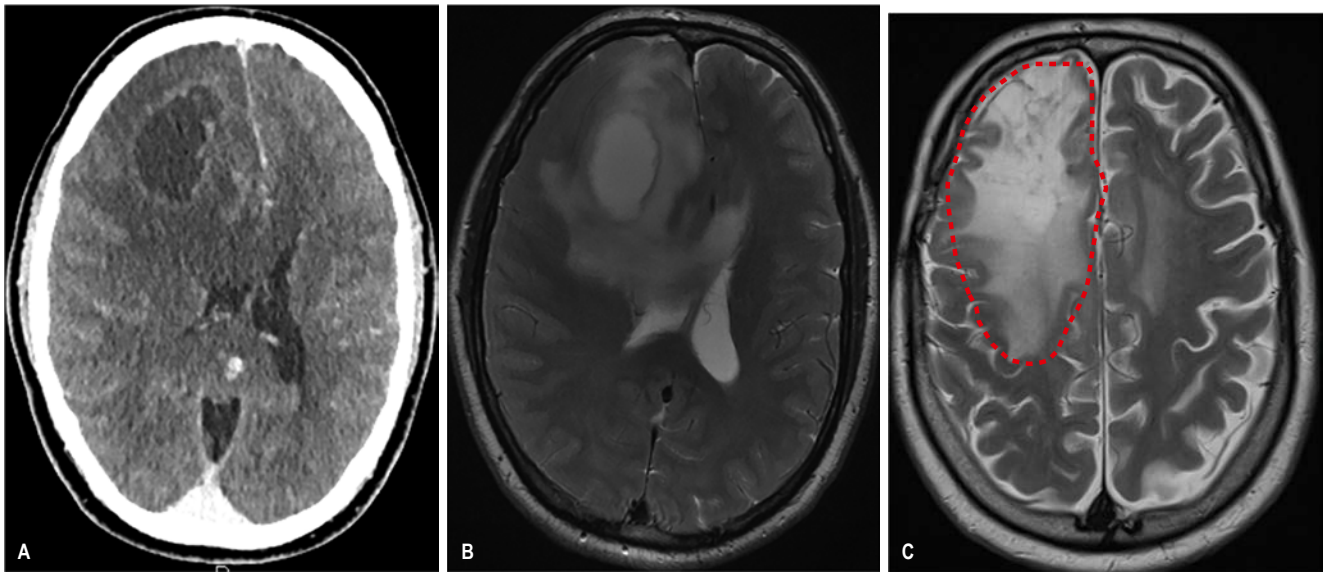

Fig. 8.54 MRI in a patient with a glioblastoma. Right frontal glioblastoma seen on CT with contrast **(A)** and MRI **(B)**. The patient underwent craniotomy with resection, followed by chemoradiotherapy. MRI 7 years later **(C)** demonstrates gliosis of the area post treatment *(red outline)*.

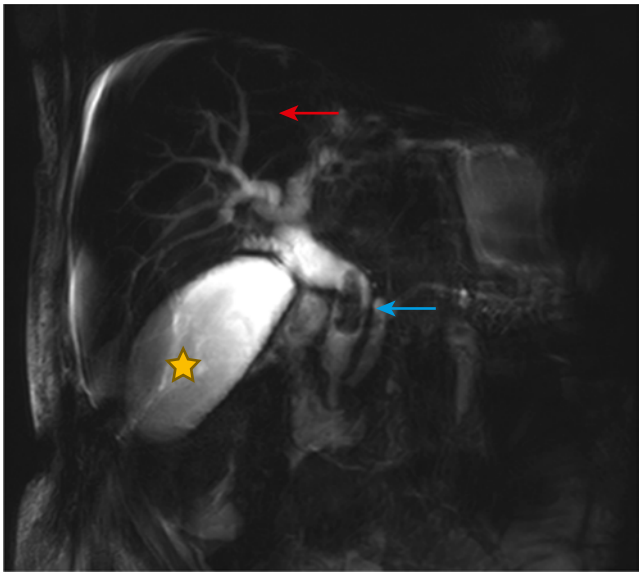

Fig. 8.55 MRCP. This MRCP performed in a patient with obstructive jaundice has identified gallstones within the dilated common bile duct *(blue arrow)*. Intrahepatic ducts are also dilated *(red arrow)*. *Star:* gallbladder.

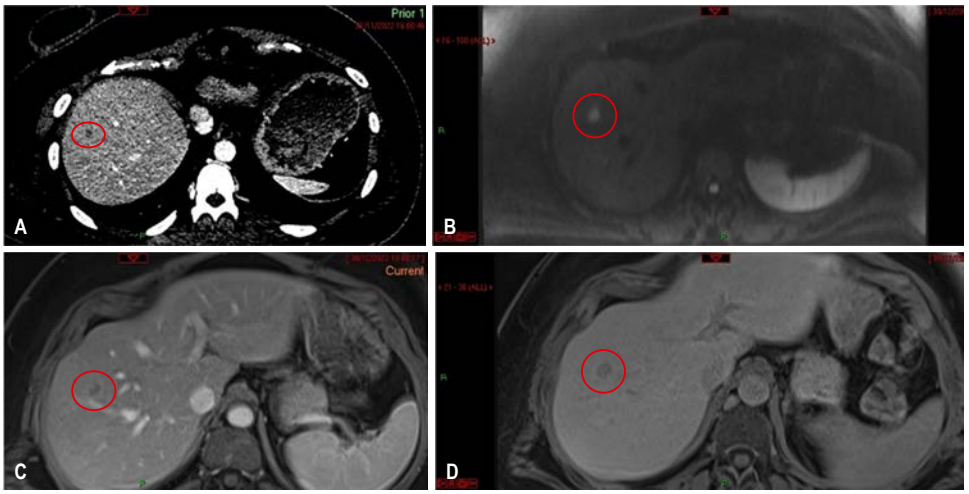

Fig. 8.56 Characterizing a liver lesion with MRI. This patient has a known gynaecologic tract malignancy with enlarged local and regional lymph nodes. Staging CT discovered an indeterminate liver lesion in segment 8 (**A**, *red circle*). MRI showed the lesion to be high signal in relation to background liver on T2W, with restricted diffusion **(B)**, rim enhancement **(C)**, and low signal to background liver on the hepatobiliary phase sequence **(D)**. Further, other lesions not seen on CT were identified on MRI. These MRI appearances are in keeping with multiple liver metastases.

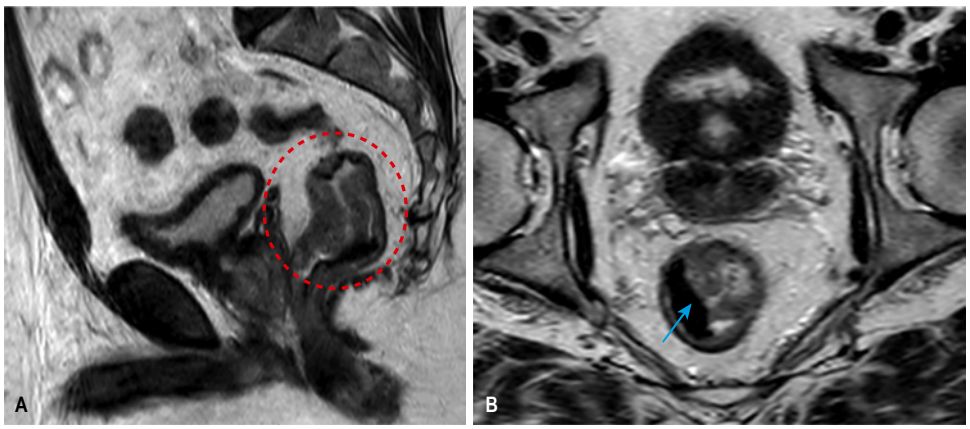

Fig. 8.57 Rectal cancer on MRI. Tumour *(circle and arrow)* seen within the lumen of rectum. The relationship between the tumour, adjacent organs, and surgically relevant operative planes is clearly visible on MRI. **(A)** Sagittal view; **(B)** axial view.

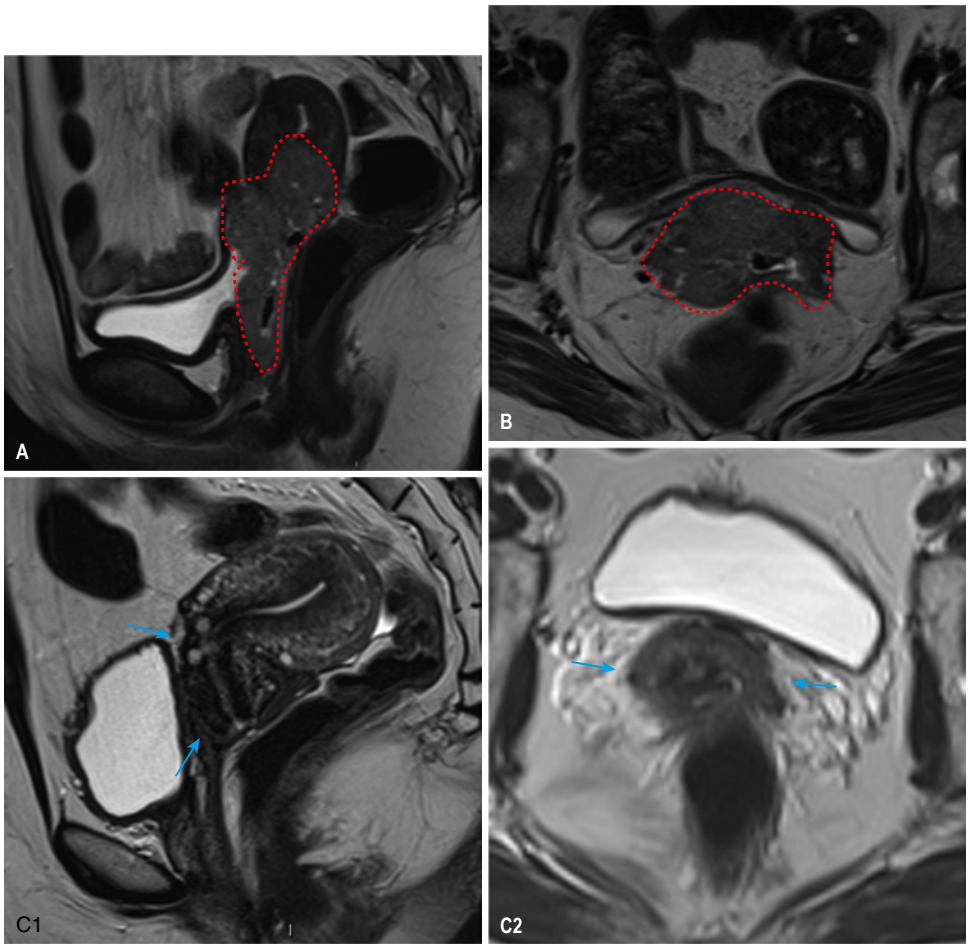

Fig. 8.58 Cervical cancer on MRI. These images (**A**, sagittal plane, **B**, axial plane) demonstrate a locally advanced cervical cancer *(red outline)* invading the bladder, in a patient with retroverted uterus. The second set of images **(C)** are of a normal cervix *(blue arrows)* in a retroverted uterus for comparison.

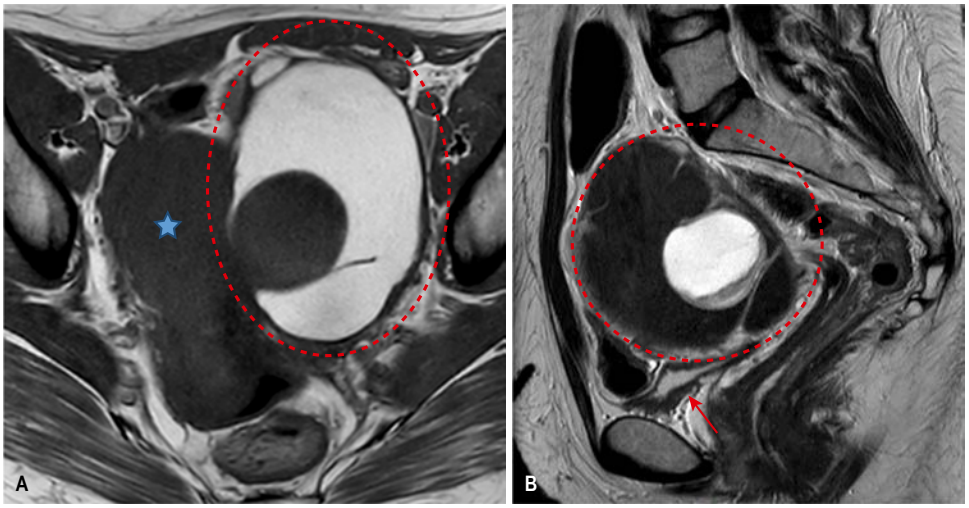

Fig. 8.59 Ovarian mass evaluated by MRI. MRI complements US in the evaluation of ovarian masses. Here is an example of a large septated left ovarian mass *(red outline)* which has high signal on T1W **(A)**, low signal on T2W **(B)** in keeping with an endometrioma. (Uterus: *blue star*; urinary bladder: *red arrow*.)

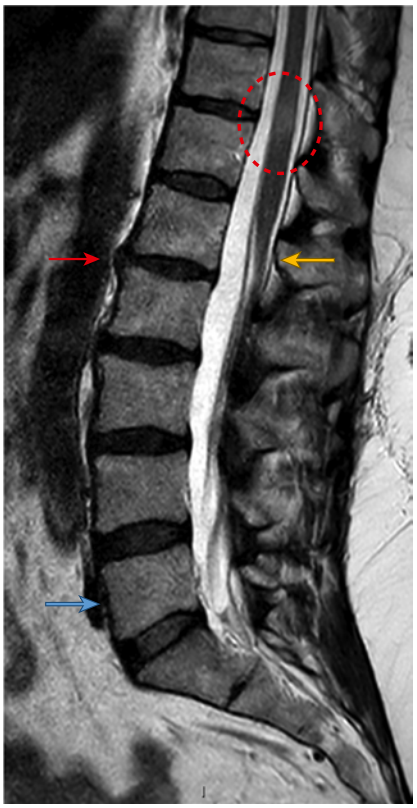

Fig. 8.60 MRI in a patient with spastic paraparesis. This patient with known multiple sclerosis presented with new bilateral leg weakness and difficulty lifting their right leg and walking, accompanied by bladder and bowel incontinence, as well as pain down the right leg. Deep tendon reflexes were brisk and plantar responses upgoing bilaterally. This image (T2W sequence) demonstrates minimal degenerative intervertebral disc changes with reasonably maintained vertebral body heights. It also demonstrates a demyelinating plaque (high-signal intensity area inside the *red dotted circle*) in the lower lumbar spinal cord which could explain the patient's symptoms. (*Amber arrow:* end of spinal cord, beginning of cauda equina; *blue arrow:* vertebral body, normal marrow signal; *red arrow:* intervertebral disc with some degenerative desiccation and loss of height.)

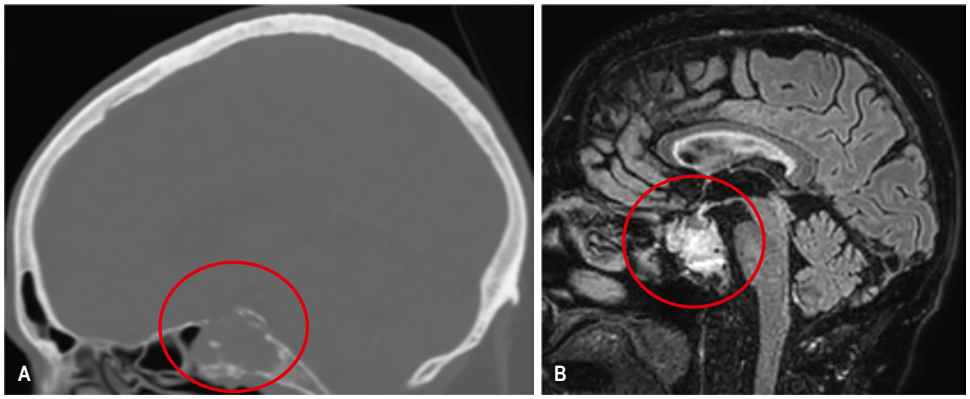

Fig. 8.61 Destructive lesion of the skull base on MRI. In this patient, bone destruction of the clivus was identified on CT **(A)**. A subsequent MRI **(B)** demonstrates the large mass causing this appearance.

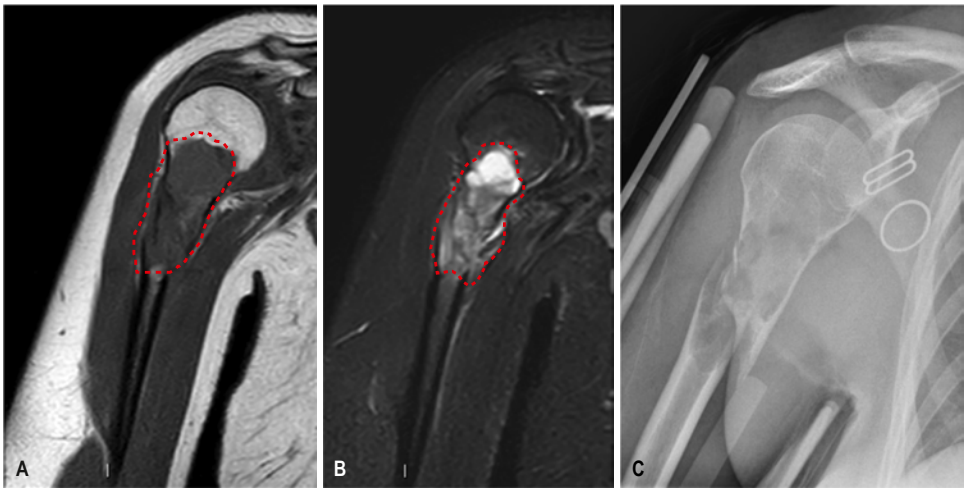

Fig. 8.62 Pathological fracture. This patient had a fracture of their right humerus through an area of abnormal bone, with extensive cystic change—a pathological fracture. MRI demonstrates the abnormal soft tissue in the marrow **(A)** T1W, **(B)** STIR sequence; **(C)** X-ray of humerus). This was a bone metastasis.

NUCLEAR MEDICINE AND POSITRON EMISSION TOMOGRAPHY

Nuclear medicine imaging uses radioactive tracers to examine organ function as well as anatomy (Box 8.12). A CT or MRI scanner may be co-located with a positron emission tomography (PET) or gamma scanner to improve anatomical correlation. This section illustrates commonly encountered system-based nuclear medicine examinations.

Brain—DaTScan (dopamine transporter scan)

DaTScan enables assessment of dopaminergic neuronal tissue in the brain and may be utilized in the evaluation of patients with tremor and dementia. Iodine-123 radioactive tracer is administered intravenously, attaches to dopamine transporters on nerve cells in the basal ganglia, and is visualized using single-photo-emission CT (SPECT) (Fig. 8.63). While DaTScan can assist in distinguishing Parkinson's disease (PD) from benign tremor, and dementia with Lewy bodies (DLB) from Alzheimer's dementia, it cannot distinguish between idiopathic PD, Parkinson-Plus syndromes (e.g., progressive supranuclear palsy or multiple system atrophy), and DLB. Patients are administered an oral dose of potassium iodide 1 hour before the tracer is injected to minimize uptake and radiation exposure to the thyroid.

Thorax—ventilation/perfusion (V/Q) scan

V/Q scanning is most commonly used in diagnosis of PE. The patient lies on a scanner bed while breathing room air mixed with minimally radioactive, tasteless, and odourless 82m krypton gas through a face mask for 10 minutes. This shows the aeration (ventilation) of the lungs. Patients are also injected with a small dose of radioactive tracer (Tc-99m-MAA) for the perfusion part of the scan. A 3D SPECT scan acquires the radiation emitted (up to 20 min) and images are processed and produced by the computer, allowing comparison and identification of ventilation/perfusion 'mismatch' (Fig. 8.64). V/Q scanning has been superseded by CTPA as a first-line diagnostic test for PE but is still employed in instances where CTPA cannot be performed (e.g., severe iodinated contrast allergy). In the absence of chronic lung

Box 8.12 Nuclear medicine imaging

- Nuclear imaging produces images by detecting radiation from different parts of the body after a radioactive tracer material is administered.
- The radioactive tracer is either injected into a vein, swallowed or inhaled as a gas and eventually accumulates in the organ or area of the body being examined. The unstable tracer degrades to a more stable isotope, releasing energy in the form of gamma rays.
- This energy is detected by a gamma camera placed close to the patient's body, then sent to a computer to generate the image. Many of these cameras are co-located with a CT scanner within the same unit to allow for better anatomical localization.
- Radiation dose is small.
- The radionuclide tracer used depends on the type of study and the body part being studied. Some examples include technetium, thallium, gallium, iodine, xenon, or fluorodeoxyglucose (FDG, for PET).
- Specific patient preparation depends on the test being performed.
- Pregnant, breast-feeding, and diabetic patients may require special consideration.

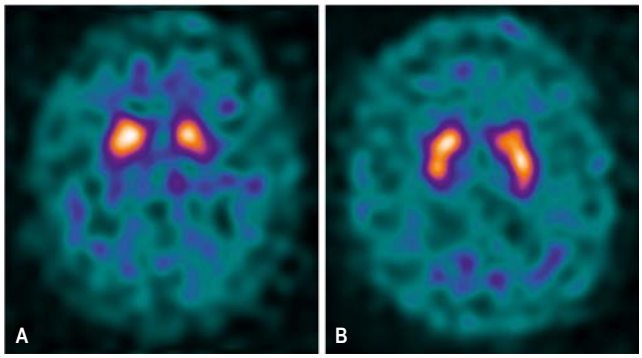

Fig. 8.63 DaTScan. This patient had a tremor in their right hand, with associated bradykinesia and rigidity (cogwheel) movement at their wrist. Scan **(A)** demonstrates markedly reduced tracer uptake in the basal ganglia, compared to a normal 'comma shaped' tracer uptake in the whole of basal ganglia in scan **(B)**, confirming a gross presynaptic dopaminergic deficit. This is consistent with a diagnosis of degenerative parkinsonism.

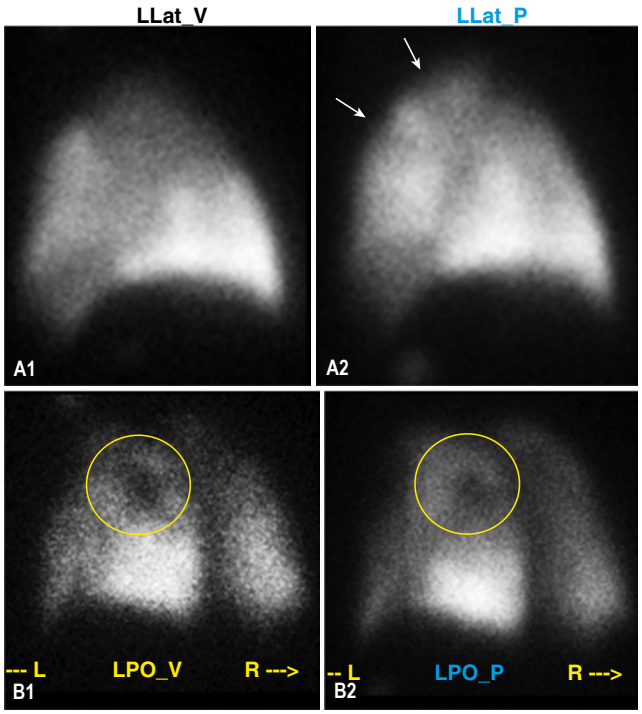

Fig. 8.64 V/Q scan. **(A)** Small wedge-shaped perfusion defects seen on left lateral lung views (*arrows*, LLat_P), mismatched to the corresponding ventilation scan which is normal (LLat_V). This is diagnostic for PE. **(B)** The perfusion defect seen on left posterior (LPO_P) view is matched to a defect on the corresponding ventilation scan (LPO_V, *circles*). This zone corresponded to severe emphysematous changes on a subsequent CT thorax.

disease and with a normal contemporaneous CXR, a perfusion-only scan may be performed, with the assumption that any perfusion defect identified would be 'unmatched', if a ventilation scan was performed.

Bone scan

Bone scan might help determine the cause of bone pain. The test is sensitive to differences in bone metabolism, which are highlighted in the body by the injected radioactive tracer (Fig. 8.65). Scanning the whole skeleton helps in diagnosing a wide range of bone disorders, including fractures, arthritis, Paget's disease of bone, cancer (primary or secondary), and infection of the bones, joints, or joint replacements.

Renal function

DMSA (dimercaptosuccinic acid, radioisotope) or **MAG-3** (mercapto acetyl triglycine) scans can both be used to estimate the individual kidneys' contribution to total renal function (so-called 'divided renal function'). DMSA images are usually acquired 2 to 3 hours after the injection (allowing sufficient time for tracer uptake into renal tubular cells; so-called 'static scanning') while MAG-3 images are obtained immediately after the injection ('dynamic scanning'). Both are bound to technetium 99m (Tc-99m) to form the radiopharmaceutical. Static DMSA scans are also used to identify zones of renal scarring (Fig. 8.66) while dynamic MAG-3 scans can be used to evaluate renal blood flow and perfusion, drainage of urine from the kidney to bladder, and assess for vesico-ureteric reflux.

Endocrine nuclear imaging

Tc-99m-Sestamibi scintigraphy is the main imaging technique for preoperative location of parathyroid adenomas (Fig. 8.67). Sestamibi is taken up by both the thyroid and parathyroid glands, but adenomatous and hyperplastic parathyroid tissue shows more avid uptake of the radiotracer and often retains the radiotracer longer than adjacent thyroid tissue. Asymmetric foci of increased radiotracer uptake on early images can be seen, representing abnormal parathyroid tissue superimposed on the normal thyroid. Delayed images, obtained approximately 2 hours after radiotracer administration, are acquired to look for foci of retained radiotracer characteristic of hyperfunctioning parathyroid gland.

Subtraction techniques have also been used to image the parathyroid glands by administering a second radiotracer taken up only by the thyroid gland. Either 123-I or Tc-99m pertechnetate can be used in conjunction with Tc-99m-Sestamibi to produce subtraction images of the parathyroid glands (although these techniques have not been clearly shown to be diagnostically superior to non-subtracted techniques).

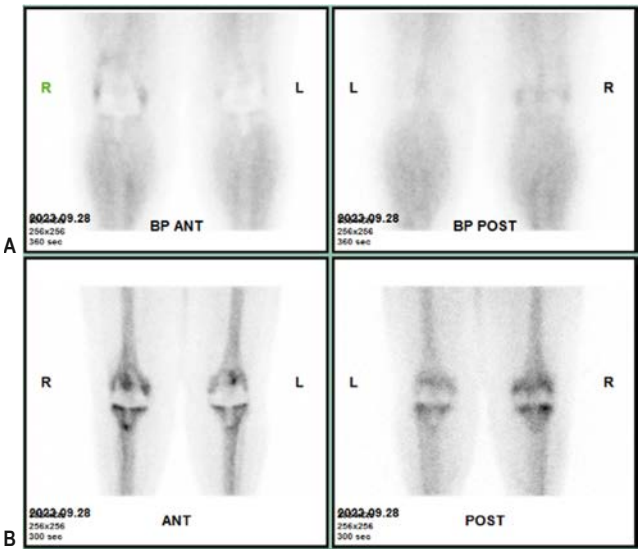

Fig. 8.65 Bone scan. This patient with bilateral knee prostheses has right knee pain. Bone scan image of the blood pool phase (**A**, anterior/posterior views) shows increased uptake in bone around the right knee prostheses. Increased uptake is also seen in the right knee more than the left during bone phase imaging **(B)**. Appearances suggest loosening and possible right knee prosthetic infection. White cell scan will distinguish between the two conditions.

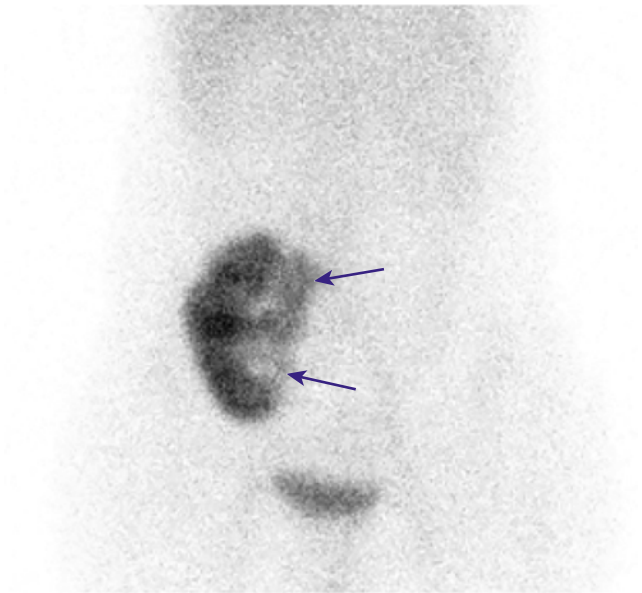

Fig. 8.66 DMSA renogram of a kidney transplant. This kidney transplant recipient had experienced repeated episodes of pyelonephritis resulting in a progressive decline in the transplant's function. In this anterior view of the transplant, defects in the usually homogeneous tracer uptake can be seen in the anteromedial portion of the upper pole and medial mid-lower pole of the transplant *(blue arrows)*.

Thyroid gland function (thyrotoxicosis, thyroid nodules, suspected ectopic thyroid tissues, and activity and/or location of the thyroid gland in neonatal hypothyroidism) can also be evaluated with nuclear medicine. Technetium 99m is taken up by the thyroid in the same way as iodine.

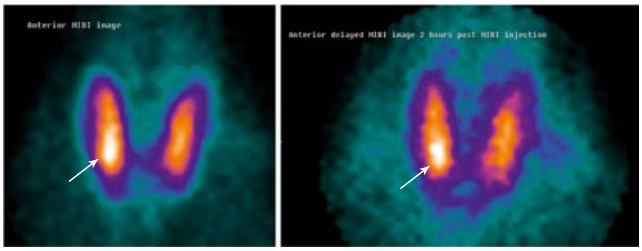

Fig. 8.67 Sestamibi scan of a parathyroid adenoma. This patient was hypercalcaemic. Increased sestamibi uptake in the parathyroid gland overlying the lower pole of right thyroid *(arrow)* is detected. Two hours after the injection, persistent uptake in the parathyroid adenoma remains visible.

Patients must refrain from ingesting iodine prior to the scan. These include certain medications or food substances such as kelp, seaweed, cough syrups, and multivitamins, as these can interfere with thyroid radiotracer uptake and the scan. Intravenous iodine-based contrast agents for CT should also be avoided.

MIBG scan involves an injection of a liquid radioactive material called iodine-123-meta-iodobenzylguanidine (MIBG), which binds to adrenergic tissue. It is typically used to identify neuroendocrine tumours such as pheochromocytomas and neuroblastomas (cancers that affect nerve tissue).

An MIBG scan takes two days—on the first day, the patient will have the isotope injection and on the second, they will have the scan. The scan is performed with a SPECT-CT scanner, which provides detailed anatomical localization of the tumour.

Octreotide scans are also used to localize neuroendocrine tumours. Octreotide binds to somatostatin receptors on cells and is therefore useful in identifying carcinoid tumours and pancreatic neuroendocrine tumours. This examination also takes 2 days.

Positron emission tomography and computed tomography

PET generates images to allow the evaluation of cellular metabolic function. Coupled to a CT scan, it allows for more precise anatomic location of the radioactivity detected.

Positron emission tomography and computed tomography (PET-CT) are routinely used to evaluate cancer, heart disease, gastrointestinal, endocrine, and neurological disorders—both to aid diagnosis as well as to evaluate treatment response.

Specific radiotracers are injected which accumulate in tumours or regions of inflammation or bind to specific proteins in the body (Box 8.13). The most common radiotracer is F-18 fluorodeoxyglucose (FDG), a molecule similar to glucose. Cancer cells are more metabolically active and may absorb glucose at a higher rate. This higher rate can be seen on PET scans (Fig. 8.68). FDG is just one of many radiotracers in use or in development.

Red and white cell scan

Occasionally the source from which a patient is bleeding is not identified by either CT or percutaneous angiography. In such cases, **red cell scans** may be helpful. A small amount of the patient's blood is extracted and mixed with radioactive technetium. The blood with

Box 8.13 PET-CT patient preparation

- No strenuous physical activity in the days (2–3) leading up to the scan.
- Limited carbohydrate diet for the previous 24 h before the examination.
- Fast (except water) for 6 h before the exam. Patients may drink as much water as they are able before and after the scan.
- Routine medications may be taken.
- Patients with diabetes are given specific instructions designed to avoid hyperglycaemia at the time of the examination (which can interfere with radiotracer uptake).
- After the radiotracer is injected, the patient will be asked to rest quietly on a reclining chair for approximately 30–60 min before being escorted into the scanner room.
- The scan will take another 30 min.
- Nursing mothers should express and delay breast-feeding for 24 h.

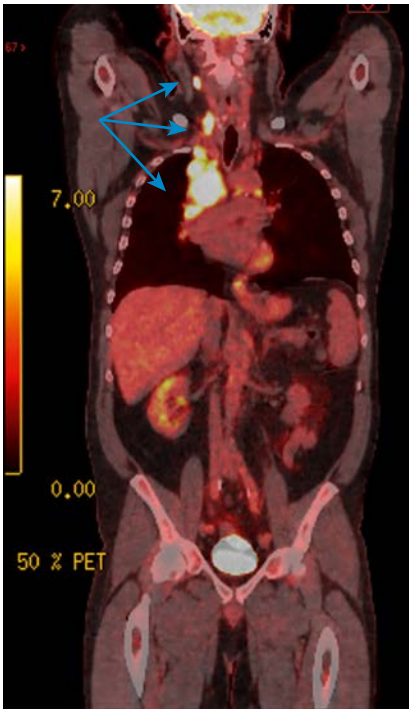

Fig. 8.68 This PET/CT image demonstrates increased FDG uptake in the cervical and upper thoracic lymph nodes *(blue arrows)*. No abnormal uptake is demonstrated below the diaphragm or spleen in this patient with lymphoma.

the technetium is then injected back into the patient's bloodstream and sequential imaging is performed to determine the site of blood loss. Red cell scan can detect bleeding at rates of 0.1 to 5 mL/minute.

White cell scan can be helpful to detect occult infection/inflammation not identified by other modalities. The process is very similar to red cell scan above, but the radioisotope used to tag the isolated white blood cells is Indium-111. Common indications include investigating prosthetic joint infections, osteomyelitis, vascular graft infections, and fever of unknown origin. The radioactive white cells are injected 1 to 2 hours after Indium-111 application. Images are taken sequentially. The whole procedure can take 1 to 4 hours or up to 30 hours depending on the clinical question to be answered.

Gastric emptying

A gastric emptying scan is performed to help diagnose motility disorders. The patient ingests a standardized meal mixed with radioisotopes (Tc-99m sulphur colloid). Sequential imaging allows accurate comparison to validated normal values for gastric emptying. This examination can take up to 4 hours.

The patient fasts for 6 hours before the scan. They should stop medicines that affect motility (e.g., metoclopramide, tegaserod, erythromycin, domperidone, and antispasmodics) for 3 days prior to the test. Patients should refrain from taking laxatives the day before or any time during the study and should not smoke on the morning of the test and during the hours of the scan.

INTERVENTIONAL RADIOLOGY

Interventional radiology (IR) is a growing field within radiology that is involved in the diagnosis and image-guided treatment of disease. With modern advancement in technology and equipment, image-guided minimally invasive procedures can be performed instead of surgery for many conditions ranging from biopsy and abscess drainage to cancer treatment (**Box 8.14**). These procedures are performed with expert technical skill and precision after years of training, and require careful patient selection, preparation, and consent in the same way as a patient undergoing surgery (**Box 8.15**). This section will consider some of the common procedures performed by the IR.

Box 8.14 Glossary of some procedures performed by interventional radiologists

- **Angiography:** Imaging of the arteries or veins to identify stenosis, occlusion, or bleeding point (fluoroscopy, MRI, CT).
- **Angioplasty:** Dilation of a (stenosed) vessel by inflating a balloon attached to a fine-bore catheter (tube) inserted percutaneously and guided into place using imaging (fluoroscopy).
- **Embolization:** Stopping or reducing the blood flow through a vessel (artery or vein) by injecting an embolic agent (coils, gelfoam, liquid or solid agents [e.g., glue, ethylene-vinyl alcohol co-polymer or cyanoacrylates] or microvascular plugs) guided precisely into place by imaging (fluoroscopy). This can be life-saving in major haemorrhage.
- **Thrombolysis:** Injecting clot-dissolving medicine (e.g., tissue plasminogen activator) directly onto the thrombus—through a percutaneously inserted fine catheter guided precisely into place through imaging.
- **Thrombectomy:** Blood clots are mechanically removed from within the vessel via a catheter inserted percutaneously and guided into place with imaging.
- **Gastrostomy tube placement:** A feeding tube is inserted (under imaging—fluoroscopy, ultrasound) from the abdominal wall directly into a stomach (percutaneously).
- **Stent placement:** A tube is precisely placed (image guided) within (i) a narrowed segment of blood vessel or bowel to 'open' up a blockage or (ii) an aneurysm to redirect flow to prevent rupture of the vessel.
- **Needle biopsy:** A sample of tissue is obtained by guiding a needle from the skin precisely into the area/organ of interest under image guidance (ultrasound, fluoroscopy, CT, or MRI).
- **Interventional oncology:** Variety of techniques (ablation, chemo-/radioembolization) are available using image guidance to treat cancer minimally invasively.
- **IVC filter insertion:** A small umbrella-shaped device placed in the inferior vena cava under image guidance to trap small thrombi, preventing embolization into the lungs.
- **Intravenous catheter insertion:** Long-term catheters are placed under image guidance to allow doctors to deliver intravenous chemotherapy, nutrition, or dialyze patients with renal failure.

Box 8.15 Patient selection, preparation, and after-care: general considerations for IR

- Patients undergoing IR procedures should be given the same considerations as for surgery.
- Informed consent should be obtained by the responsible radiologist after providing the patient with written and verbal information regarding the procedure, risks, benefits, and alternative options. The patient should be given the opportunity to ask questions and adequate time to consider their decision.
- Most procedures are performed under local anaesthesia (LA), occasionally with sedation. This is the major advantage of IR compared to surgery which usually requires general anaesthesia. Occasionally antibiotic cover may be given.
- The patient must be able to cooperate with the radiologist and tolerate the procedure by lying still on a bed. Occasionally they may be required to fast before the procedure.
- Patients should generally suspend anticoagulant therapy. Guidance from haematology services may be helpful if the patient is on long term anticoagulation for metallic heart valves or similar conditions and the radiologist should be informed if the patient is on such medications. Occasionally patients may be prescribed anticoagulation postprocedure.
- Depending on the type of procedure, patients are usually discharged home after minimal departmental observation (e.g., needle biopsy).
- Complex procedure (e.g., endovascular abdominal aneurysm repair [EVAR] or intracranial aneurysm coiling) however may require general anaesthetic and postprocedure ITU support.
- General complications for any procedure include infection, haemorrhage, unintended organ perforation, and even potentially death. However, IR procedures are less invasive than open surgery.

Surgical drainage and needle biopsies

These are commonly requested procedures for the septic patient with for example, abdominal abscess requiring drainage (Fig. 8.69) or to help facilitate diagnosis by sampling abnormal tissues in the body.

Procedure: Under image guidance (usually US or CT), a needle is guided precisely to the area inside the patient to be drained/sampled. These are minimally invasive performed under aseptic conditions with local anaesthetic (LA).

Practicalities: The area of interest should be visible on imaging, with a direct path to safely access from the skin and within the range of needles/catheters (length).

Contraindications: Area not visible on imaging for the procedure to be safely performed. Bleeding dyscrasia. Patient unable to cooperate or lie still for the duration of procedure.

Complications: These are generally safe procedures with minimal complications. (See General Considerations, Box 8.15.)

Vascular procedures

Vascular IR forms a big part of the work of the interventional radiologist. This can be life-saving in a patient with aneurysm or postpartum haemorrhage, where radiologically guided

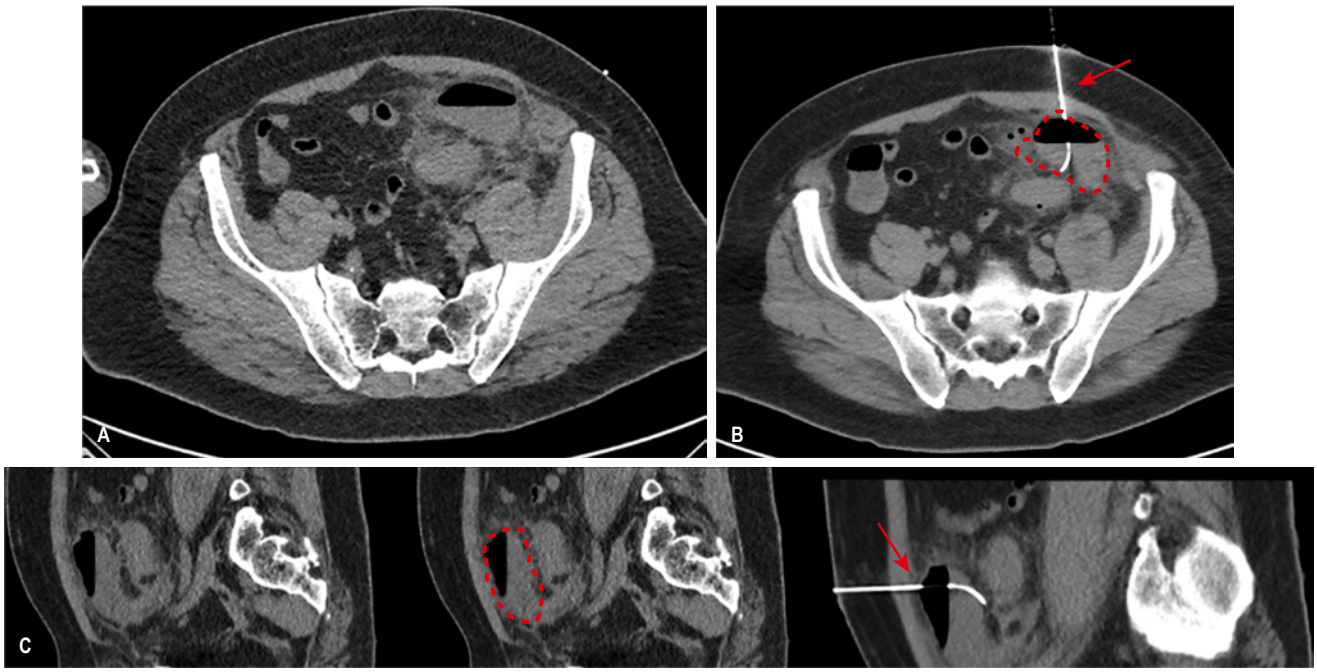

Fig. 8.69 IR drainage of an intra-abdominal collection. Drainage of the intra-abdominal collection *(red outline)* in this patient is being performed under CT guidance. A guidewire can be seen passing through the introducer needle *(red arrows)* into the collection, securing a path along which a drain can be passed. **(A), (B)** Axial views; **(C), (D)** sagittal views. *(Images courtesy of Dr Navin Mathias.)*

Box 8.16 Tumour ablation

- Common sites treated by ablation include the lung, liver, kidneys, and prostate.
- **Radiofrequency ablation (RFA)** uses a high-frequency electrical wave delivered through a probe the size of a long pencil to heat and 'burn' the tumour. A closed loop circuit is created using an RF generator, an electrode, grounding pads, and the patient. This results in ionic agitation, creating heat, coagulative necrosis, and cell death. Temperatures reach 50–100°C for approximately 4–5 min. The procedure takes around 30 min.
- **Microwave ablation (MWA)** uses microwaves, delivered via a small antenna inserted directly into the tumour. MWA is much faster than RFA, although both have similar results. It may be used with larger tumours.
- **Cryoablation** uses liquid nitrogen or argon gas to freeze tumour cells, which then rupture from the cold temperature and die. Cryoablation is often used to treat kidney tumours without damaging or affecting kidney function—useful in patients with a single kidney or in those with impaired renal function who might need dialysis if surgery is performed.
- **Percutaneous ethanol ablation (PEI)** or alcohol ablation uses absolute ethanol injected directly into the tumour. Alcohol is a potent toxin to cells and the blood vessels, making it effective in treating small tumours. PEI is used less as it often causes more discomfort than the other tumour ablation options.
- **Vertebroplasty.** Bone metastasis can also be treated by ablation, often in conjunction with cement injection to stabilize the vertebra and provide pain relief. It has been shown to reduce opioid use, improving patient function and quality of life more rapidly than radiotherapy.

interventions (e.g., stenting or embolizing blood vessels) can prevent or stop major haemorrhage (Fig. 8.70). Vascular IR can also improve blood flow to organs (e.g., limbs or the brain) through angioplasty or stent placement in stenosed or occluded vessels. When performed for the lower limbs (Fig. 8.71), this could improve the patient's function, quality of life, improve healing, and be limb saving.

Procedure: Under image guidance (usually fluoroscopy or CT), a needle then a guidewire, followed by a catheter are sequentially and expertly guided precisely to the stenosed, occluded, or bleeding vessel. Vascular access is often achieved via the superficially located femoral artery or vein at the groin. The index vessel of interest can be dilated, stented, or embolized endovascularly. These are minimally invasive performed under aseptic conditions with LA.

Practicalities: The area of interest should be visible on imaging.

Contraindications: Uncontrolled coagulopathy. No safe percutaneous access. Patient unable to cooperate or lie still for the duration of procedure.

Complications: These are generally safe procedures with minimal complications. However, vessel occlusion, haemorrhage, organ infarction, or death could ensue (particularly for more complex procedures such as intracranial or abdominal arterial coiling and aneurysm stenting). (See General Considerations, Box 8.15.)

Fig. 8.70 Coil embolization of a renal artery. This patient was bleeding from his right kidney **(A)** CT showing haematoma, *red outline*; contrast extravasation/bleeding point, *red arrow*). Angiogram showed the contrast extravasation **(B)**. A coil *(blue arrow)* was deployed and successfully stopped the bleeding **(C)**. *(Images courtesy of Dr Navin Mathias.)*

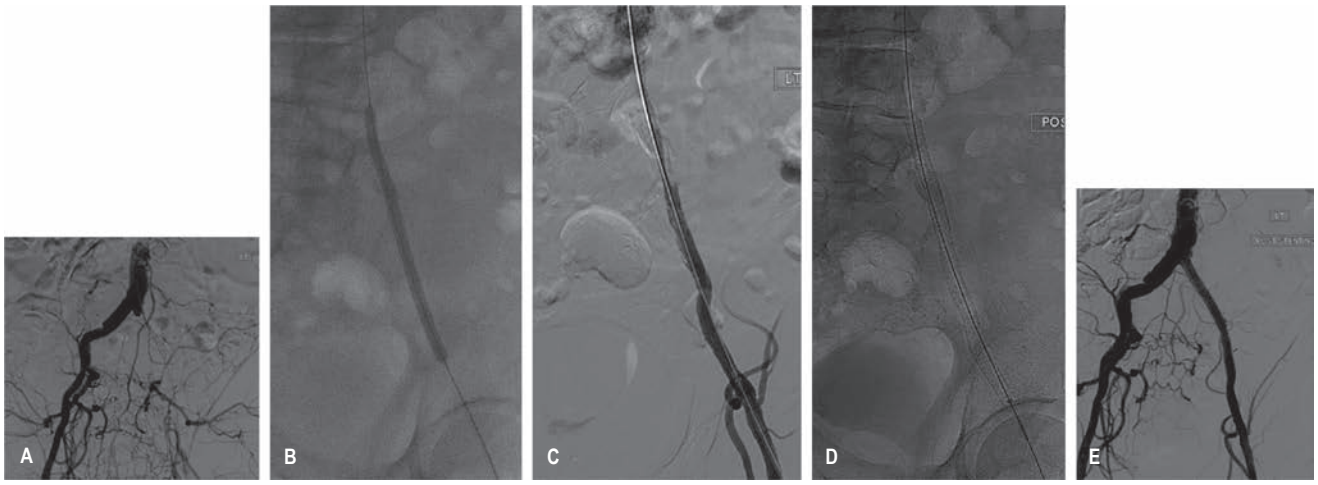

Fig. 8.71 Angioplasty of the left common iliac artery. This patient had an occluded left common iliac artery **(A)**. This was crossed with a guidewire and angioplasty performed **(B)**. Post-angioplasty angiogram showed persistent significant stenosis **(C)**. A stent was placed **(D)**. Good vascular perfusion seen with the stent in place **(E)**. *(Images courtesy of Dr Navin Mathias.)*

Abdominal IR procedures

These procedures alleviate obstructed or stenosed lumina within the abdomen. Under careful image guidance, a tube or stent can be placed to relieve an obstructed and infected urinary system (nephrostomy), palliate the cancer patient to allow swallowing/bowel movement (oesophageal or colonic stent), facilitate enteral feeding (radiologically inserted gastrostomy [RIG]) or improve transplant-free survival in patients with cirrhosis related portal hypertension and refractory ascites (transjugular intrahepatic portosystemic shunt—TIPS).

Oesophageal stenting

Indication: Palliate obstruction and dysphagia from oesophageal tumour. Treat tracheo-oesophageal fistula, post-oesophagectomy leak, or oesophageal stricture.

Procedure: A slender catheter supported by a guidewire is fed down the oesophagus past the tumour or fistula, under image guidance (fluoroscopy). The length of obstruction is measured and an appropriately sized stent is placed over the stiff guidewire at the site of luminal narrowing, creating space for food and liquid to pass. Occasionally balloon expansion of the stent may be required to create a large enough neo-lumen.

Practicalities: The patient must be able to cooperate with the radiologist for the duration of the procedure. Occasionally, an endoscopist may be required to guide the wire past a large obstructing tumour. The procedure may be performed under conscious sedation.

Contraindications: Tumour located too close to the upper oesophageal sphincter, presence of tracheal stent, and oesophageal perforation measurement greater than 50% circumference of the oesophagus or greater than 5 cm in length (absolute contraindications). Hemodynamically unstable patients, unresolved coagulopathy, tumour located too close to the gastroesophageal junction (GOJ) (relative contraindications).

Complications: Chest pain, bleeding, perforation, aspiration, stent migration, stent blockage, intractable reflux, tracheoesophageal fistula. Late complication rate ~53% to 65%, re-intervention rate up to 50%. Death 0.5% to 2%.

Colonic stenting (Fig. 8.72)

Indication: Alleviate bowel obstruction (tumour)—palliation or as a bridge to surgery.

Procedure: Guidewire is guided past the tumour per rectum (fluoroscopy). Remainder of procedure as for an oesophageal stent. Occasionally an endoscopist is required to help direct the wire through a very large tumour obstructing the lumen.

Practicalities: As for oesophageal stent above.

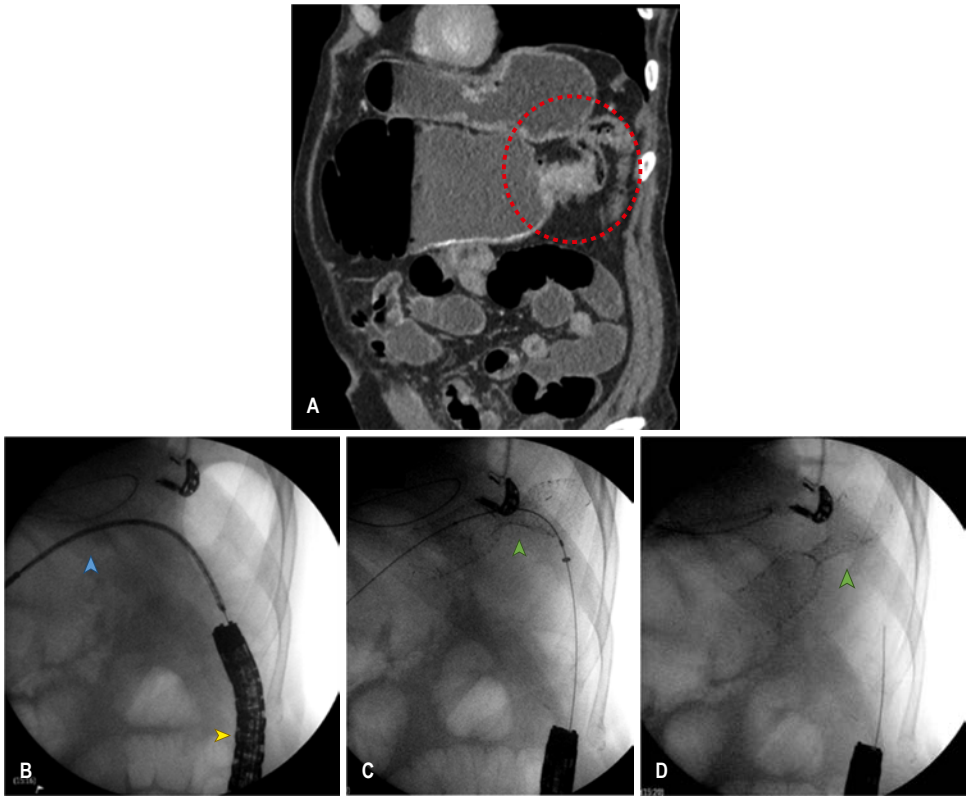

Fig. 8.72 IR colonic stent deployment for an obstructing colonic cancer. This patient has an obstructing left colonic tumour (*red circle* on CT, **[A]**). At fluoroscopy, colonoscope *(yellow arrowhead)* can be seen assisting the placement of a guidewire *(blue arrowhead)* **(B)**. The stent *(green arrowhead)* is delivered and deployed over the guidewire **(C)**. Self-expanding colonic stent can be seen in place **(D)**. *(Images courtesy of Dr Navin Mathias.)*

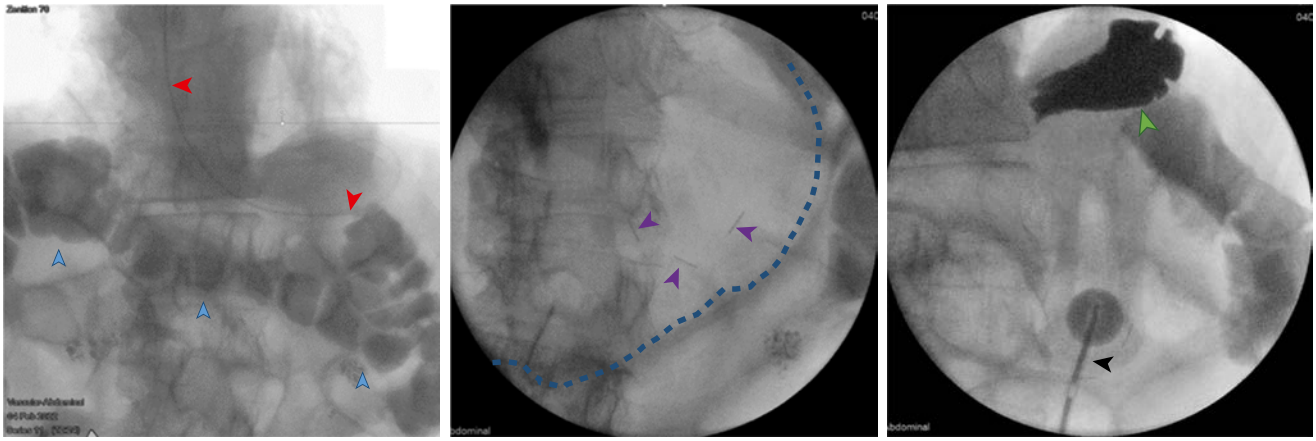

Fig. 8.73 Radiologically inserted gastrostomy (RIG) insertion. There is barium outlining the patient's colon *(blue arrowheads)* and nasogastric tube is in place *(red arrowheads)*. The stomach *(blue dotted line)* is distended with air via the nasogastric tube. Stomach is secured to the skin with clips *(purple arrowheads)*. Gastrostomy tube *(black arrowhead)* inserted percutaneously—avoiding colon—into the stomach and position checked with barium *(green arrowhead)*. *(Images courtesy of Dr Navin Mathias.)*

Contraindications: Perforated tumour. Tumour located <5 cm from anal verge (due to the likelihood of tenesmus and a higher risk of stent migration).

Complications: Perforation (associated with mortality of 16%), stent migration, tumour regrowth and re-obstruction, pain, and bleeding.

Radiologically inserted gastrostomy (Fig. 8.73)

Indication: To facilitate enteral feeding in patients with oesophageal obstruction or neurological impairment preventing safe swallow.

Procedure: A nasogastric tube (NGT) is inserted prior to the gastrostomy. The stomach is inflated with air via the NGT and visualized on fluoroscopy. Under aseptic conditions, with conscious sedation, a needle is inserted through the skin directly into the patient's stomach, avoiding the colon. A guidewire followed by the gastrostomy (feeding) tube is placed in the needle tract. The tube is stitched into place on the abdominal wall.

Practicalities: Patients may be given oral barium 1 to 2 days before the procedure to outline the colon. Oxygen is given via face mask. Procedure could take between 30 and 90 minutes. Bed rest for 4 hours. Nil by mouth for 12 hours, flushing the tube every 2 hours. Clear water per gastrostomy for 12 hours before commencing feeding per gastrostomy.

Contraindications: Severe coagulopathy. Large hiatus hernia. Interposed colon.

Complications: Leak around the gastrostomy. Infection. Bleeding.

Transjugular intrahepatic portosystemic shunt

Indication: Symptomatic portal hypertension, for example refractory ascites or variceal bleeding. Creation of a shunt between the portal and systemic circulations reduces portal pressure, thereby reducing the risk of variceal bleeding.

Procedure: Under aseptic conditions and using LA, access to the liver is achieved by puncturing the jugular vein and feeding a guidewire and catheter into the hepatic vein. Using image guidance (fluoroscopy), a needle and catheter are then passed from a hepatic vein into a branch of the portal vein. The communication is secured with a vascular stent.

Practicalities: Patient must be able to cooperate, lie still on the fluoroscopy table for the procedure (up to an hour). Patient should be fasted. Model for End-Stage Liver Disease (MELD) score predicts 90-day mortality after a TIPS procedure.

Contraindications: A high bilirubin level; severe intrinsic kidney disease (stage 4 chronic kidney disease or above), and a MELD score greater than 20 (relative contraindications). Absolute contraindications include severe refractory HE, severe pulmonary hypertension, heart failure, and significant right ventricular dysfunction (could be exacerbated by the procedure).

Complications: Hepatic encephalopathy (~24% at one year). Bleeding, infection, abscess, the aforementioned cardiac complications, bile leak or injury, acute liver failure, or stent thrombosis or migration (~1%–2%).

Nephrostomy (Fig. 8.74)

Indications: Drain an infected (pyonephrosis) or obstructed (hydronephrosis) urinary system; to divert urine from a downstream leak (e.g., ureteric injury).

Procedure: Under LA, and using US and fluoroscopic guidance, a tube is inserted from the patient's back into the renal pelvis of the kidney.

Practicalities: Patient must be able to lie still on a narrow bed for the duration of the procedure (up to an hour).

Contraindication: Uncontrolled coagulopathy. Patient unable to cooperate or tolerate the procedure.

Complications: Bleeding. Infection.

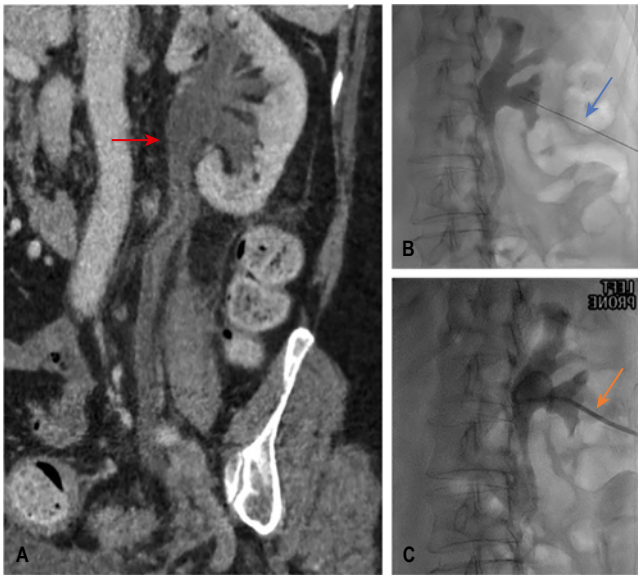

Fig. 8.74 IR nephrostomy insertion. This patient had left hydronephrosis (*red arrow*, panel **A**) secondary to a pelvic tumour. Panel **B** demonstrates guidewire *(blue arrow)* being inserted percutaneously through the introducer needle securing the tract. Contrast delineates the left renal pelvis and ureter (fluoroscopy). A nephrostomy tube *(amber arrow)* was inserted over the guidewire **(C)**. *(Images courtesy of Dr Navin Mathias.)*

Biliary drainage

Indication: Infected or obstructed biliary system, for example from bile duct or pancreatic tumour. Palliation or to allow treatment by relieving jaundice; to divert bile from a downstream leak, for example bile duct injury after cholecystectomy.

Procedure: Under LA, and using US and fluoroscopic guidance, a needle is inserted from the skin into a dilated bile duct. A guidewire is fed down the needle, the needle is removed, and a catheter is passed into the bile duct over the guidewire. If necessary, a guidewire can be navigated into the duodenum and a stent placed into the bile duct to keep it open.

Practicalities: Patient must be able to lie still on a narrow bed for the duration of the procedure (up to an hour).

Contraindication: Ascites. Uncontrolled coagulopathy. Patient unable to cooperate or tolerate the procedure.

Complications: Biliary sepsis. Bleeding. Bile leakage. (~1%–5%).

Interventional oncology

Modern multidisciplinary oncologic care is delivered by specialists in Medical, Surgical, Radiation, and Interventional Oncology (IO). IO is the branch of interventional radiology, dedicated to the diagnosis, treatment, and palliation of cancer and cancer-related problems using minimally invasive procedures performed under image guidance.

While surgical excision of tumours is generally accepted to offer the best long-term solution, occasionally this may not be possible due to the size, number, or location of the tumour. IO therapies may be applied to shrink the tumour, making surgery possible or help increase the efficacy of other treatments.

Patients can greatly benefit from IO treatments. The minimally invasive nature of the treatments means they cause less pain, fewer side-effects, and shorter recovery times. Many IO procedures can be performed on an outpatient basis, freeing up hospital beds and reducing costs. Serious complications occur in approximately 1% of patients.

Examples of IO techniques include administering chemotherapeutic drugs intra-arterially (increasing their local tumour-related potency and reducing the side-effects from system wide delivery e.g., TACE for hepatocellular carcinoma) or ablation of tumour by direct application of heat or cold energy (**Box 8.16**).

Radiofrequency ablation: liver metastasis

Indication: As a standalone therapy, in combination with surgery (curative) or for irresectable disease secondary to patient or tumour factors (see above).

Procedure: Under ultrasound and/or CT guidance, a needle probe is inserted from the skin into the liver and tumour. Heat (RFA/MWA) is transmitted from a special machine through the needle into the tumour (see **Box 8.16**).

Practicalities: Procedure is usually performed under general anaesthesia for patient comfort and control of diaphragmatic and patient movement. Recovery time is between a few hours and an overnight stay in the hospital.

Contraindications: Bile duct or major vessel invasion. Significant extrahepatic disease. Child-Pugh class C cirrhosis or active infection.

Complications: Serious complication (e.g., infection, liver failure, death) is low. Overall reported complication rate is 2.2% to 9.5%.

CUTTING EDGE AND FUTURE TECHNOLOGY

Dual/Multienergy CT is a promising new technology whereby images are acquired using 2 (or more) different spectra of X-ray energy. Harnessing variation in absorption of different X-ray energy at the molecular level, dual/multienergy CT can help identify the composition of internal body constituents, with quantification also possible. It has been shown to reduce artefacts generated from metallic prostheses and render free, active contrast extravasation/endo-leak more conspicuous. The computer processing power that is required for this technology means it is not yet widely adopted currently.

Optical imaging. Using light and special properties of photons (e.g., visible, ultraviolet, and infrared light), detailed images of organs, tissues, and cells at the cellular to subcellular level can be obtained, offering a minimally/non-invasive method to evaluate the body—without ionizing radiation. While this technology is already in use in some specialties (e.g., endoscopy and retinal imaging), clinical use in radiology is some time away.

High-intensity focused ultrasound (HIFU). Guided by MRI, radiologists are able to accurately target and use HIFU energy to ablate the area of the brain that helps regulate movement in patients with essential tremor. The procedure is done with the patient fully awake and effect is immediate. While NICE and FDA approval have been granted for essential tremor, their role in the treatment of brain tumours, epilepsy, and dementia is being investigated.

CORE SKILLS AND KNOWLEDGE

Factors that influence health stretch from climate change and poverty to health behaviours and health care. A multiprofessional approach, incorporating the epidemiological study of disease alongside practical health interventions, is required to address these complex and high-level challenges. When John Snow analysed cases of cholera in London in 1854, he not only mapped the distribution of cases and the possible link to a water pump but also dealt with the source of the outbreak by removing the pump.

The core workforce includes doctors within public health medicine, working alongside epidemiologists, analysts, commissioners, nurses, health visitors, and environmental health officers. In many parts of the world public health is led by community workers. Professionals across all medical specialties often take a population approach too, especially in primary care.

Key to understanding public health is recognizing that many patients have had their health adversely affected by social, environmental, or behavioural factors (called the 'wider determinants of health') which may contribute to health inequalities. The discipline of public health strives to improve outcomes while reducing these inequalities through three core pillars:

- ***Health improvement:*** implementing interventions to prevent ill-health and improve population health
- ***Health protection:*** preventing, controlling, and monitoring infectious, environmental, chemical, and radiological hazards to population health
- ***Healthcare public health:*** maximizing the benefits of healthcare interventions and reducing inequalities using tools such as screening and health economics.

Skills required in public health can be developed by critically appraising relevant articles in journals, by undertaking local quality improvement projects, and by seeking out opportunities to work with national or local groups focusing on health or sustainability.

BACKGROUND

When viewed on a population level, health is a broad concept. Social determinants of health are numerous and varied, stretching from climate change through to health behaviours (**Fig. 9.1**). The Alma Ata (World Health Organization [WHO] conference) declaration of 1978 stated that 'health, which is a state of complete physical, mental and social wellbeing, and not merely the absence of disease or infirmity, is a fundamental human right and that the attainment of the highest possible level of health is a most important worldwide social goal whose realisation requires the action of many other social and economic sectors in addition to the health sector'. It goes on to assert the key importance of addressing inequalities. Those working in public health strive to bring about change at a scale that will maximize benefit, while reducing inequalities in health.

For much of human history communities have been concerned about communicable disease, the availability of food and clean water, and care for the sick. The origins of modern public health in the UK lie in the big cities of industrialized nations in the mid-19th century, where pioneers such as John Snow (**Box 9.1**) began studying patterns of transmissible disease and intervening to prevent the spread of infection. The development of germ theory, the discovery of means to prevent communicable diseases (such as vaccination and sanitation), and epidemiological insights into key causes of non-communicable diseases (such as smoking) allowed public health teams, consisting of qualified individuals drawn from a variety of backgrounds, to attain a crucial position in improving the health of the whole population (**Box 9.2**). Latterly, healthcare public health has brought academic rigour to the study of aspects of healthcare delivery and to ensuring that maximum population benefit is derived from healthcare services. Globally, there has been an increasing move towards a population health approach, aiming to improve physical and mental health outcomes across populations, as well as address inequalities.

Public health and global health

This chapter focuses primarily on public health in higher-income countries. Public health issues more commonly associated with low- to middle-income countries, such as communicable and nutritional diseases, are covered in Chapter 10. However, non-communicable

Box 9.1 John Snow and the Broad Street pump

In 1854 an outbreak of cholera struck Soho in central London. Dr John Snow was a local physician who had written a paper theorizing about the transmission of cholera 5 years previously. Snow began to investigate the outbreak, reviewing local hospital records, talking to local residents, and mapping the cases he identified. He noted that 'within 250 yards of the spot where Cambridge Street joins Broad Street there were upwards of 500 fatal attacks of cholera in 10 days […] I suspected some contamination of the water of the much-frequented street-pump in Broad Street'. Snow proceeded to remove the handle of the water pump to prevent future cases, translating epidemiology into the practice of public health.

diseases, such as cardiovascular disease, cancer, and chronic respiratory disease, are now the leading cause of death globally, meaning that the contents of this chapter are relevant for all settings. Furthermore, resource prioritization and understanding population needs are integral to developing healthcare systems in low- and middle-income as well as in high-income countries.

Box 9.2 Public health teams

Public health is increasingly a multidisciplinary specialty, accessible to applicants who are not doctors but who can demonstrate suitable academic attainment and experience working in the field. Public health specialty registrar training in the UK has been multidisciplinary since 2003 and around half of public health trainees are doctors, the rest being graduates from backgrounds that include epidemiology, health policy, biostatistics, or behavioural science. Public health teams exist at local, regional, and national levels; depending on the context, they may work closely with local or national government, the emergency services, education professionals, policy experts and advocates, healthcare academics, and other local medical services.

Box 9.3 Bradford Hill criteria

Causality is more likely if:

- the effect size is large (strength)
- findings are reproducible across different samples (consistency)
- the association is demonstrable in only a specific population (specificity)
- the effect occurs after the cause (temporality)
- greater exposure leads to greater incidence of the effect (biological gradient)
- there is a feasible mechanism for the association (plausibility)
- the proposed causal relationship is not at odds with previous research (coherence)
- the effect varies measurably following a change to the causal factor (experiment)
- the effects could be proposed to be similar to other situations (analogy).

KEY CONCEPTS IN PUBLIC HEALTH

Epidemiology and causality

Epidemiology is the study of how often diseases occur in different groups of people, and why. It is central to the discipline and practice of public health medicine. Understanding the patterns of disease distribution in a population can reveal factors that may be associated with that disease. For example, the demonstration of a link between smoking and lung cancer by Sir Richard Doll and Sir Austin Bradford Hill in 1950 is a seminal piece of epidemiological research. If epidemiological associations are causal, then working to reduce or mitigate identified causes may provide an opportunity to prevent future disease. Bradford Hill laid out nine criteria to be considered when judging whether an association is likely to be causal (Box 9.3).

Health needs assessments

Health needs assessments (HNAs) are key tools used in public health medicine to drive improvement in health within a population. HNAs aim to determine healthcare needs systematically and to compare them with current service provision to identify gaps. A health need (whenever individuals are not completely well) and a health*care* need (if there is an ability for them to benefit from care) should be differentiated: health*care* needs exist only if an evidence-based intervention has been shown to improve the health of the individuals with the condition in question, as not all diseases are amenable to treatment. Real healthcare needs must be distinguished from demand (what individuals may wish to buy or use) and supply (current provision) (Fig. 9.2). Health equity audits, a process to examine how health determinants, access to services, and related outcomes are distributed across groups, may be performed in relation to needs within an HNA.

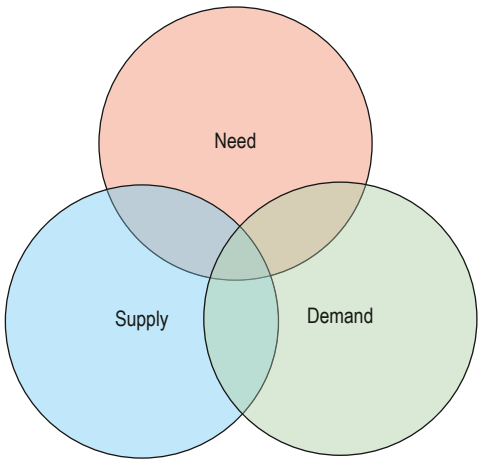

Fig. 9.2 Demand, supply, and need.

Three techniques for producing HNAs have been described (Stevens and Raftery 1997):

- ***Epidemiological***—summarizing data on healthcare needs from a range of sources by time, place, and person
- ***Comparative***—comparing needs, as well as service provision and service usage, between different populations
- ***Corporate***—consulting with stakeholders, such as healthcare professionals, commissioners, and patients, to identify priorities.

Life expectancy and quality of life

Life expectancy at birth is defined as the number of years that a newborn could be expected to live if current mortality rates continue. Life expectancy was generally rising across the world prior to 2020, although an Organization for Economic Co-operation and Development (OECD) report from 2019 noted that the rate of improvement had slowed in several European countries since 2011 (including France, Germany, Sweden, the Netherlands, and the UK), and life expectancy was falling in the USA. Falls in life expectancy became more widespread in 2020 with the COVID-19 pandemic, particularly in non-Scandinavian Europe and the USA. The largest decline within the OECD countries was reported for the USA (1.8 years), Spain (1.6 years), and Poland (1.5 years).

Healthy life expectancy, defined as the number of years lived in self-assessed good health, adds a quality-of-life component to estimates of life expectancy. While healthy life expectancy in many countries was generally rising prior to the COVID-19 pandemic, it did so at a lower rate than life expectancy. This means that people in most countries are experiencing more years in poor health. Healthy life expectancy is inversely associated with deprivation. Females in the most deprived areas of England not only die on average 8 years younger, they also experience an additional 11 years of poor health, resulting in a healthy life expectancy that is 19 years shorter than females in the least deprived areas (Fig. 9.3).

Health inequalities

Health inequalities are differences in health status between groups of individuals, which differ based on gender, ethnicity, disability, area

of residence, socioeconomic status, or other factors. Health differences arising from such characteristics often represent an injustice, especially if they are potentially avoidable and thus inequitable (inherently unjust and unfair). One of public health's fundamental principles is to strive to reduce such inequalities and to make health outcomes fairer for the population (**Box 9.4** and **Fig. 9.4**). Tudor Hart's ***inverse care law*** states that the availability of good healthcare often varies inversely with need, particularly where market forces are operating. These inequalities can be identified and addressed in relation to the access to, experience of, and outcomes from healthcare services. The COVID-19 pandemic has brought these inequalities to the fore and contributed to their widening.

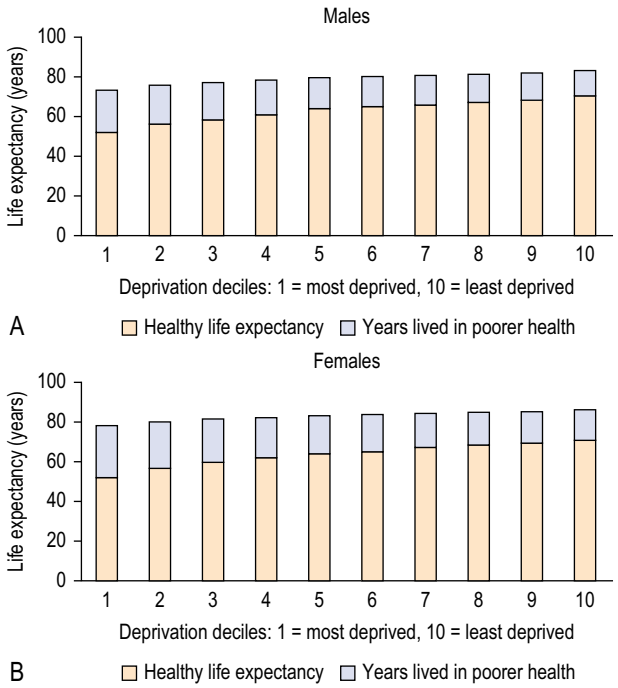

Fig. 9.3 Healthy life expectancy at birth and years lived in poorer states of health by national deprivation deciles (England, 2018–2020). (A) Males. **(B)** Females. *(Office for National Statistics. Annual Population Survey.)*

Deprivation

Examples of health inequalities that are amenable to change are those associated with deprivation. Deprivation can be measured by a basket of indicators within defined geographical areas. One example is the Index of Multiple Deprivation, which uses data across seven domains to compare relative deprivation across small areas in England. The domains include:

- income levels
- employment levels
- education and skills within a population

i Box 9.4 The Marmot review

In 2010 in the UK, Sir Michael Marmot produced a seminal report, 'Fair Society Healthy Lives', which detailed evidence-based strategies for reducing health inequalities. The report acknowledged the social gradient in health, whereby an individual's social circumstances have an impact on health, and recognized that social inequalities lead to health inequalities. Marmot concluded that, to reduce health inequalities, action is required across the wider social determinants of health and that this should exhibit proportionate universalism (i.e., actions should be universal to all but proportionate in scale and intensity to the level of disadvantage). The report stated that actions to tackle inequalities should focus on six overlapping policy objectives:

1. giving all children the best start in life
2. enabling people of all ages to maximize their potential and acquire control over their lives
3. creating fair employment and work opportunities
4. ensuring that everyone has a healthy standard of living
5. creating and developing healthy, sustainable communities
6. strengthening preventative health measures.

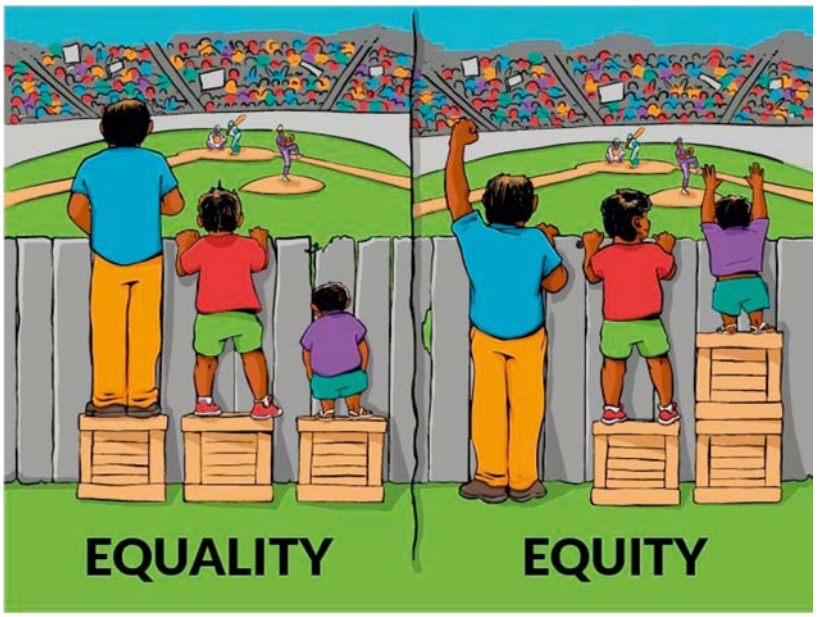

Fig. 9.4 Inequity and inequality. *(From Interaction Institute for Social Change. Artist: Angus Maguire.* Illustrating Equality vs Equity, 2016; *http://interactioninstitute.org/illustrating-equality-vs-equity/.)*

- levels of chronic ill-health and disability
- crime
- barriers to housing and local services
- the living environment.

A number of poor health outcomes have been found to correlate with deprivation. For example, children living in deprived areas have a higher prevalence of dental caries than those in less deprived areas. Water fluoridation is a public health intervention that improves oral health across the population but has been shown to have the most impact in those who are more deprived, thereby reducing health inequality. Other adverse outcomes associated with deprivation extend throughout the life-course and include low birth weight, higher infant mortality, increased chronic disease, and premature death. Data suggest that inequalities in health due to deprivation are widening. For example, over the past decade the prevalence of obesity in children aged 4 to 5 years is increasing disproportionately in those children living in the most deprived areas of England.

Politics and advocacy

The WHO defines health advocacy as 'a combination of individual and social actions designed to gain political commitment, policy support, social acceptance and systems support for a particular health goal or programme'. Advocacy is a crucial component of public health which is about making change. Targets of campaigns might be to change the law, to improve access to healthcare services, to improve standards in the food industry, to reduce climate change, or to change attitudes in society towards healthy lifestyle choices. Overcoming the powerful opposition of large corporations and/or governments is often a requirement of effective public health advocacy.

All policy decisions—not just those within the health sector but also those in other areas such as transport or housing—should be rigorously and transparently assessed to ensure that they strive to reduce health inequalities. ***Health impact assessments*** are used to understand what the health implications may be, as well as their distribution within society, to maximize positive health consequences (both indirect and direct) of projects or strategies and minimize any adverse ones.

Health advocacy has often had a larger impact on health than the introduction of new services. Examples of successful health advocacy include bans on smoking in confined public places and the reduction of salt and sugar content in processed food.

Smoking bans

Many countries have introduced bans on smoking in the workplace and in public spaces; a few (such as New Zealand and Finland) have announced a target to be 'tobacco-free' by a designated point in the future. International data from the USA and Europe have revealed a variety of improved health outcomes since the introduction of smoking bans, including reductions in preterm births, childhood hospital admissions for asthma, and emergency admissions for myocardial infarction. Despite unequivocal evidence of public health benefits, opponents of smoking bans have suggested they are examples of governments acting as a 'nanny state' or have expressed concern over the potential for a shift in smoking behaviour into private homes (which does not seem to have occurred). However, in general, smoking bans received public support, including among smokers, and much of the opposition came from large tobacco companies.

Attention is now turning to vaping. Vaping is much safer than smoking and has been supported as a tool to aid smoking cessation. However, vaping is not risk free. Concerns are growing that people, particularly if young, may start vaping despite not having previously been a smoker. There are also environmental considerations with the proliferation of non-reusable disposable vapes. Governments are introducing new vaping restrictions—including total sale bans (e.g., India) and prescription requirements (e.g., Australia). Other forms of restriction, such as on the flavour or re-usability, are also being proposed globally.

Improved nutritional content of food

Regularly exceeding the maximum amount of salt recommended for daily consumption is common across the world and is strongly associated with hypertension, cardiovascular disease, and premature mortality. Diets rich in simple sugars drive the development of obesity, insulin resistance, and diabetes, which are, in turn, risk factors for cardiovascular disease and many malignancies (see Chapter 37). Health advocacy efforts have been based on public education campaigns, clear labelling of the salt and sugar content of foods, and salt and sugar reduction targets for the food industry. Many Western diets are based on processed food, and an approach based on purely individual behaviour change is widely regarded as insufficient to tackle the problem. To make stronger gains the food industry needs to reduce salt and sugar further within prepared food in supermarkets and food outlets.

More widely, there is emerging evidence that the gut microbiome has an important impact on health and may be modified by the types of food we eat. Diets rich in plant and fermented products and low in ultra-processed foods are associated with better health outcomes. Achieving widespread change in a population's food intake requires government commitment, with imposed targets and incentives for the food industry.

PILLARS OF PUBLIC HEALTH

Although models of public health provision vary in different countries, services are often delivered at the level of local government or regional health authorities. National bodies are often responsible for collation of health statistics, support for national vaccination programmes, and advice to government on other aspects of health policy. In the USA this includes the Centres for Disease Control and Prevention (CDC) and in England, agencies include the Office of

Health Improvement and Disparities (OHID) and the United Kingdom Health Security Agency (UKHSA).

The work of public health services can be described according to the three pillars of public health:

- health improvement
- health protection
- healthcare public health.

Health improvement

While it might seem self-evident that preventing a disease is better than dealing with the consequences, there is also strong economic evidence to support the case for prevention. For example, a number of studies have demonstrated that smoking cessation services both improve population health and reduce healthcare costs overall. When considering approaches to prevention, they can be classified as primary, secondary, or tertiary (**Box 9.5**).

Wider determinants of health

Wider determinants of health (WDHs) are the broader social, economic, political, and environmental circumstances that influence health outcomes throughout life. Dahlgren and Whitehead (1991), subsequently modified by Barton and Grant (2006), developed an influential model of the main determinants of health, in which, at the core, are constitutional factors such as sex, age, and genetics; overlapping layers represent individual lifestyle factors, followed by the wider determinants (**Fig. 9.1**). The core attributes are relatively fixed but, as the layers of influence extend outwards, the determinants are amenable to change:

- The first layer represents individual ***lifestyle behaviours***, for example, diet, physical activity, smoking, and alcohol consumption.
- The second layer represents the ***communities in which individuals live***—social networks that influence health and the health behaviours we exhibit.
- Next, ***living and working conditions*** have an impact on health, for example, the quality of an individual's employment, housing, and education.

Box 9.5 Levels of prevention of disease

Primary

- Involves reduction in exposure to risk factors, focusing either on the whole population or on high-risk subgroups
- Examples include healthy lifestyle interventions for the prevention of cardiovascular disease, or workplace-based interventions to reduce asbestos exposure
- Focusing on the whole population may result in the ***prevention paradox***—such strategies often have a relatively small impact at an individual level, despite large benefits at a population level or for those at highest risk

Secondary

- Involves detecting disease at an early stage and undertaking prompt intervention to reduce the disease's impact
- Examples include screening programmes or prescription of statins for hypercholesterolaemia to reduce the likelihood of myocardial infarction or stroke

Tertiary

- Aims to reduce or mitigate long-term complications of a disease and maximize functioning
- Examples are HbA_{1c} monitoring in diabetes mellitus to minimize long-term micro- and macrovascular complications or neuro-rehabilitation after head injury

- Finally, the prevailing ***socioeconomic, cultural, and environmental conditions*** affect the health of the whole population, and these are influenced by local, regional, national, and international factors.

Air pollution

Air pollution is an example of a WDH, representing a huge environmental health risk globally. Poor air quality has a range of short- and long-term health impacts, including but not limited to cardiovascular and respiratory disease, emergency hospital admissions, and death. One of the first demonstrations of these effects was during the 'Great Smog of London' in 1952, which contributed towards many deaths. This led to the Clean Air Act of 1956, which limited the burning of solid fuel for heating in urban areas.

A range of pollutants are known to be harmful to health, including particulate matter and nitrogen dioxide. Although tackling air pollution requires individual efforts, the problem cannot be adequately addressed without local, national, and international policy change. Examples of interventions for tackling air pollution include:

- setting objectives and limits for different pollutants
- encouraging use of active transport instead of cars
- encouraging manufacturers to produce cleaner vehicles, and industry to adopt greener technologies
- introducing ultra-low emissions zones in urban areas and 'no-idling zones' around schools.

Poor air quality affects the whole population but also represents a significant health inequality in that more vulnerable members of society have higher exposure (e.g., those living in more deprived areas) or are more susceptible to harm (e.g., young children or the elderly).

Behaviour change

Behaviour change provides a crucial opportunity to improve health significantly. However, unhealthy behaviours are often complex and deeply ingrained. For example, the COM-B model recognizes that the interrelated components of *c*apability, *o*pportunity, and *m*otivation must all be addressed before *b*ehaviour is changed (**Fig. 9.5**). At a population level, instigating change requires holistic and sustained interventions across a range of policy types. Interventions may be classified as individual, structural, fiscal, or legal (**Fig. 9.6**), although there may be significant overlap between these; for instance, structural and fiscal approaches are often enshrined in legislature.

Individual interventions

Clinical consultations can be a prime setting to encourage individual-level behavioural change. The 'Making Every Contact Count' initiative seeks to encourage clinicians, and a broader range of professionals, to consider how they can build health promotion into their routine patient or client interactions. For example, professionals working in education or in the emergency services may identify issues of poor mental or physical health, isolation, or violence. They may have an initial conversation about the issues they have identified, before signposting to a range of other local services that may provide further support.

While brief advice is unlikely to instigate long-term change if delivered in isolation, it may raise the idea of change higher up the patient's agenda, particularly if delivered during a 'teachable moment' when an individual becomes especially aware of their health, such as during an unexpected hospital admission. There are several models to describe individual behaviour change, such as

Prochaska and DiClemente's 1983 Stages of Change model (Fig. 9.7). Individual-level behaviour change therapies have been found to be highly cost-effective: for example, brief advice given to adult patients in primary care about increasing their physical activity has been shown to cost £1730 per quality-adjusted life-year (QALY) gained.

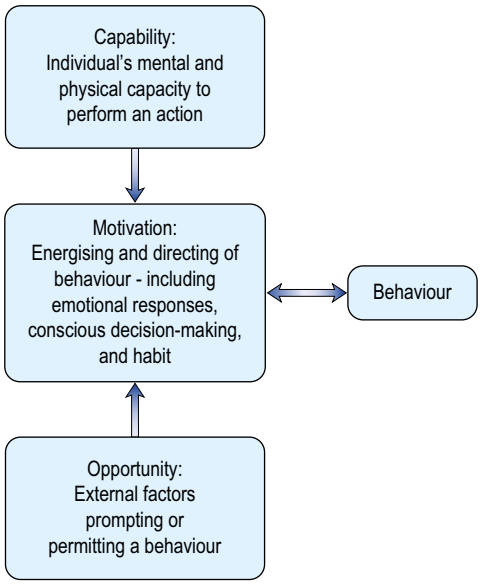

Fig. 9.5 The COM-B system. *(From Michie S, van Stralen M, West R. The behaviour change wheel: A new method for characterising and designing behaviour change interventions.* Implementation Science *2011; 6:42.)*

Fig. 9.6 Examples of initiatives to reduce smoking.

Structural interventions

Structural approaches to behaviour change may be achieved through 'nudging' individuals to default to healthier choices. The nudge theory of behavioural economics rose to prominence in 2008 with the publication of 'Nudge: Improving Decisions about Health, Wealth and Happiness' by Richard Thaler and Cass Sunstein, leading to Thaler being awarded the 2017 Nobel Prize for Economics. Nudge theory proposes that small tweaks to frame a choice more favourably or render an option easier are often sufficient to increase its uptake, and that decisions are not based purely on underlying rationale. A Cochrane review in 2015 concluded that individuals consistently eat more food when offered large portions or use larger items of tableware.

Fiscal interventions

Fiscal measures may also encourage behaviour change, through either the taxation of potentially harmful choices to render them less attractive or the subsidization of healthy ones to make them more favourable. The WHO encourages countries to tax sugary drinks, and many have implemented such legislation. Measures to improve healthy eating by subsidizing school dinners or offering free vitamin supplements to children and pregnant females may enhance health outcomes and also reduce inequality (Box 9.6).

Legal interventions

In addition to the introduction of taxes, legislative approaches to encourage behaviour change may include the regulation or prohibition of unhealthy activities. It was estimated in 2008 in the UK that over the previous 25 years since the wearing of seatbelts became compulsory, at least 60 000 lives had been saved and 600 000 severe injuries had been prevented. Legal approaches to behaviour change are often used once other methods have been tried without adequate success, since they may be perceived as paternalistic, attracting political controversy and significant lobbying from industry.

Box 9.6 Fiscal measures to improve diet and nutrition

Taxing harmful behaviours

- Poor oral health, including the presence of dental caries, is the most prevalent condition worldwide (Global Burden of Disease 2017). Reducing sugar consumption is predicted to improve oral health, as well as help tackle obesity.
- An excise tax on sugar-sweetened beverages ('sugar tax') is an example of a fiscal policy that aims to encourage manufacturers to reduce the sugar content of their products, as well as dissuading individuals from consuming products with high sugar levels.
- Such a tax has been introduced in a number of jurisdictions over recent years and initial results are promising. In the UK the government introduced a Soft Drinks Industry Levy in 2018 and it is estimated that half of manufacturers reformulated their drinks to avoid it. An evaluation of a similar tax in Berkeley, California, found that it was associated with a 21% decrease in sugar-sweetened beverages in low-income neighbourhoods, indicating that the policy has the potential not only to improve health but also to reduce health inequalities.

Subsidizing healthy behaviours

- It has been estimated that 1 billion people globally have vitamin D deficiency, and there has been a rise in cases of rickets in some countries.
- This can be prevented by eating a diet rich in vitamin D and calcium or by taking vitamin D supplements.
- The Healthy Start vitamins scheme was introduced in the UK in 2006 and provides free vitamin supplements (including vitamin D) for pregnant females and young children in low-income families.

There are three main areas of activity: control, monitoring (surveillance), and prevention.

Control

Control of infectious diseases

Rapid response to outbreaks of disease requires timely notification of new cases to the relevant public health authorities to enable controls to be established. The International Health Regulations (IHR) 2005 signify an agreement between 196 countries to build their capacities to detect, assess, and report public health events and to notify the WHO of any event that may constitute a 'public health emergency of international concern' (PHEIC). The WHO declared the novel coronavirus SARS-CoV-2 (COVID-19) as a PHEIC on 30 January 2020 and subsequently as a pandemic on 11 March 2020.

In England the most recent national legislation lists 34 diseases and 62 causative organisms as notifiable, and other infections not included on this list should also be notified if they could present significant harm to human health (such as emerging or new infections). Cases are notified based on clinical suspicion to the local health protection team, and notification should not be delayed while awaiting confirmation.

Health protection teams will then perform a risk assessment for each notification they receive and will introduce control measures specific to the disease and the context to mitigate identified risks, working in conjunction with environmental health officers from the local authority. Control measures may include:

- provision of infection prevention and control ('IPC') advice
- isolation of infected individuals
- post-exposure prophylaxis.

Identification of infected individuals through widespread testing, contact tracing, isolation of exposed individuals, closure of settings such as schools and workplaces, and reductions in movement with national and international travel restrictions were all implemented during COVID-19 to reduce infection rates.

Box 9.7 Middle East respiratory syndrome coronavirus (MERS-CoV)

- In 2015, MERS-CoV was reported to be one of the top emerging pathogens likely to cause severe outbreaks.
- It is a viral respiratory disease first reported in Saudi Arabia in 2012 and thought to be associated with bat coronaviruses.
- MERS-CoV has also been found in camels, and the WHO advises that individuals with co-morbidities should avoid contact with camels, refrain from drinking raw camel milk, and not eat undercooked camel meat.
- Patients may develop severe pneumonia and renal failure, and there is high mortality in 30% to 40% of cases.
- Thus far, all cases have been associated with countries in or near the Arabian Peninsula, and spread has been reported via close contact with infected cases or in healthcare settings.

Control of environmental hazards

Public health services are also notified of local environmental, chemical, or radiological hazards that threaten the health of the public. These threats are wide-ranging and include air pollution, drinking water contamination, and exposure to radiation. Public health professionals work with the relevant experts, emergency services, local government, and industry to identify and mitigate these hazards.

Monitoring (surveillance)

'Emerging infectious diseases' (EIDs) is a term that encompasses newly emerging pathogens, pathogens whose incidence is increasing and/or that are appearing in new populations, and pathogens that are re-emerging in different forms (e.g., multidrug-resistant [MDR] and extensively drug resistant [XDR] tuberculosis). Many of these EIDs are zoonoses (of animal origin), including, for example, human immunodeficiency virus (HIV) and Middle East respiratory syndrome coronavirus (MERS-CoV, **Box 9.7**). Other recent examples of EIDs include Zika virus associated with microcephaly; Ebola virus disease associated with outbreaks in West Africa and the Democratic Republic of Congo; and SARS-CoV-2.

The reasons why new infections appear and old ones return are multifactorial and include:

- ***population movement*** to new geographical areas, for example, displacement following war or natural disasters
- ***a rise in global trade and travel***
- ***ecological changes***, such as those driven by climate change or severe weather events (which can, for example, have an impact on vectors implicated in the transmission of pathogens); or changes in agricultural practices (which can, for example, alter the likelihood of coming into contact with sources of infection)
- ***technologies in healthcare***, for example, xenotransplantation or increased antibiotic use (associated with the development of antimicrobial resistance).

Well-developed surveillance mechanisms are key in the early detection of new and emerging pathogens that may represent a significant future threat to health. This monitoring facilitates outbreak investigations (**Box 9.8**), as well as informing broader infection prevention policy (**Box 9.9** and **Fig. 9.8**).

Box 9.8 *E. coli* outbreak investigation using whole-genome sequencing (WGS)

WGS is increasingly used in infectious disease surveillance. The identification of highly similar bacterial genomes can link individuals to the same outbreak, when there may not otherwise have been obvious similarities between cases. For example, in 2017, Public Health England surveillance identified an outbreak of 12 cases of *E. coli* O157 occurring within a 6-week window and carrying the same WGS. The cases lived across England, had no other known common features, and would not have been investigated collectively, were it not for WGS results. Using a detailed questionnaire, epidemiologists identified burgers from a particular retailer as a potential link. In collaboration with the supermarket and the Food Standards Agency, supermarket loyalty card records belonging to the affected individuals were analysed to identify the specific burger brand. The product was recalled and the supermarket contacted those known to have bought the burgers, advising them to return for a refund.

Box 9.9 Pertussis vaccination in pregnancy

Pertussis infection (whooping cough) is a significant infectious cause of morbidity and mortality in infants, particularly among those too young to have been protected by vaccination. After UK surveillance data identified that, during a 2012 pertussis outbreak the highest incidence of disease was among infants under 3 months of age, the Department of Health introduced an antenatal vaccination programme. Intrauterine transfer of maternal antibodies confers passive immunity, protecting infants until they are old enough for active immunity with routine vaccination. The antenatal programme has been shown to be effective, with a reduction in infant pertussis incidence (**Fig. 9.8**).

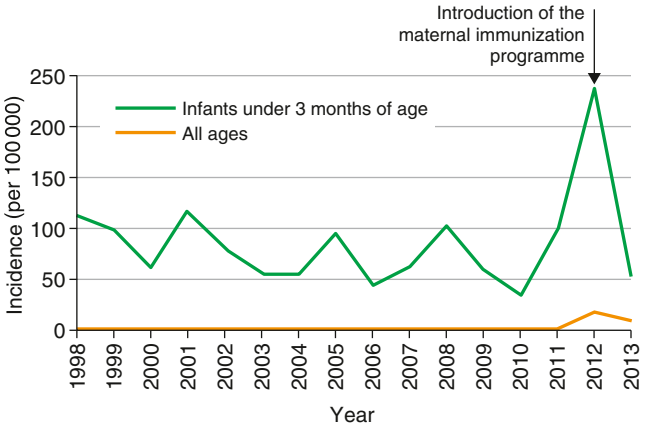

Fig. 9.8 Incidence of laboratory-confirmed cases of pertussis, England (1998–2013). *(By kind permission of Public Health England. The Green Book, Ch. 24, p. 4, Fig. 24.2. https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/514363/Pertussis_Green_Book_Chapter_24_Ap2016.pdf.)*

Prevention

Prevention within health protection is concerned with reducing the risk of transmission of infectious diseases. Two key examples of this are hand hygiene and vaccination.

Hand hygiene is a non-pharmaceutical intervention (NPI) that is one of the simplest yet most effective public health (prevention and control) measures. Basic hand-washing in communities minimizes the spread of many infections (e.g., reducing the risk of *Escherichia coli* infection in petting zoos or disrupting the transmission of norovirus in schools) but is also the main way of combatting hospital-acquired infections and preventing the spread of antimicrobial resistance.

During the COVID-19 pandemic the importance of hand-washing was promoted alongside other NPIs to reduce the spread of infection. Individual-level NPIs introduced internationally to varying degrees included physical distancing of 1 to 2 metres between individuals and the use of face masks, including in community (non-healthcare) settings. Environmental NPIs also play a role in prevention and include cleaning and adequate ventilation of indoor spaces.

Box 9.10 UK vaccination universal schedule 2022

8 weeks	Diphtheria, tetanus, pertussis, polio, *Haemophilus influenzae b*, hepatitis B
	Meningococcal group B
	Rotavirus
12 weeks	Diphtheria, tetanus, pertussis, polio, *Haemophilus influenzae b*, hepatitis B
	Pneumococcal
	Rotavirus
16 weeks	Diphtheria, tetanus, pertussis, polio, *Haemophilus influenzae b*, hepatitis B
	Meningococcal group B
1 year	*Haemophilus influenzae b* and Meningococcal type C
	Pneumococcal
	Measles, mumps, and rubella
	Meningococcal group B
3 years 4 months	Diphtheria, tetanus, pertussis, polio
	Measles, mumps, and rubella
12–13 years	Human papillomavirus
14 years	Tetanus, diphtheria, and polio
	Meningococcal groups A, C, W, Y
65 years	Pneumococcal
70 years	Shingles
Seasonal[a]	Influenza: children aged 2–10 years and adults aged 50 and over
	COVID-19: adults aged 50 and over

[a]Please note eligibility for seasonal programmes has changed annually in the UK through the COVID-19 pandemic and these are the universal (non-risk) groups eligible in Winter 2022-23.

Vaccination

Vaccination has had a huge impact on the burden of infectious disease, second only to clean water provision. Vaccination programmes confer benefit to the individual and to the population as a whole (especially its most vulnerable members) through herd immunity, whereby a high proportion of population immunity reduces person-to-person transmission. The basic reproduction number (R_0) is the number of secondary infections produced by a typical infection in a totally susceptible population. For diseases with a high R_0 (e.g., measles), higher coverage is required to attain herd protection.

Vaccination programmes are tailored to the national prevalence of particular diseases (e.g., UK schedule, **Box 9.10**) and develop

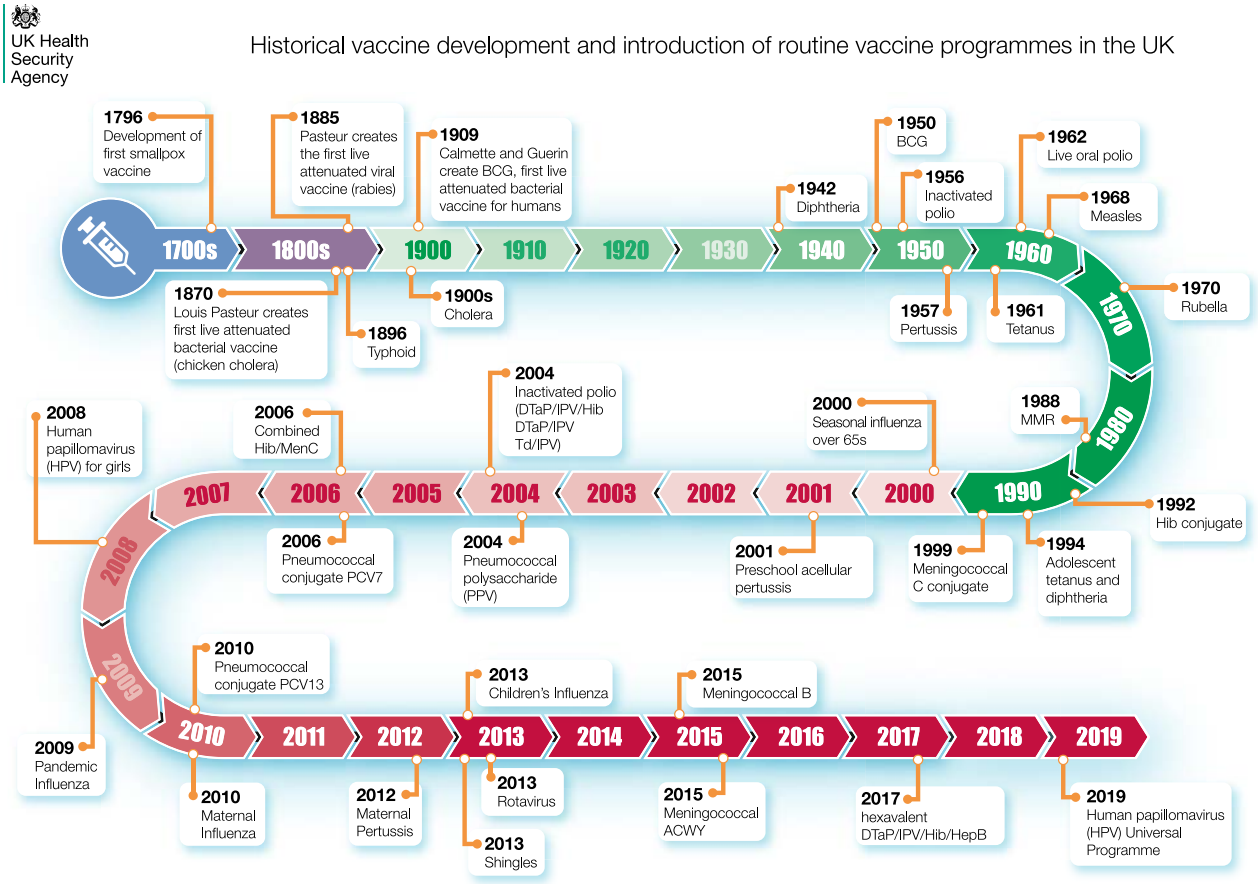

Fig. 9.9 **Development of the UK vaccination schedule.**

Box 9.11 Control, eradication, and elimination

- ***Control*** is defined as when the amount or impact of a disease within a population has reduced to a locally acceptable level.
- ***Eradication*** occurs when the disease incidence is zero worldwide and no environmental reservoir exists. This has been achieved only for smallpox.
- ***Elimination*** is when the disease incidence within a defined area is zero.

(Adapted from Dowdle WR, The principles of disease elimination and eradication. Bull World Health Organ *1998; 76[Suppl 2]:22–25.)*

Box 9.12 Notification of suspected measles cases

Recent outbreaks of measles in Europe and the USA have been seen primarily among individuals who have not received the measles, mumps, and rubella (MMR) vaccination. Post-exposure prophylaxis (PEP), if delivered promptly, can prevent contacts of known sufferers from developing measles or may attenuate their symptoms if they go on to develop the disease.

PEP can be delivered in two ways:

- ***Using a dose of MMR vaccine to induce active immunity.*** However, MMR is a live vaccine and should not be administered to immunocompromised individuals or pregnant females and is inappropriate for some infants.
- ***Using immunoglobulin to provide passive immunity.*** This is recommended for groups who cannot receive the MMR vaccine for the reasons listed above and who are often at greatest risk of morbidity and mortality from measles infection.

over time (Fig. 9.9). Selective vaccination programmes aim to protect those at highest risk of certain diseases (e.g., travel vaccines or hepatitis B vaccination for healthcare workers), while mass vaccination programmes aim to contain (control), eradicate, or eliminate disease (Box 9.11). Some vaccines provide protection *after* exposure in some cases (e.g., the measles, mumps, and rubella [MMR] vaccine, which can be used to help limit the spread of a measles outbreak by immunizing previously unvaccinated contacts of a known case, Box 9.12).

The success of a vaccination programme is driven as much, if not more, by its uptake among eligible populations as by its clinical efficacy in reducing infection and preventing transmission for an individual. Many factors may influence the acceptance of a vaccination offer (Fig. 9.10), and those that reduce uptake may coalesce in some communities, driving health inequalities. These social and behavioural barriers may spill over between vaccination programmes, with the uptake of routine childhood vaccinations falling globally during the COVID-19 pandemic, and can cluster with other behavioural risk factors for ill-health such as

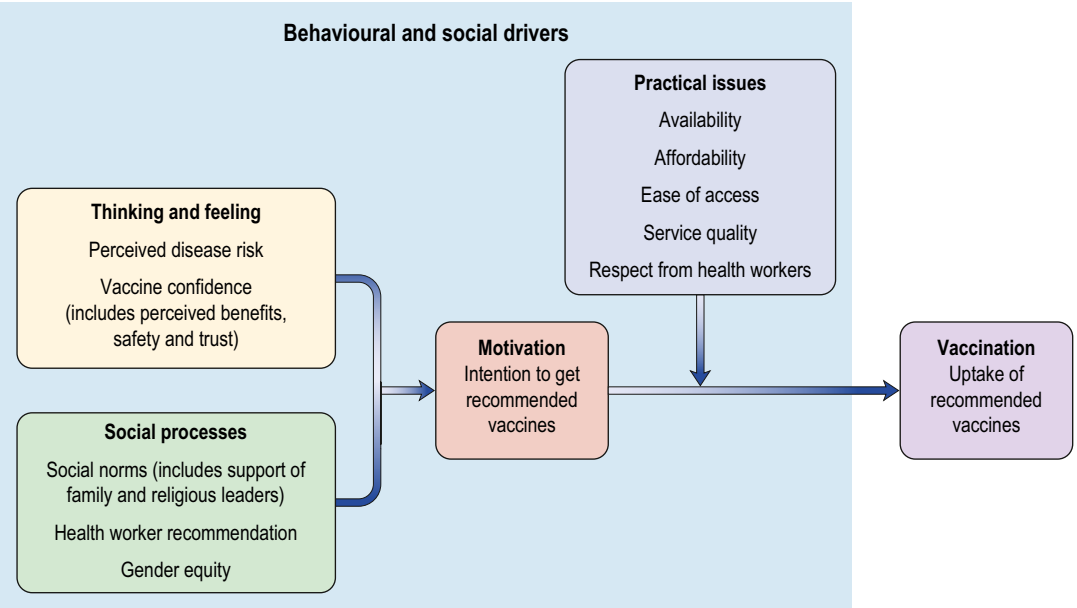

Fig. 9.10 **The WHO behavioural and social drivers (BeSD) of vaccination framework.**

smoking. Behaviour change models, such as COM-B (**Fig. 9.5**), can be used to analyse the reasons contributing to vaccine hesitancy within a community, and behavioural insights techniques can be used to design effective solutions. For example, pop-up clinic provision in community venues can address issues of capability (with knowledge transmitted through trusted community leaders), opportunity (ease of local access), and motivation (observing peers being vaccinated).

Unprecedented international coordination between academia, national governments, regulatory bodies, and the pharmaceutical industry resulted in rapid development and approval of a number of COVID-19 vaccinations. The first doses of COVID-19 vaccination were administered within a year of the global pandemic being declared. However, alongside vaccine hesitancy, another barrier to successful global vaccination uptake is inequitable distribution of vaccine supply.

Healthcare public health

Healthcare public health is the final of the three domains of public health, defined as being concerned with maximizing population benefits from healthcare interventions and reducing health inequalities. It involves the prioritization of limited resources, the prevention of disease, and the improvement of healthcare outcomes via 'design, access, utilisation and evaluation of effective and efficient health and social care interventions, settings and pathways of care' (Faculty of Public Health 2017).

Screening

Screening aims to reduce the harm caused by a disease and its complications by detecting the disease or its risk factors at an early enough stage for it to have a beneficial impact on outcome. Screening tests do not diagnose disease; they determine who should be investigated further for diagnosis and treatment. Screening can be:

- opportunistic, e.g., assessment of smoking status during a primary care visit
- part of a coordinated programme, with quality assurance and programme monitoring.

Although screening programmes are commissioned and delivered to improve health outcomes, screening has the potential to do harm, and so the benefits and risks need to be carefully considered, and screening should be implemented only when certain criteria are met (**Boxes 9.13 and 9.14**). In England, there are currently 11 population screening programmes (**Box 9.15**).

Screening for prostate cancer

An example of uncertainty around implementation of screening programmes is prostate cancer. This is the most common cancer in males in the UK, with over 50 000 cases annually. Although the rising incidence has links to increased case ascertainment through testing, as well as to increases in life expectancy, the mortality rate is highest in males over 90 years of age. It remains the second most common

cause of cancer death in males in the UK and is often aggressive in younger males, making it an attractive target for screening.

Prostate-specific antigen (PSA) is a glycoprotein that can be detected in blood and is associated with a range of conditions affecting the prostate, including but not limited to prostate cancer. This renders PSA testing of relatively poor sensitivity and specificity for a screening programme, with subsequent prostate biopsy for a definitive diagnosis not without harms. A 2018 systematic review demonstrated that PSA-based screening for prostate cancer would result in:

- a possible small reduction in disease-specific mortality over 10 years equating to 1 fewer death from prostate cancer per 1000 males screened
- no reduction in overall mortality, with 1 male hospitalized for sepsis, 3 experiencing urinary incontinence, and 25 experiencing erectile dysfunction from the same 1000 screened males.

The United Kingdom National Screening Committee does not currently recommend screening for prostate cancer, in contrast to EU recommendations (although few countries have an official population-based screening programme). In most high-income countries an opportunistic approach to PSA testing is taken on the basis of patient request, symptoms, or a high-risk family history—but this is viewed by many to be unsatisfactory and inequitable.

However, the balance between harms and benefits of screening for prostate cancer may shift with multiparametric magnetic resonance imaging (MRI) scanning, particularly if used in a targeted manner based on age, ethnicity, and a family history of prostate, breast, or ovarian cancer. Whether the UK has the capacity to deliver such a screening programme in an accessible and equitable way is currently debated and is in need of further evaluation.

Box 9.13 Wilson and Jungner criteria for screening tests

Wilson and Jungner (1968) developed the classical screening criteria to determine whether or not a condition/disease should be subject to screening:

- The condition should represent an important health problem.
- There should be an accepted treatment.
- Diagnostic and treatment facilities should be available.
- There should be a recognizable latent or early symptomatic stage.
- There should be an appropriate test or examination.
- The test should be acceptable to the population.
- The natural history of the condition should be well understood.
- There should be agreement on who to treat.
- The cost of case-finding should be economically balanced in relation to possible expenditure on medical care as a whole.
- Case-finding should be a continuous process.

Wilson JMG, Jungner G. Principles and practice of screening for disease. Geneva: World Health Organization; 1968.

Box 9.14 Screening test performance

Negative screening tests do not necessarily confirm the absence of disease. Screening test performance can be evaluated by assessing the disease status against the test result.

- ***False positives*** occur when individuals with no disease test positive.
- ***False negatives*** occur when individuals with disease test negative.
- Sensitivity and specificity describe how well the screening test performs against a gold standard (criterion) test:
  - ***Sensitivity*** is the ability of the test to detect all cases of disease.
  - ***Specificity*** is the ability of the test to detect all disease-free cases.
- Both positive and negative predictive values are dependent on the population disease prevalence:
  - ***Positive predictive value (PPV)*** is the probability of having the disease, given a positive test result.
  - ***Negative predictive value (NPV)*** is the probability of not having the disease, given a negative test result.

	Disease present	Disease absent	
Test positive	True positive (A)	False positive (B)	A+B
Test negative	False negative (C)	True negative (D)	C+D
	A+C	B+D	TOTAL

Sensitivity = A/(A + C) × 100
Specificity = D/(D + B) × 100
Prevalence = A + C/TOTAL × 100
PPV = A/(A + B) × 100
NPV = D/(D + C) × 100

Box 9.15 Screening programmes

Antenatal and newborn

- Sickle cell and thalassaemia
- Fetal anomaly
- Infectious diseases in pregnancy
- Newborn and infant physical examination
- Newborn blood spot
- Newborn hearing

Young person and adult

- Diabetic eye
- Abdominal aortic aneurysm
- Breast cancer
- Cervical cancer
- Bowel cancer

Antimicrobial resistance

This occurs when microorganisms develop resistance to commonly used antimicrobial drugs and are not suppressed by pharmacological agents that would normally inhibit their growth or kill them. Examples include methicillin-resistant *Staphylococcus aureus* (MRSA), XDR tuberculosis, and Carbapenemase-producing Enterobacteriaceae (CPE) (see Chapter 12). These multiply drug-resistant organisms are an emerging cause of hospital-acquired infections, which result in outbreaks, are associated with high morbidity and mortality, and have the potential to develop into even more drug-resistant strains (**Box 9.16**).

The cornerstones of prevention of the spread of antimicrobial resistance include:

- ***Early case recognition*** using robust surveillance mechanisms, for example, screening of all new admissions to hospital for asymptomatic carriage of such organisms.
- ***Antimicrobial stewardship:***
  1. Antibiotic prescribing practice is optimized so that antibiotics are prescribed only when clinically indicated
  2. Local prescribing guidelines are adhered to
  3. Use of broad-spectrum antibiotics is minimized
  4. Dose, route, and length of administration are monitored
  5. Antibiotics are stopped or switched promptly, as appropriate (see Chapter 12).

Box 9.16 Antimicrobial resistance

The advent of antimicrobial resistance is one of the biggest current threats to public health, as it has the potential to render individuals susceptible to a wide range of currently treatable microorganisms. As a result, 'low-risk' procedures (e.g., joint replacements) may become hazardous due to the infection risk, and treatment options for cancers or organ transplantation may become untenable if immunosuppression poses too great a threat. The O'Neill review commissioned by the UK government in 2014 estimated that, unless preventative action is taken, deaths from antimicrobial resistance could reach 10 million per year worldwide by 2050.

- ***Public education campaigns*** to try to reduce antibiotic demand
- ***Good hand hygiene*** on the part of healthcare workers
- ***Reduction of agricultural antibiotic use***
- ***Promotion of vaccination***
- ***Research*** to develop new classes of antimicrobial.

Health economics

Demand for healthcare often exceeds the finite resources available to deliver it. These finite resources include not only money but also the availability of space and appropriately trained staff. As not all demands for healthcare can be met, the concept of ***opportunity cost*** arises: if resource is used for one intervention, less will be available to do something else. The benefits gained from the chosen option must be greater than the benefits foregone by not choosing the alternate. Opportunity cost may be minimized by resourcing interventions with maximal cost-effectiveness.

Measuring outcomes

A prerequisite for maximal cost-effectiveness is maximal efficiency. Efficiency describes using the minimum resource to produce the same output or, alternatively, maximizing the output gained from using the same resource. When comparing interventions that produce the same output, such as an antihypertensive that, on average, reduces blood pressure by the same extent, the intervention that is cheaper will be most efficient (this is known as cost minimization). If the interventions produce different types of output, then a common measure of health is needed to permit comparison: if both treatments are being used for the same disease, then a disease-specific measure may be used.

Comparing treatments between completely different diseases requires a generic measure of the amount of health gained (termed '***utility***'). The two most commonly used measures of utility are the ***quality-adjusted life year (QALY)*** and the ***disability-adjusted life year (DALY)***. A QALY is 1 year of life in perfect health, whereas a DALY is the inverse: 1 year of healthy life that has been lost due to premature death or disability. The aim is to maximize the number of QALYs gained or minimize the number of DALYs lost.

Measuring cost-effectiveness

When the interventions being compared involve both different outputs and different costs, then a measure of utility in comparison to cost is produced. These cost–utility analyses produce an ***incremental cost-effectiveness ratio (ICER)***, which can then be compared by policy-makers to make funding decisions across the healthcare system (**Box 9.17**). The threshold at which interventions are deemed to be cost-effective depends on the resources available in a particular setting. For example, in England, funding recommendations are made by the National Institute for Health and Care Excellence (NICE), and a threshold of between £20 000 and £30 000 per QALY gained is currently used to determine whether an intervention should be recommended by NICE.

The ethics of funding decisions

Health economics does not only concern cost-effectiveness. The use of funds, and particularly of public funds, should be fair, as well as represent good value. The determination of 'fairness' is an ethical one, and contextual to the society in which the health system is operating. It is commonly said that the benefit of using QALYs is that they are uniform across conditions ('a QALY is a QALY is a QALY'), but whether this should be applied in all circumstances is debatable. For example:

- Is extending life by 1 month when a patient is only expected otherwise to live for 1 month the same as extending life by 1 month when a patient can be expected otherwise to live for 20 years?
- Should the amount a funder is willing to pay per QALY be the same for all diseases, when it is recognized that treatments for rare diseases are more expensive (to allow pharmaceutical companies to cover their research and development costs among a smaller sales volume)?

In the UK, specific rules have been introduced with respect to end-of-life treatments and to rare diseases in an attempt to answer these questions.

Box 9.17 Cost–utility calculations

Treatment A

- In comparison to current treatment, treatment A would extend patients' lives by a further 3 years, each at half the 'perfect' quality of life
- Net QALYs gained = 3 × 0.5 = 1.5
- Treatment A costs £45 000 per patient (one-off sum) more than the current treatment
- Cost–utility = 45 000/1.5 = £30 000 per QALY

Treatment B

- In comparison to current treatment, treatment B would not prolong patients' lives, but it would improve their quality of life from 30% to 50% (with a life expectancy from treatment of 10 years)
- Net QALYs gained = 10 × 0.2 = 2
- Treatment B costs £1600 per patient per year (ongoing)
- Cost–utility = (1600 × 10)/2 = £8000 per QALY

Therefore, treatment B is more cost-effective than treatment A.

Service delivery

Research has shown that active consideration of the needs of patient groups when planning how and where interventions are to be delivered has the potential to improve patients' health at a population level. Tailoring service design to patient needs can be observed in the use of outreach services for areas with high numbers of hard-to-reach individuals to increase accessibility. For example, homelessness is a risk factor for tuberculosis, but individuals who are homeless may be less likely to present to healthcare services with symptoms and so may remain undiagnosed; once diagnosed, they may be less likely to complete courses of treatment. Novel outreach services run to engage homeless people in the wider community have been described that use mobile X-ray diagnostic units to provide tuberculosis screening in the community.

Centralization

Where the volumes of patients with a particular condition are low the quality of care that patients receive may be improved by service centralization, which ensures they are seen by teams dealing with sufficient numbers of cases to make their care routine, not unusual. Services may be delivered using a 'hub-and-spoke' model, whereby problems of lower complexity are dealt with in local hospitals and problems of higher complexity or acuity are referred to a tertiary centre. For example, in London, city-wide stroke services were reorganized in 2010 with the introduction of a smaller number of 'hyperacute' stroke units where emergency care, including thrombolysis and mechanical

thrombectomy, is delivered; these are supported by a number of other local acute stroke units, to which patients are subsequently 'stepped down' for rehabilitation (see Chapter 29). A 2013 evaluation concluded that this service reorganization was associated with significantly improved patient survival and reduced healthcare costs.

Centralization has benefits including:

- bringing together specialized healthcare professionals and equipment
- enabling greater senior clinical presence out of hours
- helping to ensure that clinicians remain up to date with current evidence
- reducing unwarranted variation between units.

However, any centralization is a trade-off against increased travel time for patients (which might reduce accessibility and make services less equitable) and may be unpopular if there is a perception that local hospitals are being undermined.

CORE SKILLS AND KNOWLEDGE

Global and planetary health describes a high-level approach within medicine that recognizes that health is determined by challenges that transcend national boundaries, and looks at healthcare needs across the world as well as within individual nations. Such needs are complex, may be triggered by natural disasters or armed conflict, and must be addressed using a multiprofessional approach.

Efforts to improve global health are championed by non-governmental organizations such as the World Health Organization (WHO), the United Nations Children's Fund (UNICEF) and the World Food Programme, alongside individual charities and local government health systems, and interventions are often directed by international targets such as the United Nations' Sustainable Development Goals.

Opportunities for developing an understanding of global health include:

- Engaging actively in debates about the global economic and political determinants of health
- Considering the evidence for community-level interventions in improving health outcomes
- Travelling to see medicine being practised in a radically different context (e.g., as part of a medical school elective), and reflecting on the successes and ongoing challenges of local healthcare provision.

BACKGROUND

'Global health' (GH) has been described as 'an area of study, research and practice that places a priority on improving health and achieving equity in health for all people worldwide'. In 2015 this term was broadened to include 'planetary health', thereby encompassing the importance of the natural environment in supporting human health and wellbeing.

Significant improvements have been seen in many indices of GH (such as under-5 mortality), but momentum has been lost in recent years due to the effects of the COVID-19 pandemic, economic crises, and war.

In 2015, the United Nations General Assembly adopted 17 Sustainable Development Goals (SDGs) to replace the Millennium Development Goals. These offer a framework for ongoing efforts to improve global and planetary health (see **Fig. 10.1**).

Overview

Complex individual and community health needs are present in high- as well as low- and middle-income countries (LMICs). These may be particularly acute in times of crisis, for example, during or after armed conflict. Effective delivery of GH requires interprofessional collaboration between healthcare workers, politicians, economists, and scientists in pursuit of both individual wellbeing and population-based prevention and care.

Examples of successful interventions include campaigns for the provision of vaccines by the Global Alliance for Vaccines and Immunization (GAVI) and initiatives to reduce the economic exploitation of child labour (International Labour Organization [ILO]). The African Programme for Onchocerciasis Control (APOC) has transformed the lives of millions of people through the administration of a single, annual dose of the drug ***ivermectin***.

The global scale of the problem

Average global life expectancy has increased by over 6 years between 2000 and 2019 (66.8–73.4 years) but healthy life expectancy has not increased by the same level (58.3–63.7 years). In some countries, particularly in LMICs, life expectancy has actually decreased following years of economic austerity and the COVID-19 pandemic.

Some urgent global challenges:

- Around 5 million children under the age of 5 die each year; most deaths are preventable.
- Preterm birth complications account for >1 million deaths per year.

- Each day, 800 females die from preventable causes related to pregnancy and childbirth.
- Heart disease and stroke are the leading causes of death.
- Infectious diseases, including respiratory infection and tuberculosis (TB), as well as diarrhoeal disease, are significant contributors to mortality.
- An estimated 38.4 million people (2021) live with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS, 65% of the estimated 650 000 deaths from HIV/AIDS occurred in the World Health Organization [WHO] African region).
- Mental health disorders, for example, anxiety and depression, are main causes of ill health and disability worldwide.
- Tobacco use kills more than 7 million people each year and 80% of users live in a LMIC.
- The prevalence of obesity has nearly tripled since 1975. More than 1 billion adults, including 39 million children below 5 years of age and 340 million adolescents, were obese in 2022.
- The number of people living with diabetes is increasing. Approximately 1.5 million deaths were due to diabetes mellitus in 2019.
- Nearly 1.35 million people die from road traffic accidents every year.

GLOBAL HEALTH CHALLENGES

The global burden of disease

The Global Burden of Disease (GBD) study is a collaborative effort of over 5000 researchers in over 200 countries, coordinated by the Institute for Health Metrics and Evaluation (IHME). It provides regular estimates on mortality and disability-adjusted life years (DALY). DALY summarize years of life lost and years lived with disability as a result of different diseases. These are further described in Chapter 9.

This metric allows comparison of the burden of disease across society, including mortality, morbidity, disability, injuries, and risk factors. While DALYs can be affected by demographic changes, especially by changing population age profiles, they are very useful when comparing health in different populations.

While infectious diseases remain a major global disease burden, the latest iteration of the GBD study (2019) demonstrated a continuation of the global transition of health burden to non-communicable disease.

There is a global mismatch in the use of funds, with most research and development going to countries with low disease burden. Classically described as the '10 to 90 gap', with 90% of resource going to countries with only 10% of the disease burden (Fig. 10.2), it has been re-evaluated according to disease areas, but the main message remains valid.

Infectious diseases and pandemics

With more than 10 million cases and around 1.5 million deaths globally, TB causes the largest single-agent burden of disease and is the 13th most common cause of death overall. Deaths from diarrhoeal diseases, particularly among children, are even more common (1.53 million annually).

As demonstrated by numerous recent epidemics, including the recent COVID-19 pandemic, the world remains vulnerable to pathogens with pandemic potential. The new WHO Hub for Pandemic and Epidemic Intelligence is an example of new infrastructure that is being developed to mitigate future pandemic risk.

Maternal and child health

Maternal health

Although maternal mortality dropped by about 44% between 1990 and 2015, approximately 800 females die from preventable causes related to pregnancy and childbirth every day, 95% of these in LMICs.

Of major concern, 287 000 females died in childbirth in 2020, 95% in LMIC and most of these deaths were avoidable (WHO). The risk of maternal mortality is highest in adolescent girls under 15 years old. The major medical causes of death are haemorrhage, hypertensive disease of pregnancy, and infections. Hypertensive disease can be complicated by pre-eclampsia (see Chapter 48). Infections can be caused, for example, by bacteria, HIV, malaria, and syphilis. Female genital mutilation (FGM), illegal in most countries, may also lead to

Fig. 10.1 **The 17 Sustainable Development Goals.**

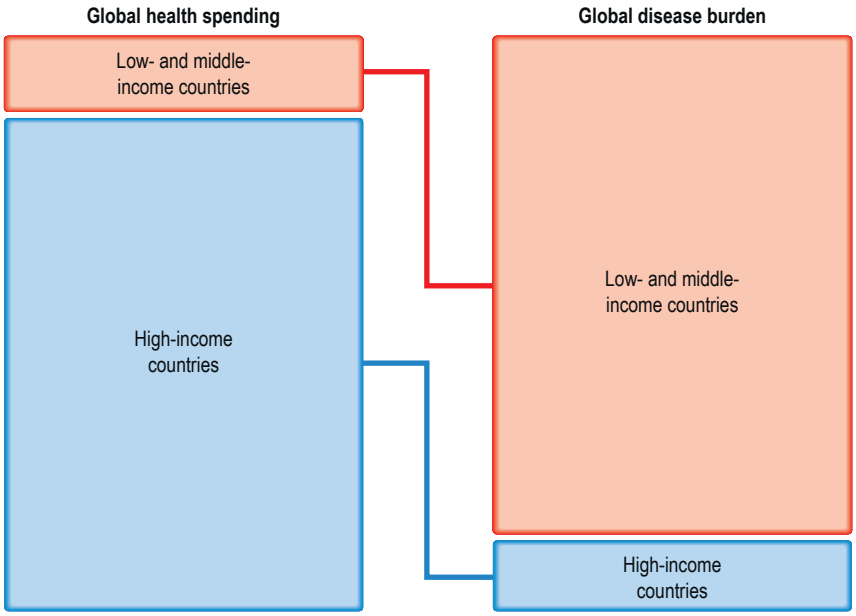

Fig. 10.2 Mismatch between health spending and resources. (*From Gottet P, Schieber G.* Health Financing Revisited: A Practitioner's Guide. *Washington: World Bank; 2006.*)

obstructed labour, with potentially fatal consequences. As most maternal and neonatal deaths occur around the time of delivery, the need for basic and emergency care before and during labour and delivery is paramount. The presence of a skilled birth attendant has been shown to reduce both maternal and neonatal mortality in LMICs. Sadly, this service is unavailable to approximately half of the pregnancies that are unplanned or unwanted, especially in adolescents.

Child health

Globally, the under-5 years mortality rate, especially in sub-Saharan Africa and Central and South-east Asia, has decreased (from 93 to 38 per 1000 live births between 1990 and 2021, UNICEF) mainly due to the prevention of pneumonia, diarrhoea, and malaria. Most of these deaths could have been prevented by access to simple and affordable interventions, including safe drinking water and vaccinations. About 45% are linked to malnutrition.

Children die from common, otherwise non-fatal, childhood ailments. Mortality figures in children under 5 have also dropped from 12.8 million in 1990 to 5 million in 2021 (WHO). Priority actions to mitigate this, advocated by the WHO, include the availability and accessibility of high-quality care in the ante-, peri-, and postnatal periods.

Vaccination

The World Health Assembly produced a framework to prevent millions of deaths by more equitable access to vaccines and developed a 'Decade of Vaccines Global Vaccine Action Plan 2011–2020'. GAVI (Global Alliance for Vaccines and Immunisation) plays a critical role in this area by financing and facilitating the delivery of vaccine platforms. By 2019, 86% of children had received the DPT vaccine (WHO) but immunization coverage decreased to 81% following the COVID-19 pandemic.

Child labour

The global number of children engaged in child labour declined by 38% between 2012 and 2017 (246 million to 152 million). Forty-eight percent of these children (73 million) were engaged in hazardous work, mainly in agriculture. More recently, the number of children in child labour has risen to 160 million (2021). Of these, approximately 9 million were forced into child labour by the COVID-19 pandemic (ILO).

Mental health

Mental health conditions or substance misuse disorders are estimated to cause the loss of 418 million DALYs globally (16% of global DALYs) and are on the increase. They are a leading cause of long-term disability (WHO).

Depression and anxiety disorders remain major clinical challenges. Approximately 5% of the adult population experience depression worldwide. Suicide is a very common cause of death among those aged 15 to 29 years (700 000 deaths annually). Over three-quarters of these deaths occur in LMICs.

The most important risk factor for suicide is a previous attempt, and unsuccessful suicide attempts are 15 to 20 times that of actual suicides. This offers the opportunity to implement effective mental health interventions. The COVID-19 pandemic has added to the external stressors, including conflict, forced migration, and poverty, which have resulted in increased anxiety, depression, and suicide. Children and adolescents have been disproportionately affected.

The global incidence of dementia is rising, and 53 million people live with this condition (2023). About two-thirds of patients live in LMICs. This creates a substantial social and financial burden. It is therefore an important cause of disability and death as well as a WHO-recognised public health priority.

Surgical challenges

Accidents

Approximately 4.4 million people die each year as a result of accidents and violence; 1.3 million result from road traffic accidents, almost all of these (93%) occurring in LMICs (WHO). In children and young adults (aged 5–29 years), road traffic accidents, homicide,

Box 10.1 International guidelines for essential trauma care ('rights of the injured')

- Obstructed airways cleared and maintained
- Impaired breathing supported until the injured person is self-ventilating
- Pneumothorax and haemothorax promptly relieved
- Bleeding stopped promptly
- Shock recognized and treated with intravenous fluid replacement
- Traumatic brain injury treated with timely decompression of space-occupying lesions
- Intestinal and other abdominal injuries promptly addressed
- Disabling extremity injuries corrected
- Unstable spinal cord injuries managed appropriately with early immobilization
- Appropriate rehabilitative services available
- Medications for the above and for pain control readily available

(Adapted from Mock C, Joshipura M, Goosen J et al. Overview of the Essential Trauma Care Project. World J Surg *2006; 30:919–929.)*

and suicide are among the most common causes of death. The WHO estimates that, by 2030, trauma from road traffic accidents will be the third most common cause worldwide of both mortality and disability (measured in DALYs).

Trauma

The Guidelines for Essential Trauma Care (WHO 2004) established a core list of 11 essential trauma services (**Box 10.1**). Implementation of these recommendations has been hampered by deficiencies in planning and infrastructure. These need to be addressed by national governments. Recent (2018) evaluation of these guidelines suggests that they remain appropriate recommendations for trauma system development.

Surgery

Around 5 billion people lack access to safe and affordable surgical and anaesthesic care when needed, especially in LMICs. Many conditions need swift surgical intervention. Less than 80% of the population in many countries can access 'bellwether procedures' (Caesarean section, laparotomy, treatment of open fracture) within 2 hours. The Lancet Commission on Global Surgery estimated that 16.5 million deaths from surgically treatable conditions occurred in 2010.

Oral disease

Oral pathology affects 45% of the world's population (3.5 billion people). From 1990 to 2023, case numbers have been increasing and now exceed, by over 1 billion, the combined numbers of the five major NCDs (Global Oral Health Status Report 2023). The remit of oral health has now been incorporated into the aspirations for universal health coverage by 2030.

Box 10.2 The nine main targets of the Sustainable Development Goal for Health (Goal 3)

1. By 2030, reduce global maternal mortality ratio to less than 70 per 100 000 live births.
2. End preventable deaths of newborns and children under 5 years of age.
3. End the epidemics of AIDS, TB, malaria, and neglected tropical diseases.
4. Reduce premature mortality from non-communicable diseases by one-third while promoting mental health and wellbeing.
5. Strengthen the prevention and treatment of substance abuse.
6. Ensure universal access to sexual and reproductive healthcare.
7. Substantially reduce the number of deaths and illnesses from hazardous chemicals and air, water, soil pollution and contamination.
8. By 2020, halve the number of deaths and injuries from road traffic accidents.
9. Achieve universal health coverage including access to essential medicines and vaccines.

SOCIAL DETERMINANTS OF HEALTH

The drivers of health inequities reside in the social, economic, and political environments (see Chapter 9). The WHO defines the social determinants of health as 'the conditions in which people are born, grow, work, live and age'.

The health and illness of populations is significantly determined by individual, hereditary, and lifestyle risk factors. These are shaped by the distribution of money, power, and resources at global, national, and local levels. The social gradient of health follows the socioeconomic pattern from the top to the bottom: the lower the individual is within their socioeconomic position, the worse their health. This is seen in HICs, as well as in LMICs. The socioeconomic status of a person is their social position in society, as determined by their education, income, and occupation. There is now clear evidence to justify national policies that aim to reduce health inequity and the health divide across all countries. The reduction in health inequities should become one of the main criteria used to assess the effectiveness of health systems and governments.

Poverty and food security

Maslow's hierarchy of human needs offers an approach to human development in which growth in higher personal domains (such as self-actualisation) is dependent on more basic needs being met, starting with the physiological: clean air, water, food, protection from cold, and shelter. Poverty and food security therefore have a direct and indirect bearing on human health. Extreme poverty (defined as <US$ 1.90 per day) decreased from 33% in 1990 to 10% of the world population in 2015 (including 385 million children). Efforts continue to reduce this incidence to less than 3% by 2030. The SDGs (SDGs 1, 2, 3, 12, 13, and 15; see **Fig. 10.1**) relate to this ambition. The nine key priorities relating to SDG 3 ('Good health and wellbeing') have a broad scope (**Box 10.2**).

Poverty, defined as living on less than US$ 5.50 per day, was seen in nearly half of the world population in 2018. This is increasing in sub-Saharan Africa and in conflict-affected states. Chronic illness and disease as well as associated healthcare expenditure can contribute significantly to poverty and extreme poverty. In 2019, over one billion people suffered catastrophic health spending (where health spending exceeded 10% of the total household budget, SDG 3.8.2).

Improving child nutrition remains a global imperative, as nearly half of the deaths in children under 5 years of age are attributable

to malnutrition. In this age group, according to data from UNICEF (2022), stunting affects 148 million children. This problem can be mitigated by appropriate interventions during pregnancy and increased access to food before the age of 2 years.

Poverty and food security illustrate the interdependence between global and planetary health. Globally, one-third of all food produced, equivalent to 1.3 billion tonnes, is wasted each year (WHO). Crop deterioration due to deficiencies in transport and storage is estimated to account for 25% of food wastage in LMICs. Food production is compromised when agricultural land is directed towards alternative priorities, such as industrial development. Conversely, unsustainable land exploitation for crop production can aggravate food security in the long term.

Education

Education has a major impact on the health of a nation. The more years that are spent in schooling, the better the health outcomes. 'Health literacy' describes an individual's ability to read and understand basic information to allow them to make decisions about their healthcare. It requires basic literacy and numeracy skills and can have a major impact on nutrition and the control of disease, for example, by encouraging the simple process of hand washing. Education helps to promote healthier lifestyles, both by improving nutrition and development and by reducing the risks associated with infectious diseases. As a result, unemployment falls while family and community wellbeing is improved.

Females have a crucial role in the welfare of their families and the development of a nation's good health by looking after the household and caring for the children, elderly, and sick.

Nearly one-third of females in LMIC begin childbearing in adolescence (≤19 years old). Forty percent of girls with a first birth at 14 years of age or younger will have a third birth before the age of 20. (UNFPA). These pregnancies have a high rate of deaths from complications of pregnancy and childbirth (see Chapter 48). Data on maternal and child mortality provide a strong argument for females to control all aspects of their own reproductive health. The cost to a country's economy of adolescent pregnancy, as a share of gross domestic product (GDP), can be as high as 30%. The education and welfare of females should be major issues in any society.

Water and sanitation

Poor water and sanitation are major causes of early mortality, particularly in children. Access to water and sanitation is a UN-recognised human right (SDG 6.1). Only 74% of the global population have access to 'safely managed drinking water services' and only 54% use 'safely managed sanitation services' (UNESCO, 2023). Almost 500 million persons collect their water from unprotected sources, including wells and ponds, rivers or streams (WHO). Where water is not directly available, it is usually collected by females, often from distant sources. This is a hazardous activity, as the females may be subject to physical attack.

A secondary effect of improved access to water is that the time saved in collecting water can be spent on income generation, food production, education, and activities that lead to social and health benefits.

Environmental degradation and pollution

In the context of conflict, the United Nations International Strategy for Disaster Reduction (UNISDR) defines environmental degradation as 'the reduction of the capacity of the environment to meet social and ecological objectives and needs'.

Environmental degradation leads to the deterioration of the quality of both biological and physical resources, such as air, water, and soil. This, together with the increase in human population, has resulted in the destruction of ecosystems and habitats, and approximately 68% falls in vertebrate wildlife populations over the last 5 decades. Fish stocks have been reduced by overfishing. Massive deforestation, for agricultural purposes, has led to the loss of carbon absorptive capacity, and the effects of climate change have contributed to forest fires and air pollution. Melting oceanic glaciers have caused a rise in sea level and widespread floods. All of these have affected vital ecosystems, for example, pollinators, pests, and soil organisms, which are all essential for food production and agriculture.

Fresh water scarcity, particularly in LMICs, is a serious problem. One in three of the world population face water shortages. This is aggravated by pollution through the use of domestic and industrial sewage, fertilizers, pesticides, and chemicals.

International agreements, for example, the yearly Conference of the Parties (COP) meetings, develop approaches to environmental protection and resource management including those on deforestation, climate temperature, and preservation of cleaner air and water. Despite advances in environmental technologies (e.g., carbon capture, wind farms), political progress has been slow in agreeing and meeting targets.

Climate change

Climate change poses major threats to human health either directly (heatwaves, floods, fires, droughts) or indirectly (agricultural losses, mass migration); for example, a 1°C rise in mean temperature in India would result in the loss of 7 million tons of wheat (Fig. 10.3). The annual United Nations Climate Change Conference (COP) reviews progress in addressing climate change. The 2015 Paris accord (COP 21), ratified by 195 parties, agreed to target a reduction in global temperature rise to below 2°C by 2100. The 2022 report of the Intergovernmental Panel on Climate Change (IPCC) emphasized the urgent need to further reduce global warming and limiting climate change to a 2°C rise in global temperatures (Fig. 10.4).

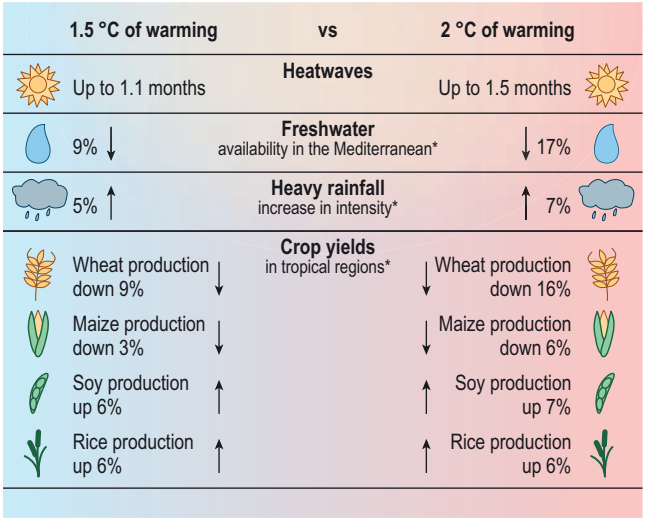

Fig. 10.3 The effects of global warming. *(All data from Schleussner CF, Tabea K, Lissner EM et al. Differential climate impacts for policy-relevant limits to global warming: the case of 1.5°C and 2°C.* Earth Syst Dynam *2016; 7:327–351.)*

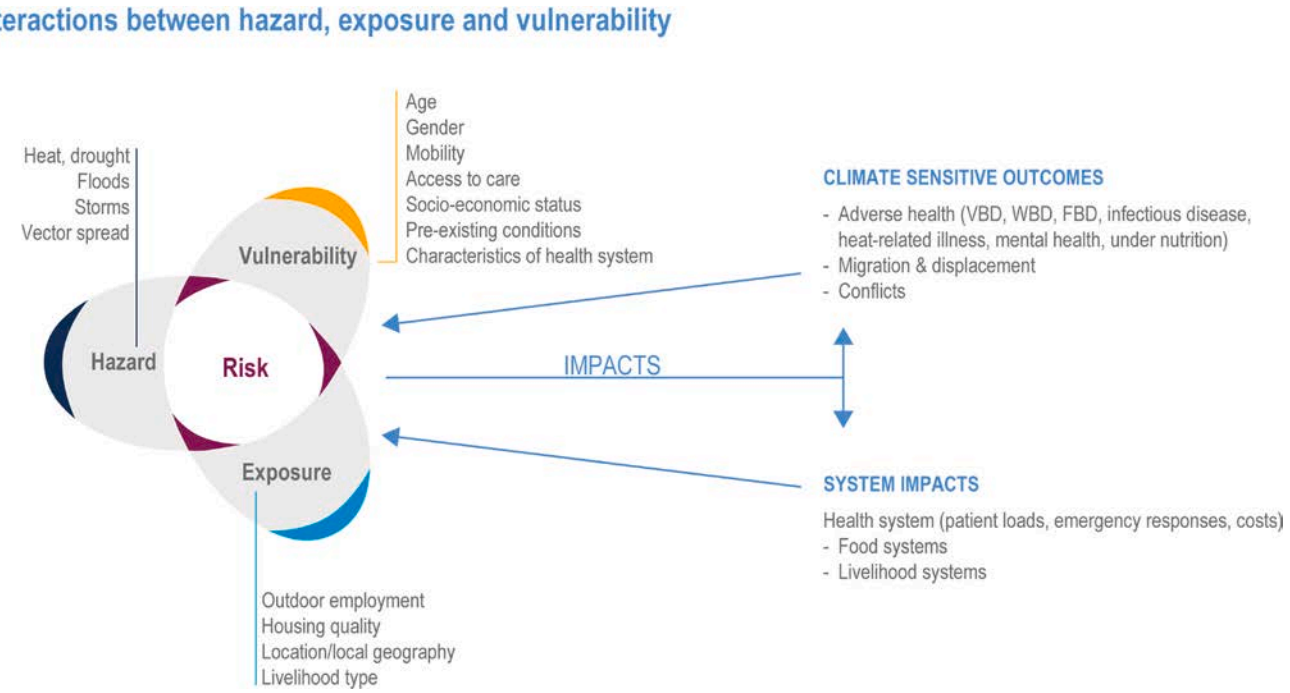

Fig. 10.4 Interactions between hazard, exposure, and vulnerability that generate impacts on health systems and outcomes, with selected examples. *FBD*, Food-borne disease; *VBD*, vector-borne disease; *WBD*, water-borne disease.

Human migration

Migration, a well-recognised social determinant of health, has been a key global phenomenon throughout human history. It continues to serve as important survival mechanism, in response to adverse environmental, economic, or social factors. Migration is likely to increase with climate change and the impact of local challenges (e.g., food shortages).

An estimated 281 million persons lived outside their country of origin in 2020. With global population growth, the number of migrants has increased significantly over the last decades (IOM). Individuals experiencing forced migration (refugees and asylum seekers) have significantly increased to 108 million (UNHCR, 2022). The health needs of migrants are dependent on their route of migration, legal status and access to services in the country of arrival, and wider socioeconomic, cultural, and linguistic factors. In many countries, migrants' health needs are not adequately met.

CONFLICT AND CATASTROPHE

Recent years have seen a number of natural disasters. Examples include earthquakes in Nepal (2015) and Indonesia (2018), hurricanes in the Caribbean (2019), flooding in Pakistan (2022), and forest fires worldwide. Conflicts persist in Ukraine, the Middle East, Ethiopia, and numerous other parts of the world. Effective global action following these unexpected events is frequently compromised by deficiencies in the disaster response. These deficiencies can be mitigated with appropriate training and long-term structural planning.

Conflicts and catastrophes severely disrupt healthcare provision, especially for females and children. The use of rape as a weapon of war magnifies this tragedy. Disruption to education and the physical and psychological sequelae of conflict lead to long-term societal healthcare burdens, especially in mental health.

GLOBAL AND PLANETARY HEALTH GOVERNANCE

Organizations

International support for GH initiatives may be directed at disease-specific projects (vertical care models) or aligned to national health system development. A number of organizations (**Box 10.3**) address the key areas for health development and infrastructural support, including the response to emergency situations (war and natural disasters).

These areas encompass service delivery, patient care, education and training, research, equipment, medicines, and human resources. Investment in healthcare systems promotes public health benefits by the provision of vaccination, hygiene, and sanitation, as well as major infrastructural projects.

The WHO is a specialized agency of the United Nations with a remit for international public health. Its constitution enshrines 'the highest attainable standard of health' as a fundamental right

Box 10.3 Some organizations involved in global aid

International organizations
- World Health Organization (WHO)
- Global Fund to fight AIDS, TB and Malaria
- Joint United Nations Programme on HIV/AIDS (UNAIDS)
- World Bank
- Department for International Development (DFID; UK)
- President's Emergency Plan for AIDS Relief (PEPFAR; USA)
- Global Alliance for Vaccines and Immunization (GAVI)

Scientific and educational organizations
- Mainly disease specific, e.g., microbiology, diabetes, infectious diseases
- Consortium of Universities for Global Health (CUGH)
- Global Health through Education, Training and Service (GHETS)

Advocacy and policy organizations
- Centre for Strategic and International Studies (CSIS)
- Global Health Policy Centre
- Global Alliance for Chronic Diseases (GACD)
- Global Health Council
- Global Health Technologies Coalition (GHTC)
- The Earth Institute (Columbia University)
- Kaiser Family Foundation (KFF)
- US Global Health Policy
- Tropical Health and Education Trust (THET)

Foundations
- Bill and Melinda Gates Foundation
- Wellcome Trust
- UN Foundation (UNF)
- Accordia Global Health Foundation

Other non-governmental organizations
- Save the Children
- United Nations International Children's Emergency Fund (UNICEF)
- Red Cross
- Oxfam
- International Rescue Committee (IRC)
- Médecins Sans Frontières (MSF)

of every human being. It has occasionally adopted legally binding health regulations, using its member state representatives through the World Health Assembly. An example is the Framework Convention on Tobacco Control (2003), ratified by 177 countries. This created binding norms for the demand and supply of tobacco products.

Sustainable Development Goals

The 17 SDGs (**Fig. 10.1**) emphasize the fact that achievement of the good health and wellbeing goal (SDG 3) is inextricably linked to other major factors including politics, economics, and agriculture. The right to health contains four elements: *availability* (of programmes of public health), *accessibility* (of health facilities and services in a non-discriminatory fashion), *acceptability* (ethical and cultural requirements), and *good-quality care*.

Economics and politics in global and planetary health

Funding for initiatives in the GH development of LMIC (also known as Development Assistance for Health, DAH) has, historically, originated from multiple sources. DAH has supported interventions in specific diseases such as malaria (see Chapter 42), TB (Chapter 42), and HIV/AIDS (Chapter 44). In contrast, an ongoing funding gap may have contributed to the slow response of the WHO and others to the 2014 outbreak of Ebola virus in Africa. Transnational collaboration is especially necessary in the face of pandemic threats.

Improvements in healthcare commonly result in economic growth. For example, a 10% reduction of malaria in endemic areas is associated with a 0.3% increase in GDP. Treatment of HIV-positive patients with anti-retroviral drugs results in net economic benefits through increased productivity and a reduction in the costs of medical care. The cumulative loss of economic productivity between 2015 and 2030, in the absence of a significant scaling up of global surgical services, is estimated at US$ 12.3 trillion. Any failure to invest in health and health systems is a threat to future global prosperity, particularly in poorer countries.

Political decisions regarding investment in healthcare and health systems must also focus on infrastructure, including food and agriculture, the environment and human rights issues, especially the rights of females. The pursuit of 'pro-poor' policies that place the poor at the centre of development policy promotes global prosperity.

Human rights and the value of engagement in global health

The Universal Declaration of Human Rights (1948), while not legally binding, serves as a 'common standard for all peoples and all nations'. It has given rise to two new legally binding covenants: the International Covenant on Civil and Political Rights and the International Covenant on Economic, Social and Cultural Rights. Additionally, the rights of children and females and the Right to Health are enshrined in global human rights legislation. This international body of law with its declarations and conventions is regularly consulted to protect individuals and populations.

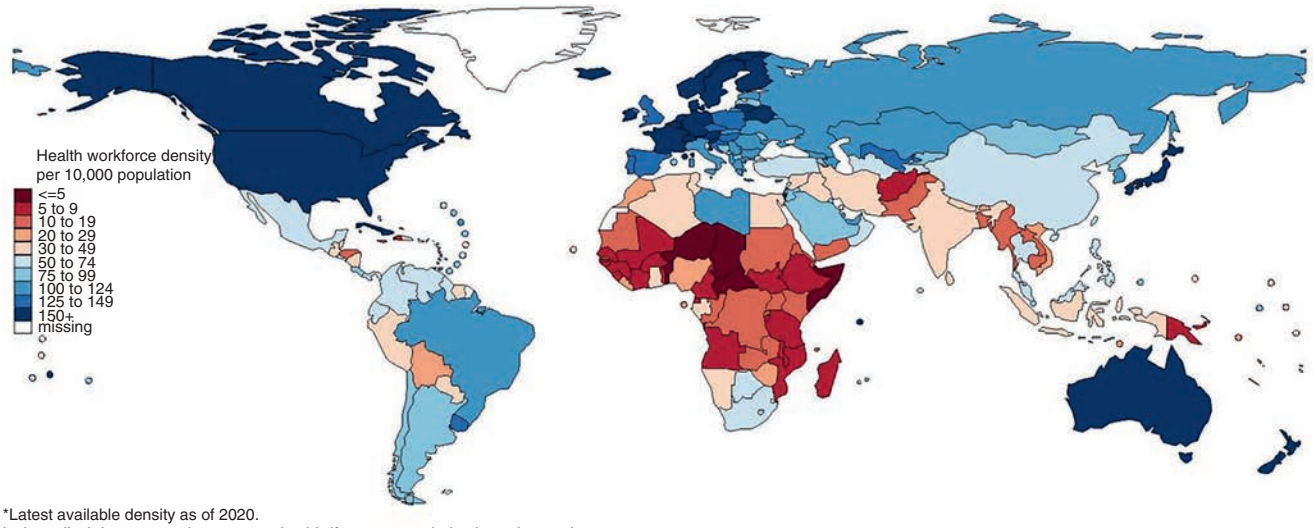
The healthcare workforce and international recruitment ethics

There is a worldwide shortage and highly unequal global distribution of healthcare workers from all disciplines (**Fig. 10.5**). Current estimates suggest that an additional 10 million healthcare workers will be required by 2030 to meet global demand. This shortage has been accentuated, to the disadvantage of LMIC, when healthcare workers migrate to wealthier countries for economic reasons. The WHO Global Code of Practice (2010) provides a framework for best practice and monitoring of global healthcare worker recruitment.

Medical electives

Engagement in GH challenges helps to promote patterns of behaviour that benefit healthcare workers and their recipients. These behaviours include altruism, team-working, and appreciation of cultural diversity.

Many medical students and doctors undertake periods of time visiting and working in unfamiliar environments, whether in their home country or abroad. This is mutually beneficial to all participants, provided that a culture of shared learning is embraced. All such visits, commonly termed 'medical electives', should have clear objectives and measurable educational outcomes. They should



*Latest available density as of 2020.
incl. medical doctors, nursing personnel, midwifery personnel, dentists, pharmacists

Fig. 10.5 Worldwide shortage of healthcare workers. There are 57 countries with a critical shortage of 2.4 million health service providers (doctors, nurses, and midwives). Africa has 25% of the world's healthcare burden and 1.3% of the providers. (*From Bonoi M, Kunjumen T, Nair TS et al. Fig. 2. The global workforce stock and distribution in 2020 and 2030: a threat to equity and 'universal' health coverage?* BMJ Global Health *2022;7:e009316. not compromise the working arrangements for host organizations. Pre-departure preparation should include consideration of culture, ethical challenges, and security issues. All visitors must work within their approved competencies, be appropriately supervised, and comply with national guidance on good medical practice. Maximum benefit from medical electives is achieved when there is a mutual commitment to long-term partnership.

CORE SKILLS AND KNOWLEDGE

Acute internal medicine (AIM) is a relatively new hospital specialty but has grown rapidly to become the fulcrum of acute medical care within the modern hospital. The evolution of AIM has ushered in numerous paradigm shifts in models of acute care, with increasing emphasis on ambulatory and same-day emergency care, patient-centred solutions such as 'hospital at home', joined-up working with allied health professionals and across the primary and secondary care interface, and effective patient flow both within the hospital and to/from the community.

Acute physicians are the hospital's 'specialist generalists'. Key skills in AIM include:

- Understanding the hospital pathways and infrastructure needed to help navigate each patient smoothly and effectively through their healthcare journey
- Acquiring a broad range of clinical procedure skills required in the investigation and treatment of medical emergencies
- Mastering the focused 'problem-based', symptom-driven patient assessments required to assign a working diagnosis, decide the appropriate location of ongoing care, and determine initial management
- Managing a broad range of medical emergencies which span the entire spectrum of subspecialty medicine.

Opportunities for learning include shadowing the acute medicine 'on-call' team and taking the opportunity to 'clerk' patients with a broad range of presenting symptoms, following ward rounds and joining multidisciplinary team meetings on the acute medical unit and, where possible, undertaking 'simulation training' to allow exposure to a range of clinical scenarios and procedures in a safe, controlled and supported learning environment.

BACKGROUND

Acute internal medicine (AIM) is a relatively new specialty that has grown out of general internal medicine (GIM), with a recognition that the acute care of medically unwell patients, and the interface with primary care, is a specialty in its own right that needs dedicated resources and a bespoke training programme. Wards such as the acute medical unit (AMU) were established, with specialist AIM in-reach into the emergency department (ED), and outreach to medical, specialty, and surgical wards.

AIM has been evolving since its inception three decades ago, and is rapidly growing in the UK, as well as in those nations that model their medical system on the National Health Service. The 'hospitalist' movement has emerged in parallel in the USA with a similar focus on acute inpatient medical care. One major difference is that hospitalists often look after patients for their whole inpatient

stay, whereas in AIM, the tendency is to diagnose and safely discharge in a timely fashion, or, when appropriate, refer to longer stay specialties, including GIM.

The AIM model revolves around intensive senior clinician-led care, often including twice daily review, improving efficiency and reducing length of stay for medical admissions. Additional roles have been absorbed into the specialty including ambulatory care, same day emergency care (SDEC), acute frailty hubs, virtual wards, and 'hospital at home' services, with AIM physicians often working closely with other specialties such as geriatric medicine. Increasingly, enhanced care units (ECUs), with higher ratios of nursing care, monitored beds, and the ability to provide advanced therapies including respiratory or basic inotropic support, may be co-located on the AMU. As such, AIM finds itself at a key intersection between primary care, EDs, critical care, and specialty services including surgery (**Fig. 11.1**).

AIM encompasses a large portion of the medical curriculum, and the AMU has become a valuable area for teaching and learning for both students and professionals from across the interprofessional team. The acute medical service is where the initial contact with patients often occurs, affording the opportunity to formulate *de novo* differential diagnoses and management plans, hone diagnostic skills, and improve clinical acumen, and as such it is a popular placement for a range of healthcare students.

PATIENT FLOW THROUGH AIM

The AMU can be viewed as a 'header tank' that fills from primary care or ED, and then empties out through discharge pathways or transfers to other specialized wards including intensive therapy units (ITUs, see Chapter 13). Smaller 'header tanks' can be interconnected with the AMU, including SDEC (which is often co-located), virtual wards, or 'hospital at home'. Given the variety of patient presentations to AIM, medical specialty team in-reach or co-location with cardiology (Chapter 17), geriatric medicine (especially with frailty services, Chapter 49), stroke medicine (Chapter 29), and

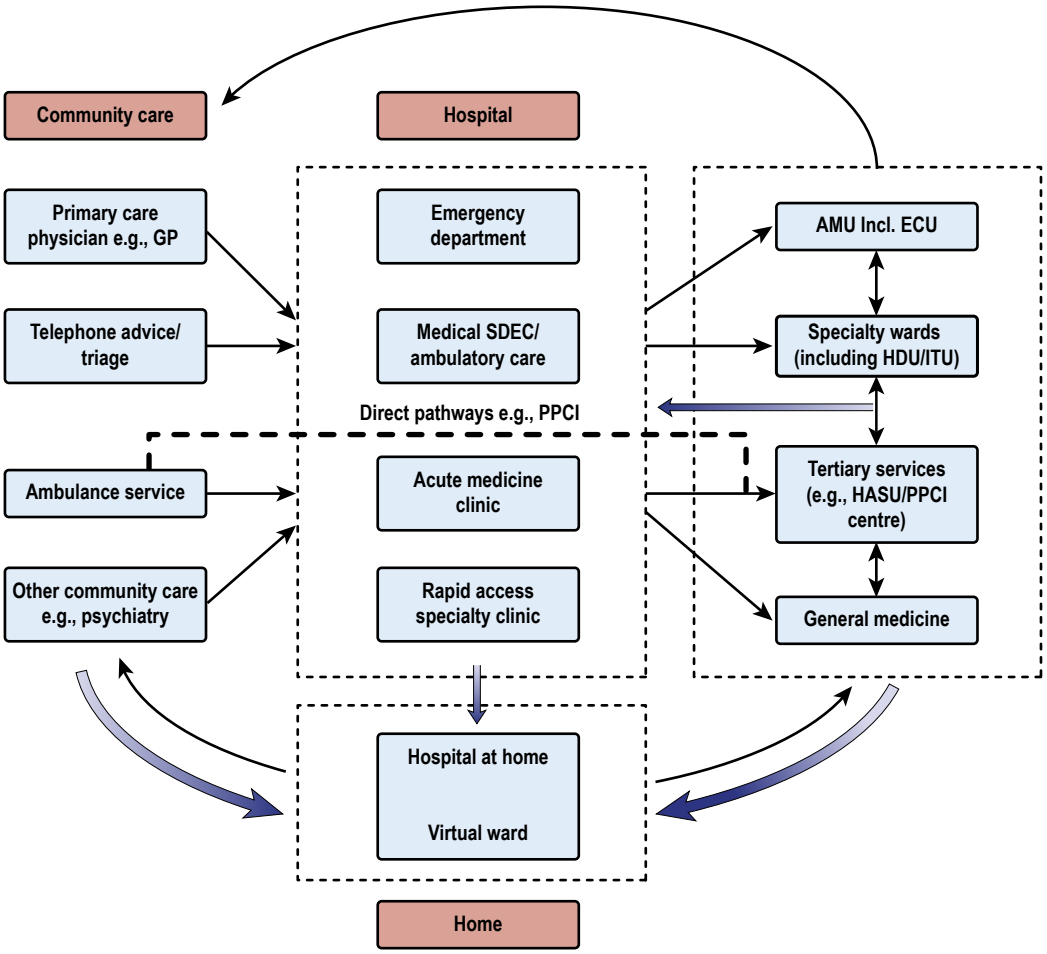

Fig. 11.1 Model of acute medical care. Patients enter acute care systems via a number of community routes, including GP consultation or direct contact with the ambulance service. The venue of acute medical assessment may be determined by triage (e.g., by discussion with an acute physician) or defined emergency care pathways (e.g., direct ambulance transfer to a Primary PCI centre for a patient with STEMI). Subsequent patient flow may be to a hospital ward (e.g., AMU or specialty ward), domiciliary treatment (e.g., 'hospital at home'), or back to community care, depending on the predicted care needs, individual circumstances of the patient and local resources. The most efficient contemporary models leverage close collaboration between primary and secondary care clinicians and allied health professionals and utilize bidirectional flow between the different silos of care. *HASU,* Hyperacute stroke unit; *PPCI,* primary percutaneous intervention.

respiratory medicine (Chapter 20) is common. By its nature, there needs to be sufficient capacity throughout the system to ensure that patient flow does not 'stagnate' and the AMU can continue to fill appropriately. Prioritization of investigations including blood taking and dedicated imaging, is important to ensure that flow is maintained. Ready availability of advice and specialty management pathways from other medical specialties (e.g., liaison psychiatry (Chapter 30)) is also critical to a successful AMU.

AMUs provide care for patients who are acutely unwell, therefore, their beds can have differing levels of staffing and observation or monitoring. Acute medical teams often help decide where patients are best placed depending on their needs and the resources available (**Box 11.1**). Infection control measures and patient and staff safety are always important in these decisions. Access to higher-level care is also important—AMUs work closely with teams in high-dependency units, ITU, and coronary care units and often collaborate in running ECUs embedded within the AMU. Each AMU is planned in response to the hospital's unique layout, staffing, resources available, and local needs; therefore, the physical configuration and clinical operation may vary greatly.

In the UK, The Royal College of Physicians (RCP) advises centralizing the care of patients either in their first 48 hours in hospital, or requiring more enhanced or higher dependency therapy. This should ideally occur within a shared hospital footprint of acute medical services comprising the 'acute care hub':

- ED
- SDEC and ambulatory care
- AMU (indicative length of stay up to 48 h)
- Short-stay beds (indicative length of stay up to 72 h)
- ITU.

Increasingly, AIM provides outreach to specialty wards, surgical liaison, and in-reach to ED to enhance patient-centred, focused care and break down the boundaries between 'silos' of care created by more traditional models of hospital operation.

Patient-centred care and admission avoidance

In recent years, there has been a global push to increase sustainability and alleviate the strain on acute healthcare systems generated by changing population demographics and increased demand on emergency care. Ambulatory care, SDEC, 'zero day admission conversions', and virtual wards/'hospital at home' models have emerged as credible alternatives to traditional inpatient medical care.

Box 11.1 Different levels of adult critical care

Level 0: Those patients whose needs can be addressed on a standard acute hospital ward with normal staffing.

Level 1: Those patients that are deemed to have the potential to deteriorate, so areas may have enhanced staffing ratios e.g., AMU. (Sometimes this may be labelled 'Level 1 plus' if it has bedside monitoring, and input from appropriate specialists including critical care outreach e.g., an ECU).

Level 2: Those patients, often with single organ failure, requiring a higher ratio of care, often one nurse to two patients (e.g., ECU or HDU/ITU).

Level 3: Those patients often with more than one organ failing, often requiring one-to-one nursing (e.g., ITU).

Ambulatory care and SDEC

Ambulatory care, often manifested as SDEC, enables selected urgent care scenarios that do not require significant time in a hospital bed to be made semi-elective, with dedicated clinic slots. Patients are able to return home in between attending an ambulatory service for daily or as-needed monitoring, investigations, or treatments, examples of which may include administration of intravenous antibiotics or fluids or subcutaneous injections such as low-molecular-weight heparin. The healthcare team assesses patients and those who clinically deteriorate may be admitted to hospital, while those who improve are discharged to their regular healthcare provider for follow-up.

Ambulatory/SDEC models have been shown to be cost-effective in high-income countries, reducing the burden on medical wards without compromising patient outcomes, while simultaneously improving the patient experience.

Virtual wards and 'hospital at home'

These models extend the care continuum beyond the physical boundaries of the hospital, allowing patients to receive treatment and monitoring traditionally associated with a hospital admission, in their own homes.

Virtual wards

Virtual wards operate through a combination of telemedicine, remote monitoring technology, and digital communication platforms. Healthcare professionals, including doctors and nurses, remotely monitor a patient's incoming data looking for signs of deterioration or changes that may require intervention. Based on the data and the patient's specific care plan, doctors provide medical advice, prescribe medication, and offer guidance on self-care techniques. During the COVID-19 pandemic, virtual wards proved valuable, playing a role in reducing the burden on hospitals and healthcare facilities. This prevented unnecessary hospital admissions, allowing hospitals to focus their resources on severe cases and emergencies. This system of care also minimized the risk of COVID-19 transmission to healthcare workers and patients. Other conditions potentially lending themselves to virtual ward management after careful patient triage include other acute respiratory infections, heart failure, acute kidney injury (AKI), and atrial fibrillation.

Digital communication platforms, such as video consultations or messaging applications, facilitate direct communication between patients and healthcare providers. A home visit, or patient visit to an SDEC facility can also be arranged for physical review if required during this period.

'Hospital at home'

'Hospital at home' provides an alternative to traditional inpatient care, allowing patients to receive hospital-style medical treatment and monitoring in their own homes by leveraging a combination of telemedicine, remote monitoring technologies, and skilled healthcare professionals. Patients are carefully selected based on specific criteria that ensure their safety and suitability. Patients then receive regular visits from a multidisciplinary team (MDT) of healthcare workers, which may include physicians, nurses, therapists, and other specialists/community teams, depending on the individual patient's needs. During these visits, necessary medical interventions are carried out, for example, administering treatments such as intravenous antibiotics, fluids, nebulizers or oxygen, conducting examinations, or adjusting medications.

Receiving care at home can reduce the stress and disruption associated with hospitalization. This is particularly helpful for frail elderly patients as it allows them to recover in a familiar environment and reduces incidence of delirium, hospital-acquired infections, and deconditioning associated with traditional hospital stays. The flexibility and convenience of home care can contribute to improved patient satisfaction and overall wellbeing.

Multidisciplinary care model and approaches to effective patient flow

In the fast-paced and complex environment of acute healthcare, effective patient flow and MDT working are crucial elements in ensuring high-quality care and optimal patient outcomes.

The multidisciplinary care model

The multidisciplinary care model involves a collaborative approach to patient care, where healthcare professionals from various disciplines work together to provide comprehensive and coordinated treatment. This team-based approach ensures that patients receive holistic care that addresses their medical, psychological, and social needs. It encompasses the participation of doctors, nurses, pharmacists, therapists, social workers, and other allied health professionals. By pooling their expertise and perspectives, the MDT can develop tailored care plans, improve patient outcomes, and enhance the overall patient experience.

Approaches to effective patient flow

Care pathways and standardized protocols

Implementing care pathways and standardized protocols helps to streamline patient flow by providing a structured and consistent approach to care. These pathways outline the optimal sequence of assessments, investigations, and interventions for specific patient conditions, promoting efficient and timely care delivery. Standardized protocols ensure that healthcare professionals follow evidence-based guidelines, reducing unnecessary variations in practice and enhancing patient safety.

Early senior review and decision-making

Early senior review and decision-making expedites formulation of definitive treatment plans, facilitates appropriate referrals, and enables early decisions to admit or discharge patients and thus optimize patient flow. This approach reduces delays and prevents bottlenecks in the care pathway.

Daily MDT meetings

Regular MDT meetings are effective for coordination and communication among healthcare professionals. These meetings provide a platform for sharing information, discussing complex cases, and aligning treatment plans. By collectively reviewing patient progress, identifying barriers to discharge, setting expected dates for discharge, and coordinating resources, the team can address any issues promptly.

Discharge planning and early allied health professional involvement

Discharge planning should commence **concurrently with admission** to the hospital. Early involvement of allied health professionals, such as physiotherapists, occupational therapists, and social workers, can help with assessment of patients' functional status, identify any potential discharge barriers, and develop appropriate and timely discharge plans.

Bed management and capacity planning

Efficient bed management and capacity planning help optimize patient flow in the acute setting. This involves monitoring and predicting bed availability, coordinating transfers, and ensuring appropriate allocation of resources. Transfer of patients to the 'right bed' with the 'right specialty' ensures the best care of patients from specialist teams and nurses. Proactively managing bed capacity and collaborating with the MDT can reduce delays, improve patient flow, and minimize long hospital stays.

In-reach to ED: enhancing acute patient care

In-reach programs facilitate rapid assessment and early intervention for patients with acute medical conditions. Direct involvement of specialists such as physicians, intensivists, and surgeons in patient care within the ED reduces delays in diagnosis and treatment, improves patient outcomes, and brings the timely expertise of different specialties directly to the patient's bedside. In-reach initiatives also ensure a smooth transition of patients from ED to specialized wards within the hospital and result in better handover to specialist teams and improved coordination of care. In-reach also helps in the **early identification of high-risk patients** who require immediate intervention or higher-intensity care such as ITU. AIM clinicians are trained to recognize deteriorating patients promptly and provide appropriate management.

THE ROLE OF THE AIM CLINICIAN

AIM physicians enjoy the diversity and breadth of medicine incorporated within the specialty: varied medical pathophysiology; diagnostic challenges; impactful quality improvement work; high-quality teaching and training in an enriched learning environment; caring for critically ill patients; working under pressure and using advanced communication skills; all while constantly being invigorated by new clinical, ethical, and academic challenges.

AIM physicians are 'specialist generalists' who thrive on multidisciplinary working in a busy, multidisciplinary, pathology-rich teaching environment. There is often a breadth of subspecialist skills within a single acute medicine team that AIM physicians acquire during higher specialty training, for example, echocardiography, education, leadership and management, obstetric medicine, and acute oncology. The AMU is a central hub encompassing disparate care pathways for patients and this has resulted in AIM physicians becoming holistic, highly skilled, and adaptable in their approach to patient care especially with regard to critical decision-making such as inpatient admission vs outpatient management and treatment escalation planning. The AIM physician leads and coordinates patient care across the acute unselected medical take including in-reach and support to ED, the AMU, SDEC, ambulatory care unit, and 'hospital at home' services.

CLINICAL SKILLS

The initial patient assessment: the 'medical clerking'

The 'medical clerking' is a critical process in the care of hospitalized patients, forming a cornerstone piece of documentation for the patient's admission (**Box 11.2**). The clerking will be referenced at any point of transition in the patient's journey through the hospital, such as transferring to a different ward, and is frequently the first clinical document that is reviewed by the out-of-hours team when a patient suddenly deteriorates. It is therefore vital that the clerking is a concise description of the patient, their acute presentation, and their background health.

The clerking involves the systematic collection of patient information in order to formulate a working differential diagnosis and rational strategy for investigation, plan admission when needed, and initiate thoughtful discharge planning. A well-executed clerking sets the stage for provision of high-quality patient care, facilitates efficient decision-making, and promotes effective communication between teams.

Gathering patient information

A detailed discussion of the medical interview, history-taking strategies, and physical examination can be found in Chapter 1. The resulting 'medical clerking' document should include the following domains:

- State the patient's ***presenting symptom:*** this should be a brief headline only e.g., 'chest pain', 'shortness of breath'. Then record a detailed history of presenting symptom noting relevant associated features or important 'negatives' (i.e., absent symptoms).
- Record a detailed background of the patient including:
  - ***Past medical and surgical history***
  - ***Current medications*** including over-the-counter medications and herbal remedies
  - ***Allergies and intolerances***
  - ***Family history***
  - ***Social history***
    - Include information on the patient's occupation, smoking (including vaping), alcohol history and recreational drug use (N.B. Cannabis is often not viewed as a drug, so may need to ask specifically), and, when relevant, travel and sexual history, and pets.
  - ***Home situation***
    - Include information on the patient's living conditions and function e.g., the patient may have a package of care in place to support their activities of daily living; the patient may have specific nutrition requirements such as thickened fluids or a soft diet.
- ***Review of systems:*** particularly useful when presenting symptoms are non-specific.
- ***Collateral history*** from an eyewitness (e.g., a family member or carer) is invaluable in scenarios where a patient is unable to communicate (e.g., coma, acute confusion, or pre-existing cognitive impairment) or experienced a period of reduced awareness (e.g., a blackout).
- Record the findings from a comprehensive ***physical examination***, focusing on pertinent findings related to the patient's presenting problem and underlying conditions.
- Review available patient data including ***previous medical records and investigations***, such as laboratory results and imaging studies. Depending on each hospital's record system, there can be a wealth of information to be gathered electronically, and it is important to consider which pieces of information are important to highlight at this point in the patient's admission. For example, if a patient is presenting with shortness of breath, it may be useful to know if they have had an echocardiogram in the last six months.
- Consider available ***point-of-care testing*** (POCT) to add to your initial assessment of the patient's presentation e.g., arterial/venous blood gas, electrocardiogram (ECG), urinalysis, point-of-care ultrasound (POCUS), forced vital capacity (FVC).

Formulating an admission plan

Identify and record the patient's primary problem(s) and establish working diagnoses, or a differential diagnosis if further targeted investigation is required.

- Consider the information gathered from the patient's background to determine their **Clinical Frailty Scale** (CFS) score (see **Fig. 49.2**). This is an important measure when considering further steps in treatment planning, as discussed further below.
- Certain conditions have established associated **risk scores** which should be calculated on admission to plan care (see section below: 'Risk assessments for common acute medical conditions').
- Formulate an **initial investigation and management plan**, addressing urgent clinical concerns and initiating targeted investigations and interventions.

Box 11.2 The admission medical clerking

Information gathering

History taking
- Presenting problem
- History of presenting problem
- Past medical and surgical history
- Allergies and intolerances
- Social history (occupation, alcohol, smoking, substance use, travel, and/or sexual history)
- Home circumstances (level of function, care provision, dietary requirements)
- Review of systems
- Collateral history if relevant

Physical examination

Medical data review
- Hospital records and clinic letters
- Previous investigations

Point-of-care testing (e.g., arterial or venous blood gas analysis, ECG, etc.)

Synthesis

Establish working diagnosis, or differential diagnosis to guide investigations and initial management

Determine Clinical Frailty Score

Apply established risk scores (e.g., GRACE score with ACS)

Actions

Initiate urgent treatment as appropriate

Request relevant diagnostic tests (e.g., CT, echocardiogram)

When admitting to hospital:
- Set goals of admission
- Consider level of care (**Box 11.1**)
- Plan frequency and type of observations and bedside measurements (e.g., CBG)
- Consider TEP and discussing CPR status
- Carry out VTE risk assessment in line with local policy

Set estimated discharge date and clinical criteria for discharge early in admission

ACS, Acute coronary syndrome; *CBG,* capillary blood glucose; *TEP,* treatment escalation plan; *VTE,* venous thromboembolism.

- Immediate **involvement of other teams** may be required e.g., critical care outreach for the critically ill patient, interventional cardiology for high-risk acute coronary syndromes; in other cases, referrals may be planned for later in the patient's admission e.g., endocrinology input for the unwell diabetic patient.
- Establish the **level of monitoring** and care required based on the patient's clinical condition (incorporating data from Fig. 13.1), planned nature and frequency of observations, and perceived risk of deterioration (see Box 11.1).
  - Within a ward environment, clearly stipulate the frequency of observations and other relevant clinical measurements e.g., urine output, pain scores, neurological observations.
- Set specific **goals of care** and discuss them with the patient and their family, ensuring shared decision-making.
- Consider discussing and documenting a **Treatment Escalation Plan (TEP)**. This should state the appropriate level of treatment for a patient should they deteriorate during their admission, taking into account the patient's wishes (including valid advance directives, or proxy opinions in cases where power of attorney for health has been decided), co-morbidities, and functional status. This includes considering appropriateness of cardiopulmonary resuscitation (CPR) in the event of cardiorespiratory arrest. For patients in whom CPR is determined not to be appropriate, it is important that a 'Do Not Attempt Cardiopulmonary Resuscitation' (DNACPR) decision is documented clearly. Every patient with a DNACPR decision should have an accompanying TEP.
  - DNACPR/TEP discussions can be challenging and require clear and compassionate communication in a safe and supportive environment for staff and patients. The point of admission, i.e., the medical clerking, is an opportunity to have these discussions with patients and their loved ones, though it will not always be the most appropriate or optimal time to do so. It is reasonable to delay this discussion until later in the admission if it is safe to do so.
  - Occasionally, patients may present to hospital with advanced, incurable disease associated with distressing symptoms that are not being adequately controlled at home. Recognizing the dying patient allows early involvement of specialist palliative care teams (Chapter 50) for effective symptom control, access to 'fast track' community support, or discharge to hospice services.
- Evaluate the patient's **risk of venous thromboembolism (VTE)** based on local risk assessment models and, when appropriate, prescribe mechanical or pharmacologic prophylaxis.

Additional considerations

Certain patients will have additional communication needs, for example, patients with learning disability; patients with dementia; patients with hearing impairment. In these circumstances every effort should be made to optimize communication for the patient and, when appropriate, an advocate should be sought to complement any history provided by the patient.

When a patient presents with acute cognitive impairment, it is important to establish their baseline cognition via an appropriate collateral history and quantify the degree of impairment at the point of admission with a suitable scoring system, for example, abbreviated mental test score (AMTS); or 4AT score (see Chapter 49).

When a language barrier is present between staff and patients, an independent translation service should be sought to obtain the information needed for the medical clerking, for example, an in-person interpreter or a telephone translation service.

Discharge planning

A proportion of patients seen by the medical admissions team will be planned for discharge on the day of admission, although many will require at least 24 hours of treatment and/or monitoring in hospital. For patients requiring admission, it is important to state their criteria for discharge (this may require the assistance of a senior AIM clinician).

The patient's presentation presents an opportunity to plan necessary investigations, although some of these investigations may be appropriately performed as an outpatient (e.g., investigations directed towards an incidental finding of microcytic anaemia). These investigations should be flagged in the admission plan to ensure that necessary referrals/follow-up arrangements are not subsequently overlooked.

Risk assessments for common acute medical conditions

The ability to estimate the risk that a patient presenting with a particular symptom or condition will experience an adverse outcome (e.g., death or disability) is a powerful tool to assist the AIM clinician in making decisions to admit to a hospital bed, facilitate early discharge or harness ambulatory care or domiciliary care pathways. Some common risk assessment tools applied by AIM clinicians are described in Box 11.3.

Ambulatory score

The ambulatory score (AMB) is a validated scoring system used in the UK to triage suitability for ambulatory care in medical patients and incorporates patient age, ability to travel, need for intravenous treatment, mental status, physiology (National Early Warning Score), and need for recent hospitalization. Patients with an AMB score ≥5 are classed as suitable for consideration of ambulatory care with 92% sensitivity in predicting discharge within 12 hours of index assessment.

Glasgow Admission Prediction score

The Glasgow Admission Prediction (GAP) score is a validated scoring system used in the UK to triage patients admitted to hospital from ED and incorporates age, physiology, triage severity category, route of referral, mode of arrival in ED, and need for recent admission. Patients with a GAP score ≤17 were classified as suitable for consideration of ambulatory care (the statistically significant threshold predictive of discharge).

Neither the AMB nor GAP score was derived to predict clinical outcomes and have limitations in identifying patients who may remain at risk of clinical deterioration, and so should only ever be used as an **adjunct** in clinical decision-making.

Communicating decisions and referrals

Clear and concise communication is an important part of medical practice in promoting effective decision-making and safe patient care and it contributes to improved patient outcomes, reduced length of stay, and good continuity of care.

SBAR

SBAR (Situation, Background, Assessment, Recommendation) is an effective structure for communication among healthcare professionals. SBAR ensures all important information is clearly relayed, reduces the risk of misinterpretation, and thus enhances patient

Box 11.3 Risk assessment tools used for common conditions presenting to the acute medical service

Condition	Risk assessment tool	Explanation
Respiratory		
Pneumonia	CURB-65	The CURB-65 score is used to assess the severity of community-acquired pneumonia. It evaluates factors such as **c**onfusion, **u**rea level, **r**espiratory rate, **b**lood pressure, and age (>**65**) to support treatment decisions.
Gastrointestinal		
Upper gastrointestinal bleed	Glasgow-Blatchford Bleeding score	The Glasgow-Blatchford Bleeding score helps stratify the risk from upper gastrointestinal bleeding, prioritize endoscopic interventions, and identify candidates for ambulatory management.
Neurological		
Subarachnoid haemorrhage	Ottawa score	The Ottawa Subarachnoid Haemorrhage (SAH) Rule is used to assess the probability of SAH in patients with acute headache.
Alcohol withdrawal	CIWA score	The Clinical Institute Withdrawal Assessment for Alcohol Scale (CIWA) evaluates the severity of alcohol withdrawal symptoms and those who require pharmacological treatment.
	AUDIT-C score	Alcohol use disorders identification test for consumption (AUDIT-C) identifies 'at-risk' drinkers.
Cardiovascular		
Acute coronary syndrome	TIMI score	The Thrombolysis in Myocardial Infarction (TIMI) score assesses the risk of adverse cardiac events in patients with acute coronary syndrome.
	GRACE score	The Global Registry of Acute Coronary Events (GRACE) score predicts the risk of death or myocardial infarction in patients with acute coronary syndrome.
Atrial fibrillation	CHA_2DS_2-VASc score	This score is used to estimate the risk of stroke in patients with atrial fibrillation.
	HAS-BLED score	The HAS-BLED score assesses the risk of bleeding in patients with atrial fibrillation on anticoagulation therapy.
	ORBIT score	Outcomes Registry for Better Informed Treatment (ORBIT) of Atrial Fibrillation is used to assess the risk of bleeding from anticoagulation for patients with atrial fibrillation.
Pulmonary embolism	Wells score	The Wells score is used to assess the probability of pulmonary embolism. It considers clinical symptoms, signs, risk factors, and alternative diagnoses to guide further diagnostic testing.
	Geneva score	The Geneva Score is another tool for assessing the probability of pulmonary embolism. It evaluates clinical criteria, such as signs and symptoms, as well as risk factors.
	PESI score	The Pulmonary Embolism Severity Index (PESI) score estimates the severity and risk of adverse outcomes in patients with pulmonary embolism. It incorporates factors such as age, co-morbidities, and vital signs.
	PERC score	The Pulmonary Embolism Rule-out Criteria (PERC) score helps exclude the need for further testing where pulmonary embolism is considered but the patient is low-risk. It evaluates clinical criteria to determine if additional investigations are necessary.
DVT (deep vein thrombosis)	Wells score	The Wells score is also used to assess the probability of deep vein thrombosis. It takes into account clinical features, risk factors, and alternative diagnoses when determining the need for further investigation.

safety. It is designed such that the person initiating the communication should have the pertinent information to hand, as well as know what the expectation is of the interaction.

Handover processes

Effective handover of patients between shifts and teams is crucial for continuity of care and patient safety, as changeover in medical and nursing staff is a potential source of error. A well-executed handover ensures that important details are accurately communicated, preventing vital information from being missed or overlooked. Utilizing succinct summaries during handovers allows for efficient transfer of knowledge, including vital patient information, current treatment plans, and any pending tasks. Written handovers (ideally using dedicated electronic handover databases) should be used whenever possible to maximize clarity and accountability. Handovers should also extend to communication with practitioners outside of hospital, for example general practitioners (GPs) or ongoing care providers when a patient is transferred to a different hospital, ensuring a smooth transition and uninterrupted follow-on care.

Passports for complex patients

Patients with complex needs, such as those with learning disabilities, sickle cell disease, or frequent hospital re-attenders, should have easily accessible passports outlining their individualized plans of action upon admission. This passport, either integrated into the

hospital records system or carried by the patient, serves as a concise reference for healthcare professionals, ensuring prompt and appropriate care delivery. By having a predefined plan in place, potential risks and challenges can be addressed proactively, enhancing patient safety and satisfaction.

Discharge planning

Commencing early discharge planning

Discharge planning should commence alongside acute care at the point of admission. Establishing an estimated date of discharge (EDD) and clinical criteria for discharge (CCD) enables the entire healthcare team to work productively towards a targeted goal. Research has shown that EDD implementation effectively reduces the length of hospital stays, benefiting both patients and the healthcare system.

Recent NHS initiatives developed to assist patients in progressing effectively through their hospital journey include:

- the SAFER care bunder (**S**enior review, **A**ll patients have EDD and CCD, Early **F**low between AMU and hospital wards, **E**arly discharges ideally before midday, MDT **R**eview of all patients with hospital stay of >7 days) and
- 'Red and Green days' ('red days' being those where little value is added to clinical care—to be avoided—and 'green days' a day of value, helping to move the patient towards discharge).

Multidisciplinary discharge planning

Discharge planning for complex patients should involve all members of the MDT and is a key function of daily 'board rounds' and AMU MDT meetings. Early inclusion of patients and families in discussions regarding discharge planning empowers them to participate in the decision-making process, consider their discharge options, and mentally prepare for life outside the hospital.

Comprehensive discharge summaries

Written discharge plans, formulated by members of the MDT, play a role in ensuring a smooth transition from hospital to discharge destination. Summaries should be provided to patients in a legible format and in a language they can understand and should include the diagnosis, investigations, medication information (including any changes to their long-term prescription made while in hospital), follow-up instructions, and potential risks or warning signs to watch for. Verbal communication should accompany the written summary, ensuring patients are well-informed and empowered to manage their health post-discharge.

Liaison with acute care MDT

Acute frailty in reach

Identifying acutely unwell frail patients from the medical 'take', using screening tools such as the Clinical Frailty Scale (CFS), enables early Comprehensive Geriatric Assessment (CGA, Chapter 49) and ensures tailored multidisciplinary input from the earliest point in their admission. Acute frailty services (usually geriatricians and geriatric clinical nurse specialists) will often provide in-reach to the AMU or ED. CGA encompasses not only physical assessment but also includes functional, social, environmental, and psychological domains enabling the formulation of an individualized holistic care plan with the intention to promote optimal outcomes and prevent unnecessary hospital admissions or re-admissions.

Chest physiotherapy for respiratory conditions

In cases of acute respiratory distress, specialist chest physiotherapists can assist in the assessment and management of patients with conditions such as pneumonia, chronic obstructive pulmonary disease (COPD), bronchiectasis, interstitial lung disease, and asthma. Their involvement in airway clearance techniques, breathing exercises, and respiratory support can optimize lung function, reduce complications, and improve patient comfort and recovery.

Drugs and alcohol liaison service

Collaboration with drugs and alcohol liaison professionals (Chapter 30) when managing patients with substance abuse disorders provides expertise in assessing and managing withdrawal syndromes, coordinating appropriate detoxification protocols, and providing support for patients struggling with addiction. Liaising with this team helps address underlying substance abuse issues and provides the necessary resources for ongoing care and rehabilitation, potentially reducing repeated admissions or further morbidity.

Specialist teams for asthma and diabetes

Asthma and diabetes clinical nurse specialists often offer valuable insights into the management of these chronic conditions during acute exacerbations, by adjusting medication regimens, providing education on self-management, and facilitating appropriate follow-up care.

Critical care outreach

Critical care outreach teams (Chapter 13) can comprise critical care physicians, nurses or respiratory therapists, providing advice and support for patients either exhibiting signs of clinical deterioration, or proactively in those patients who have recently stepped down from higher levels of care. Their input can help guide decisions regarding escalation of care, early initiation of critical care interventions, and transfer to ITU.

PROCEDURES

AIM physicians are proficient in a range of procedural skills linked to the urgent investigation and treatment of acute medical presentations (**Box 11.4**). Competency in these procedures is gained through initial training and supervision in simulation settings using anatomical models or mannequins, before undertaking the procedure under direct supervision and guidance in real patients.

Box 11.4 Core procedural skills in AIM

Procedure
Central venous cannulation (internal jugular and femoral)
Intraosseous access to circulation for resuscitation
Intercostal drain for pneumothorax/effusion
Knee aspiration
Lumbar puncture
Abdominal paracentesis
Setting up non-invasive ventilation or CPAP
Arterial line insertion
Point-of-care ultrasound

For all procedures, always check local guidelines and familiarize yourself with equipment available at that site before beginning. If a Local Safety Standard for Invasive Procedures (LocSSIP) exists, this should be adhered to and the appropriate checklist completed. Many AMUs have a dedicated 'procedure room', designed to optimize space and lighting and facilitate clean technique. A 'non-sterile' assistant is often required to aid with gowning and preparation of equipment.

The following principles apply to the preparation for and practice of all acute medical procedures.

Review blood test results and medications

Prior to any intervention, review clotting tests (prothrombin time/INR and activated partial thromboplastin time) and full blood count (haemoglobin, platelets). Review the drug chart for antiplatelets or anticoagulants and consider whether these may need to be suspended prior to the procedure. Safe thresholds for intervention differ between procedures (e.g., requirements are more stringent for lumbar puncture (LP) than central venous catheter insertion). If using lidocaine (lignocaine) during any procedure, the maximum cumulative dose must not exceed 3 mg/kg, repeated not more often than every 4 hours (for reference, 1 mL of 1% lidocaine solution = 10 mg; 1 mL of 2% lidocaine solution = 20 mg).

Review imaging

Review any relevant imaging (e.g., CXR or CT prior to intercostal chest drain insertion, CT brain prior to LP) both to confirm the indication for the procedure and exclude anatomical contraindications.

Patient consent

Informed consent should include an explanation of the procedure and its purpose and potential complications, as well as the completion of a consent form signed by both patient and operator. In emergency situations, it may not be possible to take formal consent before proceeding, in which case the rationale behind a 'best interests' decision should be recorded in the notes.

Equipment

All the necessary equipment to complete the procedure from start to finish should be gathered prior to commencing. Many hospitals purchase bundled 'procedure packs' containing common equipment including a sterile drape, gauze swabs, syringes and needles, scalpal, suture, and dressings. Non-sterile equipment such as the procedure trolley and ultrasound machine should be thoroughly cleaned and disinfected prior to use; a sterile plastic 'ultrasound sleeve' is placed over the probe with the help of an assistant once the operator has donned their sterile gown and gloves. Procedure-specific 'kits' (e.g., central venous catheter kit) contain both the catheter/drain itself, and also the necessary introducer needle, guidewire, and dilators required for insertion; these should be opened carefully by the assistant, allowing the 'sterile' operator to remove the contents and place them on their sterile field (see below).

Aseptic technique

Aseptic technique should be practised to minimize risk of introducing infection. This should include use of a dedicated and frequently cleaned procedure room where possible, thorough hand washing, donning of surgical gown and sterile gloves, and creation of a 'sterile field' (usually on a procedure trolley) where instruments and equipment are laid out for use during the procedure. For all procedures, skin should be cleaned thoroughly with a disinfectant solution (usually chlorhexidine) and a sterile fenestrated drape used to isolate the relevant area before commencing.

Documentation

On completion of the procedure, a structured entry should be placed in the notes. Details should include the volume and strength of local anaesthetic used (to avoid any inadvertent overdose if further procedures are scheduled), any problems or immediate complications encountered during the procedure, a record of the precise medical device that has been inserted and any relevant after-care instructions.

Central venous cannulation, ***intraosseous access to the circulation***, ***intercostal chest drain insertion***, ***LP***, and ***abdominal paracentesis*** are described in detail in **Boxes 11.5–11.9**, respectively. The Seldinger technique (insertion of a catheter over a metal guidewire) is common to several of these procedures and is illustrated in **Fig. 11.2** for the example of central venous catheter insertion. Joint aspiration is described in **Box 32.7** and arterial cannulation in **Box 13.2**. Setting up non-invasive ventilation (NIV) or continuous positive airway pressure (CPAP) is described in the section 'Advanced respiratory support', below.

Point-of-care ultrasound

Point-of-care ultrasonography (POCUS) is an advanced diagnostic ultrasound skill that is increasingly performed and interpreted by AIM clinicians at the bedside. In the UK, the Focused Acute Medicine Ultrasound (FAMUS) accreditation involves three modules: thoracic, abdominal (liver, renal, and bladder), and vascular. It can be used as a rapid diagnostic tool, especially in emergency and acute medicine, and to support the safe undertaking of invasive procedures (see **Box 11.10**). Growing availability of ultrasound technology in EDs and AMUs, together with an expanding pool of trained front-line clinicians means POCUS is increasingly used to make rapid and confident diagnoses in emergency scenarios where traditional radiological investigations may delay diagnosis and treatment.

Advanced respiratory support

Advanced respiratory support techniques include ***high-flow nasal oxygen*** (HFNO), ***CPAP***, and ***bi-level positive airway pressure*** (BiPAP, also referred to as non-invasive ventilation or NIV). These techniques are often delivered in ECUs embedded within AMU, respiratory wards, or critical care units. CPAP and BiPAP have additional indications in a chronic setting in the community and patients receiving these treatments at home may be seen frequently on the acute medical take. Both CPAP and BiPAP reduce cardiac output and may potentially cause haemodynamic instability and so, close monitoring of these patients is required. It is also important to consider that wearing a CPAP or BiPAP mask may reduce the oral intake of a patient and insensible losses will be higher. Careful fluid balance and consideration of supplemental i.v. fluids are important, along with oral hygiene and care, nasogastric tube feeding, pressure dressings, and patient positioning.

Indications for continuous positive airway pressure, bi-level positive airway pressure, and high-flow nasal oxygen

Common indications for initiating CPAP, BiPAP, and HFNO are summarized in **Box 11.11**.

Box 11.5 Central venous cannulation (CVC)

(also **Figs. 11.2 and 11.3**)

Indications

- Administration of medications that require central venous access e.g., inotropes, high-concentration electrolytes
- Fluid balance monitoring with central venous pressure (CVP)
- Intravenous access (long term or difficult peripherally)

Pre-procedure

- Informed consent should include: risks of infection, bleeding (arterial puncture, haematoma, haemothorax), pain, damage to surrounding structures (including pneumothorax), thrombosis, and failure to insert the catheter successfully
- For internal jugular vein placement, position patient with head down-tilt in the Trendelenburg position if they can tolerate it, with head turned away from side of planned insertion: this ensures maximum venous filling and reduces the risk of complications including carotid puncture or air embolism but may exacerbate respiratory distress and is potentially dangerous in those with raised intracranial pressure
- Scan area with US to define anatomy and ensure patency of the intended vein for CVC insertion prior to embarking on procedure

Procedure

- Under ultrasound guidance infiltrate lidocaine cutaneously, subcutaneously, and around the internal jugular vein (4 mls of 2% solution is generally sufficient)
- While lidocaine takes effect, flush all lumens of the line with saline and then clamp all lumens except the Seldinger port
- Under ultrasound guidance, take introducer needle attached to syringe and insert into the internal jugular vein
- When blood is freely aspirated, remove syringe and immediately insert guidewire—this should pass easily
- **Keeping hold of the inserted wire**, remove the needle. Ensure the wire stays in the vein as you do this
- Use a scalpel to make a small incision in the skin. This should be made cutting away from the wire so as not to risk damaging it
- Pass the dilator over the wire and gently but firmly dilate a tract through to the internal jugular. At this stage, there may be some bleeding so ensure to have some swabs ready
- Remove the dilator and pass the central line over the Seldinger wire. Do not advance the line until you have hold of the end of the wire
- Once the central line is in place, remove the wire
- Aspirate and flush all lumens and re-clamp and apply lumen caps
- Suture the line with 4 points of fixation (anchoring each hole on the catheter's hub to the skin)
- Attach plastic cap if available to secure in place
- Dress with a clear dressing so the insertion point can be clearly seen without removing the dressing, labelling with the date of insertion

Post-procedure

- Attach central line to pressure bag to allow CVP monitoring if indicated
- Run a blood gas to ensure a venous sample
- CXR to confirm correct placement and to exclude pneumothorax

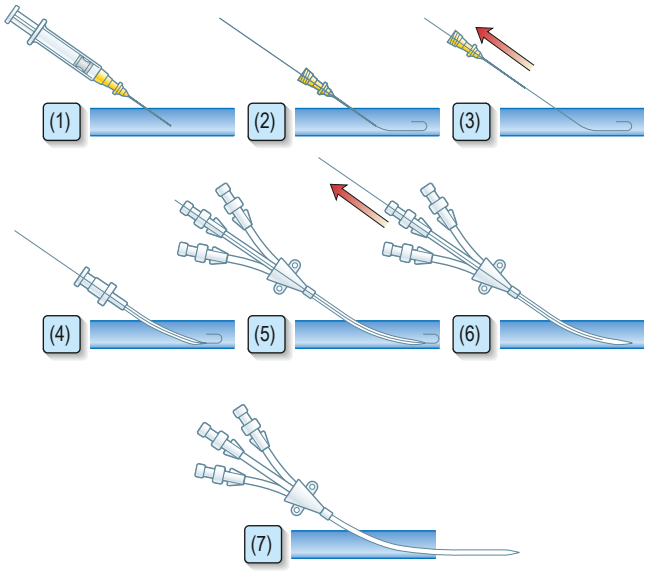

Fig. 11.2 Seldinger technique—insertion of a catheter over guidewire. This catheter insertion technique is used in a broad range of procedures including central venous cannulation, intercostal drain insertion, and paracentesis. In this example, the Seldinger technique is being used to insert a central venous catheter, although the same sequence of steps is common to all 'wire-guided' procedures. **(1)** Puncture vessel. **(2)** Advance guidewire. **(3)** Remove needle. **(4)** Dilate vessel. **(5)** Advance catheter over guidewire. **(6)** Remove guidewire. **(7)** Catheter *in situ*.

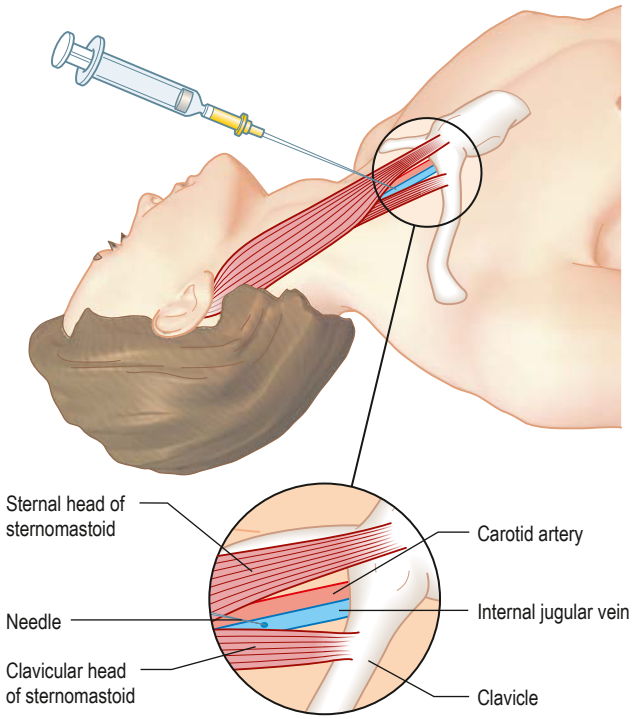

Fig. 11.3 Cannulation of the right internal jugular vein.

High-flow nasal oxygen

Also referred to as high-flow nasal therapy (HFNT) or Optiflow, HFNO is a technique of providing warmed and humidified oxygen at a higher flow rate in patients with respiratory failure when attempting to avoid intubation or to help after extubation. Oxygen administration by HFNO is distinct from standard low-flow nasal cannulae. When patients are administered low-flow nasal oxygen, the oxygen flow rates are typically between 2 and 10 L/minute (L/M). When a patient is spontaneously breathing, the inspiratory flow rate (IFR) is 20–40 L/M. Once the IFR surpasses the flow of oxygen coming from the nasal cannulae, room air is entrained which reduces the fraction of inspired oxygen (FiO_2). The effective delivered oxygen concentration is usually 25%–30%, if a patient is

Box 11.6 Intraosseous (IO) access to circulation for resuscitation

Intraosseous (IO) access refers to the use of the medullary space of a long bone to administer medications and may be obtained by using a drill insertion device (usually an EZ-IO driver) for insertion of a specialized needle and catheter, usually in an emergency e.g., cardiac arrest.

Indications

- In time-critical and/or life-threatening situations such as shock, resuscitation, or trauma settings, peripheral cannulation has been unsuccessful
- To act as an interim measure to administer life-saving medication e.g., by paramedics or pre-hospital teams until a more definitive intravenous access can be secured on arrival to hospital

Site of insertion

- The two most common sites for IO insertion in an adult are the proximal tibia and the proximal humerus
- Proximal tibia: 2 finger breadths below the patella and 1–2 cm medial to the tibial tuberosity (**Fig. 11.4**)
- Proximal humerus: insertion at the surgical neck of the humerus—place the patient's arm with the elbow adducted with the hand over the umbilicus. From the midshaft of the humerus, palpate upwards to locate the greater tubercle or 'surgical neck' of the humerus—this is the insertion site
- Other IO insertion sites include the distal tibia, femur, iliac crest, and sternum but are only usually used in isolated circumstances e.g., advanced trauma

Pre-procedure

- Obtain and document informed consent if the patient is able; otherwise document why the procedure is indicated or in the patient's best interests
- Choose insertion site (usually proximal tibia or humerus as above)
- Select the correct IO needle size and catheter: there are three different sizes, all 15G diameter but varying in length depending on the insertion location and size of the patient (**Fig. 11.5**). When inserting into the proximal humerus, the 45 mm (yellow) should always be used. In the proximal tibia, the 25 mm (blue) is most commonly used

Procedure

- Connect selected needle and catheter set to drill (turning clockwise to connect)
- Locate, palpate, and stabilize insertion site
- Remove needle cap and insert perpendicular ensuring one black line (5 mm) remains visible on the needle externally to the skin once the needle tip rests against the bone
- Once bone has been reached, gently drill and apply gentle but firm pressure to penetrate the bone cortex until a 'give' is felt on entry to the medullary space
- Disconnect the driver from the needle tip and remove the stylet by turning anti-clockwise
- Using the IO stabilizer dressing if available, secure the insertion
- Aspirate blood samples for analysis e.g., a venous blood gas at this time if required (which must be analyzed in the lab as opposed to point-of-care machines as IO samples frequently block conventional point-of-care systems)
- Connect primed extension set and flush with saline

Post-procedure

- If the patient is conscious, infusion of lidocaine (0.5 mg/kg, maximum dose 40 mg) can be given for pain relief
- When administering further IO infusions, these typically require more pressure than i.v. and therefore 50 mL syringes may be used to manually infuse therapies such as fluids. Ensure any bolus medications such as adrenaline are followed with a 10 mL saline flush; pressure delivery systems may be useful

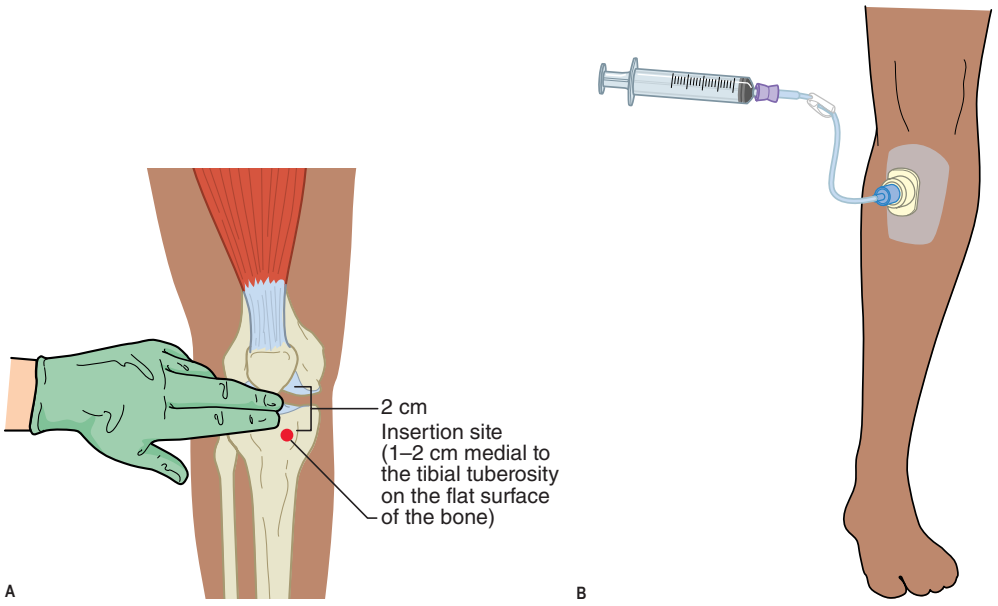

Fig. 11.4 Proximal tibia insertion site for IO access. **(A)** Landmarks for insertion. **(B)** IO needle once *in situ*.

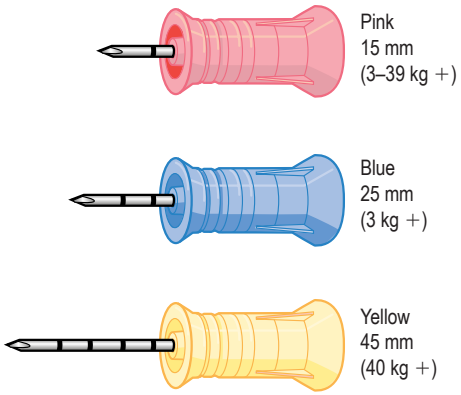

Fig. 11.5 Intraosseous needles. Colour coding corresponds to the EZ-IO system which is commonly used in the UK. Blue needle is most commonly used in adults, pink in children, and yellow in patients with excess soft tissue.

Box 11.7 Intercostal chest drain insertion (Seldinger technique)

Indications

- Diagnosis and/or therapeutic relief of a pleural effusion
- Drainage of empyema (source control of infection)
- Drainage of pneumothorax
- Other indications include in trauma settings such as a haemopneumothorax or haemathorax (but this is more often treated with a surgical chest drain as opposed to a Seldinger chest drain)

All pleural procedures should involve direct/indirect thoracic ultrasound at the time of procedure. Exceptions to this include tension pneumothorax or emergency drainage of a large pleural effusion causing significant breathlessness (peri-arrest).

Pre-procedure

- Informed consent should include: risks of infection, difficulty breathing or low oxygen levels after insertion, air leak into chest wall, bleeding, pain, damage to surrounding structures, low blood pressure, and failure of successful insertion/drainage
- Check blood tests: patients should have an INR of <1.5, and a platelet count of $>50 \times 10^9$/L.
- Review imaging prior to the procedure (either a PA CXR or CT thorax)
- Position patient: typically, pleural aspiration is performed in one of three different positions:
  - lateral decubitus
  - semi-recumbent
  - leaning forwards
- Assessment of surface anatomy: ideally, pleural aspiration should take place within the 'safe triangle' (**Fig. 11.6**). If insertion in the safe triangle is not possible, a different site can be identified, but ensure that this is 6 cm lateral to the spine to avoid injury to an intercostal artery
- Confirm site of insertion using ultrasound and mark skin
- Assemble drainage bottle. Pour 500 mL sterile water up to the underwater seal line (often marked 'start level') and leave with cap off, ready for tubing to be attached later

Procedure

- At the pre-marked US-guided site, infiltrate lidocaine (4 mls of 2% is generally sufficient). Site of entry should be 'above the rib below' in order to avoid damage to the neurovascular bundle. Use a 25G orange needle to anaesthetize the skin, and then a 21G green needle to anaesthetize the underlying soft tissue and intercostal muscle. Advance the needle perpendicular to the skin, until pleural fluid may be aspirated—or air if pneumothorax. Once the pleura has been reached and anaesthetized, withdraw the needle slowly, infiltrating the 'tract' as you draw back
- Attach the introducer needle to a 10 mL syringe and insert along the anaesthetized tract, aspirating as you advance. You may feel slight resistance as the needle passes through the pleura. Once aspirating pleural fluid or air, advance the needle a further 0.5 cm, before stopping
- Unscrew the syringe, leaving the needle in place. Ensure to keep a hand on the needle, close to the skin surface when removing the syringe to avoid accidentally advancing the needle further. Place your gloved thumb over the open end of the introducer needle to block the outflow of pleural fluid or air
- Insert guidewire through the needle—this should pass easily.
- Keeping hold of the guidewire, remove the introducer needle, leaving just the guidewire in place
- Make a small incision using a scalpel at the incision point where the wire enters the chest.
- Pass the dilator over the guidewire using a twisting motion to help separate the intercostal muscle fibres. Ensure that the dilator is only inserted as far as necessary—no further than needed originally to aspirate pleural fluid: a safety guard can be adjusted on the dilator to reduce risk of excessive dilation and lung injury. If using an 18Fr drain this will need to be done three times, once with each of the successively larger dilators
- Keeping hold of the guidewire, remove the dilator and thread your drain over the guidewire and through the chest wall into the pleural space. Continue inserting the drain until you reach the 12 cm mark
- Remove the guidewire and attach the three-way tap in OFF position
- Suture the drain in place, ensuring it is 'anchored to the skin', and apply dressing
- Connect the chest drain tubing to both the drain and the drainage bottle (**Fig. 11.7**), and open the three-way tap. You should see pleural fluid if draining effusion, or bubbles if draining pneumothorax. If you do not see bubbles for a pneumothorax, ask the patient to cough

Post-procedure

- A CXR post-procedure is recommended if unexpected complications are encountered such as pain, air-aspiration (not including that from a pneumothorax), or if pleural fluid is not draining easily
- Ensure the nursing staff are informed and are familiar with chest drain care; a chest drain chart should be started following chest drain insertion
- If samples are required, conventional tests would include: pleural fluid MC&S, fluid pH, glucose, protein, LDH, AFB smear and mycobacterial culture, and cytology (ideally 60 mL)

receiving 2–4 L/M of nasal oxygen. In contrast, HFNO uses oxygen flows of 50–100 L/M. With this technique, the high flows delivered via the specially designed nasal cannulae exceed the patient's IFR. Therefore, there is lower entrainment of room air which allows the delivery of a higher FiO_2.

HFNO should be considered in hypoxaemic acute respiratory failure of any cause, but particularly in type I respiratory failure. This includes pneumonia, COVID-19 pneumonitis, post-operatively and post-extubation, following chest trauma and for patients with impaired ventilation due to pain. HFNO may also be used to reduce hypoxia during induction of anaesthesia, during procedures under sedation, and can be a helpful adjunct to patients receiving CPAP or BiPAP, to allow breaks from face mask-based therapies. HFNO may be an option for patients not considered suitable for invasive ventilation, or for those requiring palliative care.

Continuous positive airway pressure

CPAP is delivered via a tight-fitting mask over the nose, the nose and mouth, or via a whole head hood system. It may also be delivered via a tracheostomy tube. The mask or hood is attached to a ventilator and delivers a set positive pressure throughout the respiratory cycle, although the physiological effect is equivalent to applying positive end-expiratory pressure (PEEP). The aim of CPAP is to splint open airways, reduce alveolar collapse, enable alveolar recruitment, and to increase the functional residual capacity to help reduce the work of breathing. CPAP is often used in pulmonary oedema in addition to or after optimized medical management has failed.

Bi-level positive airway pressure

BiPAP is also delivered via a tight-fitting mask but the ventilator delivers two different airway pressures: inspiratory and expiratory. The expiratory positive airway pressure (EPAP) is equivalent to PEEP (as delivered by CPAP). The inspiratory positive airway pressure (IPAP) is a higher pressure which aims to augment the patient's respiratory effort. BiPAP is used to treat **type 2 respiratory failure** and most commonly exacerbations of COPD (see Chapter 20). Close monitoring and often serial arterial blood gases are required to identify improvements or deteriorations and titrate treatment. In the event of escalating pressure requirements, respiratory and/or ITU team involvement should be sought promptly.

Prior to commencing CPAP or BiPAP, it is important to consider contraindications (see **Box 11.12**) and ensure that there is a clear

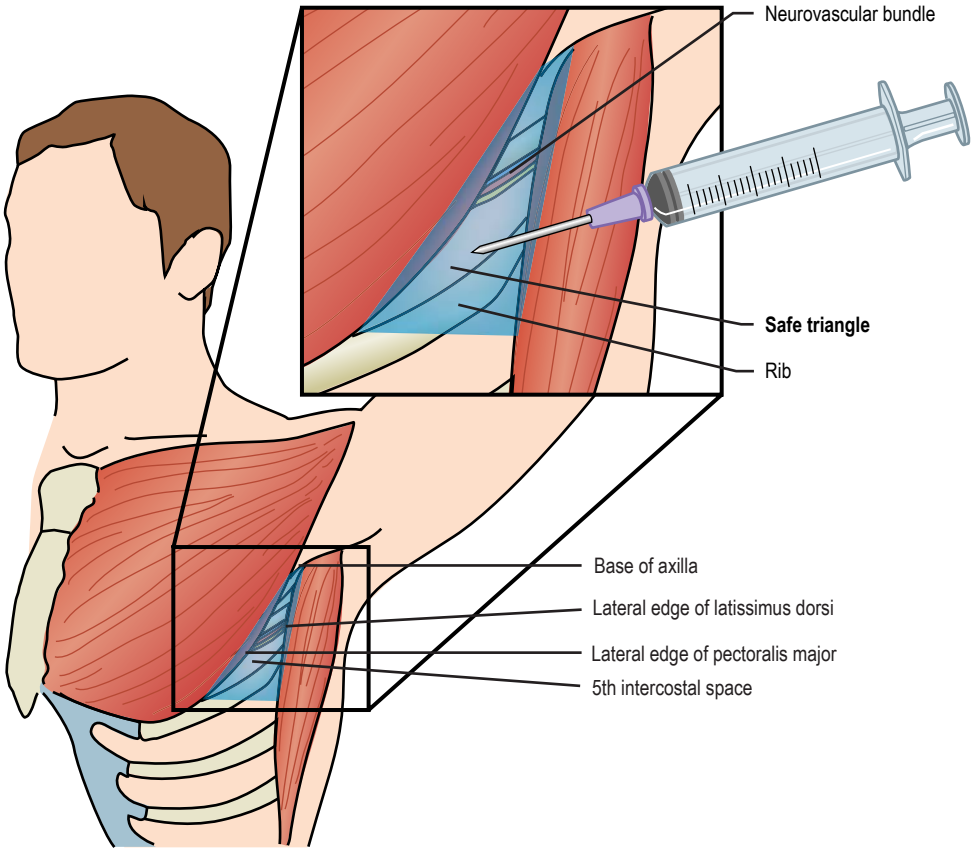

Fig. 11.6 **Intercostal drain insertion.**

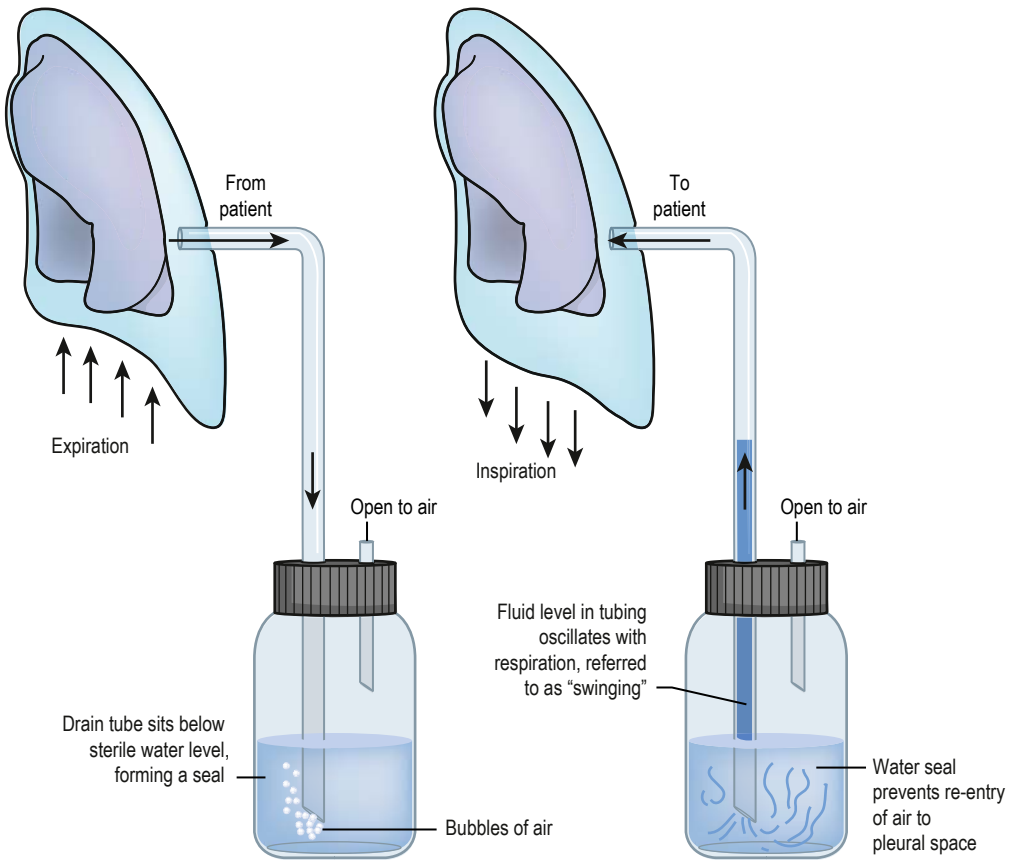

Fig. 11.7 **Intercostal drain connected to drainage system with underwater seal.**

Box 11.8 Lumbar puncture (LP)

Indications
- Diagnosis of neurological disease (e.g., meningoencephalitis)
- Measurement of CSF pressure (e.g., idiopathic intracranial hypertension)
- Removal of CSF therapeutically (e.g., idiopathic intracranial hypertension)
- Intrathecal injection of drugs (e.g., chemotherapy)

Pre-procedure
- Informed consent should include: risk of headache/worsening of headache, localized back pain, bleeding or bruising, transient neurological symptoms such as shooting pain down the legs at the time of the procedure, and failure of the procedure
- Check blood tests: patients should have an INR of <1.4, and a platelet count of >50. A minimum interval of 12 h after prophylactic doses of low-molecular-weight heparin (in patients with normal renal function) is advised
- Imaging, including a CT head (if available) should be reviewed prior to the procedure. A CT scan is mandatory in unconscious patients and those with papilloedema or other symptoms or signs of raised ICP. Removal of CSF in a patient with a mass lesion in the brain or cord may result in caudal herniation of the cerebellar tonsils (coning) and death, and LP is contraindicated in such settings. There are exceptions where an LP may be undertaken in the context of raised ICP (e.g., for treatment of idiopathic intracranial hypertension)
- Patient position: Typically LP is performed in one of two positions:
  - lateral recumbent
  - sitting and leaning forwards

  CSF opening pressure can only be accurately measured in the lateral recumbent position
- Assessment of surface anatomy: the spinal cord ends at L1, and the needle insertion point must be below this to avoid spinal cord injury. The ideal needle insertion sites for LP are between L3/L4, or L4/L5. Use surface anatomy to help identify the correct point in which to perform the procedure (Fig. 11.8)
  - Palpate the posterior superior iliac crests bilaterally. Imagine a line across the lower back connecting these two points. Follow this medially until you reach the spine, and this is typically at the level of L3/L4. Palpate this vertebral space, and the one below (L4/L5) to identify the widest space to perform the procedure

  LP is contraindicated if there is skin infection over needle insertion site.

Procedure (Fig. 11.9)
- Correct positioning for both clinician and patient is vital. Most clinicians complete this procedure sitting down, so ensure your chair is at the right height and is comfortable
- Palpate and mark the insertion site (ultrasound may be useful here)
- Infiltrate lidocaine (up to 10 mls of 1% is usually sufficient) over the pre-marked area, with needle tip pointing towards the umbilicus. Use a 25G orange needle to anaesthetize the skin and then a 21G green needle and continue to anaesthetize the underlying subcutaneous tissue.
- Take your spinal needle (typically black 22G), and insert this, bevel up, through the marked and anaesthetized area in the direction of the umbilicus. Ensure to advance slowly, and that the stylet is in place at all times
- When you pass through the spinous ligament you will feel a change in resistance. At this point, remove the stylet gently and observe for flow of CSF. If you do not visualize this, rotate the needle slightly and recheck
- Note the appearance of the CSF (clear, cloudy, yellow in xanthochromia or red) and then attach a three-way tap and manometer, and turn the tap so that it is open between the needle and the manometer. Allow the fluid to fill the manometer and record the opening pressure (if required). Normal CSF pressure is 60–150 mm of CSF
- To take diagnostic samples, an assistant should hold the bottles underneath the three-way tap. For biochemistry, microbiology, or xanthochromia 0.25 mL or approximately 6 drops of CSF is usually sufficient. If sending cytology, a larger volume (up to 10 mL) increases diagnostic yield
- Once you have collected the samples, remove the three-way tap and **replace the stylet.** Withdraw the needle and stylet together and cover the insertion site with a dressing

Post-procedure
- To minimize the risk of post-lumbar puncture headache:
  - encourage the patient to remain hydrated and caffeinated drinks can be considered
  - lying as flat as able depending on clinical setting can also help avoid this
- Samples sent will depend on indication for procedure but may include: protein, glucose, Gram stain, culture and sensitivity, xanthochromia, cytology, oligoclonal band analysis, virology, or special stains (e.g., AFB). Remember to send a simultaneous paired blood glucose sample

treatment escalation or de-escalation plan in place with a timetable of regular reviews. Initiation of respiratory support can be frightening for patients and it is vital that the indications, process, and timeline are discussed beforehand to help alleviate this.

Setting up CPAP/BiPAP

What to consider before starting

- Consent: explain the procedure, its practicalities, and potential complications to the patient
- Treatment may be uncomfortable and poor tolerance is one important cause of failure. Reassure the patient that treatment will be increased gradually and emphasize the potential benefits
- TEP/DNACPR status should be reviewed prior to commencing CPAP/BiPAP, but note that having a DNACPR does not in itself preclude the use of advanced respiratory support or invasive ventilation
- Consider contraindications to treatment (Box 11.12).

Setting up treatment

Prepare
- Select the correctly sized mask and Velcro stretch straps for the patient
- It is essential to seek the assistance of a nurse experienced in CPAP/BiPAP
- The pressure from CPAP/BiPAP often leads to pneumophagia resulting in bloating and nausea. Give an antiemetic/peppermint capsule and consider NG tube insertion to reduce gastric pressure.

Putting on the mask
- An incorrect mask fitting is one of the most common errors in initiating CPAP/BiPAP
- Select the pressure settings with the mask not on the patient
- Position the mask near the patient's face so they can feel the air blowing into their face without the mask touching them
- Hold part of the mask on their face, giving them time to adjust
- When ready, hold the mask to their face allowing them to acclimatize gradually to the pressure
- Secure the mask using the Velcro stretch straps to ensure a proper fit.

Initial settings

CPAP
- Initial pressure settings are usually 5, 7.5, or 10 cmH_2O
- Some machines allow a slow increase in the pressure over time (e.g., 10 min) to allow patients to adjust, otherwise, manually increase the pressure to the desired setting

BiPAP
- The aim is to commence BiPAP at settings of 12 cmH_2O/4 cmH_2O (IPAP of 12, EPAP of 4) and escalate the IPAP in

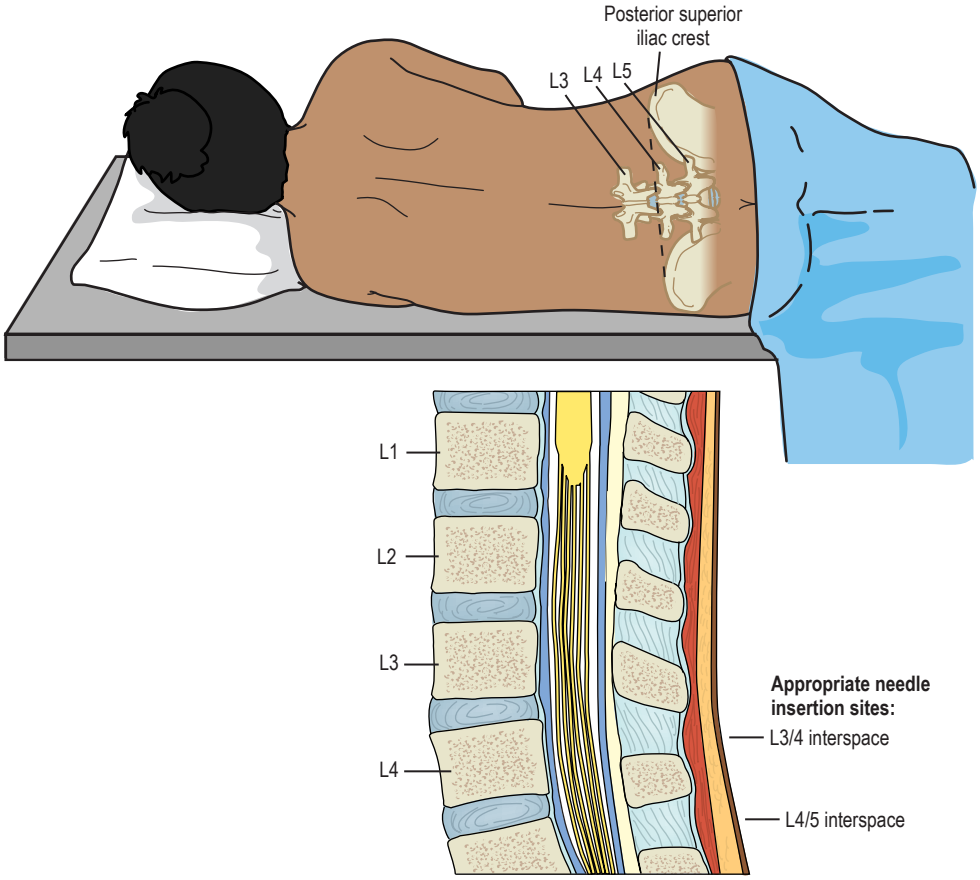

Fig. 11.8 **Lumbar puncture: patient position and anatomy.**

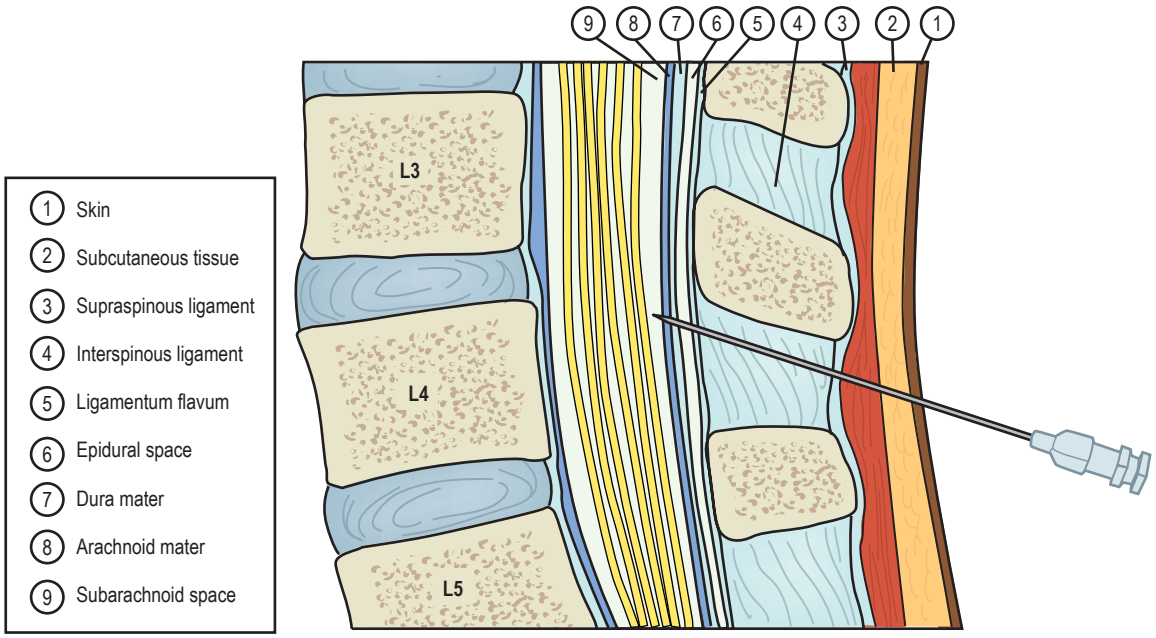

Fig. 11.9 **Anatomical layers relevant to passage of the lumbar puncture needle.**

Box 11.9 Abdominal paracentesis

Indications

- Diagnostic evaluation of ascites (including exclusion of spontaneous bacterial peritonitis)
- Therapeutic relief of gross ascites (liver cirrhosis, malignancy)

Pre-procedure

- Informed consent should include: pain, bleeding or bruising, low blood pressure (especially in cases where it is predicted larger volumes of ascites may be removed), infection (either of the drain site itself or introduction of infection to the peritoneal cavity/peritonitis), damage to surrounding structures, blocked tubing or failure of drainage
- Coagulopathy and thrombocytopenia are often present in liver disease and though it is a caution, it is not a contraindication to paracentesis or drainage. Always discuss with the local gastroenterology/haematology team if uncertain
- Depending on indication, consider ordering human albumin solution (HAS) 20% prior to drain insertion
- Best practice is to use ultrasound at the bedside to identify and mark a suitable pocket of fluid for drainage. In cases where ascites is clinically obvious, the procedure may be performed blind, although an ultrasound scan is mandatory prior to drainage of malignant ascites, where there is doubt regarding the cause of abdominal distension or suspicion that fluid may be loculated
- Patient position: the procedure is usually performed with the patient supine
- Surface anatomy: the patient should be asked to empty their bladder. A drainage site is usually selected in either the left or right iliac fossa, to avoid contact with an enlarged liver or spleen, and at least 10 cm from the midline to ensure avoidance of the inferior epigastric artery

Procedure (Fig. 11.10)

- Infiltrate lidocaine (4 mls of 2% is generally sufficient) over marked, US-guided site. Use an orange 25G needle to anaesthetize the skin and a green 21G needle to anaesthetize the underlying subcutaneous tissue down to the peritoneal membrane (you will often aspirate ascites at this point). Once the peritoneum has been anaesthetized, withdraw the needle slowly, infiltrating the 'tract' as you draw back

If performing a diagnostic ascitic tap:

- Take a 20 mL syringe with a green 21G needle and aspirate as you advance. Stop when you aspirate ascites and fill up your syringe
- Withdraw the needle and place an adhesive island dressing or similar to cover the area

If performing a therapeutic ascitic drain:

- Assemble your drain kit: a paracentesis catheter with three-way tap (which usually requires preparation by insertion of the long introducer needle into the catheter, slowly so as to not pierce the tubing, and removal of the external plastic sheath), a 20 mL syringe, a scalpel, along with preparation of the drainage tubing by connecting to a drainage bag with stand
- Ensure the three-way tap is turned off and connect a 20 mL syringe to the end of the introducer needle (which is now within the paracentesis catheter)
- Use a scalpel to make a small cut in the skin where previously marked and anaesthetized
- Insert the introducer needle and drain perpendicular to the skin through the premade cut and slowly advance, aspirating the syringe periodically, until entering the peritoneal cavity
- Once able to aspirate ascitic fluid, advance a further centimetre and then keep the long introducer needle still while sliding the paracentesis catheter forward, off and over the needle until flush with the skin. Then withdraw the needle leaving the drain *in situ*
- Secure with 2–3 cannula-type adhesive dressings (the steri-strips can be useful)
- Attach a 2 L drainage bag
- Open three-way tap and ascitic fluid should start draining. You can use the 3-way tap to draw off your required samples

Post-procedure

- For cirrhotic ascites, ensure 20% HAS is prescribed and instructions for monitoring and infusion clearly handed over to the nursing staff (usually 100 mL of 20% HAS for each 2 L ascites drained)
- Ensure removal after no more than 6 h (drains are sometimes left *in situ* for longer when draining malignant ascites, although the risk of infection rises proportionally to the duration of drainage)

2–5 cm increments at a rate of approximately 5 cmH_2O every 10 minutes with a usual pressure target of 20 cmH_2O or until a therapeutic response is achieved or the limit of patient tolerability has been reached

- Setting changes should be guided by serial ABGs and the respiratory team should be involved to help guide this.

Monitoring of patients on CPAP/BiPAP

- Try to stay with the patient for at least five minutes to ensure they are comfortable, using this time to start optimizing settings
- ABGs should be taken as a minimum at 1, 4, and 12 hours after the initiation treatment; consider placement of an arterial line to facilitate this without repeated arterial puncture if the patient is being managed in an ECU/HDU setting
- A decision as to whether to escalate to invasive mechanical ventilation should normally be taken within 4 h of initiating CPAP/BiPAP
- With both CPAP and BiPAP the FiO_2 can be titrated to achieve a target P_aO_2 or saturation

Escalation or de-escalation of respiratory support

Escalation plans when commencing CPAP/BiPAP generally fall into one of four categories:

- If treatment fails, escalate to intubation
- If treatment fails, consider palliation if it is not appropriate to proceed to intubation
- Continue treatment if there is a response to therapy and seek specialist respiratory input with regards to duration of therapy and weaning
- It is inappropriate to commence treatment and palliate from the outset.

How to wean CPAP/BiPAP

- Initially weaning should be during the day with extended periods off the ventilator for meals, physiotherapy, nebulized therapy, etc.
- After successfully weaning during the day, most patients will require an additional night with treatment continued
- Depending on the indication, some may wean quicker than others e.g., CPAP to treat pulmonary oedema may often be weaned quickly if the response to medical therapy is good
- Usual practice involves a 2–5 day weaning period
  - Day 2: Continue treatment for 16 h (including 6–8 h overnight)
  - Day 3: Continue treatment for 12 h (including 6–8 h overnight)
  - Day 4–5: Treatment may be discontinued unless continuation is clinically indicated.

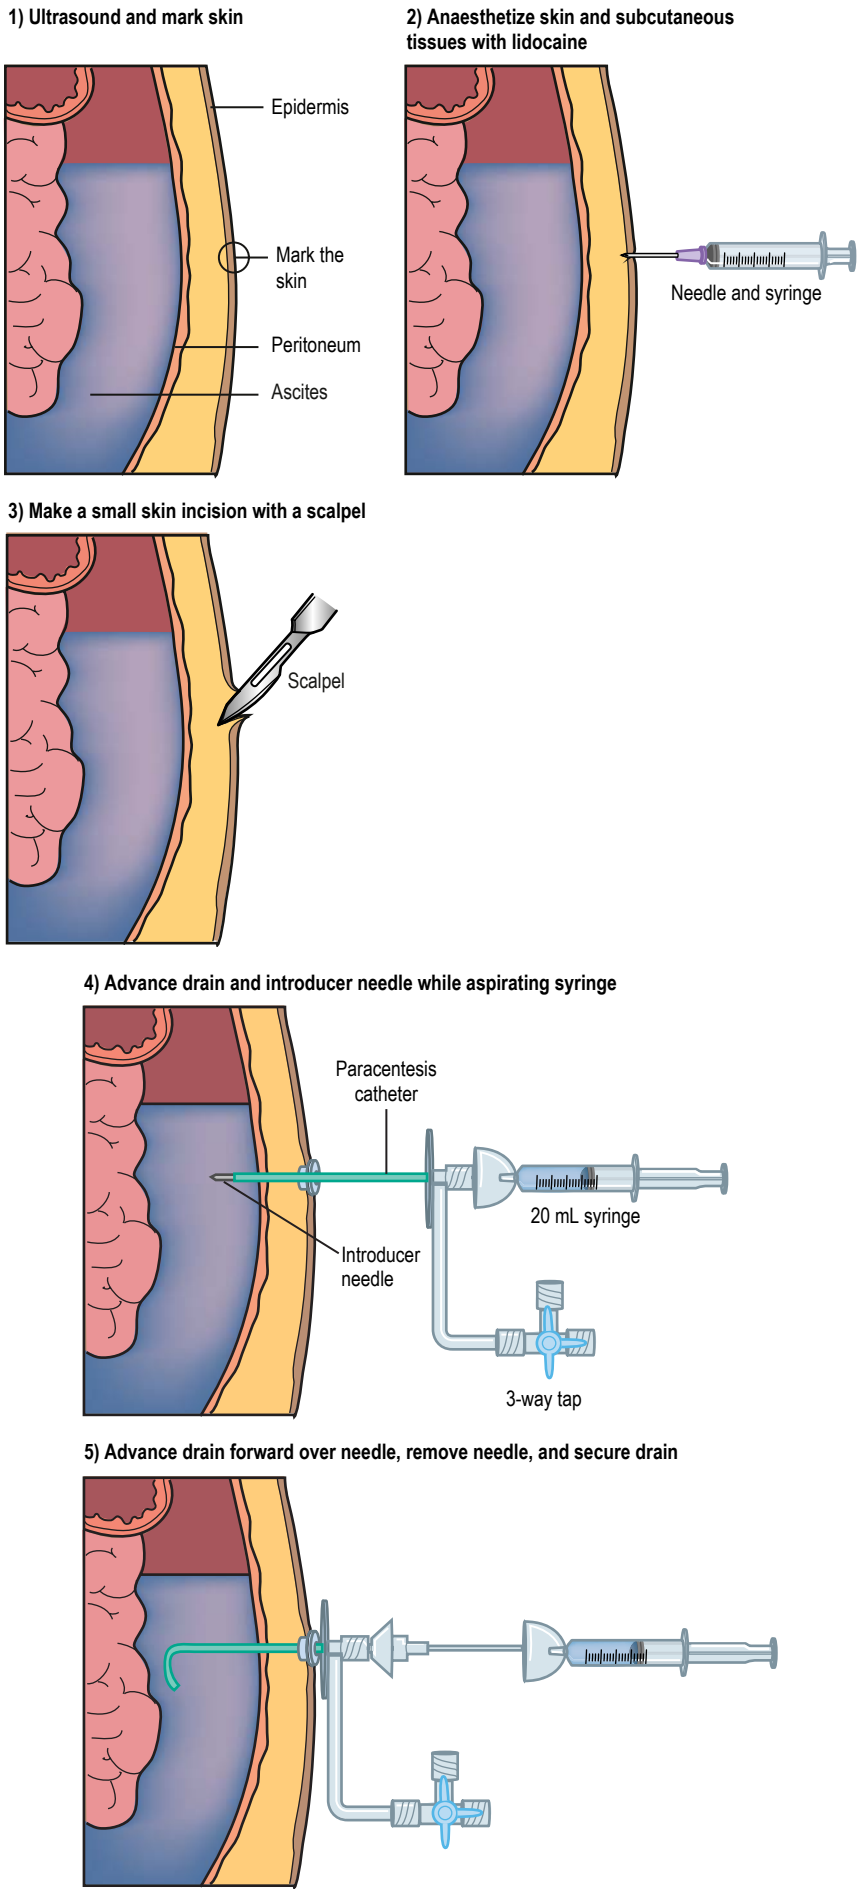

Fig. 11.10 Abdominal paracentesis.

CORE CLINICAL PRESENTATIONS IN AIM

Below are 25 common clinical presentations seen in the context of AIM. Other common emergency presentations are dealt with in specialty-specific chapters elsewhere in the book, but four other chapters are focused specifically on acute presentations requiring a tailored approach:

- sepsis (Chapter 12)
- acute poisoning (Chapter 15)
- environmental emergencies (Chapter 16)
- stroke (Chapter 29).

Cardiac arrest

Every year in the UK, there are approximately 100 000 unexpected deaths occurring within 24 hours of the development of cardiac symptoms. About half of these deaths are almost instantaneous. Most deaths are due to ventricular fibrillation or rapid ventricular tachycardia; a small proportion are caused by severe bradyarrhythmias. Coronary artery disease accounts for approximately 80% of sudden cardiac deaths in Western society. Transient ischaemia is suspected of being the major trigger factor; however, only a small proportion of survivors have clinical evidence of acute myocardial infarction.

When cardiac arrest occurs, basic life support must be started immediately. The longer the period of respiratory and circulatory arrest, the lower is the chance of restoring healthy life. The chain of survival (Fig. 11.11) includes:

- early recognition of cardiac arrest
- early activation of emergency services
- early CPR
- early defibrillation and early advanced life support
- high-quality post-resuscitation care.

Basic life support

The first step in basic life support (BLS) is to ensure the safety of the victim and rescuer. The next is to ascertain that the victim is unresponsive by shaking them and shouting into one ear. If no response is obtained, help should be sought immediately prior to commencement of BLS. If the victim has absent or abnormal breathing, then cardiac arrest is confirmed and BLS should be started (Box 11.13).

Box 11.10 Point-of-care ultrasound (POCUS)

Body system	Core diagnoses	Core skill
Thoracic	Pulmonary oedema Pneumonia Pleural effusion Pneumothorax	Site mark for drainage of pleural effusions (as per British Thoracic Society guidance)
Abdominal/renal	Hydronephrosis Bladder distension Abdominal free fluid	Site mark for abdominal paracentesis/ascitic tap
Lower limb	DVT (rule in)	Three-point compression test
Peripheral vascular access		Ultrasound-guided peripheral vascular access

Box 11.12 Contraindications to ward-based non-invasive ventilation

Absolute

- Severe facial deformity
- Facial burns/trauma
- Asthma
- Vomiting
- Fixed airway obstruction
- Undrained pneumothorax
- Bowel obstruction

Relative

- Glasgow Coma Scale score <8[a] or if patient is unable to protect their own airway
- Hypotension (systolic blood pressure <90 mmHg)
- Copious secretions
- Confusion or agitation[a] (unless caused by hypoxia or hypercapnia which would be reversed by NIV)
- Severe cognitive impairment
- Recent upper GI surgery

With regard to treatment of type 2 respiratory failure (i.e., BiPAP/NIV):

- pH < 7.15[a]
- pH < 7.25 and additional adverse features[a]
- NIV is not the treatment of choice for patients with consolidation on CXR but is sometimes used if escalation to intubation and ventilation is deemed inappropriate

[a]Consider NIV in a critical care setting.

Box 11.11 Indications for CPAP, BiPAP, and HFNO

	CPAP	BiPAP	HFNO
Type of respiratory failure	Type 1 (hypoxemic) respiratory failure	Type 2 (hypercapnic) respiratory failure	Type 1 (hypoxemic) respiratory failure
Arterial blood gas values	P_aO_2 < 8 kPa	pH < 7.35, P_aCO_2 >6.5 kPa	P_aO_2 < 8 kPa
Aetiology	Pulmonary oedema Viral pneumonitis Obstructive sleep apnoea (OSA) Postoperative respiratory failure Weaning from invasive ventilation	Chronic obstructive pulmonary disease (COPD) Bronchiectasis Pulmonary oedema Neuromuscular disease-causing weakness (e.g., motor neurone disease (MND)) Obesity hypoventilation syndrome (OHS) OSA Chest wall deformity (e.g., scoliosis) Weaning from invasive ventilation	Pneumonia Viral pneumonitis Asthma Bronchiectasis Acute respiratory distress syndrome (ARDS) Postoperative respiratory failure Weaning from invasive ventilation

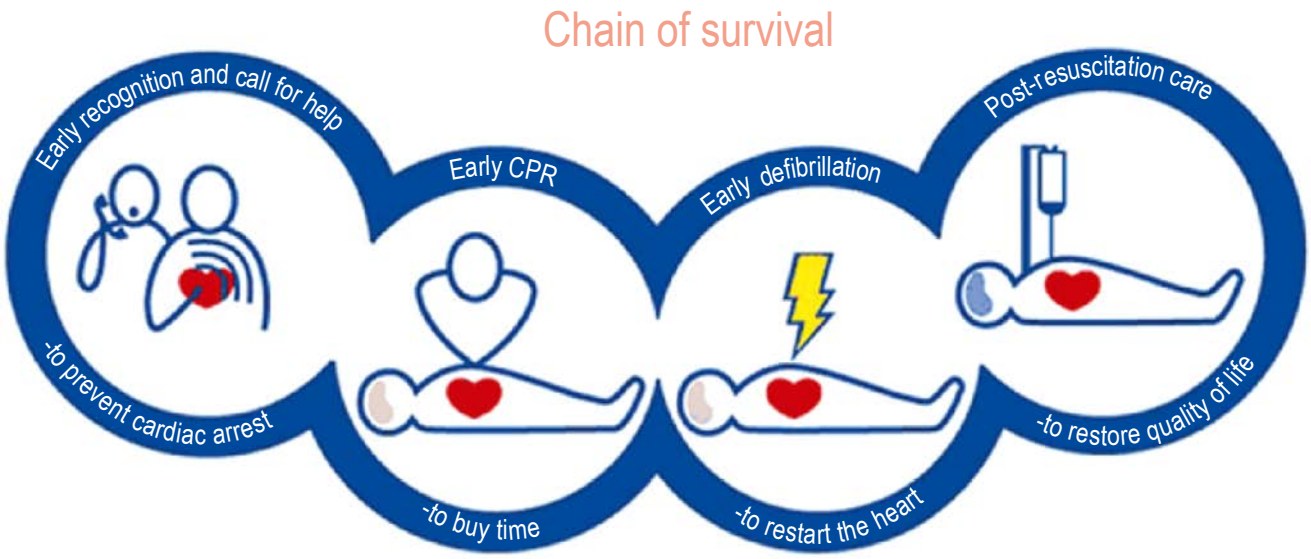

Fig. 11.11 **Cardiopulmonary resuscitation chain of survival.**

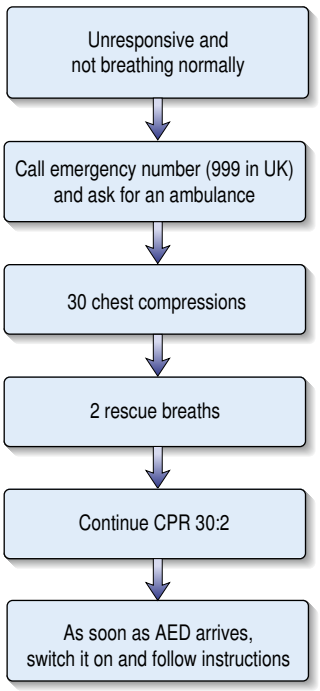
Box 11.13 Adult basic life support (out of hospital)



Airway

Debris (e.g., blood and mucus) in the mouth and pharynx should be removed, as should loose or ill-fitting dentures. The airway should be opened gently by flexing the patient's neck and extending the head ('sniffing the morning air' position). This manoeuvre is not recommended if a cervical spine injury is suspected. Any obstruction deep in the oral cavity or upper respiratory tract may need to be removed using abdominal and/or chest thrusts (see Box 20.12).

Circulation

Most adult cardiac arrest is due to a primary cardiac disorder, such as acute coronary syndrome or arrhythmia, that results in circulatory collapse. Pulse detection can be difficult, and if the victim is unresponsive, with absent or abnormal breathing, external chest compression should be started immediately. The heel of one hand is placed over the centre of the patient's chest and the heel of the second hand is placed over the first with the fingers interlocked. The arms are kept straight and the sternum is rhythmically depressed by 5–6 cm at a rate of approximately 100–120 per minute, allowing for complete recoil between compressions.

Chest compressions do not massage the heart; rather the thorax acts as a pump and the heart provides a system of one-way valves to ensure forward circulation. Respiratory and circulatory support is continued by providing two effective breaths for every 30 cardiac compressions (30:2 for one or two persons in an adult patient, 15:2 in paediatric patients). It is easier for the lay public to give compressions without interruption ('hands only CPR'), with mouth-to-mouth resuscitation considered less effective, and with obvious potential infection control consequences. CPR may be considered an aerosol-generating procedure, so adequate personal protective equipment should be considered in certain conditions including COVID-19 infection.

CPR maintains adequate cerebral and coronary perfusion pressures. The initiation of early CPR by the lay public at the site of the arrest saves lives. There is evidence to suggest that if the person performing compressions tires, the quality of resuscitation deteriorates. Mechanical CPR devices are available but not yet universally used; they may be of most use in more prolonged resuscitation attempts, for example after thrombolysis in pulmonary embolism (PE). Cardiac enzyme levels will likely rise after CPR.

Breathing

After 30 compressions, the rescuer opens the victim's airway by tilting the head backwards ***(head tilt)*** and pulling the chin forwards (***chin lift*** or ***jaw thrust***). The rescuer then pinches the victim's nostrils firmly, takes a deep breath, and seals their lips around the mouth of the victim. Two effective breaths are given, each over 1 second. In paediatric patients, respiratory arrests are more common

and patients should be given rescue breaths and a minute of CPR before a sole rescuer leaves the victim to seek help. CPR should not be interrupted to reassess the victim unless they start to show signs of life and begin to breathe normally.

Advanced cardiac life support

By the time effective life support has been established, more help should have arrived and advanced cardiac life support (ACLS) can begin. This consists of ECG monitoring, advanced airway management (endotracheal intubation or supraglottic airway tube) and establishment of an intravenous infusion in a large peripheral or central vein (an intraosseous needle [see **Box 11.6**] may be used if intravenous access is not possible). As soon as feasible, the cardiac rhythm should be established, as this determines which pathway of the European Resuscitation Council and the Resuscitation Council UK ACLS algorithm is followed (**Fig. 11.12**). This can be determined with an automated external defibrillator (AED), or the paddles or limb leads of a standard defibrillator.

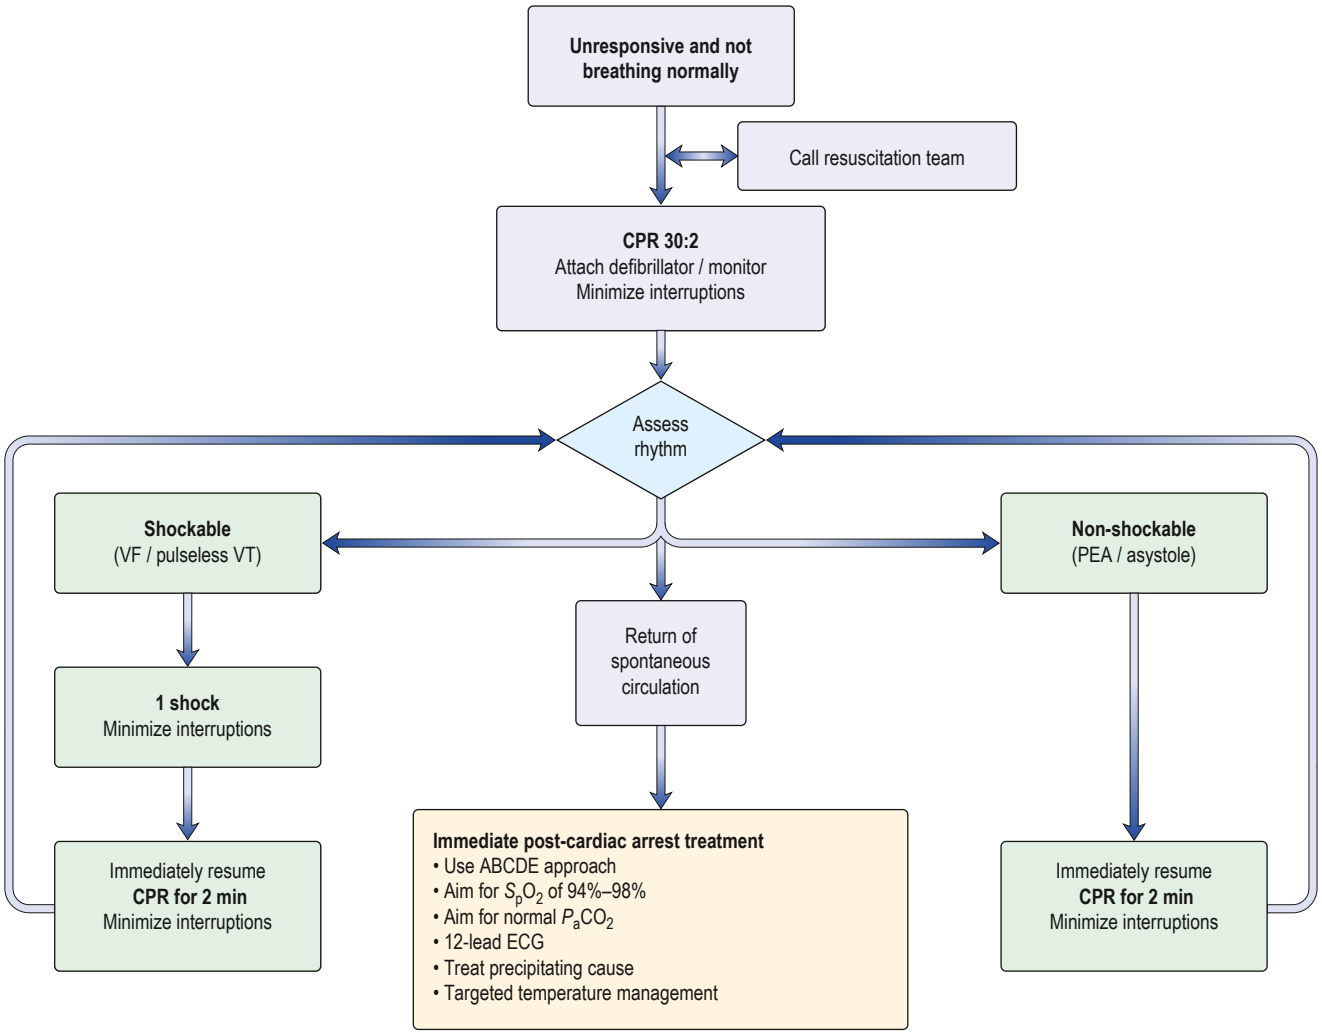


Fig. 11.12 Adult advanced life support algorithm. *ABCDE,* Airway, Breathing, Circulation, Disability, Exposure; *CPR,* cardiopulmonary resuscitation; *PEA,* pulseless electrical activity; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia. *(Reproduced with permission from the Resuscitation Council; http://www.resus.org.uk.)*

- If the ECG shows a shockable rhythm—ventricular fibrillation or pulseless ventricular tachycardia—then an unsynchronized shock of 150–200 J biphasic (360 J monophasic) is delivered without delay via paddles or self-adhesive pads, followed immediately by 2 min of CPR.
- For a non-shockable rhythm—asystole or pulseless electrical activity—2 minutes of CPR is delivered with 1 mg of intravenous adrenaline (epinephrine).

For both sides of the algorithm, it is vital to maintain CPR, ensure oxygenation, and exclude or treat reversible causes—the ***'four Hs and four Ts':***

- ***Hypoxia*** should be minimized by ventilating the patient with oxygen and a bag-valve mask or advanced airway (endotracheal intubation or supraglottic airway), ensuring that there is bilateral air entry and chest expansion. With an advanced airway, CPR should continue, with a ventilation rate of 10 per minute without interrupting cardiac massage.
- ***Hypovolaemia*** is a frequent cause of pulseless electrical activity due to haemorrhage. Intravenous volume should be replaced.
- ***Hyper-*** or ***hypokalaemia*** may cause ECG abnormalities and should be detected by biochemical testing. Intravenous calcium chloride may be helpful in hyperkalaemia or hypocalcaemia. Acidosis should be managed with effective ventilation.
- ***Hypothermia*** should be excluded with a low-reading thermometer and treated with external or internal warming.
- ***Thrombosis of the heart*** and massive PE may cause pulseless electrical activity and patients should be considered for thrombolysis, thrombectomy, or primary PCI as appropriate, and if available.
- ***Tension pneumothorax*** may occur during central venous cannulation, or following chest trauma including barotrauma. Diagnosis is clinical (deviated trachea, hyper-resonant chest, absent breath sounds, ultrasound) and needle thoracocentesis or thoracostomy may be required. The 'safe triangle' (**Box 11.7**), using a specialist longer 10G non-kinking thoracocentesis catheter, is the preferred site of insertion and has a lower failure rate than the traditional approach of inserting a 14G or 16G cannula in the 2nd intercostal space, midclavicular line.
- ***Tamponade*** should be excluded with echocardiography; if present, it should be treated with pericardiocentesis ('Pericardiocentesis' section in Chapter 17).
- ***Toxins*** may have been ingested by accident or deliberate self-harm, and standard care, as well as specific antidotes should be used in appropriate patients.

POCUS is increasingly used by competent members of the resuscitation team as an adjunct to diagnosis of cardiac tamponade and tension pneumothorax, but should be deployed skilfully and not at the expense of effective chest compressions.

Defibrillation

This technique is used to convert ventricular fibrillation or pulseless ventricular tachycardia to sinus rhythm. When the defibrillator is discharged, a high-voltage field envelops the heart, depolarizing the myocardium and allowing an organized heart rhythm to emerge. Electrical energy is discharged through two paddles with gel pads or adhesive pads placed on the chest wall.

The paddles are placed in one of two positions:

- One paddle is placed to the right of the upper sternum and the other over the cardiac apex.
- One paddle is placed under the tip of the left scapula and the other over the anterior wall of the left chest.

All personnel should stand clear of the patient. The person performing defibrillation has responsibility for ensuring the safety of the patient and of the other people present. Conventional defibrillators employ a damped monophasic waveform. Biphasic defibrillators, which require less energy, are increasingly common. AEDs, which recognize ventricular fibrillation automatically, deliver a shock if indicated. These are available in some public places (in the UK, their location is signalled by a specific sign, **Fig. 11.13**). It is the responsibility of all healthcare practitioners to be familiar with the range of defibrillators they may be called on to use in their workplace.

Post resuscitation—targeted temperature management

Early studies suggested that 24 hours of therapeutic hypothermia (32°C–34°C for 12–24 h) might potentially improve outcomes in unconscious adult patients with spontaneous circulation after an out-of-hospital cardiac arrest due to ventricular fibrillation. A recent large international trial (TTM2) randomizing 1900 patients to either hypothermia (33°C) or normothermia (avoidance of temperatures >37.8°C) in the 28-hour period following out-of-hospital cardiac arrest did not demonstrate a difference in either all-cause mortality or functional outcomes, casting doubt over the routine employment of therapeutic hypothermia after cardiac arrest. The current European Resuscitation Council guidelines, however, do continue to recommend a target temperature between 32°C and 36°C in patients who remain unresponsive (GCS < 8) for the 24-hour period following ROSC.

Neurological recovery appears to be more favourable in patients with purposeful movements and electroencephalogram activity within 3 days of a cardiac arrest.

Therapeutic procedures used for peri-arrest rhythms

Direct current cardioversion

Tachyarrhythmias that do not respond to medical treatment or are associated with haemodynamic compromise (heart failure, infarction, shock, syncope—'HISS') may be converted to sinus rhythm by the use of a transthoracic electric shock. A short-acting general anaesthetic is used. Muscle relaxants are not usually given.

Fig. 11.13 **UK sign indicating the location of automated external defibrillators.**

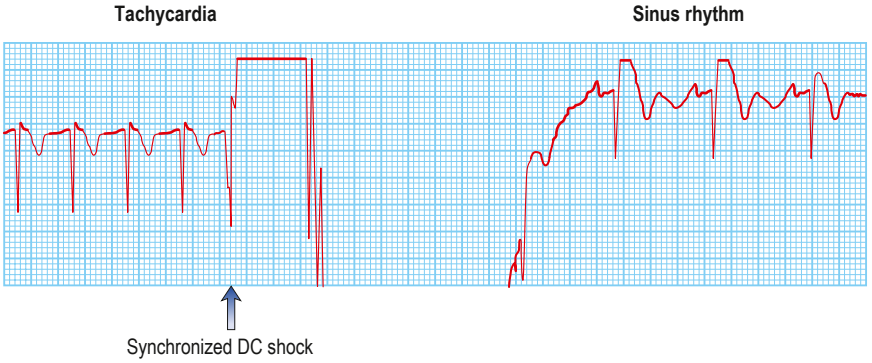

Fig. 11.14 Direct current (DC) cardioversion of a supraventricular tachycardia to sinus rhythm.
The direct current shock is delivered synchronously with the QRS complex.

When the arrhythmia has definite QRS complexes, delivery of the shock should be timed to coincide with the downstroke of the QRS complex (synchronization, Fig. 11.14). The machine being used to perform the direct current cardioversion (DCC) will do this automatically if the appropriate button is pressed. There is a crucial difference between defibrillation and cardioversion: a non-synchronized shock is used to defibrillate. Accidental defibrillation of a patient who does not require it may itself precipitate ventricular fibrillation.

Typical indications for DCC include:

- atrial fibrillation (often refractory so consider higher voltage)
- atrial flutter
- sustained ventricular tachycardia
- junctional tachyarrhythmias.

If atrial fibrillation or flutter has been present for more than 48 hours, it is necessary to anticoagulate the patient adequately for 3 weeks before elective cardioversion to reduce the risk of embolization. The duration of anticoagulation after successful cardioversion for atrial fibrillation is a complex issue and depends on a number of factors: it should be given for at least 4 weeks after the procedure and may well be given for much longer.

Digoxin toxicity may lead to ventricular arrhythmias or asystole following cardioversion. Therapeutic digitalization does not increase the risks of cardioversion, but it is conventional to omit digoxin several days prior to elective cardioversion in order to be sure that toxicity is not present.

Cardiac enzyme levels may rise after a cardioversion.

Temporary cardiac pacing

Therapeutic cardiac pacing is employed in any patient with sustained symptomatic or haemodynamically compromising bradycardia. Bradycardias may be due to either a slow intrinsic heart rate (e.g., sinus node dysfunction) or atrioventricular (AV) block. Reversible causes of bradycardia should be addressed in parallel (e.g., electrolyte abnormalities, overdose of beta-blockers or digoxin) and the use of a positive chronotropic medication such as isoprenaline may be required as an interim measure.

Transvenous pacing is the preferred method in patients with symptomatic bradycardias. In summary, a thin (French gauge 5 or 6), bipolar pacing electrode wire is inserted via an internal jugular vein, a femoral vein, or a subclavian vein and is positioned at the right ventricular apex using cardiac fluoroscopy. The energy needed for successful pacing (the pacing threshold) is assessed by reducing the energy until the pacemaker fails to stimulate the tissue (loss of capture). The output energy is then set at three times the threshold value to prevent inadvertent loss of capture. If the threshold increases above 5 V, the pacemaker wire should be resited. A temporary pacemaker unit (Fig. 11.15) is almost always set to work 'on demand'—to fire only when a spontaneous beat has not occurred. The rate of temporary pacing is usually 60–80 per minute.

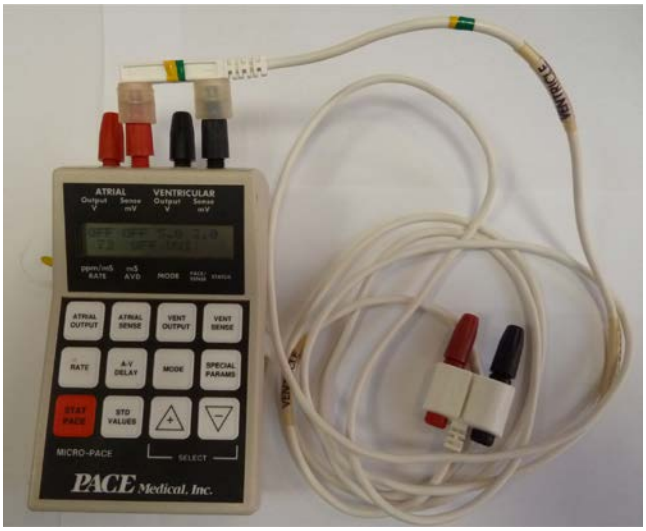

Fig. 11.15 Pacemaker. A temporary pacemaker unit.

Transcutaneous pacing may be life-saving when a cardiac arrest is precipitated by bradycardia or in instances of severe symptomatic bradycardia where transvenous pacing is not readily available. In this method the myocardium is depolarized by current flow between two large adhesive electrodes positioned anteriorly and posteriorly on the chest wall. Most modern monitor/defibrillator devices have transcutaneous pacing capability. Transcutaneous pacing is uncomfortable for the conscious patient (so safe sedation and appropriate analgesia should be sought) but can usually be tolerated until a temporary transvenous pacemaker is inserted.

Insertion of the various types of permanent pacemaker is discussed in Chapter 17.

Ventricular tachyarrhythmias

Ventricular tachyarrhythmias can be discussed under the following headings:

- life-threatening ventricular tachyarrhythmias
  - sustained ventricular tachycardia
  - ventricular fibrillation
  - torsades de pointes
- normal heart ventricular tachycardia

- non-sustained ventricular tachycardia
- ventricular premature beats (ectopics).

Some of these conditions are caused by cardiac channelopathies, congenital disorders resulting from mutations that affect the function of cardiac ion channels and hence the electrical activity of the heart. They include Brugada syndrome, congenital long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT) and idiopathic ventricular fibrillation, Torsades de pointes, normal heart VT, non-sustained VT, and ventricular premature beats (discussed further in Chapter 17).

Sustained ventricular tachycardia

Sustained ventricular tachycardia (>30 sec) often results in ***presyncope*** (a feeling that one might collapse), ***syncope***, ***hypotension***, and ***cardiac arrest***, although it may be remarkably well tolerated in some patients. Examination reveals a pulse rate typically between 120 and 220 b.p.m. Usually, there are clinical signs of atrioventricular dissociation (i.e., intermittent cannon 'a' waves in the neck and variable intensity of the first heart sound).

The ECG shows a rapid ventricular rhythm with broad (often ≥0.14 sec), abnormal QRS complexes (**Fig. 11.16**). AV dissociation may result in visible P waves, which appear to march through the tachycardia, capture beats (an intermittent narrow QRS complex owing to normal ventricular activation via the AV node and conducting system) and fusion beats (intermediate between ventricular tachycardia beat and capture beat).

Supraventricular tachycardia (SVT) with bundle branch block may resemble ventricular tachycardia on the ECG. However, if a broad-complex tachycardia is due to SVT with either right or left bundle branch block, the QRS morphology should resemble a typical right bundle branch block or left bundle branch block pattern (see **Figs. 17.39A and 17.40**). Other ECG criteria to differentiate ventricular tachycardia from SVT with aberrancy are indicated in **Box 11.14**. Some 80% of all broad-complex tachycardias are due to ventricular tachycardia and the proportion is even higher in patients with structural heart disease. Therefore, in all cases of doubt, ventricular tachycardia should be diagnosed.

Management

Treatment may be urgent, depending on the haemodynamic situation. If the patient is haemodynamically compromised (e.g., hypotensive or pulmonary oedema), emergency DC cardioversion may be required. On the other hand, if the blood pressure and cardiac output are well maintained, intravenous therapy with amiodarone is often started, although upon specialist advice, other therapies such as intravenous beta-blockers (esmolol) or class I drugs (e.g., lidocaine) can be considered. DC cardioversion is necessary if medical therapy is unsuccessful, although it is important to consider correcting any potential reversible contributory causes including electrolyte abnormalities or toxins, to reduce the risk of relapse.

Ventricular fibrillation (VF)

This involves very rapid and irregular ventricular activation with no mechanical effect. The patient is pulseless and becomes rapidly unconscious; respiration ceases (cardiac arrest). The ECG shows shapeless, rapid oscillations and there is no hint of organized complexes (**Fig. 11.17**). It is usually provoked by a ventricular ectopic beat. Ventricular fibrillation rarely reverses spontaneously. The only effective treatment is electrical defibrillation. Basic and advanced cardiac life support is needed. Again, correcting any reversible causes may help with management.

Box 11.14 ECG distinction between supraventricular tachycardia with bundle branch block and ventricular tachycardia

Ventricular tachycardia is more likely than supraventricular tachycardia with bundle branch block where there is:

- a history of ischaemic heart disease
- a very broad QRS (>0.14 sec)
- atrioventricular dissociation
- a bifid, upright QRS with a taller first peak in V_1
- a deep S wave in V_6
- a concordant (same polarity) QRS direction in all chest leads (V_1–V_6)

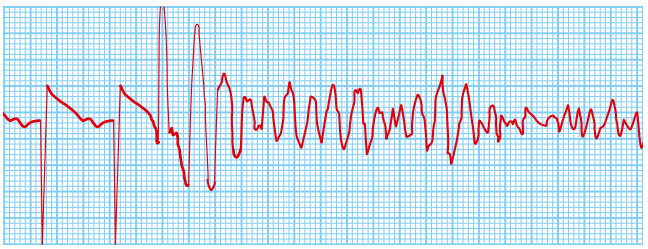

Fig. 11.17 Ventricular fibrillation. Two beats of sinus rhythm are followed by a ventricular ectopic beat that initiates ventricular fibrillation. The ST segment during sinus rhythm is elevated, owing to acute myocardial infarction in this case.

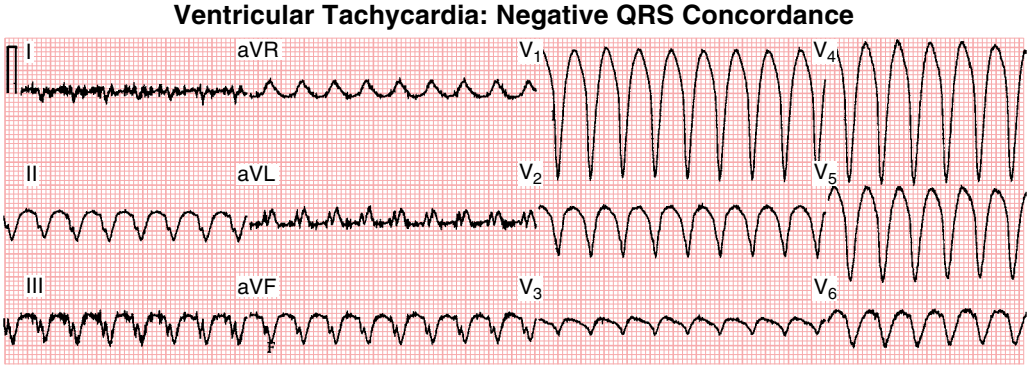

Fig. 11.16 Ventricular tachycardia.. Note the concordance (same polarity) of QRS complexes in all chest leads. *(Adapted from Goldberger's Clinical Electrocardiography: A Simplified Approach, Tenth Edition.)*

If the attack of VF occurs during the first day or two of an acute myocardial infarction, it is probable that prophylactic therapy will be unnecessary. If the ventricular fibrillation was not related to an acute infarction, the long-term risk of recurrent cardiac arrest and sudden death is high.

Survivors of these ventricular tachyarrhythmias are, in the absence of an identifiable reversible cause (e.g., acute myocardial infarction, severe metabolic disturbance), at high risk of sudden death. Implantable cardioverter–defibrillators are first-line therapy in the management of these patients (see Chapter 17).

Anaphylaxis

Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death. It arises as an acute, generalized IgE-mediated immune reaction involving specific antigen, mast cells, and basophils. The reaction requires priming by the allergen, followed by re-exposure. To provoke anaphylaxis, the allergen must be systemically absorbed, after either ingestion or parenteral injection. A range of allergens that provoke anaphylaxis has been identified (**Box 11.15**).

Anaphylaxis is rare, but the symptom/sign constellation ranges from widespread urticaria to cardiovascular collapse, laryngeal oedema, airway obstruction, and respiratory arrest leading to death:

- Fatal reactions to penicillin occur once every 7.5 million injections.
- Between 1 in 250 and 1 in 125 individuals have severe reactions to bee and wasp stings, and a death takes place every 6.5 million stings, with 60–80 deaths per year in North America and 5–10 in the UK.

Central to the pathogenesis of anaphylaxis is the activation of mast cells and basophils, with systemic release of some mediators and generation of others. The initial symptoms may appear innocuous: tingling, warmth, and itchiness. The ensuing effects on the vasculature lead to vasodilation and oedema. The consequence may be no more than a generalized flush, with urticaria and angio-oedema. More serious sequelae are hypotension, bronchospasm, laryngeal oedema, and cardiac arrhythmia or infarction. Death may occur within minutes.

Serum platelet-activating factor (PAF) levels correlate directly with the severity of anaphylaxis, whereas PAF acetylhydrolase (the enzyme that inactivates PAF) correlates inversely and is significantly lower in peanut-sensitive patients with fatal anaphylactic reactions.

Box 11.15 Sources of allergens known to provoke anaphylaxis

Foods
- Nuts: peanuts (protein—*Arachis hypogaea* Ara h 2), Brazil, cashew
- Shellfish: shrimp (allergen Met e 1), lobster
- Dairy products
- Egg
- More rarely: citrus fruits, mango, strawberry, tomato

Venoms
- Wasps, bees, yellow-jackets, hornets

Medications
- Antisera (tetanus, diphtheria), intravenous iron, latex, some antibiotics

Management

Early recognition and treatment are essential (**Box 11.16**). Longer-term avoidance and desensitization strategies for patients who experience anaphylaxis are discussed in Chapter 6.

Chest pain

Chest pain is a common presenting symptom with a large number of potential causes (**Box 11.17**). Causes can be broken down anatomically into cardiac, vascular (aortic or pulmonary) GI, musculoskeletal, neuropathic, or respiratory. Patients with pathology below the diaphragm may also experience referred pains within the chest.

Clinical assessment

Initial emergency assessment should follow the 'ABCDE' approach to ensure that serious or life-threatening perturbations of physiology are identified promptly. In unwell patients, clinical assessment, point-of-care testing, and emergency resuscitative management measures may need to commence in parallel, with definitive treatment initiated once the diagnosis is clear.

History

- Determining the **character of pain** is vital: ischaemic pain is typically 'oppressive' in character and described as a 'heaviness', 'tightness', or 'pressure' behind the sternum and may radiate to the left shoulder, arm, or jaw. Pleuritic pain is sharp and worse on breathing and indicates pleural inflammation or irritation (commonly

Box 11.16 Treatment of acute anaphylaxis

Clinical features
- Bronchospasm
- Facial and laryngeal oedema
- Hypotension
- Nausea, vomiting, and diarrhoea

Management
- ABCDE (airway, breathing, circulation, disability, exposure)
- Position the patient lying flat with the feet raised
- Ensure the airway is free
- Give high-flow oxygen
- Monitor blood pressure
- Establish venous access
- Administer 0.5 mg *intramuscular* adrenaline (epinephrine) 0.5 mL of 1:1000 adrenaline, i.e., 1 mg/mL, and repeat after 5 min if shock persists. Note that antihistamines and steroids are not currently routinely indicated as per Resus Council UK
- If refractory, consider a peripheral low-dose i.v. adrenaline infusion 0.5–1.0 mL/kg/h with specialist guidance, and titrate to effect. Further i.m. adrenaline every 5 minutes may be needed until an i.v. infusion is established
  - If hypotension persists, give 1–2 L of intravenous fluid
  - If hypoxia is severe, assisted ventilation may be required, however, be aware that the airway may be oedematous and may become compromised
  - Take blood for tryptase levels within 1–2 h ideally (aids diagnosis)

Box 11.17 Differential diagnosis of acute chest pain

Cause	History clues	Examination clues	Investigations	Other comments
ACS (unstable angina, NSTEMI/STEMI)	Oppressive pain radiating from chest to arm, neck, or jaw. Heavy/pressure. May be atypical especially in older patients/those with diabetes	Often normal but may be sweaty (diaphoresis)	ECG: Dynamic changes may accompany pain; ST elevation/depression, LBBB, Q waves if delayed presentation. Normal ECG does not exclude ACS CXR: Often normal, may have cardiomegaly, signs of LVF Troponin may be raised if NSTEMI/STEMI (but elevations may take up to 12 hours after pain to become apparent)	Risk stratification e.g., GRACE score (Box 17.33). If NSTEMI or STEMI refer urgently to cardiology
Aortic dissection	Pain often sudden onset and radiating to the back or abdomen. May cause TLOC. May have history of aortic or connective tissue disease	Asymmetrical or absent pulses. Discrepancy in BP between limbs. Murmur of AR (EDM) may be evident if dissection involves aortic valve. Hypotension suggests tamponade or uncontained rupture and requires immediate surgery	ECG: May be normal, often shows LVH, may have similar changes to ACS if coronary blood supply is compromised CXR: Often normal, may have cardiomegaly or widened mediastinum, signs of LVF. Pericardial effusion (globular heart) if aortic root involved Troponin often elevated D-dimer often raised	Maintain an index of suspicion for aortic dissection as treating incorrectly for ACS may be fatal. May be apparent on echo, CT angiography diagnostic. Referral to surgical team imperative
Gastrointestinal (gastro-oesophageal reflux, diffuse oesophageal spasm)	Nocturnal pain, especially when lying on back/right-hand side. Acid brash in throat. Delayed response to GTN. Relief with belching. Dysphagia or dyspepsia. Relationship to meals	May have epigastric tenderness	ECG and CXR usually normal Blood tests: Usually normal, but severe anaemia could elevate troponin and cause a type II MI	Consider raising head end of bed/sleeping on left-hand side. Avoiding spicy food, alcohol, or certain medications such as NSAIDs/steroids may help Consider treatments such as alginates/H_2-receptor antagonists (e.g., famotidine) or PPIs (e.g., lansoprazole)
Musculoskeletal (e.g., costochondritis)	Pain worse on movement. History of straining or recent viral illness	Reproducible with movement of chest especially against opposition Joint tenderness may be present	ECG, CXR, and blood tests usually normal	Vitamin D replacement, if low levels noted, may be helpful for some patients Simple analgesia as treatment
Neuropathic (e.g., herpes zoster infection)	Pain over one dermatome/radiates. May feel like electric shock. Previous or current shingles	Rash or scar of shingles	ECG, CXR, and blood tests usually normal	Consider medications for neuropathic pain including amitriptyline/gabapentin/pregabalin
Pericarditis	Retrosternal sharp stabbing pain that radiates to arm or shoulder, may be relieved by leaning forwards. Cardiac surgery/MI in past 2 months may suggest Dressler syndrome	Pericardial friction rub may be heard left lower sternal border on inspiration (if patient leaning forwards)	ECG: Diffuse saddle-shaped ST elevation with accompanying PR depression CXR: May be normal, if effusion then globular cardiac silhouette Elevated troponin suggests myopericarditis and warrants further investigation	Consider uraemia, chronic inflammatory diseases e.g., SLE or familial fevers Consider aspirin/NSAIDs/colchicine. If effusion may need to exclude tamponade
Pulmonary embolism	Usually pleuritic pain if small peripheral clot, pain from a central clot may be non-specific quality	Tachypnoea, tachycardia, possibly new AF. If large clot then raised JVP and TR (right ventricular strain)	ECG: Tachycardia most common, followed by AF. Right axis deviation, RBBB may suggest large burden of clot. S1Q3T3 suggestive of PE but rarely seen CXR: Oligaemic lung fields (Westermark sign), elephant trunk pulmonary arteries may indicate pulmonary hypertension. Small pleural effusions or wedge-shaped lung infarction may be noted D-dimer positive, Troponin and BNP being raised suggestive of more severe disease	CTPA usually used, or V/Q SPECT scan considered if pregnant/contrast allergy/CKD Echo may be helpful if suspect right heart strain and consideration of thrombolysis or thrombectomy

Continued

Box 11.17 Acute causes chest pain: Differential diagnoses—cont'd

Cause	History clues	Examination clues	Investigations	Other comments
Respiratory pathology e.g., pneumonia/pleural disease	Pleuritic pain often accompanied by other symptoms of respiratory disease (e.g., cough, productive of sputum, fevers)	Pleural friction rub indicates pleural inflammation of any cause. Additional lung signs may point to cause (e.g., bronchial breathing and coarse crackles in pneumonia)	ECG usually normal CXR: Lobar collapse/consolidation, pleural effusion/reaction/ pneumothorax Raised inflammatory markers in pneumonia, also note D-dimer and troponin may be elevated in sepsis	Treatment is that of underlying disease. Colchicine may be of use in inflammatory pleural disease

ACS, Acute coronary syndrome; *AR,* aortic regurgitation; *EDM,* early diastolic murmur; *GRACE,* Global Registry of Acute Coronary Events; *LBBB,* left bundle branch block; *LVF,* left ventricular failure; *LVH,* left ventricular hypertrophy; *RBBB,* right bundle branch block; *TLOC,* transient loss of consciousness; *TR,* tricuspid regurgitation.

pneumonia, PE, or pneumothorax). A 'tearing' sensation or pain of sudden onset radiating to the back should always raise suspicion of aortic dissection. The pain of pericarditis is often sharp, may be worsened by breathing or lying flat, and is classically eased by leaning forwards. Pain from gastro-oesophageal causes is usually easily recognized ('heartburn') although diffuse oesophageal spasm may mimic cardiac ischaemic pain. Atypical pain descriptions are more common in elderly patients and those with diabetes.

- **Onset:** pain of very sudden onset often implies either a vascular (cardiac ischaemia, aortic dissection, PE) or mechanical (pneumothorax, rib fracture) cause.
- Consider **aggravating and relieving factors:** does the patient describe a prodrome of chest pain provoked by exertion and relieved by rest? (angina—although myocardial infarction (MI) is often the first manifestation of coronary artery disease). Is there a relationship to meals? (gastro-oesophageal reflux disease). Improvement in pain after sublingual GTN is often held to reflect ischaemic pain, but carries a poor predictive value for this diagnosis.
- Seek **associated symptoms:** cough with production of sputum or fever may signify pneumonia. Haemoptysis may reflect pulmonary infarction (PE) or infection.
- Consider the **past medical history:** has the patient undergone previous coronary revascularization procedures (e.g., angioplasty or stenting)? Have they had recent investigations for coronary ischaemia (e.g., angiography)? Do they have a known risk factor for PE (e.g., recent major surgery, immobility) or aortic dissection (e.g., Marfan's syndrome or history of bicuspid aortic valve)?
- History should include an assessment of **clinical risk factors for ischaemic heart disease** (including smoking history, hypertension, diabetes, obesity, and hypercholesterolaemia).

Physical examination

Examination should be systematic and include a full assessment of respiratory and cardiovascular systems (including peripheral vascular examination) along with focused examination of the abdomen and relevant neurology. Tachycardia and tachypnoea are non-specific but often signify the presence of significant cardiac or respiratory pathology. Patients with ischaemic chest pain may be diaphoretic (sweating, pale) or reveal stigmata of risk factors for coronary disease (e.g., tar staining of fingertips, xanthelasmata) but examination is often normal.

- A difference in systolic blood pressure >20 mmHg between the arms or pulse deficits should raise suspicion of aortic dissection.
- General examination should include a search for signs of atheromatous disease in other territories (absent foot pulses, vascular bruits) and DVT (asymmetrical calf swelling or tenderness). Signs of conditions which may unmask or aggravate angina (e.g., anaemia, thyrotoxicosis, aortic stenosis) should also be noted.
- Atrial fibrillation (characterized by an irregularly irregular pulse) may either complicate or aggravate (in the context of a rapid ventricular response rate) cardiac ischaemia, while AV block (bradycardia) may develop in patients with an inferior MI.
- A dermatomal vesicular rash implies shingles, although dermatomal pain may precede the onset of rash.
- Point tenderness at the margin of the sternum is typical of costochondritis, although many patients with chest pain will describe local tenderness on palpation and this should hence be interpreted with caution.
- Elevated JVP may indicate right ventricular strain (submassive PE) or compression (cardiac tamponade, tension pneumothorax) or congestive cardiac failure (e.g., complicating a myocardial infarction). These patients are typically very unwell and may be hypoxic or haemodynamically unstable.
- Patients with pleuritic chest pain may have an audible pleural rub (indicating pleural inflammation) while a pericardial rub may be audible in patients with pericarditis.
- Chest examination may yield signs consistent with a specific pulmonary diagnosis (e.g., bronchial breathing and coarse crackles in a patient with pneumonia, reduced breath sounds, and hyperresonant percussion note in a patient with pneumothorax). Care should be taken to examine all lung areas, including the apices (supraclavicular) and axillae.
- Abdominal examination will identify epigastric tenderness (sometimes interpreted by a patient as 'chest' pain) and possible sources of subdiaphragmatic referred pain (e.g., cholecystitis, pancreatitis).

Investigations

- **Oxygen saturations** will identify a hypoxic patient at the bedside.
- **Core laboratory tests** may reveal a low haemoglobin (anaemia), elevated white blood cell count and CRP (infection), or metabolic abnormalities. Renal function testing is required for GRACE score calculation (a widely used ACS risk model, **Box 17.33**). A pregnancy test should be conducted in premenopausal female patients.
- **ECG** is a high-yield investigation in patients presenting with chest pain. Careful examination may disclose signs of ischaemia (ST elevation or depression, new LBBB or T-wave inversion), pericarditis (diffuse saddle-shaped ST elevation accompanied by PR segment depression), or PE (right axis deviation, RBBB or S1Q3T3 pattern). ACS may be complicated by both tachy- or bradyarrythmias. Serial ECG monitoring (initially every 15 min) is indicated in patients with persistent ischaemic pain.
- **Cardiac troponins** rise rapidly (hours) in myocardial infarction and remain elevated for several days. Levels correlate with cardiac myocyte damage and positive predictive value (PPV) for

myocardial infarction increases with higher levels (levels >5× the upper reference limit have a PPV >90% for acute MI). Serial levels will discriminate acute cardiac injury (rising troponin level) from chronic cardiomyocyte damage (static levels). New high-sensitivity troponin T assays have enabled development of rapid 'rule-out' algorithms in low-risk individuals although protocols still vary widely between hospitals. Importantly, troponin rises are not specific for cardiac ischaemia and may be seen when cardiac myocyte damage occurs for other reasons (e.g., myocarditis or PE).

- **D-dimer testing** may be indicated (see section 'Deep vein thrombosis and pulmonary embolism').
- **Chest X-ray** (ideally postero-anterior) may reveal consolidation (pneumonia), mediastinal widening (aortic dissection), and signs of congestive cardiac failure or pneumothorax. Globular heart enlargement suggests presence of a pericardial effusion. Bones and soft tissues should be inspected carefully for fractures or presence of surgical emphysema.
- **POCUS or bedside echo** could be used to look for pneumothoraces, pleural effusions, consolidation, dissections, biliary dilatation or right ventricular overload, and pericardial disease. In experienced hands, it may also support assessment of intravascular filling or in diagnosis of a DVT in a patient with possible PE.
- **Further testing** may include departmental echocardiography (to assess for left ventricular function, the presence of regional wall motion abnormalities or pericardial effusion), CT scanning (e.g., diagnosis of aortic dissection or pulmonary embolus), or emergency coronary angiography (STEMI or very high-risk NSTE-ACS).

Management

Management of the patient with chest pain varies with the underlying cause.

Patients with ischaemic chest pain require continuous cardiac monitoring and often need intravenous analgesia and antiemetics for symptom control. Patients predicted to require emergency coronary angiography (STEMI or very high-risk NSTE-ACS) are often transported directly by paramedic crews to cardiac hubs, but otherwise require immediate discussion with local primary PCI services. Aspirin (300 mg) is indicated in all patients with ACS and often administered by paramedics.

Management of acute coronary syndromes is discussed in Chapter 17 (see 'Acute coronary syndrome' section).

Palpitations

Palpitations are a common presenting problem across all age groups and are a frequent reason for referral to acute medical services. Palpitations can be defined as the awareness of a hard, irregular, or rapid heartbeat. A key factor in patients deciding to seek medical advice is that this subjective awareness of cardiac activity is experienced as unpleasant or distressing. Palpitations may be benign or physiological (e.g., in stressful situations or pregnancy), or pathophysiological (e.g., arrhythmias). The majority of patients experiencing palpitations have a very good prognosis and so the challenge of the acute physician is to identify the minority who have an underlying arrhythmia or other significant disorder.

Differential diagnosis

Causes of palpitations can be classified as either arrhythmic or non-arrhythmic (**Box 11.18**). The latter includes any cause of sinus tachycardia. Arrhythmic causes of palpitations each, in turn, have their own list of potential causes (e.g., for atrial fibrillation, causes may include ischaemia, sepsis, thyrotoxicosis, alcohol, electrolyte disturbances, etc.).

? Box 11.18 Causes of palpitations

Arrhythmic	Non-arrhythmic (usually sinus tachycardia)
Sinus arrhythmia (rarely, usually asymptomatic)	Cardiopulmonary • Heart failure • Myocarditis • Myocardial infarction • Pulmonary embolus • Hypoxia (any cause)
Ectopic beats (atrial or ventricular)	Anaemia
Vasovagal syncope (more commonly experienced as dizziness)	Endocrine • Thyrotoxicosis • Phaeochromocytoma • Carcinoid syndrome
Tachyarrhythmias • Atrial fibrillation or flutter • Atrial tachycardia • Supraventricular tachycardias (including pre-excitation syndromes such as Wolff-Parkinson-White) • Ventricular tachycardia • Torsade de pointes • Ventricular fibrillation (the patient will not be conscious at presentation)	Drugs • Caffeine • Recreational stimulants (e.g., cocaine, amfetamine) • β_2 agonists (e.g., salbutamol), certain decongestants (e.g., pseudoephedrine) • Nicotine • Alcohol or therapeutic drug withdrawal)
Bradyarrhythmias (less commonly felt as palpitations than tachyarrhythmias) • Sick sinus syndrome • Heart (AV) block	Physiological • Stress/anxiety • Fever • Pregnancy

Clinical assessment

As with all medical emergencies, an initial focused assessment following the ABCDE approach should proceed in parallel with information gathering. In the case of ongoing tachy- and bradyarrhythmias accompanied by haemodynamic compromise ('peri-arrest rhythms'), immediate interventions are required (see 'Therapeutic procedures used for peri-arrest rhythms').

When taking a history, care should be taken to ascertain precisely what the patient means by 'palpitations'; in some cases, careful probing may establish that the patient is in fact experiencing another symptom for example, breathlessness. **Box 11.19** outlines helpful questions to ask patients who present with palpitations.

Investigations

- **Laboratory investigations:** Full blood count (exclude anaemia), urea and electrolytes, CRP (infection), thyroid function tests (TFTs).
- **12 lead ECG:** A high-yield investigation. Where the palpitations are ongoing, this will demonstrate the associated cardiac rhythm. In patients where the palpitations have resolved, look for electrical abnormalities which may point towards the diagnosis (e.g., the short PR interval and 'delta wave' of Wolff-Parkinson-White syndrome; signs of conduction disease such as prolonged PR interval or bundle branch block).
- **24- or 48-hour Holter monitor** or 7-day event recorder depending on frequency. Required for patients with intermittent

Box 11.19 Questions for patients presenting with palpitations

1. What were you doing at the time of onset (or in the hours before)? Including an enquiry about potential precipitants including caffeine, prescription and recreational drug use.
2. Are the palpitations constant or do they come and go?
Many patients are asymptomatic by the time of presentation. Ongoing symptoms of 'palpitations' in the absence of tachycardia may indicate inaccurate labelling. A sensation of transient 'jumping' or 'jolting' may indicate ectopic beats.
3. Did the palpitations start suddenly or gradually? Did they stop suddenly or gradually?
Paroxysmal arrhythmias are typically of sudden onset. This is particularly true of SVTs, where both onset and 'offset' may be abrupt. Palpitations due to sinus tachycardia often build up and resolve more gradually.
4. Can you describe the palpitations or 'tap out' the rhythm? Was it regular or irregular?
This is particularly helpful in discriminating paroxysmal atrial fibrillation from regular tachycardias.
5. Any 'red flag' symptoms e.g., syncope or presyncope, chest pain, breathlessness. Or other associated symptoms (e.g., tremor, flushing, diarrhoea, wheezing)?
The presence of red flag symptoms points towards a significant underlying disorder (usually an arrhythmia). Other symptoms may point towards a systemic disorder (e.g., thyrotoxicosis, carcinoid syndrome, or phaeochromocytoma).
6. What is happening in your life at present? (stress, pregnancy, other illness)
7. Is there any personal or family history of cardiac disease, or family history of sudden cardiac death?

symptoms where a reasonable index of suspicion exists for a paroxysmal arrhythmia.
- Consider **echocardiogram** (if personal or family history of cardiac disease, presence of red flags in history, audible murmur, or other signs of structural heart disease)
- Other targeted investigations may be required both to investigate the cause of an arrhythmia if one is identified, or if clinical assessment has suggested another specific cause of palpitations (e.g., phaeochromocytoma).

Management

Management varies with underlying cause.

Patients with 'red flag' symptoms (syncope, chest pain, breathlessness) where the cause is not immediately identified or rectifiable, will typically need admission for a period of observation with continuous recorded monitoring of cardiac rhythm (telemetry).

'Low-risk' patients in whom palpitations have resolved, do not have red flag symptoms and with a normal 12-lead ECG can usually be investigated further via outpatient ambulatory pathways.

Management of peri-arrest rhythms and ventricular tachyarrhythmias is discussed earlier in the chapter (see 'Therapeutic procedures used for peri-arrest rhythms').

Atrial fibrillation

Atrial fibrillation (AF) is commonly seen on the acute medical take either in isolation, or more commonly secondary to other acute illnesses. The context in which AF presents will determine its management, and treating the underlying driving cause is often as important as measures directed towards the arrythmia itself.

For a description of the causes, pathogenesis, classification, and clinical features, please refer to, 'Atrial fibrillation' section in Chapter 17. The European Society of Cardiology suggest an ABC mnemonic for management of atrial fibrillation (**A**void stroke, **B**etter symptom control, manage **C**ardiovascular risk factors, and detect **C**oncomitant diseases).

Acute management

When confronted with a patient with acute-onset atrial fibrillation (see **Fig. 17.42A**), considerations should include identifying and treating any precipitant or underlying cause, controlling symptoms (either by slowing ventricular rate or cardioverting to sinus rhythm, as appropriate), and minimizing risk of stroke due to embolization of left atrial thrombus.

Treating the underlying cause

When atrial fibrillation is due to an acute precipitating event, such as alcohol toxicity, chest infection, or hyperthyroidism, the provoking cause should be treated which will often result in spontaneous cardioversion. In the absence of life-threatening features, rate control strategies are thus usually preferred, although in patients with critical illness and/or severe left ventricular systolic dysfunction, i.v. amiodarone (which has both rate and rhythm-controlling properties) may be used.

Controlling symptoms

AF accompanied by a rapid ventricular rate causes unpleasant symptoms which may interfere with patients' activities and if sustained may lead to tachycardia-induced cardiomyopathy. Likewise, older patients with other associated co-morbidities may tolerate tachycardias poorly if sustained.

Strategies for the acute management of atrial fibrillation are:
- ***Ventricular rate control***, achieved by drugs that block the AV node.
- ***Cardioversion***, achieved electrically by synchronized DC shock (see 'Therapeutic procedures used for peri-arrest rhythms'), or medically by intravenous infusion of an antiarrhythmic drug such as flecainide or amiodarone.

The choice of whether to deploy rate or rhythm control for a patient presenting acutely depends on:
- how well the arrhythmia is tolerated (is cardioversion urgent?)
- the time of onset of the arrythmia (more or less than 48 h—in practice this may be uncertain, in which case proceed as if onset was more than 48 h prior)
- whether spontaneous cardioversion is likely (previous history? reversible cause?)—if likely, a rate-control strategy should be favoured.

Patients with life-threatening haemodynamic instability

When caused directly by new-onset atrial fibrillation, life-threatening features including shock, syncope, myocardial ischaemia, or severe heart failure are indications for emergency synchronized DC cardioversion. While action should still be taken to minimize risk of embolic stroke as best possible (see later), the balance of benefits and risks favours immediate restoration of sinus rhythm.

Patients without life-threatening haemodynamic instability

Ideally, expert help should be sought (e.g., from a cardiologist) to enable the highest quality decision-making; numerous factors influence treatment choice in atrial fibrillation (including patient age and co-morbidities, presence or absence of left ventricular dysfunction or other structural heart disease, concern for pre-excited atrial

fibrillation conducted via an accessory pathway and important medication contraindications such as asthma precluding beta-blocker use, see 'Atrial fibrillation (rate control) section' in Chapter 17.

In patients with a clear onset of new AF symptoms **with onset less than 48 hours**, the risk of left atrial thrombus formation is deemed to be low and either rate or rhythm control strategies may be used.

In patients with symptom onset **more than 48 hours previous (including symptoms suggesting paroxysmal AF), or where the time of onset is unclear**, rate control should be employed due to the unacceptable risk of left atrial thrombus, embolism of which may be precipitated by reversion to sinus rhythm.

Rate control may be achieved with beta-blockers (e.g., metoprolol or bisoprolol), non-dihydropyridine calcium channel antagonists (e.g., verapamil), or digoxin. The choice of intravenous or oral route should be made based on the perceived urgency of rate control, tolerance of symptoms, and factors which may impact bioavailability (e.g., unavailability of the oral route after surgery). Beta-blockers are contraindicated in asthma and avoided in AHF/pulmonary oedema. Calcium channel antagonists should not be used in patients with heart failure and a reduced ejection fraction. Renal function should be checked prior to digoxin use, and dose reduction may be required.

The optimal heart rate target in patients with AF is unclear, although clinical trials indicate that a lenient target (<110 bpm) is not inferior to a strict target (<80 bpm) and the former is thus a reasonable goal for initial management.

Patients managed initially with rate control may subsequently be considered for elective DC cardioversion after a period of at least 3 weeks' therapeutic anticoagulation, which is successful in approximately 80% of patients. If cardioversion is urgent and the patient is not on any anticoagulation, some expert centres will perform transoesophageal echocardiography to exclude the presence of atrial thrombus to facilitate an earlier procedure.

Rhythm control (cardioversion to sinus rhythm) in a patient without emergency indications for DC cardioversion, is usually attempted by pharmacologic means. Options include flecainide (contraindicated in patients with ischaemic heart disease or significant structural heart disease including left ventricular hypertrophy), propafenone (to be avoided in patients with hypotension, recent acute coronary syndromes, severe heart failure or aortic stenosis, or prolonged QT interval), or amiodarone (usually the preferred agent in heart failure). Amiodarone is usually administered i.v. but may cause phlebitis, and should be given via a central venous catheter or large peripheral vein. Baseline thyroid function tests should be checked. Flecainide is effective by both oral and i.v. routes, and is a common 'pill in the pocket' solution for patients with repeated episodes of AF in the absence of structural heart disease.

Longer-term, cardiac ablation (see Chapter 17) is increasingly used as a rhythm control strategy in AF.

Aside from duration of symptoms, factors which may influence the decision to pursue rhythm or rate control may include younger age, first episode, absence of co-morbidities (favouring rhythm control), or the presence of cardiac or non-cardiac disease likely to favour further episodes (favouring rate control).

Preventing stroke

AF is associated with a fivefold increased in stroke risk, attributable to the formation and embolism of left atrial thrombus and risk of clot formation rises with time spent in AF.

Current UK NICE guidelines recommend that in the absence of contraindications, patients presenting with acute AF are offered treatment with low-molecular-weight heparin, pending further risk stratification and risk/benefit assessment. CHA_2DS_2VASc scores (see **Box 17.13**) and HAS-BLED score (see **Box 17.14**) should subsequently be used to compute individualized thrombosis and bleeding risks in all patients.

Onset less than 48 hours

Where the patient fulfills criteria for anticoagulation based on CHA_2DS_2VASc score and benefit is considered to outweigh risks, the following patients should be offered ongoing anticoagulation:

- those in whom sinus rhythm is not restored within the same 48-hour period
- those with a high risk for recurrence of AF (e.g., structural heart disease, previous recurrences).

DOACs are now generally the preferred agents for anticoagulation in non-valvular AF; vitamin K antagonists are reserved for those with contraindications or valvular AF (defined as prosthetic heart valves or moderate-to-severe mitral stenosis).

Onset more than 48 hours or uncertain

All such patients who fulfill criteria for anticoagulation based on CHA_2DS_2VASc score and benefit is considered to outweigh risks, should be offered ongoing anticoagulation. For patients in whom future elective DC cardioversion is planned, full anticoagulation with a DOAC or warfarin (with confirmation that the patient has attained a therapeutic INR of 2–3) is required for at least 3 weeks prior to the procedure and 4 weeks after the procedure, regardless of CHA_2DS_2VASc score.

Atrial fibrillation with pre-excitation

AF with pre-excitation results from antegrade atrioventricular conduction via an accessory pathway and may be the presenting manifestation of Wolf-Parkinson-White (WPW) syndrome. Pre-excited AF is always an emergency and may precede ventricular fibrillation and sudden death. Consider this diagnosis in young patients with AF, with very rapid ventricular rates (often >200 bpm) and broad QRS complexes, the morphology of which often changes from beat to beat, reflecting the aberrant pathway of conduction (see **Fig. 17.41D**). Baseline ECGs (to identify typical WPW morphology) are rarely available, and thus a high index of suspicion is required. Importantly, **all AV nodal-blocking drugs (including beta-blockers, verapamil, and digoxin) should be avoided, as they potentially enhance accessory pathway conduction**. Amiodarone may also enhance pathway conduction. The European Society of Cardiology recommends ibutilide (a class III antiarrhythmic), although this drug is not available in the UK and flecainide is most commonly used under expert guidance. Emergency DC cardioversion facilities should be readily available.

Atrial flutter

Management of a symptomatic acute paroxysm of atrial flutter (see **Fig. 17.42B**) is by electrical ***cardioversion***. Patients who have been in atrial flutter for more than 1–2 days should be treated in a similar manner to those with atrial fibrillation and require ***anticoagulation*** for 3 weeks prior to cardioversion, using AV nodal modulating drugs (beta-blockers, calcium channel antagonists) to control rate as best possible in the interim. Acute pharmacological cardioversion can be achieved using class Ic (flecainide, propafenone) or certain class III antiarrhythmic agents (dofetilide, ibutilide; these have better efficacy than in atrial fibrillation but are not available in many countries).

In the long term, catheter ablation (Chapter 17) is highly effective in interrupting flutter pathways and preventing episodes.

Paroxysmal supraventricular tachycardia

Although technically speaking, all arrythmias arising from the conduction system above the ventricles are 'supraventricular' in origin (including atrial arrythmias, see **Box 17.12**), the term 'paroxysmal supraventricular tachycardia' (or simply 'SVT') is usually used in reference to tachycardias arising from the atrioventricular junction: either AV nodal re-entrant tachycardias (AVNRT, where the re-entry circuit is located within the AV node or AV re-entrant tachycardias (AVRT, where a macroscopic 'accessory pathway' for re-entry is present, see 'Atrioventricular junctional tachycardias' section in Chapter 17). These most commonly affect young people, often with age of first presentation <30 years and usually no or minimal underlying structural heart disease.

Clinical features

The leading symptom of most SVTs is rapid regular palpitations, usually with abrupt onset and sudden termination, which can occur spontaneously or be precipitated by simple movements. A common feature is termination by Valsalva manoeuvres. In younger individuals with no structural heart disease, the rapid heart rate can be the main pathological finding. Other symptoms may include anxiety, dizziness, dyspnoea, neck pulsation, central chest pain, and weakness. Polyuria may occur because of the release of atrial natriuretic peptide in response to increased atrial pressures during the tachycardia. Prominent jugular venous pulsations due to atrial contractions against closed AV valves may be observed during AVNRT.

Syncope has been reported in 10%–15% of patients, usually just after initiation of the arrhythmia or in association with a prolonged pause following its termination. It is more common if the person is standing. However, in older patients with concomitant heart disease, such as aortic stenosis, hypertrophic cardiomyopathy, and cerebrovascular disease, significant hypotension and syncope may result from moderately fast ventricular rates.

Management

In an emergency, distinguishing between AVNRT and AVRT may be difficult but is usually not critical, as both tachycardias respond to the same treatment. Patients presenting with SVTs and haemodynamic instability (e.g., hypotension, pulmonary oedema) require emergency cardioversion. If the patient is haemodynamically stable, vagal manoeuvres, including right carotid massage (see **Box 17.8**), the Valsalva manoeuvre, and facial immersion in cold water, can be successfully employed.

If physical manoeuvres have not been successful, intravenous adenosine should be tried. Give 6 mg by i.v. push initially, followed if needed by 12 mg 1–2 minutes later. If required, a second dose of 12 mg can be given after a further 1–2 minutes. Adenosine is a very short-acting (half-life <10 sec), naturally occurring purine nucleoside that causes complete heart block for a fraction of a second following intravenous administration. It is highly effective at terminating AVNRT and AVRT or unmasking underlying atrial activity, but rarely affects ventricular tachycardia. The side-effects of adenosine are very brief but may include chest pain, sense of impending doom, bronchospasm, flushing, or heaviness of the limbs. Adenosine should be used with caution in patients with a history of asthma. An alternative treatment is verapamil 5–10 mg i.v. over 5–10 min or beta-blockers (esmolol, propranolol, metoprolol). Verapamil must not be given after beta-blockers *or* if the tachycardia presents with broad (>0.12 sec) QRS complexes.

The longer-term management of junctional tachycardias is discussed under 'Long-term management' subsection of 'Atrioventricular junctional tachycardias' section in Chapter 17.

European Society of Cardiology 2020 Guidelines for Management of Atrial Fibrillation. Accessed at: https://www.escardio.org/Guidelines/Clinical-Practice-Guidelines/Atrial-Fibrillation-Management.

Breathlessness

Breathlessness (dyspnoea) is one of the most common presenting symptoms encountered on the acute medical take. It is usually experienced as difficult or laboured breathing and can result from a range of underlying medication conditions (**Box 11.20**). Respiratory and cardiovascular disorders predominate with other potential causes including severe anaemia, neuromuscular disease, obesity, deconditioning, and rarely functional breathing disorders. Care should be taken to differentiate true dyspnoea from other symptoms which a patient may report as 'breathlessness' (e.g., palpitations).

Clinical assessment

Evaluation should begin with a **focused history**, although emergency measures (e.g., application of supplemental oxygen if the patient is hypoxic) may need to commence in parallel.

- **Onset and duration of symptoms:** sudden onset dyspnoea may implicate a 'mechanical' (e.g., pneumothorax) or vascular cause (e.g., acute embolism [PE], or acute pulmonary oedema resulting from myocardial infarction or arrhythmia)
- **Aggravating or relieving factors:** dyspnoea due to left ventricular failure usually worsens when lying flat (orthopnoea); dyspnoea due to acute asthma may be eased by inhaled or nebulized bronchodilators
- Identify associated symptoms:
  - **Pleuritic chest pain** (worse on deep inspiration) suggests pneumonia, pneumothorax, or PE
  - **Wheeze** may reflect bronchospasm, or accompany pulmonary oedema ('cardiac asthma')
  - Expectoration of **purulent sputum** suggests bronchitis or pneumonia

Box 11.20 Common emergency causes of breathlessness

Respiratory

- Acute asthma exacerbation
- COPD exacerbation
- Pulmonary infection (bronchitis/pneumonia)
- Viral pneumonitis (COVID-19, influenza)
- Pneumothorax
- Pleural effusion
- Upper airway obstruction (e.g., aspiration, anaphylaxis)

Cardiovascular

- Heart failure
- Pulmonary embolism
- Cardiac tamponade

Other

- Anaemia
- Obesity
- Deconditioning
- Metabolic acidosis ('air hunger' e.g., in DKA)
- Panic attack
- Neuromuscular disorders (e.g., myasthenia gravis)

- **Haemoptysis** may imply infection, infarction (i.e., PE), pulmonary oedema, malignancy (e.g., a bronchial tumour causing lung collapse), or rarely pulmonary haemorrhage

- Enquire about relevant medical history, including pre-existing respiratory conditions, cardiac diseases, or other co-morbidities that may contribute to breathlessness. Does the patient have home oxygen, nocturnal CPAP, or BiPAP (NIV)?
- Ask about previous episodes and their severity, including any times when the patient may have required admission to ITU and any interventions required (e.g., intubation). Much information may be gathered from a thorough review of old notes, although it is important to keep an open mind (e.g., in a patient with frequent hospitalizations due to COPD exacerbations who presents with sudden dyspnoea, consider PE or pneumothorax)
- Additionally, ask about smoking history, recent travel, occupational exposures, pets, and social history

The **physical examination** should begin with a detailed respiratory examination, looking for digital clubbing, central or peripheral cyanosis, signs of deep venous thrombosis (DVT), presence of tracheal deviation, quality of breath sounds, the presence of wheezing or crackles, and signs of respiratory distress. Evaluate the cardiovascular system, checking for pallor, oedema, signs of heart failure, and murmurs. Depending on the suspected cause of breathlessness, examine other systems as appropriate.

- Presence of a polyphonic expiratory wheeze suggests bronchospasm (acute asthma or some exacerbations of COPD), or pulmonary oedema ('cardiac asthma')
- A gallop rhythm (third heart sound), elevated jugular venous pressure (JVP), and fine bi-basal inspiratory crackles suggest acute left ventricular failure
- Bronchial breathing, coarse crackles, and fever suggest pneumonia
- Hypoxia and tachycardia despite a clear chest should raise suspicion of PE
- Reduced breath sounds on one side accompanied by a 'stony dull' percussion note suggests a pleural effusion; reduced breath sounds accompanied by a hyper-resonant percussion note suggest pneumothorax
- Muffled heart sounds with hypotension and neck vein engorgement suggest pericardial effusion with tamponade
- Drowsiness, bounding pulse, and flapping tremor (asterixis) suggest the presence of type II respiratory failure
- Neurological weakness may signify a neuromuscular disorder
- Pallor may suggest anaemia

Investigations

- **Oxygen saturations** will identify a hypoxic patient at the bedside
- **Peak expiratory flow rate** (PEFR) is essential in asthma exacerbation to help quantify severity
- **ABG** will quantify hypoxia and is essential to detect type II respiratory failure (hypercapnia). ABG also allows detection of metabolic acidosis (e.g., DKA) and provides other point-of-care laboratory data (e.g., haemoglobin)
- **COVID-19/influenza lateral flow or antigen test**
- **ECG:** This may reveal arrhythmia or ischaemia (as a cause of acute pulmonary oedema). Low voltage complexes should raise suspicion of pericardial effusion. A right ventricular strain pattern, right bundle branch block, or the 'S1, Q3, T3' pattern may be present in PE, although all are insensitive for the diagnosis, and sinus tachycardia may be the only finding
- **CXR:** This is a high-yield investigation in the breathless patient and will provide confirmation of a range of diagnoses including pneumonia, pulmonary oedema, lobar collapse, and pleural effusion (see Chapter 8). Think of PE in the hypoxic patient with a normal CXR. Pneumothorax may be subtle: turning the CXR film 90 degrees may help in detecting the boundary between lung edge and non-aerated lung
- **Core laboratory tests** may reveal a low haemoglobin (anaemia), elevated white blood cell count and C-reactive protein (infection), or metabolic abnormalities (e.g., renal failure as a cause of pulmonary oedema)
- **POCUS:** This can be useful in identifying pneumothorax: look for lack of lung sliding, absence of comet-tails, and the 'lung point' sign. POCUS can also be used to assess for pleural effusion, pulmonary oedema (B lines), or evidence of right ventricular strain in submassive PE
- **Further diagnostic tests** may include computed tomography pulmonary angiogram (CTPA) or ventilation–perfusion (VQ) scan if PE is suspected or echocardiography, to assess left ventricular function and valvular integrity in acute pulmonary oedema and detect pericardial effusion

Management of the breathless patient varies with the underlying cause, although the ABCDE (airway, breathing, circulation, disability, exposure) approach to initial emergency care is common to all scenarios and should be applied in parallel to the clinical evaluation and diagnostic work-up.

Acute severe asthma

The term acute severe asthma is used to mean an exacerbation of ('bronchial') asthma that has not been controlled by the use of standard medication (inhaled bronchodilators ± corticosteroids). Patients frequently have a prior diagnosis of chronic asthma, although acute severe asthma may, on occasion, be the first presentation of disease. A discussion of the epidemiology and pathophysiology of bronchial asthma can be found in Chapter 20.

Clinical assessment

Assess for evidence of respiratory distress, air entry, wheeze, and for tracheal deviation (superadded tension pneumothorax).

Patients with **acute severe asthma** typically have:

- an inability to complete a sentence in one breath
- a respiratory rate of ≥25 breaths/min
- a tachycardia of ≥110 b.p.m. (pulsus paradoxus is not useful, as it is present in only 45% of cases)
- a PEFR of 33%–50% of predicted normal or best.

Features of **life-threatening attacks** are:

- a silent chest, cyanosis, or feeble respiratory effort
- exhaustion or altered level of consciousness
- bradycardia, hypotension, or arrhythmia
- a PEFR of <33% of predicted normal or best (often <150 L/min in adults) or S_pO_2 of <92%.

Investigations

- All patients should have their initial observations measured and supplementary oxygen offered to any patient who is hypoxic.
- Bedside PEFR is important in defining severity and monitoring treatment response.
- Send respiratory viral swab and COVID-19 and influenza rapid tests, consider atypical pneumonia screen if appropriate depending on the history.
- CXR should be performed in all those requiring admission to exclude pneumothorax and pneumonia.

Arterial blood gases should only be measured in asthmatic patients requiring admission to hospital who look to be tiring, with particular attention paid to the P_aCO_2. It is important to note that a 'normal' P_aCO_2 (4.6–6 kPa, 35–45 mmHg) is a worrying feature in an asthmatic patient suggesting the patient is tiring and is a marker of a life-threatening attack. ***Pulse oximetry*** is useful in monitoring oxygen saturation during the admission and can reduce the need for repeated arterial puncture.

Features suggesting very severe life-threatening attacks are:

- a high P_aCO_2 of >6 kPa
- severe hypoxaemia: P_aO_2 < 8 kPa despite treatment with oxygen
- a low and/or falling arterial pH.

Management (see Box 11.21)

Management consists of nebulized short-acting bronchodilators; nebulized antimuscarinics (e.g., ipratropium bromide) are also helpful. Intravenous hydrocortisone should be given together with prednisolone (40–50 mg daily) orally. When treating an acute severe exacerbation of asthma, an initial dose of oral prednisolone should be given alongside intravenous hydrocortisone. Failure to do so is a common cause of 'late deterioration' due to the shorter half-life of hydrocortisone (6–8 h). If symptoms are not controlled, consider a single dose of intravenous magnesium sulphate (1.2 g–2 g infusion over 20 min).

Intravenous β_2-adrenoceptor agonists or aminophylline may be considered. Ventilation is required for patients who deteriorate despite this initial regimen.

If the patient is improving, discharge can be considered if PEFR is >75% of best or predicted and PEFR diurnal variability <25%. Inhaler technique should be assessed prior to discharge and the patient should have inhaled corticosteroid therapy started if new diagnosis (or inhaler reviewed if repeated admissions in a short period of time). In the UK, this is often guided by specialist respiratory nurses who will also provide the patient with their own peak flow metre and asthma action plan.

Box 11.21 Treatment of acute severe asthma

At home

1. The patient is assessed. Tachycardia, a high respiratory rate and inability to speak in sentences indicate a severe attack.
2. If the peak expiratory flow rate (PEFR) is <150 L/min (in adults), an ambulance should be called.
3. Nebulized salbutamol 5 mg or terbutaline 10 mg is administered.
4. Hydrocortisone 200 mg i.v. is given.
5. Oxygen 40%–60% is given if available.
6. Prednisolone 40–50 mg is given orally.

In hospital

1. The patient is reassessed.
2. Oxygen 40%–60% is given.
3. The PEFR and O_2 saturation are measured.
4. Nebulized salbutamol 5 mg or terbutaline 10 mg is repeated and administered 4-hourly.
5. Nebulized ipratropium bromide 0.5 mg is added to nebulized salbutamol/terbutaline.
6. Hydrocortisone 200 mg i.v. is given.
7. Prednisolone is continued at 40–60 mg orally daily for at least 5 days.
8. Arterial blood gases are measured; if the P_aCO_2 is >8 kPa, ventilation may be required.
9. A chest X-ray is performed to exclude pneumothorax.
10. If there is no improvement, i.v. magnesium sulphate is given at 1.2–2 g over 20 min.
11. If there is still no improvement, urgent transfer to the intensive therapy unit is arranged.

The patient should be discharged with a minimum of 5 days of oral prednisolone 40 mg once a day. Consider prescribing a proton pump inhibitor as gastric protection particularly in older patients. The patient should see their GP within 2 working days and should have follow-up with a respiratory physician within 4 weeks.

Exacerbation of chronic obstructive pulmonary disease (COPD)

Acute exacerbations of COPD may be precipitated by a viral or bacterial infection. Patients may have symptoms of cough, wheeze, and dyspnoea. Type I or type II respiratory failure (the latter often acute-on-chronic) may occur as a consequence of a COPD exacerbation.

Many patients will have a prior diagnosis of COPD (confirmed by spirometry) or have previously been hospitalized for exacerbations. Underlying COPD should be suspected in a patient with a significant smoking history (>20 pack/years) and a background history of *progressive* dyspnoea with reduction in exercise tolerance.

A discussion of the epidemiology and pathophysiology of COPD can be found in Chapter 20.

Clinical assessment

Clinical signs of COPD exacerbation vary widely and in particular the presence of wheeze, which ranges from severe to absent. Patients may use accessory muscles of respiration and signs of thoracic hyperinflation may be present (e.g., increased cricoid-sternal distance). The traditional paradigms of disease phenotype (the 'pink puffer'—cachexic with marked tachypnoea and pursed-lip breathing—and the 'blue bloater'—cyanosed and oedematous, resulting from cor pulmonale and right heart failure) do correlate loosely with propensity to type I and type II respiratory failure, respectively, but are insufficiently sensitive to guide clinical decisions.

Investigations

- PEFR is of limited use in assessing severity of COPD exacerbation
- **ABG** is essential in order to detect type II respiratory failure
- **Viral respiratory swab, COVID-19 and influenza rapid testing**, and **sputum** cultures should be sent
- **ECG** will detect concomitant atrial fibrillation (common in this group)
- **CXR** will exclude pneumonia and pneumothorax and may yield incidental diagnosis (e.g., bronchial malignancy). An appropriate index of suspicion should be maintained for PE as risk factors (e.g., immobility) commonly coexist in this population

Management (see also Fig. 11.19)

- ***Oxygen therapy.*** COPD is by far the most common cause of respiratory failure. In managing respiratory failure, the main goal is to improve the P_aO_2 by continuous oxygen therapy. A fixed-percentage mask (Venturi mask, Fig. 11.18) is used to deliver controlled concentrations of oxygen. Initially, 24% oxygen is given, and the concentration of inspired oxygen can be gradually increased, provided the P_aCO_2 does not rise unacceptably. In chronic type II respiratory failure, recognized by elevated P_aCO_2 and plasma bicarbonate (indicating renal compensation), application of *excessive* supplemental oxygen will nearly always cause a further rise in P_aCO_2. Historically this was ascribed to dependency on 'hypoxic respiratory drive' to

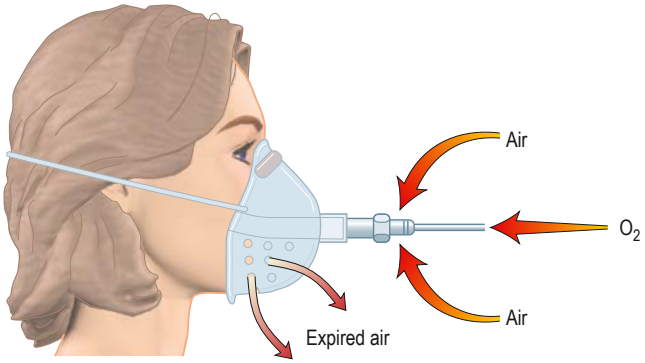

Fig. 11.18 'Fixed-performance' device for administration of oxygen to spontaneously breathing patients (Venturi mask). Oxygen is delivered through the injector of the Venturi mask at a given flow rate. A proportionate amount of air is entrained and the inspired oxygen can be predicted accurately. Masks are available that deliver 24%, 28%, and 35% oxygen.

maintain adequate ventilation, although displacement of carbon dioxide from haemoglobin by oxygen and a loss of pulmonary hypoxic vasoconstriction (resulting in increased pulmonary 'dead space') are more plausible mechanisms. Patients at risk of hypercapnia (particularly those with chronic type II respiratory failure, on long-term oxygen therapy, or with previous need for NIV or invasive ventilation) should be managed with controlled oxygen therapy to maintain the saturations within a target range of 88%–92%. It is important to monitor arterial blood gases closely if there is any risk of decompensated type II respiratory failure. If there is evidence of respiratory acidosis (pH < 7.35 with an elevated P_aCO_2), despite medical management, the patient should be considered for NIV unless there are any contraindications (**Fig. 11.19**).

- ***Corticosteroids, antibiotics, and bronchodilators.*** These should be administered in the acute phase of an exacerbation but decisions on long-term use should wait until the patient has recovered.
- ***Removal of retained secretions.*** Patients should be encouraged to cough up secretions. Chest physiotherapy is helpful in achieving adequate chest clearance.

Type II respiratory failure in COPD

- ***Respiratory support:*** BiPAP (see 'Advanced respiratory support') should be offered if a patient has a persistent respiratory acidosis with a pH of <7.35. Randomized controlled trials have demonstrated that BiPAP reduces the need for intubation and lowers mortality. Indications and contraindications are shown in **Boxes 11.11 and 11.12**. Assisted ventilation with an endotracheal tube is occasionally necessary for patients with COPD who have severe respiratory failure but only when there is a clear precipitating factor and the overall prognosis is reasonable. Assessing the likelihood of reversibility in an acute setting can present a difficult ethical problem.

Acute heart failure

Acute heart failure (AHF) occurs with the rapid onset of symptoms and signs of heart failure secondary to abnormal cardiac function, causing elevated cardiac filling pressures. This leads to severe dyspnoea, and fluid accumulates in the interstitium and alveolar spaces of the lung (pulmonary oedema). AHF is the leading cause of hospital admission in people above the age of 65 years; it has a poor prognosis, with a 60-day mortality rate of nearly 10% and a rate of death or rehospitalization of 35% within 60 days. In patients with ***acute pulmonary oedema***, the in-hospital mortality rate is 12% and by 12 months, this rises to 30%. Poor prognostic indicators include a high (>16 mmHg) pulmonary capillary wedge pressure (see Chapter 13), low serum sodium concentration, increased left ventricular end-diastolic dimension on echo, and low oxygen consumption.

Often heart failure will be categorized into heart failure with reduced ejection fraction (left ventricular ejection fraction (LVEF) less than 40%) or preserved (LVEF > 40%) ejection fraction.

The aetiology of AHF is similar to that of chronic heart failure (CHF) (see **Box 17.17**):

- ***Ischaemic heart disease*** patients present with an acute coronary syndrome or develop a complication of myocardial infarction, such as papillary muscle rupture or ventricular septal defect requiring surgical intervention.
- ***Valvular heart disease*** patients also present with AHF due to valvular regurgitation in endocarditis or prosthetic valve thrombosis. A thoracic aortic dissection may produce severe aortic regurgitation.
- ***Hypertension*** patients present with episodes of 'flash' pulmonary oedema despite preserved left ventricular systolic function.
- ***Acute and chronic kidney disease*** both involve fluid overload and reduced renal excretion, which will produce pulmonary oedema.
- ***Atrial fibrillation*** is frequently associated with AHF and may require emergency cardioversion.

Several clinical syndromes of AHF can be defined (**Box 11.22**). In a clinical environment, both the Killip score (used to assess severity of AF post-MI, see Chapter 17, 'Complications of myocardial infarction') and Forrester classification (based on right heart catheterization findings) provide therapeutic and prognostic information.

Pathophysiology

The pathophysiology of AHF is similar to that of CHF with activation of the renin–angiotensin–aldosterone axis and sympathetic nervous system. In addition, prolonged ischaemia (e.g., in acute coronary syndromes) results in myocardial stunning (see Chapter 17—'Hibernating myocardium and myocardial stunning'), which exacerbates myocardial dysfunction but may respond to inotropic support. If myocardial ischaemia persists, the myocardium may exhibit hibernation (persistently impaired function due to reduced coronary blood flow), which may recover with successful revascularization.

Clinical assessment

History

- Enquire about the patient's medical history, including the presence of hypertension, diabetes, renal disease or coronary artery disease, previous cardiac surgeries, or percutaneous coronary interventions and a prior history of CHF.
- For patients with CHF, check adherence with medications (including diuretics) and enquire regarding recent treatment changes. Do they know their recent body weight and, if so, has it increased (indicating hypervolaemia)?
- An antecedent history of chest pain or palpitations may point towards the underlying cause of AHF.
- Note any recent illnesses or infections, as they can precipitate acute pulmonary oedema in a patient with CHF.

Physical examination

- Measure vital signs, with particular attention to heart rate and rhythm, blood pressure, respiratory rate and oxygen saturation, to assess respiratory and haemodynamic status. Blood pressure

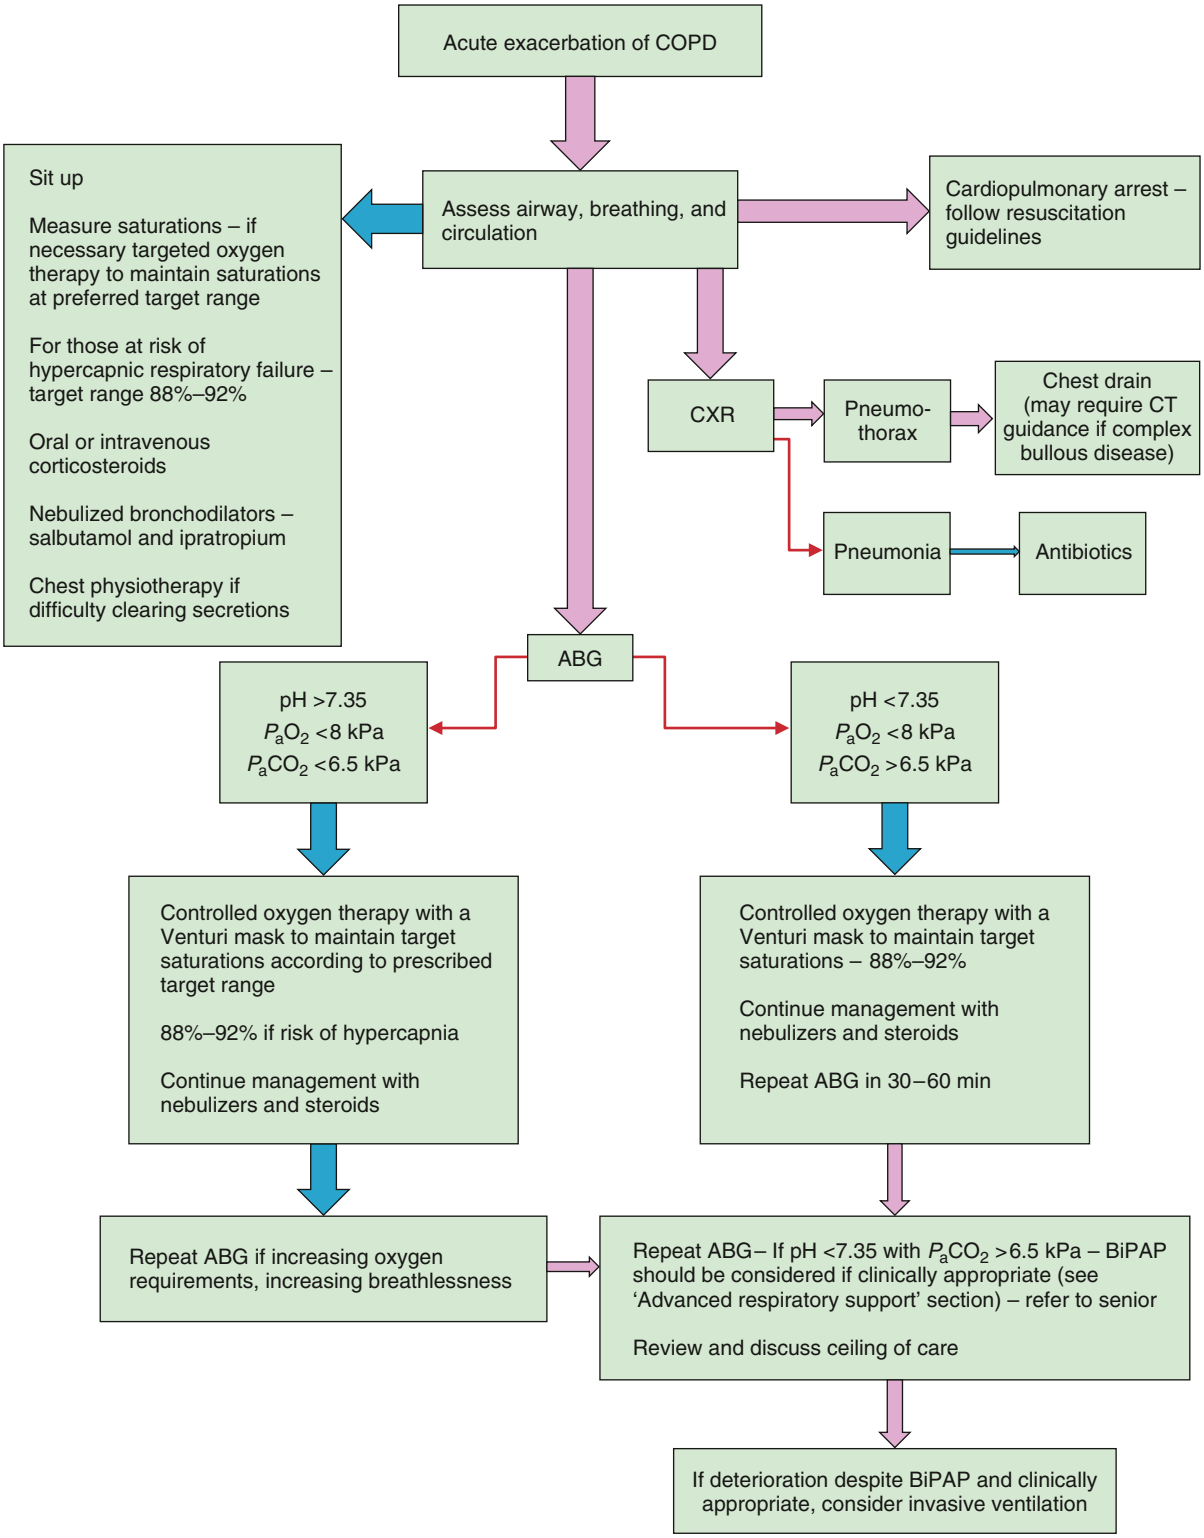

Fig. 11.19 Algorithm for the treatment of respiratory failure in COPD. *BiPAP,* Bilevel positive airway pressure.

is often markedly elevated in patients with acute pulmonary oedema and does not always indicate a hypertensive aetiology; hypotension, conversely, is a worrying sign.

- Evaluate JVP and look for signs of hypervolaemia, including peripheral and sacral oedema and ascites (absent in very acute presentations without background CHF).
- Auscultate for abnormal heart sounds, such as murmurs or the gallop rhythm of a 3rd of 4th heart sound.
- Bilateral fine inspiratory crackles, initially in the dependent zones (lung bases), but extending throughout all lung zones in severe cases, are the most characteristic sign of pulmonary oedema. Pleural effusions (bilateral, but often more prominent

Box 11.22 Clinical syndromes of acute heart failure (AHF)

Type	Clinical features
Acute decompensated heart failure	Mild features of heart failure e.g., dyspnoea
Hypertensive AHF	High blood pressure, preserved left ventricular function, pulmonary oedema on CXR
Acute pulmonary oedema	Tachypnoea, orthopnoea, pulmonary crackles, oxygen saturation <90% on air, pulmonary oedema on CXR
Cardiogenic shock	Systolic blood pressure <90 mmHg, mean arterial pressure drop >30 mmHg, urine output <0.5 mL/kg per hour, heart rate >60 b.p.m.
High-output heart failure	Warm peripheries, pulmonary congestion, blood pressure may be low e.g., septic shock
Right heart failure	Low cardiac output, elevated jugular venous pressure, hepatomegaly, hypotension

(Modified from the European Society of Cardiology.)

on the right) may also be present in acute decompensated heart failure.

Investigations

Initial investigations should include:

- ***Laboratory investigations:*** serum creatinine and electrolytes, full blood count, blood glucose, cardiac enzymes and troponin, C-reactive protein (CRP), and consideration of D-dimer.
- ***Plasma BNP*** or ***NT-proBNP*** (BNP > 100 pg/mL or NT-proBNP >300 pg/mL is suggestive of heart failure).
- ***A 12-lead ECG*** will identify acute coronary syndromes, left ventricular hypertrophy, atrial fibrillation, some valvular heart disease, and left bundle branch block.
- ***A CXR*** may demonstrate cardiomegaly, pulmonary oedema, pleural effusions, or non-cardiac disease.
- ***Transthoracic echocardiogram (TTE)*** should be performed without delay to assess ventricular structure and function and possibly identify the cause.

Management

The goals of treatment in a patient with AHF include:

- immediate relief of symptoms and stabilization of haemodynamics (short-term benefits)
- reduction in length of hospital stay and rates of re-admissions to hospital
- reduction in mortality from heart failure.

Patients with AHF who are unwell should be managed in a high-dependency area (e.g., coronary care unit) with regular measurement of temperature, heart rate, blood pressure, and cardiac monitoring. All require prophylactic anticoagulation with low-molecular-weight heparin (LMWH), unless contraindicated.

Individuals with haemodynamic compromise may need arterial lines for invasive blood pressure monitoring and arterial gas sampling, central venous cannulation (intravenous medication, inotropic support, monitoring of central venous pressure) and pulmonary artery catheterization (calculation of cardiac output/index, peripheral vasoconstriction, and pulmonary wedge pressure), and consideration of NIV.

Initial therapy (Fig. 11.20 and Box 11.23) includes oxygen and diuretics (e.g., i.v. furosemide 40 mg). Given intravenously, furosemide

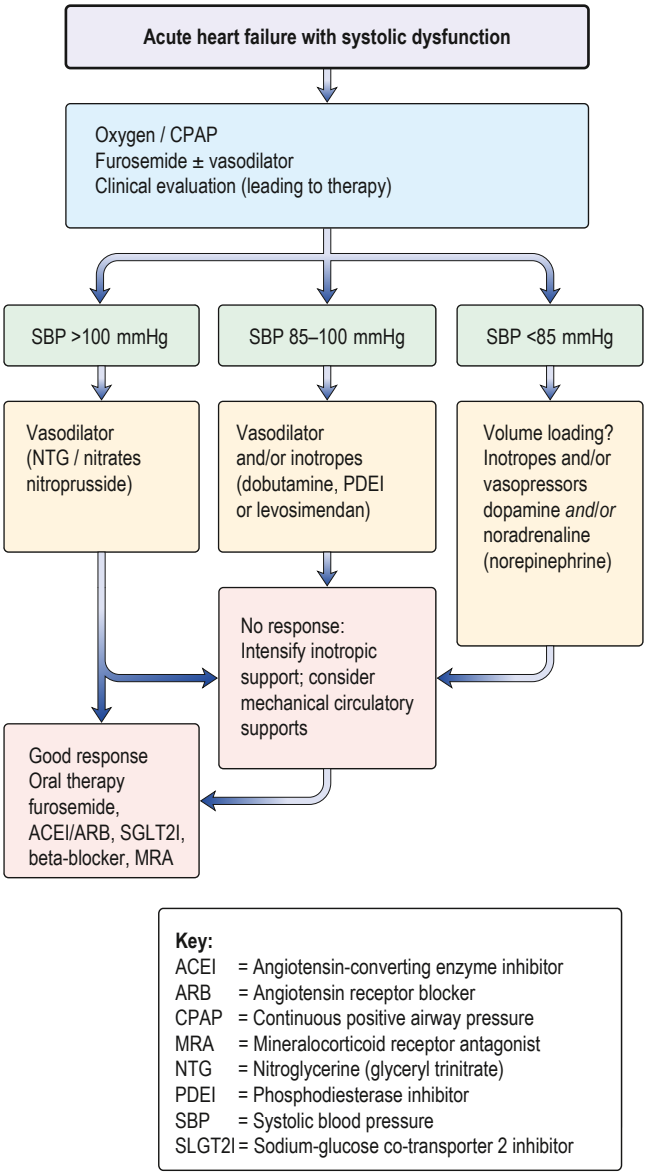

Fig. 11.20 Algorithm for the management of acute heart failure with systolic dysfunction. *(Modified from Nieminen MS, Böhm M, Cowie MR et al. Executive summary of the guidelines on the diagnosis and treatment of acute heart failure: the Task Force on Acute Heart Failure of the European Society of Cardiology.* Eur Heart J *2005; 26:384–416, Fig. 6, with permission from Oxford University Press and the European Society of Cardiology.)*

has venodilating properties resulting in clinical benefit before diuresis becomes apparent. If intravenous nitrates (e.g., glyceryl trinitrate infusion 10–200 μg/min) are required (e.g., concomitant myocardial ischaemia, severe hypertension), careful monitoring of the blood pressure is mandatory. Inotropic support with dobutamine, phosphodiesterase inhibitors (milrinone), or levosimendan can be added in patients who do not respond to initial therapy. Specialist options for treating severe AHF which do not respond to initial management include extracorporeal membrane oxygenation (ECMO), miniature cardiac pumps, and (less used now) intra-aortic balloon pumps; these are discussed further in 'Temporary mechanical cardiac support' in Chapter 17.

If there is limited improvement with bolus furosemide, furosemide infusion can be considered.

Box 11.23 Pharmacological therapy in acute heart failure

Drug	Dose	Indications/mechanism of action
Myocardial oxygenation		
Oxygen	35%–50% inspired oxygen concentration	Ensure airway is patent and maintain arterial saturation at 95%–98%
Non-invasive positive pressure e.g., CPAP		Use if failing to maintain arterial saturation Increases pulmonary recruitment and functional residual capacity—reduces work of breathing
Intubation/mechanical ventilation		Use if patient is failing to maintain arterial saturation and is fatigued (reduced respiratory rate, increased arterial CO_2, confusion)
Opiate		
Morphine	2.5–5.0 mg i.v. (with antiemetic metoclopramide 10 mg i.v.)	Use in agitated patient Relieves dyspnoea, venous and arterial dilation
Antithrombin		
Low-molecular-weight heparin	E.g., Enoxaparin 1 mg/kg s.c. ×2 daily (ACS) or 40 mg s.c. daily (prophylaxis)	Use in patients with AHF, ACS, or atrial fibrillation, or for DVT prophylaxis Caution if creatinine clearance <30 mL/min
Vasodilators		
Glyceryl trinitrate	10–200 μg/min i.v. infusion	Reduces pulmonary congestion; at low doses causes venodilation, reducing preload; at high doses causes arterial vasodilation, reducing afterload Ensure BP > 85–90 mmHg
Sodium nitroprusside	0.3–5 μg/kg per min i.v. infusion (initially 0.5–1.5 μg/kg per min, adjust by 0.5 μg/kg per min every 5 minutes, stop if response unsatisfactory with maximum dose in 10 mins)	Use in severe AHF where there is predominantly high afterload e.g., hypertensive AHF Needs arterial BP monitoring as risk of profound hypotension
Diuretic		
Furosemide	Bolus 40–100 mg i.v. or infusion 5–40 mg/h	Low doses produce vasodilation, reduce right atrial pressure and PCWP, and promote diuresis Need to monitor sodium, potassium, and creatinine
Inotropes		
Dopamine	Low dose <2 μg/kg per min	Low dose acts on peripheral dopamine receptors to produce vasodilation (renal, splanchnic, coronary, cerebrovascular) and may improve diuresis although evidence of significant improvements in outcomes is lacking
	Medium dose >2 μg/kg per min	Medium dose acts on β-receptors to increase myocardial contractility and cardiac output
	High dose >5 μg/kg per min	High dose acts on α-receptors, causing vasoconstriction and increasing total peripheral resistance (increases afterload, PAP)
Dobutamine	2–20 μg/kg per min (patients on beta-blockers may need high dose)	Stimulates β_1 and β_2-receptors, producing vasodilation. Increases heart rate and cardiac output, and also diuresis as haemodynamics are improved
Milrinone	Bolus 25–75 μg/kg over 10–20 min then 0.375–0.75 μg/kg per min	Inhibits phosphodiesterase and maintains cAMP Increases cardiac output and stroke volume, reduces PAP/PCWP/total peripheral resistance/BP
Levosimendan	Bolus 6–12 μg/kg over 10 min then 0.05–2 μg/kg per min	Positive inotropic drug with vasodilator effects by increasing sensitivity of contractile proteins to calcium and opening potassium channels Increases cardiac output and reduces PCWP
Vasopressors		
Noradrenaline (norepinephrine)	0.2–1.0 μg/kg per min	Stimulates α-receptors Increases total peripheral resistance and BP
Adrenaline (epinephrine)	Bolus 1 mg at resuscitation then 0.05–0.5 μg/kg per min	Stimulates α-, β_1-, and β_2-receptors Increases cardiac output, heart rate, total peripheral resistance, and BP
Cardiac glycoside		
Digoxin	0.5 mg i.v. repeated after 2–6 h	Inhibits myocardial sodium/potassium ATPase, leading to increased calcium and sodium exchange Increases cardiac output and slows AV conduction Use in AF; avoid in ACS

ACS, Acute coronary syndrome; *AF,* atrial fibrillation; *AHF,* acute heart failure; *ATPase,* adenosine triphosphatase; *AV,* atrioventricular; *BP,* blood pressure; *cAMP,* cyclic adenosine monophosphate; *CPAP,* continuous positive airway pressure; *DVT,* deep venous thrombosis; *i.v.,* intravenous; *PAP,* positive airway pressure; *PCWP,* pulmonary capillary wedge pressure; *s.c.,* subcutaneous.

Patients with profound hypotension may require inotropes and vasopressors to improve haemodynamic status and alleviate symptoms but these have not been shown to improve mortality. Non-invasive continuous positive airway pressure/positive pressure ventilation (CPAP/NIPPV; see 'Advanced respiratory support') has been shown to provide earlier improvement in dyspnoea and respiratory distress than standard oxygen via mask; mortality is, however, unaffected.

Patients who present with mild to moderate decompensation of chronic heart failure can be considered for outpatient management of their condition if there is access to intravenous furosemide, regular monitoring via hospital at home or ambulatory care services, and input from heart failure teams (specialist nurses and cardiologists) to aid with titrating/optimizing medication. Point-of-care echo and lung/abdominal ultrasound can be useful adjuncts to assess volume status alongside clinical assessment of the patient. Daily weight monitoring, along with renal function and clinical fluid status assessments, is important.

Discharge

Hospitalization with AHF carries a high risk for future re-admission to hospital, the risk of which can be reduced by instigating a follow-on community care plan. Nurse-led community heart failure teams are fundamental to this process and referral should be made prior to discharge. Once euvolaemia is achieved, it is helpful to document a 'dry weight' to enable patients to monitor weight, identify early fluid reaccumulation and adjust diuretic doses under medical guidance.

Evidence-based treatments for CHF are discussed further from 'Management of heart failure' in Chapter 17, and comprise:

- lifestyle measures
- multidisciplinary interventions including cardiac rehabilitation
- cardiac resynchronization therapy ('Cardiac resynchronization therapy' section in Chapter 17)
- four main drug treatment classes:
  - ACE inhibitor, ARB, or combined angiotensin receptor-neprilysin inhibitors
  - beta-blocker
  - mineralocorticoid receptor antagonist (MRA)
  - SGLT2 inhibitor.

These pharmacological agents should be initiated in hospital where appropriate and up-titrated proactively in the weeks following admission. The STRONG-HF trial demonstrated that up-titration of ACEi/ARB, beta-blocker, and MRA to optimal doses within 2 weeks of discharge resulted in reduced all-cause mortality and 180-day hospitalization rates compared to usual management, with benefits seen irrespective of baseline left ventricular ejection fraction. This study predated routine use of SGLT2 inhibitors in heart failure although it is widely assumed that these should also be initiated early. Combined use of ACEi/ARB and MRA carries a risk of hyperkalaemia and AKI and requires careful oversight and monitoring by heart failure teams.

? Box 11.24 Common causes of respiratory viral infections

- Influenza virus
- Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; causative agent of COVID-19)
- Respiratory syncytial virus (RSV)
- Parainfluenza virus
- Adenovirus
- Rhinovirus
- Metapneumovirus
- Other non (SARS-CoV-2) coronaviruses e.g., Middle East respiratory syndrome coronavirus (MERS/MERS-CoV)

Acute viral illness

Acute viral illnesses are a common cause of breathlessness presenting to the acute medical take, either via induction of pneumonitis or through exacerbation of a pre-existing respiratory condition (e.g., asthma). Common pathogens are listed in **Box 11.24**.

Clinical assessment

History

- Enquire about fever, cough, shortness of breath, coryza, myalgia, and joint ache
- Ask about recent exposure to individuals with similar symptoms
- Enquire about loss or disturbance of taste or smell (frequently reported with COVID-19)
- Ask about travel and vaccination history (COVID-19/flu vaccine)
- Take full systems history as viral respiratory illnesses can also present with systemic manifestations (a description of the clinical syndromes associated with individual pathogens can be found in Chapter 42)

Physical examination

- Check vital signs, including temperature, heart rate, and oxygen saturation
- Evaluate respiratory rate and effort and identify signs of respiratory distress
- Chest examination findings may include signs of consolidation (crackles, bronchial breathing) or polyphonic wheeze if small airway inflammation predominates. Examination findings may be minimal even in the presence of severe hypoxia
- Assess any other systems that might have been affected as described from the history

Investigations

- **Point-of-care tests:**
  - Rapid PCR or antigen tests for COVID-19 and influenza
  - Respiratory viral swabs for other respiratory viruses
- **Blood tests:**
  - Full blood count (FBC) and basic metabolic panel to check electrolyte levels. Lymphopaenia is common with respiratory viral pathogens
  - Procalcitonin and CRP
- **CXR** to evaluate for evidence of pneumonitis, pneumonia, or other lung pathology
- **Thoracic CT scan** in selected cases for detailed lung assessment. The possibility of PE should be considered in patients with COVID-19 infection which may warrant CT-PA.

Positive PCR or antigen test results indicate the presence of a specific viral pathogen. Sometimes the cause of an acute respiratory viral illness is not identified.

Pairing CRP with procalcitonin (PCT, regarded as a marker of bacterial infection) may help guide the rational use of antibiotic therapy in the setting of acute viral illness.

Management

Principles of managing an acute viral respiratory infection are outlined in **Box 11.25**. A more detailed discussion of management of acute COVID-19 pneumonitis can be found in Chapter 20.

Virtual wards and telehealth

Virtual wards are an emerging and valuable tool in managing respiratory viral illnesses, including COVID-19. Virtual wards facilitate remote monitoring of patients with mild to moderate symptoms who do not require immediate hospitalization. Pulse oximeters and thermometers are provided to patients for home monitoring and regular 'check-ins' are conducted to assess evolution of symptoms.

Prevention

Vaccination

It is important to highlight the value of annual influenza and COVID-19 vaccinations for at-risk individuals.

Patient education

Patients should be advised of respiratory hygiene, respiratory isolation, and staying home when ill. They should be advised about symptoms of deterioration and when to seek medical help.

Community mitigation strategies

For some respiratory viruses, mask mandates, social distancing, and travel restrictions have been implemented to reduce spread of disease with use of public health campaigns for awareness and prevention. Surveillance and research on respiratory viruses have informed vaccination strategies and public health responses.

Pneumonia

Pneumonia is defined as inflammation of the substance of the lungs. It is usually caused by bacteria but can also be caused by viruses and fungi. Clinically, it usually presents as an acute illness with cough, purulent sputum, breathlessness, and fever, together with physical signs or radiological changes compatible with consolidation of the lung (**Fig. 11.21**). However, it can present with more subtle symptoms, particularly in the elderly.

Pneumonia is usually ***classified*** by the setting in which the patient has contracted the infection, for example:

- ***community-acquired pneumonia*** in a person with no underlying immunosuppression or malignancy
- ***hospital-acquired pneumonia*** (sometimes called 'healthcare-associated pneumonia', reflecting the role of other institutions such as nursing homes)
- ***aspiration pneumonia***, associated with the aspiration of food material or stomach contents into the lungs, and caused by impaired swallowing
- ***pneumonia in immunocompromised patient***, acquired through either a genetic defect, immunosuppressive medication, or acquired immunodeficiency, as in human immunodeficiency virus (HIV) infection
- ***ventilator-acquired pneumonia***, acquired through mechanical ventilation in a critical care unit.

Community-acquired pneumonia

Community-acquired pneumonia (CAP) occurs across all ages but is more common at the extremes of age. *Streptococcus pneumoniae* is the most common cause overall; however, in 30%–50% of cases, no organism is identifiable, while in about 20% more than one organism is present. Infection can be localized, when the whole of one or more lobes is affected ('lobar pneumonia'), or diffuse, when the lobules of the lung are mainly affected, often due to infection centred on the bronchi and bronchioles ('bronchopneumonia'). Factors that increase the risk of developing CAP are shown in **Box 11.26**.

Clinical features

The clinical presentation varies according to the immune state of the patient and the infecting agent. Features include:

Box 11.25 Management of an acute viral respiratory infection

Isolation and infection control measures
- Rapid identification of the viral pathogen
- Strict infection control protocols (PPE, hand hygiene)
- Visitor restrictions if in hospital and contact tracing when necessary

Supportive care
- Hydration, rest, and symptom management
- Antipyretic medications (paracetamol, ibuprofen if not contraindicated)
- Hospitalization for severe cases or specific viruses

Antiviral medications
- Considered for severe cases or vulnerable populations e.g., immunocompromised
- Choice of antiviral depends on the specific viral pathogen

Antibiotics and bacterial coinfections
- On occasion, when superadded bacterial infection is suspected, antibiotics may be considered as guided by clinical judgement and diagnostic tests

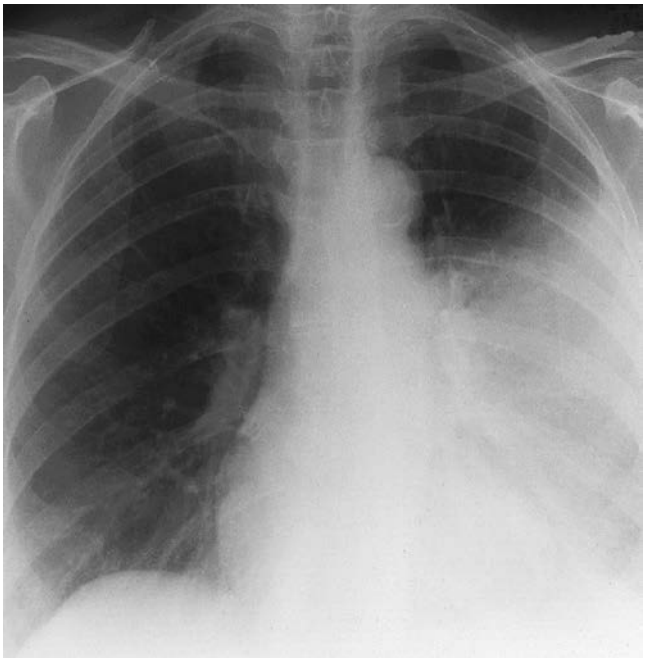

Fig. 11.21 CXR showing lobar pneumonia.

- ***a dry or productive cough***, sometimes with haemoptysis
- breathlessness
- ***fevers***, which, if swinging, may indicate empyema
- ***chest pain*** may be experienced, commonly pleuritic in nature and due to inflammation of the pleura; a pleural rub may be heard early on in the illness
- extrapulmonary features (**Box 11.27**).

In the elderly, CAP can present with confusion or non-specific symptoms such as recurrent falls. CAP should always be considered in the differential diagnosis of sick elderly patients, given their frequently atypical presentation.

Initial assessment

The type and extent of investigations depend on the severity of the illness, which also guides where the patient should be managed and predicts their outcome. Diagnostic microbiological tests are not needed in mild infection, which should be treated at home with standard oral antibiotics (amoxicillin, or clarithromycin for those with a history of penicillin allergy). Where patients have mild disease, CXR is not routinely recommended unless they fail to improve after 48–72 hours.

Severity is commonly assessed by the ***CURB-65*** or the ***CRB-65 score***; the CRB-65 score is used in the community where the serum urea level is not usually available (**Box 11.28**). These give a guide to the likely risk of fatal outcome but antibiotic choice must always be tempered by clinical assessment and judgement, taking into account other factors associated with increased rates of mortality (see 'other markers' in **Box 11.28**). These scoring systems are also helpful as clinical adjuncts to decisions regarding intravenous versus oral antibiotics, discharge, admission, and ambulatory management.

Box 11.26 Risk factors for community-acquired pneumonia

- ***Age:*** <16 or >65 years
- ***Co-morbidities:*** HIV infection, diabetes mellitus, chronic kidney disease, malnutrition, recent viral respiratory infection
- ***Other respiratory conditions:*** cystic fibrosis, bronchiectasis, chronic obstructive pulmonary disease, obstructing lesion (endoluminal cancer, inhaled foreign body)
- ***Lifestyle:*** cigarette smoking, excess alcohol, intravenous drug use
- ***Iatrogenic:*** immunosuppressant therapy (including prolonged corticosteroids)

Box 11.27 Extrapulmonary features of community-acquired pneumonia

- ***Myalgia, arthralgia, and malaise*** are common, particularly in infections caused by *Legionella* and *Mycoplasma*
- ***Myocarditis and pericarditis*** are cardiac manifestations of infection, most commonly in *Mycoplasma* pneumonia
- ***Headache*** is common in *Legionella* pneumonia. Meningoencephalitis and other neurological abnormalities also occur but are much less common
- ***Abdominal pain, diarrhoea, and vomiting*** are common. Hepatitis can be a feature of *Legionella* pneumonia
- ***Labial herpes simplex*** reactivation is relatively common in pneumococcal pneumonia
- ***Other skin rashes***, such as erythema multiforme and erythema nodosum, are found in *Mycoplasma* pneumonia. Stevens–Johnson syndrome (see 'Stevens-Johnson Syndrome and toxic epidermal necrolysis' later in this chapter) is a rare and potentially life-threatening complication of pneumonia

Investigations

All patients admitted to hospital with suspected CAP should have a CXR, blood tests, and microbiological tests.

Chest X-ray (CXR)

Radiological abnormalities can lag behind clinical signs. A normal CXR on presentation should be repeated after 2–3 days if CAP is suspected clinically. The CXR must be repeated 6 weeks later to rule out an underlying bronchial malignancy causing pneumonia due to bronchial obstruction.

Blood tests

Full blood count, serum creatinine and electrolytes, biochemistry, and CRP are helpful.

- ***Strep. pneumoniae.*** White cell count is usually >15 × 5^9/L (90% leucocytosis neutrophils). Inflammatory markers are significantly elevated: erythrocyte sedimentation rate (ESR) >100 mm/h; CRP >100 mg/L.
- ***Mycoplasma.*** White cell count is usually normal. In the presence of anaemia, haemolysis should be ruled out (direct Coombs' test and measurement of cold agglutinins, see Chapter 38).
- ***Legionella.*** There is often lymphopenia without marked leucocytosis, hyponatraemia, hypoalbuminaemia, and high serum levels of liver aminotransferases.

Other tests

- ***Sputum culture and blood cultures*** are required for all patients who have moderate to severe CAP, ideally before antibiotics are administered. In *S. pneumoniae* infection, positive blood cultures indicate more severe disease with greater mortality.
- ***Arterial blood gas analysis*** is necessary if oxygen saturation is <94%. Raised serum lactate suggests the presence of sepsis (Chapter 12).
- ***Urinary antigen testing*** for suspected pneumococcal or legionella pneumonia.
- ***An HIV test*** should be offered to all patients with pneumonia since it is a common indicator condition of previously undiagnosed HIV infection.

Box 11.28 CURB-65 score and other markers of severe community-acquired pneumonia

CURB-65:
C: ***Confusion*** present (abbreviated mental test score <8/10)
U: (plasma) ***Urea*** level >7 mmol/L
R: ***Respiratory rate*** >30 breaths/min
B: systolic ***Blood pressure*** <90 mmHg; diastolic <60 mmHg
65: ***age >65***

1 point for each of the above:

- ***Score 0–1:*** Treat as outpatient
- ***Score 2:*** Admit to hospital
- ***Score 3+:*** Often require care in intensive treatment unit

Mortality rates increase with increasing scores.

Other markers

- ***CXR:*** more than one lobe involved
- P_aO_2: <8 kPa
- ***Low albumin:*** <35 g/L
- ***White cell count:*** <4 × 10^9/L or >20 × 10^9/L
- ***Blood culture:*** positive
- Other ***co-morbidities***
- ***Absence of fever*** in the elderly

Management

Initial management and assessment should follow the guidelines for management of sepsis (see Chapter 12), particularly when a patient appears to have a moderate to severe pneumonia. In general:

- ***Oxygen.*** Supplemental oxygen should be administered to maintain saturations between 94% and 98% (provided the patient is not at risk of carbon dioxide retention, due to loss of hypoxic drive in COPD). In patients with known COPD, oxygen saturations should be maintained between 88% and 92%.
- ***Intravenous fluids.*** These are required in hypotensive patients showing any evidence of volume depletion and hypotension.
- ***Antibiotics.*** The first dose of antibiotic should be administered *within 1 hour of identifying any high-risk criteria* and treatment should not be delayed while investigations are awaited. Parenteral antibiotics should be switched to oral once the temperature has settled for a period of 24 h, provided there is no contraindication to oral therapy. If patients fail to respond to initial treatment, microbiological advice should be sought and alternative diagnoses considered. The antibiotic regimen should be adjusted specifically once culture and sensitivity results are available (Fig. 11.22).
- ***Thromboprophylaxis.*** If the patient is admitted for >12 h, subcutaneous LMWH should be prescribed and thromboembolism deterrent (TED) stockings should be fitted, unless contraindications exist.
- ***Physiotherapy.*** Chest physiotherapy is not needed unless sputum retention is an issue.
- ***Nutritional supplementation.*** Need is assessed by a dietician, particularly in severe disease.

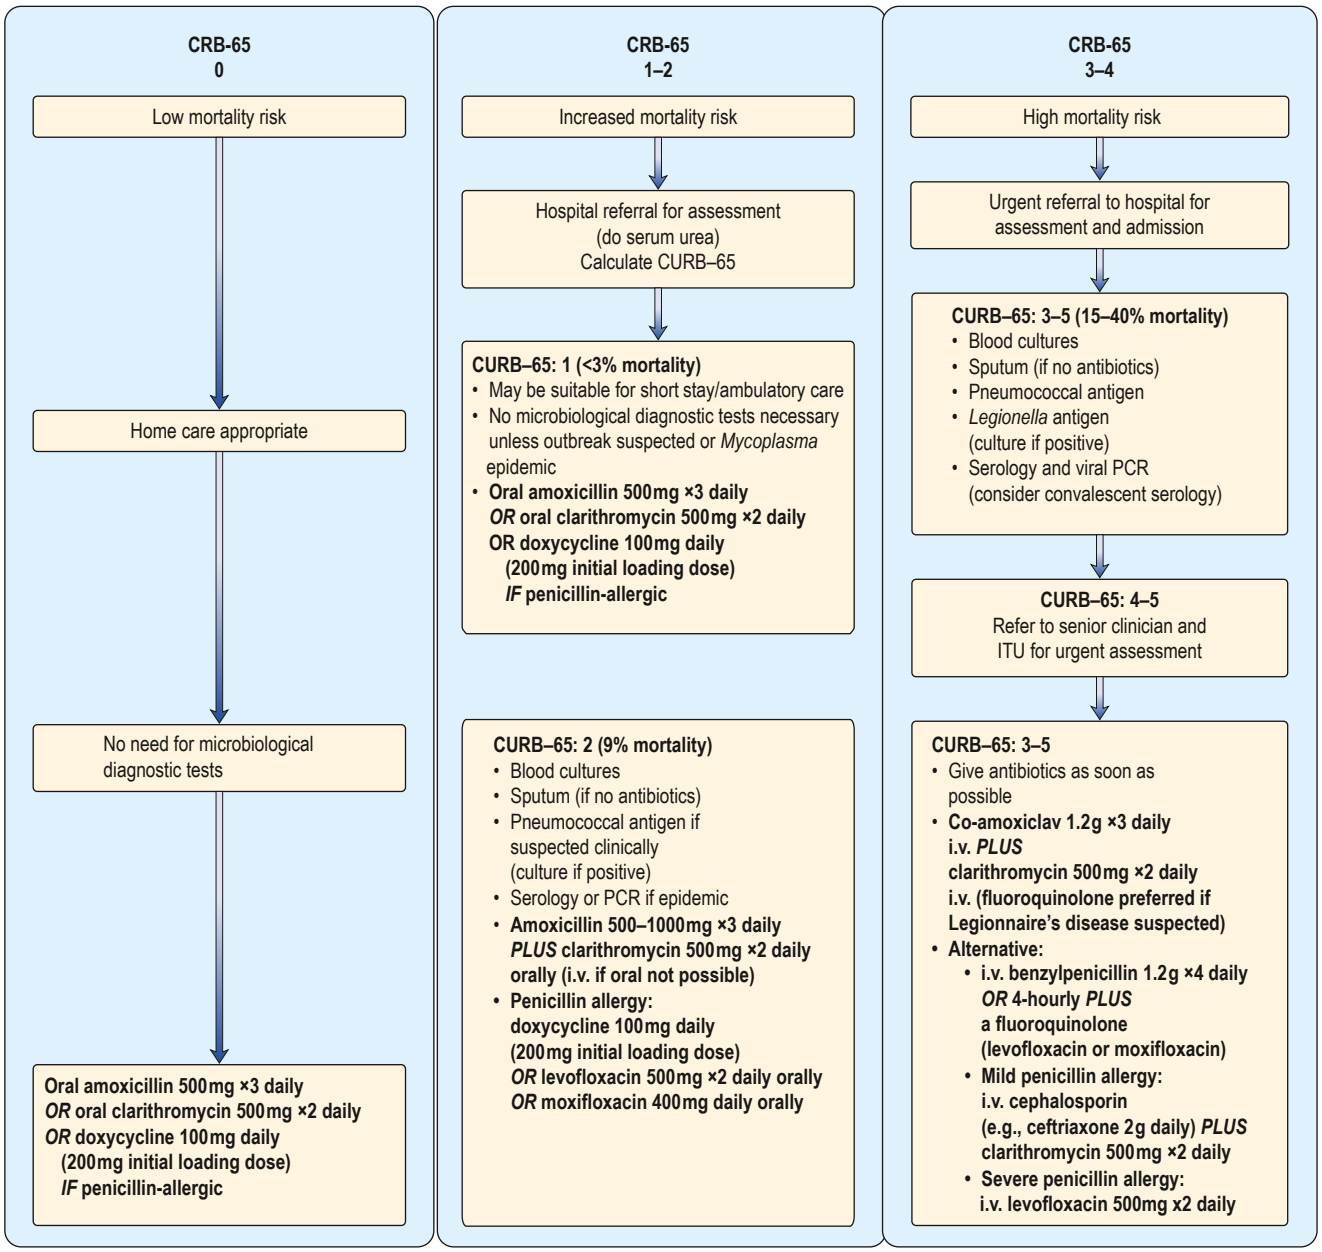

Fig. 11.22 Algorithm for the assessment and treatment of community-acquired pneumonia.
CRB, Confusion, respiratory rate, blood pressure (CURB includes urea); *ITU,* intensive treatment unit; *PCR,* polymerase chain reaction.

Box 11.29 Causes of slow-resolving pneumonia

Incorrect or incomplete antimicrobial treatment
- Underlying antibiotic resistance
- Inadequate dose/duration
- Non-adherence
- Malabsorption

Complication of community-acquired pneumonia
- Parapneumonic pleural effusion (exudative)
- Empyema
- Lung abscess

Underlying neoplastic lesion or other lung disease
- Obstructing lesion
- Bronchoalveolar cell carcinoma
- Bronchiectasis
- Tuberculosis

Alternative diagnosis
- Pulmonary thromboembolic disease
- Cryptogenic organizing pneumonia
- Eosinophilic pneumonia
- Pulmonary haemorrhage

Box 11.30 Complications of pneumonia

General
- Respiratory failure
- Sepsis—multisystem failure

Local
- Pleural effusion
- Empyema
- Lung abscess
- Organizing pneumonia
- Immunothrombosis *in situ*

- ***Analgesia.*** Simple analgesia, such as paracetamol or an NSAID (unless contraindicated), helps treat pleuritic pain, thereby reducing the risk of further complications due to restricted breathing because of pain (e.g., sputum retention, atelectasis, or secondary infection).

Causes of a slow-resolving pneumonia are outlined in **Box 11.29**.

Complications of pneumonia (Box 11.30)

Parapneumonic effusion and empyema

- Pleural effusions complicate around one-third to one-half of CAP. The majority of these are simple exudative effusions but empyema (purulent fluid in the pleural space) may develop. Early indications of empyema are ongoing fever and rising or persistently elevated inflammatory markers despite appropriate antibiotic therapy. Pleural aspiration should be performed under ultrasound guidance and sent for Gram stain, culture, fluid protein, glucose, and LDH (with comparison to serum levels). Light's criteria (see **Box 20.32**) can be applied to assess whether an effusion is transudative or exudative. Pathogens are often detectable and sensitivity analysis can guide antimicrobial therapy.
- An exudative effusion with pleural fluid pH of <7.2 is strongly suggestive of empyema. If an empyema develops, the fluid should be urgently drained to prevent further complications such as development of a thick pleural rind and prolonged hospital admission. Empyema increases mortality risk. The duration of antibiotic administration will usually need to be extended. Thoracic surgical intervention may be necessary.

Box 11.31 Causes of lung abscess and causative organisms

Causes
- Aspiration pneumonia
- Tuberculosis
- *Staphylococcus aureus* or *Klebsiella pneumoniae*
- Septic emboli usually containing staphylococci
- Inadequately treated community-acquired pneumonia
- Spread from an amoebic liver abscess
- Bronchial obstruction by an endoluminal cancer
- Foreign body inhalation

Common causative organisms
- *Klebsiella pneumoniae*
- *Staphylococcus aureus*
- Gram-negative enteric bacilli
- *Mycobacterium tuberculosis*
- *Streptococcus milleri*
- Anaerobic bacteria (post aspiration)
- *Haemophilus influenzae*

Lung abscess

This term is used to describe localized suppuration within the lung associated with cavity formation visible on the chest radiograph or CT scan, often with a fluid level (which indicates an air–liquid interface). There are several causes of lung abscess (**Box 11.31**). Clinical features include persisting or worsening pneumonia associated with the production of large quantities of sputum, which is often foul-smelling owing to anaerobic organisms. There is usually a swinging fever. Malaise and weight loss are frequent. There may be few signs on physical examination, although clubbing occurs in chronic suppuration. Patients have a normocytic anaemia and raised inflammatory markers (ESR/CRP). CT scanning is diagnostic, and bronchoscopy can be undertaken to obtain samples or remove foreign bodies. Treatment should be guided by available clinical judgement and culture results and is often prolonged (4–6 weeks). Surgical drainage is sometimes necessary.

Prevention

Cigarette smoking is an independent risk factor for CAP; if the patient still smokes, cessation advice and support should be given.

Vaccination against influenza and pneumococcus is recommended for at-risk groups. All patients over the age of 65 who have not previously been vaccinated and are admitted with CAP should have the pneumococcal vaccine before discharge from hospital.

Pneumonia in other settings

Hospital-acquired pneumonia

Hospital-acquired pneumonia (HAP) is defined as new onset of cough with purulent sputum, along with a compatible CXR demonstrating consolidation, in patients who are beyond 2 days of their initial admission to hospital or who have been in a healthcare setting within the last 3 months (including nursing or residential homes, as well as acute care facilities such as hospitals). HAP is the second most common form of hospital-acquired infection after urinary tract infections and carries a significant mortality risk, particularly in the elderly or those with comorbidities such as stroke, respiratory disease, or diabetes. In HAP, the causative organisms differ from those causing CAP (**Box 11.32**). Viral or fungal pathogens only affect immunocompromised hosts.

Ventilator-associated pneumonia

This occurs in the context of mechanical ventilation in a critical care setting. Often multidrug-resistant Gram-negative organisms

Box 11.32 Organisms implicated in hospital-acquired pneumonia

- Gram-negative bacteria (*Pseudomonas* spp., *Escherichia* spp., *Klebsiella* spp.)
- Anaerobic bacteria (*Enterobacter* spp.)
- *Staphylococcus aureus* (including methicillin-resistant *S. aureus*)
- *Acinetobacter* spp.

(such as *Acinetobacter baumannii*) are responsible, requiring careful selection of an appropriate antibiotic in association with a clinical microbiologist.

Aspiration pneumonia

Acute aspiration of gastric contents into the lungs can produce an extremely severe and sometimes fatal illness owing to the intense destructiveness of gastric acid. This can complicate anaesthesia, particularly during pregnancy (Mendelson's syndrome). Because of the bronchial anatomy, the most common sites for aspirated material to end up are the right middle lobe and the apical or posterior segments of the right lower lobe. Persistent pneumonia is often due to anaerobes and may progress to lung abscess or even bronchiectasis if protracted. It is vital to identify any underlying problem, as aspiration will recur without appropriate corrective measures.

Treatment should be directed specifically against positive cultures if available. If not, then co-amoxiclav is used for mild to moderate disease, which covers Gram-negative and anaerobic bacteria. Treatment needs to be escalated when there is a lack of response or cases are severe.

Pneumonia in immunocompromised patients

Patients who are immunosuppressed (either iatrogenically or due to a defect in host defences) are at risk not only from all the usual organisms that can cause pneumonia but also from opportunistic pathogens that would not be expected to cause disease. These opportunistic pathogens can be commonly occurring microorganisms (that are ubiquitous in the environment) or bacteria, viruses, and fungi that are less common (see **Box 44.13**). The symptom pattern may resemble CAP or be more non-specific. A high degree of clinical suspicion is therefore necessary when assessing an ill patient who is immunocompromised.

Pneumocystis jirovecii pneumonia

Pneumocystis pneumonia is one of the most common opportunistic infections encountered in clinical practice. It affects patients on immunosuppressant therapy, such as long-term corticosteroids, monoclonal antibodies, or methotrexate for autoimmune disease; those on anti-rejection medication after a solid organ or haematopoietic stem cell transplantation; and those infected with HIV. Individuals with CD4 counts of less than 200/mm^3 are at particular risk. *Pneumocystis jirovecii* is found in the air, and pneumonia arises from re-infection rather than reactivation of persisting organisms acquired in childhood.

Clinically, the pneumonia is associated with a high fever, breathlessness, and dry cough. A characteristic feature on examination is rapid desaturation on exercise or exertion. The typical radiographic appearance is one of diffuse bilateral alveolar and interstitial shadowing beginning in the perihilar regions and spreading out in a butterfly pattern. Other CXR appearances include localized infiltration, nodules, cavitation, or a pneumothorax but in approximately 10% of cases is normal. Empirical treatment is justified in very sick high-risk patients; wherever possible, however, the diagnosis should be confirmed by indirect immunofluorescence on induced sputum or bronchoalveolar lavage fluid. First-line treatment of *Pneumocystis* pneumonia is with high-dose co-trimoxazole (see Chapter 44), with adjunctive corticosteroids in patients with HIV infection.

Pulmonary embolism

Refer to the section 'Deep venous thrombosis and pulmonary embolism'.

Pneumothorax

'Pneumothorax' means air in the pleural space. Primary spontaneous pneumothoraces occur predominantly in young people. Traditionally, patients are tall, thin, and male but shape, size, and sex often do not follow this rule. Primary pneumothoraces are usually caused by rupture of a pleural bleb, typically apical, and are thought to be due to congenital defects in the connective tissue of the alveolar walls. Both lungs are affected with equal frequency.

Secondary pneumothoraces occur in conjunction with pre-existing lung disease such as COPD, infection, and cystic fibrosis. Iatrogenic pneumothoraces are caused by instrumentation to the thorax, such as central venous line insertion, percutaneous or transbronchial lung biopsy, or trauma.

Clinical features

Patients commonly present with sudden onset of pleuritic chest pain and breathlessness. On careful questioning, they may be discovered to have had a milder version of these symptoms in the past but not sought medical attention. Clinical signs are of reduced or absent breath sounds over the affected lung and a hyper-resonant percussion note.

A high index of suspicion should be maintained for tension pneumothorax, an uncommon but immediately life-threatening condition, most commonly seen after trauma or in the context of mechanical ventilation, where air enters the pleural space and is unable to escape, meaning intrapleural pressure progressively increases. With tension pneumothorax, the trachea will deviate progressively away from the affected side, and embarrassment of right ventricular venous return results in jugular venous engorgement, hypotension, and ultimately cardiac arrest. Immediate treatment is required (hence the old adage that a clinician should never see an X-ray showing tension pneumothorax) although POCUS can provide real-time confirmation of the diagnosis. Emergency decompression is preferably using a specialist longer 10G non-kinking thoracocentesis catheter, inserted in the 'triangle of safety' and has a lower failure rate than the traditional approach of inserting a 14G or 16G cannula in the 2nd intercostal space, mid-clavicular line. Subsequent open thoracostomy or chest tube insertion is required. Chest compressions will help to treat pneumothorax, so if the patient is in cardiopulmonary arrest, then this is prioritized.

Investigations

Plain CXR is the baseline investigation and the size of pneumothorax should be recorded (Fig. 8.5). There are several ways to measure: in North America the apex to cupola distance tends to be used, while UK guidelines recommend the pleura to edge-of-lung distance. If a patient's first pneumothorax resolves and there is no recurrence, cross-sectional imaging with a CT thorax is unnecessary. However, if the CXR is abnormal on resolution, a CT scan should be requested. With the common use of cannabis and other recreational drugs, bullae and associated emphysema are being more commonly seen in young people.

POCUS can also be used to confirm and localize a pneumothorax.

Management

Pneumothoraces can be managed in a number of ways (**Fig. 11.23**), depending on the cause and the severity of symptoms on presentation. Treatment includes simple observation, pleural aspiration, intercostal drain, and surgical management, both in the more acute situation and electively.

- ***Observation:*** For asymptomatic patients with a primary spontaneous pneumothorax, or those with minimal symptoms (no significant pain, breathlessness, or physiological compromise), conservative management can be considered regardless of the size of the pneumothorax. Likewise, for patients with mild

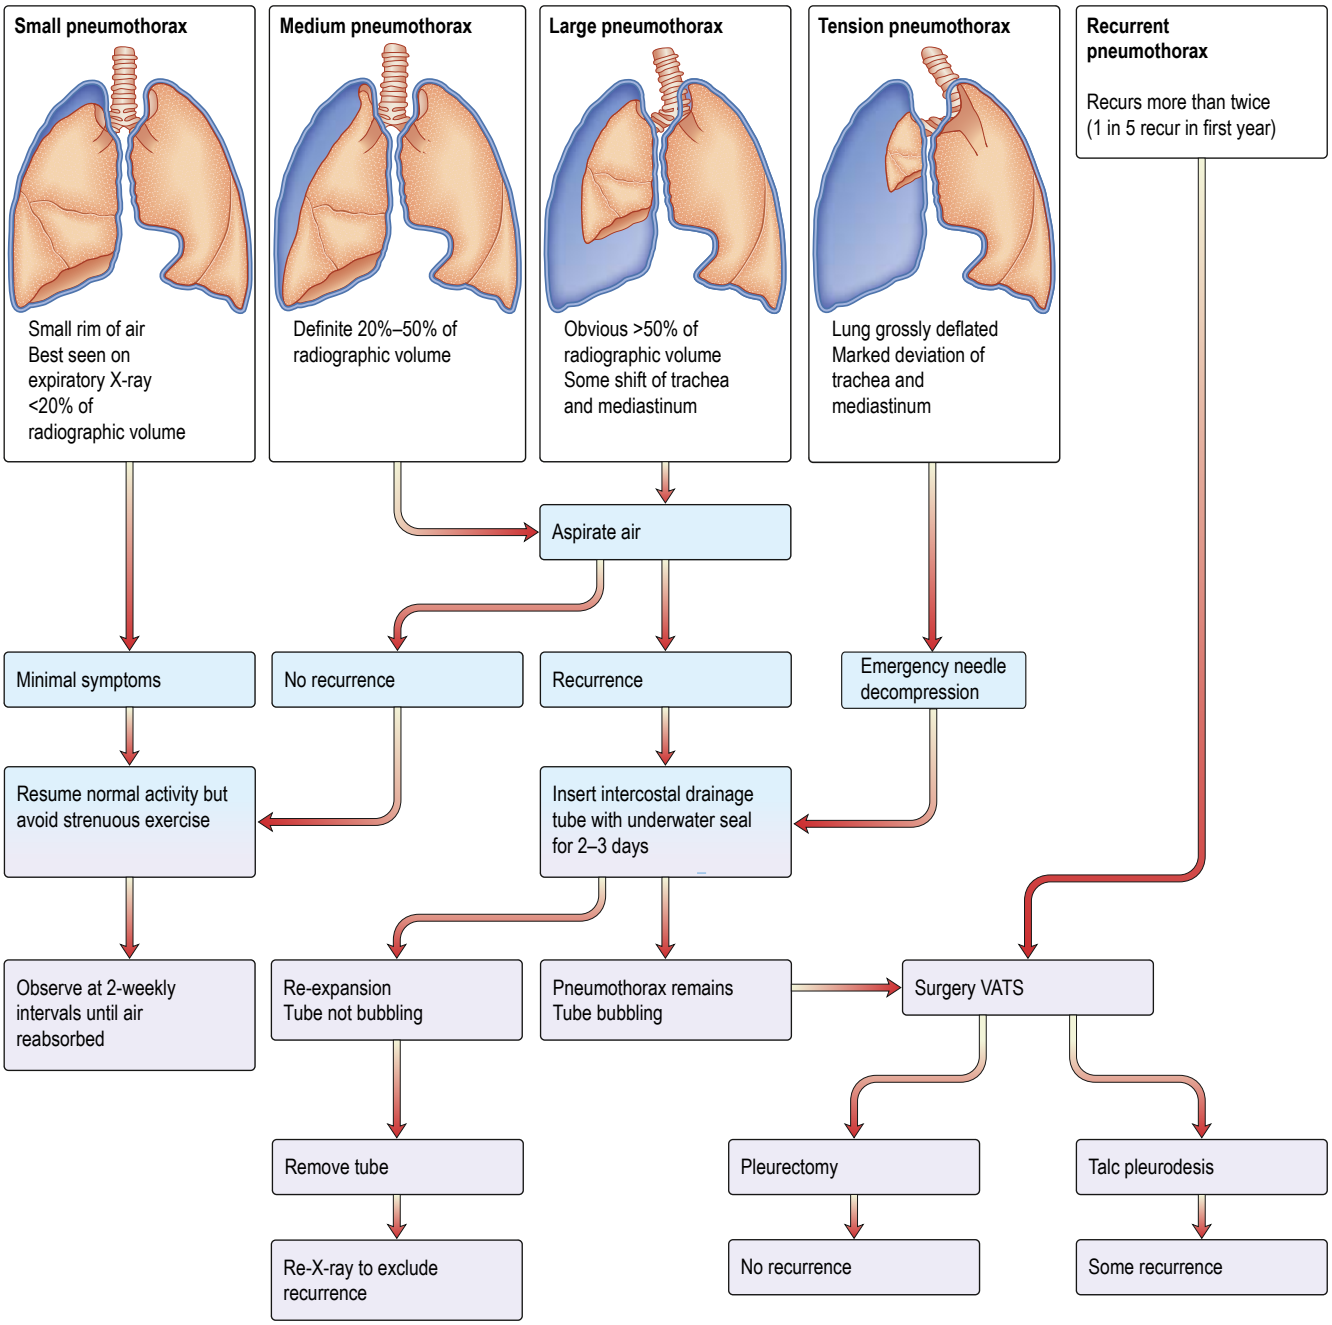

Fig. 11.23 Pneumothorax: an algorithm for management. Recent British Thoracic Society Guidelines (2023) recommend considering initial conservative management in asymptomatic/minimally symptomatic patients with primary spontaneous pneumothorax of any size (not tension pneumothorax). *VATS,* Video-assisted thoracoscopic surgery.

symptoms and a pneumothorax of <2 cm simple observation is enough. Patients can be discharged from the ED with instructions to return if their symptoms become worse. They should be advised not to fly until the pneumothorax has completely resolved and never to scuba dive unless they have had surgical pleurodesis (Box 11.33). They have a 30% chance of a recurrent pneumothorax. Patients often ask about sport and exercise, and while there are no real restrictions apart from diving, they should generally rest for a few days before exercising in moderation and should avoid contact sports for a week or two. Outpatient follow-up should be arranged within 10 days.

- ***Aspiration:*** This can be considered in symptomatic patients with a primary spontaneous pneumothorax of >2 cm or >1 cm in a secondary pneumothorax. It is undertaken using a 16 French gauge needle attached to a three-way tap and a 50 mL syringe (Box 11.34). Generally, aspiration should not be attempted in most cases of traumatic pneumothorax. It should be followed by a repeat CXR, discharge advice (as described), and outpatient follow-up.
- ***Pleural intercostal drain:*** If aspiration fails to inflate the lung satisfactorily, the patient is very breathless on admission, there is evidence of a tension pneumothorax or the cause is related to trauma, an intercostal drain should be inserted, normally in the mid-axillary line 4th intercostal space (see **Box 11.7**). The tube should be connected to an underwater drain and bottle, which are kept below the level of the patient's chest. It should be checked daily for evidence of infection at the insertion site and for kinks and leaks along its course.
- ***Surgical pleurodesis and bleb resection:*** An open surgical pleurodesis via thoracotomy or VATS procedure should be considered when the lung fails to re-inflate. Elective surgery may be appropriate after a first episode of pneumothorax in those with tension pneumothorax or who work in high-risk professions where the risk of recurrence needs to be maximally reduced (e.g., airline pilot) and after a second episode in others.
- ***Smoking:*** Patients should be strongly advised to stop smoking both tobacco and recreational drugs. Cannabis, in particular, can cause marked emphysematous changes in younger people, which leads to subcutaneous blebs and bullae.
- ***Psychological effects:*** Medical staff underestimate the concern that patients often feel, knowing that they have a medical condition that can potentially recur at any time. Some become very anxious and often request surgical pleurodesis after their second or third recurrence.

Box 11.33 Advice to patients after pneumothorax

- No flying for 1 week after complete resolution
- No diving
- Smoking cessation
- 30%–50% chance of recurrence
- Future management: consider surgery

Box 11.34 Simple aspiration of pneumothorax

1. Explain the nature of the procedure and obtain consent.
2. Infiltrate 2% lidocaine (maximum dose 3 mg/kg, not to exceed 200 mg) down to the pleura in the second intercostal space in the mid-clavicular line.
3. Push a 3–4 cm 16-gauge cannula through the pleura.
4. Connect the cannula to a three-way tap and 50 mL syringe.
5. Aspirate up to 2.5 L of air. Stop if resistance to suction is felt or the patient coughs excessively.
6. Repeat the chest X-ray (in expiration) in the X-ray department.

Ambulatory pleural drainage devices have been shown to be a feasible alternative to conventional inpatient management in patients with primary spontaneous pneumothorax in the absence of significant chronic lung disease, albeit with an increased risk of complications such as enlarging pneumothorax or device dislodgement, and may gather popularity in coming years.

Haemoptysis

Haemoptysis is defined as the expectoration of blood originating from the lower respiratory tract below the glottis. It has the potential to lead to life-threatening complications and requires prompt and careful evaluation of its severity and the patient's overall status (ABCDE approach) as well as of the underlying cause.

Massive haemoptysis

Massive haemoptysis—the expectoration of a significant volume of blood—presents a substantial risk and should be addressed urgently. Definitions of massive haemoptysis vary but include expectoration of blood equal to or exceeding either 500 mL within 24 hours or a rate of 100 mL per hour, or any haemoptysis impairing gas exchange or resulting in haemodynamic instability. It is important to note that haemoptysis often involves aerated blood, which can be mistaken for a lesser severity.

Common causes of haemoptysis

Haemoptysis can be broadly categorized into five main groups based on the underlying aetiology: infective, neoplastic, vascular, autoimmune, and drug-related (Box 11.35).

It is important to discriminate true haemoptysis from 'pseudo-haemoptysis'. Examples of pseudo-haemoptysis include misinterpretation of haematemesis as haemoptysis, or coughing of blood originating from sources other than the lower respiratory tract, such as the nasopharynx, which would require different treatment approaches.

Box 11.35 Common causes of haemoptysis

Category	Common causes of haemoptysis
Infective	Pneumonia Bronchiectasis Tuberculosis Lung abscess Mycetoma
Neoplastic	Lung cancer (primary or secondary) Bronchial adenoma
Vascular	Pulmonary embolism Arteriovenous malformations Pulmonary hypertension Mitral stenosis (severe) Pulmonary oedema
Autoimmune	Granulomatosis with polyangiitis Anti-glomerular basement membrane disease (anti-GBM disease, Goodpasture's syndrome)
Drug-related	Anticoagulants and antiplatelet agents

Clinical assessment

History

- **Characterize the haemoptysis:** Establish the quantity and characteristics of the blood expectorated, such as whether it is streaked, mixed with coloured sputum or pure blood. This aids in determining both the severity and source of the haemoptysis (e.g., the haemoptysis of pulmonary oedema is often described as 'pink and frothy').
- Ask questions aimed at **ruling out pseudo-haemoptysis** (e.g., was the haemoptysis preceded by epistaxis or vomiting?)
- Ask about **bleeding at other sites**, which may point to a more generalized bleeding tendency
- Ask about **associated symptoms:**
  - Cough with coloured sputum and fever suggest infection
  - Pleuritic chest pain might suggest pulmonary infarction (PE)
  - A prodrome of constitutional symptoms including anorexia, weight loss, or chronic cough might suggest malignancy or tuberculosis
- Daily cough productive of sputum or a history of childhood respiratory disease may suggest bronchiectasis
- Ask about skin rashes, ocular or nasal symptoms, and joint aches which might suggest vasculitis
- Take a **smoking history** as a risk factor for lung cancer/chronic lung disease
- Enquire about relevant **co-morbidities** (e.g., heart failure or valvular disease, coagulation disorders)
- Seek a **family history** of bleeding disorders, cancer, or hereditary conditions that may contribute to haemoptysis (e.g., hereditary haemorrhagic telangiectasia, HHT)
- **Review medications** (particularly antiplatelets or anticoagulants)
- Enquire about **occupational or environmental exposures**, recent **travel**, and **risk factors for VTE**.

Physical examination

Physical examination should include an assessment for possible haemodynamic or respiratory compromise and should focus primarily on cardiovascular and respiratory systems.

- Generalized cachexia suggests malignancy or chronic infection
- Fingernail clubbing suggests bronchogenic carcinoma, chronic suppurative lung disease (bronchiectasis or lung abscess), or pulmonary TB
- Purpura may suggest underlying vasculitis or a generalized bleeding disorder
- Examine the skin for telangiectasia suggesting HHT
- Lymphadenopathy in the neck or axillae may suggest malignancy or infection
- Look for signs of DVT in the legs (which may imply PE)
- Listen for the low-pitched 'rumbling' mid-diastolic murmur of mitral stenosis (which may lead to bronchial venous bleeding, so-called 'pulmonary apoplexy')
- Examine the chest:
  - A localized wheeze may indicate an obstructing endobronchial lesion
  - A pleural rub may be present in patients with pneumonia or pulmonary infarction
  - Signs of lung collapse (reduced breath sounds, dull percussion noted, deviation of trachea towards affected side) suggest an endobronchial lesion
  - The presence of coarse crackles or bronchial breathing may indicate infection, but can also be heard over zones of pulmonary haemorrhage

Investigations

- **Oxygen saturations** will identify a hypoxic patient at the bedside.
- **Core lab tests** should include a full blood count to check haemoglobin and exclude thrombocytopaenia. Coagulation studies may identify a generalized bleeding tendency. Elevated white blood cell count and CRP suggest infection. Significant AKI raises the possibility of a pulmonary-renal vasculitis.
- **Additional blood tests** may include D-dimer (in the diagnostic pathway for PE), BNP or NT-proBNP (congestive cardiac failure), or autoantibody testing (e.g., ANCA, anti-GBM antibody).
- **Chest X-ray** is a high-yield investigation in the work-up of haemoptysis and may show a solitary lung lesion or lobar collapse (suggestive of malignancy), an apical cavity (suggestive of TB), or signs of congestive cardiac failure. Consolidation may be due to infection or pulmonary haemorrhage; pulmonary vasculitis often results in bilateral airspace shadowing ('diffuse alveolar haemorrhage'). Pulmonary cavities may result from malignancy, infection (including TB), or vasculitis (usually granulomatosis with polyangiitis).
- Other tests may include urinalysis (haemoproteinuria may suggest renal vasculitis), sputum microscopy, culture and cytology (including AFB smear for mycobacteria), and respiratory viral panel.
- **Further tests** required may include CT chest (diagnosis of bronchiectasis, characterization of lung diseases including cancer and TB, identification of mycetoma), CT pulmonary angiogram (diagnosis of PE), echocardiography (diagnosis of left ventricular dysfunction, pulmonary hypertension or valvular disease), or bronchoscopy.

Management of massive haemoptysis

Boxes 11.36 and 11.37 summarize the steps that should be taken in management of a patient with massive haemoptysis. Timely intervention, including airway protection, resuscitation, and consultation with respiratory or interventional radiology specialists, is important.

Box 11.36 Management of massive haemoptysis

Management of massive haemoptysis	Description
Correct patient positioning	Position the patient according to the affected lung, aligning them to lie on the same side as the lesion or abnormality observed on imaging.
Establish a patent airway	Ensure a clear airway through suctioning to facilitate effective ventilation and oxygenation.
Maintain gas exchange and cardiovascular function	Implement supportive measures to sustain adequate gas exchange and cardiovascular stability. Red cell transfusion may be required.
ITU referral	In cases of massive haemoptysis, referral to ITU is often necessary for specialized management and monitoring. Intubation, to secure the airway and allow for effective suctioning, and mechanical ventilation may also be required.
Control the bleeding	Definitive treatments to control bleeding include arterial embolization and bronchoscopic therapy (**Box 11.37**). The anti-fibrinolytic drug tranexamic acid may help temporize while planning definitive treatment.

Box 11.37 Diagnostics and therapeutic procedures employed in massive haemoptysis

Test	Description
CT angiogram	This is helpful in confirming active bleeding and identifying a bleeding point and targets for treatment, but is diagnostic only
Direct angiography ± arterial embolization	Direct angiography performed by an interventional radiologist will confirm an active site of bleeding and facilitate arterial embolization as an option by which to control bleeding.
Flexible bronchoscopy	Usually the first choice for diagnostic bronchoscopy, particularly if the patient is stable.
Rigid bronchoscopy under general anaesthesia	Provides larger suction channels and facilitates jet ventilation (a form of specialized mechanical ventilation), preferred in cases of catastrophic bleeding.
Lasertherapy	Applied bronchoscopically, can be used to manage bleeding tumours in some cases.

Nausea and vomiting

Nausea and vomiting are common symptoms encountered in clinical practice, resulting from a wide range of underlying aetiologies. Management of patients presenting with nausea and vomiting is focused on identifying and treating the underlying cause.

The origins of nausea and vomiting are diverse (Box 11.38), encompassing metabolic factors, infectious agents, surgical or mechanical triggers, and adverse reactions to both foods and medications. Additionally, these symptoms can manifest in the absence of organic disease.

Clinical assessment

History should include details on the onset, duration, and frequency of symptoms and any associated features; for example, abdominal pain, weight loss. Enquire about potential triggers or exacerbating factors; for example, changes in diet, pregnancy. Consider features which may indicate a need for urgent intervention; for example, severe abdominal pain, haematemesis. Obtain a review of systems which may provide clues to the underlying cause; for example, GI symptoms such as diarrhoea and constipation, and neurological symptoms such as headache and dizziness.

Consider the patient's medical history, focusing on conditions known to cause nausea and vomiting; for example, peptic ulcer disease. Enquire about new medications, alcohol and drug use, and travel history.

Perform a thorough physical examination, specifically assess hydration status and examine the abdomen for tenderness, distension, organomegaly, masses, or abnormal bowel sounds.

Investigations

When the underlying cause remains elusive, further investigations such as imaging (e.g., abdominal ultrasound or CT) or gastroscopy may become necessary. Appropriate specialty referral should be considered.

Management

Management hinges on identification and treatment of the underlying cause. Supportive measures, applicable to all patients, may involve oral or intravenous rehydration and antiemetic therapy (see Box 22.7).

Box 11.38 Common causes of nausea and vomiting

Infective	Gastroenteritis (viral, bacterial)
Metabolic	Diabetic ketoacidosis Hypercalcaemia Uraemia
Abdominal	Mechanical bowel obstruction Paralytic ileus Biliary obstruction Pancreatitis Gastric outlet obstruction/pyloric stenosis Gastro-oesophageal reflux Peptic ulcer disease Gastroparesis
Neurological	Raised intracranial pressure (e.g., brain tumour) Migraine Brainstem or cerebellar syndromes
Vestibular	Vertigo (any cause)
Drugs	Opiates Chemotherapy Antibiotics
Psychiatric	Bulimia nervosa
Other	Cyclical vomiting syndrome Cannabis smoking Alcohol (toxicity, or 'hangover') Myocardial infarction Hyperemesis gravidarum

Diarrhoea

Diarrhoea is formally defined as more than 300 g per day of dry faeces passed in three motions or more, however, its meaning has changed somewhat in everyday language such that it is often used to describe loose stool, urgency, or watery stool of any amount.

Clinical assessment

Patients presenting to acute medical services would usually have diarrhoea that falls into the acute (less than four weeks duration) category. Travel, social, and past medical history can be key to establishing a cause, while many medications can also cause loose stool, also making a detailed drug history important. Loose stool can also be a non-specific sign of general illness including sepsis. Box 11.39 summarizes the causes of acute diarrhoea and clues to resolving the differential diagnosis.

Investigations

- **Arterial or venous blood gas:** lactic acidosis may reflect volume depletion in severe diarrhoeal illnesses, or bowel ischaemia.
- **Core blood tests:** FBC, urea and electrolytes, creatinine, calcium, phosphate, LFTs, and CRP. Severe or prolonged diarrhoea may result in hypomagnesaemia. Additional tests depending on circumstance may include thyroid function, haematinics, and coeliac serology.
- **Stool tests:** stool cultures and *Clostridium difficile* glutamate dehydrogenase (GDH) and toxin testing are important first-line investigations. Low faecal calprotectin (<50 µg/g) excludes inflammatory bowel disease (IBD), but elevated levels are not specific and may occur with infectious colitis. Stool microscopy for ova, cysts, and parasites is indicated in the returning traveller and immunocompromised patients; the diagnostic

Box 11.39 Acute diarrhoea on the medical take: causes and diagnostic clues

Cause	Bloody stool?	History clues	Examination clues	Investigation clues
Infective colitis	Can be bloody	Short history (<14 days, even duration <24 h if viral), recent travel, social history of illness, visiting farms (*E. coli* 0157). Receptive anal sex may suggest Shigella or other STIs. Immunocompromised may suggest CMV, cryptosporidium, or fungal infections.		Eosinopenia may suggest typhoid species incl. *Salmonella*
Clostridium difficile infection	No	Recent antibiotics Previous *C. diff* carriage PPI use		WCC may be elevated (>25 × 10^9/L) May have toxic megacolon (transverse colon >6 cm width) *C. diff*. toxin or PCR positive
Drug induced	No	Causative drugs including recent antibiotics, immunotherapies, laxatives, overflow from anticholinergics or opiates, prokinetic medications	Faecal impaction	
Crohn's disease	Often bloody	Personal or family history, bimodal age peaks 15–40 and 50–60 Ulcers potentially from mouth to perianal region, mucus, and pus in stool Extraintestinal features may include episcleritis, seronegative arthritis	Lesions potentially from mouth (ulcers) to perianal region (skin tags, fistulae, scarring, sinuses) Skins lesions e.g., pyoderma gangrenosum or erythema nodosum Scars from previous surgery	Positive faecal calprotectin >50 μg/g
Ulcerative colitis	Often bloody	Personal or family history, younger age peak 15–30. History of primary sclerosing cholangitis Extraintestinal features may include uveitis, iritis, seronegative arthritis	Skins lesions e.g., erythema nodosum	May have toxic megacolon Positive faecal calprotectin >50 μg/g
Diverticular disease	Often bloody	Often older age group with history of constipation or previous diverticular disease		
Microscopic colitis	No	Female predominance, usually older age groups		By definition, no macroscopic disease such as ulcers on colonoscopy, requires biopsies to diagnose
Bacterial overgrowth	No	Colonization with bacteria after previous radiation, small bowel surgery, blind gut loop		Often B_{12} deficiency alongside that of fat-soluble vitamins (ADEK)
Bile salt malabsorption/ pancreatic insufficiency	No	Steatorrhoea Previous surgery e.g., cholecystectomy/ terminal ileum resection Alcohol misuse/pancreatitis	Scars from previous surgery	Faecal elastase low in pancreatic insufficiency
Coeliac disease	No	History of anaemia	Dermatitis herpetiformis Perioral stomatitis from iron deficiency	Anti-TTG/gliadin antibodies (check not IgA deficient)
Colon cancer	Can be bloody	Altered bowel habit, urgency. Family history of cancer	Mass on DRE	
Ischaemic colitis	Often bloody	Frequently abdominal pain, may be sudden onset. Cardiovascular risk factors or history of atrial fibrillation	Localized peritonism common	Neutrophil leucocytosis, hyperlactataemia unresponsive to fluid therapy
Irritable bowel syndrome	No	Largely diagnosis of exclusion		

yield for amoebiasis is optimal when examining a very fresh sample.

- **Abdominal X-ray:** detection of toxic megacolon in patients with severe *Clostridium difficile* or flare of IBD.
- Other investigations may be required if there is diagnostic uncertainty or symptoms fail to settle. These may include flexible sigmoidoscopy, abdomino-pelvic CT, small bowel MRI, or capsule endoscopy. Specialist input from

gastroenterology or infectious diseases teams may be required.

Management

Where suspicion exists for an infective cause, or the cause is unclear, patients with acute diarrhoea should be nursed in a side-room with appropriate barrier precautions and signage.

Acute gastrointestinal infections

These are common and often self-limiting in nature. Passage of bloody stool may indicate perianal disease (often bright red and coating the stool), or presence of an invasive organism causing enteritis (blood mixed with stool). Examples of invasive organisms include shigella (which may be acquired as a sexually transmitted infection), salmonella, campylobacter (both often called 'food poisoning'), or more rarely *Entamoeba histolytica* (if travel related; see Chapter 42). Empirical antibiotics, for example, azithromycin may be warranted although are usually reserved for those with severe or prolonged symptoms, or risk factors for severe illness such as immunocompromise. The management of acute diarrhoeal illness is usually supportive: treat dehydration with i.v. or oral fluids (oral rehydration solutions may be needed), check electrolytes, and replace as required.

Clostridium difficile (CD) colitis

This results from infection with a toxin-secreting strain of *Clostridium difficile* (CD) and typically follows broad-spectrum antibiotic treatment, depleting the normal colonic bacterial flora and allowing rapid multiplication. Previous carriage of CD (usually detected by glutamate dehydrogenase testing) or a very high white cell count may be clues to the diagnosis.

The initial treatment of CD is usually with oral metronidazole or oral vancomycin. There is a risk of toxic megacolon, which can be diagnosed on plain imaging or CT, and is a surgical emergency. Occasionally other medications (e.g., fidaxomicin), or even stool transplantation, taken as either frozen capsule or via nasogastric tube, are required to treat severe or chronic disease.

Drug-induced diarrhoea

Many medications can provoke a change in bowel habit with common offenders including metformin, opiates (constipation with overflow), laxatives, antiemetics (including metoclopramide), and weight loss medications (such as orlistat or acarbose). Non-infective diarrhoea is also a common side-effect of antibiotic therapy or for those patients receiving enteral feeding.

Non-infective colitis may present after treatment with immune checkpoint inhibitors for malignancy. Commonly, onset is approximately 5 to 10 weeks after the second or third dose of treatment. Infective causes may still need to be excluded. Affected patients may exhibit other organ-specific toxicity including adrenalitis, hypophysitis, thyroiditis, etc. Treatment is with high-dose immunosuppression for example, prednisolone 1 mg/kg or i.v. methylprednisolone.

Inflammatory bowel disease flare

Chronic inflammatory bowel diseases (IBD) that cause acute relapsing disease ('flares') include Crohn's disease and ulcerative colitis (UC) and are most often seen in younger patients (less than 40 years). Crohn's disease is characterized by transmural patchy inflammatory changes that can affect any portion of the bowel from the mouth (ask about ulcers) to the anus (ask about perianal disease). Ulcerative colitis is, as the name suggests, confined to the colon and manifests with mucosal inflammation that is usually confluent. Extraintestinal manifestations are well recognized in both conditions, including erythema nodosum, arthritides, and eye involvement, among others.

Clinical assessment

Patients often present with episodes of diarrhoea (often with blood or mucus) as well as weight loss, abdominal pain, and bloating. It is sometimes difficult to differentiate an infectious aetiology from an inflammatory one, and often the two coexist. Usually, a purely infective cause will settle after a few days whereas inflammatory causes may persist and recur. While patients with flares of UC will most commonly present with bloody diarrhoea, patients with Crohn's disease exhibit a much broader range of presentations including strictures (signs of intestinal obstruction), terminal ileitis (sometimes mimicking appendicitis), perforations, enteric fistulae (to bladder, vagina or skin) and perianal disease (including abscesses) and so need close examination and observation, and often a low threshold for cross-sectional imaging (e.g., CT abdomen and pelvis). The clinical status of patients should be monitored regularly (fever, tachycardia, stool frequency) and specialized gastroenterological advice should be sought early.

Investigations

FBC, CRP, liver function tests, urea and electrolytes and magnesium should be performed. Serial abdominal X-rays are required if concern exists for toxic megacolon (a thin-walled colon with diameter of >6 cm suggests impending perforation and requires urgent surgical referral). Stool cultures should be sent to exclude enteric infection. The incidence of concomitant *C. difficile* infection in patients admitted with severe colitis is increasing. This is associated with a significant increase in morbidity and must be sought and treated promptly.

Early flexible sigmoidoscopy should be performed to confirm diagnosis and biopsies taken to evaluate for cytomegalovirus. Additional small bowel assessments (e.g., MRI) may be required in Crohn's disease. Full colonoscopy should **not** be undertaken during severe attacks due to unacceptably increased risk of perforation and instead examinations limited to an unprepared flexible sigmoidoscopy.

Management

Ulcerative colitis

Patients with acute severe colitis (see **Box 11.40**) should be admitted to hospital and treated initially with hydrocortisone 100 mg i.v. 6-hourly, and with prophylactic doses of s.c. LMWH to prevent VTE. Corticosteroids should not be delayed while waiting for stool culture or *C. difficile* toxin results, although if *C. difficile* is strongly suspected, oral vancomycin should be commenced in parallel.

Success or failure of medical treatment of a severe attack of UC must be judged by an experienced gastroenterologist and colorectal surgeon. If patients have not responded to intravenous steroids within 3 days, either salvage medical therapy or surgery is required. If patients respond to intravenous steroids, they should be switched to oral prednisolone after approximately 5 days, which they can be weaned off over 8–10 weeks. All patients who have been admitted for severe colitis should be considered for long-term maintenance therapy with a thiopurine (azathioprine/mercaptopurine), biological agents such as anti-TNF or newer immunomodulatory therapies (see Chapter 22).

Crohn's disease

Management should always be in conjunction with a gastroenterology with IBD expertise and will vary widely depending on the acute

Box 11.40 Definition and management of a severe attack of ulcerative colitis

Definition (Modified Truelove and Witts criteria)

- Stool frequency: >6 stools/day with blood +++
  AND systemic toxicity defined by one of:
- Fever: >37.8°C
- Tachycardia: >90 beats/min
- Anaemia: <105 g/L haemoglobin
- CRP: >30 mg/L

Management

- Admit to hospital
- Test bloods: FBC/U&E/magnesium/CRP/LFTs
- Abdominal X-ray (assess for toxic megacolon)
- Exclude enteric infection (stool culture, CDT assay)
- Confirm diagnosis with unprepared limited flexible sigmoidoscopy (include histology to evaluate for CMV)
- Assess fluid status
- Give prophylactic anticoagulation
- i.v. hydrocortisone 100 mg, 4 times daily
- Monitor daily:
  - Stool frequency
  - Abdominal X-ray
  - Bloods (FBC/CRP/albumin)

clinical manifestation (e.g., intestinal obstruction vs. diarrhoea vs. abscess vs. enterocutaneous fistula, etc.). Early nutritional assessment and support is vital. Hospitalized patients should receive prophylactic s.c. LMWH for prevention of VTE.

In all cases, close liaison with a specialist IBD multidisciplinary service is required for longer-term management or for those patients with severe acute complications requiring anything other than a short hospital stay.

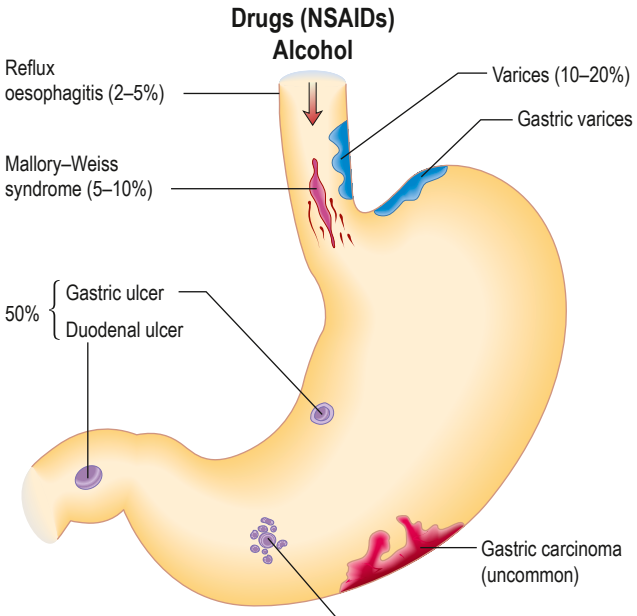
Haematemesis and melaena

Acute upper GI bleeding impacts approximately 1.33 individuals per 1000 in the population, equating to 85 000 cases annually. Notably, the 2015 NCEPOD report on GI haemorrhage management highlighted that 40% of patients receiving treatment for acute upper GI bleeding were inpatients initially admitted for a different medical condition.

The cardinal features are haematemesis (the vomiting of blood) and melaena (the passage of black tarry stools, the black colour being due to blood altered by passage through the gut). Melaena can occur with bleeding from any lesion proximal to the right colon. Rarely, melaena can also result from bleeding from the right colon.

Following a bleed from the upper GI tract, unaltered blood can appear *per rectum*, but the bleeding must be massive and is almost always accompanied by shock. The passage of dark blood and clots without shock is most often due to lower GI bleeding. Of note, stool may be frankly bloody or maroon with massive or brisk upper GI bleeding.

The **causes of upper GI bleeding** are summarized in Fig. 11.24. Peptic ulceration is the leading and most common cause of serious and life-threatening bleeding. Other important causes include oesophageal or gastric varices, arteriovenous malformations, tumours, and oesophageal (Mallory–Weiss) tears. Drugs including aspirin and NSAIDs can induce ulcers and erosions, with the risk of GI haemorrhage particularly marked in the elderly. Combining glucocorticoids and NSAIDs amplifies the incidence of GI haemorrhage. Anticoagulants and other antiplatelet agents do not cause acute GI haemorrhage *per se*, but bleeding from any cause is greater if the patient is anticoagulated.



Other uncommon causes
Gastric antral vascular ectasia (GAVE)
Hereditary telangiectasia (Osler–Weber–Rendu syndrome)
Pseudoxanthoma elasticum
Blood dyscrasias
Dieulafoy gastric vascular abnormality
Portal gastropathy
Aortic graft surgery with fistula

Fig. 11.24 Causes of upper gastrointestinal haemorrhage. The approximate frequency is also given. *NSAID,* Non-steroidal anti-inflammatory drug.

Clinical assessment

Evaluation should begin with focused history and examination, although emergency management measures (e.g., establishing intravenous access, resuscitation, and obtaining blood samples for crossmatching) may need to commence in parallel.

History

- Take a description of the **nature and quantity of blood** vomited or passed per rectum. Whenever possible a sample of vomitus or faeces should be inspected directly: the 'faeculant' vomiting of small bowel obstruction may be mistaken for the 'coffee ground' appearance of altered/coagulated blood; likewise the green-black/greyish stools of patients taking oral iron supplements may be mistaken for melaena
- **Onset and time course of symptoms:** A preceding history of vomiting/retching may indicate a Mallory-Weiss tear. A prodrome of epigastric discomfort relieved by eating or antacids may indicate a duodenal ulcer (the pain from which is often absent when haemorrhage occurs)
- **Medication use:** NSAIDs, aspirin, anticoagulants, antiplatelet agents
- **Alcohol history**
- **Previous GI bleeding** or endoscopic examinations
- **History of liver disease** (risk of varices) or **coagulopathy**

Physical examination

- **Vital signs:** Tachycardia and orthostatic blood pressure changes suggest moderate to severe blood loss; hypotension suggests life-threatening blood loss (hypotension may be late finding in healthy young adult)
- **Rectal examination** is performed to assess stool colour (melaena vs. haematochezia vs. brown)
- Significant abdominal tenderness accompanied by signs of peritoneal irritation (e.g., involuntary guarding) suggests perforation
- Look for signs of CLD (Chapter 23)

Investigations

- Laboratory tests should include full blood count, renal and liver function tests, clotting screen, blood group/antibody screening, and in all cases of severe bleeding or high-risk patients, cross-matching of red cell units.
- Venous blood gas sampling for rapid Hb measurement and lactate.
- In very brisk upper GI bleeds, the initial haemoglobin may be misleading and serial FBC samples are required.

Risk assessment

The routine use of validated risk scores for upper GI bleeding facilitates optimal triage decisions regarding timing of endoscopy.

The **Rockall score** (Boxes 11.41 and 11.42) predicts risk of rebleeding and death based on combined clinical and endoscopy findings. The 'pre-endoscopy Rockall' score (calculated based on age, circulatory status, and co-morbidities) is also validated to predict mortality in patients prior to undergoing gastroscopy.

The **Glasgow-Blatchford score** (Box 11.43) uses the level of plasma urea, haemoglobin, and clinical markers, but not endoscopic findings, to determine the need for intervention such as blood transfusion or endoscopy in GI bleeding.

Patients with very low pre-endoscopy Rockall scores (0–1) or Glasgow-Blatchford scores (0) may be suitable for ambulatory management if appropriate local pathways exist.

Scoring systems should never be relied upon exclusively for assessment of risk and urgency and should always be combined with common sense and clinical judgement.

The following factors affect the risk of rebleeding and death:

- age
- evidence of co-morbidity e.g., cardiac failure, ischaemic heart disease, CKD, and malignant disease
- presence of the classical clinical features of shock (pallor, cold peripheries, tachycardia, and low blood pressure)
- endoscopic diagnosis e.g., Mallory–Weiss tear, peptic ulceration, gastric antral vascular ectasia (GAVE; Fig. 11.25)
- endoscopic stigmata of recent bleeding e.g., adherent blood clot, spurting vessel
- clinical signs of CLD.

Bleeding associated with liver disease is often severe and recurrent if it is from varices. Liver failure can develop.

Management

Immediate management

This is shown in Box 11.44. In addition, stop NSAIDs, aspirin, clopidogrel, warfarin, and DOACs if patients are taking them (Box 11.45). Stopping antiplatelets may be hazardous (e.g., in patients with coronary artery stents) and can provoke thrombosis; discuss this urgently with a cardiologist.

Many hospitals have multidisciplinary specialist teams with agreed major haemorrhage protocols and the latter should be followed. Patients should be managed in monitored beds or ITU depending on the severity of bleeding. Oxygen should be given and the patient should be kept nil by mouth until an endoscopy has been performed.

Patients with large bleeds and clinical signs of shock require urgent resuscitation (see Fig. 13.22).

Blood volume

See Box 11.46. The major principle is to restore the blood volume rapidly to normal via two or more large-bore intravenous cannulae; plasma expanders or crystalloids are given until red cells become available. Transfusion of red cell concentrates is used with

Box 11.42 Rockall scores post-endoscopy

Rockall score	Predicted probabilities	
	Rebleeding risk (%)	Mortality (%)
0	5	0
1	3	0
2	5	0
3	11	3
4	14	5
5	24	11
6	33	17
7	44	27
8+	42	41

Box 11.41 Rockall risk assessment score in non-variceal upper gastrointestinal haemorrhage

Variable	Score			
	0	1	2	3
Age (years)	<60	60–79	>79	–
Circulation	BP >100 mmHg	BP > 100 mmHg	BP < 100 mmHg	–
	Pulse < 100 beats/min	Pulse >100 beats/min	Pulse > 100 beats/min	
Co-morbidity	None	–	Cardiac disease, any other major co-morbidity	Chronic kidney disease, liver failure, disseminated malignancy
Endoscopic diagnosis	Mallory–Weiss tear, no lesion	All other diagnoses	Malignancy of the upper gastrointestinal tract	–
Major SRH	None, or dark spots	–	Blood in the upper gastrointestinal tract, adherent clot, or spurting vessel	–

BP, Blood pressure (systolic); *SRH*, stigmata of recent haemorrhage.

Box 11.43 The Glasgow-Blatchford bleeding score

Criterion	Threshold	Score
Blood urea (mmol/L)	6.5–7.9	2
	8.0–9.9	3
	10.0–24.9	4
	>25	6
Haemoglobin in males (g/L)	120–129	1
	100–119	3
	<100	6
Haemoglobin in females (g/L)	100–119	1
	<100	6
Systolic blood pressure (mmHg)	100–109	1
	90–99	2
	<90	3
Pulse	≥100/min	1
Melaena at presentation	Yes	1
Syncope at presentation	Yes	2
Hepatic disease	Yes	2
Cardiac failure	Yes	2

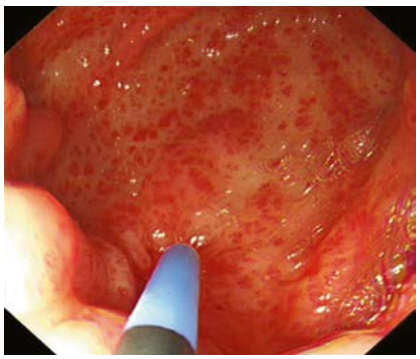


Fig. 11.25 Endoscopic view of gastric antral vascular ectasia (GAVE). An argon plasma coagulation catheter is shown at 6 o'clock.

a proposed transfusion threshold of 70 g/L. A higher threshold (90 g/L) may be appropriate in those with significant cardiopulmonary co-morbidities (e.g., coronary artery disease) or the elderly.

Transfusion must be monitored to avoid overload leading to heart failure, particularly in the elderly. The pulse rate and venous pressure are guides to adequacy of transfusion. A central venous pressure line is inserted for patients with organ failure who require blood transfusion, and in those most at risk of developing heart failure.

Haemoglobin levels are generally a poor indicator of the need to transfuse because anaemia does not develop immediately as haemodilution has not taken place. In most patients, the bleeding stops, albeit temporarily, so that further assessment can be made.

Endoscopy

Endoscopy will usually diagnose, stratify risk, and enable therapy to be performed if needed. Endoscopy should be carried out as soon as possible after the patient has been resuscitated. Patients with Rockall scores of 0 or 1 pre-endoscopy or Glasgow-Blatchford score of 0 may be candidates for immediate discharge (see below) and outpatient endoscopy the following day, depending on local policy.

Box 11.44 Management of acute gastrointestinal bleeding

- Take history and perform examination. Note co-morbidity
- Monitor pulse and BP half-hourly
- Take blood for haemoglobin, urea, electrolytes, liver biochemistry, coagulation screen, group, and crossmatching (2 units initially)
- Establish intravenous access—two large-bore i.v. cannulae (16 gauge or larger)
- Give oxygen therapy
- Give blood transfusion/crystalloid/colloid as necessary to correct haemodynamic instability. Indications for blood transfusion include:
  a. Shock (pallor, cold nose, systolic BP below 100 mmHg, pulse >100 beats/min)
  b. Haemoglobin <70 g/L in low-risk patients, <90 g/L in high-risk patients (elderly or cardiovascular co-morbidities)
- Consider need to activate major haemorrhage/massive transfusion protocols
- Keep 'nil by mouth'
- Perform urgent endoscopy in shocked patients/liver disease
- Continue to monitor pulse and BP
- Re-endoscope for continued bleeding/hypovolaemia
- Arrange surgery if bleeding persists

Box 11.45 Management of major upper GI bleed in patients with coagulopathy

- Initial resuscitation
- Blood transfusion with care
- Platelets if platelets <50 *and* actively bleeding/haemodynamically unstable and/or platelet dysfunction (e.g., chronic aspirin therapy)
- Fresh frozen plasma if fibrinogen <1 g/L *or* PT/INR or APTT > 1.5 times normal
- Prothrombin complex concentrate if taking warfarin and actively bleeding
- The half-lives of DOACs are short and in most cases GI bleeds will settle with resuscitation, blood products, and cessation of the drug; with massive or life-threatening bleeds, consider use of reversal agents (idracizumab for dabigatran, andexanet alfa for rivaroxaban/apixaban) in discussion with haematology. If specific reversal agents are not available, prothrombin complex concentrate can be considered.

Box 11.46 Blood transfusion in upper GI bleeding

- Avoid over-transfusion in variceal bleeds
- Hypovolaemic patients with normal Hb may need blood
- Haemodynamic instability despite crystalloid resuscitation
- Hb <90 g/L in high-risk patients (e.g., elderly, coronary artery disease)
- Hb <70 g/L in low-risk patients

Endoscopic treatment of acute GI bleeding is discussed further in Chapter 22, see 'Endoscopic management of acute gastrointestinal bleeding'.

Balloon tamponade may be performed as a temporizing measure for patients with uncontrollable haemorrhage likely due to varices using any of several devices (e.g., Sengstaken–Blakemore tube). Tracheal intubation is necessary if such a device is to be placed; ensure proper device placement prior to inflation to avoid oesophageal rupture.

Drug therapy

Use of acid suppression treatments (proton pump inhibitors) **before endoscopy** in patients with non-variceal upper GI bleeding is currently controversial. UK NICE guidance recommends *against* this in light of limited evidence of impact on mortality, rebleeding risk,

or need for surgery. The practice remains common, however, and may be associated with a reduction in the need for endoscopic interventions.

The antifibrinolytic agent, tranexamic acid, is no longer widely used in upper GI bleeding in light of a recent large randomized controlled trial (HALT-IT trial) showing no benefit on mortality but increased risk of VTE.

If suspecting *variceal* bleeding, immediate management should include:

- Full septic screen and prophylactic antibiotics
- Terlipressin 2 mg i.v., four times daily
- Erythromycin 3 mg/kg i.v. (20 min) (or metoclopramide 10 mg i.v.) in patients with severe bleeding; 30–90 min prior to endoscopy

After endoscopy, an intravenous PPI (e.g., omeprazole 80 mg followed by infusion 8 mg/h for 72 h) should be given to all patients with actively bleeding ulcers or ulcers with a visible vessel, as it reduces rebleeding rates and the need for surgery.

Uncontrolled or repeat bleeding

Endoscopy should be repeated to assess the bleeding site and to treat, if possible. Embolization by an interventional radiologist may be necessary if the bleeding persists. If this is not available locally or is unsuccessful, surgery is used to control the haemorrhage primarily.

Discharge policy

The patient's age, diagnosis on endoscopy, co-morbidity, the presence or absence of shock, and the availability of support in the community should be taken into consideration. In general, all patients who are haemodynamically stable and have no stigmata of recent haemorrhage on endoscopy (Rockall score post endoscopy ≤1) can be discharged from hospital within 24 hours. All shocked patients and patients with significant co-morbidity need longer inpatient observation.

Abdominal swelling

A swelling in the abdomen can be *focal*; for example, hepatomegaly, splenomegaly, hernia; or *generalized*; for example, ascites or small bowel obstruction (Box 11.47). The common causes of generalized abdominal swelling can usually be easily separated through history/examination and readily available laboratory and imaging tests:

- ***Ascites:*** Dull percussion note over fluid (dullness shifts on rolling), presence of a 'fluid thrill', confirmed with POCUS or departmental USS.
- ***Bowel obstruction:*** Symptoms include colicky abdominal pain, vomiting, and (absolute) constipation but vary depending on the level of obstruction; tympanic percussion note over gaseous distension; exaggerated high-pitched ('tinkling') bowel sounds in mechanical bowel obstruction; typical bowel gas patterns of large or small bowel obstruction on abdominal X-ray (see 'Plain radiography/X-rays' section, Chapter 8)
- ***Constipation:*** Faecal impaction should be recognized by digital rectal examination. Patients may experience 'overflow diarrhoea' which may obscure diagnosis. Risk factors include immobility, prolonged hospitalization, and opiate use.
- ***Pregnancy:*** Occasionally unsuspected by both patient and clinician. Point-of-care pregnancy testing should be considered in the assessment of all females of childbearing age.
- ***Obesity:*** Rarely a reason for acute presentation but may hinder recognition of other causes of abdominal swelling. A patient's subjective view on changes in their abdominal girth may be helpful.

? Box 11.47 Causes of abdominal swelling

Focal

- Organomegaly (e.g., massive hepatomegaly or splenomegaly, polycystic kidney disease, fibroid uterus, pancreatic pseudocyst)
- Distended hollow viscus (e.g., gastric outlet obstruction, urinary retention)
- Hernia
- Solid organ tumour
- Lymphadenopathy
- Haematoma (e.g., within the rectus sheath)

Generalized (sometimes remembered as the '5 Fs')

- Ascites ('Fluid')
- Small or large bowel obstruction ('Flatus')
- Pregnancy ('Foetus')
- Constipation ('Faeces')
- Obesity ('Fat')
- Ruptured aneurysm

? Box 11.48 Causes of ascites according to type of fluid

- **Straw-coloured**
  - Malignancy (most common cause)
  - Cirrhosis
  - Infective:
    - Tuberculosis
    - Following intra-abdominal perforation—any bacterium may be found (e.g., *Escherichia coli*)
    - Spontaneous in cirrhosis
  - Hepatic vein obstruction (Budd–Chiari syndrome)—protein level high in fluid
  - Chronic pancreatitis
  - Congestive cardiac failure
  - Constrictive pericarditis
  - Meigs' syndrome (ovarian tumour)
  - Hypoproteinaemia (e.g., nephrotic syndrome)
- **Chylous**
  - Obstruction of main lymphatic duct (e.g., by carcinoma)—chylomicrons are present
  - Cirrhosis
- **Haemorrhagic**
  - Malignancy
  - Ruptured ectopic pregnancy
  - Abdominal trauma
  - Acute pancreatitis

Ascites

Ascites, the accumulation of fluid within the peritoneal cavity, has a broad differential diagnosis (Box 11.48), with first presentation often to acute medical services.

Clinical assessment

- When did the patient first notice abdominal swelling and at what rate did this progress?

Box 11.49 Common abnormal blood results faced by the AIM physician

Blood test	Reference range	Mild derangement	Moderate derangement	Severe derangement
Potassium (mmol/L)	3.5–5.0	3.0–3.4 5.1–5.9	2.5–2.9 6.0–6.4	<2.5 ≥6.5
Sodium (mmol/L)	135–145	130–134 146–150	125–129 151–155	<125 >155
Calcium (corrected) (mmol/L)	2.20–2.60	2.10–2.19 2.61–2.75	1.90–2.09 2.76–3.00	<1.90 >3.00
Creatinine (μmol/L)	53–97	98–133	134–177	≥178
Platelets ($\times 10^9$/L)	150–400	100–149	50–99	<50

Note: Reference ranges may vary slightly between laboratories, and the values provided here are indicative. Interpretation of results should consider patient context, clinical history, and any specific guidelines from the relevant healthcare institution. This table serves as a general guide and is not exhaustive.

- Are there associated symptoms which may point towards underlying malignancy (appetite or weight loss or localizing symptoms such as rectal or abnormal vaginal bleeding or change in bowel habit) or infection (e.g., fevers or night sweats)?
- **Jaundice** may signify malignancy (commonly pancreatic cancer or liver metastases) or liver disease.
- Seek risk factors for CLD (alcohol and drug use, medications including herbal or traditional remedies, sexual history, travel history, vaccination history, and any known previous liver disease) and examine for signs of CLD and portal hypertension (see Chapter 23).
- **Abdominal pain** could signify Budd–Chiari syndrome (usually right upper quadrant accompanied by tender hepatomegaly and jaundice), an underlying malignancy (e.g., pancreatic or ovarian carcinoma) or the superadded complication of spontaneous bacterial peritonitis.
- **Generalized body swelling** may indicate nephrotic syndrome, congestive cardiac failure (most commonly right heart failure, for instance due to cor pulmonale), or cirrhosis.
- **Tense ascites** may splint the diaphragm and increase the patient's work of breathing and is one indication for paracentesis.

Investigations

- **Laboratory investigations** should include full blood count, 'liver function tests' (including serum albumin), renal function, and clotting profile.
- **Urinalysis** will show heavy proteinuria (3–4+) in ascites due to nephrotic syndrome.
- **Chest X-ray** may show cardiomegaly or pulmonary oedema (congestive cardiac failure), pulmonary metastases, or signs of pulmonary tuberculosis.
- **Ultrasound:** POCUS is commonly used to confirm the presence of ascites and mark sites for diagnostic aspiration or drainage. Departmental ultrasound will allow detailed organ assessment to seek evidence of hepatic cirrhosis or portal hypertension, hepatic vein thrombosis or liver metastases.
- **CT** (contrast enhanced): Request where a high index of suspicion exists for malignant ascites.
- **Ascitic fluid analysis:** This should be performed under ultrasound guidance and is essential for determining the underlying aetiology. An ascitic tap should be performed in all patients presenting with ascites, and the fluid should be sent for analysis, including cell count, total protein, albumin, culture (including acid-fast bacilli smear where appropriate), and cytology. The serum-ascites albumin gradient (SAAG) can be calculated to differentiate between portal hypertension-related ascites (SAAG ≥ 11 g/L) and non-portal hypertension causes (SAAG < 11 g/dL), see **Box 23.20**. A neutrophil count ≥250 cells/mm^3 in ascitic fluid is diagnostic for SBP and empirical antibiotic therapy should be initiated without waiting for culture results.

Management

Management of ascites should be directed towards the underlying causes and varies depending on aetiology.

Potential indications for therapeutic drainage of ascites include:

- Relief of symptoms (commonly performed in patients with decompensated cirrhosis or malignancy)
- Diaphragmatic splinting impairing ventilation
- Hepatorenal syndrome with tense ascites (relief of abdominal hypertension).

Large-volume paracentesis in patients with decompensated cirrhosis requires albumin replacement to support colloid oncotic pressure (usually 8 g albumin per litre of ascites removed, using a 20% solution). Albumin replacement is not required when draining non-cirrhotic ascites, although it is customary to do this in a staggered fashion to allow for assessment of haemodynamic tolerance.

Abnormal blood results

A frequent challenge faced by the AIM physician is the management of unexpected abnormal outpatient blood results in an out-of-hours setting. Examples include electrolyte disturbances, full blood count abnormalities, renal dysfunction, or prolonged clotting times. Gather as much relevant information regarding the patient as possible and then take steps to ensure patient safety. Information gathering can be challenging, as the laboratory may have very limited documentation related to the requested blood test. Search the available records of the patient for information on their medical history and medications and for clues as to the indication for the blood test concerned.

Box 11.49 offers some common examples of abnormal blood results which the AIM physician may encounter out-of-hours. Severely deranged results should trigger patient contact and emergency review.

A common example is an alert from the biochemistry laboratory regarding a significantly elevated potassium level. After reviewing available electronic records, the next step is to consider the abnormal result's severity: a serum potassium ≥6.5 mmol/L is considered severe and potentially life-threatening and requires immediate assessment. The patient should be contacted and advised to attend their local ED for a repeat blood test and an ECG to look for features of severe hyperkalaemia.

In the case of mild hyperkalaemia (serum potassium 5.1–5.9 mmol/L) it is usually unnecessary for the patient to attend emergency services immediately and instead they could be advised to attend ambulatory emergency care within 24 hours.

Box 11.50 Five key questions to ask when confronted by an abnormal creatinine result

1. Why was the blood test taken—routine monitoring or acutely unwell patient?
2. Do they have a previous creatinine result to compare with?
3. Does the patient have known chronic kidney disease (CKD)?
4. Have any new medications been commenced that could be responsible?
5. Has the patient recently completed a pregnancy? (creatinine falls below 80% of normal in second trimester)

For moderate hyperkalaemia (serum potassium 6.0–6.4 mmol/L) context becomes pivotal; for instance, a patient with chronic kidney disease (CKD) and hyperkalaemia may require different management than someone with apparently new hyperkalaemia of unclear origin. When uncertain, proceed cautiously and arrange urgent repeat testing and assessment.

The original requestor should be notified, outlining the abnormal result and the subsequent management undertaken. Follow-up investigations and consultations should be arranged as necessary to comprehensively address the patient's condition and ensure resolution.

Acute kidney injury

Acute kidney injury (AKI) refers to a sudden reduction in renal function, potentially impairing fluid, electrolyte, and acid–base homeostasis. It is associated with up to 20% of emergency hospital admissions and has been linked to overall poorer health outcomes. AKI is often seen on the acute medical take, either in conjunction with other pathology or as a standalone referral from primary care having been discovered on a blood test. As AKI is a clinico-biochemical syndrome, biochemistry results need to be interpreted with an understanding of the clinical context in which the blood test was taken (Box 11.50).

Definition and staging

AKI is recognized either by an acute rise in serum creatinine or fall in urine output and categorized into three stages of severity by the Kidney Disease Improving Global Outcomes (KDIGO) staging criteria (Box 11.51). Increasing severity of AKI correlates with worse clinical outcomes.

AKI may cause sudden, life-threatening metabolic and clinical disturbances such as hyperkalaemia or pulmonary oedema, particularly when a patient is oligo-anuric. While there is no explicit threshold for referral and admission to hospital, AKI stage 1 is usually investigated and managed via outpatient pathways such as ambulatory care or SDEC. Management of stage 2 and 3 AKI depends on clinical context, although most patients require referral to secondary care for inpatient management.

When assessing a patient with AKI, the parallel aims should be to identify and treat life-threatening complications and determine the cause—pre-renal, renal, or postrenal.

Causes of AKI

AKI may result from:

- ***Pre-renal*** causes—Falling kidney blood flow leads to a falling glomerular filtration rate (GFR). This might be due either to changes in the circulation, or to intrarenal vasomotor changes that drop glomerular perfusion pressures. Common causes of a falling effective circulating volume leading to renal hypoperfusion are outlined in Box 11.52. Common drugs interfering with intrarenal blood flow include non-steroidal anti-inflammatory drugs (NSAIDs) and ACE inhibitors/angiotensin receptor blockers (ARBs), which may contribute to AKI in patients with concomitant factors causing renal hypoperfusion (Fig. 11.26).
- ***Intrarenal*** parenchymal disorders (injury to glomerulus, tubule or vessels)—Most commonly acute tubular injury (ATI; formerly referred to as acute tubular necrosis), but with a broad differential diagnosis (see section on 'Intrarenal parenchymal AKI').
- ***Postrenal*** causes (urinary tract obstruction—functioning kidneys cannot excrete urine with back-pressure affecting function).

A useful mnemonic for common causes of AKI encountered on the medical take is 'STOP'—**S**epsis, **T**oxins, **O**bstruction, **P**arenchymal.

Box 11.51 KDIGO[a] classification of acute kidney injury

Stage	Serum creatinine concentration (SCr)	Urine output criteria
1	SCr 1.5–1.9 times baseline OR ≥ 26.5 μmol/L (0.3 mg/dL) increase	<0.5 mL/kg/h for 6–12 h
2	SCr 2–2.9 times baseline	<0.5 mL/kg/h for 6–12 h
3	SCr 3 times baseline OR initiation of kidney replacement therapy OR in patients <18 years, decrease in eGFR to <35 mL/min per 1.73 m^2	Anuria for ≥12 h

[a]Kidney Diseases: Improving Global Outcomes.

Box 11.52 Causes of a reduced effective circulating volume

- Dehydration
- Reduced intake (nil by mouth, confusion)
- Gut losses (vomiting, nasogastric tube losses, diarrhoea)
- Kidney losses (diuretics, hyperglycaemia)
- Burns, sweating
- Haemorrhage
- Third space losses (pancreatitis, peritonitis, bowel obstruction)
- Systemic vasodilation (septic shock, cirrhosis)
- Cardiac failure or shock (myocardial infarction, arrhythmias, cardiomyopathy, tamponade)

Clinical assessment

- What is the **clinical context** (Box 11.50)? Is the patient unwell?
  - A large proportion of AKI in acute medical patients is pre-renal and a cause (e.g., sepsis, hypovolaemia, recent surgery) will be readily apparent.
  - A patient with seizures or who has fallen with a 'long lie' is at risk of rhabdomyolysis.
  - Recent angiography may lead to contrast-induced AKI or cholesterol emboli.
- Does the patient have any common **risk factors for AKI** (Box 11.53)?
- Has any **new medication** been started?
  - ACE inhibitors/ARBs may provoke AKI when started in a patient with unrecognized bilateral renal artery stenosis.
  - NSAID use is often not volunteered and should be specifically sought.

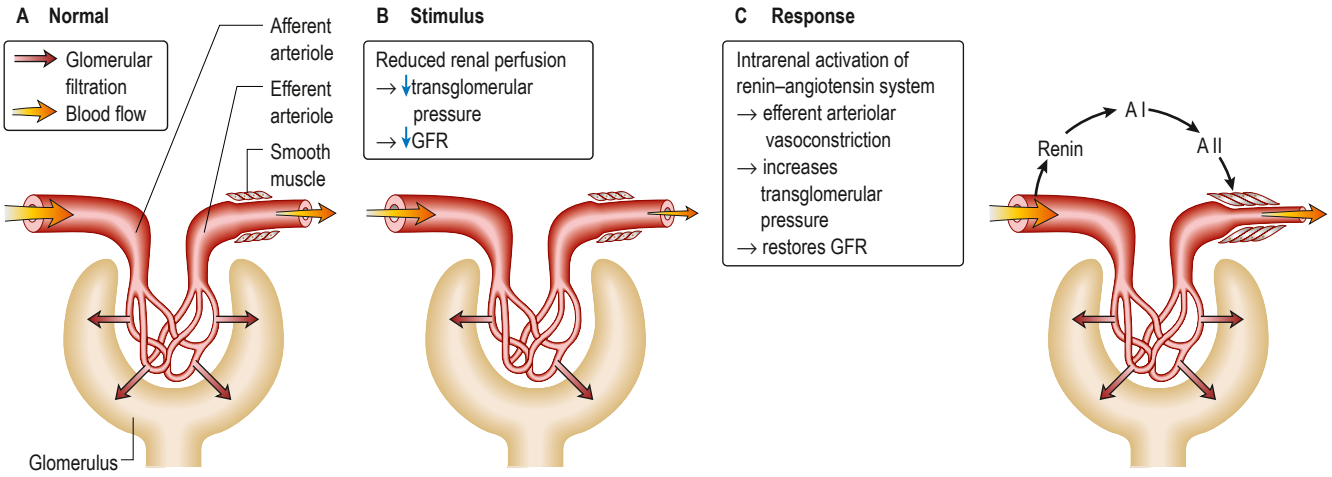

Fig. 11.26 Glomerular dynamics. **(A)** Glomerulus under 'resting' conditions; **(B)** reduced renal perfusion (e.g., due to systemic hypotension) results in a drop in transglomerular pressure and filtration; **(C)** intra-renal activation of the renin-angiotensin system restores GFR. ACE inhibitors/ARBs impair efferent arteriolar vasoconstriction and interrupt the normal glomerular haemodynamic response to a reduction in renal perfusion, compounding AKI. *AI,* Angiotensin I; *AII,* angiotensin II; *GFR,* glomerular filtration rate.

Box 11.53 Risk factors associated with development of AKI

Age >70
Immunosuppression or reduced immunity
CKD (eGFR < 60 mL/min/1.73 m^2)
Diabetes mellitus
Heart failure
Liver disease
Previous history of AKI
Neurological impairment (limiting access to fluids)
Nephrotoxic medication
Exposure to iodinated contrast agents in the prior week
Predisposing risk factors for urological obstruction such as enlarged prostate or previous history of hydronephrosis

- Recent antibiotic treatment may trigger tubulointerstitial nephritis.

- **Obstructive voiding symptoms** (e.g., poor stream, urinary hesitancy) raise suspicion of bladder outflow obstruction and postrenal AKI. A distended bladder may be palpable or detected with a bedside bladder scan.
- **Visible haematuria** may indicate bladder pathology (e.g., infection or malignancy) but should also prompt consideration of parenchymal renal disease (e.g., anti-GBM nephritis).
- **Systemic symptoms or signs** may point to a rarer multisystem disorder (e.g., purpuric rash or haemoptysis in small vessel vasculitis; bone pain and anaemia in multiple myeloma).
- **Fluid status assessment** to identify hypo- or hypervolaemia is critical (see Chapter 27). Reviewing fluid intake and losses, diuretic and antihypertensive medication, postural change in blood pressure, and general fluid status examination is paramount in any patient with an AKI. A fall in systolic blood pressure of 40 mmHg or more from a previous baseline, or a systolic pressure of ≤90 mmHg is a red flag. The most likely cause of shock can often be deduced from clinical examination (**Box 11.54**).

Box 11.54 Distinguishing causes of shock on clinical examination

	Hypovolaemia	Low cardiac output	Vasodilation
Hypotension	Postural hypotension	Hypotension	Hypotension
Peripheries	Cool	Cool	Warm
Jugular venous pressure	Low	Raised	Low

- Are any clinical features of **uraemia** present (e.g., encephalopathy, pericarditis)?

Investigations

- **Urinalysis:** Usually negative for blood and protein in pre-renal AKI or ATI. Blood and protein together should prompt consideration of a parenchymal cause (glomerulonephritis). Myoglobinuria in rhabdomyolysis causes a false-positive result for blood (due to cross-reaction with haemoglobin). Urinalysis is ideally performed prior to catheterization to avoid traumatic contamination.
- **Urine tests:** Urine sodium and markers of urine concentration may help to discriminate between pre-renal AKI and ATI (**Box 11.55**). Phase contrast microscopy may detect red cell casts or dysmorphic red cells indicating glomerulonephritis.
- **Arterial or venous blood gas** will provide a point-of-care potassium level and acid–base status.
- **Core lab tests:** These should include full blood count, urea and electrolytes (including potassium and calcium), and liver function tests. Serum CK should be checked in patients at risk of rhabdomyolysis and urate in patients at risk of tumour lysis syndrome.
- Depending on the clinical context, **additional laboratory tests** may be indicated (e.g., myeloma screening in a patient with hypercalcaemia or normocytic anaemia; autoantibody and blood-borne virus screening in a patient with possible glomerulonephritis). Indiscriminate use of advanced lab tests in AKI is costly

Box 11.55 Criteria for distinction between pre-renal and intrinsic causes of kidney dysfunction

Criteria	Pre-renal	Intrinsic
Urine specific gravity	>1.020	<1.010
Urine osmolality (mOsm/kg)	>500	<350
Urine sodium (mmol/L)	<10	>20
$Fe_{Na} = \frac{U_{Na}}{P_{Na}} + \frac{U_{Cr}}{P_{Cr}} \div 100$	<1%	>1%

With pre-renal AKI, the kidney avidly retains sodium and progressively concentrates urine in an effort to maintain renal blood flow, leading to increases in urine specific gravity and osmolality and a fall in urine sodium and fractional excretion of sodium. With established acute tubular injury ('intrinsic renal failure') these autoregulatory mechanisms cease to function. These criteria lack absolute specificity to discriminate pre-renal from intrinsic AKI and should be interpreted in parallel with clinical assessments of cause.
Cr, Creatinine; *Fe,* fractional excretion; *Na,* sodium; *P,* plasma; *U,* urine.

and may be misleading; where doubt exists the patient should be discussed with a nephrologist.

- An **ECG** may show electrical changes consistent with hyperkalaemia.
- **CXR** may reveal pulmonary oedema complicating oliguric AKI, or point towards an underlying cause (e.g., bihilar lymphadenopathy in sarcoidosis).
- **Ultrasound:** POCUS may be used to detect bladder outflow obstruction or hydronephrosis. Departmental ultrasound will provide more detailed assessment of renal size and architecture.
- **Kidney biopsy:** Usually requested and performed by a nephrologist, indications include unexplained or non-resolving AKI, or where a high index of suspicion exists for a parenchymal cause such as glomerulonephritis or tubulointerstitial nephritis.

While the finding of small kidneys (<8 cm in bipolar length) on ultrasound scan usually indicates significant CKD, the presence of anaemia or secondary hyperparathyroidism are not sensitive or specific discriminators between AKI and CKD. Conversely, normal kidney size on ultrasound does not exclude CKD (diabetic nephropathy and amyloidosis are both notably associated with preserved kidney size).

Management of AKI

Patients with severe AKI (including most with AKI stage 3) or adverse risk factors for ambulatory care management require admission. Early specialist review is advisable. Often unwell, patients with AKI should ideally be nursed in an ECU or high-dependency unit. Cardiac monitoring is required in patients with significant electrolyte disturbance, particularly hyperkalaemia.

General measures

Good nursing, infection control, and early physiotherapy are vital. Fluid balance monitoring, as intake and output (particularly urine output) and daily body weights, is key to monitoring progress and recovery and avoiding fluid overload. Medications require careful scrutiny, both to withhold nephrotoxins and adjust doses for current GFR, which may change on a daily basis. There is a particular risk with anticoagulants (oral and heparins; see Chapter 40). Patients with AKI stage 3 are at high risk of gastric stress ulceration and prophylactic treatment with an anti-acid (PPI or H_2 receptor antagonist) is usually indicated. Serial blood tests are required to monitor electrolytes (including serum potassium and calcium) and acid–base status.

Sepsis

Infection needs to be treated promptly, avoiding nephrotoxic antibiotics where possible. Use of prophylactic antibiotics or protective barrier nursing is not usually recommended. If there is loose stool, precautions will be necessary as appropriate.

Fluid and electrolyte balance

Replacement fluid may be a balanced crystalloid solution, 0.9% saline (e.g., burns, pancreatitis) or 4% albumin. There are no significant differences between these with respect to death rates, organ failure, need for RRT, or duration of hospitalization.

In general, once the patient is euvolaemic, daily fluid intake should equal urine output plus losses from the gut (including nasogastric losses) plus an allowance of 500 mL daily for insensible loss. Febrile patients will require an additional allowance. Most patients will meet this intake through oral fluids.

Large-volume fluid infusion or changes in daily weight (reflecting changes in fluid balance) make more regular reviews necessary. When overload is present, loop diuretics may be useful. Non-oliguric patients with AKI fare better than oliguric patients. However, conversion of oliguria to non-oliguria has not been shown to decrease mortality, and diuretics have not been demonstrated to prevent AKI or improve outcomes.

Nutrition

Salt and potassium should be restricted. Protein intake is sometimes limited to approximately 0.5 g/kg per day to try and delay progression to RRT, but this poses the risk of a negative nitrogen balance and is not standard practice in the UK. Patients on RRT are managed with 1–1.5 g/kg protein per day diet, though hypercatabolic individuals may require a greater nitrogen intake. Ideally, nutrition should be by mouth or nasogastric tube, or, as a last resort, by parenteral feeding.

Pre-renal AKI

Management largely depends on the underlying cause. Many cases of AKI are associated with hypovolaemia, so prompt fluid resuscitation is most often indicated. When there is uncertainty as to the volume status of a patient, a fluid challenge of 250 mL crystalloid will often prove whether hypotension and urine output are fluid responsive. Crystalloids and particularly balanced solutions such as Hartmann's solution and Ringer's lactate are the recommended resuscitative fluid, as 0.9% saline can lead to hyperchloraemic acidosis. Colloids such as hydroxyethyl starch are contraindicated, as they can lead to worsening AKI. Heart rate, blood pressure, and urine output will all guide response to resuscitation. For cardiogenic shock and septic shock, see Chapter 13.

Postrenal AKI

Obstruction of the urinary tract may occur at any point from the calyces to the external urethral orifice but commonly takes the form of bladder outflow obstruction (prostate disease in men) or bilateral ureteric obstruction (stones or tumours). The causes and presentation of urinary tract obstruction are dealt with in Chapter 26. Almost every case of unexplained AKI should result in an ultrasound to exclude obstruction, as once this is relieved (and if acute), kidney function will return to baseline.

Intrarenal parenchymal AKI

This is most commonly (80%–90%) due to ***acute tubular injury*** (ATI; see Chapter 26, **Box 26.28**). Almost any cause of pre-renal AKI, if prolonged to the point at which kidney autoregulation fails will lead to ischaemic ATI. If not ischaemic, then ATI usually results from

direct tubular toxins (often drugs). As a result, ATI is common in hospital practice. Other causes of parenchymal AKI include:

- Disease affecting the intrarenal arteries and arterioles, as well as glomerular capillaries, such as a vasculitis, accelerated hypertension, cholesterol embolism, haemolytic uraemic syndrome, pre-eclampsia, and crescentic glomerulonephritis.
- Acute TIN (see Chapter 26). Other mechanisms of tubulointerstitial injury include acute obstruction by crystals e.g., after rapid lysis of certain malignant tumours following chemotherapy (acute hyperuricaemic nephropathy), light chain casts (myeloma cast nephropathy), or pigment casts (rhabdomyolysis).
- Acute bilateral suppurative pyelonephritis or pyelonephritis of a single kidney, which can cause acute uraemia.

Conclusive diagnosis of intrarenal AKI often requires a diagnostic kidney biopsy and management is directed towards the underlying cause.

Renal replacement therapy—haemodialysis and haemofiltration

Regardless of cause, severe AKI may require supportive treatment with renal replacement therapy (RRT). The main indications are:

- symptomatic uraemia (including pericarditis or tamponade)
- hyperkalaemia not controlled by medical management
- pulmonary oedema not controlled with medical diuresis
- acidosis not controlled by medical management
- for removal of drugs causing toxicity e.g., gentamicin, lithium, aspirin overdose.

Contemporary RRT options include intermittent haemodialysis or haemodiafiltration (HDF), continuous venovenous haemofiltration (CVVHF) or peritoneal dialysis, the latter mainly in resource-poor countries. There is no data to favour haemodialysis or CVVHF as a superior mode of therapy in AKI. However, in haemodynamically unstable patients, particularly those on the ITU, continuous treatments like CVVHF are more widely used for systemically unwell patients with AKI.

Management of the recovery phase of AKI

Signs of recovery include an increase in urine output and a fall in serum creatinine (in the absence of kidney replacement). Dialysis or haemofiltration can be discontinued when kidney function is sufficient. A characteristic polyuric recovery phase develops as GFR recovers ahead of kidney tubular reabsorptive capacity for sodium, potassium, and water. Intravenous fluids with replacement sodium and potassium may be needed to prevent slowing of recovery due to volume depletion. Typically, the diuretic phase lasts for only a few days.

Key points in the management of AKI are summarized in **Box 11.56**.

Further discussion of specific causes of AKI can be found in Chapter 26.

Hyperkalaemia

Hyperkalaemia can be classified as mild, moderate, and severe.
Mild: 5.5 to 5.9 mmol/L
Moderate: 6.0 to 6.4 mmol/L
Severe: ≥6.5 mmol/L

Box 11.56 Summary of key points (AKI)

- Clinically stable patients with stage 1 AKI can often be assessed and managed in an ambulatory care setting depending on local pathways and resources
- Patients identified with AKI should be reviewed early to ensure adequate volume resuscitation, prompt treatment of underlying infection, ensure obstruction is excluded, and nephrotoxic medication withheld ('STOP' AKI)
- Actively monitor for and treat complications of AKI including hyperkalaemia, acidosis, fluid overload, and manifestations of uraemia (e.g., pericarditis or encephalopathy)
- Development of complications or non-resolution with initial management should prompt referral to a nephrologist (or critical care unit) to consider the need for specialist investigations (e.g., kidney biopsy) and timely renal replacement therapy if needed

Box 11.57 Risk states and causes for hyperkalaemia

- Acute kidney injury
- Dialysis-dependent end-stage kidney disease (haemodialysis or peritoneal dialysis)
- Chronic kidney disease stages 4 and 5 (CKD, eGFR < 30 mL/min/1.73 m^2)
- Drugs (renin-angiotensin-aldosterone inhibitors, NSAIDs, trimethoprim)
- Cardiac failure (cardio-renal syndrome, RASi drugs, mineralocorticoid receptor antagonists)
- Diabetes mellitus (RASi drugs, diabetic ketoacidosis)
- Liver disease (mineralocorticoid receptor antagonists, hepatorenal failure)
- Addison's disease (primary adrenal insufficiency)
- Hyporeninaemic hypoaldosteronism (type 4 renal tubular acidosis)

Common risk states and causes for the development of hyperkalaemia are listed in **Box 11.57**.

Spurious causes for hyperkalaemia (e.g., delayed separation of a laboratory sample or resulting from thrombocytosis) can be excluded by measuring potassium on a point-of-care venous blood gas sample.

Management

The UK Kidney Association guidelines recommend that all patients with severe hyperkalaemia (potassium value of ≥6.5 mmol/L) irrespective of kidney function are referred to hospital for immediate assessment and treatment. Severe hyperkalaemia may be life-threatening, leading to cardiac dysrhythmias, particularly asystole or ventricular fibrillation. Mild to moderate hyperkalaemia (potassium values of 5.5–6.4 mmol/L) prompts urgent clinical and medication review but may sometimes be managed via ambulatory pathways depending on clinical context (see section on 'Abnormal blood results').

Treatment for severe hyperkalaemia requires emergency, acute, and subacute measures to stabilize the myocardium and prevent cardiac arrest, lower potassium, and prevent rebound, as summarized in **Box 11.58**. In parallel, the cause or contributors to development of hyperkalaemia should be sought and removed or treated. In patients with severe hyperkalaemia, patients should be managed in a higher dependency setting such as the resuscitation area of ED, enhanced care unit of AMU, or in an HDU setting with cardiac monitoring.

High potassium levels are cardiotoxic, as they inactivate sodium channels. Divalent cations, for example, **calcium**, restore the voltage

Box 11.58 Treatment of severe hyperkalaemia

This is a potentially life-threatening emergency. Management is divided into emergency, acute, and subacute management.

Emergency management

- ECG monitor and i.v. access

Protect the myocardium

- If there are ECG changes (tall T waves, widened QRS, prolonged PR interval, loss of P wave, or ultimately, sinusoidal waves), then 30 mL of 10% calcium gluconate i.v. over 10 min or 10 mL 10% calcium chloride i.v. over 5 min via a large vein
- Repeat dose after 5 min if ECG changes persist

Acute management

Drive K^+ into cells

- Insulin 10 units in 25 g glucose (either 50 mL of 50% glucose or 125 mL of 20% glucose) i.v. over 15–30 min, followed by regular checks of blood glucose and plasma K^+. Note: monitor for hypoglycaemia in the 6 h period following insulin/dextrose
- Consider correction of severe acidosis (pH < 6.9)—infuse $NaHCO_3$ (1.26%)
- Consider salbutamol 10–20 mg nebulized
- In a hyperkalaemic cardiac arrest, consider a sodium bicarbonate i.v. bolus (50 mL of 8.4% solution)

Subacute

Deplete body K^+ (to decrease plasma K^+ over the next 24 h)

- Novel potassium binders (sodium zirconium cyclosilicate, SZC, or patiromer) bind potassium in the GI tract in exchange for sodium and hydrogen ions. Consider SZC 10 g thrice daily for up to 72 h, or patiromer 8.4 g once daily
- Old potassium binders (e.g., polystyrene sulphonate resins such as calcium resonium) have been rendered obsolete since the advent of SZC and patiromer
- Renal replacement therapy, such as haemodialysis, haemofiltration, or peritoneal dialysis if the above fails

Monitoring and prevention

- Monitor serum potassium closely (1, 2, 4, 6, and 24 h) after emergency treatment to check effectiveness and exclude rebound
- Monitor blood glucose for 6 h after treatment with insulin-dextrose
- Consider cause of hyperkalaemia and prevent recurrence as best possible. This may include withdrawal of potassium supplements and potassium-sparing medications (e.g., ACEi/ARB or mineralocorticoid receptor antagonists) and dietary modifications

dependability of the channels. Calcium ions protect the cell membranes from the effects of hyperkalaemia but do not alter the potassium concentration.

Supraphysiological **intravenous insulin** (10 units) drives potassium into the cell and lowers plasma potassium by ~1 mmol in 60 min, but **must be accompanied by intravenous glucose** (25 g) to avoid hypoglycaemia. Regular measurements of blood glucose for at least 6 hours after use of insulin should be performed and extra glucose must be available for immediate use. The use of glucose alone in non-diabetic patients, to stimulate endogenous insulin release, does not produce the high levels of insulin required and therefore is not recommended.

Hypertonic (8.4%) **sodium bicarbonate** may reduce serum potassium through correction of systemic acidosis; potential unwanted effects include a paradoxical worsening of intracellular acidosis and reduction in cardiac output. As such, 8.4% sodium bicarbonate is only recommended for use in hyperkalaemic cardiac arrest.

Patiromer and ***sodium zirconium cyclosilicate*** (SZC) are new non-absorbed agents that bind potassium in the gastrointestinal (GI) tract to facilitate faecal excretion. Clinical trials of patiromer and SZC have demonstrated clear evidence of a dose-dependent potassium-lowering effect. Patiromer and SZC are effective and well tolerated and have now largely superseded ion-exchange resins for the treatment of hyperkalaemia. Potassium binders are now also prescribed for long-term use in patients with heart failure and CKD to attenuate ACE inhibitor/ARB-induced hyperkalaemia.

Ion-exchange resins (polystyrene sulphonate resins, SPS, such as calcium resonium) are an older form of gut-acting therapy to maintain normokalaemia after emergency treatment. Their use has now been superseded by the newer gut-acting potassium binders described above.

In general, all of these measures are simply ways of 'buying time' either to correct the underlying disorder (e.g., stopping a culprit drug) or to arrange removal of potassium by dialysis, which is the definitive treatment for hyperkalaemia in severe acute or chronic kidney failure.

Follow-up

Potassium should be monitored frequently during the 24-hour period following emergency treatment of severe hyperkalaemia both to confirm effectiveness and to exclude early rebound (e.g., 1, 2, 4, 6, and 24 h). Blood glucose should be monitored for 6 hours following insulin-dextrose treatment (risk of hypoglycaemia).

Measures should be taken to reduce the risk of recurrent hyperkalaemia: often withdrawal of potassium supplements, suspension of potassium-sparing medications, or dietary modifications. Handover to the patient's usual clinician is important: suspension of potassium-sparing antihypertensive medications warrants closer monitoring of blood pressure and pro-activity to prevent deterioration in control. Likewise, interruption of potassium-sparing medications prescribed for prognostic benefit in CKD or heart failure (e.g., ACEi/ARB) should trigger early reassessment and re-evaluation of treatment options. The novel potassium binders may now be prescribed long term in patients with CKD or heart failure to facilitate re-introduction and up-titration of ACEi/ARB under close supervision in patients where hyperkalaemia has previously proved limiting.

The unconscious patient

Consciousness is dependent on the functioning of two separate anatomical and physiological systems:

- The ascending reticular activating system (ARAS), projecting from brainstem to thalamus. This determines arousal (the level of consciousness).
- The cerebral cortex, which determines the content of consciousness.

Impaired functioning of either anatomical system may cause coma.

Disturbed consciousness: definitions

- ***Coma:*** a state of unrousable unresponsiveness. Level of consciousness represents a continuum between being alert and deeply comatose. It may be quantified using the Glasgow Coma Scale (GCS) with a score between 3 and 15 (**Box 11.59**). Coma may be conveniently defined as a GCS score of 8 or lower. Terms such as stupor and obtundation have been superseded by the GCS score and are no longer used.

Box 11.59 Glasgow Coma Scale (GCS)[a]

Parameter	Score
Eye opening *(E)*	
Spontaneous	4
To speech	3
To pain	2
No response	1
Verbal response *(V)*	
Orientated	5
Confused conversation	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1
Motor response *(M)*	
Obeys	6
Localizes	5
Withdraws	4
Flexion	3
Extension	2
No response	1

[a]GCS score = *E* + *V* + *M* (GCS minimum = 3; maximum = 15).

- ***Delirium:*** a confusional state in which reduced attention is a cardinal feature, usually with altered behaviour, cognition, orientation, and a fluctuating level of consciousness (from agitation to hypoarousal; see **Box 11.80**).

Mechanisms and causes of coma

Altered consciousness is produced by four mechanisms affecting the ARAS in the brainstem or thalamus and/or widespread impairment of cortical function (**Box 11.60**)

- ***Diffuse brain dysfunction.*** Generalized severe metabolic or toxic disorders (e.g., alcohol, sedatives, uraemia, hypercapnia) depress cortical and ARAS function.
- ***Massive cortical damage.*** Unlike brainstem lesions, extensive damage of the cerebral cortex and cortical connections is required to cause coma e.g., meningitis or hypoxic–ischaemic damage after cardiac arrest (**Fig. 11.27**).
- ***Brainstem lesion.*** A discrete brainstem or thalamic lesion e.g., stroke, may damage the ARAS.
- ***Brainstem compression.*** A supratentorial mass lesion within the brain compresses the brainstem, inhibiting the ARAS e.g., 'coning' from a brain tumour or haemorrhage. Mass lesions within the posterior fossa are particularly prone to causing brainstem compression and hydrocephalus.

A single focal hemisphere (or cerebellar) lesion does not produce coma, unless it compresses the brainstem. Cerebral oedema frequently surrounds masses, increasing their pressure effects.

The most common causes of coma are:

- metabolic disorders—35%
- drugs and toxins—25%
- mass lesions—20%
- other—including trauma, stroke, and CNS infections.

Immediate assessment and management of the unconscious patient

- Check the ***a***irway, ***b***reathing, ***c***irculation, ***d***isability, and ***e***xposure/***e***xamination.

Box 11.60 Principal causes of coma: examples of mechanisms

Diffuse brain dysfunction
- Drug overdose (accidental or deliberate), including alcohol
- Carbon monoxide poisoning
- Traumatic brain injury
- Hypoglycaemia, hyperglycaemia
- Severe uraemia (see Chapter 26)
- Hepatic encephalopathy (see Chapter 23)
- Respiratory failure with CO_2 retention (see Chapter 20)
- Hypercalcaemia, hypocalcaemia
- Hypoadrenalism, hypopituitarism and hypothyroidism
- Hyponatraemia, hypernatraemia
- Metabolic acidosis
- Hypothermia, hyperpyrexia
- Seizures—post-ictal state and non-convulsive status
- Metabolic rarities e.g., porphyria

Extensive cortical damage
- Hypoxic–ischaemic brain injury e.g., cardiac arrest
- Encephalitis, meningitis, cerebral malaria
- Subarachnoid haemorrhage

Direct effect within brainstem
- Brainstem haemorrhage, infarction, or demyelination
- Brainstem neoplasm e.g., glioma
- Wernicke–Korsakoff's syndrome

Pressure effect on brainstem
- Tumour
- Massive hemisphere infarction with oedema
- Intracranial haematoma
- Cerebral abscess
- Cerebellar mass

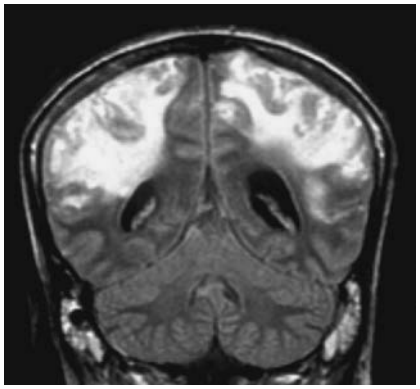

Fig. 11.27 Magnetic resonance image showing extensive cortical damage following meningitis. A permanent vegetative state resulted.

- Use a point-of-care testing device to measure blood glucose; if the patient is hypoglycaemic, give glucose (consider e.g., 50 mL 10% glucose in adults, repeating every minute until the patient has regained consciousness or a total of 250 mL has been administered). If intravenous access is not available, consider intraosseous administration or intramuscular glucagon 1 mg.
- Treat seizures with buccal midazolam (community) or intravenous lorazepam (hospital); if not terminated, use a second-line anticonvulsant (intravenous levetiracetam, phenytoin, or sodium valproate).
- If there is fever and meningism, give appropriate intravenous antibiotics.
- Give intravenous naloxone if opiate overdose is suspected or flumazenil (for *isolated* benzodiazepine overdose) and i.v.

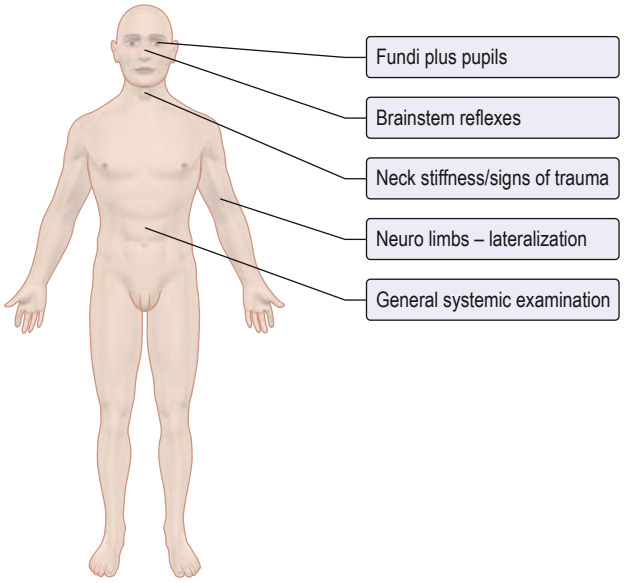

Fig. 11.28 **Assessing the unconscious patient.**

thiamine (in Wernicke's encephalopathy) in people who may be malnourished.

Obtain as much history as possible. A limited history is one of the problems in assessing the unconscious patient. What were the circumstances? Ask paramedics, police, and witnesses. Contact the patient's relatives, friends, and GP, and obtain past hospital notes. Look for drug details/bottles and identification data.

General and neurological examination (see Fig. 11.28)

General examination

- Measure the patient's temperature (with a low-reading rectal thermometer if hypothermic).
- Check for meningism.
- Sniff the patient's breath for ketones, alcohol, and hepatic fetor.
- Survey the skin for signs of trauma or spinal injury, rash (meningococcal sepsis), jaundice or stigmata of chronic liver disease (CLD), cyanosis, and injection marks.
- Assess the respiratory pattern e.g., Cheyne–Stokes (alternating hyperpnoea and periods of apnoea, indicating bilateral cerebral or upper brainstem dysfunction) or Kussmaul respiration (deep, sighing hyperventilation seen in metabolic acidosis including DKA and renal failure).

Neurological examination

Neurological examination aims to determine:

- depth of coma (GCS)
- brainstem function
- lateralization of pathology.

Depth of coma

GCS. Assessment of the GCS score is repeated regularly to determine whether the patient's level of consciousness is progressively declining. Use deep stimulation such as a trapezius squeeze or pressure over the supraorbital nerve, and record the *best* response. Shout commands.

Fundi. Look for papilloedema and subhyaloid retinal haemorrhage (sometimes seen in subarachnoid haemorrhage [SAH]).

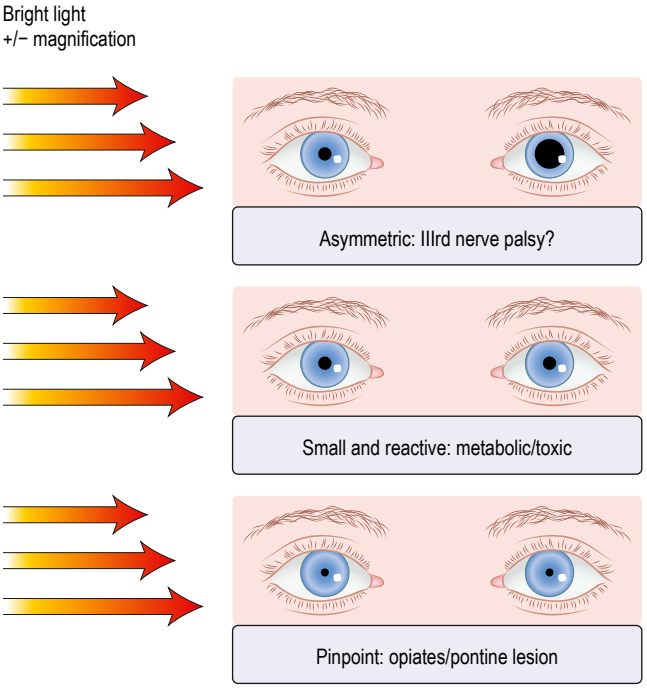

Fig. 11.29 **Examination of the pupils.**

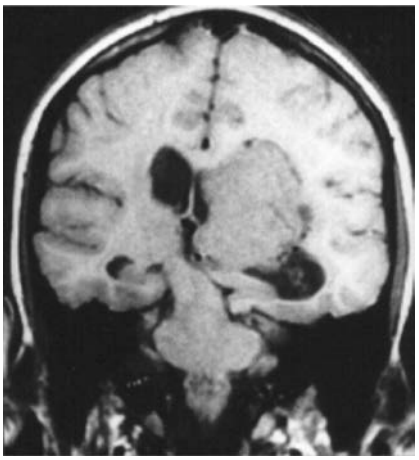

Fig. 11.30 **Medial temporal lobe (uncal) herniation causing third nerve compression.**

Brainstem function

Pupils

Record their size and reaction to light (Fig. 11.29):

- ***Dilation of one pupil*** that then becomes fixed to light indicates compression of the IIIrd nerve. This may indicate a potential neurosurgical emergency (Fig. 11.30).
- ***Bilateral midpoint reactive pupils*** (i.e., normal pupils) are characteristic of metabolic comas and secondary coma due to sedative drugs (except opiates).
- ***Bilateral light-fixed, dilated pupils*** are one cardinal sign of brain death. They can occur in deep coma of any cause, but particularly in barbiturate intoxication and hypothermia.
- ***Bilateral pinpoint, light-fixed pupils*** occur with pontine lesions (e.g., haemorrhage) and with opiates.

Mydriatic drugs and previous ophthalmic surgery can cause diagnostic difficulty.

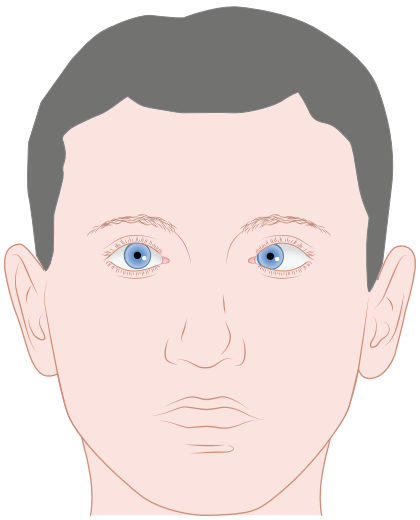

Fig. 11.31 Disconjugate eye position. This usually indicates brainstem lesion (the eyes may be mildly disconjugate in metabolic coma).

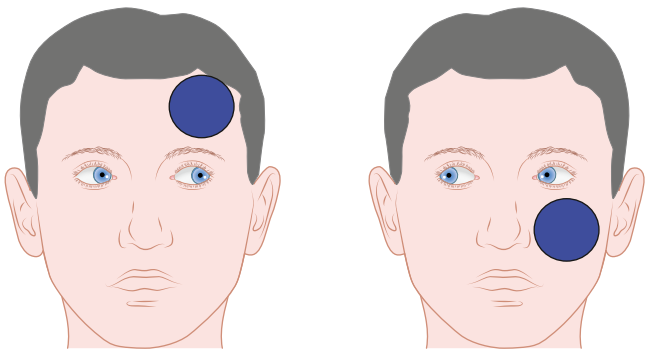

A B

Fig. 11.32 Conjugate gaze deviation. (A) Frontal lesion. (B) Brainstem lesion.

Eye movements and position

- Disconjugate eyes (divergent ocular axes) indicate a brainstem lesion e.g., ***skew deviation*** (one eye up, one eye down; Fig. 11.31).
- Conjugate gaze deviation means the eyes deviate towards the lesion in the frontal lobe and the normal limbs (unopposed activity of the intact frontal eye fields drives eyes to the opposite side); and away from the lesion in the brainstem and towards the weak limbs (the paramedian pontine reticular formation in the pons controls lateral gaze to the ipsilateral side; see Chapter 26) (Fig. 11.32).
- Vestibulo-ocular reflex means that passive head-turning produces conjugate ocular deviation away from the direction of rotation (doll's eye reflex). This reflex disappears in deep coma, brainstem lesions, and brain death (Fig. 11.33).
- In light coma, slow, side-to-side eye movements are seen ('windscreen wiper' eyes; Fig. 11.34). This is also seen with extensive cortical damage in deep coma.

Other brainstem reflexes

- Corneal reflex.
- Gag/cough reflex (via endotracheal tube if intubated).
- Respiratory drive.

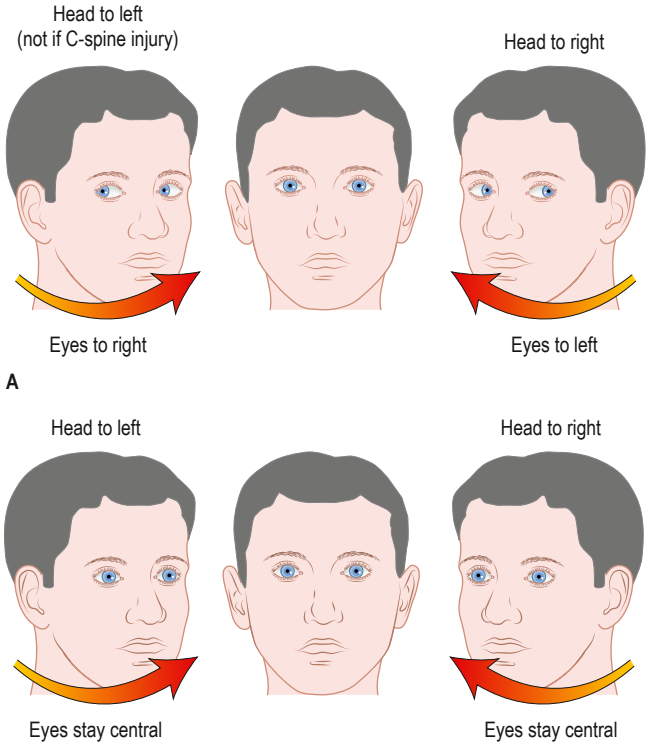

Fig. 11.33 Doll's eye movements. (A) Normal. (B) Abnormal.

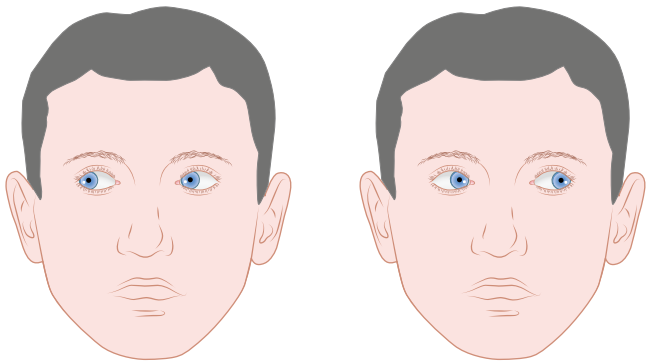

Fig. 11.34 'Windscreen wiper' eyes ('ping pong' eyes). Slow, side-to-side movements demonstrate diffuse cortical dysfunction. This is common in light coma and implies normal brainstem function. In deep coma it indicates extensive cortical damage.

Lateralizing signs

Coma makes it difficult to recognize lateralizing signs. These are helpful:

- ***Asymmetry of response to visual threat*** in a stuporous patient: suggests hemianopia.
- ***Asymmetry of face:*** drooping or dribbling on one side; blowing in and out of mouth when the paralyzed cheek does not move.
- ***Asymmetry of tone:*** unilateral flaccidity or spasticity—may be the only sign of hemiparesis.
- ***Asymmetry of decerebrate and decorticate posturing.***
- ***Asymmetrical response*** to painful stimuli.
- ***Asymmetry of tendon reflexes and plantar responses:*** both plantars are often extensor in deep coma.

Coma 'look-alikes'

- Psychogenic coma.
- 'Locked-in' syndrome—complete paralysis, except for vertical eye movements/blinking in ventral pontine infarction. Patients have a functioning cerebral cortex and are fully aware but unable to communicate, except through eye movements
- Severe paralysis e.g., myasthenic crisis or severe Guillain–Barré syndrome.

Diagnosis and investigations in coma

Often the cause is evident (e.g., head injury, metabolic disorder, overdose). Where lateralizing signs or brainstem pathology are found on examination, a mass lesion or infarction/haemorrhage is likely (note that hypoglycaemia may also cause focal signs). If no cause is obvious after clinical assessment, further investigations are essential.

Blood and urine

- ***Drug screen***—blood ethanol, paracetamol, and when indicated, salicylate levels, urine toxicology including screening for benzodiazepines, narcotics, amfetamines.
- ***Biochemistry***—urea, electrolytes, glucose, calcium, liver biochemistry. Consider ammonia level (needs to be on ice) in advanced liver disease or a history of ingestion of certain medications including valproate and topiramate.
- ***Metabolic and endocrine studies***—thyroid-stimulating hormone, cortisol.
- ***Arterial blood gases***—for acidosis or high CO_2 levels. Also check carboxyhaemoglobin (HbCO) and methaemoglobin (MetHb) levels.
- ***Other***—for example, cerebral malaria (request antigen test and *thick* blood film; see Chapter 42) and porphyria (Chapter 36).

Brain imaging

CT brain imaging is the most readily available and safest modality in the unconscious patient (MRI is useful where CT is normal but presents greater monitoring challenges in the unconscious patient). CT is quick and effective in demonstrating all types of brain haemorrhage and most mass lesions; infarcts may be missed in the early stages and where only the brainstem is affected.

Cerebrospinal fluid (CSF) examination

An LP should be performed in coma only after careful risk assessment. It is contraindicated when an intracranial mass lesion is a possibility; CT is essential to exclude this. Cerebrospinal fluid (CSF) examination is likely to alter therapy only if undiagnosed meningoencephalitis or other infection is present, or in SAH where CT may give a false-negative result, particularly after 24 hours.

Electroencephalography (EEG)

Electroencephalography (EEG) is of some value in the diagnosis of metabolic coma, encephalitis, and non-convulsive status epilepticus.

General management

Comatose patients need careful nursing, meticulous attention to the airway, and frequent monitoring of vital functions.

Longer-term essentials are:

- skin care—turning (to avoid pressure ulcers and pressure palsies)
- oral hygiene—mouthwashes, suction
- eye care—prevention of corneal damage (lid taping, irrigation)
- fluids—nasogastric or intravenous
- feeding—via a fine-bore nasogastric tube or via PEG
- sphincters—catheterization when essential (use a penile urinary sheath if possible in men); rectal evacuation.

The ongoing management and prognosis of longer-term disorders of consciousness is discussed in Chapter 28.

Box 11.61 Terms relating to dizziness and blackouts

Dizziness covers many symptoms, from a vague feeling of unsteadiness to severe, acute vertigo. It is frequently used to describe light-headedness (e.g., due to hypotension), panic, anxiety, palpitations, and chronic ill-health. The real nature of this symptom must be determined.

Vertigo means the illusion of movement, a sensation of rotation or tipping. The patient feels the surroundings are spinning or moving. This is distressing and often accompanied by nausea or vomiting.

Blackout, like dizziness, is simply descriptive, implying either altered consciousness (e.g., epilepsy or syncope), transient visual disturbance as part of presyncope or falling, or hypoglycaemia in a diabetic patient. A good history is essential.

Collapse is a vague term but often used. It should be avoided.

Fatigue is common. When it is an isolated symptom, it rarely indicates neurological disease, although it may be a symptom of many neurological disorders. General medical causes, such as anaemia and endocrine disorders, should be excluded.

Dizziness and blackouts

The potential causes for blackouts and dizziness are diverse and include vestibular, cardiovascular, neurological, and psychogenic disorders. Detailed history taking is essential, with particular focus on the precise nature of symptoms, time course of onset and offset, any identifiable triggers of symptoms, and a third-party eye-witness account if available.

Descriptive terms for blackouts and dizziness are often used inconsistently or incorrectly by both patients and doctors (**Box 11.61**); when probed, a patient complaining of 'blackout' may have actually experienced presyncopal symptoms without loss of consciousness, or even a simple fall. A careful history will usually allow the clinician to reach a 'syndromic diagnosis' (e.g., syncope, as opposed to seizure), with further focused history, clinical examination, and investigations then directed towards elucidating the underlying cause, although when the history is unclear a more extensive work-up may be required.

A helpful approach to the differential diagnosis of blackouts and dizziness is to consider causes associated with loss of consciousness and those without (see **Box 11.62**).

Clinical assessment

History taking is an essential skill to define the precise nature of the episode. A helpful structure to the history of the presenting problem is to adopt a 'before, during, and after' approach (**Box 11.63**). If the episode resulted in a fall, enquire about pain or injury, including whether the patient struck their head. If the patient describes dizziness, the character of this (particularly rotational dizziness vs. light-headedness) should be carefully established.

Examination

Examination should be focused both on eliciting signs that may aid in diagnosis but also those resulting from physical injury that may have been sustained if the patient lost consciousness.

Box 11.62 Differential diagnoses of dizziness, blackouts, and syncope

With loss of consciousness	Without loss of consciousness
Syncope • Vasovagal syncope • Cough or micturition syncope • Arrhythmia (e.g., complete heart block, ventricular tachycardia) • Other cardiovascular disorders (e.g., severe aortic stenosis, aortic dissection) • Massive pulmonary embolism	Presyncope • Orthostatic hypotension • Severe anaemia • Other causes for 'syncope'
Seizure • Generalized tonic–clonic • Complex partial • Absence ('petit mal')	Vertigo • Vestibular causes e.g., benign positional paroxysmal vertigo (BPPV), Ménière's disease, vestibular neuritis, labyrinthitis • Central causes e.g., cerebellar stroke
Other • Hypoglycaemia • Vertebrobasilar insufficiency • Migraine (severe basilar migraine) • Stroke (haemorrhagic or ischaemic), either with brainstem involvement or massive and resulting in 'coning' • Intoxication or substance misuse/withdrawal • Psychogenic e.g., dissociative seizures • Narcolepsy	Other • Hypoglycaemia • Migraine • Stroke or transient ischaemic attack • Focal seizures • Drop attacks • Panic attacks

- Signs of physical injury e.g., haematomas, open wounds, fractures, or dislocations.
- Inspection of the tongue and oral cavity may reveal signs of biting or trauma sustained during a seizure.
- Bedside observations: blood pressure (including **lying and standing blood pressure** to exclude orthostatic hypotension), heart rate and regularity (arrhythmias), temperature, respiratory rate, oxygen saturations, and blood glucose (to exclude hypo- or hyperglycaemia—either causative or concurrent).
- Peripheral and central pulse: irregularity may indicate arrhythmia, other signs may be present suggestive of valvular heart disease (e.g., the low volume, slow-rising pulse of severe aortic stenosis).
- Murmur e.g., ejection systolic murmur radiating to the carotid arteries in aortic stenosis.
- Physical features of substance misuse e.g., tremor for alcohol withdrawal, needle track marks in i.v. drug abuse.
- Neurological signs: nystagmus is expected in a patient with true vertigo; focal weakness may be present following a seizure (Todd's paresis) or resulting from a space-occupying lesion or intracranial bleed; cerebellar signs such as past-pointing and ataxia may be elicited in an 'unsteady' patient.

Investigations

Investigations should be tailored to the working diagnosis or differential diagnosis based on history and examination, although those commonly requested for a patient presenting with a transient loss of consciousness are listed below.

- **Laboratory investigations** including full blood count to exclude anaemia, 'liver function tests', bone profile including magnesium, renal function, blood glucose, and consideration of thyroid function tests.

Box 11.63 History taking in the patient experiencing a blackout or dizziness

Before	During	After
What is the last thing you remember before it occurred? *A preceding sensation of déjà vu or jamais vu suggests a seizure while sweating more likely suggests syncope*	Do you have any recollection during the event e.g., hearing people around you? *Maintained awareness during the event suggests it was not a generalized tonic–clonic seizure or complete loss of consciousness*	What is the next thing you remember after it occurred? *Patients experiencing a seizure typically have no recollection of abnormal behaviours witnessed before or after loss of consciousness*
When did it happen (time of day) or is there any pattern to episodes (if repeated)? Any triggers such as turning your head *(suggestive of vestibular disease if vertigo, or vertebrobasilar ischaemia if syncope)* or postural changes *(suggestive of vestibular disease or orthostatic hypotension)*?	Did you bite your tongue?—*may support the diagnosis of a seizure (but does not exclude syncope)*	Was there any evidence of injury afterwards? *E.g., facial injury suggestive of cardiac syncope*
How did you feel before it happened that day? E.g., at work, food and drink intake, sleep, stress, travel, social events *(considering fluid status, insensible losses, substance misuse)*	Did you experience faecal or urinary incontinence?—*This may support the diagnosis of a seizure (but does not exclude syncope)*	How long did it take for you to recover?—*May help differentiate causes, recovery of full consciousness is typically slower with seizures than syncope*
Who were you with? Did anyone witness the event?	Are there any witness descriptions of the event e.g., rhythmic limb jerking, snoring, unusual posturing, confusion? *Head-turning to one side during a loss of consciousness is strongly suggestive of seizure*	Do you remember how you got to the hospital?
Do you or did you get any warning symptoms? *(e.g., light-headedness, aura, palpitations)*		How are you feeling now? Do you feel any ongoing symptoms? *Recovery from a simple faint may be far quicker than other causes*
Has this ever happened before? If so, how frequent?		

- **Bedside tests:** a 12-lead ECG should always be performed after a syncopal episode to identify heart block, pre-excitation, or long QT syndrome.
- **Focused Acute Medical Ultrasound (FAMUS):** if presenting features are suspicious for cardiovascular causes such as aortic dissection or massive PE, or shock including sepsis.
- **CT brain** (plain or contrast enhanced): request where an intracranial/neurological cause is suspected or where concern exists for a traumatic complication of a blackout (e.g., subdural haematoma [SDH]).
- **Echocardiography and cardiac rhythm monitoring**—Holter monitoring and echocardiography are required where cardiac syncope is suspected. An implantable loop recorder (ILR) is occasionally needed for infrequent events with a possible cardiac origin (see Chapter 17, 'Ambulatory taped electrocardiography' and **Fig. 17.19**). Tilt-table testing (see Chapter 17, 'Tilt testing') is sometimes diagnostic in patients with recurrent unexplained syncope, but has low sensitivity.

Syncope or fainting

The simple faint that over half the population experiences at some time (particularly in childhood, youth, or pregnancy) is due to sudden reflex bradycardia with vasodilation of both peripheral and splanchnic vasculature *(neurocardiogenic or vasovagal syncope)*.

- ***Precipitants:*** a common response to prolonged standing, fear, venesection, or pain. Syncope almost never occurs in the recumbent posture.
- ***Prodrome:*** usually brief. There is dizziness and a light-headed feeling, often with nausea, sweating, a feeling of heat, and visual grey-out.
- ***Blackout:*** patients usually lie still but jerking and twitching movements can occur and are sometimes mistaken for a convulsion. Their appearance is pale. Incontinence of urine or faeces can occur and is not a good discriminator between seizure and syncope.
- ***Recovery:*** rapid, usually taking place over seconds, but may be followed by a feeling of general fatigue (as opposed to post-ictal drowsiness and confusion following a seizure).

Other types of syncope

- ***Cardiac syncope*** (Stokes–Adams attacks) is potentially serious and often treatable. Typically, there is little or no warning. Cardiac arrhythmias, such as those due to heart block, or left ventricular outflow tract obstruction may be the cause. Syncope during exercise is often cardiac in origin.
- ***Micturition syncope*** occurs during micturition in men, particularly at night.
- ***Cough syncope*** occurs when venous return to the heart is obstructed by bouts of severe coughing; it is also seen with laughter occasionally.
- ***Postural hypotension*** (see **Box 27.7**) can cause syncope and occurs in the elderly, in autonomic neuropathy, and with some drugs, such as antihypertensives.
- ***Carotid sinus syncope*** is due to a vagal response caused by pressure over the carotid sinus baroreceptors in the neck: for example, due to a tight collar.
- ***Convulsive syncope*** is when collapsing in a propped-up position following a syncope results in delayed restoration of cerebral blood flow and may lead to a secondary anoxic seizure following syncope.

Other conditions to consider

Seizures are discussed in **Box 11.78**.

Dissociative seizures (sometimes referred to as non-epileptic attack disorder or psychogenic seizures, see also Chapter 28) regularly cause difficulty in diagnosis as attacks may sometimes closely resemble generalized tonic–clonic seizures. Usually, there are bizarre thrashing, non-synchronous limb movements, but on occasion there can be extreme difficulty in separating these attacks from seizures. EEG video telemetry is valuable. People who are diagnosed with this condition can have periods of loss of control and/or awareness, that can appear like an epileptic seizure, and even be incorrectly labelled as status epilepticus. Blood gas analysis may resemble that of an epileptic seizure if prolonged (raised carbon dioxide, raised lactate, metabolic acidosis). An accurate bystander or personal witness account is paramount to try to elucidate the exact nature of an episode.

Serum prolactin level may rise (typically 3–4 times baseline) following an epileptic seizure; however, there is a significant false-positive rate (up to 25%) in patients with dissociative seizures and thus this test is of limited clinical value to discriminate between the two conditions.

Panic attacks trigger sudden sympathetic activation and often hyperventilation, leading to respiratory alkalosis. They cause some or all of the following symptoms: dizziness, chest pains or tightness, a feeling of choking or shortness of breath, tingling in face and extremities, palpitations, trembling, and a feeling of dissociation or of impending doom. Consciousness is usually preserved and attacks are easily recognized.

Drop attacks are instant, unexpected episodes of lower limb weakness with falling, largely in females over 60 years. Awareness is preserved. They are due to sudden change in lower limb tone, presumably of brainstem origin. Sudden attacks of leg weakness also occur in hydrocephalus. A specific cause for drop attacks often cannot be identified, but this diagnostic label should only be applied after a careful diagnostic work-up has excluded cardiac and vestibular disease and other neurological disorders.

Vertigo (see also Chapter 21)

Vertigo is defined as the false sense of motion of the body or its surroundings, which can be spinning, swaying, or tilting and can be subdivided into peripheral and central causes. Peripheral vertigo encompasses the inner ear apparatus and vestibular nerve and accounts for the majority of cases of vertigo. Central vertigo is caused by pathology in the brainstem or cerebellum. These present with distinct clinical features albeit with some overlap. **Box 11.64** summarizes the different causes of peripheral and central vertigo.

The majority of patients who present to the acute medical take with vertigo have continuous symptoms. Most cases, while debilitating for the patient, are of benign aetiology, with an acute peripheral vestibulopathy (APV, either vestibular neuronitis or labyrinthitis) being the most common cause. Vertigo can however indicate serious pathology within the brainstem, cerebellum, or inner ear and vertebrobasilar stroke in particular is an important differential diagnosis in sudden onset cases. It is therefore important to follow a systematic clinical approach focused on discriminating benign and self-limiting vertigo from serious underlying disorders. **Red flags** pointing to potentially life-threatening or disabling diagnoses are listed in **Box 11.65**.

Clinical assessment

The history must initially determine the symptom as true vertigo. The question *'Did you just feel lightheaded or did you see the world spin around as though you had just got off a playground roundabout?'* is validated for differentiating vertigo from non-rotatory dizziness.

Box 11.64 Causes of vertigo

Peripheral	Central
Benign paroxysmal positional vertigo (BPPV)	Cerebellar stroke (bleed or infarct)
Acute peripheral vestibulopathy • Vestibular neuronitis • Labyrinthitis	Brainstem stroke (bleed or infarct)
	Vestibular migraine
Ménière's disease	Multiple sclerosis
Ramsay Hunt syndrome[a]	Space-occupying lesion
	CNS infection

[a]NB—Lower motor neuron facial weakness present in Ramsay Hunt syndrome.

Box 11.65 Red flags for more serious causes of vertigo

	Red flags	Possible causes
Vertigo +	Abnormal neurology/ new onset headache	Vertebrobasilar stroke
		Tumour
		Multiple sclerosis
		Intracranial infection
Vertigo +	Tinnitus/deafness	Ramsay Hunt syndrome
		Ménière's disease
		AICA stroke
		Labyrinthitis
Vertigo +	Unable to tolerate oral fluids (risk of dehydration, AKI, etc.)	Multitude

AICA, Anterior inferior cerebellar artery.

The **timing of the vertigo episode**(s) is important. It is crucial to clarify whether vertigo is persistent or episodic, and if so, what exactly triggers the vertigo (e.g., head movement). Episodic vertigo lasting seconds is usually indicative of benign paroxysmal positional vertigo (BPPV). Onset of symptoms in APV (e.g., labyrinthitis) is often rapid and thus speed of onset is not a good discriminator between benign vertigo and cerebrovascular causes.

The patient should be questioned directly about the presence of **associated symptoms:**

- Neurological symptoms, including focal weakness, ataxia, speech disturbance, visual change, or headache, suggest a central cause of vertigo and require urgent investigation.
- Audiological symptoms, namely hearing loss, tinnitus, or ear pain, point towards peripheral causes other than APV.
- Severe nausea and vomiting points towards a peripheral cause, though it can also be present in central causes. Inability to keep fluids down poses a risk of dehydration and warrants effective symptom control before considering discharge.

Past medical history is an important part of the initial risk assessment. The presence of stroke risk factors such as atrial fibrillation, hypertension, and diabetes increases suspicion of a cerebrovascular cause. Personal or family history of multiple sclerosis or Ménière's disease would increase the likelihood of vertigo attributed to these causes prompting focused assessments and/or onward referral to a specialist clinic.

Clinical examination should focus on gait (when safe/possible to assess), neurological and otological assessment. **Box 11.66** outlines the important clinical features discriminating central from peripheral causes of vertigo elicited on examination.

The Hallpike manoeuvre is of particular use in diagnosing BPPV and is only appropriate when vertigo is paroxysmal (i.e., non-continuous) (**Box 11.67**)

The HINTS examination (Head impulse—Nystagmus—Test of skew) is used in patients with continuous vertigo and helps to differentiate peripheral from central causes. (**Box 11.67**)

Management

Further investigation and management depends on the underlying cause. Symptomatic treatment with prochlorperazine or certain antihistamines (e.g., cinnarizine) may be warranted, particularly in cases accompanied by severe nausea or vomiting. Both vertigo itself and side-effects of medication may have implications for fitness to drive or work, for example operating machinery, and patients should be counselled accordingly.

Although a careful clinical assessment will usually allow discrimination between benign causes of vertigo and more serious pathology, confident clinical separation of peripheral and central causes of vertigo by the general physician is not always possible and in cases of diagnostic uncertainty or the presence of red flag features, further assessment with brain imaging (most commonly MRI with diffusion-weighted sequences) is usually performed.

Increasingly, SDEC services can provide therapeutic options such as intravenous antiemetics and vestibular suppressants, or arrange admission if deemed unsafe to investigate or manage on an ambulatory basis, with access to expedited specialist opinions such as ENT, neurology, or stroke.

Headache

Headache is a common presenting problem on the acute medical take and is a symptom often referred to SDEC or ambulatory services for further investigation and management. History taking is vital and a broad range of primary and secondary pathology can result in a headache (see **Box. 11.68**). Many SDEC services now have robust pathways for the investigation and management of acute headache; these are quick and accessible for both patients and primary care physicians and allow for rapid diagnosis or exclusion of certain causes of secondary headache in the presence of red flag symptoms (**Box 11.69**). For example, temporal (giant cell) arteritis is now commonly managed through SDEC with a dedicated temporal arteritis pathway, with streamlined access to rheumatology services and temporal artery ultrasound ± biopsy.

Clinical assessment

History

A careful history of the presenting problem is essential and SOCRATES is a helpful mnemonic:

- **Site:**
  - Migraine is often felt as unilateral ('hemicranial') throbbing although may become generalized as an attack progresses

Box 11.66 Clinical features of central vs. peripheral vertigo

Clinical features	Peripheral	Central
Gait	Can walk, may be unstable and reluctant to mobilize	Complete inability to stand up or walk even with the eyes open
Hearing loss or tinnitus	Possible (e.g., Ménière's disease, labyrinthitis)	Rare e.g., AICA stroke or intracranial tumour
Otoscopy	Discharge, vesicular eruptions (suggestive of Herpes Zoster), or evidence of cholesteatoma	No relevant findings
Other neurological symptoms	No	Usually present e.g., cranial nerve dysfunction, visual disturbance, dysphasia, dysarthria, weakness, sensory changes
Nystagmus	Horizontal nystagmus (with a torsional component) Does not alter in direction when the gaze changes (unidirectional) Inhibited by gaze fixation, fatiguable	Pure vertical or torsional nystagmus Direction-changing (bidirectional) nystagmus on lateral gaze (right beating on right gaze, left beating on left gaze) Not inhibited by gaze fixation Non-fatiguable
Manoeuvres	**Box 11.67** describes expected results for Hallpike manoeuvre (paroxysmal vertigo) and HINTS test (continuous vertigo) for peripheral and central causes	

Box 11.67 Hallpike manoeuvre and Head Impulse—Nystagmus—Test of Skew (HINTS)

Name	Hallpike manoeuvre	HINTS
Aim	Diagnose *paroxysmal* vertigo.	Differentiate central from peripheral causes of *continuous* vertigo.
Mechanism	Positional manoeuvre to reproduce vertigo and identify canalithiasis.	Highly sensitive and specific triad predicting a central cause of continuous nystagmus.
Process	1. Ask the patient to sit up on the couch. Extend the neck and turn 45 degrees to one side. From this position rapidly lie the patient down, supporting the head until it is 20–30 degrees over the end of the couch. 2. Observe the eyes for 30 seconds for the presence of nystagmus. Note its direction, duration, and type. Ask the patient to report symptoms of vertigo. 3. Slowly sit the patient up and repeat with head facing to the opposite side.	1. **Head impulse test.** With the patient resting flat on a couch, ask them to fix on your nose. Gentle move their head to each side, each time returning to the neutral position. In a 'positive' test, you will see an obvious 'catch up' saccade when the head is turned, as the patient re-fixes on your nose. This is absent in a 'negative' test. 2. **Nystagmus.** Carefully observe the nystagmus: is it unidirectional or bidirectional? Is it purely horizontal or are there vertical or rotary components? Does nystagmus direction change with different directions of gaze? 3. **Test of skew.** Cover one eye for several seconds and then uncover. Look for vertical realignment of the eye back to the primary position (i.e., abnormal vertical 'skew').
Interpretation	In BPPV: Horizontal nystagmus is seen when turning the head to the affected side. Nystagmus takes a few seconds to evolve ('latency') and diminishes on repeated tests ('fatiguability'). In central causes of paroxysmal vertigo: Nystagmus onset is immediate (i.e., without latency) and does not fatigue with repeated tests; direction is often not classical (e.g., horizontal towards the downward ear).	Head impulse test: Positive if a visible 'catch-up' saccade is seen on head turning. This implies a peripheral vestibular cause. A negative test or bilateral findings indicate a central cause. Nystagmus: Unidirectional horizonal nystagmus is in keeping with a peripheral cause. Bidirectional, vertical, or gaze-changing nystagmus implies a central cause. Test of skew: Vertical realignment movements indicate a central cause.

- Excruciating, unilateral retro-orbital pain may suggest cluster headache
- Occipital pain may point to sub-arachnoid haemorrhage (SAH), vertebral artery dissection, or meningitis
- Pain and tenderness specific to one temporal region may suggest temporal arteritis, rare in patients under 50 years of age

- **Onset and duration of symptoms:**
  - What time of day did the headache start? Did they awake from sleep?
  - Was there a specific trigger e.g., a sudden neck movement or turning to look over their shoulder for instance while reversing their car, which could suggest vertebral artery dissection
  - Has there been a history of trauma? (Consider an intracerebral bleed or fracture)
  - Did the headache come on suddenly or gradually and if so, over weeks (i.e., subacute), days, hours, or minutes?
- **Character**
  - A headache described as a tight band across the forehead may suggest tension-type headache (TTH) while migraine is often described as 'throbbing'
  - Is the headache constant or intermittent in nature, or does it fluctuate in severity?
  - The sensation of being 'hit across the back of the head' is a common patient description of SAH
- **Radiation**
  - Does the headache radiate down the neck? (This may suggest meningism or vertebral artery dissection)
  - Does the headache start behind the eyes or across the forehead and then radiate to one side of the head (which may

Box 11.68 Causes of headache

Primary headache disorders	Secondary headache disorders
Migraine	Raised intracranial pressure (e.g., idiopathic intracranial hypertension, primary or secondary tumour)
Tension-type headache	Intracranial infections (e.g., meningitis, sinusitis)
Trigeminal autonomic cephalalgias (incl. cluster headache)	Cerebral venous sinus thrombosis
Other primary headache disorders (e.g., primary cough headache, primary exercise headache, primary headache associated with sexual activity)	Giant cell/temporal arteritis
	Intracranial bleed (e.g., subdural haematoma, extradural haematoma, and subarachnoid haemorrhage)
	Cervicogenic headache
	Acute glaucoma
	Low CSF volume (low-pressure) headache
	Medication overuse headache
	Facial pain syndromes (e.g., trigeminal neuralgia, temporomandibular joint disorders)

Box 11.69 Red flag features for secondary headache

- New onset or change in headache in patients who are aged >50 years
- Thunderclap: rapid time to peak headache intensity (seconds to 5 min)
- Focal neurological symptoms (e.g., limb weakness, aura <5 min or >1 hour)
- Non-focal neurological disturbance (e.g., cognitive disturbance)
- Change in headache frequency, characteristics, or associated symptoms
- Abnormal neurological examination
- Headache that changes with posture
- Headache waking up the patient
- Headache precipitated by physical exertion or Valsalva manoeuvre (e.g., coughing, laughing, straining)
- Patients with risk factors for cerebral venous sinus thrombosis
- Jaw claudication or visual disturbance
- Neck stiffness
- Fever
- New onset headache in a patient with a history of human immunodeficiency virus (HIV)
- New onset headache in a patient with a history of cancer

suggest migraine), or all over the head (more suggestive of tension-type headache)?

- **Associated symptoms**
  - Was the headache preceded by an aura? (suggestive of migraine)
  - Is there associated vomiting? (This may accompany headache of any cause, but occurs more commonly in migraine and raised ICP)
  - Are there any visual symptoms? (In one eye, this may suggest temporal arteritis; both eyes are more frequently affected in migraine. Transient disturbances of vision ('obscurations') may occur with raised ICP)
  - Is there associated neck stiffness, fever, loss of appetite, drowsiness, or a reported change in behaviour? (These features may suggest meningoencephalitis)
  - Is it painful to brush or wash their hair, or chew food? (This may be a feature of trigeminal neuralgia, although overlaps with symptoms also described by patients with temporal arteritis and temporomandibular joint dysfunction. The character of the pain in trigeminal neuralgia—usually shock-like and paroxysmal—usually allows it to be separated quite readily from these other possibilities)
  - Is there any excessive lacrimation or ptosis? (This may be reported in cluster headache)
  - A prodrome of weight loss, low-grade fever, malaise, and muscular aches and stiffness (particularly shoulder and hip girdle) may indicate temporal arteritis. Jaw claudication is present in ~50% of patients
- **Time/Duration**
  - Did the headache reach its maximum severity within the first 60 seconds from time of onset? (This is known as a 'thunderclap headache', a classical feature of SAH)
  - How long did the headache last from initial onset to resolution, and if intermittent in nature, how long between episodes?
- **Exacerbating factors**
  - Is the headache worse on lying down or first thing in the morning, or when you cough, sneeze, or bend down e.g., to tie shoelaces? (This may be suggestive of raised ICP)
  - Is the headache worse on sitting up/positional? (This may be the case in a low-pressure headache)
- **Severity**
  - Use a pain scale and ask the patient to grade the severity out of 10 (where 1 is mild, and 10 is the worst headache they have ever had). Does the intensity vary with time of day or when they are doing specific things? Does this change?
- **Past medical history**
  - Are there any relevant underlying medical conditions (e.g., adult polycystic kidney disease, posing risk of berry aneurysm and SAH)?
  - Do they have a history of hypertension, increasing risk of intracerebral bleed?
  - Do they have a history of obesity (associated with idiopathic intracranial hypertension)?
  - Are they pregnant (risk factor for venous sinus thrombosis)?
- **Medication history**
  - Are they taking antiplatelets or anticoagulants?
  - Are they taking any medication that may increase venous thromboembolic risk e.g., combined oral contraceptive pill?
  - Are they taking any known medication which can cause headaches as a side-effect? E.g., calcium channel blockers such as nifedipine.
  - Are they taking a high amount of over-the-counter analgesia (possibly suggestive of medication overuse headache)?
- **Social history**
  - What is their caffeine intake usually like?
  - Do they smoke?
  - Any recent travel or long-haul journeys?
  - Any history of alcohol or recreational drug use?
- Is there something very stressful occurring in their life currently?

Physical examination

- General bedside assessment: Does the patient appear distressed and in pain? Do you need to consider simple analgesia during your assessment?

- What is the Glasgow Coma Score (GCS)? Do you need to consider urgent imaging?
- Is there evidence of photophobia or phonophobia? (e.g., the patient preferring to lie in a darkened room with the door closed)—causes may include migraine and meningeal irritation (meningitis, SAH)
- Are there other signs of meningism (e.g., neck stiffness) suggesting SAH or meningitis?
- What is the blood pressure?
- Is there any evidence of alcohol withdrawal or intoxication?
- A full neurological examination—is there any focal neurological deficit?
- Ophthalmology assessment including fundoscopy—is there papilloedema indicating raised ICP? Are there any abnormalities of visual fields suggestive of space-occupying lesion?

Investigations

Investigations will be guided by history and clinical examination and most primary headache disorders are diagnosed by this alone. For secondary causes of headache, consider the following:

- **Laboratory investigations** including inflammatory markers such as erythrocyte sedimentation rate (ESR) and CRP if considering temporal arteritis
- **Brain imaging**
  - A non-contrast CT head is the first-line investigation for suspected SAH or other intracranial bleeds
  - Contrast-enhanced CT is usually required for identification and characterization of space-occupying lesions (e.g., tumour or abscess)
  - CT or MRI venography is required for diagnosis of cerebral venous sinus thrombosis
- **Lumbar puncture** is required where concern exists for intracranial infection. This is contraindicated with raised ICP resulting from a space-occupying lesion or hydrocephalus due to the attendant risk of tonsillar herniation (coning). While neuroimaging should not be used as a surrogate for the clinical identification of raised ICP, brain imaging is recommended in patients with symptoms and signs which could associate with the presence of structural CNS disease (e.g., decreased conscious level, focal neurological deficit, recent seizure or an immunocompromised state). LP for detection of xanthochromia is also indicated in patients with suspected SAH presenting late (>6 h) after symptom onset where CT does not confirm the diagnosis. In this setting, LP should be postponed until at least 12 h after symptom onset to maximize diagnostic yield.
- **Diagnosis of temporal arteritis** requires temporal artery ultrasound or biopsy, however, empirical treatment with prednisolone is usually commenced where a high index of suspicion exists for the diagnosis to reduce the risk of irreversible visual loss (discussed further in Chapter 32).

Migraine

Migraine is the most common primary headache disorder, affecting approximately 6 million people in the UK in the age range 16–65 years. In the Global Burden of Disease Study 2010 (GBD2010) migraine was ranked as the third most prevalent disorder in the world, and in GBD2015 it was ranked the third-highest cause of disability worldwide in both males and females under the age of 50. Migraine can be split into two types: with and without aura. A detailed description of pathogenesis and clinical features may be found in Chapter 28.

Box 11.70 POUND criteria for diagnosis of migraine

Pulsatile
One-day duration (4–72 h)
Unilateral
Nausea/vomiting
Disabling

Clinical assessment

The POUND criteria (**Box 11.70**) are useful in the diagnosis of migraine in an acute medicine setting. If four or more of these features are present, there is a 93% likelihood that this headache is a migraine. Sufferers often describe a 2- to 24-hour prodrome which may include myalgia, change in bowel habit, or mood change followed by an aura, and then progressing to the pain phase. It is crucial to intervene early when the pain is still mild, using adequate drug doses and appropriate routes of administration.

Management

Management can be divided into non-pharmacological (e.g., trigger avoidance) and pharmacological therapies. After acute management of migraine, it is also important to consider future prophylaxis. In the UK, both NICE and the British Association for the Study of Headache (BASH) advise that patients suffering from migraines should avoid over-the-counter remedies containing opiates as they will exacerbate nausea, impair gastric absorption of medication, and are strongly linked to the development of medication overuse headache: an intractable and often debilitating condition. Patients should be educated as to which over-the-counter treatments contain opiates.

Many patients with migraine find good relief with simple analgesics. These include paracetamol 1 g (up to four times daily), aspirin 900 mg (single dose, taken at onset of migraine), diclofenac 50 mg (up to three times daily), and naproxen 500 mg (up to twice daily).

There is mixed evidence for intravenous fluid as a treatment for acute migraine. While dehydration is a known trigger for migraine, and migraine-associated nausea often limits oral fluid intake, there is insufficient evidence to endorse admission to hospital or ambulatory care units for cannulation and fluid therapy. Liberal fluid therapy may be associated with adverse effects.

Oral medications should be administered with a prokinetic agent such as metoclopramide to facilitate enteral absorption; stomach emptying is greatly reduced in the pain phase of acute migraine. Triptans (5-$HT_{1B/1D}$ agonists) may also be effective in those not responsive to simple analgesics and parenteral administration (subcutaneous injection) may be effective where vomiting limits oral absorption.

Migraine suppression and recurrent migraine management are discussed in Chapter 28.

Tension-type headache

Tension-type headache (TTH) is the second most common disabling primary headache disorder and is characterized by a predisposition to attacks of mild to moderate headache with fewer associated symptoms. The diagnostic criteria are summarized in **Box 11.71**.

Management

For TTH; NICE guidelines advise simple analgesia such as paracetamol, aspirin, or NSAIDs in the first instance as soon as possible after the onset of the attack. Opioids should not be offered and, if so severe that they are needed, the diagnosis should be

Box 11.71 Diagnostic criteria for tension-type headache

(A) At least 10 episodes fulfilling the criteria B-D

(B) Headache lasting from 30 min to 7 days

(C) Headache has at least two of the following characteristics:
- Bilateral location
- Pressing/tightening (non-pulsatile) quality
- Mild to moderate intensity
- NOT aggravated by routine physical activity such as walking or climbing stairs

(D) Both of the following:
- No nausea or vomiting (anorexia may occur)
- No more than one episode of photophobia or phonophobia

(E) Not attributable to another disorder

reconsidered. Some co-morbidities that may be associated with TTH include stress, mood disorders, chronic pain, and sleep disorders. In the long term, there is no evidence for the use of SSRIs, botulinum toxin, homoeopathy, or beta-blockers. There is good evidence for the use of amitriptyline and regular exercise.

Intracranial bleeds

This comprises:
- intracerebral and cerebellar haemorrhage (see Chapter 29)
- subarachnoid haemorrhage
- subdural and extradural haemorrhage/haematoma.

Subarachnoid haemorrhage

Subarachnoid haemorrhage (SAH) means spontaneous arterial bleeding into the subarachnoid space, and is usually clearly recognizable clinically from its dramatic onset. SAH accounts for some 5% of strokes and has an annual incidence of 6 per 100 000.

Aetiology

The causes of SAH are shown in **Box 11.72**; it is unusual to find any contributing disease.

Saccular (berry) aneurysms

Saccular aneurysms (**Fig. 11.35**) develop within the circle of Willis and adjacent arteries. Common sites are at arterial junctions:

a. between posterior communicating and internal carotid artery—posterior communicating artery aneurysm
b. between anterior communicating and anterior cerebral artery—anterior communicating and anterior cerebral artery aneurysm
c. at the trifurcation or a bifurcation of the middle cerebral artery—middle cerebral artery aneurysm.

Other aneurysm sites are on the basilar, posterior inferior cerebellar, intracavernous internal carotid, and ophthalmic arteries. Saccular aneurysms are an incidental finding in 1% of postmortems and can be multiple.

Box 11.72 Underlying causes of subarachnoid haemorrhage

Cause	(%)
Saccular (berry) aneurysms	70%
Arteriovenous malformation (AVM)	10%
No arterial lesion found	15%
Rare associations Bleeding disorders Mycotic aneurysms—endocarditis Acute bacterial meningitis Tumours (e.g., metastatic melanoma, oligodendroglioma) Arteritis (e.g., systemic lupus erythematosus) Spinal AVM → spinal subarachnoid haemorrhage Coarctation of the aorta Marfan or Ehlers–Danlos syndromes Adult polycystic kidney disease	<5%

Fig. 11.35 Digital subtraction angiogram: posterior communicating artery aneurysm.

Aneurysms cause symptoms either by spontaneous rupture, when there is usually no preceding history, or by direct pressure on surrounding structures; for example, an enlarging unruptured posterior communicating artery aneurysm is the most common cause of a painful IIIrd nerve palsy (see Chapter 28).

Arteriovenous malformation

Arteriovenous malformation (AVM) is a vascular developmental malformation, often with a fistula between arterial and venous systems, causing high flow through the AVM and high-pressure arterialization of draining veins. An AVM usually presents following a spontaneous intracerebral haemorrhage or with a seizure, often focal in onset. The risk of a first haemorrhage in unruptured AVMs (20% fatal and 30% resulting in permanent disability) is approximately 2%–3% per year. Once an AVM has caused a haemorrhage, the risk of rebleeds is increased to approximately 10% per year. AVMs may be ablated with endovascular treatment (catheter injection of glue into the nidus, usually), microsurgery, or stereotactic radiotherapy. An MDT approach with neurologist, interventional neuroradiologist, and neurosurgeon is required in deciding on treatment options. There is no clear consensus on the best treatment modality or, indeed, whether the considerable risk of intervention is lower than with a conservative approach.

Fig. 11.36 Magnetic resonance T2-weighted image: symptomless frontal cavernoma *(arrowed)*.

Fig. 11.37 Subarachnoid haemorrhage. Axial, non-contrast CT showing blood filling the basal cisterns around the brainstem.

Cavernous haemangiomas (cavernomas) are common (0.1%–0.5% prevalence) and consist of a tangle of low-pressure dilated vessels without a major feeding artery; they are frequently symptomless (Fig. 11.36) and seen incidentally on imaging. Multiple cavernomas often have a genetic basis. Cavernomas may cause seizures. Small haemorrhages may occur but are usually low-pressure bleeds and rarely cause severe deficits. Surgical resection is rarely needed, except where the cavernoma is gradually enlarging or causing significant neurological symptoms.

Clinical assessment

Patients with SAH classically present with a sudden, very severe headache, often occipital (mean time to peak headache 3 min). Headache is usually followed by vomiting and often by coma and death. Survivors of SAH may remain comatose or drowsy for hours, days, or longer. SAH is a *possible* diagnosis in any sudden headache.

Following major SAH, there is neck stiffness and a positive Kernig's sign. Papilloedema is sometimes present, with retinal and/or subhyaloid haemorrhage (tracking beneath the retinal hyaloid membrane). Minor bleeds cause few signs but almost invariably do cause headache (approximately 17% of patients have small 'sentinel bleeds' in the weeks before presenting with SAH).

Investigations

CT imaging (non-contrast) is the immediate investigation (Fig. 11.37). Subarachnoid and/or intraventricular blood is usually seen (sensitivity of CT to detect subarachnoid blood is 95% within 24 hours of onset but much lower over subsequent days).

If a CT scan performed *within 6 hours of symptom onset* (reported by a radiologist) shows no blood in the subarachnoid space, this can usually be considered to exclude the diagnosis, unless a very strong index of suspicion persists.

If a CT scan performed *more than 6 hours after symptom onset* shows no blood in the subarachnoid space, this should not be considered to exclude the diagnosis, and an LP should be considered.

A **lumbar puncture** is not necessary if SAH is confirmed by CT. In cases where doubt remains and a CT has not shown blood in the subarachnoid space, at least 12 hours from symptom onset should be allowed before conducting an LP (the time required for the yellow colour of xanthochromia to appear within the CSF, which subsequently remains detectable for 2 weeks). Visual inspection of supernatant CSF is usually sufficiently reliable for diagnosis. Spectrophotometry to estimate bilirubin in the CSF released from lysed cells is used to define SAH with certainty.

CT angiography or catheter angiography to identify the aneurysm or other source of bleeding is performed in patients potentially fit for surgery. In some, no aneurysm or source of bleeding is found, despite a definite SAH.

Differential diagnosis

SAH must be differentiated from migraine. This is sometimes difficult but a short time to maximal headache intensity and the presence of neck stiffness usually indicate SAH. ***Thunderclap headache*** is used (confusingly) to describe either SAH or a sudden (benign) headache for which no cause is ever found. The syndrome of reversible cerebral vasoconstriction (Call–Fleming's syndrome) presents with thunderclap headache. Acute bacterial meningitis occasionally causes a very abrupt headache, when a meningeal microabscess ruptures; SAH also occasionally occurs at the onset of acute bacterial meningitis. Cervical arterial dissection can present with a sudden headache.

Complications

Blood in the subarachnoid space can lead to obstructive hydrocephalus, seen on CT. Hydrocephalus can be asymptomatic but may cause deteriorating consciousness following SAH. Shunting may be necessary. Arterial spasm (visible on angiography and a cause of coma or hemiparesis) is a serious complication of SAH and a poor prognostic feature.

Management

Immediate treatment of SAH involves bed rest and supportive measures. Hypertension should be controlled. Nimodipine, a calcium-channel blocker given for 3 weeks, reduces mortality.

All SAH cases should be discussed urgently with a neurosurgical centre. Nearly half of SAH cases are either dead or moribund before reaching hospital. Of the remainder, a further 10%–20% rebleed

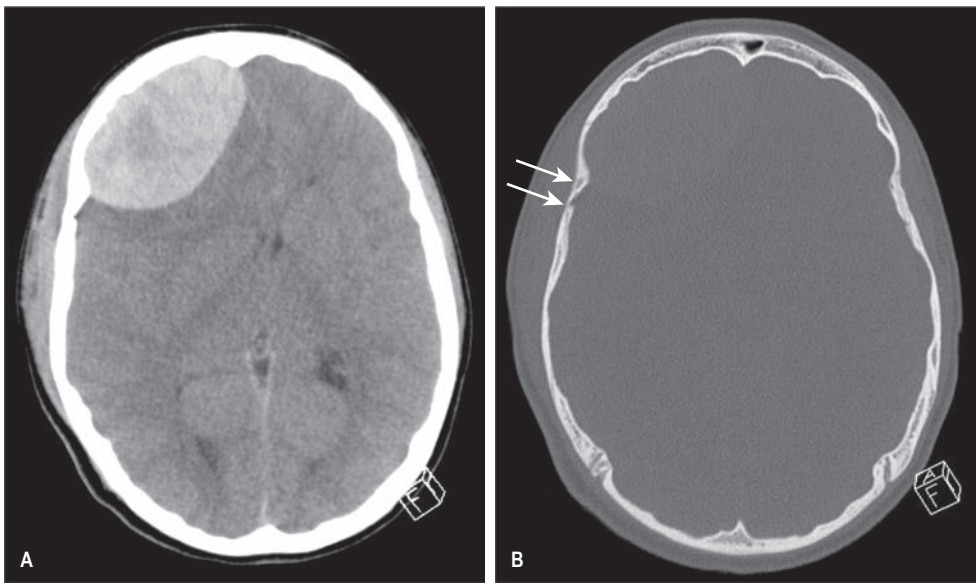

Fig. 11.38 Extradural haematoma. (A) Shown on hyperintensity on CT brain window. **(B)** Note the subtle linear non-depressed fracture of the right frontal bone *(arrows)*. This extended adjacent to the middle meningeal artery.

and die within weeks. Failure to diagnose SAH—for example, mistaking SAH for migraine—contributes to this mortality.

Where angiography demonstrates an aneurysm (the cause of the vast majority of SAHs), endovascular treatment by placing platinum coils via a catheter in the aneurysm sac, to promote thrombosis and ablation of the aneurysm, is now the first-line treatment. Endovascular coiling has a lower complication rate than surgery but direct surgical clipping of the aneurysm neck is still required in some selected cases. For asymptomatic (unruptured) aneurysms over 8 mm in diameter, the risk of treatment is less than the risk of haemorrhage if not treated. Patients who remain comatose or who have persistent severe deficits after SAH have a poor outlook.

Subdural and extradural bleeding

These conditions can cause death following head injuries unless treated promptly.

Subdural haematoma

Subdural haematoma (SDH) means accumulation of blood in the subdural space following rupture of a vein. This usually follows a head injury, sometimes a trivial one. The interval between injury and symptoms can be days, or may extend to weeks or months. Chronic, apparently spontaneous, SDH is common in the elderly, and also occurs with anticoagulants.

Headache, drowsiness, and confusion are common; symptoms are indolent and can fluctuate. Focal deficits, such as hemiparesis or sensory loss, develop. Epilepsy occasionally occurs. Stupor, coma, and coning may follow.

Extradural haemorrhage

Extradural haemorrhage (EDH) typically follows a linear skull vault fracture tearing a branch of the middle meningeal artery. Extradural blood accumulates rapidly over minutes or hours. A characteristic picture is that of a head injury with a brief duration of unconsciousness, followed by improvement (the lucid interval). The patient then becomes stuporose; there is an ipsilateral dilated pupil and contralateral hemiparesis, with rapid transtentorial coning. Bilateral fixed, dilated pupils, tetraplegia, and respiratory arrest follow. An acute progressive SDH presents similarly.

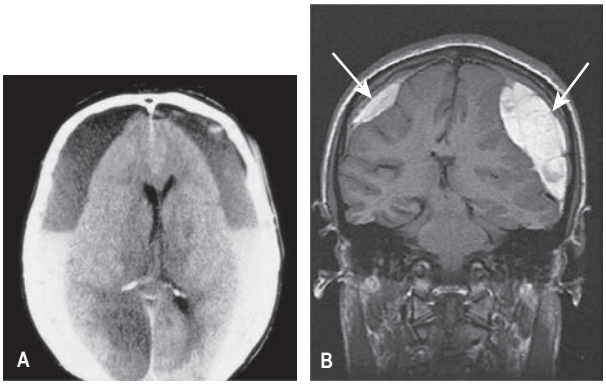

Fig. 11.39 Bilateral subdural haematomas. (A) CT scan. (B) Magnetic resonance T1-weighted image.

Management

Possible extradural or subdural bleeding needs immediate imaging. CT (Figs. 11.38 and 11.39A) is the most widely used investigation because of its immediate availability. MRI is more sensitive for the detection of small haematomas. T1-weighted MRI (Fig. 11.39B) shows bright images due to the presence of methaemoglobin.

EDHs *require urgent neurosurgery*; if it is performed early, the outlook is excellent. When the patient is far from a neurosurgeon, such as in wartime or at sea, drainage through skull burr holes has been lifesaving when an EDH has been diagnosed clinically.

Subdural bleeding usually needs less immediate attention but close neurosurgical liaison is necessary. Even large collections can resolve spontaneously without drainage. Serial imaging is required to assess progress.

Cortical venous thrombosis and dural venous sinus thrombosis

Intracranial venous thromboses are usually (>50%) associated with a prothrombotic risk factor, such as oral contraceptives, pregnancy, genetic or acquired prothrombotic states, and dehydration.

Head injury is also a cause. Infection, such as from a paranasal sinus, may be present. Venous thromboses can also arise spontaneously.

Cortical venous thrombosis

The venous infarct leads to headache, focal signs (e.g., hemiparesis), and/or seizures. Cortical haemorrhagic infarction is shown on MRI.

Dural venous sinus thromboses

Cavernous sinus thrombosis causes eye pain, fever, proptosis, and chemosis. External and internal ophthalmoplegia with papilloedema develops.

Thrombosis of the dural venous sinuses, such as when the sagittal sinus causes raised ICP with headache, papilloedema, and frequently seizures, may progress to coma.

Management

MRI and MR venography (MRV) show occluded sinuses and/or veins. Treatment is with heparin initially, followed by warfarin or other oral anticoagulants for 6 months. Anticonvulsants are given if necessary.

Meningitis

Meningitis is an infection of the meninges and bacterial meningitis is fatal unless treated. Microorganisms have usually travelled from mucosal surfaces such as the ears or nasopharynx via the bloodstream, or from a cranial injury or congenital meningeal defect. Immunocompromised patients are at risk of infection with unusual organisms. Non-infective causes of meningeal inflammation include malignant meningitis, intrathecal drugs, and blood following SAH. Infective causes are listed in (**Box 11.73**). Discussion of global trends in the incidence, causative agents, and role for vaccination against meningitis is found in Chapter 42.

? Box 11.73 Infective causes of meningitis in the UK[a]

Bacteria
- *Neisseria meningitidis*
- *Streptococcus pneumoniae*[a]
- *Staphylococcus aureus*
- Streptococcus group B
- *Listeria monocytogenes*
- Gram-negative bacilli e.g., *Escherichia coli*
- *Mycobacterium tuberculosis*
- *Treponema pallidum*

Viruses
- Enteroviruses:
  - ECHO
  - Coxsackie
- (Poliomyelitis—mainly eradicated worldwide)
- Mumps
- Herpes simplex
- HIV
- Epstein–Barr

Fungi
- *Cryptococcus neoformans*
- *Candida albicans*
- *Coccidioides immitis, Histoplasma capsulatum, Blastomyces dermatitidis* (USA)

[a]These organisms account for 70% of acute bacterial meningitis outside the neonatal period. A wide variety of infectious agents are responsible for the remaining 30% of cases. *Haemophilus influenzae b* (Hib) has been eliminated as a cause in many countries by immunization. Malaria often presents with cerebral symptoms and a fever.

In acute bacterial meningitis, the pia-arachnoid is congested with neutrophils. A layer of pus forms. This may organize to form adhesions, causing cranial nerve palsies and hydrocephalus. In chronic infection (e.g., tuberculosis), the brain is covered in a viscous grey–green exudate with numerous meningeal tubercles. Adhesions are invariable. Cerebral oedema occurs in any bacterial meningitis. In viral meningitis there is a predominantly lymphocytic inflammatory CSF reaction without pus formation, polymorphs, or adhesions; there is little or no cerebral oedema unless encephalitis develops.

Clinical assessment

Meningitis often presents with a triad of symptoms: headache, neck stiffness, and fever. Photophobia and vomiting are often present. In acute bacterial infection, there is usually intense malaise, fever, rigors, severe headache, photophobia, and vomiting, developing within hours or minutes. The patient is irritable and often prefers to lie still. Neck stiffness and a positive Kernig's sign usually appear within hours. Brudzinski's sign (severe neck stiffness causing a patient's hips and knees to flex when the neck is flexed) may be present.

Meningococcal meningitis may be part of a generalized meningococcal septicaemia: a non-blanching purpuric rash may be present and these patients may deteriorate rapidly with septic shock and peripheral vascular infarcts.

It is important to assess for signs suggesting raised ICP which should trigger urgent brain imaging and may impact the safety of LP:
- reduced or fluctuating level of consciousness
- relative bradycardia and hypertension
- focal neurological signs
- abnormal posture or posturing
- unequal, dilated, or poorly responsive pupils
- papilloedema
- abnormal 'doll's eye' movements (**Fig. 11.33**).

In uncomplicated meningitis, consciousness remains intact, although anyone with a high fever may be delirious. Progressive drowsiness, lateralizing signs, and cranial nerve lesions indicate complications such as venous sinus thrombosis, severe cerebral oedema or hydrocephalus, or an alternative diagnosis such as cerebral abscess or encephalitis.

It may be difficult to distinguish between the sudden headache of SAH, migraine, and acute meningitis. Meningitis should be considered seriously in anyone with headache and fever, and in any sudden headache. Neck stiffness should be looked for; it may not be obvious.

In less severe cases (e.g., many viral meningitides), there are less prominent meningitic signs. However, bacterial infection may also be indolent, with a deceptively mild onset.

Specific varieties of meningitis

Clinical clues point to the diagnosis (**Box 11.74**). If there is access to the subarachnoid space via skull fracture (recent or old) or occult spina bifida, bacterial meningitis can be recurrent, and the infecting organism is usually pneumococcus. **Box 11.75** summarizes typical CSF changes in different forms of meningitis.

Acute bacterial meningitis

Onset is typically sudden, with rigors and high fever. Meningococcal septicaemia is associated with a petechial rash, sometimes sparse (**Fig. 11.40**). The meningitis may be part of a generalized meningococcal septicaemia with septic shock and peripheral vascular

infarcts (see Chapter 42). Acute septicaemic shock may develop in any bacterial meningitis.

Viral meningitis

This is almost always a benign, self-limiting condition lasting 4–10 days. Headache may follow for some months. There are no serious sequelae, unless an encephalitis is present (see below). Causes are listed in **Box 42.34**.

Chronic meningitis

For further discussion on chronic meningitis, see Chapter 28.

Chronic meningitis sometimes resembles an intracranial mass lesion, with headache, epilepsy, and focal signs. *Cerebral malaria* (Chapter 42) can mimic bacterial meningitis.

Investigations

When meningococcal meningitis is diagnosed clinically by the presence of the typical petechial rash, immediate parenteral antibiotics should be given, ideally in the pre-hospital setting (see **Box 11.77**); in this situation LP is unnecessary. In other cases of meningitis, an LP is performed if there is no clinical suspicion of a mass lesion.

- **Laboratory investigations should** include full blood count, CRP, renal profile, liver function tests, and coagulation screening. Blood cultures are important, ideally prior to commencing intravenous antibiotics. Whole blood polymerase chain reaction (PCR) testing for meningococcus and pneumococcus should be sent. Be aware that a normal CRP and white blood cell count does not rule out bacterial meningitis.
- **CT/MRI brain** may be indicated if there are red flag features on presentation or examination including any signs of raised ICP, focal neurological signs, or risk factors for a space-occupying lesion (e.g., immunocompromised patient). Identification of a mass lesion on LP contraindicates LP, as coning of the cerebellar tonsils may follow LP. Importantly, normal brain imaging does not exclude raised ICP and clinical features of raised ICP also contraindicate LP.
- **Lumbar puncture and CSF analysis** (**Box 11.75**)—Guidance recommends obtaining CSF samples within 1 h of presentation to increase probability of a positive culture. Opening pressure should be measured and samples sent for white cell count, microscopy, culture and sensitivity, viral PCR, total protein, glucose, and cytology. CSF stains demonstrate organisms (e.g., Gram-positive intracellular diplococci—pneumococcus; Gram-negative cocci—meningococcus). Ziehl–Neelsen stain demonstrates acid-fast bacilli (tuberculosis), though TB organisms are rarely numerous. Indian ink stains fungi.
- Meticulous attention should focus on microbiological studies in suspected CNS infection with close liaison between clinician and microbiologist. Specific techniques, such as PCR for meningococci and viruses, or CSF bacterial antigen testing, are invaluable. Syphilis and HIV serology should always be carried out.

Management

Recognition and immediate treatment of acute bacterial meningitis are vital. Minutes save lives. Bacterial meningitis has a high mortality and morbidity. Even with optimal care, mortality is around 15%. The following applies to adult patients; management is similar in children. Immediate antibiotic treatment for suspected meningococcal meningitis is indicated at first contact before investigation (**Box 11.76**).

? Box 11.74 Clinical clues in meningitis

Clinical feature	Possible cause
Petechial rash	Meningococcal infection
Skull fracture Ear disease Congenital CNS lesion	Pneumococcal infection
Immunocompromised patients	HIV with opportunistic infection
Rash or pleuritic pain	Enterovirus infection
International travel	Malaria
Occupational: work in drains, canals, polluted water, recreational swimming Clinical: myalgia, conjunctivitis, jaundice	Leptospirosis

Fig. 11.40 Rash of meningococcal septicaemia with meningitis. Purpuric lesions.

i Box 11.75 Typical changes in cerebrospinal fluid in viral, pyogenic, and tuberculous meningitis

	Normal	Viral	Pyogenic	Tuberculous
Appearance	Crystal clear	Clear/turbid	Turbid/purulent	Turbid/viscous
Mononuclear cells	<5/mm^3	10–100/mm^3	<50/mm^3	100–300/mm^3
Polymorph cells	Nil	Nil[a]	200–300/mm^3	0–200/mm^3
Protein	0.2–0.4 g/L	0.4–0.8 g/L	0.5–2.0 g/L	0.5–3.0 g/L
Glucose	⅔–½ blood glucose	>½ blood glucose	<½ blood glucose	<½ blood glucose

[a]Some CSF polymorphs may be seen in the early stages of viral meningitis and encephalitis.

Antibiotics (Box 11.77)

- A third-generation cephalosporin (intravenous ceftriaxone or cefotaxime) provides adequate cover for the majority of important community-acquired bacterial meningitis pathogens.
- High-dose penicillin such as amoxicillin is indicated in *Listeria monocytogenes* meningitis and should be added empirically in high-risk groups.

Corticosteroids

- Adjunctive immediate high dose steroid (dexamethasone 0.15 mg/kg i.v. 6-hourly), commenced with or before the first dose of antibiotics, has been shown to reduce neurological complications including deafness in bacterial meningitis due to pneumococcus or Haemophilus influenza type B (Hib). Dexamethasone should be commenced in all patients with bacterial meningitis of unknown cause, continued for 4 days in those with pneumococcus/Hib and stopped for all other organisms. In cases where no causative organism is found, advice should be sought from an infectious diseases physician as to whether dexamethasone should be continued.

Box 11.76 Meningococcal meningitis and meningococcaemia: emergency treatment

Suspicion of meningococcal infection is a medical emergency requiring treatment immediately.

Clinical features

- Petechial or non-specific blotchy, red rash
- Fever, headache, neck stiffness

Not all these features may be present—and meningococcal infection may sometimes begin like any apparently non-serious infection.

Immediate treatment for suspected meningococcal meningitis at first contact before investigation (pre-hospital, with GP/paramedics).

- i.v. or i.m. benzylpenicillin unless history of anaphylaxis

In meningitis, minutes count—delay is unacceptable.

On arrival in hospital

- Blood tests, including blood cultures, immediately
- Monitoring for septic shock
- Third-generation cephalosporin e.g., cefotaxime or ceftriaxone, as empirical therapy (increasing rates of penicillin resistance)
- Dexamethasone is not indicated for meningococcal meningitis; in bacterial meningitis of unknown cause, commence dexamethasone 0.15 mg/kg i.v. 6-hourly, but continue only if pneumococcus or Haemophilus influenza type B is isolated and discontinue if meningococcus

Local infection (e.g., paranasal sinus) should be treated surgically if necessary. Repair of a depressed skull fracture or meningeal tear may be required.

Prophylaxis

Meningococcal infection should be notified to the public health authorities, and advice sought about immunization and prophylaxis of contacts. Chemoprophylaxis with rifampicin or ciprofloxacin should be offered to all close contacts. MenC vaccine is given in the UK and MenB, a meningococcal B vaccine, is now available for population immunization of infants and for use in outbreaks. A combined A and C meningococcal vaccine is sometimes used prior to travel from the UK to endemic regions, such as Africa or Asia, and there is a quadrivalent ACWY vaccine for specific events, such as the Hajj and Umrah in Mecca.

Pneumococcal conjugated vaccine is now given to infants in many countries and pneumococcal polysaccharide vaccine is offered to older adults and those with, for example, immunodeficiency or splenectomy. Pneumococcal immunization has reduced the incidence of pneumococcal meningitis.

Hib (Haemophilus influenzae) vaccine is given routinely in childhood in the UK and many other countries, virtually eliminating a common cause of fatal meningitis.

Contact tracing is important and identifying any at-risk contacts:

- Identify those at risk
- Be aware that meningitis and meningococcal disease are notifiable disease
- Inform close contacts that the risk to a contact is low with meningococcal disease. The risk is highest in the first 7 days after a case is diagnosed and falls sharply thereafter
- Prophylaxis or vaccination for close contacts is usually arranged by secondary care
- Prophylaxis against meningococcal disease should be considered for the following close contacts, regardless of meningococcal vaccination status:
  - People who have had prolonged contact with case in a household-type setting during the 7 days before onset of illness (e.g., household contacts, pupils in the same dormitory, partners, or university students sharing a kitchen in a hall of residence).
  - People who have had transient close contact with a case only if they have been directly exposed to large particle droplets/secretions from the respiratory tract of a case around the time of admission to hospital.
- Antibiotic prophylaxis should be given as soon as possible (ideally within 24 h) after the diagnosis of the index case.

Box 11.77 Antibiotics in acute bacterial meningitis

Organism	Antibiotic	Alternative (e.g., allergy)
Unknown pyogenic	Third-generation cephalosporin e.g., ceftriaxone/cefotaxime (+ vancomycin in areas of high pneumococcal penicillin/cephalosporin resistance)	Chloramphenicol
Age >50 or immunocompromised	As above but add amoxicillin to cover *Listeria*	Co-trimoxazole for *Listeria*
Meningococcus	Third-generation cephalosporin initially Switch to benzylpenicillin if confirmed sensitive	Cefotaxime
Pneumococcus	Third-generation cephalosporin	Chloramphenicol
Haemophilus	Third-generation cephalosporin	Chloramphenicol

Viral encephalitis

Viral encephalitis is an inflammation of the brain parenchyma caused by a virus. It is the most common type of encephalitis and may coexist with viral meningitis (see **Box 42.34**). The viruses isolated from adult UK cases are usually herpes simplex (HSV 1 and 2), varicella zoster (VZV) and other herpes group viruses, HHV-6, 7, enteroviruses, and adenovirus. HSV encephalitis typically affects the temporal lobes initially and is often asymmetric. Frequently, the virus is never identified. Outside the UK, in endemic regions, different pathogens cause encephalitis, including flaviviruses (Japanese encephalitis, West Nile virus, tick-borne encephalitis) and rabies.

Local epidemics can occur. For example, in New York in the 1990s, West Nile virus caused an epidemic and Venezuelan equine virus was isolated from encephalitis cases in South America.

Clinical features

- Flu-like symptoms such as headache, fever, myalgia, fatigue, or weakness
- Confusion
- Headache
- Personality changes or agitation
- Seizures
- Loss of consciousness including coma

In cases of autoimmune encephalitis (see Chapter 28), symptoms may develop more slowly over several weeks.

Investigations

- MRI classically shows areas of inflammation and swelling, generally in the temporal lobes in HSV encephalitis. Raised ICP and midline shift may occur, leading to coning.
- EEG shows periodic sharp and slow-wave complexes.
- CSF shows an elevated lymphocyte count (95%).
- Viral detection by CSF PCR is highly sensitive for several viruses, such as HSV and VZV. However, a false-negative result may occur within the first 48 h of symptom onset. Serology (blood and CSF) is also helpful.
- Brain biopsy is rarely required since the advent of MRI and PCR.

Management

Suspected HSV and VZV encephalitis is treated immediately with intravenous aciclovir (10 mg/kg three times a day for 14–21 days), even before investigation results are available. Early treatment significantly reduces both mortality and long-term neurological damage in survivors. Seizures are treated with anticonvulsants. Occasionally, decompressive craniectomy is required to prevent coning but coma confers a poor prognosis.

Long-term complications are common and include memory impairment, personality change, and epilepsy.

Seizures

Seizures are a common neurological emergency encountered in the acute medical setting. An epileptic seizure is defined as a sudden synchronous discharge of cerebral neurons causing symptoms or signs apparent to the patient or observer, with a broad spectrum of manifestations ranging from a subjective 'aura' noticeable only to the patient to a generalized tonic–clonic seizure with loss of awareness. Causes of seizures are summarized in **Box 11.78**.

Seizure types

Seizures may be generalized (involving both cerebral hemispheres with loss of awareness) or focal (arising within one hemisphere, with preservation of awareness if 'motor' only). Distinguishing between generalized and focal seizures is important, both with regard to potential causes (e.g., focal motor seizures may localize to an

? Box 11.78 Causes of seizures

Causes of seizures	Description
Primary generalized epilepsy	A chronic neurological disorder characterized by recurrent, seizures with a structurally normal brain, usually with onset in childhood or early adulthood. Thought usually to be polygenic, although taking a family history is important.
Febrile seizures	Seizures triggered by high fever in young children (typically under the age of 5). This diagnosis should not be made in adults, and the coexistence of seizures and fever should prompt consideration for serious pathology such as intracranial infection.
Metabolic disturbances	E.g., Electrolyte imbalances (e.g., hyponatraemia or hypocalcaemia), hypoglycaemia, or uraemia.
Structural brain lesions	E.g., Tumours, vascular malformations, or traumatic brain injury.
Infections	Meningitis, encephalitis, or brain abscess may present with seizures. Consider the possibility of immunocompromise and HIV infection.
Toxic exposures	Exposure to toxins, such as recreational drugs, alcohol (particularly in withdrawal), or environmental toxins.
Prescription medication	A number of medications may trigger seizures either in toxicity (e.g., tricyclic antidepressants, antipsychotics, lidocaine, ciclosporin) or withdrawal (e.g., benzodiazepines)
Vascular events	A cerebral infarct (stroke) can disrupt blood flow to the brain and lead to seizures, either at the time of an acute event, or subsequently as a result of a cerebral 'scar'. Cerebral venous sinus thrombosis may also result in seizures. Enquire about both cardiovascular and venous thromboembolic risk factors when taking a history.
Autoimmune encephalitis	An autoimmune response against brain tissue can cause seizures. Evaluate for autoimmune disorders and ask about cancer (which can cause paraneoplastic encephalitis).
Hypoxic-ischemic events (Anoxia)	Lack of oxygen to the brain due to conditions like drowning or cardiac arrest may result in seizures.
Genetic disorders (e.g., Dravet syndrome)	Certain genetic conditions predispose individuals to seizures. Enquire about family history and genetic testing.
Idiopathic (unknown)	In some cases, no underlying cause is identified, and seizures are categorized as idiopathic.
Dissociative seizures	Seizures without underlying neurological causes, often associated with psychological stressors.

underlying structural brain lesion) and management. Seizures may or may not lead to a diagnosis of epilepsy; classification is complex and the latest classification of seizures, epilepsy types, and epilepsy syndromes is discussed further in Chapter 28.

Clinical assessment

When a patient presents with an acute seizure, the primary focus is on ensuring safety and stabilizing their condition. This involves protecting the patient from injury during the seizure, evaluating their airway, breathing, and circulation, and providing necessary immediate interventions like administering oxygen and initiating cardiac monitoring.

History

Detailed history from the patient and **any witnesses** helps understand the nature of the seizure and identify any predisposing factors or underlying causes. Specifically, enquire about events preceding, during and after the episode (including any aura, alteration in awareness, or post-ictal confusion or headache), potential triggers or seizure risk factors (e.g., previous stroke or head injury), as well as alcohol or recreational drug use (see **Box 28.29**). Patients with a prior diagnosis of epilepsy should be asked about any recent changes to their prescription medications or new medicines which may alter the seizure threshold and concordance with treatment. A seizure is a clinical diagnosis and needs to be carefully separated from other causes of impaired consciousness (e.g., syncope) and dissociative seizures (**Box 11.63**).

Physical examination

Once the seizure has terminated, carry out a full neurological examination and assess for any signs of injury or trauma resulting from the seizure. Transient focal neurological symptoms and signs may be seen following a generalized tonic–clonic seizure (Todd's paralysis), but persistent abnormal findings raise concern for a vascular event or structural brain lesion.

Investigations

Blood tests, including full blood count, electrolyte panel, glucose, renal and liver function tests, toxicology screen if indicated, and antiepileptic drug levels, can provide information about potential underlying causes or contributing factors. A 12-lead ECG should be performed to assess rhythm, conduction abnormalities, and QT interval.

Brain imaging is almost always indicated for a first presentation with seizure although the optimal modality varies with the scenario: MRI (± venography or diffusion-weighted imaging) often provides the most data, although non-contrast CT is a rapid and sensitive test where intracranial bleeding is suspected. EEG may be useful in selected cases, such as suspected non-convulsive status epilepticus or to differentiate seizure types; it is frequently requested as part of the post-discharge 'first seizure' work-up although it is insensitive and often normal.

Management

Most seizures last only minutes and terminate spontaneously. A prolonged seizure (>5 min) or repeated seizures may be terminated with rectal diazepam, intravenous lorazepam, or buccal midazolam. Oxygen should be given and the airway monitored in the post-ictal phase. Additionally, it is important to protect the patient from injury during the post-ictal period.

Many hospitals run rapid-access first seizure clinics accepting referrals directly from ED and acute medical services. Where such services exist, patients who experience a single seizure with full recovery, and have a normal examination and first-line investigations (blood tests/ECG) may be discharged with outpatient follow-up (see **Box 28.31** for first seizure checklist).

For patients with recurrent seizures or suspected epilepsy, it is advisable to consult a neurologist for further evaluation and guidance on long-term management (see Chapter 28).

In all instances, patients and families should be provided with education and support regarding seizure recognition, management, and safety. Information about potential triggers of seizures and advice on lifestyle modifications, such as ensuring adequate sleep, avoiding excessive alcohol consumption, and managing stress, should be given. Patients should be educated about the importance of medication adherence and potential side-effects.

On discharge, patients should receive clear instructions regarding their condition and any necessary precautions. It is important to advise patients to avoid potentially hazardous activities (e.g., bathing or swimming alone) and to stop driving and in the UK, inform the Driver and Vehicle Licensing Agency (DVLA). Patients and their families should be encouraged to have a seizure action plan in place, including when to seek medical help and how to provide immediate assistance during a seizure.

Status epilepticus

This medical emergency (**Box 11.79**) means continuous seizures for 30 minutes or longer (or two or more seizures without recovery of consciousness between them over a similar period). Status epilepticus has a mortality of 10%–15%. The longer the duration of status, the greater the risk of permanent cerebral damage. Rhabdomyolysis may lead to AKI in convulsive status epilepticus.

Over 50% of cases occur without a previous history of epilepsy. Some 25% with apparent refractory status have dissociative (psychogenic or non-epileptic) seizures.

Not all status is convulsive. In non-convulsive status epilepsy; the patient is in a continuous, distant, stuporous state. ***Focal status*** also occurs. ***Epilepsia partialis continua*** is continuous seizure activity in one part of the body, such as a finger or a limb, without loss of consciousness. This is often due to a cortical neoplasm or, in the elderly, a cortical infarct.

Delirium

Delirium, otherwise referred to as 'acute confusional state', is characterized by an acute and fluctuating disturbance in attention and cognition and represents a frequent presentation to the acute medical service. This transient mental state alteration can arise from various underlying causes and demands a comprehensive approach for accurate assessment and management.

Delirium can be considered as an acute or subacute 'brain failure', in which impairment of attention is accompanied by abnormalities of perception and mood (**Box 11.80**). During the acute phase of delirium, thought and speech are incoherent, memory is impaired, and misperceptions occur. Patients may experience episodic visual hallucinations (or illusions) or persecutory delusions occur and as a consequence, the patient may be frightened, suspicious, restless, and possibly uncooperative.

Delirium is often subclassified as 'hyperactive' (agitated, restless, wandering if physically able) or 'hypoactive' (withdrawn, lethargic, immobile) although in practice patients may fluctuate between psychomotor states. Agitation is usually worse at night, with consequent sleep reversal, so that the patient may be asleep in the day and awake all night.

Box 11.79 Status epilepticus: management

Early status (up to 30 min)—first-line treatments

- Administer oxygen, monitor ECG and blood pressure, perform routine blood tests (include glucose, calcium, drug screen, anticonvulsant levels urgently)
- Give lorazepam i.v. 4 mg bolus. Repeat once if necessary. Buccal midazolam is an alternative

Established status (30–90 min)—second-line treatments

- Levetiracetam: give at a loading dose of 60 mg/kg (maximum 4500 mg) infused over 15 min in 100 mls of sodium chloride 0.9% (often preferred as first-line in view of quicker administration and fewest adverse effects)

or

- Phenytoin: give 20 mg/kg i.v. (max. 2 g) diluted to 10 mg/mL in saline into a large vein at 25–50 mg/min (ECG monitoring required)

or

- Fosphenytoin: this is a prodrug of phenytoin and can be given faster than phenytoin. Doses are expressed in phenytoin equivalents (PE): fosphenytoin 1.5 mg = 1 mg phenytoin. Give 15 mg/kg (PE) fosphenytoin (15 mg × 1.5 = 26.5 mg) diluted to 10 mg/mL in saline at 50–100 mg (PE)/min

or

- Valproate: given at a loading dose of 40 mg/kg at a rate of 10 mg/kg per min (maximum dose 3000 mg)

If ongoing seizures:

- Consider using an alternative second-line treatment under expert guidance

or

- Phenobarbital 10 mg/kg i.v. diluted 1 in 10 in water for injection at <100 mg/min

Refractory status (>90 min)—general anaesthesia

- Only in intensive care setting; intubation and ventilation usually required
- Propofol 1–2 mg/kg bolus, followed by a continuous infusion of up to 4 mg/kg per hour for a minimum of 24 hours
- Thiopental and midazolam infusions may also be used
- Use continuous EEG monitoring to assess efficacy of treatment—aim for EEG burst suppression pattern
- Reinstate previous AED medication via nasogastric tube
- Establish diagnosis: CT or MRI may reveal an underlying cause
- Remember: 25% of apparent status cases turn out to be pseudostatus

Box 11.80 Delirium: diagnostic criteria

- Disturbance of consciousness:
  - ↓ Clarity of awareness of environment
  - ↓ Ability to focus, sustain, or shift attention
- Change in cognition:
  - Memory deficit, disorientation, language disturbance, perceptual disturbance
- Disturbance develops over a short period (hours or days)
- Fluctuation over the course of a day

(Derived from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th edn. Text revision [DSM-5]. Washington, DC: APA; 2013.)

The differential diagnosis of delirium is laid out in **Box 11.81**. Patients with pre-existing brain disease (e.g., dementia, cerebrovascular disease), sensory impairment, or advanced age are at increased risk of delirium during periods of intercurrent illness (**Box 11.82**).

Clinical assessment

When confronted with a patient manifesting delirium, a thorough and systematic evaluation is essential to establish the cause and implement appropriate investigations/interventions.

Box 11.81 Common causes of delirium

- Infection:
  - Any systemic infection, particularly with high fever (e.g., malaria, septicaemia)
  - Intracranial infection (e.g., encephalitis, cerebral abscess)
- Metabolic disturbance:
  - Hepatic failure
  - Chronic kidney disease (uraemia)
  - Disorders of electrolyte balance, dehydration
  - Hypoxia
- Vitamin deficiency:
  - Thiamine (Wernicke–Korsakoff's syndrome, beriberi)
  - Nicotinic acid (pellagra)
  - Vitamin B_{12}
- Endocrine disease:
  - Hypothyroidism
  - Cushing's syndrome
- Intracranial causes:
  - Trauma
  - Tumour
  - Subarachnoid haemorrhage
  - Epilepsy
- Drug intoxication:
  - Anticonvulsants
  - Antimuscarinics
  - Anxiolytics/hypnotics
  - Tricyclic antidepressants
  - Dopamine agonists
  - Digoxin
- Drug/alcohol withdrawal
- Postoperative states

Box 11.82 Predisposing factors in delirium

Endogenous

- Extremes of age (developing or deteriorating brain)
- Damaged brain:
  - Any dementia (most common predisposition)
  - Previous head injury
  - Alcohol brain damage
  - Previous stroke
- Visual or hearing impairment

Exogenous

- Dislocation to an unfamiliar environment (e.g., hospital admission)
- Sleep deprivation
- Sensory extremes (overload or deprivation)
- Immobilization

History

A **collateral history** (e.g., from a relative or bystander) is a key component of this process, both in establishing a change in affect or behaviour where delirium is subtle, and as the patient themself may be unable to provide a coherent account of their illness.

- **Onset and duration:** Crucial both for discerning potential causes and discriminating from chronic forms of confusion (e.g., dementia).
- **Precipitating factors:** A history of preceding fall or trauma should raise suspicion of an intracranial injury (e.g., SDH). A detailed social history should include assessment of both alcohol and recreational substance use which may cause confusion both in toxicity or withdrawal, the latter sometimes manifesting several days after hospitalization in patients admitted for other reasons. Environmental changes (hospitalization, unfamiliar

surroundings) may provoke delirium in the elderly or those with underlying dementia (acute-on-chronic confusional state).

- **Associated symptoms:** Explore for symptoms of the underlying cause, such as fever or other focal symptoms indicating infection or headaches or focal neurological symptoms, suggesting an intracranial disorder. Visual hallucinations are more common in delirium associated with alcohol and drug withdrawal.
- **Medication review:** Conduct a thorough review of the patient's medications, including prescription and over-the-counter drugs, to identify potential culprits contributing to delirium. Overdose (either intentional or inadvertent) should be considered as should prescription drug withdrawal states.
- **Past medical history:** Scrutinize past medical history for pre-existing conditions that may predispose the patient to delirium (e.g., post-ictal delirium, anticonvulsant toxicity, or non-convulsive status epileptics in a patient with epilepsy). Some patients may wear medical alert bracelets with important information which may be diagnostically helpful (e.g., history of Addison's disease). Patients with a preceding history of dementia or brain injury are at heightened risk of developing delirium.

Physical examination

- Fever may indicate infection (and should prompt consideration of encephalitis, in the appropriate context).
- Bedside tests will usually identify hypoxia and hypoglycaemia.
- Look for external signs of head injury.
- Examine for signs of CLD and check for asterixis (the flapping hand tremor which may be seen in both hepatic and uraemic encephalopathy and with CO_2 retention).
- Look for signs of meningeal irritation (e.g., neck stiffness) but remember that meningism is uncommon in encephalitis (e.g., due to HSV-1).
- If possible, examine the optic fundi for papilloedema (raised intracranial pressure [ICP]).
- Ophthalmoplegia and ataxia may suggest Wernicke encephalopathy while focal motor weakness (e.g., hemiparesis) may result from intracranial bleeds or mass lesions.

The presence of delirium may not be immediately evident when a patient presents to an acute medical admission setting. It is important to screen for delirium in patients who are susceptible. The 4 'A's Test **(4AT)** is a rapid and systematic tool designed for the assessment of delirium (**Box 11.83**). This screening instrument is particularly useful in busy clinical settings to promptly identify individuals at risk of or currently experiencing delirium. The 4AT incorporates four key domains, each beginning with the letter 'A', to facilitate easy recall and application.

Box 11.83 The 4 'A's' Test (4AT) for identification of delirium

Alertness	Normal (0) Mild sleepiness for less than 10 seconds after waking, then normal (0) Clearly abnormal (4)
Acute Abbreviated Mental Test Score (AMT4) *Ask the patient to state their age, their date of birth, the current year, and the name of the current location.*	No mistakes (0) 1 mistake (1) 2 or more mistakes, or untestable (2)
Altered Attention *Instruct the patient to list the months of the year in reverse order, starting with December.*	Lists 7 or more months correctly (0) Starts but lists less than 7, or refuses to start (1) Untestable (2)
Acute Onset or Fluctuating Course *Evidence of significant change or fluctuation in mental status within the last 2 weeks and still persisting in the last 24 hours*	No (0) Yes (4)

A total score of 4 or more suggests a high likelihood of delirium, necessitating further assessment and intervention.

Investigations

Investigations required will vary depending on the clinical context and findings on clinical assessment.

- **Laboratory:** First-line blood tests include full blood count, renal and liver profiles, electrolytes including serum calcium, and thyroid function tests.
- **Urinalysis:** While urinary tract infection may provoke delirium particularly in older adults, the high incidence of asymptomatic bacteriuria in the elderly means urinalysis has a poor PPV for this diagnosis in patients over 65 and should not be relied upon in isolation.
- **Imaging:** Brain imaging (CT or MRI) is warranted if focal neurological symptoms or signs are present, a structural brain abnormality is suspected or LP is planned. In practice, brain imaging is often requested early in the diagnostic pathway where the cause of delirium is not readily apparent.
- **Toxicology:** This may include blood or urine testing for substances of abuse or prescription drug levels (e.g., digoxin, antiepileptic drugs).
- **Further testing:** LP is usually warranted where meningitis or encephalitis is suspected. In cases where the cause remains elusive, EEG can aid in detecting abnormal brain wave patterns associated with delirium and discriminate between metabolic encephalopathy and non-convulsive status epilepticus.

Management

The management of delirium hinges on identifying and addressing the underlying causes. Assessment of mental capacity should be undertaken when making treatment decisions (in the UK, a Deprivation of Liberty or 'DoLS' application may be made to offer treatment in line with the guiding principles of the Mental Capacity Act in patients unable to consent).

Key management principles encompass:

- **Treatment of underlying causes:** Address the specific cause(s) of delirium, whether it be infection, metabolic derangements, or substance withdrawal.
- Patients with a history of alcohol dependency should receive empirical treatment with thiamine (as Pabrinex) to diminish risk of permanent neurological sequelae. In patients with suspected encephalitis, treatment with acyclovir should be commenced immediately and even before definitive investigation results are available.
- **Environmental modification:** Optimize the patient's environment by minimizing stimuli, ensuring adequate lighting, and promoting a consistent daily routine.
- **Medication review and adjustment:** Re-evaluate and adjust medications, particularly those with sedative or anticholinergic properties.
- **Multidisciplinary team:** Engage an MDT, including nursing, therapies, and specialty involvement as appropriate e.g., care of the elderly, psychiatry, neurology.
- **Reassurance and support:** Offer reassurance and support to the patient and their caregivers, emphasizing the reversible nature of delirium with appropriate interventions.

- **Psychoactive drugs** should be avoided if possible and reserved for instances where a delirious patient is considered at risk to themselves or others and verbal and non-verbal de-escalation techniques have failed to mitigate this. When needed, short-term haloperidol is usually preferred and benzodiazepines avoided.

The longer-term inpatient and outpatient management of delirium in the context of underlying dementia is discussed in Chapter 49).

Alcohol withdrawal syndrome

Acute alcohol withdrawal syndrome, sometimes refer to as delirium tremens (DTs), is a serious withdrawal state and occurs 1–3 days after alcohol cessation. Patients may present to hospital with a symptomatic withdrawal state but may also develop this 1–2 days after admission to hospital for other, unrelated reasons.

Patients become disorientated and agitated and typically have a marked tremor and may experience visual hallucinations (e.g., insects or small animals). Signs include sweating, tachycardia, tachypnoea, and pyrexia. Complications can include dehydration, seizures, infection, or the Wernicke–Korsakoff's syndrome (see Chapter 30). Patients may have other alcohol-related health issues (e.g., CLD), concomitant psychiatric disease, or a history of dependence on other substances and need a careful global assessment to ensure their holistic needs are met as best possible.

Recognizing a patient at risk of alcohol withdrawal

In patients who drink alcohol on a regular basis, symptoms of alcohol dependence syndrome should be sought at the point of admission (see **Box 30.31**). Screening instruments like AUDIT (Alcohol Use Disorders Identification Test) are useful to detect alcohol dependence (https://auditscreen.org/). High AUDIT scores point to dependence and should prompt proactive measures to act to prevent withdrawal in patients requiring hospitalization. Additional tools such as SADQ (Severity of Alcohol Dependence Questionnaire) or LDQ (Leeds Dependence Questionnaire) may be used to further stratify severity of dependence.

Patients may conceal alcohol use for many different reasons (including employment, cultural, or religious reasons) and thus an index of suspicion should be maintained for alcohol withdrawal even in the absence of a positive alcohol history in the appropriate circumstances.

Management

The principles of management of a patient with acute alcohol withdrawal are summarized in **Box 11.84**. Most UK hospitals have well-developed guidelines for identification of, monitoring, and management of patients with alcohol withdrawal.

Intravenous thiamine (as Pabrinex) should be given to all patients with acute alcohol withdrawal, a severe dependence on alcohol, or additional risk factors for Wernicke-Korsakoff's syndrome (e.g., malnutrition), and oral thiamine replacement continued subsequently. Wherever possible, thiamine should be given before use of i.v. glucose, but should not delay emergency treatment of severe or symptomatic hypoglycaemia.

The CIWA-Ar scale (Clinical Institute Withdrawal Assessment for Alcohol) is commonly used to monitor clinical progress during treatment of withdrawal, or to trigger symptom-driven treatment in patients at risk of developing a withdrawal state. Benzodiazepine requirements can vary widely from patient to patient, and careful monitoring and titration is required to prevent complications of either over-treatment (sedation) or under-treatment (seizures or severe DTs).

All patients hospitalized with alcohol withdrawal syndrome should be offered referral to outpatient substance abuse services (see Chapter 30 for further discussion).

Box 11.84 Management of alcohol withdrawal syndrome

General measures

- Admit the patient to a medical bed
- Correct electrolyte abnormalities (including magnesium) and dehydration
- Treat any co-morbid disorder (e.g., infection)
- Give parenteral thiamine as Pabrinex slowly (1 pair of ampoules = 250 mg thiamine daily for 3–5 days). *Note:* Beware small risk of anaphylaxis. A higher dose regimen is indicated if clinical features of Wernicke-Korsakoff syndrome are present (usually, 2–3 pairs thrice daily for 3–5 days, followed by 1 pair once daily for a further 3–5 days or for as long as improvement continues)
- Control seizures with a fast-acting benzodiazepine (either buccal midazolam or i.v. lorazepam)

Specific drug treatment

- Give one of the following orally:
  - Chlordiazepoxide 20–40 mg 6-hourly (depending on severity of symptoms; preferred due to lower toxicity risk and lesser potential for abuse)
  - Diazepam 10–20 mg 6-hourly (longer half-life, sometimes preferred in patients requiring very large doses of benzodiazepines)

In cases of severe liver impairment, specialist advice should be sought; lorazepam and oxazepam are favoured due to shorter half-life and reduced risk of accumulation.

Monitoring and continued treatment

Patients should be monitored for:

- Over-sedation (sedation scale)
- Adequacy of symptom control (CIWA-Ar)

Initial response should be assessed at 1 hour—additional PRN benzodiazepine should be available if symptoms and signs are not adequately controlled.

Subsequent treatment may be either via a fixed-schedule taper (usually gradually reducing dose over 5–7 days) or using a protocolized, symptom-triggered regimen based on regular CIWA-Ar scoring (not in patients with withdrawal seizures, and only where sufficient nursing expertise and staffing is available to ensure timely assessments and treatment).

Functional neurological disorder

Functional neurological disorder (FND) refers to a group of disorders mediated via the central nervous system but without evidence of physical neurological disease (see Chapter 30). The precise underlying mechanisms remain the subject of ongoing research. Although motor symptoms are most common, memory, concentration, cognition, and sensation can also be affected.

Early diagnosis and treatment can help lessen symptoms, aid appropriate management, and possibly minimize any stigmatization of sufferers, as well as potential harm from over-investigation or inappropriate management.

Clinical features

FND causes real symptoms that significantly interfere with daily life. Unplanned movements and symptoms can occur subconsciously and are distinct from symptoms that are intentionally produced. Symptoms may appear suddenly, and intermittently increase in severity, but also potentially decrease when the patient is distracted.

FND can be difficult for patients, family members, and healthcare workers to understand.

FND has two primary categories:

1. Dissociative seizures (sometimes referred to as psychogenic non-epileptic attack disorder)
2. Functional movement disorder

There are many types of FND, manifesting with a diverse range of neurologic symptoms.

Dissociative seizures may resemble generalized tonic–clonic seizures, or other forms of epileptic seizures, but are not caused by obvious abnormal electrical signalling in the brain. There may be episodes of abnormal movement, sensation, or behaviour (including temporary loss of attention or memory lapse) similar to an epileptic seizure. Dissociative seizures may occur in patients with proven epilepsy, so delineating an accurate history of the acute episode is always important.

In some instances, dissociative seizures may occur in relation to psychological stress or in correlation to current or past life events. The disorder is more common in females and often begins in young adulthood. In severe cases, attacks may be frequent or prolonged although with treatment, attacks may cease or decrease in frequency.

Functional movement disorder affects movement of the body. Symptoms may include:

- Limb weakness or paralysis
- Tremor
- Sudden, brief, involuntary twitching or jerking of a muscle or group of muscles
- Involuntary muscle contractions that cause slow repetitive movements or abnormal postures (dystonia)
- Problems with walking motion (gait), posture, or balance
- Spasms and contractures (in which the tendons become fixed in awkward or uncomfortable positions)
- Muscle stiffness
- Tics

FND may manifest as symptoms relating to **other brain functions** that may include:

- Speech difficulties, such as sudden onset of stuttering or trouble speaking
- Problems with seeing or hearing
- Pain (including migraine)
- Extreme slowness and fatigue
- Numbness or perceived reduced sensation

Clinical assessment

Risk factors for FND include:

- Factors in the patient's personal history (such as childhood trauma, anxiety, being witness to violence, maltreatment, or sexual abuse).
- Sociological factors (including interpersonal relationships and stress).
- Psychological factors: FND may sometimes overlap with somatic symptoms disorder, typically with other multisystem symptoms resulting in distress to the patient.

A detailed medical and family history and physical examination is required to rule out organic neurological or systemic disease that may provide an alternative explanation for symptoms, or may coexist with FND neurology experts, preferably with experience of FND, should assist with timely accurate diagnosis and management.

Investigations

No single test can confirm a diagnosis of FND. Tests, if indicated, may include brain imaging, primarily to exclude other disorders. Other tests such as electromyography (EMG) and EEG can help identify a biological movement disorder. Video EEG can aid with diagnosis of dissociative seizures.

Management

There are no specific treatments for FND but interventions may be directed at some of its symptoms. Clear, empathic, and patient-centred communication about medically unexplained or functional symptoms is crucial in helping patients manage their condition, discussed further in Chapter 30. The patient's social support network should ideally also be involved to help understand FND and to support the patient in dealing with symptoms, treatment, and any stigma associated with the condition.

- **Medications:** Medications may be effective in treating associated pain, anxiety, depression, or insomnia. Unless a patient also suffers from epileptic seizures there is no role for anticonvulsant medications in the treatment of dissociative seizures.
- **Psychotherapy:** Cognitive behavioural therapy (CBT) can help modify thought patterns to address emotional or behavioural factors contributing to FND. Relaxation therapy or mindfulness activities may help alleviate psychological stress.
- **Physical, speech, and occupational therapy:** Therapy input can help with rehabilitation of muscular weakness or impaired movement and is a particularly important component of therapy in instances where symptoms are prolonged or repetitive.

Polysymptomatology

With improved healthcare, patients are living longer, often with one or more chronic health conditions and frequently presenting with multiple simultaneous symptoms or problems to the acute medical take. While the initial patient assessment should include a brief description of all active symptoms, an initial 'symptom triage' may be required to separate problems that require immediate attention (severe, progressive, or potentially life-threatening) from those more effectively dealt with at a later stage.

Formulation of a 'problem list' as part of the medical clerking, dividing problems into 'acute', 'chronic' or 'resolved' and indicating the proposed course of action for each, can help maintain an orderly and structured approach to a hospital admission and assist with criterion-based discharge. Importantly, the symptom deemed most impactful by a patient may not concord with that identified as a concern by the referrer or acute clinician and an initial exploration of a patient's ideas, concerns, and expectations can help with 'expectation setting' with regard to the agenda of an acute hospital admission. In an ideal medical system, every encounter would serve as an opportunity to provide holistic patient care, however, with limitations in time, resources, and capacity this might not always be attainable.

Swollen joint

The painful swollen joint is a common clinical presentation to acute medical services. A solitary hot, swollen, and tender joint (monoarthritis) should always raise concern for infection (septic arthritis) which may lead to rapid destruction of the joint and lasting disability unless diagnosed and treated promptly. Other potential causes include acute crystal arthropathies (gout or pseudogout), haemarthrosis (e.g., following trauma, or spontaneously in patients with a history of bleeding disorder or anticoagulation), or reactive arthritis. Systemic disorders (e.g., rheumatoid arthritis, seronegative spondyloarthropathies, SLE) more typically associated with multiple joint involvement (polyarthritis) may occasionally present acutely as a monoarthritis. Periarticular inflammation

(e.g., bursitis, enthesitis, or cellulitis) may mimic arthritis and be considered during the clinical assessment. The common causes of monoarthritis with key accompanying clinical features are outlined in Box 11.85.

Clinical assessment

History

- Take a description of the **onset and time course** of symptoms (truly acute, or following a longer history of pain, swelling, or stiffness in the joint?)
- Enquire regarding **prior episodes** and/or diagnoses (e.g., have they required a diagnostic joint aspiration in the past?)
- Describe the **pattern of joint involvement** in patients with multi-joint symptoms, including the presence of back or neck pain
- **Fever or chills** is a cardinal sign of infection but may be absent in the elderly or immunosuppressed patient with a septic joint
- **Prosthetic joints** are at higher risk for infection and diagnosis and management usually requires specialist orthopaedic involvement
- **Systemic anticoagulation** or a history of **trauma** should prompt consideration of haemarthrosis
- **Systems enquiry** should include seeking a history of recent GI symptoms (prompting consideration of reactive arthritis or IBD) or genitourinary symptoms (reactive arthritis or gonorrhoea), together with relevant travel and sexual history

Physical examination

- Assess for signs of sepsis
- Examine the affected joint: the inflamed joint (e.g., infection or crystal arthritis) will feel warm compared to the opposite side and a joint effusion usually present
- Other joints should be inspected for the presence of swelling and deformity pointing towards systemic disorders, including the joints of the feet and spine
- Skin should be inspected for the presence of rashes (e.g., erythema nodosum in sarcoidosis, pustular lesions in gonorrhoea), nail changes (e.g., pitting in psoriasis), rheumatoid nodules over extensor surfaces or tendons, or gouty tophi
- Examine the cardiovascular system for signs of endocarditis or more rarely, rheumatic fever
- Conjunctivitis should raise suspicion of reactive arthritis

Investigations

- **Laboratory investigations** should include:
  - Full blood count e.g., neutrophil leucocytosis in septic arthritis or crystal arthritis.
  - Basic metabolic tests including urea and electrolytes, liver function tests, and bone profile.
  - Random glucose may identify occult hyperglycaemia, a risk factor for infection.
  - Coagulation screen is required where joint aspiration is being considered, or if coagulopathy is suspected.
  - CRP is typically elevated in inflammatory arthritis of any cause, including septic and crystal arthritis
  - **Blood cultures** are essential if local or systemic infection is suspected.
  - Urate levels can be sent but may be normal or even low in the acute phases of gout.
  - Where appropriate, additional tests for systemic disorders (e.g., rheumatoid factor/anti-CCP antibody if suspecting rheumatoid arthritis, anti-nuclear antibodies, anti-dsDNA, and serum complement levels if suspecting SLE).
- **Plain radiographs** can be useful to rule out fractures or avascular necrosis and may identify chronic changes (e.g., those typical of osteo- or rheumatoid arthritis) but may only show soft tissue swelling in the acute phases of many arthritides. Look for the presence of chondrocalcinosis (often present in joints affected by pseudogout).
- **Joint aspiration** (Fig. 32.2) is key in diagnosis of septic or crystal-induced arthritis. Samples should be sent for cell count and Gram stain, microbiological culture testing and cytology, including examination under polarized light. Synovial fluid aspirated from an infected joint may appear turbid or purulent to the naked eye. In the absence of another identifiable cause, a high fluid WBC (neutrophils) remains suspicious for infection, even if cultures are negative; of note, only ~50% of joint aspirates in patients with gonococcal arthritis are culture positive. Consider synovial PCR or ribosomal 16S testing if culture negative and high index of suspicion for infection.
- **Other microbiological samples including** throat, cervical, rectal, or skin lesion swabs may be of use (e.g., haematogenous spread of infection from bacterial pharyngitis, urethritis triggering reactive arthritis, gonococcal arthritis).

Septic arthritis

Septic arthritis of native (non-prosthetic) joints occurs via direct injury or by blood-borne infection from an infected skin lesion or other site, with approximately 2 cases per 100 000 people per year. It is a medical emergency that requires prompt treatment to prevent irreversible joint destruction and has a significant mortality of up to 11%, reaching 50% in polyarticular sepsis.

The organism that most commonly causes septic arthritis is *Staphylococcus aureus*. Other organisms include streptococci, other species of staphylococcus, *Neisseria gonorrhoeae*, *Haemophilus influenzae* in children, and these and other Gram-negative organisms in the elderly or complicating RA.

Clinical features

In young and previously fit people, the joint is hot, red, swollen, and agonizingly painful; it is held immobile by muscle spasm. In contrast, the onset may be insidious with a lack of systemic symptoms in the elderly, the immunosuppressed, and patients with RA, and a high index of suspicion is needed. In 20% of patients, the infection affects more than one joint. Recent aspiration or steroid injection of the joint may lead to clinical suspicion of infection.

Investigations

- ***Aspirate*** the joint and send the fluid for urgent Gram-staining and culture. The fluid is usually frankly purulent. The culture techniques should include those for gonococci and anaerobes.
- ***Blood cultures*** are often positive.
- ***Leucocytosis*** is usual, unless the person is severely immunosuppressed.
- ***X-rays*** are of no value in diagnosis in acute septic arthritis, but may show other pathologies such as chondrocalcinosis in pseudogout.
- ***Skin wound swabs, sputum and throat swab, or urine*** may be positive and indicate the source of infection.

Management

There are no RCTs to guide management in adults. The prognosis is similar for patients with a proven microbiological diagnosis to those with a suspected but not proven diagnosis; therefore, it is vital to treat on the basis of clinical suspicion, probability (with subsequent

Box 11.85 Acute monoarthritis (and mimics): common causes and clinical features

Disease	History	Examination	Investigation	Management
Septic arthritis	Risk states include extremes of age, immunocompromise including diabetes and alcohol excess), pre-existing joint disease including prostheses, history of i.v. drug use, or recent intra-articular injection	Often large joints (knee, hips, wrist, ankle, and shoulder) Look for signs of endocarditis Pustular skin rash common with gonococcal infection	Blood cultures are essential Throat, cervical, and rectal swabs in selected cases Joint aspiration is required for definitive diagnosis	Systemic antibiotics Purulent arthritis usually requires joint washout
Gout	Rare in premenopausal females Risk factors include alcohol consumption, use of diuretics, and a prior history of gout	Multiple joints may be involved simultaneously, usually lower limb 1st MTP joint ('podagra') is classic site Gouty tophi if chronic	Raised inflammatory markers (WBC/CRP) Serum urate may be normal in acute flare X-ray may reveal erosions Joint aspiration—needle-shaped negatively birefringent urate crystals	NSAIDs, colchicine, steroids Offer lifestyle and dietary advice, review medications (e.g., diuretics)
Pseudogout (acute calcium pyrophosphate deposition disease)	Often older (>55), coexists with osteoarthritis	Multiple joints may be involved simultaneously, upper or lower limb joints Rarely syndrome of acute or recurrent neck and shoulder pain ('Crowned dens syndrome')	Raised inflammatory markers (WBC/CRP) X-rays may reveal chondrocalcinosis CT will identify Crowned dens syndrome Weakly positively birefringent crystals may be seen on microscopy	Consider NSAIDs, steroids Check ferritin (haemochromatosis) and thyroid function
Trauma	History of trauma may not be recalled if patient lost consciousness (e.g., seizure)	Signs of intra-articular trauma (e.g., meniscal tear, ligamentous rupture) may be difficult to detect if a large joint effusion is present	X-ray may reveal a peri-articular fracture MRI is usually required to delineate intra-articular injury	Acute joint effusion usually responds to conservative management Orthopaedic referral required if suspicion of damage to structures within the joint
Haemarthrosis	Recent trauma, bleeding diatheses, or anticoagulation	Bruising may be evident	Check coagulation and platelets	Consider clotting factors or reversal of anticoagulation
Reactive arthritis	Recent infection, usually diarrhoea or urethritis	Mono-, oligo-, or polyarthritis, usually asymmetrical. Knee commonly involved and low back pain (SIJ) common. Look for extra-articular signs: conjunctivitis, perianal or genital ulceration, keratoderma blennorrhagica (soles and palms)	Throat, cervical, and rectal swabs may be of use in identifying underlying infection	Usually self-limiting. NSAIDs first-line for symptomatic treatment although corticosteroids may be prescribed in severe or polyarticular forms. Genitourinary infection should be treated with appropriate antibiotics
Osteoarthritis	Older patients, pain worse with activity, relieved by rest	Single/multi-joint and generalized forms Gradual onset—an acute arthritis in an osteoarthritis joint should raise concern for infection or crystal arthritis PIP and DIP joints involved in generalized forms (Bouchard's and Heberden's nodes)	Inflammatory markers usually normal Radiology may show loss of cartilage, subchondral sclerosis, osteophytes, and subarticular cysts	Simple analgesia and exercise are mainstay of treatment

Box 11.85 Acute monoarthritis (and mimics): common causes and clinical features—cont'd

Disease	History	Examination	Investigation	Management
Systemic disorders	Rheumatoid arthritis (RhA), seronegative spondyloarthritides, sarcoidosis, and SLE may all rarely present with acute monoarthritis Chronic infections e.g., tuberculosis, Lyme disease, may occasionally simulate an acute, septic joint Serum sickness may complicate immune therapies (e.g., anti-thymocyte globulin) Rarely mono- or polyarthritis may be paraneoplastic	Multiple joint involvement more common Low back pain (SIJ) and enthesitis common in seronegative arthritis Look for rheumatoid nodules (RhA), erythema nodosum (sarcoidosis, TB), facial butterfly rash (SLE) Serum sickness/ immune complex arthritis often favours temporomandibular joint	Tailored to presentation but may include Rheumatoid factor/ anti-CCP Ab testing (RhA), anti-nuclear antibody, anti-dsDNA antibody and serum complement testing (SLE), and serum ACE (sarcoidosis) Joint aspirates should be sent for mycobacterial and fungal cultures in atypical or subacute presentations	Directed towards underlying cause
Bursitis	Often related to trauma or overuse injuries	Common sites include olecranon process and pre-patellar bursa Secondary infection may occur ('septic bursitis')	Diagnosis often clinical although ultrasound or MRI may be useful Blood cultures and bursal aspiration if concern of septic bursitis	Antibiotics towards causative agent if septic bursitis
Cellulitis	May mimic arthritis if skin overlies joint	Entry point may be evident Absence of joint effusion	Avoid aspirating a joint with overlying cellulitis (risk of bacterial innoculation)	Antibiotics towards causative agent
Tendonitis	Injury or repetitive exercise Quinolone antibiotic use may predispose	Quinolones typically cause Achilles tendon inflammation	Ultrasound or MRI may be of use in diagnosis	Rest, ice packs, and support. Analgesia and physiotherapy may be needed

DIP, Distal interphalangeal; *MTP,* metatarsophalangeal; *PIP,* proximal interphalangeal; *SIJ,* sacro-iliac joint; *SLE,* systemic lupus erythematosus.

confirmed identity) of the organism, local pattern of antibiotic sensitivity, and microbiological advice.

Therapy should be started immediately before culture results are available because joint destruction may occur rapidly.

- The joint should be aspirated and then immobilized initially, followed by early physiotherapy to prevent stiffness and muscle wasting.
- Intravenous antibiotics should be given for 2 weeks and then oral antibiotics for a further 4 weeks. Response is monitored clinically and with ESR or CRP.

Empirical treatment in septic arthritis

Empirical regimens vary according to local advice and index of suspicion. For suspected Gram-positive infection first-line therapy is vancomycin, with clindamycin or cephalosporin second-line. For suspected Gram-negative infection first-line therapy is a third-generation cephalosporin with i.v. ciprofloxacin second-line. In confirmed methicillin-sensitive *Staphylococcus aureus* (MSSA) primary options include flucloxacillin alone or combined with fusidic acid or gentamicin, while penicillin-allergic patients should receive vancomycin with clindamycin. In cases of methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin is the drug of choice. Antibiotics should be altered according to sensitivities. Drainage of the joint and/or arthroscopic joint washouts are required in all cases.

Management of infected prostheses

Long-term goals of prosthetic joint infection are to eradicate the infection, reduce pain, and restore function. Two-stage surgery is required to remove the prosthesis followed by treatment with appropriate i.v. antibiotics for 4–6 weeks before a new prosthesis is inserted. A 2–6-week course of pathogen-directed i.v. antibiotics followed by 3–6 months of oral antibiotics are also given.

The unwell diabetic patient

Patients with diabetes may present to acute medical services with an emergency directly related to their diabetes (e.g., hyperglycaemia, diabetic ketoacidosis (DKA), hyperosmolar hyperglycaemic state (HHS), hypoglycaemia, a foot emergency, continuous subcutaneous insulin infusion (CSII) pump failure) or may be admitted for many other emergencies where diabetes is a secondary diagnosis (e.g., sepsis, stroke, trauma). Patients presenting to emergency services may also have an elevated blood glucose and no previous diagnosis of diabetes; a proportion of these patients will have unrecognized diabetes, while some will have stress hyperglycaemia. This section will cover:

- Diabetic ketoacidosis
- Hyperosmolar hyperglycaemic state
- Hyperglycaemia
- Hypoglycaemia

Terms used with reference to the acutely unwell diabetic patient are defined in **Box 11.86**.

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) remains a frequent and life-threatening complication of diabetes, with a mortality rate of approximately 1%.

Box 11.86 Terms used in diabetes-related emergencies

Term	Definition
Ketonuria	Detectable ketones in the urine; it should be appreciated that ketonuria occurs after fasting in people without diabetes and may be found in people with relatively well-controlled type 1 diabetes
Ketosis	Elevated plasma ketone levels in the absence of acidosis
Diabetic ketoacidosis	A metabolic emergency in which hyperglycaemia is associated with a metabolic acidosis due to greatly raised (>3 mmol/L) ketone levels
Hyperosmolar hyperglycaemic state	A metabolic emergency in which uncontrolled hyperglycaemia induces a hyperosmolar state in the absence of significant ketosis
Lactic acidosis	A metabolic emergency in which elevated lactic acid levels induce a metabolic acidosis. In people with diabetes, it is rare and most commonly associated with biguanide therapy

Population studies suggest that there are 5–8 episodes annually per 1000 people with diabetes. It occurs more frequently in younger people, but the mortality is higher in older people. Although treatment has improved with better outcomes, the incidence is rising. As DKA results from marked insulin deficiency, it mostly occurs in people with type 1 diabetes but may occasionally present in people with type 2 diabetes. It is usually seen in the following circumstances:

- previously undiagnosed diabetes (10%–20% of cases)
- interruption of insulin therapy (15%–30% of cases)
- the stress of intercurrent illness and infection (30%–40%)
- sodium-glucose co-transporter-2 (SGLT2) inhibitor-related DKA.

Many cases of DKA can be prevented by earlier diagnoses, better communication between the person with diabetes and their healthcare professional, and better self-management education. A common error is to reduce or omit insulin because the individual feels unable to eat, owing to nausea or vomiting. This is a factor in at least 25% of all hospital admissions. Although insulin adjustment is necessary, it should never be stopped. The UK National Diabetes Inpatient Audit found that many people developed DKA while in hospital, suggesting that healthcare professionals also make the same mistakes.

Pathogenesis

Ketoacidosis is a state of uncontrolled catabolism associated with marked insulin deficiency and elevated counter-regulatory hormones, which accelerate the effects of insulin deficiency (Fig. 11.41). The insulin deficiency leads to hyperglycaemia secondary to increased hepatic glucose output and diminished insulin-mediated peripheral glucose uptake, which in turn causes an osmotic diuresis and profound dehydration and loss of electrolytes (Fig. 11.42). However, the most important biochemical abnormality in DKA is not the hyperglycaemia but the uncontrolled lipolysis in adipose tissue and uncontrolled ketogenesis in the liver. Marked insulin deficiency is a necessary precondition for DKA since very little insulin is needed to inhibit hepatic ketogenesis and the breakdown of adipose triglycerides to non-esterified fatty acids (NEFAs). NEFAs are transported to the liver where they are partially oxidized to acidic ketone bodies, such as acetoacetic acid and 3-hydroxybutyric acid, and acetone. This occurs because the absence of insulin impairs hepatic

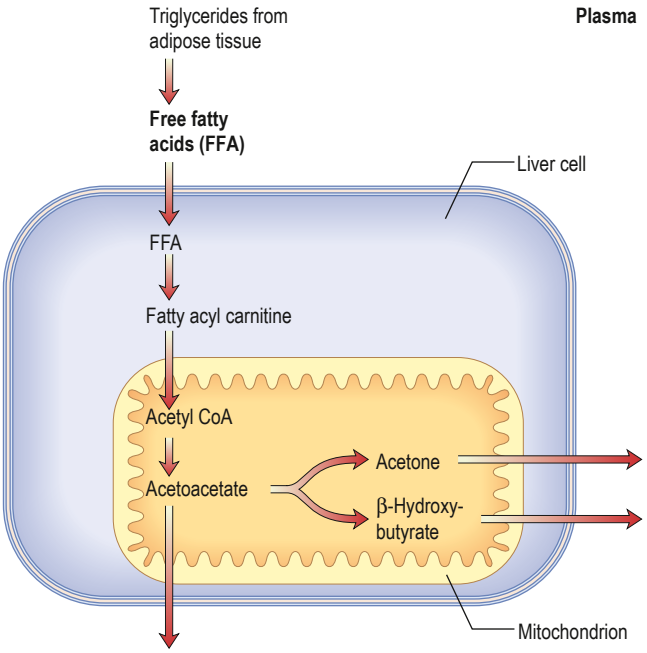

Fig. 11.41 Ketogenesis. During insulin deficiency, lipolysis accelerates and free fatty acids taken up by liver cells form the substrate for ketone formation (acetoacetate, acetone, and β-hydroxybutyrate) within the mitochondrion. These ketones pass into the blood, producing acidosis. *CoA,* Coenzyme A.

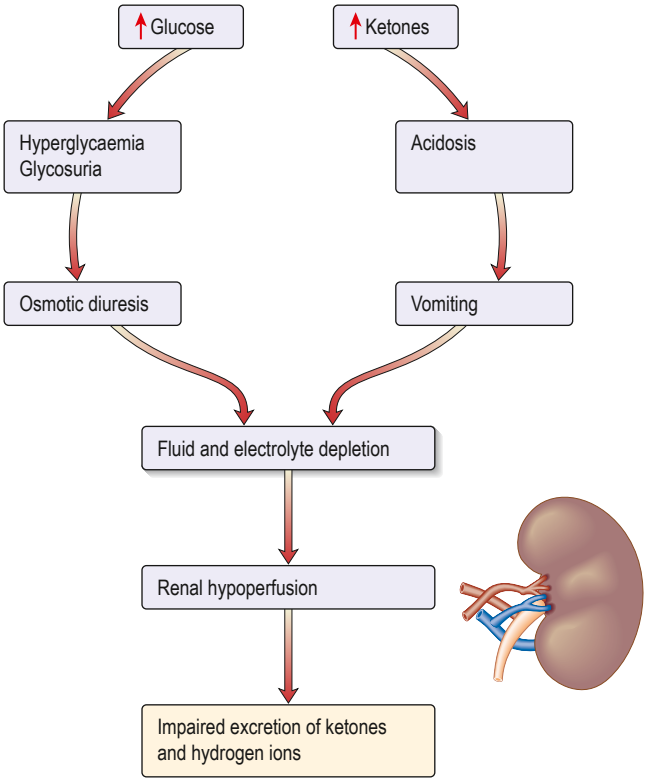

Fig. 11.42 Dehydration occurs during ketoacidosis as a consequence of two parallel processes. Hyperglycaemia results in osmotic diuresis, and hyperketonaemia results in acidosis and vomiting. Renal hypoperfusion then occurs and a vicious circle is established as the kidney becomes less able to compensate for the acidosis.

re-esterification of NEFA to triglyceride. The liver exports the ketone bodies as an alternative fuel supply, but these build up in the circulation because of impaired uptake into peripheral tissues, such as muscle. The excess ketones are excreted in the urine but also appear in the breath, producing a distinctive smell like that of acetone. Ketone bodies are strong organic acids that rapidly exceed the body's buffering capacity and cause severe metabolic acidosis. Ketone bodies are nauseating, and many people will vomit, worsening the dehydration and electrolyte loss further. Plasma osmolality rises and renal perfusion falls, which impairs renal excretion of hydrogen ions and ketones, aggravating the acidosis. Respiratory compensation for the acidosis leads to hyperventilation, graphically described as 'air hunger'.

As the pH falls below 7.0 ($[H^+]$ >100 nmol/L), pH-dependent enzyme systems in many cells function less effectively and, untreated, severe ketoacidosis is invariably fatal.

Clinical assessment

Patients presenting with DKA often have a variety of signs and symptoms on presentation and usually these develop rapidly within several hours of the precipitating event.

History

Symptoms of hyperglycaemia preceding presentation are most common, including polyuria, polydipsia, and unintentional weight loss. Other common symptoms of DKA include:

- Nausea and vomiting
- Abdominal pain—this is sometimes so severe that it can be confused with a surgical acute abdomen
- Weakness and fatigue
- Complaining of 'brain fog' or the inability to think straight.

Physical examination

Clinical examination signs include:

- Clinical features of dehydration: dry mucous membranes, reduced skin turgor, hypotension and tachycardia, reduced urine output, and in severe cases, features of shock
- Lethargy, confusion, and reduced GCS (up to 5% present in coma)
- Smell of ketones on breath (not all people are able to detect this odour)
- Hypothermia
- Increased respiratory rate as a result of acidosis, often referred to as Kussmaul breathing (rapid and deep respiratory effort in attempt to compensate for metabolic acidosis).

Investigations and diagnosis

- **Point-of-care bedside testing** including capillary blood glucose, blood ketones, and blood gas analysis. The **diagnosis of DKA** is confirmed by demonstrating hyperglycaemia with ketonaemia or heavy ketonuria, and acidosis as follows:
  - Ketonaemia ≥3 mmol/L (31 mg/dL) *or* significant ketonuria (≥2 on standard urine sticks)
  - Blood glucose >11 mmol/L (200 mg/dL) *or* known diabetes mellitus
  - Bicarbonate (HCO_3^-) below 15 mmol/L (15 mEq/L) and/or venous pH <7.3.
- **Laboratory investigations** including renal function and electrolytes in particular potassium. Acidosis causes hyperkalaemia as potassium is exchanged for hydrogen ions moving into the cell. As insulin promotes the co-transport of potassium along with glucose into cells, insulinopaenia further exacerbates hyperkalaemia. Although serum potassium may be elevated at presentation, there is a severe whole-body potassium *deficiency* as significant quantities of potassium are lost in vomit and urine and serum potassium often falls rapidly after initiation of treatment. Inflammatory markers such as CRP are also important.
- **Septic screen including** blood cultures, urine culture, and CXR if features suspicious of infection. Respiratory viral testing (including COVID-19, which has been associated with an increased risk of DKA) should be considered
- **12-lead ECG** if tachycardic, concern of arrhythmia (either related to infection or shock), significant electrolyte imbalance, or suspicion for cardiac ischaemia.

The indicators of severe DKA are shown in **Box 11.87**.

Management

Management is summarized in **Box 11.88**. If the patient has severe DKA (**Box 11.87**), they should be managed in an enhanced care area or high dependency unit.

Replacement of the fluid losses

Individuals with DKA have a typical water deficit of 100 mL/kg, equivalent to 7.5 L in a 75 kg adult. The replacement fluid of choice is 0.9% sodium chloride with additional potassium chloride (potassium cannot be added to Hartmann's solution). The aim of the first few litres of fluid is to correct any hypotension, replenish the intravascular deficit, and counteract the effects of the osmotic diuresis with correction of the electrolyte disturbance. Over-rapid fluid replacement may lead to cerebral oedema in children and young adults and so the remainder of the fluid should be replaced more cautiously over the next 2 days. The rate and volume of fluid replacement need to be modified in older people and in those with renal or heart failure.

Replacement of the electrolyte losses

Typical electrolyte deficits are sodium 7–10 mmol/kg, chloride 3–5 mmol/kg, and potassium 3–5 mmol/kg. After the initiation of treatment with insulin, potassium levels can fall rapidly as insulin promotes potassium uptake by the cells. Commercially, 0.9% sodium chloride is available with premixed potassium chloride (40 mmol/L (0.3%)) allowing the potassium to be replaced safely. Hypokalaemia and hyperkalaemia are potentially life-threatening conditions during the management of DKA and so potassium levels should be monitored frequently. Patients are frequently hyperkalaemic at presentation and so potassium is typically not prescribed with the initial fluid resuscitation (1 L 0.9% NaCl infused over 1 hour), but proactive replacement is subsequently required to prevent hypokalaemia and KCl supplementation only withheld if serum potassium level remains above 5.5 mmol/L.

Box 11.87 Indicators of severe diabetic ketoacidosis

- Blood ketones over 6 mmol/L
- Bicarbonate level below 5 mmol/L
- Venous/arterial pH below 7.0
- Hypokalaemia on admission (under 3.5 mmol/L)
- Glasgow Coma Scale less than 12 or abnormal AVPU scale
- Oxygen saturation below 92% on air (assuming normal baseline respiratory function)
- Systolic BP below 90 mmHg
- Pulse over 100 or below 60 beats/min
- Anion gap above 16 [anion gap = $(Na^+ + K^+) - (Cl^- + HCO_3^-)$]

Box 11.88 Management of diabetic ketoacidosis (DKA)

Immediate measures (0–60 min after diagnosis and initiation of intravenous fluids)

1. Carry out clinical assessment to determine the severity of the DKA episode
2. Perform initial investigations, including blood ketones, capillary and venous glucose, serum creatinine and electrolytes, venous blood gases, full blood count, cultures, ECG, CXR if indicated, and cardiac monitoring
3. Initiate the intravenous infusion with 0.9% sodium chloride
   a. Give 1 L over the first hour unless there is hypotension requiring more rapid correction of fluid deficit
   b. Serum potassium is often elevated at presentation and thus potassium is not added to the initial 1 L of 0.9% saline. Serum potassium will subsequently fall rapidly with rehydration and insulin treatment and needs proactive replacement with subsequent fluids
4. Commence a fixed-rate intravenous insulin infusion at a rate of 0.1 unit/kg per h using soluble human insulin. Estimate the weight if necessary
5. Continue the long-acting basal insulin at the usual dose and time

Management from 60 min to 6 h

1. Reassess the patient
   a. Consider urinary catheterization if the patient is incontinent or anuric after 2–4 h
   b. Consider nasogastric tube insertion if the patient has a reduced GCS or is persistently vomiting
2. Continue intravenous fluids
   a. 0.9% sodium chloride 1 L with potassium chloride over 2 h
   b. 0.9% sodium chloride 1 L with potassium chloride over 2 h
   c. 0.9% sodium chloride 1 L with potassium chloride over 4 h
   d. 0.9% sodium chloride 1 L with potassium chloride over 4 h
   e. 0.9% sodium chloride 1 L with potassium chloride over 6 h

   40 mmol KCl is typically added to each litre of fluid if serum potassium is in the range of 3.5–5.5 mmol/L. No KCl should be added if serum potassium is >5.5 mmol/L, and senior advice sought if serum potassium is <3.5 mmol/L.
3. Measure blood ketones and capillary glucose hourly
   a. If blood ketones are not falling by at least 0.5 mmol/L per h, increase the insulin infusion rate by 1.0 unit per h increments hourly until the ketones are falling at target rates. Seek senior review
   b. An alternative to blood ketones is venous bicarbonate which should rise by at least 3.0 mmol/L per h
   c. A further alternative is glucose that should fall by at least 3.0 mmol/L per hour (50 mg/dL)
   d. If the glucose falls below 14.0 mmol/L (250 mg/dL), commence 10% glucose given at 125 mL per h alongside the 0.9% sodium chloride solution
4. Measure venous blood gas for pH, bicarbonate and potassium at 60 min and hourly thereafter
   a. Adjust the potassium replacement accordingly
5. Identify and treat precipitating factors

Management from 6 to 12 h

1. Reassess the patient and review biochemical and metabolic measurement to check for resolution of DKA

Conversion to subcutaneous insulin

- Convert the patient to an appropriate subcutaneous regimen when biochemically stable (blood ketones less than 0.6 mmol/L, pH over 7.3) and ready and able to eat.

Hyperchloraemic acidosis may develop during treatment since a large variety of negatively charged electrolytes are lost in DKA, which are replaced with chloride. The kidneys usually correct this spontaneously within a few days.

Restoration of the acid–base balance

In most cases, once the circulating volume is restored, the metabolic acidosis will rapidly compensate. Supplemental i.v. bicarbonate is seldom indicated because it is implicated in the development of cerebral oedema and may cause a paradoxical increase in CSF acidosis. It is used only if the pH is <7.0 ($[H^+]$ >100 nmol/L) and is best given as an isotonic (1.26%) solution.

Insulin replacement

Insulin should be given by an intravenous infusion using a fixed rate 0.1 units/kg per hour (typically 6–10 units per h). This modest insulin dose is sufficient to suppress ketogenesis, lower the glucose, and correct the electrolyte disturbance. For those already treated with insulin, the long-acting basal subcutaneous insulin should be continued.

As the intravenous insulin should be continued until the ketosis has resolved, intravenous glucose alongside the 0.9% sodium chloride is often needed to prevent hypoglycaemia; 10% glucose is recommended once the blood glucose falls below 14.0 mmol/L (250 mg/dL) and should be continued until the person is eating and drinking normally.

Monitoring progress

The aim of treatment is lower the blood ketone concentration by 0.5 mmol/L per hour, increase the venous bicarbonate by 3.0 mmol/L per hour, and reduce capillary blood glucose by 3.0 mmol/L per hour (50 mg/dL per h) while maintaining potassium between 4.0 and 5.5 mmol/L. If these targets are not met, the insulin infusion rate should be increased.

Seeking the underlying cause

Physical examination may reveal a source of infection. Two common markers of infection are misleading: fever is unusual, even when infection is present; and polymorphic leucocytosis is present, even in the absence of infection as a result of demargination of circulating neutrophils due to metabolic acidosis. Relevant investigations include a CXR, urine and blood cultures, and an ECG (to exclude myocardial infarction). If infection is suspected, broad-spectrum antibiotics are started once the appropriate cultures have been taken.

Other measures

As patients are significantly dehydrated on admission, it is unlikely that they will pass urine for several hours after the initiation of fluid replacement. However, if no urine is passed within 2–4 hours of admission, the insertion of a urinary catheter should be considered.

A central venous cannula may be required to monitor fluid balance in older people and those with cardiac disease.

Aspiration of vomit may be fatal in people with an impaired conscious level and so a nasogastric tube should be considered.

The dehydration, increased blood viscosity, and coagulability of DKA increase the risk of a potentially fatal thromboembolism and so thromboprophylaxis with LMWH should be considered in older or high-risk individuals unless contraindicated.

Complications of diabetic ketoacidosis

Cerebral oedema is a rare but serious complication with high mortality and mostly happens in children or young adults. Severe hypothermia with a core temperature of more than 33°C may occur and can be overlooked unless a rectal temperature is taken with a low-reading thermometer.

Ongoing management

Once the person is able to eat and keep food down, subcutaneous insulin treatment should be resumed or initiated. A subcutaneous

bolus insulin is given with the meal and for those whose long-acting basal insulin was continued during the DKA episode, the insulin infusion and fluids can be discontinued 30 minutes after the meal. If the long-acting insulin was stopped, the intravenous insulin infusion and fluids should be continued until some form of background insulin has been given.

The inpatient stay provides an educational opportunity to assess why the DKA occurred and what steps are needed to prevent it from happening again. Any admission with DKA should prompt review of current insulin therapy, and consideration of whether an alternative therapy system such as a continuous glucose monitor or closed-loop insulin pump system may be appropriate (Chapter 35).

Sodium-glucose co-transporter-2 (SGLT2) inhibitor-related DKA

SGLT2 inhibitors (including dapagliflozin, empagliflozin, and canagliflozin) are a relatively new class of drugs for the treatment of type 2 diabetes and act by inhibition of renal glucose reabsorption (see Chapter 35). They are prescribed with increasing frequency due to a generally favourable side-effect profile, ease of administration, mild associated weight loss, and additional benefits for renal and cardiac health above and beyond their effect on serum glucose.

SGLT2 inhibitors are associated rarely with DKA, usually in the context of a normal blood glucose ('euglycaemic DKA'). DKA likely results from insulinopaenia (due, in turn, to suppression of insulin secretion as a result of induction of glycosuria) and risk is highest in patients with reduced pancreatic β cell mass (e.g., patients with type 2 diabetes and low C-peptide levels, or unrecognized latent autoimmune diabetes) or in clinical scenarios where insulin counter-hormone secretion is high driving lipolysis and ketogenesis. (e.g., infection or surgery). Other contributors may include increased renal ketone body resorption (driven by an increased concentration of sodium ions within renal tubules) and the diuretic effect of SGLT2 inhibitors, reducing overall blood volume and promoting ketoacidosis. Patients prescribed SGLT2 inhibitors should be counselled about 'sick day rules' and treatment interrupted in any patient hospitalized for major surgery or with a serious acute illness. SGLT2 inhibitors should be borne in mind as a risk-factor for euglycaemic DKA, and the clinician should have a low threshold to test plasma ketones and blood gases in an unwell patient who has continued to take this medication up until presentation.

Hyperosmolar hyperglycaemic state

Hyperosmolar hyperglycaemic state (HHS) is a medical emergency typically seen in patients with type 2 diabetes, characterized by severe hyperglycaemia (>30 mmol/L), marked dehydration, and elevated serum osmolality (usually >320 mOsm/kg). Unlike DKA, ketonaemia and metabolic acidosis are usually absent. People affected are often in middle or later life, with poorly controlled or previously undiagnosed diabetes. Common precipitating factors include infection (most commonly chest or urine), consumption of glucose-rich fluids, or new prescription medication (e.g., corticosteroids).

Box 11.89 Comparison of the biochemical changes in diabetic ketoacidosis and the hyperosmolar hyperglycaemic state

Examples of blood values	Severe ketoacidosis	Hyperosmolar hyperglycaemic state
Na^+ (mmol/L)	140	155
K^+ (mmol/L)	5	5
Cl^- (mmol/L)	100	110
HCO_3^- (mmol/L)	5	25
Urea (mmol/L)	8	15
Glucose (mmol/L)	30	50
Arterial pH	7.0[a]	7.35

HHS

Patients become severely hypernatraemic as a result of free water losses and inadequate water intake (contrast with uncomplicated hyperglycaemia, where the serum sodium is typically low as a result of osmotic water movement out of the intracellular compartment). The normal range of osmolality is 285–300 mOsm/kg. It can be measured directly, or can be calculated approximately from the formula $2(Na^+ + K^+)$ + glucose + urea. Serum osmolality is typically >320 mOsm/Kg in HHS (in this example 385 mosm/kg). Ketonaemia is not a feature and hence arterial pH and venous HCO_3^- are both within normal limits.

DKA

DKA is defined by an arterial pH of <7.30, although patients are often severely acidotic with very low serum bicarbonate. Anion gap can be calculated by $(Na^+ + K^+) - (Cl^- + HCO_3^-)$ and is elevated in DKA, due to ketone bodies acting as an unmeasured anion (in this instance anion gap is 40, compared to a normal upper limit of 16). Anion gap falls progressively with treatment, although resolution of acidosis and normalization of serum bicarbonate may 'lag behind' as a result of increasing serum chloride resulting from 0.9% NaCl infusion (which induces a normal anion gap metabolic acidosis).

[a]$[H^+]$ >100 nmol/L.

The cardinal biochemical differences between HHS and DKA are summarized in **Box 11.89**. The biochemical differences may partly be explained as follows:

- ***Age.*** Older people (the typical demographic developing HHS) experience thirst less acutely and become dehydrated more readily. In addition, the mild renal impairment associated with age results in increased urinary losses of fluid and electrolytes. Onset of HHS is also more gradual, usually over a few days, allowing for the development of more profound dehydration.
- ***The degree of insulin deficiency.*** This is less severe in the hyperosmolar hyperglycaemic state. Endogenous insulin levels are sufficient to inhibit hepatic ketogenesis but insufficient to inhibit hepatic glucose production.

Overlap presentations of HHS and DKA may sometimes occur, and it is important to test blood ketones in all patients at presentation.

Pathogenesis of HHS

- HHS is often triggered by an *acute stressor*, which increases levels of cortisol and catecholamines (thereby reducing insulin sensitivity).
- HHS occurs in patients with *enough* insulin to prevent ketoacidosis, but *not* enough insulin to control hyperglycaemia.
  - Higher endogenous levels of insulin are required to control hyperglycaemia, compared to the amount required to prevent ketogenesis (as seen in the way that many patients in the ICU

develop mild insulin resistance and *hyperglycaemia—without* developing ketoacidosis).
- Uncontrolled hyperglycaemia causes an *osmotic diuresis*, with loss of water.
- Patients *fail* to compensate adequately for water loss by increasing oral water intake (e.g., due to baseline debility, bed-bound status, or a relatively insensitive central drive to maintain normal tonicity).
- Over a period of several days, uncontrolled water loss leads to a hypertonic state and progressive hypernatraemia. This may lead to altered mental status (which exacerbates the patient's inability to drink an adequate amount of water).

Clinical assessment

The characteristic clinical features of HHS are severe dehydration, and stupor or coma. Impaired consciousness is directly related to the degree of hyperosmolality. Evidence of underlying illness, such as pneumonia or pyelonephritis, may be present, and the hyperosmolar state may predispose to stroke, myocardial infarction, or lower limb arterial insufficiency.

Investigations

Core investigations are as for DKA (see previous section). In HHS, the plasma osmolality is usually extremely high (>320 mOsm/kg). It can be measured directly or calculated as $(2(Na^+ + K^+)$+glucose+urea), all in mmol/L. Plasma osmolality should be calculated hourly during the early stages of treatment to ensure that over-rapid changes in osmolality are avoided which may otherwise rarely provoke neurological complications including cerebral oedema or central pontine myelinolysis.

Management

The most important aspect of management in HHS is **fluid replacement**, with the intent of correcting dehydration and gradually reducing blood glucose and serum osmolality. **Serum osmolality should be calculated hourly** during treatment, with the goal of fluid therapy being to achieve a sufficiently positive fluid balance to result in a fall in osmolality between 3.0 and 8.0 mOsm/kg/hour. Despite the majority of patients being hypernatraemic, 0.9% sodium chloride is the treatment of choice, and 0.45% sodium chloride should only be considered if the osmolality is not declining despite adequate positive fluid balance (usual target is to achieve a positive balance of ~2–3 L over the initial 6 hours of treatment). Serum sodium may be observed to rise initially with treatment, as a result of falling plasma glucose levels and consequent redistribution of water into the intracellular compartment; subsequently the rate of fall of plasma sodium should not exceed 10 mmol/L in 24 hours to reduce the risk of neurological complications.

Fluid replacement alone is often sufficient to lower the glucose and in the majority of patients insulin should *not* be started as part of initial therapy. Many patients are extremely sensitive to insulin and the glucose concentration may fall rapidly with initiation, potentially provoking haemodynamic instability or over-rapid changes in osmolality. Insulin (0.05 units/kg per h) may be started once adequate fluid replacement has been provided if the glucose is no longer falling with fluids alone or if the patient develops significant ketonaemia (in which case the diagnosis of HHS should be reconsidered). In order to reduce risk of cerebral damage, the fall in blood glucose should be no more than 5 mmol/L per hour (90 mg/dL per h). Patients fulfilling criteria for concomitant diabetic ketoacidosis (significant ketonaemia >3 mmol/L with pH < 7.3) require immediate insulin and should be treated in line with DKA guidance.

Serum potassium requires careful monitoring and often falls during treatment; local protocols for fluid infusion in HHS usually include protocolized potassium replacement.

Prophylactic LMWH should be given. Regular clinical assessment of fluid balance is vital given the frequent coexistence of cardiovascular disease and heart failure. Foot checks and pressure care (including heel off-loading) are also priority tasks.

While it may seem daunting to balance changes in serum osmolality (aiming for a fall between 3.0 and 8.0 mOsm/kg/h), serum sodium (limiting hourly fall to <10 mmol) and plasma glucose (limiting hourly fall to <5 mmol), in reality all three parameters closely co-vary during treatment and these criteria can usually be satisfied simultaneously with an attentive approach to monitoring and following the principles laid out above.

Prognosis

The reported mortality ranges as high as 15%–20%, mainly because of the more advanced age of the patients and the frequency of intercurrent illness. Unlike ketoacidosis, the hyperosmolar hyperglycaemic state is not an absolute indication for subsequent insulin therapy, and survivors may do well on diet and oral agents.

Metformin associated lactic acidosis

The risk of lactic acidosis in people taking metformin is extremely low, provided that the therapeutic dose is not exceeded and the drug is withheld in people with advanced hepatic or renal dysfunction. Current guidance is to discontinue metformin in patients with an estimated GFR < 30 mL/min/1.73 m^2. Severe lactic acidosis usually occurs in scenarios where patients have experienced an intercurrent illness (e.g., diarrhoea or vomiting), leading to dehydration and AKI and have continued to take metformin as usual during this period, leading to drug accumulation. Systemic upset is common at presentation (potentially also contributing to lactic acidosis) and AKI may also aggravate acidosis. Patients often have a severe metabolic acidosis with a high anion gap, usually without significant hyperglycaemia or ketosis. Treatment is by rehydration, discontinuation of metformin, and infusion of isotonic 1.26% bicarbonate. Critical care admission is often required, with haemofiltration if there is severe coexistent AKI. The mortality is in excess of 50%.

Hyperglycaemia

Hyperglycaemia alone without the additional adverse features of DKA or HHS is often seen in patients in the ED or admitted to the AMU, either as a result of long-standing poor glycaemic control (as evidenced by HbA_{1c}) or stress counter-hormone secretion secondary to acute illness.

Patients with type 1 diabetes should be instructed **not to omit** their basal (long-acting) insulin, or ketosis will surely develop.

Plasma ketones should be checked in all patients with blood glucose >10 mmol/L (regardless of diabetes type, although risk of ketosis is substantially higher in type 1 diabetics). Those with

elevated ketones (>1.5 mmol/L) often warrant i.v. fluids (0.9% NaCl) and require more formal testing to exclude DKA.

In patients without ketosis, a blood glucose >13 mmol/L (type 1 diabetes) or >18 mmol/L (type 2 diabetes) is commonly regarded as the threshold where further immediate intervention is required. The most appropriate response will vary depending on whether the patient has a known diagnosis of diabetes (and if so, what type), recent control, whether the patient is already on insulin treatment and whether the patient otherwise requires admission to the hospital or may be suitable to discharge.

NHS England (London) guidance created for AMUs during the COVID-19 pandemic advocates the use of a stat dose of fast-acting insulin (e.g., Novorapid, dose adjusted based on body weight and prior insulin dose) paired with a bolus of i.v. 0.9% NaCl to achieve prompt glycaemic control, and enable a continuation plan to be devised based on the patient's individual characteristics and in conjunction with the local diabetes team. Stat insulin doses should not be repeated within 2 hours and variable rate insulin infusion may need to be started if multiple stat doses are required.

The approach to management for patients with newly diagnosed type 2 diabetes is discussed in Chapter 35).

Hypoglycaemia

Hypoglycaemia (low blood glucose) is the most common side-effect of insulin therapy and is the major limitation to what can be achieved with insulin treatment. A glucose concentration below 3.0 mmol/L (54 mg/dL) is defined as 'clinically significant hypoglycaemia' but it is recognized that any value below 4.0 mmol/L (70 mg/dL) represents an 'alert value' that requires treatment. 'Severe hypoglycaemia' is defined as hypoglycaemia requiring external help for recovery. Most people treated with insulin will experience several episodes of symptomatic hypoglycaemia per week and one to two severe episodes per year. Interestingly with the advent of continuous blood glucose monitoring, it is apparent that asymptomatic hypoglycaemia occurs much more frequently than previously thought. Hypoglycaemia is more common in people with type 1 diabetes, where there is absolute insulin deficiency, and with longer duration of diabetes. It occurs more frequently in young children and those trying to achieve tight glycaemic control.

Hypoglycaemia greatly impairs quality of life and induces fear and anxiety in the person with diabetes, their family, and carers. In an older study, the fear of severe hypoglycaemia was worse than the fear of developing blindness or end-stage renal disease. Nocturnal hypoglycaemia can be particularly disruptive. In addition to the psychological effects, hypoglycaemia is associated with a number of long-term medical consequences, including cardiovascular events and falls (**Box 11.90**).

Hypoglycaemia is caused when more insulin is injected than is needed. Irregular eating habits, unusual exertion, and alcohol excess may all precipitate hypoglycaemic episodes but insulin errors and variation in insulin absorption, for example as a result of lipohypertrophy, are also important. The times of greatest risk are before meals, during the night, and during and after exercise.

Box 11.90 Some of the consequences of hypoglycaemia

Acute symptoms
- Autonomic
  - Sweating, paraesthesia, feeling hot, shakiness, anxiety, palpitations and pallor
- Neuroglycopenia
  - Slurring of speech, altered behaviour, loss of concentration, drowsiness, low mood, dizziness, hemiplegia, fits, coma, and rarely, death
  - Loss of warning with recurrent hypoglycaemia and long duration of diabetes

Medical
- Increased risk of falls
- Increased risk of myocardial infarction
  - Increased thrombosis
  - Atherosclerotic plaque instability
  - Cardiac arrhythmias
- Increased risk of hospitalization
- Increased risk of sudden death

Psychological
- Poor quality of life
- Embarrassment
- Fear of hypoglycaemia
  - Reduced medication taking to avoid future episodes
  - Higher HbA_{1c}

Financial
- Inability to work effectively
- Increased out-of-pocket expenses
- Increased medical costs
  - Extra visits
  - More glucose testing

The mechanisms that protect against hypoglycaemia in people without diabetes are compromised because of abnormal islet cell function or defective counter-regulatory hormone secretion. The delivery of insulin after injection cannot be halted and glucagon secretion is impaired because its main regulator is a fall of intra-islet insulin. Even the third-line defence of counter-regulatory hormones and other sympathetic nervous system responses to hypoglycaemia may become diminished in people with longstanding diabetes or recurrent hypoglycaemia.

Clinical assessment

The symptoms of hypoglycaemia can be divided into two main categories, ***autonomic*** and ***neuroglycopenic***, although non-specific symptoms may also be experienced (see **Box 11.90**). Autonomic symptoms and signs occur because of activation of the adrenergic and cholinergic parts of the autonomic nervous system. As the brain is dependent on glucose as its primary fuel source, neuroglycopenic symptoms arise from inadequate glucose supply to the brain.

Usually, autonomic symptoms develop before cognitive impairment. This is clinically important as these symptoms alert the individual to hypoglycaemia and prompt them to take corrective action. In longstanding diabetes or after repeated episodes of hypoglycaemia, the autonomic symptoms may only develop at glucose levels below the threshold for neuroglycopenic symptoms. When this occurs, hypoglycaemia awareness becomes impaired and the person is at increased risk of severe hypoglycaemia. Awareness improves if hypoglycaemia is scrupulously avoided.

The symptoms and signs of hypoglycaemia resolve once the hypoglycaemia is treated and the glucose returns to within the normal range.

Management

Hypoglycaemia is an acute medical emergency that requires immediate treatment with 15–20 g of oral glucose. This should be repeated after 15 minutes if the glucose concentration has not risen above 4.0 mmol/L (70 mg/dL). The glucose can be taken either as a liquid or solid food containing fast-acting carbohydrate, such as glucose tablets or sugary sweets, for example, Jelly Babies. More carbohydrate than necessary should not be taken in order to prevent rebound hyperglycaemia.

The diagnosis of severe hypoglycaemia resulting in confusion or coma is simple and usually made on clinical grounds, backed by a bedside blood test. Many people with diabetes carry a card or wear a bracelet or necklace saying that they have diabetes, and these should be sought in unconscious patients. The treatment is either intramuscular glucagon or intravenous glucose. Glucagon acts by mobilizing hepatic glycogen and works almost as rapidly as glucose. It is simple to administer and can be given at home by relatives. It does not work when liver glycogen levels are low, for example, after a prolonged fast.

Once the individual revives, they should eat some longer-acting carbohydrate to replenish glycogen reserves (e.g., two biscuits or a slice of bread). After the acute event has been treated, it is important to ascertain why the hypoglycaemia occurred to try to prevent future episodes.

Deep vein thrombosis and pulmonary embolism

Definitions

Most often, venous thrombosis originates in the deep veins of the legs, hence the term ***deep vein thrombosis (DVT)***. It is thought that the process starts within the pocket of one of the valves that line the veins, where flow may be turbulent and localized hypoxia may develop, resulting in endothelial dysfunction. The thrombus may remain localized to the leg veins or may embolize through the circulation to result in a **pulmonary embolism (PE)**. A minority (about 10%) of episodes of venous thrombosis arise in other sites, such as the upper limb, the cerebral venous sinuses, and the splanchnic veins (hepatic, portal, and mesenteric veins). Apart from upper limb venous thrombosis, these ***unusual-site thromboses*** are described further in relevant specialty-specific chapters (see 'Cortical venous thrombosis' further on in this chapter as well as Chapters 23 and 26). Immunogenic thrombosis *in situ* is well recognized in some conditions, where the pulmonary clot has not embolized but developed locally in the lungs. This is relatively common in inflammatory pulmonary conditions including bronchopneumonia and COVID-19 infection.

If confined to the calf veins, the thrombus is called a ***calf, distal, or below-knee DVT***. Untreated, the thrombus may extend proximally and, when it reaches the popliteal vein or above, is called a ***proximal, or above-knee DVT***. Thrombi at this level are larger, and more likely to embolize and be transported with blood flow through the large veins of the pelvis and abdomen to the right atrium and ventricle. From there, they are pumped into the pulmonary arteries, which progressively divide into smaller arteries as they course through the lungs to supply the alveoli. The emboli stop in the pulmonary arteries, where they are no longer physically able to progress, and, in so doing, obstruct the flow of blood distally. It is thought to take at least several days for venous thrombi to become clinically evident.

Box 11.91 Risk factors for venous thromboembolism

Transient

- Surgery, especially major, lower limb/pelvis or cancer related
- Trauma, especially lower limb/pelvis
- Active cancer
- Acute medical admission
- Immobilization (bed rest >3 days)
- Plaster cast
- Pregnancy/puerperium
- Oestrogen administration (combined hormonal contraception, oral hormone therapy)
- Recent long-haul travel (>4 h)
- Central venous catheter
- Heparin-induced thrombocytopenia
- Superficial vein thrombosis

Persistent

- Increasing age
- Body mass index >30 kg/m^2
- Ethnicity
- Previous episode of venous thromboembolism
- Inflammatory conditions e.g., inflammatory bowel disease, systemic lupus erythematosus, Behçet's syndrome
- Nephrotic syndrome
- Lower limb paresis e.g., after stroke
- Heritable thrombophilia (factor V Leiden, prothrombin gene mutation, deficiencies of antithrombin, protein C or protein S)
- Antiphospholipid syndrome
- Myeloproliferative neoplasms

Epidemiology and risk factors

The annual incidence of VTE within the community is estimated at around 1 per 1000 per year overall and is age dependent. VTE is uncommon in childhood, affects around 1 per 10 000 young adults per year and 1 per 1000 middle-aged adults per year, and approaches an incidence of 1 in 100 elderly adults per year. Historical autopsy data suggest that about 10% of patients who died in hospital did so from PE. Over 5% of people will develop one or more episodes of VTE during their lifetime. Clinically, about 60% of episodes of VTE present with DVT and the other 40% with PE, with or without accompanying features of DVT.

Some conditions may predispose to immunothrombosis *in situ* in the pulmonary vasculature such as Behçet's disease and pneumonias or pneumonitis including COVID-19 infection. Steroids may be indicated in their therapy, with or without anticoagulation therapy (without usually in the case of Behçet's).

Other risk factors for VTE are shown in **Box 11.91**. They can be divided into transient provoking factors (such as major surgery) and longer-term predisposing factors (such as obesity or heritable thrombophilias).

- ***Stasis-related factors*** include surgery, bed rest, plaster cast immobilization, pregnancy, and long-haul travel.
- ***Hypercoagulability*** may be caused by cancer, surgery, pregnancy, and administration of oestrogens in combined hormonal contraception and hormone replacement, as well as the heritable thrombophilias.
- ***Vessel wall factors*** including previous thrombosis and invading malignancy.

Risk factors differ in the degree to which they increase the likelihood of VTE occurring:

- ***Strong risk factors*** increase the risk ten- to fiftyfold and include major surgery, trauma, and absolute bed rest.

Box 11.92 Differential diagnosis of venous thromboembolism

Deep vein thrombosis

- Ruptured Baker's cyst
- Musculo-tendinous—trauma, haematoma, myositis, tendonitis
- Superficial vein thrombosis
- Post-thrombotic syndrome
- Cellulitis
- Osteoarthritis, osteomyelitis, synovitis, fracture, tumour
- Acute arterial occlusion
- Lymphoedema
- Congestive cardiac failure and hypoalbuminaemia—usually cause bilateral leg swelling

Pulmonary embolism

- Chest infection/pneumonia
- Exacerbation of chronic obstructive pulmonary disease
- Asthma
- Pneumothorax
- Congestive cardiac failure
- Acute coronary syndrome
- Costochondritis
- Musculoskeletal pain or rib fracture
- Aortic dissection
- Pericardial tamponade
- Lung cancer
- Primary pulmonary hypertension
- Anxiety/hyperventilation

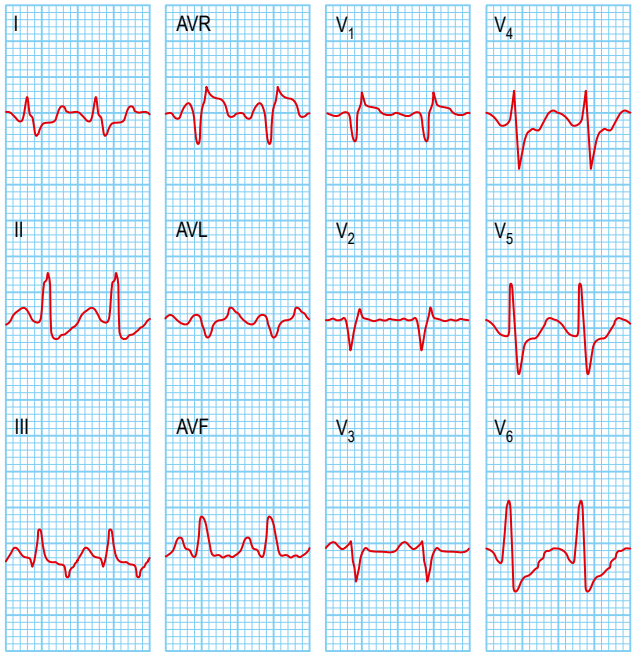

Fig. 11.43 Acute pulmonary embolism shown on a 12-lead ECG. There is an S wave in lead I, a Q wave in lead III, and an inverted T wave in lead III (the S1, Q3, T3 pattern). There is sinus tachycardia (160 beats/min) and an incomplete right bundle branch block pattern (an R wave in AVR and V_1 and an S wave in V_6).

- ***Moderate risk factors*** increase the risk three- to tenfold and include pregnancy, oestrogen therapy, and minor surgery under general anaesthesia. Most heritable thrombophilias also increase the risk three- to tenfold.
- ***Weak risk factors*** increase the risk up to threefold and include obesity and long-haul travel. For reasons that are not yet evident, the incidence of VTE is highest in people of African descent, intermediate in white people and lower in, for example, East Asian populations.

Clinical assessment

The differential diagnosis of suspected DVT or PE is very wide (Box 11.92), and most patients (>80%) who present with suspected VTE have the diagnosis excluded rather than confirmed. The clinical features are often non-specific and the majority of people who die from PE probably do so because earlier warning signs were missed rather than because of sudden collapse and death or failure of treatment. The challenge in the diagnostic work-up of suspected DVT and PE is therefore to identify rapidly and accurately, when urgent treatment is required, and to distinguish these patients from those who do not have the condition, in whom unnecessary investigation and treatment would be potentially harmful.

The typical features of ***DVT*** include pain and swelling in one leg. The leg may be red and warm to the touch. There may also be tenderness along the course of the deep veins, especially in the popliteal fossa, and dilation of the collateral superficial veins.

PE presents:

- In about 65% of cases, with pleuritic chest pain and breathlessness, sometimes but rarely accompanied by haemoptysis. Tachypnoea and tachycardia are typically present. Crackles and a pleural rub over a localized area of pulmonary infarction may be evident on auscultation.
- In another 25%, with isolated breathlessness, sometimes only evident on exertion.
- In the remaining 10%, with more severe features, including syncopal episodes, systolic hypotension or shock, and myocardial ischaemia with associated central chest pain. With this more severe presentation, the patient is tachypnoeic, and has a tachycardia with peripheral shutdown, a raised jugular venous pulse (JVP) with a prominent α-wave, right ventricular heave, gallop rhythm and a widely split second heart sound. Cardiac arrest may occur, typically with pulseless electrical activity. The severity of presentation depends on both the thrombus burden and the individual's cardiopulmonary reserve.

At least one-third of patients presenting with DVT have clinically silent pulmonary emboli. About 70% of people presenting with symptomatic PE have an associated DVT that is symptomatic in about a quarter of cases.

Investigations

The initial investigations that might be undertaken because of chest pain or breathlessness are often non-diagnostic in patients with PE:

- ***ECG*** (Fig. 11.43): A right ventricular strain pattern may be seen, with T wave inversion in the inferior (II, III, AVF) and right precordial (V1–V4) leads. The classical ECG is of an 'S1Q3T3' pattern, with a prominent S wave in lead I and a prominent Q wave and inverted T wave in lead III, but this is present in only a minority of patients. It is more common to see a sinus tachycardia or atrial fibrillation.
- ***CXR:*** This may be normal but more often shows non-specific abnormalities, including atelectasis, parenchymal abnormalities, cardiomegaly, elevation of the hemidiaphragm, or a small pleural effusion. Occasionally, there may be a lack of vessel markings distal to a large thrombosis, known as Westermark sign.

- ***Arterial blood gas analysis:*** Blood gases typically show hypoxia and hypocapnia, but again these are non-specific findings and are not always present.
- ***Biomarkers of cardiac injury:*** Plasma levels of brain natriuretic peptide (BNP) or its precursor, amino-terminal pro-BNP, may be elevated because of stretching of the right ventricle, and troponin may be increased because of right ventricular injury due to strain, but once again these findings are non-specific. They are useful indicators of severity and may guide therapeutic options including whether to admit the patient, or consider advanced therapies.
- ***POCUS/point-of-care echocardiography:*** Focused ultrasound can help diagnose DVTs (loss of colour flow, and loss of compressibility of deep veins). Standard point-of-care echocardiography (using a phased array (cardiac) probe, or a curvilinear (abdominal) probe utilizing the liver as an acoustic window for a subcostal view, may show signs of right ventricular (RV) strain including flattening of the intraventricular septum, or even RV bulging in to the left ventricular cavity (which should have a higher pressure). The acquisition of these images may help guide diagnosis and clinical assessment, but recognition of possible chronic pulmonary hypertension is important to avoid cognitive bias.

Diagnosis of DVT and PE

For patients in the UK, other than those with shock or hypotension due to suspected PE, the approach to the diagnosis of VTE recommended by the National Institute for Health and Care Excellence (NICE) is generally used.

Risk scoring

The diagnostic process starts with assessment of the clinical probability using a clinical prediction score that takes account of the individual patient's clinical features, the presence or absence of risk factors for VTE, and whether an alternative diagnosis is likely to explain the symptoms and signs. There are a number of clinical prediction scores available, and NICE recommends the modified two-level ***Wells score*** for DVT (Box 11.93) and the two-level **Wells score** for PE (Box 11.94); these categorize patients into groups that are likely or unlikely to have DVT or PE, respectively. Clinical prediction scores standardize clinical assessment and increase reproducibility among less experienced clinicians. However, in themselves, they do not confirm or exclude the diagnosis of VTE and further assessment is necessary, although experienced clinicians may use the pulmonary embolism rule-out criteria (the PERC rule) to help determine whether any further investigations for PE are needed in patients in whom the clinical suspicion of PE is low (estimated pretest likelihood <15%) (Box 11.95).

Measurement of D-dimer

In those considered unlikely to have VTE based on the Wells score, the next step is D-dimer testing. D-dimer is a fibrin degradation product that can be measured in plasma or whole blood by using highly sensitive, fully quantitative laboratory point-of-care tests. Raised levels indicate activation of the coagulation system but are not specific for VTE, as they are also seen, for example, with advanced age, infection, inflammation, postoperatively, in cancer and during pregnancy. As D-dimer can rise with age, some centres use an age-adjusted D-dimer test threshold for people aged over 50.

The value of D-dimer in VTE diagnosis is based on its high negative predictive value: that is, VTE is very unlikely in a patient who has a low pretest probability of DVT or PE by the Wells score and in whom D-dimer, measured by a sensitive assay, falls below a predefined cut-off (typically quoted as 'normal'). Such patients do not need further diagnostic testing for VTE and alternative diagnoses should be considered. With this approach, it must be borne in mind that there is a small failure rate (<2% within 3 months) and that it does not absolutely exclude VTE. The signs and symptoms of DVT and PE, and where to seek further medical help, should be discussed with the patient.

In contrast, patients whose Wells score indicates that VTE is unlikely but whose D-dimer is raised (lies above the cut-off value) require formal radiological imaging to confirm or exclude VTE.

Box 11.93 Wells score for deep vein thrombosis (DVT) (two-level)

Clinical feature	Points
Active cancer (treatment ongoing, within 6 months, or palliative)	1
Paralysis, paresis, or recent plaster mobilization of the lower extremities	1
Recently bedridden for ≥3 days or major surgery within 12 weeks requiring general or regional anaesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than asymptomatic side	1
Pitting oedema confined to the symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Previously documented DVT	1
Alternative diagnosis at least as likely as DVT	–2
Clinical probability simplified score	
DVT *likely*	≥2
DVT *unlikely*	≤1

(From Wells PS, Anderson DR, Rodger M et al. Evaluation of D-dimer in the diagnosis of suspected deep-vein thrombosis. *N Engl J Med* 2003; 349:1227–1235.)

Box 11.94 Wells score for pulmonary embolism (PE) (two-level)

Clinical feature	Points
Clinical signs and symptoms of deep vein thrombosis (DVT) (minimum of leg swelling and pain with palpation of the deep veins)	3
Alternative diagnosis less likely than PE	3
Heart rate >100 beats/min	1.5
Immobilization (for >3 days) or surgery in the previous 4 weeks	1.5
Previous DVT/PE	1.5
Haemoptysis	1
Malignancy (on treatment, treated in the last 6 months, or palliative)	1
Clinical probability simplified score	
PE *likely*	>4
PE *unlikely*	≤4

(From Wells PS, Anderson DR, Rodger M et al. Derivation of a simple clinical model to categorise patients probability of pulmonary embolism: increasing the model's utility with the SimpliRED D-dimer. *Thromb Haemost* 2000; 83:416–420.)

Box 11.95 The Pulmonary Embolism Rule-out Criteria (PERC) rule

If any items are present in a patient with a low likelihood of PE, the PERC test is positive and further assessment is required

- Age ≥50 years
- Heart rate ≥100 beats/min
- Oxygen saturation <95% while patient is breathing room air
- Swelling in one leg
- Haemoptysis
- Surgery or trauma within past 4 weeks
- Previous DVT or PE
- Hormone use

Similarly, imaging is also required for all patients whose Wells score indicates that VTE is likely. There is no evidence to support the use of D-dimer in pregnancy (see Chapter 48).

Imaging for DVT

The diagnosis of DVT is generally confirmed by ***ultrasonography*** of the deep venous system, which has long replaced the historical gold standard of venography, as it is quicker and non-invasive. At a minimum, ultrasonography involves examination of the proximal venous system. Typically, this includes compression of the popliteal and femoral veins by the ultrasound probe to determine whether the vein is compressible or not (see Fig. 8.33). This is usually supplemented by direct thrombus imaging with vein enlargement and assessment of blood flow by colour Doppler. Ultrasonography is very sensitive for proximal DVTs (>95%) but less so for distal DVTs (70%). In general terms, a positive scan will confirm the diagnosis. However, in those with a Wells score indicating that a DVT is likely, a negative scan, if limited to the proximal venous system, does not exclude the diagnosis, as it will not identify a proportion of patients who have a distal DVT. Further assessment of these patients is required (**Fig. 11.44**).

Alternatively, whole-leg ultrasonography can be performed. This may avoid the need for repeat scanning but is more time-consuming and requires greater expertise.

The diagnosis of DVT in those with a prior event is often problematic because of the presence of residual vein occlusion, and expert radiological advice should be sought.

Imaging for PE

The approach to the diagnosis of PE is similar in principle (**Fig. 11.45**). When the Wells score indicates that a PE is unlikely, a negative D-dimer excludes the diagnosis without further investigation. However, imaging is essential in those who either have a raised D-dimer level or are categorized as likely to have a PE based on their Wells score.

The most common imaging technique is ***computed tomographic pulmonary angiography (CTPA)*** (**Fig. 11.46**), which is widely available and sensitive, and can provide an alternative diagnosis when PE is excluded. The alternative is isotope lung scanning. Historically, planar ***ventilation–perfusion ($\dot{V}/\dot{Q}$) isotope lung scanning***, has been used (**Fig. 11.47**). This test is performed in two stages:

- ***a perfusion phase***, in which technetium-labelled albumin aggregates are injected intravenously and blood flow to the lungs is assessed
- ***a ventilation phase***, in which patients inhale radiolabelled xenon or technetium to assess air delivery to the lungs (sometimes this phase is not performed in pregnancy, to minimize radiation exposure, as assume ventilation will be normal).

A diagnosis of PE is made if there are mismatched defects in the perfusion scan, indicating impaired blood flow to the lungs, but normal ventilation because air entry to the lungs is normal. A normal $\dot{V}/\dot{Q}$ scan excludes the diagnosis of PE. This technique has the advantage of a lower radiation dose and is preferred in those with severe renal impairment (estimated GFR < 30 mL/min/1.73 m^2) or allergies to intravenous contrast agents. The disadvantages are that it is less readily available and the results are often non-diagnostic because other lung pathologies can cause matched or smaller mismatched defects. Increasingly centres offer ventilation/perfusion single photon emission computed tomography (V/Q SPECT) as a superior alternative to planar V/Q scanning.

Timescale of investigation

Diagnostic testing for VTE should be performed urgently and completed within 24 hours of initial presentation. Interim anticoagulation should be given if imaging for a PE that is likely by Wells score cannot be done immediately or if it will take more than 4 hours to investigate either a suspected PE that is considered unlikely by Wells score or a suspected DVT. Interim anticoagulation should be stopped after 24 hours if diagnostic testing is negative.

The approaches described apply only to patients presenting to primary care, EDs, or other acute medical services including SDEC. Inpatients (especially surgical, if bleeding risk) and pregnant patients should be regarded as high-risk and require appropriate expedited imaging if DVT or PE is suspected.

Emergency presentations

In the minority of patients with suspected PE who present with hypotension, mortality is high and prompt diagnosis is essential. If an urgent CTPA is not possible, a bedside transthoracic echocardiogram may be diagnostic, showing acute pulmonary hypertension and right ventricular dysfunction (see **Fig. 11.48**).

Upper limb DVT

The diagnostic algorithm for suspected upper limb venous thrombosis is less well established and patients with suggestive clinical features of arm pain and swelling typically require ultrasound imaging.

Management

Anticoagulant therapy is the standard treatment for VTE. It is traditionally divided into three phases:

- the acute phase, lasting 5–14 days
- a maintenance primary treatment phase, lasting 6 weeks to 3 months
- a long-term secondary prevention phase beyond this.

The aim of treatment in the initial phase is to prevent thrombus extension and hence reduce the risk of embolization as well as post-thrombotic syndrome; the goal thereafter is to prevent thrombus recurrence.

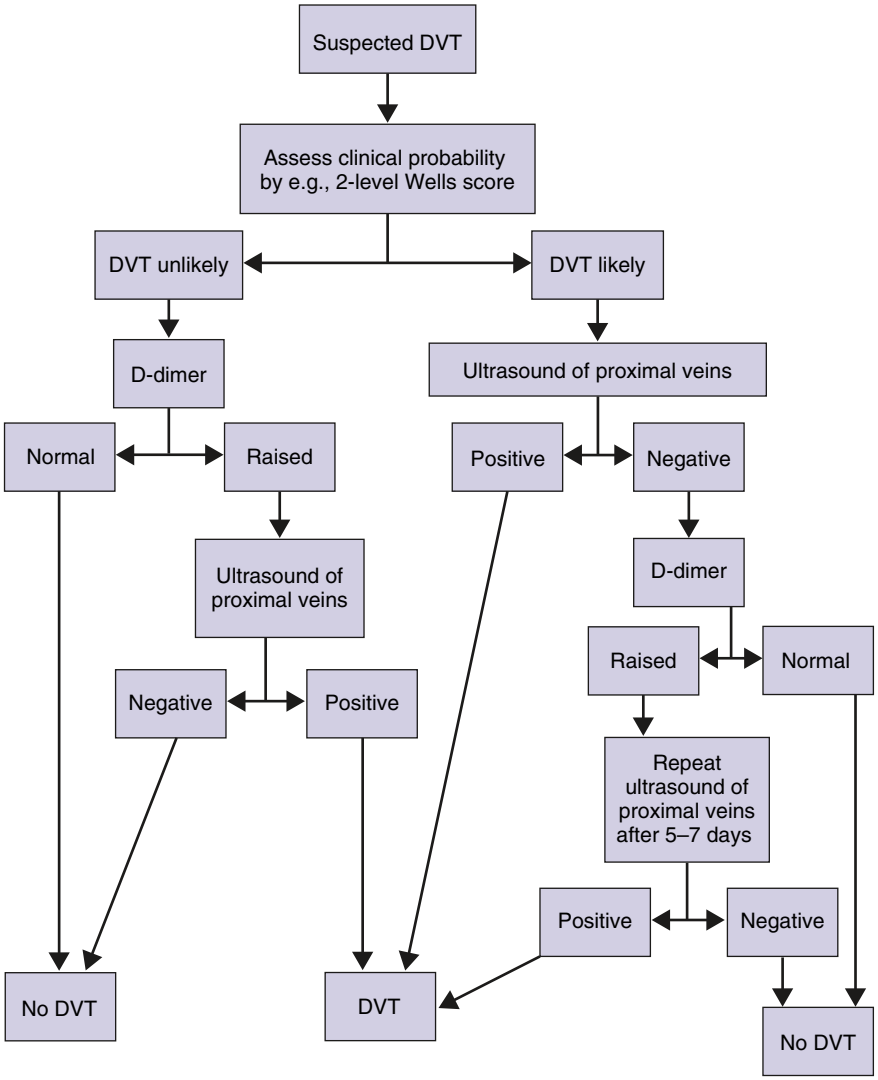

Fig. 11.44 **Investigation of suspected DVT.**

Primary treatment initiation

The long-established initial treatment of VTE involves a ***parenteral anticoagulant***, most commonly subcutaneous LMWH; alternatively, intravenous unfractionated heparin (UFH) or subcutaneous fondaparinux may be used. These provide an almost immediate anticoagulant effect.

Effective oral anticoagulant alternatives, the oral factor Xa and thrombin inhibitors (previously known as direct oral anticoagulants (DOACs) or non-vitamin K antagonist oral anticoagulants (NOACs)), are licensed for VTE treatment. Two of these, apixaban and rivaroxaban, can be used from the outset without any initial parenteral anticoagulant therapy. The initial dose is higher for the first 7 days for apixaban and 21 days for rivaroxaban.

For two others, edoxaban and dabigatran, the initial treatment consists of at least 5 days of parenteral therapy. The parenteral therapy (such as LMWH) is then stopped and on day 6, the edoxaban or dabigatran is started instead with no overlap.

Traditionally vitamin K antagonists such as warfarin were used as oral anticoagulant therapy and are still preferred in some circumstances such as the antiphospholipid syndrome and end-stage kidney failure. An overlap period in which they are used alongside the parenteral drug is essential to ensure effective management of the VTE because it takes at least 5 days before they provide therapeutic anticoagulation as judged by their effect on the ***International Normalized Ratio (INR)***. Heparin or fondaparinux can be stopped and warfarin continued alone once the INR is 2.0 or more on 2 consecutive days, indicating that the vitamin K antagonist is now providing sufficient anticoagulation.

The different treatment models are shown in **Fig. 11.49** and the drugs are described further in Chapter 40.

Special circumstances

A minority of patients warrant a different initial approach.

Pregnancy and lactation

LMWH is the treatment of choice. Warfarin, oral factor Xa, and thrombin inhibitors cross the placenta and should not be used in pregnancy. Warfarin is teratogenic and causes embryopathy between 6 and 12 weeks' of pregnancy, with skeletal abnormalities including nasal hypoplasia and stippled epiphyses. Later in pregnancy it causes bleeding in the fetus, particularly intracerebral bleeding, and a significant risk of intrauterine death. However, warfarin is safe until the 6th week of pregnancy. It is therefore important to recognize pregnancy early and to switch by the 6th week to LMWH, which does not cross the placenta and is safe for the fetus.

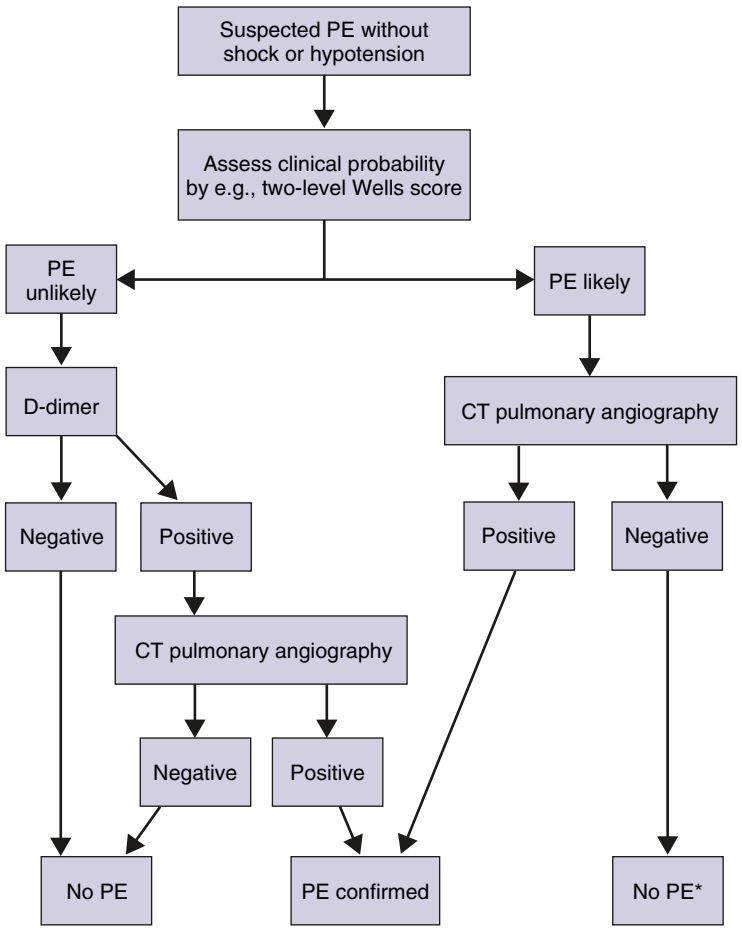

Fig. 11.45 Investigation of suspected PE without haemodynamic compromise. *In selected cases where clinical suspicion remains high, it may be necessary to consider either bilateral lower limb ultrasonography or V/Q scan.

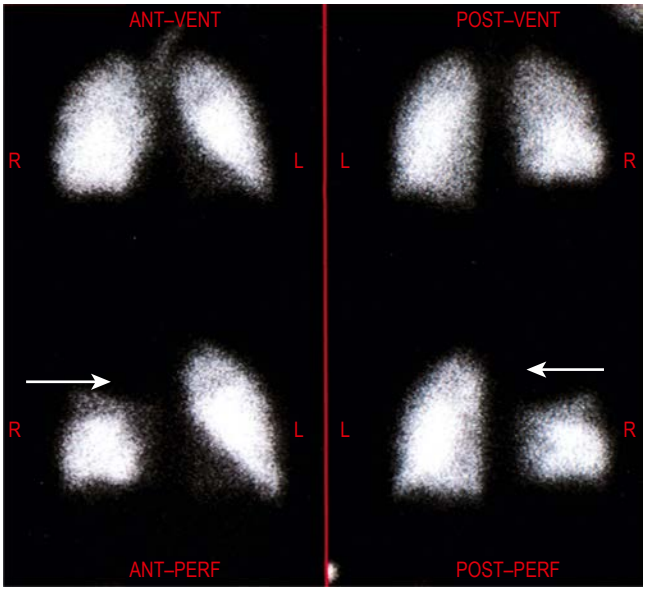

Fig. 11.47 Radionuclide ventilation/perfusion scanning. Ventilation *(top)* and perfusion *(bottom)* lung scans demonstrate an absence of perfusion in the right upper lobe: that is, probable pulmonary embolism *(arrowed)*.

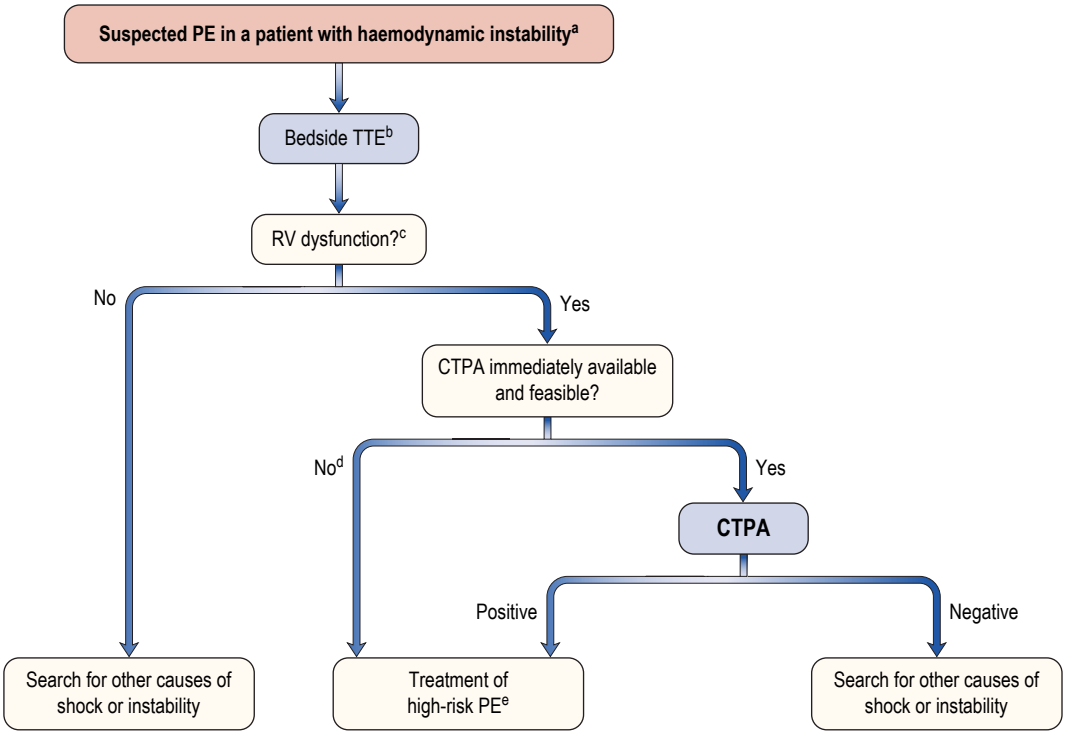

Fig. 11.48 Investigation of patients with suspected PE and shock or hypotension. Key: a = systolic blood pressure <90 mmHg (or vasopressors) with end-organ hypoperfusion OR need for resuscitation OR sustained systolic blood pressure <90 mmHg or fall in blood pressure > = 40 mmHg not due to another cause. b = or transoesophageal echocardiography or compression ultrasonography confirming VTE. c = right ventricular dysfunction with pressure overload. d = critical condition allowing only bedside diagnostic tests. *(Adapted from 2019 ESC guidelines on diagnosis and management of acute PE, Konstantinides et al. DOI: 10.1183/13993003.01647-2019. From Konstantinides S, Meyer G, Becattini C et al. 2019 ESC guidelines for the diagnosis and management of acute pulmonary embolism.* Eur Heart J *2020; 41:543–603.)*

Regular pregnancy testing should be performed by women taking warfarin who are trying to conceive. The consequences of fetal exposure to oral thrombin and factor Xa inhibitors are uncertain and these drugs are therefore avoided in pregnancy. Anticoagulation in pregnancy in those at very high risk of thrombotic complications; for example, metal heart valves should be done with expert counselling and surveillance. See Chapter 48 for further details of anticoagulation in pregnancy.

Both warfarin and LMWH are safe in breast-feeding but this has not been established for the oral thrombin and factor Xa inhibitors, which are therefore avoided (see also Chapter 48).

Patients with cancer

For many years LMWH has been the treatment of choice for cancer-associated thrombosis because of demonstrated superiority over warfarin. Recent trial data suggest that oral factor Xa inhibitors are as effective as LMWH in preventing recurrent cancer-associated DVT and PE, avoiding the need for daily subcutaneous injections, though they may increase the risk of bleeding particularly from the GI tract. Guidelines now support use of these agents for first-line treatment of cancer-associated DVT or PE after taking into account tumour site, interactions with other drugs including those used to treat the cancer, and bleeding risk.

Ambulatory care

Many patients with DVT can be managed on an outpatient basis, admission being reserved for those with a complex presentation or significant co-morbidities. Increasingly too, low-risk PE can be managed on an outpatient basis. Low-risk patients can be identified using the ***Pulmonary Embolism Severity Index (PESI) or simplified PESI*** (**Box 11.96**); management as an outpatient or with early discharge might be considered for this group. Higher-risk patients need admission for close observation or administration of oxygen therapy.

Role of thrombolysis

Anticoagulants help prevent thrombus extension and recurrence but do not dissolve blood clots, in contrast to thrombolytic agents. The latter are seldom used in the treatment of VTE because they carry a higher risk of major bleeding than anticoagulation, including a 2% risk of intracranial haemorrhage. However, in patients presenting with massive PE characterized by systolic hypotension (blood pressure ≤90 mmHg), there is a high risk of early death, and systemic thrombolysis administered intravenously, or occasionally by catheter infusion directly into the thrombus, may be lifesaving by rapidly restoring pulmonary perfusion.

The role of thrombolysis in the management of intermediate-risk PE—that is, without systolic hypotension but with evidence of right ventricular dysfunction and raised pro-BNP or troponin levels—remains controversial. Thrombolysis—either systemic, catheter-directed or pharmaco-mechanical—is occasionally used in the setting of management of limb-threatening ilio-femoral vein thrombosis. Local thrombolysis is also sometimes used in non-limb-threatening ilio-femoral vein thrombosis in an attempt to reduce

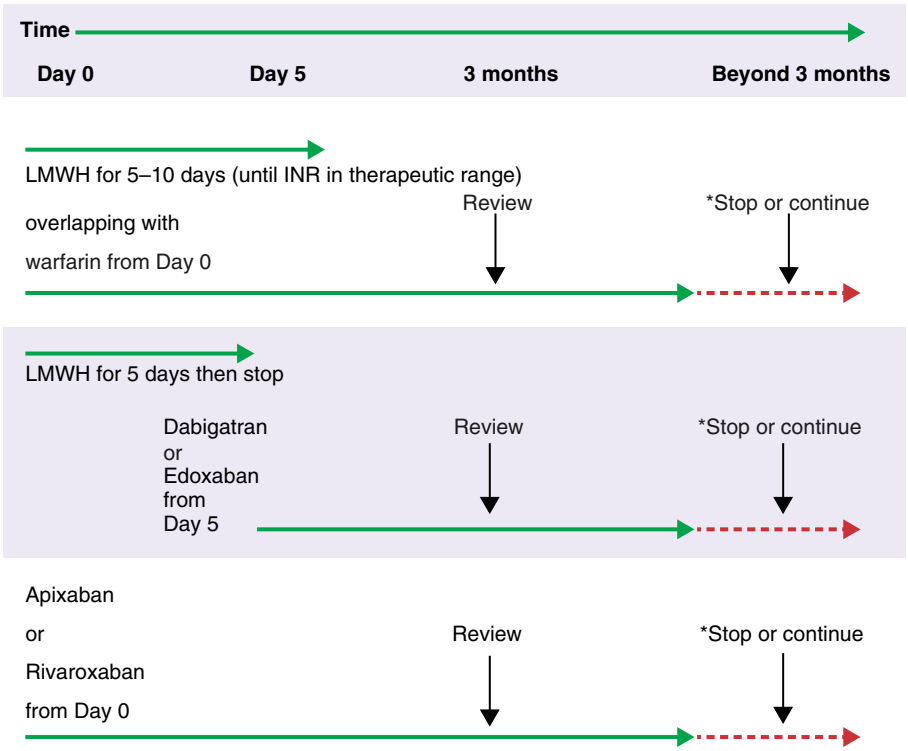

Fig. 11.49 Models for anticoagulant management of newly diagnosed venous thromboembolism (VTE). *The decision to stop or continue anticoagulation beyond 3 months is based on the balance of recurrence risk if anticoagulants are stopped, bleeding risk if anticoagulants continue, and patient preference. *INR,* International Normalized Ratio; *LMWH,* low-molecular-weight heparin.

symptoms and prevent the post-thrombotic syndrome, although there is variable evidence of long-term benefit.

Interventional approaches

Embolectomy

When patients present with massive PE and thrombolysis is contraindicated, emergency pulmonary embolectomy can be lifesaving. This can be done surgically or percutaneously via a catheter inserted via the deep venous system.

Inferior vena cava filters

Occasionally, patients with newly diagnosed VTE have a contraindication to anticoagulation—for example, active bleeding—or a major bleeding risk, such as the need for urgent surgery. In such settings an inferior vena cava (IVC) filter can be inserted by an interventional radiologist to prevent emboli from the deep veins in the leg reaching the lungs. Contraindications to anticoagulation are usually temporary, and anticoagulant treatment should be started as soon as it is safe to do so because filters do not entirely prevent pulmonary emboli and are independently associated with an increased risk of DVT. IVC filters do not reduce the risk of recurrent PE compared to anticoagulation alone. As IVC filters can give rise to complications that include thrombosis, migration, and embolization, retrievable filters are preferred over permanent ones and they should be removed as soon as anticoagulation has been safely established.

For a discussion of treatment duration, complications, investigation of underlying cause, and prevention of venous thromboembolic disease, see Chapter 40.

The unwell cancer patient

Patients living with cancer may present to the acute medical team for a variety of reasons including illness due to disease, complications of anticancer treatment, as a first presentation of malignancy, or due to an unrelated illness. This section details some of the more common medical emergencies which the acute medicine physician is expected to recognize and manage in this population of patients.

Many hospitals have developed an 'acute oncology service' (AOS) offering rapid specialist input for patients being treated for cancer who present to hospital via acute medical services. They provide a vital link between outpatient cancer services and the acutely unwell patient, and may have additional specialist information about the treatment patients have already received, as well offering a route to accessing urgent treatment modalities such as radiotherapy for metastases causing pain or spinal cord compression.

Neutropaenic sepsis

Neutropaenic sepsis is defined as the coexistence of a neutrophil count $<0.5 \times 10^9$/L accompanied by fever (>38°C) or other signs or symptoms consistent with sepsis in a patient undergoing anticancer therapy. This is the most common cause of attendance in the ED for any cancer patient and must always be considered in anyone who is unwell within a month of chemotherapy. Neutropenic patients are at high risk of bacterial and fungal infections, most often from enteric bowel flora; hence, some units will advocate a specific neutropenic diet that is low in bacterial and fungal contamination (**Box 11.97**). Patients must be warned of the possibility of neutropenic fever occurring.

Assessment should be focused on identifying potential sources of infection and establishing severity of infection. Common sources of infection in this population include the respiratory, GI, and urinary tracts. Ask specifically about cough, vomiting, diarrhoea, and dysuria. It will not always be possible to identify a source, and non-specific symptoms are also common, such as nausea, breathlessness, and drowsiness. A fever may not always be present.

The critical test is the full blood count. Although by strict criteria, neutropaenia is defined as a neutrophil count $<0.5 \times 10^9$/L, patients with falling neutrophils $<1.0 \times 10^9$/L after chemotherapy and fulfilling other criteria for sepsis are also managed as neutropaenic sepsis. Immediate introduction of broad-spectrum antibiotics is indicated. Signs of systemic illness, such as tachycardia, hypotension, or oliguria, mandate urgent admission and resuscitation with intravenous treatment (**Box 11.98**). Initial empirical therapy should be reviewed following microbiological results.

All such patients need to be discussed with the appropriate specialist oncology team and hospitals should have clear protocols for the rapid institution of antibiotics within an hour of arrival in the ED. In units practiced in the assessment of febrile neutropenia, it is possible to follow a more risk-stratified antibiotic policy and to avoid or curtail admission with oral co-amoxiclav plus ciprofloxacin when low-risk features are present: that is, absence of tachycardia, hypotension, hypoxia, and mucositis, and an expected short duration of myelosuppression.

Complications of immune checkpoint inhibitors

These relatively new agents act directly on T cells to reverse immune tolerance and encourage anti-tumour activity of the immune system (see Chapter 41). Because of their mechanism of action, side-effects include a variety of autoimmune phenomena which may cause disease affecting a wide range of organ systems (such as acute colitis, AKI secondary to tubulointerstitial nephritis, a variety of skin rashes, acute hepatitis). A high index of suspicion for drug side-effects is required in any patients receiving these agents, with close liaison with oncology teams.

Box 11.97 Neutropenic diet

Foods and drinks that should be avoided:
- All uncooked vegetables and most fruits—peel off thick skin from foods like oranges and bananas
- Raw or rare meat
- Fish
- Uncooked or undercooked eggs
- Foods from salad bars and delicatessen counters
- Soft blue/mould cheeses e.g., brie, camembert, stilton
- 'Well' water—or boil it for 1 min before drinking

Foods and drinks that are safe:
- Cooked vegetables
- Canned fruits and juices
- Well-done meat
- Hard-boiled eggs (no runny yolks)
- Vacuum-packed lunch meats (not freshly sliced meats)
- Pasteurized milk, cheese, yoghurt, and other dairy products only
- Tap water if the source is known—or boil it; bottled water

Box 11.98 Management of neutropaenic sepsis

Immediate intervention is essential

- Resuscitate with intravenous fluids to restore circulatory function; monitor vital signs, urine output, and Glasgow Coma Scale score
- Take cultures of peripheral blood, urine, sputum and stool and blood cultures drawn through any indwelling venous catheters
- Consider the need for admission to critical care, invasive monitoring (e.g., central venous pressure), and consider inotropic support at an early stage
- Give empirical antibiotics as per local policy and sensitivities:
  - Commonly used antibiotics should include activity against enteric Gram-negative bacteria and *Pseudomonas* e.g., ceftazidime or piperacillin–tazobactam with gentamicin; or meropenem monotherapy
  - Antibiotics against staphylococci may be needed e.g., vancomycin, especially with indwelling venous access lines
- Change antibiotics according to culture results, or empirically broaden Gram-negative cover and consider adding Gram-positive cover, if the patient deteriorates clinically and/or temperature is still elevated after 48 h; discuss with the microbiology department
- Consider imaging e.g., thoracic CT, if fever is not responding to broad-spectrum antibiotics, to detect an occult source of fever; consider adding treatment for opportunistic infections:
  - Liposomal amphotericin B or voriconazole—*Candida* and *Aspergillus*
  - High-dose co-trimoxazole—*Pneumocystis*
  - Clarithromycin—*Mycoplasma* and *Legionella*
  - Anti-tuberculous therapy—*Mycobacterium tuberculosis*
- Granulocyte colony-stimulating factor (G-CSF) is usually reserved for cases with profound neutropaenia (neutrophil count $<0.1 \times 10^9$/L) accompanied by adverse prognostic features (e.g., septic shock, prolonged neutropaenia, fungal disease)

Pulmonary embolus

This is a common complication of the coagulopathy of cancer and may be a side-effect of chemotherapy. In the context of malignancy, pulmonary embolus (PE) often presents with unexplained breathlessness and episodic exacerbations from multiple small emboli, rather than chest pain. A high level of suspicion should be maintained in any cancer patient with breathlessness, hypoxia, or chest pain. CT pulmonary angiography is the investigation of choice (**Fig. 11.46**). Prophylactic anticoagulation should be given to all immobilized patients. Treatment is discussed earlier in this chapter in the section 'Deep vein thrombosis and pulmonary embolism (special circumstances)'.

Spinal cord compression

Spinal cord compression (SCC; see Chapter 28), usually due to bony metastatic disease, needs to be rapidly diagnosed, and urgent treatment arranged within 24 hours of onset of paresis, to salvage as much functional capacity as possible. Symptoms include neck or back pain, which is frequently progressive and may be severe and unremitting, bladder or bowel dysfunction, numbness or paraesthesia, limb weakness, or difficulty walking. Neurological examination findings include signs of spastic (upper motor neuron) paraparesis or tetraparesis and sensory loss below the compression with a 'sensory level' usually 2–3 dermatome levels below the anatomical compression, although early neurological clinical features may be incomplete, and more subjective than objective in nature. Whole spine MRI scanning, including both T1-weighted images to identify spinal metastases and T2-weighted images to delineate compression of the cord is the investigation of choice. Treatment should begin with high-dose corticosteroids (usually dexamethasone 16 mg p.o. daily) and analgesia and both neurosurgical and oncological opinions sought. A neurosurgeon should advise on spinal stability, the need for spinal precautions for movement, and the role of decompressive surgery and external bracing for limited-extent disease although patients should be immobilized pending this input and nursed in a supine position to minimize axial weight-bearing. Where surgery is not considered, radiotherapy alone may be used.

Fig. 11.50 Superior vena caval obstruction resulting from a bulky anterior mediastinal mass in a patient presenting with T-lymphoblastic lymphoma.

The cauda equina syndrome

Lumbosacral bony metastatic deposits may result in the cauda equina syndrome: that is, bilateral flaccid (compare spasticity in spinal cord lesions), lower limb weakness, sacral numbness, retention of urine, erectile dysfunction, and areflexia, usually with back pain. Multiple lumbosacral nerve roots are involved. Onset is either acute—an acute flaccid paraparesis—or chronic, sometimes with intermittent claudication (usually with prominent exercise-induced sensory symptoms in addition to pain). Management is the same as for malignant spinal cord compression, with urgent imaging (whole spine MRI), analgesia, corticosteroids, and neurosurgical involvement with a view to surgical decompression.

Superior vena cava obstruction

Superior vena caval obstruction (SVCO; **Fig. 11.50**) can arise from any upper mediastinal mass but is most commonly associated with extrinsic compression from lung cancer and lymphoma. The patient presents with difficulty breathing and/or swallowing, stridor, a swollen, oedematous face and arms, venous congestion in the neck, and dilated veins in the upper chest and arms. CXR may show an abnormal mediastinal contour or widening although diagnosis requires contrast-enhanced CT scanning.

SVCO is a medical emergency and requires immediate assessment and treatment. The patient should be nursed sitting upright and supplemental oxygen administered. Initial treatment is with corticosteroids (usually dexamethasone 16 mg p.o. daily) followed by chemotherapy where the tumour is expected to respond (e.g., lymphomas, small-cell lung cancers, and germ cell tumours), and possibly mediastinal radiotherapy. Sometimes, vascular stents and anticoagulation are also required. Critical care team input and ITU supportive care may be required, pending a response to treatment.

Raised intracranial pressure

Raised ICP due to intracerebral metastases presents classically with headache, nausea and vomiting. There are often no localizing

neurological signs and almost never papilloedema until very late in the disease. However, for many, there is a slower onset with non-specific symptoms such as drowsiness or mental deterioration. Treatment is by high-dose steroids and investigation by MRI. Surgery is appropriate if the condition is unifocal and/or threatening the fourth ventricle; otherwise, whole-brain or local stereotactic CyberKnife radiotherapy is required.

Tumour lysis syndrome

This occurs if treatment triggers a massive breakdown of tumour cells, leading to increased serum levels of urate, potassium, and phosphate, and a secondary hypocalcaemia. These biochemical changes can give rise to cardiac arrhythmias and seizures. Urate deposition in the renal tubules can cause AKI (hyperuricaemic nephropathy). Vigorous hydration, combined with loop diuretics if needed, is crucial to maintain high urine outputs in such patients; however, a proportion will require dialysis for uraemia, oliguria, or severe electrolyte disturbances. The xanthine oxidase inhibitor allopurinol should be given before treatment is started in low-risk patients. Intravenous rasburicase, a recombinant urate oxidase, is used for prophylaxis in high-risk patients and in the treatment of tumour lysis syndrome.

Acute hypercalcaemia

Acute hypercalcaemia of malignancy often presents with dehydration, nausea and vomiting, nocturia and polyuria, drowsiness, and altered consciousness. The serum Ca^{2+} is >3 mmol/L and sometimes as high as 5 mmol/L. While investigation of the cause is under way, immediate treatment is mandatory if the patient is seriously ill or if the Ca^{2+} is >3.5 mmol/L.

Treatment is by resuscitation with intravenous fluids first, to establish a saline diuresis, and then an intravenous bisphosphonate, such as pamidronate or the more potent zoledronic acid (**Box 11.99**). Treating the cause is crucial. Denosumab and calcitonin can be used in intractable cases.

Hypercalcaemia of malignancy is a poor prognostic indicator and patients should have a full holistic assessment in collaboration with their parent oncology team.

Malignant bile duct obstruction

This presents with cholestatic jaundice. Lymphomatous obstruction responds very well to prompt initiation of therapy. A small proportion of pancreatic and bile duct tumours are surgically resectable, more commonly those in the distal bile duct as compared to those in the hilar region. However, in the greater proportion of patients, treatment is palliative. In recent years, endoscopic techniques have allowed the insertion of stents into the biliary tree to re-establish bile flow. Self-expanding metal stents have long periods of patency but are at risk of ascending infection. In the small proportion of patients in whom bile duct drainage is not possible endoscopically, the percutaneous route offers an alternative. Endoscopic photodynamic laser therapy with a photoporphyrin sensitizer can also prolong patency.

European Society for Medical Oncology Clinical Practice Guidelines. Accessed at: https://www.esmo.org/guidelines.
Treatment of hypercalcemia of malignancy in adults: An endocrine society clinical practice guideline. *J Clin Endocrinol Metab*. 2023; 108:507–528.

Box 11.99 Management of acute severe hypercalcaemia

- **Rehydrate** using at least 4–6 L of 0.9% saline on day 1, and 3–4 L for several days thereafter, aiming to maintain a urine output of 100–150 mL/h. Central venous pressure (CVP) may need to be monitored to control the hydration rate. Fluid infused will correct dehydration and increase urinary calcium excretion, usually lowering serum calcium by 0.25–0.375 mmol/L over the first 24 h.
- **Intravenous bisphosphonates** are the treatment of choice for hypercalcaemia of malignancy or of undiagnosed cause. Pamidronate is preferred (15–60 mg, either as a single intravenous infusion in 0.9% saline or glucose over 2–4 h or in divided doses over 2–4 days with dose adjustment for serum calcium concentration; maximum 90 mg per course). Levels fall after 24–72 h, lasting for approximately 2 weeks. Zoledronic acid is an alternative. Renal function should be assessed prior to treatment and dose adjusted according to creatinine clearance.
- **Denosumab** (a monoclonal antibody against RANK ligand, inhibiting bone resorption) may be used as an alternative to bisphosphonates depending on local protocols, or under specialist supervision in circumstances where response to other therapies has been poor.
- **Prednisolone** (30–60 mg daily) is effective in some instances (e.g., in myeloma, sarcoidosis, and vitamin D excess) but in most cases is ineffective.
- **Calcitonin** (4–8 units/kg i.m. or s.c. every 6–12 h) rapidly lowers serum calcium by 0.25–0.50 mmol/L and may be useful as bridging treatment while awaiting a response to bisphosphonates/denosumab. Calcitonin inhibits bone resorption through interference with osteoclast function, although tachyphylaxis occurs within 48–72 h.
- **Oral phosphate** (sodium cellulose phosphate 5 g three times daily) produces diarrhoea and is now rarely used
- **Haemodialysis** may be required in refractory cases, usually where hypercalcaemia is accompanied by established renal failure.

Rash

Rashes constitute a frequently encountered clinical presentation, encompassing a myriad of underlying aetiologies. Managing patients presenting with a rash revolves around identification of the specific cause to tailor an effective treatment strategy. The origins of rashes are diverse and may stem from infectious, allergic, autoimmune, or systemic conditions. The clinical assessment and stepwise approach to assessing a skin rash is suggested in **Fig. 45.4**.

Important dermatological conditions which may present to the acute physician include skin infections (including cellulitis, necrotizing fasciitis, and toxic shock syndrome), erythroderma, and severe cutaneous adverse drug reactions. The sections below detail information gathering required to enable first-line investigation and treatment and, when required, enable effective discussion and referral to a dermatologist.

Clinical assessment

History

- **Onset and duration:** Determine when the rash first appeared and its evolution over time, noting any changes in size, shape, or associated symptoms.
- **Symptoms:** Enquire about associated symptoms such as pruritus, pain, or systemic manifestations like fever. This aids in discerning infectious or systemic causes.
- **Triggers and exacerbating factors:** Investigate potential triggers or exacerbating factors, including exposure to new substances, recent infections, or changes in environment (e.g., heat or sunlight exposure).
- **Medical and drug history:** Gather information on the patient's medical history, including any history of allergy, atopy, or autoimmune disease, focusing on conditions linked to dermatological manifestations. Explore recent changes in medications and enquire about supplements and recreational substances. Enquire about family history of skin disease.

- **Occupational and environmental exposures:** Enquire about the patient's occupation and environmental exposures, as these may contribute to certain types of rashes.
- **Review of systems:** Perform a review of systems to identify any concurrent or preceding symptoms that may be linked to the rash (e.g., respiratory symptoms, joint pain).

Physical examination

- **Rash characteristics:** Scrutinize the morphology, distribution, and configuration of the rash. Consider whether it presents as macules, papules, vesicles, pustules, or other distinctive patterns. Does the rash blanch with pressure? A non-blanching (petechial or vasculitic) rash should always prompt consideration of meningococcal sepsis, although the differential diagnosis is contextual and broad.
- **Distribution:** Assess the distribution of the rash across the body, considering localized versus generalized patterns. Note if it follows a specific dermatomal or anatomical distribution. Ask specifically about involvement of mucosal surfaces (e.g., eyes, mouth, genital area) and hair and nail disease.

Investigations

Core laboratory tests (including full blood count, urea and electrolytes, liver function tests, and CRP) will be warranted in all but the most mild presentations. Targeted investigations will vary widely depending on the nature of rash identified, although appropriate investigations may include:

- blood cultures (for the febrile patient or where suspicion exists for bacterial sepsis)
- pus swabs or viral nucleic acid testing (for pustular or vesicular eruptions)
- skin scrapings (to confirm a possible fungal rash)
- additional investigations to investigate for underlying cause (e.g., the finding of a vasculitic rash will prompt broad investigation for underlying infectious or autoimmune disorders).

Where the causes remain unclear, or the rash fails to resolve spontaneously or with treatment, skin biopsy by a dermatologist may be indicated.

Management

Tailor the management plan to the identified cause of the rash. Any culprit medication should be withdrawn. ***Erythroderma*** (inflammation involving >90% skin area, irrespective of cause, see 'Erythroderma and loss of skin function') is a medical emergency, threatening autoregulation of body temperature and fluid and electrolyte balance, and requires prompt clinical assessment (ABCDE approach) and resuscitation and may warrant critical care admission. Topical emollients may bring symptomatic relief in a broad range of dermatoses, while more definitive treatment is planned. Dermatology referral should be considered for any patient where the cause of rash is unclear or symptoms are severe (e.g., blistering eruptions or mucosal involvement) and is mandatory in erythrodermic eruptions.

Acute skin infections

Cellulitis and erysipelas

Cellulitis and erysipelas are caused by superficial and deeper infection of the dermis and subcutaneous tissues, respectively (Fig. 11.51). It is not always possible to make a clear distinction. Both present with tender confluent areas of inflamed skin and are often associated with fever and malaise. Cellulitis typically affects the lower leg or arm and may spread proximally. Other sites that may be affected include the abdomen and perianal and periorbital areas. Erysipelas is more common on the face and is more sharply demarcated. Localized blistering (clear or blood-stained), necrosis, abscess formation,

Fig. 11.51 Acute skin infections. **(A)** Cellulitis extending from the dorsum of the left foot to the shin. **(B)** Facial erysipelas.

lymphangitis, and lymphadenopathy may occur. The most common infective organisms are β-haemolytic streptococcus and *S. aureus*. Gram-negative or anaerobic bacteria may cause infection in immunocompromised people and those with diabetes.

Lymphoedema, obesity, venous stasis, and toe-web fungal infection are risk factors for lower limb cellulitis. The skin should be carefully examined to look for fissures or erosions that can allow entry of pathogens. Skin swabs are usually negative unless taken from broken skin. Serological tests can confirm a streptococcal infection (antistreptolysin O titre (ASOT) and anti-DNAse B titre).

Management

Systemic antibiotics (flucloxacillin or erythromycin) are indicated; they may be given as high-dose oral therapy, or intravenously via ambulatory care or as an inpatient, depending on the patient's age, disease severity, and co-morbidities. Single-dose dalbavancin may be an alternative to conventional antibiotics in the treatment of acute bacterial skin infections in adults, avoiding the need for hospitalization or repeat attendance.

Up to 50% of people with cellulitis experience repeat episodes. Prophylactic antibiotic therapy reduces the risk of further attacks during treatment but the effect wears off after discontinuation.

Necrotizing fasciitis

This fulminant, rapidly spreading, life-threatening bacterial infection of the subcutaneous and deep soft tissues causes severe tissue destruction and is associated with a high mortality. A number of organisms can cause necrotizing fasciitis: spontaneous disease that arises in previously healthy people is often caused by group A streptococcus (GAS), while disease related to abdominal surgery or immunosuppression is often caused by mixed aerobic and anaerobic populations.

Necrotizing fasciitis is characterized by severe pain that is out of proportion to the apparent signs of skin inflammation. Infection tracks rapidly along tissue planes, causing spreading erythema, swelling, pain, and sometimes tissue crepitus. Patients are typically febrile and severely unwell, and urgent surgical intervention (with extensive debridement or amputation) and intravenous antibiotic therapy are required. High-dose benzylpenicillin and clindamycin are used in confirmed GAS infection, and a broad-spectrum antibiotic combination with additional metronidazole is used where the pathogen is unknown. Typically, the CRP and white cell count are significantly raised. Imaging is sometimes helpful (e.g., by revealing gas in deep tissues) but should not delay urgent surgical intervention. Multiorgan failure is common and mortality is high.

Gas gangrene

Gas gangrene is caused by deep tissue infection with *Clostridium* spp. (especially *C. perfringens*), following contaminated penetrating injuries—historically, battlefield wounds but now commonly found in intravenous drug users and patients who have undergone GI tract surgery. Initial infection develops in damaged, necrotic tissue; toxins secreted by the bacteria destroy surrounding tissue and permit rapid spread of infection, contributing to severe systemic effects. Treatment is by surgical debridement of necrotic tissue and intravenous benzylpenicillin and clindamycin.

Toxin-mediated skin disease

Staphylococcal scalded skin syndrome (SSSS) and toxic shock syndrome (TSS) are diseases caused by bacterial secretion of toxins, the latter representing a life-threatening illness requiring urgent medical treatment. Blistering lesions seen in SSSS can resemble toxic epidermal necrolysis (TEN, see later) but the mucous membranes are not involved in SSSS and blistering occurs higher in the epidermis. The intraepidermal split of SSSS can be demonstrated by histology of a frozen section of skin.

Potential sources of infection and toxin production include tampons and menstrual cups (particularly if left *in situ* for longer than recommended), and cutaneous wounds or abscesses. Treatment revolves around resuscitation, antibiotics, and identification and elimination of the bacterial 'driver' (e.g., removal of a retained tampon, surgical debridement of an abscess). Critical care management may be required.

Erythroderma and loss of skin function ('skin failure')

Erythroderma ('red skin') is a term used to describe widespread inflammation affecting 90% or more of the body surface. There are several causes (**Box 11.100**), of which underlying skin disease and drug hypersensitivity are the most common. Extensive skin inflammation causes pain, soreness, and irritation, and leads to loss of normal skin function, especially fluid and temperature regulation. Symptoms include thirst, fever and chills, malaise, and dizziness. Erythroderma requires urgent medical treatment to avoid life-threatening complications (see next section). Examination should seek features of an underlying dermatosis, such as scalp or nail psoriasis. There may be associated generalized lymphadenopathy and a skin biopsy may be indicated, especially in suspected cutaneous lymphoma. In non-malignant disease, lymph nodes are often mildly enlarged and histology shows non-specific, reactive changes.

Complications

These include:

- high-output cardiac failure from increased blood flow
- hypothermia from heat loss
- pre-renal AKI from fluid depletion
- hypoalbuminaemia
- catabolism and increased basal metabolic rate
- secondary bacterial infection
- capillary leak syndrome: the most severe complication and potentially fatal, though rare. Release of inflammatory mediators from the skin causes extensive vascular leakage with oedema, hypovolaemic shock, and acute respiratory distress syndrome (ARDS) (see Chapter 13).

? Box 11.100 Causes of erythroderma

Common

- Atopic eczema
- Psoriasis
- Drugs (e.g., sulphonamides, gold, sulphonylureas, penicillin, allopurinol, captopril)
- Seborrhoeic eczema
- Idiopathic

Rare

- Chronic actinic dermatitis
- Cutaneous T cell lymphoma (Sézary's syndrome)
- Malignancy (especially leukaemias)
- Pemphigus foliaceus
- Pityriasis rubra pilaris (a hereditary disorder of keratinization)
- HIV infection
- Toxic shock syndrome

Box 11.101 Severe cutaneous adverse drug reactions

- Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN)
- Drug reaction with eosinophilia and systemic symptoms (DRESS)
- Acute generalized exanthematous pustulosis (AGEP)
- Erythroderma/exfoliative dermatitis
- Serum sickness-like reactions

Management

Intensive supportive treatment includes maintaining body temperature (with space blankets and heaters) and close monitoring of vital signs and fluid and electrolyte balance. Skin swabs should be taken and antibiotics commenced if secondary infection is suspected. All non-essential medication should be stopped. Topical therapy with a bland emollient or mild topical steroid can be initiated while the underlying cause is identified, at which point systemic therapy may be indicated under specialist guidance: for example, ciclosporin for psoriasis (see Chapter 45).

Severe cutaneous adverse drug reactions

Severe drug rashes are listed in **Box 11.101**. Common causes include antibiotics, NSAIDs, anticonvulsants, allopurinol, dapsone, and nevirapine. Early recognition and drug withdrawal can minimize morbidity and mortality. Recent advances in pharmacogenetics have identified human leucocyte antigen (HLA) associations, and cytochrome P450 polymorphisms that are associated with an increased risk of reaction to certain drugs.

Stevens–Johnson syndrome and toxic epidermal necrolysis

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are severe mucocutaneous disorders that are considered variants of a disease spectrum. They are characterized by varying extents of blistering/epidermal detachment and mucosal ulceration:

- SJS: <10% skin detachment; one or two mucosal sites involved (oral, genital, ocular)
- SJS–TEN overlap: 10%–30% skin detachment
- TEN: >30% skin detachment; all mucosal sites involved in most cases.

The onset is usually 1–2 weeks after drug exposure. Initial symptoms are non-specific (malaise, myalgia, fever, and cough). These are followed by tender maculopapular erythematous lesions on the torso and inflamed mucosal surfaces. 'Target lesions' (as seen in erythema multiforme, see Chapter 45) usually affect the hands and feet in SJS. In TEN there is widespread flaccid blistering with skin that wrinkles like wet wallpaper on gentle pressure (Nikolsky's sign). Features of skin failure can ensue (see above). Respiratory mucosal and pulmonary involvement may require ventilation, and upper GI involvement can cause haemorrhage. Patients are at high risk of sepsis and require expert intensive supportive care, as for extensive burns. Multiorgan failure may occur and the mortality for TEN ranges from 30% to 50%. 'SCORTEN' is a clinical severity score that can help assess prognosis (**Box 11.102**). All potential causative drugs should be stopped.

Box 11.102 SCORTEN prognostic score in toxic epidermal necrolysis

Risk factor	0	1
Age	<40 years	>40 years
Associated malignancy	No	Yes
Heart rate (b.p.m.)	<120	>120
Serum urea (mmol/L)	<9.6	>9.6
Detached or compromised body surface	<10%	>10%
Serum bicarbonate (mmol/L)	>20	<20
Serum glucose (mmol/L)	<13.9	>13.9

The more risk factors present, the higher the SCORTEN score, and the higher the mortality rate:
0–1 risk factors: 3.2% mortality
2: 12.1%
3: 35.3%
4: 58.3%
≥5: >90%

(From Bastuji-Garin S, Fouchard N, Bertocchi M et al. SCORTEN: a severity-of-illness score for toxic epidermal necrolysis. J Invest Dermatol 2000; 115:149–153.)

Specialist dermatology input is essential. Treatment with high-dose steroids, ciclosporin, and intravenous immunoglobulin therapy remains controversial, as high-quality clinical trials are lacking.

Drug reaction with eosinophilia and systemic symptoms/drug hypersensitivity syndrome

Drug reaction with eosinophilia and systemic symptoms (DRESS)/drug hypersensitivity syndrome usually starts 2–6 weeks after initial exposure and is characterized by widespread erythema, facial oedema, fever, lymphadenopathy, and hepatosplenomegaly. Blood eosinophilia is usual with elevated hepatic transferases. Pneumonia and nephritis can develop and a mortality rate of 10% has been reported. Treatment is with systemic steroids tapered over at least 3 months. Aromatic anticonvulsants are one of the most common causes of DRESS and, as they cross-react, all drugs of this group must be avoided in the future. Sodium valproate is a suitable alternative.

Acute generalized exanthematous pustulosis/toxic pustuloderma

Acute generalized exanthematous pustulosis (AGEP)/toxic pustuloderma is an exanthem with numerous small, non-follicular, sterile pustules around the neck, axillae, and groin. It usually starts a few days after drug exposure and resolves with peeling. There may be mild systemic upset but internal organs are not involved. Localized forms can occur. Florid cases can resemble pustular psoriasis. Topical steroids and emollients can be used to relieve symptoms.

CORE SKILLS AND KNOWLEDGE

Sepsis is a serious complication of infection in which a dysregulated immune response leads to organ dysfunction and sometimes death. It is the final common pathophysiological pathway in patients who die from infection. It is estimated that, worldwide, 49 million people develop sepsis every year, and 11 million die.

All healthcare staff should be aware of sepsis, which may present via the hospital emergency department having started in the community or develop on general medical or surgical wards. Specialist care for patients with severe complications of sepsis may be provided in a critical care unit. Infectious diseases (ID) physicians become involved in managing patients with complex or disseminated infections and may run outpatient antibiotic treatment (OPAT) services and specialist ID clinics.

Key skills in this chapter area include:

- Identifying sepsis and instituting emergency management using the Sepsis Six care bundle
- Appreciating the potential complications of sepsis and recognizing the need for appropriate escalation of care in acutely unwell or deteriorating patients
- Becoming familiar with the appropriate use of antibiotics to treat commonly encountered infections.

Opportunities for students to learn about sepsis and infection are gained by reviewing patients with suspected infection in the emergency department or acute assessment units, ID wards or critical care settings, or those deteriorating on general wards who may be identified by attending critical care outreach rounds. Observing specialist ID and OPAT clinics (including multidisciplinary team meetings) provides an insight into the longer-term follow-up of patients with infection.

CLINICAL SKILLS

History

When taking a history, this should be tailored to cover the points in **Box 12.1**, which are highly relevant to a presentation with suspected sepsis or infection.

Management of sepsis

Sepsis is a medical emergency, and an approach based on the Sepsis Six care bundle ensures that management and investigation proceed hand in hand, and patients are cared for in the most appropriate location for their needs (see **Fig. 12.1**).

Box 12.1 Features in the history relevant to sepsis

Symptoms
- Duration
- Symptoms of inflammatory response: fevers, chills, rigors, malaise, confusion, vomiting
- Localizing symptoms indicating site of infection:
  - Chest: cough, sputum, shortness of breath
  - Urinary tract: dysuria, urgency, loin pain
  - Central nervous system: headache, meningism
  - Biliary tract: upper abdominal pain, jaundice, vomiting
  - Skin and soft tissue: localized heat, erythema, and pain

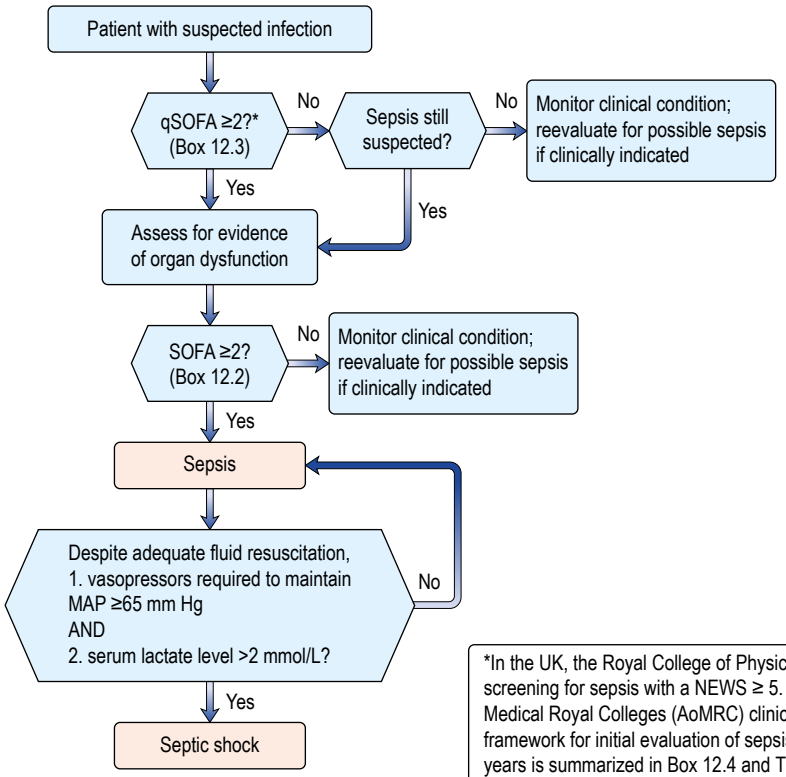
Past medical history
- Immunosuppression (diabetes, asplenism, human immunodeficiency virus, etc.)
- Pregnancy or patient in the puerperium
- Recent surgery or indwelling devices
- Previous sepsis

Drug history
- Immunosuppressant medication
- Recent courses of antibiotics

Risk factors for specific pathogen types
- Recent contact with medical institutions
- Previous infection with antibiotic-resistant organisms
- Travel history

General investigations

Bloods	FBC U&E LFTs CRP Lactate Glucose Coagulation
Urine	Nitrites Leucocyte esterase Culture
Arterial blood gas	
Imaging	X-ray Ultrasound CT/MRI Echo PET
Bacteriological	Blood culture x2 Specific site culture (e.g. CSF) PCR



*In the UK, the Royal College of Physicians recommends screening for sepsis with a NEWS ≥ 5. The Academy of Medical Royal Colleges (AoMRC) clinical decision support framework for initial evaluation of sepsis in adults ≥ 16 years is summarized in Box 12.4 and The Sepsis Six care bundle for initial treatment and resuscitation of suspected sepsis in Box 12.5.

End-organ failure
- Systolic blood pressure (SBP) <90 mmHg or >40 mmHg fall from baseline or mean arterial pressure (MAP) <65 mmHg
- Bilateral pulmonary infiltrates with no new need for oxygen to maintain saturations >90% or with PaO_2/FiO_2 ratio <300 mmHg or 39.9 kPa
- Serum lactate >2.0 mmol/L
- Serum creatinine >170 mol/L or urine output <0.5 mL/kg per hour for 2 successive hours
- INR >1.5 or an (activated) partial thromboplastin time (PTT) >60 sec
- Platelet count <100 10^9/L
- Bilirubin >32 mol

Examination

Highlighted in red are sites of infection that are common causes of sepsis, with associated clinical signs. This list is not exhaustive and, in a patient with the sepsis syndrome but no clear source, careful examination is vital to establish the underlying diagnosis.

SITES AND SIGNS OF INFECTION

Observation chart
Fever
Tachypnoea (a key sign of clinical deterioration)
Tachycardia and hypotension
Hypoxia (may suggest lower respiratory tract infection)

General observation
Appears 'unwell'
Hot to touch
Confused or reduced consciousness

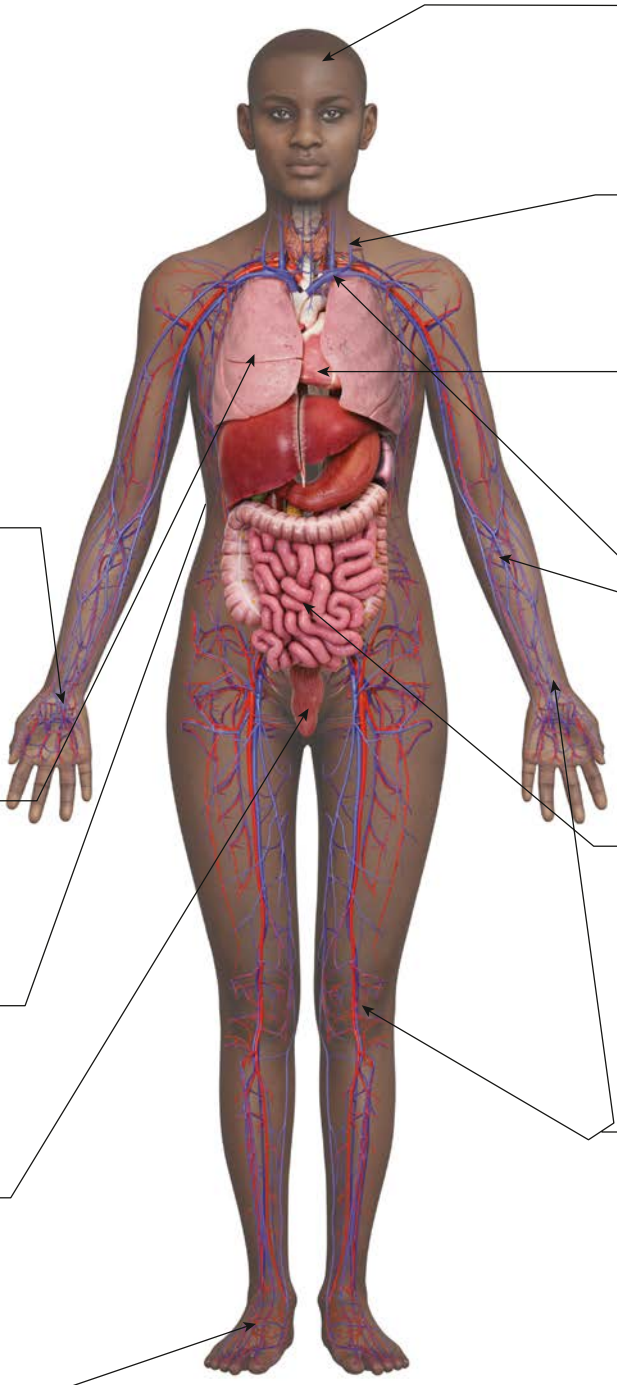
Pulse
Tachycardia common; acute atrial fibrillation possible
May be high-volume ('bounding') due to vasodilation
May be low-volume if 'peripherally shut down' due to relative hypovolaemia

Chest
Tachypnoea
Consolidation may be present in lower respiratory tract infection

Back
Localized tenderness may indicate discitis or spinal abscess
Loin tenderness common in pyelonephritis

Genital examination
Males – signs of epididymo-orchitis
Females – pelvic inflammatory disease; consider retained tampons causing toxic-shock syndrome

Feet
Infected ulcers (especially in patients with diabetes)



Central nervous system
Drowsiness and confusion common signs of sepsis in the elderly
Examine for signs of meningitis

Jugular venous pressure
May be reduced in dehydration/volume depletion

Heart
New or changed murmur may indicate infective endocarditis

Indwelling devices (e.g., Hickman lines)
Examine for signs of intravenous device infection such as discharge or induration
Obtain additional culture from line where possible

Abdomen
Examine for signs of peritonitis
Right upper quadrant tenderness common in biliary sepsis
Right lower quadrant tenderness seen in appendicitis, pelvic inflammatory disease and cystitis
Left-sided tenderness common in diverticulitis

Extremities
Coolness (may indicate hypotension or intravascular volume depletion)
Cellulitis or soft tissue infection (consider devastating infection such as necrotizing fasciitis)
High index of suspicion for septic arthritis if any joints are swollen

BACKGROUND

Sepsis is a rare but serious complication of infection. The syndrome arises when the adaptive immune response to infection becomes maladaptive, leading to organ dysfunction. Multiorgan failure in septic shock is the final common pathway for most patients who die from infection.

PATHOPHYSIOLOGY

The pathophysiology of sepsis is complex and includes the activation of both pro- and anti-inflammatory mechanisms, which can both contribute to clearance of infection but also organ injury. Pathogen-associated molecular patterns (PAMPs), which include components of bacterial, fungal, and viral pathogens, activate the innate immune system, which is chiefly comprised of macrophages, monocytes, granulocytes, natural killer cells, and dendritic cells (see Chapter 6). This activation occurs through Toll-like and C-type lectin receptors on cell surfaces and nucleotide-binding oligomerization domain (NOD)-like and retinoic acid-inducible gene-I (RIG-I)-like receptors in the cytosol. The downstream effects of these activation events, mediated through the upregulation of multiple genes, include the production of pro-inflammatory cytokines such as tumour necrosis factor-alpha (TNF-α) and interleukins 1 (IL-1) and 6 (IL-6). Further effects include increased innate immune activity, production of hepatic acute phase proteins (e.g., complement, fibrinogen, and C-reactive protein [CRP]), release of microparticles containing inflammatory, pro-oxidant and procoagulant lipids and proteins, and elaboration of neutrophil extracellular traps (NETs), which are scaffolds of DNA and antimicrobial proteins and enzymes. The release of microparticles and NETs, combined with increased intravascular tissue factor expression, leads to the phenomenon of 'immunothrombosis', whereby microbes are trapped in microthrombi, which, in turn, attract and further activate leucocytes.

This highly conserved innate response is usually very effective at controlling and neutralizing local infection. When the response exceeds a certain threshold, damage to the host becomes clinically evident. This may be mediated through mitochondrial dysfunction, leading to deficient adenosine triphosphate (ATP) production, and through widespread immunothrombosis as complement activation increases vascular permeability and causes disseminated intravascular coagulation (DIC); this leads to further inflammation, impaired microvascular function and oxygen delivery, and subsequent organ dysfunction. Sepsis becomes a self-reinforcing pathophysiological phenomenon, associated with fierce catabolism to fuel it.

Organ dysfunction

At organ level, sepsis represents a systemic loss of homeostasis, the dysfunction of each organ system adversely affecting the function of every other. The physiological demand requires an increased cardiac output, which most patients achieve after fluid resuscitation. However, the syndrome itself, and associated acidosis, can exert a negatively inotropic influence on the heart (septic cardiomyopathy). Vasoplegia leads to reduced total peripheral resistance, and capillary leak of plasma and protein-rich fluid causes tissue oedema, which in turn impairs oxygen delivery to cells. In the lungs, it can cause acute lung injury and adult respiratory distress syndrome (ARDS). Epithelial disruption in the gut can lead not only to malabsorption but also to translocation of bacteria into the bloodstream, further amplifying the septic insult. Acute kidney injury (AKI) is common and associated with an increased risk of death. Brain dysfunction manifests as septic encephalopathy, ranging from mild drowsiness and confusion to coma.

Consensus definition (Sepsis-3)

The complexity of the sepsis syndrome does not lend itself to a simple diagnostic test. Many biomarkers have been proposed but none is specific enough to be used to define the condition.

In 1991, the first consensus conference to agree a definition of sepsis allied it to the concept of the systemic inflammatory response syndrome (SIRS). This definition was modestly revised in 2001. The latest definition was published in 2016. In anticipation of further updates, as our understanding of the syndrome evolves, it was given the name 'Sepsis-3'.

Sepsis is currently defined as '***life-threatening organ dysfunction caused by a dysregulated host response to infection***'. SIRS is no longer used to define sepsis, although components of this syndrome (e.g., pyrexia, neutrophil leucocytosis) remain important in recognizing the presence of infection; the term 'sepsis' is reserved the syndrome of organ dysfunction attributable to the dysregulated host response to infection in contradistinction to simple infection. Clinicians must be clear about the diagnosis. Inappropriate use of the term 'urosepsis' to describe a simple urinary tract infection (UTI), for example, is misleading and distorts healthcare statistics.

Examination of a large dataset of electronic patient records enabled the authors of the Sepsis-3 definition to construct clinical criteria that best predicted which patients with infection developed life-threatening organ dysfunction, for which the surrogate measure of in-hospital mortality or a requirement for 3 or more days of intensive care treatment was used. In intensive care this consisted of changes in the Sequential Organ Failure Assessment (SOFA) score (**Box 12.2**), where are an increase of SOFA score by ≥2 points from baseline consequent on infection satisfies the Sepsis-3 criteria for organ dysfunction.

The best predictor of death or a requirement for 3 days or more of intensive care for ward patients was a new construct, the 'quick SOFA' (qSOFA) score, consisting of three simple parameters (GCS, respiratory rate, systolic blood pressure); **Box 12.3**. qSOFA is an effective bedside clinical tool to rapidly identify patients at high risk of mortality and who may require admission to critical care. In the UK the Royal College of Physicians recommends using a National Early Warning Score (NEWS 2) of 5 or more as an indicator that a patient is at higher risk of having sepsis (see Fig. 13.1). Remember that neither the qSOFA nor the NEWS 2 are themselves diagnostic of sepsis; they merely indicate that a patient is at higher risk of having sepsis and should be assessed for the condition (**Fig. 12.1**).

Septic shock

The term 'septic shock' is reserved for the subset of patients with sepsis whose circulatory and metabolic dysfunction is such that their risk of death is significantly increased. Clinically, patients are identified as in septic shock if they require vasopressor support to maintain a mean arterial pressure of 65 mmHg or more and have an elevated serum lactate concentration (>2 mmol/L) despite adequate volume resuscitation.

Urine output (mL/day)	—	—	—	<500	<200

[a]An increase in SOFA score of ≥2 points identifies patients with organ dysfunction for the purposes of the Sepsis-3 definition. Any such patients should be considered for admission to the critical care unit.
[b]PaO_2/FiO_2 (FiO_2 as a fraction ≤1).
MAP, Mean arterial pressure; *MV*, mechanically ventilated.

Box 12.3 The 'quick SOFA' (qSOFA) score

	Score = 1 for each
Glasgow Coma Score (see Chapter 11)	<15
Respiratory Rate (breaths/min)	≥22
Systolic blood pressure (mmHg)	≤100
Patients are 'positive' for qSOFA if score is ≥2	

RECOGNITION OF SEPSIS

At-risk groups

Whether a simple infection will progress to sepsis or not depends on a range of factors, including the virulence of the pathogen, the microbial load, the site of infection, and the host response. The latter is influenced by genetic make-up, co-morbidities, past medical history, and chronic treatments. Groups at higher risk of developing sepsis include:

- older people (>65 years of age) and the very young (neonates)
- people who have previously had sepsis
- people with immunosuppressive medical conditions (such as HIV, asplenism, cirrhosis, autoimmune diseases, cancer)
- people who are iatrogenically immunosuppressed (those on immunosuppressive drugs, including systemic corticosteroids)
- patients with indwelling devices, especially if they breach normal barriers against infection
- pregnant (and recently pregnant) women
- people who abuse alcohol or intravenous drugs.

In-hospital surveillance

Inpatients have a higher risk of developing sepsis than patients in the community. Hospitals should therefore have systems in place to identify deteriorating patients early, aligned with processes that enable a prompt medical response. In the UK the NEWS 2 score (see earlier) assigns a numerical score to patients' observations, weighted according to the degree of deviation from normal values. It has long been known that cardiac arrest is usually preceded by several hours of increasingly deranged physiology, reflected by an increasing NEWS 2 score.

Most hospitals empower ward staff to call for help at certain NEWS 2 thresholds. In many instances this will be on the basis of a total NEWS 2 of 5 or more or on clinical concern even if the numerical score is lower. The request for assistance (conveyed using the SBAR approach, e.g., see Chapter 2) should prompt an urgent medical review, including screening for sepsis.

There is no binary test for sepsis. Screening consists of a risk assessment, carried out by an experienced and informed clinician, of the likelihood that a deteriorating patient is developing sepsis. That likelihood is increased in the presence of extreme physiological derangement, highly suspicious elements of recent medical history, AKI, or raised serum lactate, as incorporated into many guidelines. The diagnosis should be made on the basis of bedside observations and limited point-of-care testing, in order to minimize the time to treatment. Given that early antimicrobial therapy may alter the natural history of the syndrome, waiting for laboratory blood tests and other investigations to confirm the presence of organ dysfunction is counterproductive. Where available, point-of-care lactate measurement can be especially useful. Lactate level is prognostic in patients with sepsis; a raised lactate should never be ignored and is usually a sign of organ dysfunction, even in patients who might otherwise seem relatively well.

Recent guidance from the Academy of Medical Royal Colleges suggests tailoring the response to deteriorating patients with possible sepsis to the degree and rapidity of that deterioration. Early initiation of broad-spectrum antibiotics should be reserved for the sickest (NEWS 2 score of 7 or above, or NEWS 2 of 5 to 6 with other adverse signs), while less unwell patients can tolerate a delay to allow for further investigations to be undertaken (**Box 12.4**).

Box 12.4 The Academy of Medical Royal Colleges (AoMRC) clinical decision support framework for initial evaluation of sepsis in adults ≥ 16 years

Vital signs	Vital signs: NEWS-2 'Physiology first'	0	1–4	5–6	>7
Initial assessment	**History, examination, lab results**	*If clinical or carer concern, continuing deterioration, surgically remediable sepsis, neutropaenia, or blood gas/lab evidence of organ dysfunction, including elevated serum lactate, upgrade actions at least to next NEWS-2 level*			
	Comorbid disease, frailty, patient preferences?	*Consider influence of comorbid disease, frailty, and ethnicity on NEWS-2, and patient preferences for treatment intensity, limits, end-of-life care*			
Initial (generic) actions	**Monitoring and escalation plan**	Standard observations	• Registered nurse review <1 hour • Obs 4–5 hourly if stable • Escalate if no improvement	• Obs hourly • Review <1 hour by clinician competent in acute illness assessment • Escalate if no improvement	• Obs every 30 minutes • Review <30 minutes by clinician competent in acute illness assessment • Senior doctor review <1 hour if no improvement: refer to Outreach or ICU
	Initial treatment of precipitating condition	Standard care	<6 hours	<3 hours	<1 hours

Academy of Medical Royal Colleges Statement on the Initial Antimicrobial Treatment of Sepsis. Academy of Medical Royal Colleges 2022.

Origins of sepsis

Sepsis may be either community acquired, healthcare associated, or hospital acquired. Community-acquired disease is defined as sepsis occurring within 48 hours of hospital admission, whereas hospital-acquired sepsis occurs after 48 hours. Healthcare-associated sepsis, a subset of community-onset sepsis, is defined as sepsis occurring in:

- patients within 30 days of hospital discharge
- nursing home residents but not those living in residential homes
- patients accessing medical treatment in the community (e.g., patients on haemodialysis).

Community-acquired infection tends to be severe and is likely to be caused by virulent but more antibiotic-sensitive organisms. Examples include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Escherichia coli*, *Klebsiella pneumoniae*, and *Neisseria meningitidis*. The most common sites of infection are the urinary tract, biliary tract, and lower respiratory tract (pneumonia); rarely, there may be infective endocarditis or meningitis.

In contrast, organisms causing ***hospital-acquired infection*** are less virulent but often multidrug resistant; they are therefore harder to treat. Examples include *Stenotrophomonas maltophilia* and *Acinetobacter baumannii*. Infection is often procedure or medical device related. The risk of procedure-related sepsis (e.g., following surgical procedures or tissue biopsy) can be minimized by appropriate antibiotic prophylaxis, and where sepsis is associated with a medical device (e.g., a blocked urinary catheter or infected intravascular catheter), this should be removed (termed 'source control').

Clinical features

Early sepsis can be difficult to diagnose. Signs and symptoms evolve in variable fashion along a continuum from those of localized infection (e.g., cough, dysuria) to more systemic evidence of organ dysfunction (e.g., confusion, oliguria, petechial haemorrhage). Some patients' organ dysfunction evolves gradually, while others may exhibit a precipitous deterioration from minor symptoms to multiorgan failure in a matter of hours. No symptom is pathognomonic but patients typically complain of rigors, breathlessness, muscle pain, vomiting, mottled skin, and a feeling of being extremely unwell, in addition to the symptoms relating to

their underlying infection. Signs correspond to those of the infective source, together with those of systemic inflammation, such as tachycardia, tachypnoea, hypotension, warm peripheries, oliguria, and confusion or drowsiness. Immunosuppressed patients may display relatively few signs and symptoms of inflammation, although those relating to the physiological response should still be present.

Investigations reveal non-specific evidence of inflammation and organ dysfunction, such as raised white cell count and CRP, rising creatinine and bilirubin, falling platelet count, possible infiltrates on chest X-ray, and dysrhythmias on the electrocardiogram (ECG). Imaging may help identify the site of infection.

Sepsis in special situations

Returning travellers

A detailed history is required, with dates of travel, areas visited, and onset of symptoms. Exposures that put travellers at risk of tropical infections (e.g., insect bites or freshwater swimming) should be elicited, and enquiry should be made as to whether patients took malaria prophylaxis or were immunized prior to travel. Assessments should be carried out for viral haemorrhagic fever (in patients with fever within 21 days of return from an endemic region) and Middle East respiratory syndrome coronavirus (MERS-CoV) (in patients with onset of respiratory symptoms within 14 days of arrival from the Middle East). Minimum investigations include blood cultures and a malaria screen, in addition to routine blood tests. The approach to a returned traveller is covered more fully in Chapter 42.

People who inject drugs

Most episodes of sepsis are related to infected thrombophlebitis or local abscesses at or around injection sites. The most common causative bacteria are meticillin-sensitive and meticillin-resistant *S. aureus* (MSSA and MRSA, respectively) and *Streptococcus pyogenes*. Occasionally, staphylococcal infections can disseminate to distant sites, including heart valves, the vertebral column, and joints (see also Chapter 42). If the tricuspid valve becomes infected, embolization to the lungs may occur, resulting in multiple lung abscesses. In addition to source control (e.g., drainage of paraspinal collections, washout of peripheral joints, and, rarely, tricuspid valve replacement), patients often require weeks of antibiotic treatment.

People who inject drugs are more prone to aspiration pneumonia or empyema because of diminished cough reflex and fluctuating levels of consciousness. Rarely, when lemon juice is used as a solvent, yeasts in the blood may cause ocular endophthalmitis. Optimal management requires vitreal amphotericin implants and prolonged antifungal treatment.

Neutropenic patients

Most commonly, sepsis occurs in haematological oncology patients post chemotherapy (see Chapter 11). Due to the risk of overwhelming pseudomonal infection, most empirical treatment includes piperacillin/tazobactam (Tazocin) with or without an aminoglycoside.

Paralysed patients

Acutely, these patients are most commonly cared for in a critical care setting. The greatest risk is that posed by medical devices (e.g., central venous catheters, urinary catheters, and endotracheal tubes). Implementation of care bundles around the placement and aftercare of such devices minimizes the risk of infection, which may be caused by multidrug-resistant organisms that, consequently, are often harder to treat. Pressure sores can be prevented by use of appropriate mattresses and regularly turning the patient. Individuals with spinal cord injuries may present with signs and symptoms of autonomic dysreflexia rather than infection if the site is below the level of injury.

MANAGEMENT OF SEPSIS

Surviving Sepsis Campaign guidelines

The cornerstones of management for sepsis are urgent treatment of the infection and support of failing organs. It is likely the patient will need to be admitted to a critical care unit in order to access specialized organ support. Suspected sepsis is a medical emergency, however, so initial treatment and resuscitation should start without delay. The Sepsis Six is a suggested bundle of care, which includes early broad-spectrum antibiotics (**Box 12.5**).

The Surviving Sepsis Campaign (SSC) produces regularly updated international guidelines on the management of sepsis and septic shock. The various recommendations and suggestions are graded according to the quality of research evidence available. The key recommendations are given in **Box 12.6**.

Supporting a failing circulation: fluid resuscitation

Fluid resuscitation is the first step in supporting organ perfusion. The SSC recommends infusing at least 30 mL/kg of crystalloid solution within 3 hours of diagnosis. Such early high-volume resuscitation is common practice in well-resourced healthcare systems. However, trial evidence is emerging that bolus resuscitation is not beneficial in all populations. Two high-quality trials conducted in low-income countries demonstrated that fluid resuscitation in patients with sepsis increased mortality, despite early improvement in indices of perfusion. Proposed explanations for these unexpected findings include lack of critical care support to counteract harmful side-effects of high-volume fluid resuscitation, and excessive reperfusion injury, which may be worse in a population that presents later in the natural history of the condition. Whether earlier initiation of vasopressor therapy (e.g., by administration of lower concentrations of noradrenaline through a peripheral cannula) while reducing fluid volumes may prove beneficial is the subject of ongoing research.

Box 12.5 The Sepsis Six

1. Give oxygen to maintain SpO_2 >94%
2. Take blood cultures
3. Give broad-spectrum intravenous antibiotics
4. Give a fluid challenge
5. Measure lactate
6. Measure urine output and chart hourly fluid balance

Box 12.6 Surviving Sepsis Campaign: main recommendations for early management

Screening
- Have systems in place to screen acutely ill high-risk patients for sepsis

Initial resuscitation
- Instigate i.v. fluid resuscitation with 30 mL/kg crystalloid within the first 3 hours
- Give further fluid guided by haemodynamic assessment and use of dynamic variables to ascertain fluid responsiveness
- Target mean arterial pressure to 65 mmHg
- Guide resuscitation to normalize lactate in patients with raised lactate

Diagnosis
- Obtain cultures before starting antibiotic treatment

Antimicrobial therapy
- Give i.v. antibiotics within 1 hour of recognition of septic shock or a high likelihood of sepsis; for patients at lower risk, a delay of up to 3 hours to enable further investigation is appropriate
- Start with broad-spectrum empirical therapy, with the aim of de-escalating once the pathogen and its sensitivities are known; assess for de-escalation daily

Source control
- Establish anatomical diagnosis and arrangements for emergency source control as soon as possible
- Remove potentially infected vascular access devices as soon as new access is obtained

Fluid therapy
- Apply a fluid challenge technique when on-going fluid administration is required
- Use balanced crystalloids (as opposed to normal saline) if available
- Consider human albumin solution in addition, when large volumes of fluid are required
- Avoid hydroxyethyl starch and gelatin-based solutions

Treating the underlying infection: antimicrobials and source control

A retrospective study of patients with sepsis found that, after the onset of hypotension, for every hour's delay in the administration of broad-spectrum antibiotics, the risk of death rose by 7.6%. More recent data from 49331 emergency department patients in New York State confirm a rise in mortality in direct proportion to the time to first antibiotic administration. This finding is biologically plausible, given that it is the microbial burden that is driving the immune response, which is, in turn, giving rise to the sepsis syndrome; however, the research underpinning these findings is fraught with difficulty (e.g., defining time zero, linearising non-linear changes). The evidence is strongest in the most unwell patients (e.g., those with septic shock), which, along with concerns about rising antimicrobial use and resistance, is the reason for increasingly nuanced recommendations for the timing of antibiotic administration in the guidelines (see above).

Not every infection can be cured with antimicrobials alone. Infected collections with an inadequate or absent blood supply, such as deep abscesses, infected prostheses, or intravascular devices, need physical removal. This process, whether it requires open surgery or percutaneous drainage, is termed source control (see later).

Useful diagnostic samples and laboratory processing

There is always time to obtain blood cultures before starting empirical antibiotic treatment. This is critical, even in an acutely septic or unstable patient. In adults a minimum of 5 mL of blood should be inoculated into both aerobic and anaerobic blood culture bottles. The one exception is in suspected meningococcal septicaemia, where antibiotic administration should never be delayed. Administration of antibiotics prior to sample collection may result in sterile blood cultures, but polymerase chain reaction (PCR) testing for bacterial DNA in whole blood may still enable detection of the causative bacterial pathogen (**Box 12.7**).

For other acute infections the ability to take further samples before antibiotics will depend on the stability of the patient. Examples include midstream urine (MSU), cerebrospinal fluid (CSF), stool, intravenous line tips, and pus. Where bacteria are cultured in pure growth, these samples can help to define sites of infection. The laboratory can also provide susceptibility data for bacteria, particularly when resistance to commonly used antibiotics is unpredictable. An example is a UTI associated with Gram-negative bacteraemia, typically with *E. coli* or *K. pneumoniae*, in which susceptibility to beta-lactams, quinolones, and aminoglycosides, often used as empirical therapy, is highly unpredictable. In stable patients whose site of infection remains undefined, imaging may reveal collections that require drainage or surgical intervention.

Culture-independent molecular methods of identifying pathogens may improve the speed and sensitivity of microbiological diagnosis, although the use of these technologies is not yet widespread (see **Box 12.7**). For example, if samples from a tissue collection are culture-negative post antibiotic exposure, they should be processed additionally for 16S PCR, a molecular test capable of identifying bacterial DNA.

In established chronic infections (e.g., diabetic foot infection, osteomyelitis, and chronic respiratory disorders), where patients rarely exhibit signs of sepsis, empirical treatment can be delayed while deep-tissue, pus, or sputum samples are obtained. Superficial swabs are rarely useful and may confuse management. Samples should always be transported to the laboratory in a timely fashion. As most results are available within 72 hours, this is the point when they may help with rationalizing antibiotic choices.

Source control

Management of infection requires not only appropriate antibiotic treatment but also an understanding of the site of infection. Occasionally, interventions at these sites are required and this is termed 'source control'. For example:
- Biomedical devices are commonly associated with infection and source control necessitates the removal of infected intravascular and urinary catheters, particularly when these are blocked.
- Obstructed biliary and urinary tract systems are common causes of sepsis and, under these circumstances, placement of a common bile duct stent, urinary catheter, or nephrostomy tube may be required.
- Intra-abdominal collections require drainage, as do empyemas and paraspinal collections.
- If a native peripheral joint is infected, an arthroscopic washout is required, and an infected prosthetic joint may require debridement and removal of the prosthesis.
- Valvectomy is increasingly used to optimize management of infective endocarditis, particularly for acute infections caused by *S. aureus.*
- Rapid surgical debridement of infected tissue is required for optimal management of monomicrobial necrotizing fasciitis caused by *S. pyogenes* or Fournier gangrene.

Box 12.7 Molecular identification of infectious agents causing sepsis

While traditional culture-based methods remain the gold standard, their disadvantages include:

- delay in obtaining results (it generally takes around 24 hours for cultures to become positive, and 48 hour for a firm bacterial identification to be made)
- the fact that cultures may be negative if antibiotics were administered before samples were taken.

Two methods have become widely accepted into clinical practice:

16S polymerase chain reaction (PCR) sequencing

- 16S ribosomal RNA is a component of the 30S small subunit of all prokaryotic ribosomes
- Due to the slow evolution of 'conserved' areas within the gene, to which DNA primers can anneal (allowing PCR amplification), sequencing of the hypervariable regions can be used to detect and speciate bacteria from a variety of clinical specimens (e.g., pus and deep tissue samples)
- Unlike culture, this diagnostic test does not provide susceptibility data but is of particular value for clinical samples that are culture-negative due to antibiotic exposure

Matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectroscopy

- Bacterial isolates are fixed in a matrix, which is then fragmented and subjected to mass spectroscopy
- Each protein-containing fragment of matrix has a different mass/charge profile, allowing a spectral profile to be generated that is unique to individual bacterial species
- Sometimes, genes conferring antibiotic resistance are detectable by MALDI-TOF, e.g., meticillin-resistant *Staphylococcus aureus* (MRSA) produces a different spectral profile to that of meticillin-sensitive *Staphylococcus aureus* (MSSA)

ANTIMICROBIAL STEWARDSHIP

Antimicrobial stewardship, or the prudent use of antibiotics, is a key component in the fight against the emergence of multidrug-resistant organisms. It is both a national and an international public health priority. In lay terms, it can be summarized as administering the right antibiotic for the right condition, given at the right dose, for the right duration.

UK-based targets

In 2017, Commissioning for Quality and Innovation (CQUIN) targets were introduced in the UK for hospital-based National Health Service (NHS) trusts. Key performance indicators (KPIs) were a reduction in total antibiotic prescribing, particularly of carbapenems and tazobactam–piperacillin (Tazocin), and a documented antibiotic review at 72 hours. In subsequent years the reduction in total prescribing and carbapenem usage targets has continued but hospital doctors are now required to specify different prescribing options at 72 hours (see later). In general practice, KPIs are based on reductions in ciprofloxacin and amoxicillin/clavulanate usage and, for uncomplicated UTIs, prescribing nitrofurantoin rather than trimethoprim (as it is more effective against common urinary pathogens, including multidrug-resistant *E. coli*).

Considerations before starting empirical antibiotics

Most hospitals will have an empirical antimicrobial policy. Policies differ, depending on the local prevalence of antimicrobial resistance to key surveillance organisms. To prescribe appropriately likeliest site of infection must be determined, based on clinical assessment and other investigations. Previous microbiology results, such as previous infection/colonization with extended-spectrum beta-lactamase (ESBL)-producing Enterobacteriaceae, may help to determine appropriate choices of antimicrobial: for example, whether or not to prescribe a carbapenem.

Considerations that should be documented when choosing an initial antibiotic regimen include:

- route of administration
- frequency
- duration of treatment
- monitoring for potential toxicity
- where appropriate, drug levels (e.g., pre-dose gentamicin or amikacin levels)
- dose adjustment in renal/hepatic failure
- need for adjuvant therapy (e.g., rifampicin or fusidic acid for severe *S. aureus* infection)
- alternative antibiotics for severe or non-severe penicillin allergy.

Antimicrobial decision-making at 72 hours

At 72 hours, when most culture results are available, one of the following five decisions should be made:

- ***Stop antibiotic treatment.*** Symptoms of sepsis, such as confusion, may be caused by many different factors. After a period of observation and review of investigations, cessation of antibiotics is the appropriate action when patients are thought not to have had an infection after all.
- ***Step down to an oral alternative.*** For uncomplicated infections, e.g., pneumonia or pyelonephritis, treatment can normally be switched from intravenous to oral after 2 to 3 days if the patient is clinically stable and is showing signs of clinical improvement.
- ***Switch treatment.*** This may be necessary because of an unanticipated site of infection (e.g., infective endocarditis requiring prolonged intravenous antibiotic treatment) or unanticipated resistance (such as urosepsis and bacteraemia caused by an ESBL-producing *E. coli* requiring treatment with an intravenous carbapenem).
- ***Continue with intravenous treatment.*** The patient has a more complicated or difficult-to-treat infection, such as meningitis or septic arthritis.
- ***Discharge on outpatient parenteral antibiotic treatment.*** This is defined as the provision of intravenous antibiotics to patients out of hospital in either the community or an ambulatory care setting. For conditions such as skin and soft tissue infection, UTIs, and bone and joint infection, where the patient is otherwise well, treatment may be continued in the community, provided proper governance arrangements are in place (see later).

Where a switch or step down to an oral alternative is made, a key component of good antimicrobial stewardship is the choice of a narrow-spectrum agent when culture results are available. This reduces the risk of *Clostridium difficile* infection and colonization with multidrug-resistant organisms and is therefore both safer for patients and cost-effective.

Outpatient parenteral antimicrobial treatment

Outpatient parenteral antimicrobial treatment (OPAT) has been cited as one of five antimicrobial prescribing decision options in UK Department of Health guidance on antibiotic stewardship after 72 hours of treatment. It may be accessed via several routes:

- through the hospital emergency or ambulatory care department, where patients can be clinically assessed, investigated, and commenced on intravenous antibiotics for conditions such as lower limb cellulitis without hospital admission; OPAT is increasingly used for admission avoidance
- following a hospital admission for infections requiring inpatient admission (such as severe community-acquired pneumonia requiring supplementary oxygen), after the patient improves clinically but still requires intravenous antibiotics
- following a hospital admission required for source control (e.g., surgical removal of an infected joint prosthesis); OPAT is an option for carefully selected groups of patients, as it allows hospital discharge earlier than expected.

OPAT is associated with high levels of patient satisfaction, as most prefer to be treated out of hospital. Because there is less clinical supervision, governance arrangements around patient care are important, and clinical guidelines, published in both the UK and USA, should be complied with.

Conditions suitable for OPAT services

Skin and soft tissue infections—in particular, lower limb cellulitis—are the most common medical conditions referred to OPAT services. Patients are typically treated for 3 to 5 days with intravenous antibiotics but those with lymphoedema or underlying skin conditions typically require longer courses. Increasingly, multidrug-resistant UTIs may be treated in the community with intravenous antibiotics, and patients may be recruited for OPAT by direct laboratory referral after a multi-resistant organism is grown. Those with bone and joint infection, such as vertebral osteomyelitis or native or prosthetic joint infection, invariably require prolonged intravenous antibiotic courses. Other conditions suitable for OPAT include infected diabetic foot ulcers (with or without osteomyelitis), infective endocarditis, empyema, and abscesses of the brain and liver, once patients are deemed clinically stable.

The suitability of a patient to receive OPAT needs careful assessment and is dependent on age, co-morbidities, and severity of infection. OPAT also requires patients to engage reliably with therapy. Therefore intravenous drug users and patients with serious mental health problems are generally not suitable.

Delivery of OPAT services

Commonly used antibiotics are given once daily and reduce nursing time, although some teams can administer intravenous antibiotics up to four times per day. Examples of antibiotics suitable for once-daily dosing include ceftriaxone, ertapenem, amikacin, teicoplanin, and daptomycin. Some services deliver the first dose of antibiotic in hospital where resuscitation equipment is at hand in the event of allergic reaction, but many now give the first dose of intravenous antibiotics in the community to low-risk individuals. OPAT teams may need to monitor drug levels (e.g., pre-dose teicoplanin levels for efficacy, or pre-dose amikacin levels for nephrotoxicity). For most intravenous antibiotics, full blood count, urea and electrolytes, CRP, and liver function tests should be monitored on a weekly basis at least.

Antibiotics can be administered through a peripheral intravenous cannula, but for longer durations of treatment (>7 days), administration through a Hickman line or a peripherally inserted central catheter (PICC) is preferable. Insertion by a suitably trained healthcare professional or interventional radiologist reduces the risk of line infection. Patients can also be taught to self-administer or attach 'infusion devices', commonly known as elastomeric devices, which save district nurse time.

There are different models for delivering OPAT services. These are ***community-based*** (nurses deliver treatment within the patient's home) or ***hospital-based*** (patients attend hospital or an ambulatory care centre on a daily basis for intravenous antibiotic treatment). Ideally, an OPAT multidisciplinary team should consist of doctors, hospital-based nurses, community nurses, and a pharmacist.

Monitoring patients in OPAT services

Patients must be appropriately monitored with clinical assessments, blood tests, and, where relevant, imaging at appropriate intervals. In the UK, some NHS trusts capture patients on 'virtual wards', which facilitates clinical ownership and follow-up. Good practice includes regular multidisciplinary team meetings (where cases are discussed with an infection specialist), the taking of blood tests, and organization of other investigations. While many conditions can be managed exclusively by a clinical microbiologist or ID physician, joint care is required for orthopaedic or neurosurgical cases. The treatment of lower limb cellulitis can be managed by nurses and requires minimal involvement from medical staff.

Strict governance arrangements are required for OPAT services to help mitigate risk from the reduced level of clinical supervision. Adverse drug reactions are not uncommonly reported and central venous access can be associated with access site infections and thrombophlebitis. Overuse of broad-spectrum intravenous antibiotics can be associated with *C. difficile* infection and, depending on the condition being treated, relapse and hospital re-admission can occur. There should therefore be formal re-admission pathways to secondary care. Evidence suggests that OPAT is safe, provided it is administered through a formal service, designed to minimize risk, with doctors and nurses working together across primary and secondary care. OPAT services are expanding across the UK, driven by good safety data, high levels of patient satisfaction, and healthcare efficiencies.

Assessment of allergy risk

Around 10% of the population report a history of penicillin allergy but data show that the true figure is only around 1%. In some infections, penicillins are the first-choice antibiotic and other agents are associated with a worse outcome.

Anaphylaxis to penicillins or any antibiotic can be fatal, so careful evaluation is required. The timing of the reaction is of paramount importance:

- ***Immediate hypersensitivity reactions***, which include anaphylaxis, are immunoglobulin E (IgE)-mediated and classically begin within 1 hour of the dose, and often within minutes. Typically, they are characterized by facial swelling, rash, and severe shortness of breath.

- ***Delayed reactions*** appear after multiple doses of treatment, typically after days or weeks. While they may be immune mediated, they are not associated with anaphylaxis, although in some rare cases they can lead to severe or life-threatening conditions such as Stevens–Johnson syndrome and toxic epidermal necrolysis (see Chapter 11).

When a patient reports an antibiotic allergy the following information should be ascertained:

- the name(s) of the antibiotic(s) they report an allergy to
- the timing between starting the antibiotic and the symptoms or signs
- the nature of the symptoms or signs, asking specifically about rash, wheeze, swelling, and loss of consciousness
- time to resolution of the symptoms
- whether they tried the same or similar antibiotics since.

Severe allergy is typically a hypersensitivity reaction but occasionally can also be a delayed reaction. In type 1 (IgE-mediated allergy, Chapter 6) and other severe penicillin allergies, cephalosporins and carbapenems should also be avoided.

Non-severe allergy is typically non-IgE mediated and is commonly described as a mild rash. In these circumstances, cephalosporins, carbapenems, and monobactams can be cautiously used. Other antibiotic classes are safe alternatives.

Selected patients reporting a penicillin allergy should be referred to allergy services for formal testing. These include:

- patients with a history of an allergic reaction when on multiple drugs, e.g., during general anaesthesia
- patients allergic to multiple antibiotics
- patients for whom there is no reliable alternative antibiotic
- patients in whom there is a current requirement for a prolonged course of antibiotics and an allergy to 'gold standard' treatment
- patients with an absolute requirement for penicillin, e.g., those with central nervous system syphilis, immunodeficiency, or cardiac valve disorders requiring prophylaxis, or post splenectomy
- patients likely to need repeated courses of antibiotics, e.g., those with haematological malignancies, cystic fibrosis, or inflammatory bowel disease.

It is possible to desensitize patients with carefully introduced, gradually increasing doses of specific antibiotics. For example, a well-recognized protocol for co-trimoxazole sensitization has been used since the late 1990s.

Antibiotic chemoprophylaxis

The value of antibiotic chemoprophylaxis has been questioned, as there are relatively few controlled trials to prove efficacy. The evidence for chemoprophylaxis against infective endocarditis is an example. National Institute for Health and Care Excellence (NICE) guidelines recognize that procedures can cause bacteraemia but without a significant risk of infective endocarditis. Even patients at 'high risk', such as those with previous infectious endocarditis, prosthetic heart valves, and surgical shunts, do not always require prophylaxis (**Box 12.8**). However, there are a number of indications for which the prophylactic use of antibiotics is still advised. These

i Box 12.8 Antibiotic chemoprophylaxis

Clinical problem	Aim	Drug regimen[a]
General		
Splenectomy/spleen malfunction	To prevent serious pneumococcal sepsis	Phenoxymethylpenicillin 500 mg twice daily
Rheumatic fever	To prevent recurrence and further cardiac damage	Phenoxymethylpenicillin 250 mg twice daily or sulfadiazine 1 g if allergic to penicillin
Meningitis:		
Due to meningococci	To prevent infection in close contacts	Adults: rifampicin 600 mg twice daily for 2 days Children: <1 year: 5 mg/kg; >1 year: 10 mg/kg Alternative (single-dose) ciprofloxacin 500 mg (p.o.) or ceftriaxone 250 mg (i.m.)
Due to *Haemophilus influenzae* type b	To reduce nasopharyngeal carriage and prevent infection in close contacts	Adults: rifampicin 600 mg daily for 4 days Children: <3 months 10 mg/kg; >3 months 20 mg/kg
Tuberculosis	To prevent infection in exposed (close contacts) tuberculin-negative individuals, infants of infected mothers, and immunosuppressed patients	Oral isoniazid 300 mg daily for 6 months Children: 5–10 mg/kg daily
Endocarditis[b]		
Antibacterial prophylaxis and chlorhexidine mouthwash are *not* recommended for the prevention of endocarditis in patients undergoing dental procedures		
Antibacterial prophylaxis is *not* recommended for the prevention of endocarditis in patients undergoing procedures of the: upper and lower respiratory tract (including ear, nose, and throat procedures and bronchoscopy) genitourinary tract (including urological, gynaecological, and obstetric procedures) upper and lower gastrointestinal tract		
Any infection in patients at risk of endocarditis should be investigated promptly and treated appropriately to reduce the risk of endocarditis		
If patients at risk of endocarditis are undergoing a gastrointestinal or genitourinary tract procedure at a site where infection is suspected, they should receive appropriate antibacterial therapy that includes cover against organisms that cause endocarditis		
Patients at risk of endocarditis should be: advised to maintain good oral hygiene told how to recognize signs of infective endocarditis and advised when to seek expert advice		

[a]Unless stated, doses are those recommended in adults. For surgical procedure, see individual procedures in text.
[b]NICE guidelines for adults and children undergoing interventional procedures, March 2008, updated in 2016.
(Adapted from Joint Formulary Committee. British National Formulary, *70th edn. London: BMJ Group and RPS Publishing; 2015.)*

include surgical procedures carrying a high risk of infection (i.e., colon surgery) or with potentially serious consequences of infection (organ transplantation, post-splenectomy sepsis). The choice of agent(s) is determined by the likely infectious risk and the established efficacy and safety of the regimen. Antibiotic prophylaxis for the vast majority of surgical or radiological procedures should not extend for more than 24 hours post procedure and, for most operations, a single dose at induction is all that is required.

ANTIBIOTIC THERAPIES

Timely administration of antibiotics that are active against the infecting pathogen is critical in the effective management of sepsis. Delays in administration of antimicrobial therapy are well documented as having an impact on the survival and outcome of patients with septic shock.

The selection of an antibiotic requires knowledge of its spectrum of antimicrobial activity (**Fig. 12.2**) as well as standard pharmacokinetic considerations of absorption, distribution, metabolism, and excretion (see Chapter 7). Empirical antibiotic prescribing (prior to the availability of microbiological cultures with antibiotic sensitivities) also requires knowledge of the likely culprit organisms determined by infection site and the corresponding recognized antibiotic options (**Box 12.9**). Parenteral administration is usually indicated in the severely ill patient to ensure rapid, high, and consistent blood and tissue concentrations. Whether an antibiotic is able to kill bacteria (bactericidal) or can only inhibit the growth of the organism (bacteriostatic) at the infection site is another factor used for antibiotic selection.

Antibiotics commonly used in the treatment of sepsis

Beta-lactams (penicillins, cephalosporins, monobactams) and carbapenems

Beta-lactams are the most widely used antimicrobials in human medicine. They are naturally derived compounds that share a common ring structure. Modifications to the β-lactam ring and/or the side-chain may expand the antimicrobial spectrum to include many Gram-negative and positive organisms. Following the discovery of penicillin, dozens of β-lactam-based drugs (first to fifth generations) have been developed for clinical use, either from bacterial or fungal sources (e.g., cephalosporins, carbapenems) or by chemical engineering of the β-lactam ring. All β-lactams block bacterial cell-wall synthesis by binding to and inactivating specific penicillin-binding proteins, peptidases, which are involved in the final stages of cell-wall assembly and division. They are generally bactericidal to susceptible bacterial cells in a time-dependent manner.

Many bacteria produce β-lactamase enzymes, which inactivate antibiotics of this class. The emergence of Gram-negative organisms producing extended-spectrum β-lactamases (ESBLs) and carbapenemases (see below) has rendered some bacteria resistant to all β-lactams.

Penicillins

Benzylpenicillin can only be given parenterally and is still the drug of choice for some serious infections. However, due to increasing antimicrobial resistance, it should not be used empirically in serious infections without laboratory confirmation that the organism is penicillin sensitive. Uses include serious streptococcal infections (including infective endocarditis), group A streptococcus *(S. pyogenes)* necrotizing fasciitis, and gas gangrene (usually combined with other antibiotics).

Flucloxacillin is used in infections caused by penicillinase-producing staphylococci and remains the drug of choice for serious infections caused by MSSA.

Amoxicillin is susceptible to β-lactamase but its antimicrobial activity includes streptococci, pneumococci, and enterococci, as well as Gram-negative organisms such as *Salmonella* spp., *Shigella* spp., *E. coli*, *Haemophilus influenzae*, and *Proteus* spp. The extended-spectrum penicillin ***ticarcillin*** is active against Pseudomonas infections, as is the acylureidopenicillin ***piperacillin*** in combination with tazobactam (Tazocin).

Pivmecillinam is used for the treatment of UTI and has activity against Gram-negative bacteria, including ESBL-producing *E. coli*, *Klebsiella*, *Enterobacter*, and *Salmonella* spp. but not *Pseudomonas aeruginosa*.

Temocillin is active against Gram-negative bacteria only, including many ESBL producers. It appears to be less relatively likely to trigger *C. difficile* infection and is increasingly used because of resistance but also as a carbapenem-sparing agent. It is not active against *Pseudomonas* or *Acinetobacter* spp.

Generally, the penicillins are safe. Hypersensitivity (skin rash, urticaria, and anaphylaxis), encephalopathy, and tubulointerstitial nephritis can occur. Amoxicillin and ampicillin produce a hypersensitivity rash in approximately 90% of patients with infectious mononucleosis (glandular fever) who receive this drug. Amoxicillin/clavulanate (co-amoxiclav) (see below) causes cholestatic jaundice six times more frequently than amoxicillin, as does flucloxacillin.

Cephalosporins

The cephalosporins (**Fig. 12.3**) have an advantage over penicillins in that they are not inactivated by staphylococcal penicillinases. Except for the newer fifth-generation cephalosporins ***ceftaroline*** and ***ceftobiprole***, they are not active against MRSA. Activity extends to many Gram-negative and positive organisms, except for enterococci and Gram-negative anaerobic bacteria. Only certain cephalosporins (e.g., ***ceftazidime*** and ***cefepime***) are active against *P. aeruginosa*.

Second- and third-generation cephalosporins are reserved for the treatment of specific serious infections, as empirical use against Gram-negative infections can be rendered ineffective due to ESBL production and has been associated with an increased risk of *C. difficile* infection.

The toxicity is similar to that of the penicillins but is less commonly encountered. Some 10% of patients allergic to one group are also allergic to the other. The early cephalosporins caused proximal tubule damage, although the newer derivatives have fewer nephrotoxic effects.

Monobactams

Aztreonam is the only member of this class available. It is a synthetic β-lactam and, unlike the penicillins and cephalosporins, has no ring other than the β-lactam one: hence its description as a monobactam. Aztreonam spectrum of activity is limited to aerobic Gram-negative bacilli. It is a useful alternative to aminoglycosides in combination therapy, largely for the treatment of intra-abdominal sepsis, as it has activity against some carbapenem-resistant strains

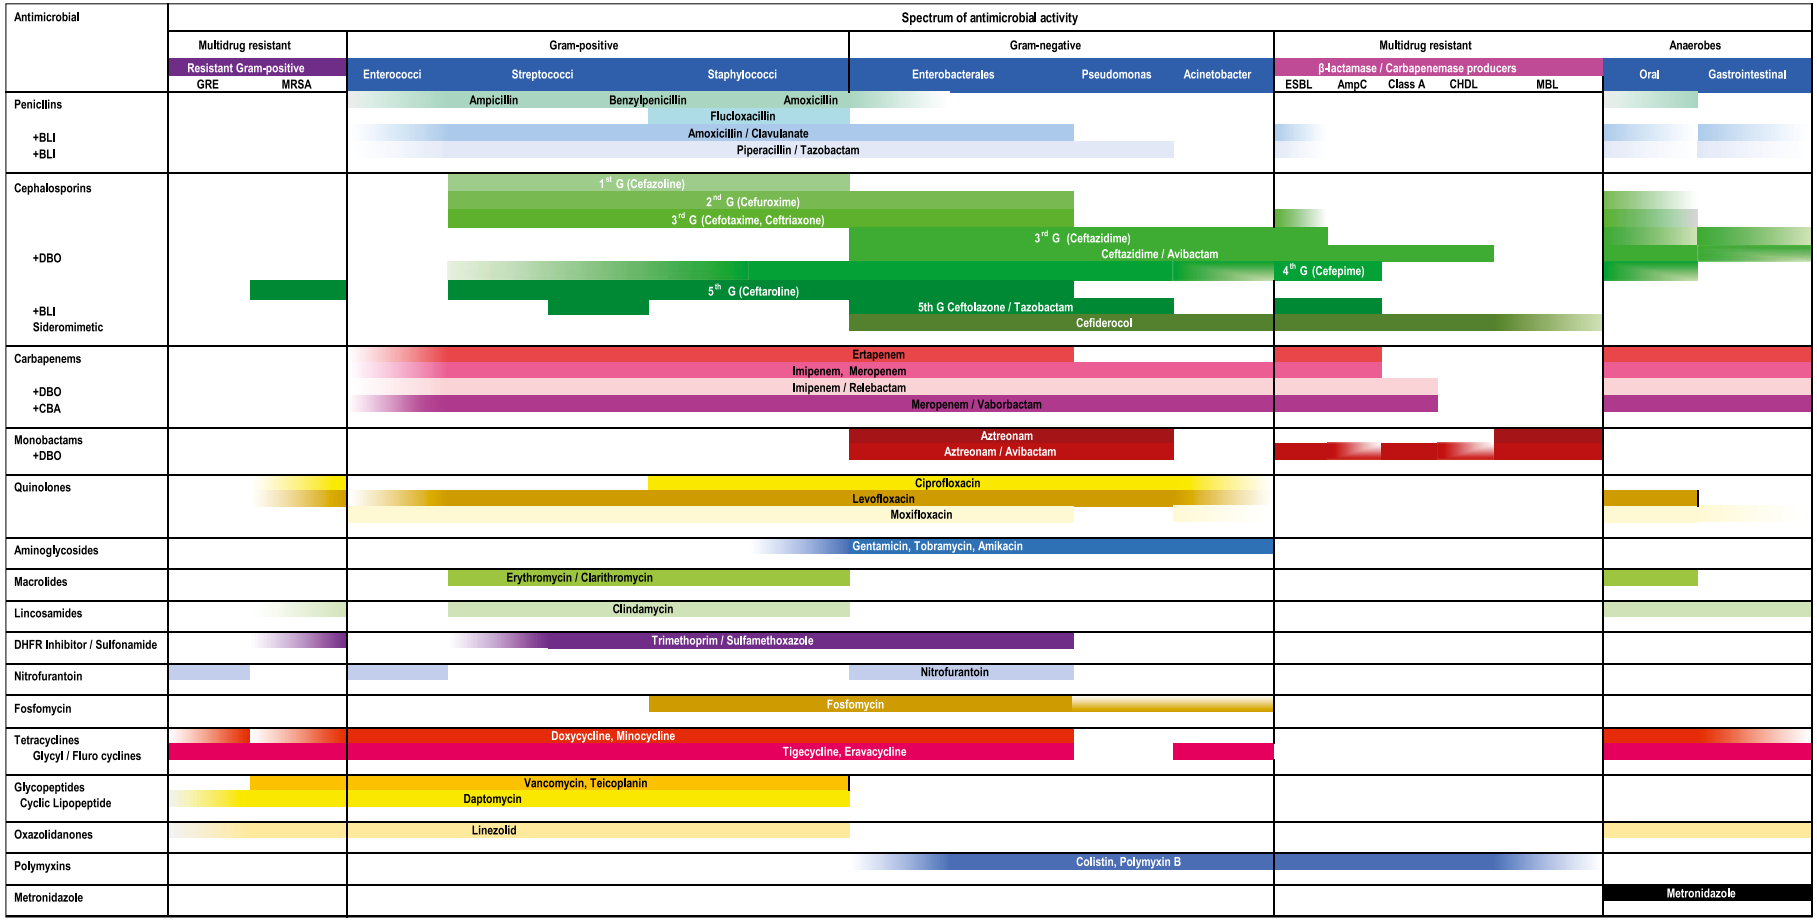

Fig. 12.2 The spectrum of antimicrobial activity. *1st 5th G,* Generation; *BLI,* β-lactamase inhibitor; *CBA,* cyclic boronic acid; *CHDL,* carbapenem-hydrolyzing class D β-lactmase; *DBO,* diazabicyclooctane (a non-β-lactam BLI); *DHFR,* dihydrofolate reductase; *ESBL,* extended-spectrum β-lactamase; *GRE,* glycopeptide-resistant *Enterococcus*; *MBL,* metallo-β-lactamase; *MRSA,* meticillin-resistant *Staphylococcus aureus*.

Box 12.9 Clinical uses of antibiotics

		SSTI	CAP	HAP	UTI	Meningitis	Other uses/notes
PENICILLINS	Benzylpenicillin	+	+			+	
	Amoxicillin		+		+		
	Flucloxacillin	+					Susceptible staphylococcal infections
	Amoxicillin/clavulanate	+	+	+	+		Pyelonephritis, abdominal infections
	Piperacillin/tazobactam	+	+	+	+		Pyelonephritis, abdominal infections, septicaemia
CEPHALOSPORINS	1st G cephalosporins (cefazoline)	+					Surgical prophylaxis
	2nd G cephalosporins (cefotaxime)	+	+	+	+		Pyelonephritis, abdominal infections, surgical prophylaxis
	3rd G cephalosporins (ceftazidime)				+	+	UTI, susceptible Gram-positive and Gram-negative infections
	Ceftazidime/avibactam			+	+		VAP, abdominal infections, susceptible Gram-negative infections
	4th G cephalosporins (cefepime)				+	+	Susceptible Gram-positive and Gram-negative infections
	5th G cephalosporins (ceftaroline)	+	+				
	Ceftolazone/tazobactam			+	+		VAP, abdominal infections
	Cefiderocol						MDR Gram-negative infections with limited treatment options
CARBAPENEMS	Ertapenem	+	+				Abdominal infections
	Meropenem						Susceptible Gram-positive and Gram-negative infections, hospital-acquired sepsis
	Imipenem/relebactam						MDR Gram-negative infections with limited treatment Options
	Meropenem/vaborbactam			+	+		VAP, Gram-negative infections with limited treatment options
MONOBACTAMS	Aztreonam				+		Severe Gram-negative infections
	Aztreonam/avibactam						MDR Gram-negative infections with limited treatment options
QUINOLONES	Ciprofloxacin				+		VAP, pseudomonas infections
	Levofloxacin	+	+	+	+		
	Moxifloxacin	+	+				
AMINOGLYCOSIDES	Aminoglycosides (e.g., gentamicin)				+		Septicaemia
MACROLIDES	Clarithromycin	+	+				
	Clindamycin	+					Abdominal infections
TRIMETHOPRIM	Trimethoprim/ sulfamethoxazole	+			+		
NITROFURANTOIN	Nitrofurantoin				+		
FOSFOMYCIN	Fosfomycin				+		Osteomyelitis
TETRACYCLINES	Doxycycline	+		+			
	Tigecycline	+					Abdominal infections
GLYCOPEPTIDES	Vancomycin	+	+	+			
	Daptomycin	+					Endocarditis
OXAZOLIDINONES	Linezolid	+	+				
POLYMYXINS	Colistin						MDR Gram-negative infections with limited treatment options
METRONIDAZOLE	Metronidazole						Anaerobic infections

The table should not be considered exhaustive guidance for use in clinical practice and does not replace specific local, national, or regional guidelines. Guidance on licensed indications and clinical dosing regimens can be found in the British National Formulary (BNF) | NICE and European Committee on Antimicrobial Susceptibility Testing (EUCAST): Clinical breakpoints and dosing of antibiotics.

1st 5th G, Generation; *CAP,* community-acquired pneumonia; *DHFR,* dihydrofolate reductase; *HAP,* hospital-acquired pneumonia; *MDR,* multidrug resistant; *SSTI,* skin and skin structure infection; *UTI,* urinary tract infection; *VAP,* ventilator-acquired pneumonia.

that produce metallo-β-lactamases. It is also used in *P. aeruginosa* infection (including lung infection in cystic fibrosis).

Carbapenems

The carbapenems are semi-synthetic β-lactams and include ***imipenem***, ***meropenem***, ***doripenem***, and ***ertapenem***. They currently have the broadest spectrum of the antibiotics, being active against the majority of Gram-positive, Gram-negative, and anaerobic bacterial pathogens (but not against MRSA). Ertapenem, unlike the others, is not active against *Pseudomonas* or *Acinetobacter* spp. They differ in their dosage and frequency of administration. Imipenem is partially inactivated in the kidney by enzymatic inactivation and is therefore administered in combination with cilastatin.

Carbapenems are the mainstay of treatment for severe ESBL-producing Gram-negative infections (e.g., urinary tract or biliary tract sepsis) and are also used for severe hospital-acquired infections when multidrug-resistant Gram-negative bacilli or mixed aerobic and anaerobic infections are suspected.

Their side-effect profile is similar to that of β-lactam antibiotics. Nausea, vomiting, and diarrhoea occur in less than 5% of cases. Imipenem and ertapenem may cause seizures and should not be used to treat meningitis. Meropenem is safe for this indication.

β-lactam/β-lactamase inhibitor combinations

One approach to the problem of β-lactamase-mediated resistance is to combine β-lactams with 'inhibitor' molecules (BLIs). Classical 'inhibitors' include clavulanic acid, sulbactam and tazobactam given in combination with amoxicillin (amoxicillin/clavulanate), ticarcillin (ticarcillin/clavulanate), ampicillin (ampicillin/sulbactam), piperacillin (piperacillin/tazobactam), and ceftolozane (ceftolozane/tazobactam). These BLIs are themselves β-lactams and act as inhibitors by protecting the partner molecule as suicide compounds that are more readily hydrolysed than the active compound, preserving its antimicrobial activity.

Avibactam is the first non-β-lactam inhibitor of β-lactamase enzymes; it has recently been developed and combined with ceftazidime (ceftazidime/avibactam). The combination appears to be stable to most ESBLs and some carbapenemase (KPC, OXA-48) enzymes in Enterobacterales.

Quinolones

The quinolone group of drugs inhibits bacterial DNA synthesis by inhibiting topoisomerase i.v. and DNA gyrase, the enzymes responsible for maintaining the super-helical twists in DNA.

Extended-spectrum quinolones such as ***ciprofloxacin*** have activity against Gram-negative bacteria, including *P. aeruginosa*, and some Gram-positive bacteria. They are useful in Gram-negative bloodstream infections, bone and joint infections, urinary and respiratory tract infections, meningococcal carriage, some sexually transmitted diseases such as gonorrhoea and non-specific urethritis due to *Chlamydia trachomatis*, as well as in severe cases of travellers' diarrhoea. The newer oral quinolones (e.g., ***levofloxacin***, ***moxifloxacin***) provide an alternative to β-lactams in the treatment of community-acquired lower respiratory tract infections and are effective against *S. pneumoniae*, *H. influenzae*, and the 'atypical' respiratory pathogens. They can also be used in the treatment of tuberculosis.

In many countries a high proportion of *E. coli* and *Klebsiella* spp. are now resistant (>80%). Resistance is also an emerging problem among *Salmonella*, *Vibrio cholerae*, *S. pneumoniae*, and *S. aureus*.

Gastrointestinal disturbances, photosensitive rashes, and occasional neurotoxicity can occur. Use should be avoided in pregnancy and childhood, and in patients taking corticosteroids (due to increased risk of tendinitis), unless the benefit outweighs the risk. Tendon damage, including rupture, can occur within 48 hours of use. MRSA and *C. difficile* infections in hospitals have been linked to high prescribing rates of quinolones, particularly when the O27 hypervirulent strain of *C. difficile* was endemic in most UK hospitals. Use is discouraged where an effective alternative is available. There is concern about QTc prolongation, and concomitant prescribing with other QTc prolongation drugs should be avoided whenever possible.

Aminoglycosides

Aminoglycosides (Fig. 12.4) interrupt bacterial protein synthesis by inhibiting ribosomal function (messenger RNA reading and transfer RNA binding). ***Gentamicin*** and ***tobramycin*** are given parenterally. They are highly effective against many Gram-negative organisms, including *Pseudomonas* spp. They are synergistic at low doses with penicillins against *Enterococcus* spp. and *Streptococcus viridans* and are therefore often used in endocarditis. ***Amikacin*** has a similar spectrum but is more resistant to the aminoglycoside-modifying enzymes (phosphorylating, adenylating, or acetylating) produced by some bacteria, in particular ESBL-producing Enterobacterales. Its use should be restricted to gentamicin-resistant organisms.

Dose-related nephrotoxicity and ototoxicity (vestibular and auditory) can occur, particularly in the elderly. Enhanced nephrotoxicity occurs with other nephrotoxic drugs, and enhanced ototoxicity with some diuretics. The m.1555A > G mutation has been associated with gentamicin ototoxicity but appears to occur in less than 1% of the general population. Monitoring is necessary to ensure therapeutic and non-toxic drug concentrations. Once-daily dosing is used for most indications, with a serum drug level taken at 6 to 14 hours post dose, followed by application of an appropriate nomogram to determine the subsequent frequency of dosing (e.g., every 24 or 48 hours). When aminoglycosides are used for endocarditis, low doses are prescribed every 12 hours with different target pre- and post-dose level ranges than for once-daily dosing. Alternatively, and more simply, a pre-dose level can be checked prior to drug administration and appropriate drug adjustments made with subsequent doses. Neuromuscular blockade can occur with curariform drugs and aminoglycosides should be avoided in patients with myasthenia gravis.

Glycopeptides

The glycopeptides are active against Gram-positive bacteria and act by inhibiting cell-wall synthesis.

Vancomycin is given intravenously for MRSA and other multiresistant, Gram-positive organisms. It is only slowly bactericidal (in contrast to β-lactams). It is also used for treatment of and prophylaxis against Gram-positive infections in penicillin-allergic patients. It is given in *S. pneumoniae* meningitis, in combination with other

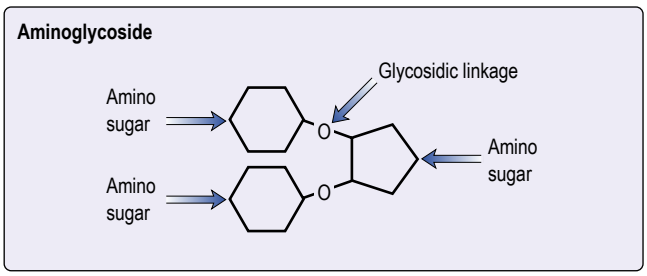

Fig. 12.4 The structure of an aminoglycoside.

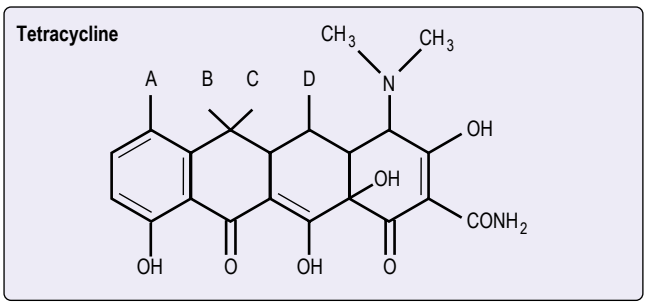

Fig. 12.5 The structure of a tetracycline. Substitution of CH_3, OH, or H at positions A–D produces variants of tetracycline.

effective antibiotics, when disease is caused by penicillin-resistant strains.

Vancomycin can cause ototoxicity and nephrotoxicity, and thus pre-dose (trough) serum levels should be monitored regularly. Serum levels at 1 hour post dose (peak) are also monitored to optimize drug efficacy. Care must be taken to avoid extravasation at the injection site, as this causes necrosis and thrombophlebitis. Too rapid infusion can produce symptomatic release of histamine (red man syndrome).

Teicoplanin is less nephrotoxic than vancomycin. It has more favourable pharmacokinetic properties, allowing once-daily or thrice-weekly dosage. It is given intravenously and pre-dose (trough) serum levels are monitored to optimize efficacy.

Lipopeptides

Daptomycin is a lipopeptide with a similar spectrum to that of vancomycin and is given by the intravenous route. It is used particularly for complicated skin and soft tissue infections, including those caused by MRSA, and is also a useful alternative agent for endocarditis, bone and joint infections, and Gram-positive bloodstream infections. Lipopeptides with very long elimination times, such as ***dalbavancin***, are used as single-dose therapies for skin and soft tissue infections.

Oxazolidinones

Linezolid was the first oxazolidinone antibacterial to be developed. ***Tedizolid*** has recently been approved for use in skin and skin structure infections. These drugs act by inhibiting protein synthesis, binding to the bacterial 23S ribosomal RNA of the 59S subunit, thereby preventing the formation of a functional 70S complex that is essential to bacterial translation.

Oxazolidinones are active against a variety of Gram-positive pathogens, including vancomycin-resistant *Enterococcus faecium* (although resistant organisms have been reported), MRSA, and penicillin-resistant *S. pneumoniae*. They are also active against group A and group B streptococci. Clinical experience with linezolid has demonstrated efficacy in a variety of hospitalized patients with severe to life-threatening infections, including bacteraemia, hospital-acquired pneumonia, skin and soft tissue infection, and bone and joint infection. These drugs can be given both intravenously and by mouth and are almost 100% bioavailable by the oral route in patients with normal gastrointestinal absorption.

Oxazolidinones interact reversibly as non-selective inhibitors of monoamine oxidase and have the potential for interacting with serotoninergic and adrenergic agents. Side-effects include gastrointestinal disturbances, headache, rash, hypertension, reversible but potentially severe cytopenias, and occasional reports of optic and peripheral neuropathy in patients receiving linezolid for longer than 28 days. Tedizolid is less myelotoxic and can also be given once daily (in contrast to twice-daily linezolid). Weekly monitoring of the full blood count for cytopenias, and for other serious adverse effects, is mandatory. Safety has not yet been shown in pregnancy but linezolid has been used successfully for serious infections in children.

Tetracyclines

These are bacteriostatic drugs possessing a four-ring hydronaphthacene nucleus (Fig. 12.5). Included among the tetracyclines are ***tetracycline***, ***oxytetracycline***, ***doxycycline***, and ***minocycline***. ***Tigecycline*** is an injectable glycylcycline that is structurally related to the tetracyclines.

Tetracyclines inhibit bacterial protein synthesis by interrupting ribosomal function (transfer RNA binding) and are active against Gram-positive and Gram-negative bacteria. Tigecycline is active against many organisms resistant to tetracycline, as it avoids common bacterial efflux pump systems. This includes vancomycin-resistant enterococci (VRE), MRSA, and Gram-negative bacilli, such as *Acinetobacter baumannii*, but not *Pseudomonas* or *Proteus* spp. Tigecycline is increasingly used in combination with other antibiotics (e.g., polymyxins) to treat infections caused by highly resistant, carbapenemase-producing, Gram-negative bacteria. The licensed indications are complicated skin and soft tissue infections and intra-abdominal sepsis. Tigecycline is also used to treat spirochaetal and rickettsial infections and also has a role as malaria prophylaxis. However, a 2010 US Food and Drug Administration (FDA) alert raised concerns about the efficacy of tigecycline in some serious infections (notably ventilator-associated pneumonia) and it should be used only on expert advice. The efficacy of tetracyclines is reduced by antacids and oral iron-replacement therapy.

Tetracyclines are generally safe drugs but they may enhance established or incipient renal failure, although doxycycline is safer than others in this group. They cause brown discoloration of growing teeth and thus are not given to children or pregnant women. Photosensitivity occurs in approximately 1 in 20 patients. Nausea and vomiting are the most frequent adverse effects of tigecycline.

Macrolides

Macrolides inhibit protein synthesis by interrupting ribosomal function. ***Erythromycin*** has a similar (but not identical) antibacterial spectrum to that of penicillin and may be useful in individuals with penicillin allergy, especially in the management of bacterial respiratory infections. It can be given orally or parenterally, but oral intake is associated with significant gastrointestinal side-effects, while the intravenous formulation is very irritant and causes phlebitis. For these reasons, ***clarithromycin*** (which has similar antimicrobial properties but fewer side-effects) is often preferred. These drugs are useful in the treatment of pneumonias caused by *Legionella* and *Mycoplasma* spp. They are also effective in the treatment of

infections due to *Bordetella pertussis* (whooping cough), *Campylobacter*, and *Chlamydia* spp. Macrolides are otherwise not usually used for life-threatening or serious infections, such as endocarditis and meningitis.

Other macrolides include ***azithromycin*** and ***telithromycin***. They have a broad spectrum of activity that covers selective Gram-negative organisms *(Salmonella, Shigella)*. Compared with erythromycin, they have superior pharmacokinetic properties with enhanced tissue and intracellular penetration and a longer half-life that allows once-daily dosage. Concern has been raised about the use of azithromycin in bloodstream infections (bacteraemia) because of low serum bioavailability. Azithromycin is also employed for trachoma, cholera, and some sexually transmitted infections.

Erythromycin and other macrolides interact with theophyllines, carbamazepine, digoxin, and calcineurin inhibitors (e.g., ciclosporin), occasionally necessitating dose adjustment of these agents. Diarrhoea, vomiting, and abdominal pain are the main side-effects of erythromycin (less so with clarithromycin and azithromycin) as a consequence of the intestinal prokinetic properties of the macrolides. QTc prolongation is a recognized cardiac effect of the macrolides and may lead to the potentially life-threatening syndrome of 'torsades de pointes' (see Chapter 17). Concomitant use of other drugs that cause QTc prolongation should be avoided unless absolutely essential.

Polymyxins (polymyxin B, colistimethate sodium [polymyxin E])

This is an old antibiotic class that, until recently, was rarely used in clinical practice because of concerns about neuro- and nephrotoxicity. The emergence of multidrug-resistant Gram-negative bacteria, in particular carbapenemase-producing Enterobacterales, has resulted in the increased use of drugs in this class as an agent of last resort, often in combination with other antibiotics. Colistimethate sodium (CMS) is an inactive prodrug, metabolized *in vivo* to the active component ***colistin***. This complicates dosing strategies and increases the potential for toxicity. The mechanism of bacterial killing of polymyxins is thought to be disruption of the bacterial cell membrane following binding to the lipopolysaccharide (LPS) component. They are active against most Gram-negative bacilli (except *Proteus* and *Providencia* spp.) and are administered intravenously for serious infections. Plasmid-mediated resistance, due to the MCR-1 phosphoethanolamine enzyme that modifies bacterial LPS, has recently been described, although mostly in veterinary strains in South and South-east Asia.

Sodium fusidate

Sodium fusidate has a structure resembling that of bile salts and is a potent inhibitor of bacterial protein synthesis. Its entry into cells is facilitated by the detergent properties inherent in its structure. It is mainly used for penicillinase-producing *S. aureus* infections, such as osteomyelitis (it is well concentrated in bone) or endocarditis, and as an adjunctive agent for other staphylococcal infections accompanied by septicaemia. The drug is well absorbed orally but must be given in combination with another staphylococcal agent to prevent resistance, which may occur rapidly.

Sodium fusidate commonly causes gastrointestinal adverse effects and may occasionally be hepatotoxic; however, it is generally a safe drug and can be given during pregnancy if necessary. Concomitant statin use is avoided. Sodium fusidate is also available in topical preparations for use in minor skin conditions (impetigo) but these should be avoided to limit the risk of emerging resistance.

Sulphonamides and trimethoprim

The sulphonamides are all derivatives of the prototype sulfanilamide and act by blocking thymidine and purine synthesis by inhibiting microbial folic acid synthesis. Trimethoprim is a 2,4-diaminopyrimidine, which prevents the bacterial reduction of dihydrofolate to tetrahydrofolate.

Sulfamethoxazole is mainly used in combination with trimethoprim (as ***co-trimoxazole***). Because of its adverse effect profile, use in high-income countries was largely restricted to the treatment and prevention of *Pneumocystis jirovecii* infection and listeriosis; however, it is increasingly being prescribed in hospitals again for other infections, such as acute exacerbations of chronic bronchitis and UTI, as it appears to carry a relatively lower risk for triggering *C. difficile* infection and remains useful for some resistant Gram-negative infections. It may also be given for toxoplasmosis and nocardiosis. ***Trimethoprim*** alone is often used for empirical treatment of UTIs.

Resistance to sulphonamides is often plasmid-mediated and results from the production of a sulphonamide-resistant dihydropteroate synthase. Sulphonamides potentiate oral anticoagulants and some hypoglycaemic agents.

The adverse effects of co-trimoxazole are most commonly due to the sulphonamide component. Sulphonamides cause a variety of skin eruptions, including toxic epidermal necrolysis, the Stevens–Johnson syndrome, thrombocytopenia, folate deficiency, and megaloblastic anaemia, with prolonged usage. They can provoke haemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency and therefore should not be used in such people. Trimethoprim is similar in molecular structure to the potassium-sparing diuretic amiloride; monitoring of electrolytes and renal function is required when using trimethoprim or co-trimoxazole, particularly when the patient is prescribed other potassium-sparing drugs (e.g., angiotensin-converting enzyme [ACE] inhibitors) and during prolonged therapy to avoid hyperkalaemia.

Nitroimidazoles

These agents are active against anaerobic bacteria and some pathogenic protozoa. The most widely used drug is ***metronidazole*** (Fig. 12.6). Others include ***tinidazole*** and ***nimorazole***. After reduction of their 'nitro' group to a nitrosohydroxyl amino group by microbial enzymes, nitroimidazoles cause strand breaks in microbial DNA.

Metronidazole plays a major role in the treatment of anaerobic bacterial infections, particularly those due to *Bacteroides* spp. It is also used prophylactically in colonic surgery. It may be given orally, by suppository (well absorbed and cheap), or intravenously (more expensive). It is also the treatment of choice for mild *C. difficile* infection, amoebiasis, giardiasis, and infection with *Trichomonas vaginalis*.

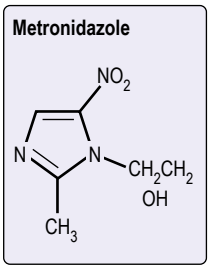

Fig. 12.6 The structure of metronidazole, a nitroimidazole.

Nitroimidazoles can produce a disulfiram-like reaction with ethanol and enhance the anticoagulant effect of warfarin; patients should be warned not to drink alcohol while taking them. They are tumorigenic in animals and mutagenic for bacteria, although carcinogenicity has not been described in humans. They cause a metallic taste and polyneuropathy with prolonged use. High-dose regimens should be avoided in pregnancy and during breast-feeding, unless the benefit is deemed to outweigh the risk.

Other antibiotics

Clindamycin

This is not widely used because of its strong association with *C. difficile* infection. It is active against Gram-positive cocci, including some penicillin-resistant staphylococci, and is a useful agent for severe streptococcal or staphylococcal cellulitis. It has the added effect of inhibiting staphylococcal toxic shock syndrome toxin 1 (TSST-1) and alpha toxin production and has a role in infections caused by *S. aureus*-secreting Panton–Valentine leukocidin (PVL). It is also active against anaerobes, especially *Bacteroides*. It is well concentrated in bone and used for osteomyelitis.

Nitrofurantoin

This is an old agent that is still widely used as an oral treatment for uncomplicated UTI. It is active against almost all the common urinary pathogens, with the exception of *Proteus* spp., and resistance remains rare. It is extensively metabolized, with only about 20% of the active component excreted in the urine, which makes it unsuitable for complicated UTI or pyelonephritis. Nausea is the main side-effect and there are rare reports of peripheral neuropathy, usually in patients with pre-existing renal impairment. It can cause haemolysis in patients with glucose-6-phosphate dehydrogenase deficiency and should be avoided in this group.

Mupirocin

Mupirocin prevents bacterial RNA and protein synthesis. It is only used topically, mainly for the nasal eradication of *S. aureus*, including MRSA, but can also be employed for minor skin infections and treatment of peritoneal dialysis catheter site infection. High-level resistance to mupirocin in MRSA due to plasmid-encoded MupA may lead to failure of topical therapies.

Fosfomycin

This is a relatively old antibiotic that has been used in some European countries for many years. It inhibits bacterial peptidoglycan biosynthesis. It requires a functional sugar transport system (glucose-6-phosphate) for uptake by Enterobacterales, thus requiring modifications to standard susceptibility testing methods. It is active against many Gram-positive organisms and *E. coli*, but many other Gram-negative bacteria have been slow to produce an enzyme (FosA) that is able to destroy the drug. The clinical significance of FosA-mediated resistance is unclear. Fosfomycin retains activity against many ESBL-producing *E. coli* and is therefore the subject of renewed interest. It is increasingly used in the UK, particularly for resistant UTI and is available in oral and intravenous formulations.

Rifaximin

This is a rifamycin with poor gastrointestinal absorption. It is used in portosystemic encephalopathy (see Chapter 23) and the prevention of travellers' diarrhoea; it may be of short-term benefit in irritable bowel syndrome.

Treatment of infection caused by multidrug-resistant organisms

Meticillin-resistant *Staphylococcus aureus*

Meticillin resistance is mediated through changes in the cell-wall penicillin-binding protein 2a, an enzyme that catalyzes cell-wall cross-linking, which meticillin or flucloxacillin is unable to inhibit. In the UK, most MRSA infections are healthcare associated. Uncomplicated infections are typically associated with intravascular catheters or devices; in these cases, line removal (source control) should form part of management. In approximately 5% of cases, infection may disseminate, with haematogenous spread to bones, joints, and heart valves.

For decades the treatment drug of choice has been intravenous ***vancomycin***; pre-levels of 15 to 20 mg/L are required for maximum therapeutic efficacy. Renal function should be closely monitored, as vancomycin is nephrotoxic. Treatment is for a minimum of 2 weeks, and for complicated infection, the addition of a second agent should be considered (e.g., fusidic acid, rifampicin, gentamicin, or ciprofloxacin). There is, however, no good evidence that this improves clinical outcomes: recently, a large UK trial of adjunctive rifampicin demonstrated no clinical benefit in staphylococcal bacteraemic infection.

An alternative to intravenous vancomycin is the oxazolidinone ***linezolid***. The major advantage is that it can be taken orally and is not nephrotoxic. However, it can cause reversible myelosuppression, in particular thrombocytopenia, and so weekly full blood count monitoring is required. In the longer term, there is a smaller risk of peripheral neuropathy or optic neuritis.

While MRSA is primarily seen in the UK in association with intravascular devices, in the USA it has been described as frequently causing severe skin and soft tissue infections. Empirical treatment therefore includes antibiotics such as linezolid, clindamycin, or co-trimoxazole.

Vancomycin-resistant enterococci

Vancomycin resistance in enterococci is mediated through changes in the peptidoglycan precursor from D-Ala-D-Ala to D-Ala-D-Lac, preventing glycopeptides (vancomycin and teicoplanin) binding to these cell-wall precursors and inhibiting cell-wall synthesis. Most infections caused by VRE are healthcare associated. This organism is of low virulence but is difficult to treat, and with the exception of infective endocarditis, infection with VRE is generally of low consequence. More common sites of infection include the urinary and biliary tracts. The only oral treatment is ***linezolid***; intravenous options include ***daptomycin*** and ***tigecycline***.

Carbapenem-resistant *Pseudomonas*

The most common cause of carbapenem resistance in *Pseudomonas* is increased expression of efflux systems or increased impermeability due to decreased porin expression. Most commonly, carbapenem-resistant *Pseudomonas* causes device-related infections or infection of the lower respiratory tract. If disease is mono-resistant, treatment options include ***ciprofloxacin***, ***gentamicin***, ***ceftazidime***, and ***piperacillin/tazobactam*** (Tazocin). Often, however, isolates are multidrug-resistant, with the exception of intravenous ***colistin***. This needs to be dosed appropriately and pre-drug levels should be taken to minimize the risk of both nephrotoxicity and neurotoxicity. More recently, ceftolazone/tazobactam has become available and is effective against multidrug-resistant *Pseudomonas*, as well as less toxic than colistin.

Extended-spectrum β-lactamase-producing Enterobacteriaceae

ESBLs are inactivating enzymes that confer resistance to most β-lactam antibiotics, including penicillins, cephalosporins, and aztreonam. In the UK, ESBL-producing *E. coli* of the CTX-M-15 type suddenly emerged in 2004 and approximately 15% of all *E. coli* bacteraemic isolates are now ESBL producers. Other Enterobacteriaceae, most commonly *K. pneumoniae*, can also be ESBL producers. The most common sites of infection for ESBL-producing Enterobacteriaceae are the urinary tract and, less frequently, the gastrointestinal or hepatobiliary tract. For both organisms, these isolates are often multidrug resistant and may express resistance to antibiotics such as ciprofloxacin, co-trimoxazole, and gentamicin. The mainstay of treatment is a carbapenem, either intravenous ***meropenem*** three times daily or, if OPAT is considered, once-daily intravenous ***ertapenem***. Potential carbapenem-sparing options include intravenous ***amikacin*** or intravenous ***temocillin*** but the suitability of these choices depends on sites of infection. Even when the infecting organism is shown to be susceptible to penicillins by minimum inhibitory concentration (MIC), a carbapenem should be used, as piperacillin/tazobactam has been found to be inferior to carbapenems in a recent trial.

Carbapenem-resistant Enterobacteriaceae

Carbapenem resistance is mediated through the production of enzymes that inactivate carbapenems, together with most β-lactams, and are therefore called carbapenemases. Like ESBL-producing Enterobacteriaceae, carbapenem-resistant Enterobacteriaceae (CRE) most frequently cause UTIs. Worldwide, the five most common types of carbapenemase are *K. pneumoniae* carbapenemases (KPC), New Delhi metallo-β-lactamases (NDM), Verona integron-encoded metallo-β-lactamase (VIM), imipenemase (IMP) metallo-β-lactamase, and the oxacillin carbapenemase (OXA). In the UK, the most common CRE types are OXA-48, NDM, and KPC. Carbapenem-resistant isolates with OXA-48 or KPC production may be susceptible to quinolones and aminoglycosides, and so other commonly used therapeutic options are available for treatment. Resistance to ceftazidime/avibactam in KPC and OXA-48 producers has been reported but remains rare. Isolates that produce NDMs tend to be pan resistant, with the exception of ***colistin***, ***fosfomycin***, and ***tigecycline***. Susceptibility testing for each of these drugs against CRE isolates is not well standardized. Genetic analysis suggests that *Klebsiella* is intrinsically resistant to fosfomycin and that heteroresistance to colistin and tigecycline can emerge during therapy. In these circumstances, colistin is the mainstay of treatment, with tigecycline and sometimes fosfomycin used as adjuvant therapy, depending on susceptibility data. Meropenem, given as a bolus or an infusion, is also of benefit as targeted therapy when organisms demonstrate intermediate sensitivity, as evidenced by a MIC of 8 to 16 mg/L.

Until recently an understanding of the mechanisms of CRE production was helpful when choosing different treatment options. Many of these treatments, described above, have been superseded by cefiderocol, a 5th-generation cephalosporin, which is also effective against NDM producers. The advantages of cefiderocol are monotherapy, simplicity, better tolerability, and less toxicity. While currently most isolates are susceptible, isolates need to be referred to a reference laboratory for testing.

CORE SKILLS AND KNOWLEDGE

Critical care medicine is concerned predominantly with the management of patients with acute life-threatening conditions in specialized units. In addition to emergency cases, intensive care units (ICUs) electively admit high-risk patients after major surgery. The proportion of a hospital's resources dedicated to intensive care varies widely internationally, with the UK providing 6.6 ICU and high-dependency unit (HDU) beds per 100 000 population and Germany providing 29.2.

ICU staff also provide care throughout the hospital in the form of medical emergency and outreach teams. These teams recognize critically ill patients and provide resuscitation and safe transport to the ICU. They also identify patients who are deteriorating on the ward and intervene early, potentially preventing the need for intensive care admission.

Key skills provided by specialists in critical care medicine include:

- Recognizing and managing acutely ill and deteriorating patients and implementing basic resuscitation with advanced medical care and organ support
- Working as part of a multidisciplinary team that includes medical, nursing, and allied health professionals
- Developing an ability to communicate effectively, taking into consideration the risks and benefits of critical care management and advanced life support, especially when these treatments may be futile and not in the best interest of the patient.

Opportunities for learning critical care medicine include attending ward rounds on ICUs and HDUs, accompanying critical care outreach teams who are reviewing deteriorating patients on the wards, observing key procedures such as endotracheal intubation or arterial cannulation, and observing the titration of organ support systems as patients' clinical parameters change.

BACKGROUND

Critical care medicine describes the care given to some of the sickest patients (**Box 13.1**). This might be provided initially by outreach teams in clinical areas such as the emergency department or general medical or surgical wards, but appropriate patients are transferred to either an ICU or an HDU.

ICUs are usually reserved for patients with established or impending organ failure and provide facilities for the diagnosis, prevention, and treatment of multiple organ dysfunction. They are fully equipped with monitoring and technical facilities, including an adjacent laboratory and 'near-patient testing' devices for the rapid determination of blood gases and simple biochemical data such as serum potassium, blood glucose, and serum lactate levels. Technological advances have introduced more compact and complex devices to manage ventilation, cardiac and renal support, and extracorporeal therapies. Portable ultrasound and echocardiography equipment is commonly available. Most importantly, patients receive continuous expert nursing care and the constant attention of appropriately trained medical staff.

HDUs offer a level of care between that available in the general ward and that provided in an ICU. They ensure monitoring of and support for patients with acute (or acute-on-chronic) single-organ failure and for those who are at risk of developing organ failure. They can also provide a 'step-down' facility for patients being discharged from intensive care.

The different levels of hospital critical care bed are discussed further in Chapter 11.

Box 13.1 Some common indications for admission to intensive care

Surgical emergencies
- Acute intra-abdominal catastrophe:
  - Perforated viscus, especially with faecal soiling of peritoneum (often complicated by sepsis/septic shock)
  - Ruptured/leaking abdominal aortic aneurysm
- Trauma (often complicated by hypovolaemic shock and later sepsis/septic shock):
  - Multiple injuries
  - Massive blood loss
  - Severe head injury

Medical emergencies
- Respiratory failure:
  - Exacerbation of chronic obstructive pulmonary disease (COPD)
  - Acute severe asthma
  - Severe pneumonia (often complicated by sepsis/septic shock)
- Cardiac failure (cardiogenic shock) often following myocardial infarction, arrhythmias, and cardiac arrest
- Meningococcal infection
- Status epilepticus
- Severe diabetic ketoacidosis
- Coma

Elective surgical admissions
- Extensive/prolonged procedure (e.g., oesophagogastrectomy)
- Cardiothoracic surgery
- Major head and neck surgery
- Coexisting cardiovascular or respiratory disease

Obstetric emergencies
- Severe pre-eclampsia/eclampsia
- Haemorrhage
- Amniotic fluid embolism

CLINICAL APPROACH TO THE CRITICALLY ILL PATIENT

Recognition and diagnosis of critical illness

Early recognition, targeted resuscitation, and stabilization are fundamental to the successful management of the critically ill. In order to facilitate the identification of 'at-risk' patients on the ward and early referral to the critical care team, a number of early warning systems have been devised (e.g., the Modified Early Warning Score, MEWS). These are based primarily on bedside observations, assigning a single score reflecting the degree of physiological abnormality, which can be used to flag patients who require further assessment. The MEWS score has been superseded by the National Early Warning Score (NEWS2) in the UK, which has been optimized to recognize sepsis and new-onset confusion (**Fig. 13.1**). On average, 5% of hospital inpatients in the UK will score 5 (key threshold for urgent response) at some point during their admission; of these, 5% will suffer a cardiac arrest, die, or require ICU admission in the following 24 hours.

These early warning systems are not infallible and have not been universally implemented. It is therefore imperative that clinicians are trained to recognize critically ill patients at the bedside. The initial assessment may elicit obvious signs. The patient may be unduly agitated or, perhaps more worryingly, unresponsive. Of particular concern is the obtunded patient who is unable to protect their own airway from aspiration of gastric or oral contents. Snoring, grunting, or other respiratory sounds may indicate an obstructed airway, which can be caused by posterior displacement of the tongue due to lax oropharyngeal musculature in a comatose patient or perhaps by secretions pooling in the oropharynx in a patient with a depressed cough reflex. Obvious use of the accessory respiratory muscles and a tracheal tug are sensitive signs of impending respiratory decompensation. Patients in severe respiratory distress frequently sit forwards, grip the sides of the bed, and cannot complete sentences in a single breath. Review of the nursing observations may reveal a sudden deterioration in recorded variables, such as a sharp rise in temperature, increasing heart rate, a fall in blood pressure, or decreased urine output.

On examination, cool peripheries in conjunction with diaphoresis indicate increased sympathetic drive and may be a sign of cardiogenic shock, hypovolaemia, or hypoglycaemia. In contrast, flushed, warm peripheries may be a sign of a hyperdynamic circulation consistent with sepsis (see Chapter 12). ***Abdominal catastrophes*** are a common cause of an acute deterioration; an abdominal examination should always be performed and may reveal a distended, tender abdomen and often absent or altered bowel sounds consistent with a perforated viscus or ischaemic bowel. ***Blood gas analysis*** should be performed as soon as possible. Acid–base status, haemoglobin concentration, blood glucose, and electrolyte levels obtained from an arterial blood gas sample are helpful when assessing the cause and severity of acute illness. Increased lactate levels usually indicate severe illness. An ***electrocardiogram (ECG)*** can allow the rapid diagnosis of treatable conditions, as can a portable ***chest X-ray***.

Frequently, the precise underlying diagnosis is initially unclear but, in all cases, the immediate objective is to preserve life and prevent, reverse, or minimize damage to vital organs such as the lungs, brain, kidneys, and liver. A systematic approach to the recognition and initial treatment of acute illness should be adopted, as well as the performance of investigations to search for the underlying cause. A rapid assessment following the ABC approach (*A*irway, *B*reathing, *C*irculation; see **Fig. 13.22**) should be undertaken, with simultaneous institution of treatment. In practice, resuscitation, assessment, and diagnosis usually proceed in parallel.

General aspects of managing the critically ill

Critically ill patients require multidisciplinary care that should include the following elements.

Intensive skilled nursing care

In the UK, this usually entails a 1:1 nurse-to-patient ratio in an ICU (level 3 care) or 1:2 in an HDU (level 2 care). Frequent clinical observations and treatment are required.

Monitoring

Every patient in critical care is monitored to a far greater extent than generally practiced on wards. Most patients undergo continuous monitoring of ECG, oxygen saturation, end-tidal CO_2 (if intubated), invasive arterial blood pressure, and central venous

Physiological parameter	3	2	1	Score 0	1	2	3
Respiration rate (per minute)	≤8		9–11	12–20		21–24	25
SpO_2 Scale 1 (%)	≤91	92–93	94–95	≥96			
SpO_2 Scale 2 (%)	≤83	84–85	86–87	88–92 ≥93 on air	93–94 on oxygen	95–96 on oxygen	≥97 on oxygen
Air or oxygen?		Oxygen		Air			
Systolic blood pressure (mmHg)	≤90	91–100	101–110	111–219			≥220
Pulse (per minute)	≤40		41–50	51-90	91–110	111–130	≥131
Consclousness				Alert			CVPU
Temperature (°C)	≤35.0		35.1–36.0	36.1–38.0	38.1–39.0	≥39.1	

Fig. 13.1 The National Early Warning Score (NEWS2) system. S_pO_2 Scale 1 should be used in all patients except those where there is previously confirmed and documented hypercapnoeic respiratory failure demonstrated on blood gas analysis. Aggregate scores of 0 to 4 (low clinical risk) require a ward-based response, and those of 5 to 6 (medium risk) require an urgent response from the clinical team. Aggregate scores of 7 or more (high clinical risk) should receive an urgent emergency response from critical care staff. *CVPU,* Confusion, voice, painful stimulus, unresponsive. *(Reproduced from Royal College of Physicians. National Early Warning Score (NEWS) 2: Standardising the assessment of acute-illness severity in the NHS. Updated report of a working party. London: RCP, 2017.)*

pressure (CVP), with periodic recording of values. Settings and measurements from devices are also recorded (e.g., ventilator settings and measurements such as airway pressures, tidal and minute volume). In addition, strict fluid balance monitoring is essential, with a full record kept of fluids entering the patient (i.v. fluids and blood products, medications, liquid feed, and even fluid orally consumed by awake patients) and fluids leaving (urine output, drain fluid, CSF, with some units making an estimate of insensible losses). Furthermore, systematic regular assessments (e.g., GCS, sedation level, pupillary responses, limb perfusion) are also recorded. Increasingly, records are kept electronically, with monitor and device data downloaded directly into the record after ratification by the bedside nurse.

Specialized physiotherapy

This should include chest physiotherapy, mobilization, and rehabilitation.

Management of pain and distress

There should be judicious administration of analgesics and sedatives (see 'Sedation, analgesia, and muscle relaxation' section).

Constant reassurance and support

Critically ill patients easily become disorientated; delirium (a transient alteration in consciousness, attention, orientation, perception, or behaviour) is common. Delirium may be hypoactive, agitated (hyperactive), or a combination of the two. Pain, advanced age, sleep/sensory deprivation, sedative administration (especially benzodiazepines), alcohol/drug withdrawal, neurological injury, severe illness, and medical co-morbidities all play a role. Patients with delirium are more difficult to wean from ventilation, require larger doses of sedatives, and have an associated increased mortality and length of hospital stay. Treatment focuses on effective pain control, minimizing sensory deprivation, early mobilization, avoidance of benzodiazepines, and limiting sedative administration. Newer sedative agents, such as the α_2-agonist dexmedetomidine, may reduce the incidence of delirium and time on the ventilator, as do processes of care that mandate daily interruptions to sedative infusions and careful titration to the minimum required.

Gastric protection

H_2-receptor antagonists or proton pump inhibitors reduce gastric acidity and prevent stress-induced ulceration. They may, however, encourage bacterial overgrowth in the upper gastrointestinal tract and predispose patients to ventilator-associated pneumonia; they are also associated with *Clostridium difficile* colitis.

Deep vein thrombosis prevention

All critically ill patients are at increased risk of deep venous thrombosis and pulmonary embolism. Prophylaxis should be instigated with the use of compression stockings, pneumatic compression devices and regular subcutaneous heparin.

Mouth care, tooth-brushing, and oropharyngeal suction

These measures help to reduce hospital-acquired infections and ventilator-associated pneumonia by reducing the burden of pathogenic oral flora that may be aspirated into the respiratory tree. Chlorhexidine body washes may reduce the total carriage of resistant microorganisms.

Prevention of constipation and pressure ulcers

Steps should be taken to prevent constipation and pressure ulcers from developing.

Organ support

For example, inotropes and vasopressors may be required for cardiovascular support, invasive and non-invasive ventilation for respiratory failure, and dialysis for renal failure. Specialized units may provide extracorporeal membrane oxygenation (ECMO) for severe respiratory failure, mechanical support of the circulation for cardiac failure, and advanced liver support in the form of liver dialysis (e.g., the molecular adsorbent recirculation system, MARS).

Nutritional support

(See Chapter 25). Protein–energy malnutrition is common in critically ill patients and is associated with muscle wasting, weakness, delayed mobilization, difficulty weaning from ventilation, immune compromise, and impaired wound healing. ***Enteral nutrition***, usually delivered via a fine-bore nasogastric tube, is preferred because it is less expensive, preserves gut mucosal integrity, is more physiological, and is associated with fewer complications. However, the value of enteral nutrition early in the course of an acute illness remains uncertain. If enteral feeding is not possible due to gut dysmotility and malabsorption associated with critical illness, the alternative is ***intravenous (parenteral) nutrition***. This is more invasive and expensive and can be complicated by deranged liver function tests, hypertriglyceridaemia, hyperglycaemia, and increased susceptibility to hospital-acquired infections. Hypocaloric enteral nutrition is usually continued for up to a week in previously well-nourished patients before parenteral nutrition is considered. Administering parenteral nutrition early in order to maintain caloric input and prevent an energy deficit may be detrimental.

Although all nutrition should contain carbohydrates, proteins, lipids, and some micronutrients, the precise optimal formulation is unclear. Supplementation with the amino acid glutamine has theoretical advantages in some conditions (burns and trauma) but not in multiorgan failure. The omega-3 fatty acids derived from fish oils also have potentially beneficial antioxidant activity but have not been convincingly shown to improve outcome, as has been the case for micronutrient supplementation with selenium, copper, manganese, zinc, iron, and vitamins.

Many critically ill patients are at risk of developing a ***'re-feeding syndrome'*** (see Chapter 25) when nutritional support is first initiated and should be monitored closely.

Insulin treatment

Treatment should be given for critical illness-induced hyperglycaemia (which is associated with hospital-acquired infections, renal impairment, and poor wound healing, see Chapter 35). Insulin is often required in high doses due to insulin resistance. Although the use of intensive insulin therapy to achieve 'tight glycaemic control' (blood glucose level between 4.4 and 6.1 mmol/L) was initially shown to improve outcome, subsequent studies found that this approach is associated with an unacceptably high incidence of hypoglycaemia, and possibly increased mortality. Current recommendations suggest that blood glucose levels should be maintained below 10 mmol/L.

Discharge from the ICU/HDU

Discharge of patients from intensive care should normally be planned in advance and ideally take place during normal working hours. Frequently, when the condition of critically ill patients improves, they are initially 'stepped down' to HDU (level 2) care. Premature or unplanned discharge from the ICU or HDU, especially during the night, has been associated with higher hospital mortality and is best avoided. A discharge summary, including 'points to review', should be included in the clinical notes, with a detailed handover to the receiving team (medical, nursing, and therapies). The intensive care team should continue to review the patient (who might deteriorate following discharge) on the ward and be available for advice on further management (e.g., tracheostomy care, nutritional support). In this way, deterioration and re-admission to intensive care (which is associated with a particularly poor outcome), or even cardiorespiratory arrest, are hopefully avoided.

This chapter concentrates on cardiovascular, respiratory, renal, and neurological problems. Many patients also have failure of other organs, such as the liver; treatment of these is dealt with in more detail in the relevant chapters.

APPLIED CARDIORESPIRATORY PHYSIOLOGY

Oxygen delivery and consumption

Normal cellular, tissue, and organ function depend on adequate delivery of oxygen and fuel to mitochondria to produce energy, a process integrating the heart, lungs, and vascular and haematological systems. Adequate blood flow requires proper functioning of the three components of the circulation: the muscle pump, circulating volume, and arterial tone or resistance to flow to perfuse distal tissues. Each area has its own regulatory system and may develop pathology either independently or as a part of multisystem response to an insult such as sepsis.

The term oxygen delivery (DO_2) describes the total amount of oxygen supplied to the body per unit time (**Fig. 13.2**). Its main determinants are the amount of blood pushed through the microcirculation by the cardiac output (Q_t) and the amount of oxygen carried in that blood (i.e., arterial oxygen content, C_aO_2). Oxygen is transported primarily in combination with haemoglobin:

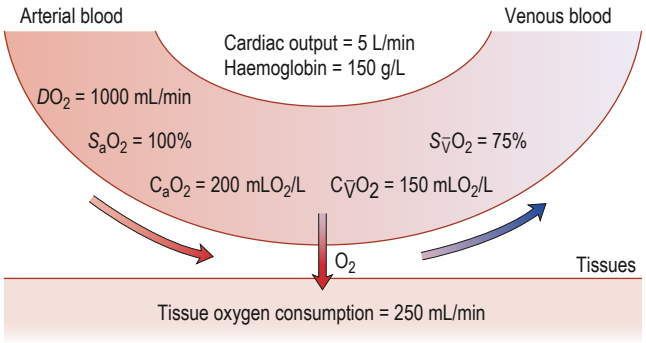

Fig. 13.2 Tissue oxygen delivery and consumption in a normal 70 kg person breathing air. Oxygen delivery (DO_2) = cardiac output × (haemoglobin concentration × oxygen saturation [S_aO_2] × 1.34). In normal adults, oxygen delivery is roughly 1000 mL/min, of which 250 mL is taken up by tissues. Mixed venous blood is thus 75% saturated with oxygen. C_aO_2, Arterial oxygen content; $C_{\bar{v}}O_2$, mixed venous oxygen content; $S_{\bar{v}}O_2$, mixed venous oxygen saturation.

the amount combined is determined by its oxygen capacity (usually 1.34 mL of oxygen per gram) and percentage saturation (SO_2). Oxygen is also dissolved in plasma at a proportion dependent on the partial pressure of oxygen (PO_2), but this is usually insignificant.

'Global' oxygen delivery as a concept is of limited clinical value, as differing tissues have differing metabolic requirements and blood flow. Generally, delivery is matched to individual metabolic requirements; some organs (such as the heart) have high oxygen requirements relative to their blood flow and may receive insufficient oxygen, whereas others such as the kidneys extract relatively little oxygen compared to the 20% cardiac output that flows through them. Microcirculatory flow is also reduced by increased blood viscosity and needs to be considered when thinking about oxygen delivery to the tissues, even if overall measured delivery appears adequate.

Oxygenation of the blood

Oxyhaemoglobin dissociation curve

The saturation of haemoglobin with oxygen is determined by the partial pressure of oxygen (PO_2), with this relationship being described by the oxyhaemoglobin dissociation curve (Fig. 13.3). The sigmoid shape of this curve is significant for a number of reasons:

- Modest falls in the partial pressure of oxygen in arterial blood (P_aO_2) have little effect on oxygen content, provided percentage saturations remain above about 92%.
- Increasing the P_aO_2 to above normal has only a minimal effect on oxygen content, unless hyperbaric oxygen is administered (when the amount of oxygen in solution in plasma becomes significant).
- On the slope of the curve (percentage saturation below 90%), a small decrease in P_aO_2 can cause large falls in oxygen content, whereas increasing P_aO_2 only slightly, e.g., by administering 28% oxygen to a patient with chronic obstructive pulmonary disease (COPD), can lead to a useful increase in oxygen saturation and content.

If the PCO_2 increases, the oxyhaemoglobin curve moves to the right, facilitating oxygen unloading to the tissues (Bohr effect).

The P_aO_2 is influenced, in turn, by the alveolar oxygen tension (P_AO_2), the efficiency of pulmonary gas exchange, and the partial pressure of oxygen in mixed venous blood ($P_{\bar{v}}O_2$).

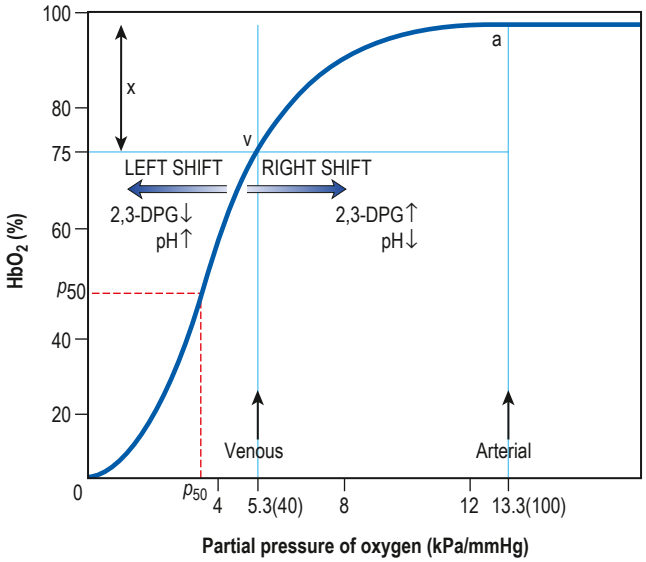

Fig. 13.3 The oxyhaemoglobin dissociation curve. HbO_2 (%) is the percentage saturation of haemoglobin with oxygen. The curve will move to the right in the presence of acidosis (metabolic or respiratory), pyrexia, or an increased red cell 2,3-diphosphoglycerate (2,3-DPG) concentration. For a given arteriovenous oxygen content difference, the mixed venous PO_2 will then be higher. Furthermore, if the mixed venous PO_2 is unchanged, the arteriovenous oxygen content difference increases, and more oxygen is off-loaded to the tissues (see Chapter 38). P_{50} (the PO_2 at which haemoglobin is half-saturated with O_2) is a useful index of these shifts—the higher the P_{50} (i.e., shift to the right), the lower the affinity of haemoglobin for O_2. *a,* Arterial point; *v,* venous point; *x,* arteriovenous oxygen content difference.

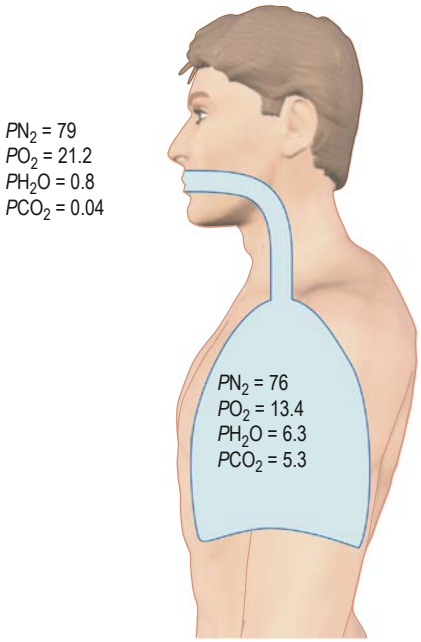

Fig. 13.4 The composition of inspired and alveolar gas. (Partial pressures in kPa.)

Alveolar oxygen tension (P_AO_2)

The partial pressures of inspired gases are shown in Fig. 13.4. By the time the inspired gases reach the alveoli, they are fully saturated with water vapour at body temperature (37°C), which has a

partial pressure of 6.3 kPa (47 mmHg), and contain CO_2 at a partial pressure of approximately 5.3 kPa (40 mmHg); the P_AO_2 is thereby reduced to approximately 13.4 kPa (100 mmHg).

The clinician can influence P_AO_2 by administering oxygen or by increasing the barometric pressure (hyperbaric therapy).

Pulmonary gas exchange

In *normal* subjects, a small alveolar–arterial oxygen difference ($P_{A–a}O_2$) exists due to:

- a small (0.133 kPa [1 mmHg]) pressure gradient across the alveolar membrane;
- a small amount of blood (2% of total cardiac output) bypassing the lungs via the bronchial and cardiac Thebesian veins; and
- a small degree of ventilation/perfusion mismatch.

There are three pathological causes of an increased $P_{A–a}O_2$ difference:

- ***Diffusion defect.*** This is *not* a major cause of hypoxaemia, even in conditions such as lung fibrosis, in which the alveolar–capillary membrane is considerably thickened. Carbon dioxide is also not affected, as it is more soluble than oxygen.
- ***Right-to-left shunts.*** In cyanotic congenital heart disease or following collapse of a lung segment, a proportion of venous blood passes to the left side of the heart without taking part in gas exchange, causing arterial hypoxaemia that cannot be corrected by administering oxygen to increase the P_AO_2 because blood leaving normal alveoli is already fully saturated. Further increases in PO_2 will not, therefore, significantly affect its oxygen content. On the other hand, because of the shape of the carbon dioxide dissociation curve (**Fig. 13.5**), the high PCO_2 of the shunted blood is compensated for by over-ventilating patent alveoli; hence many patients with acute right-to-left shunts hyperventilate, producing a low or normal P_aCO_2.
- ***Ventilation/perfusion mismatch*** (see Chapter 20). This happens when parts of the lung ventilate without much blood flow (e.g., pulmonary embolism), or when there is blood flow but no ventilation, such as in parenchymal lung disease (pneumonia, pulmonary oedema). Both of these states result in hypoxaemia. The increased dead space can be compensated for by increasing overall ventilation. In contrast to the hypoxia resulting from a true right-to-left shunt, that due to areas of low $\dot{V}/\dot{Q}$ can be partially corrected by administering oxygen and thereby increasing the P_AO_2.

Oxygen cascade

Oxygen levels fall further as it is unloaded into the tissues and diffuses to the mitochondria. Tissue oxygen content varies depending on the distance travelled from the local capillary network. Some mitochondria continue to function at a PO_2 as low as 0.07 kPa (0.5 mmHg) (**Fig. 13.6**).

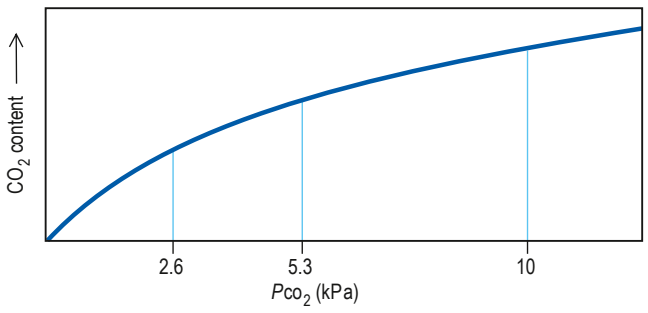

Fig. 13.5 The carbon dioxide dissociation curve. Note that, in the physiological range, the curve is essentially linear.

Mixed venous oxygen tension and saturation

Mixed venous oxygen tension ($P_{\bar{v}}O_2$) is the partial pressure of oxygen in pulmonary arterial blood that has been thoroughly mixed in the right heart. Assuming P_aO_2 remains constant, both $P_{\bar{v}}O_2$ and mixed venous oxygen saturation ($S_{\bar{v}}O_2$) fall as more oxygen is extracted by tissues. Low $S_{\bar{v}}O_2$ therefore indicates either inadequate oxygen delivery or a rise in tissue requirements beyond compensations in cardiac output. This may exacerbate pulmonary shunting; hence worsening hypoxaemia does not necessarily indicate declining pulmonary function. Conversely, rises in venous oxygen content may reflect impaired tissue extraction due to microcirculatory abnormalities and/or reduced utilization due to mitochondrial dysfunction, as in severe sepsis or certain poisons (see later). Monitoring central venous oxygen saturation from the superior vena cava ($S_{cv}O_2$) rather than the pulmonary artery is less invasive and approximates $S_{\bar{v}}O_2$ to within around 5% in most situations, although this relationship becomes less predictable at the extremes of physiology.

Adaptation to hypoxia

Acute exposure to severe hypoxia may lead to sudden death if the immediate adaptive responses fail to maintain mitochondrial oxygen delivery. Chronic exposure to low oxygen tension, on the other hand, allows time for compensatory mechanisms to develop. Among the first is an increase in cardiac output, achieved primarily by increasing heart rate. Given the reciprocal relationship between the partial pressures of oxygen and carbon dioxide in the alveoli, as defined by the alveolar gas equation ($P_AO_2 = P_IO_2 - P_ACO_2/R$, where R is the respiratory quotient [usually 0.8]), an increase in respiratory rate serves to decrease alveolar PCO_2 and thereby increase alveolar PO_2 (see also **Fig. 13.4**). Over time, increased erythropoietin production stimulates haemoglobin synthesis, leading to a marked increase in haematocrit. Over the longer term, capillary bed density in specific tissues adjusts to the physiological demand. In those

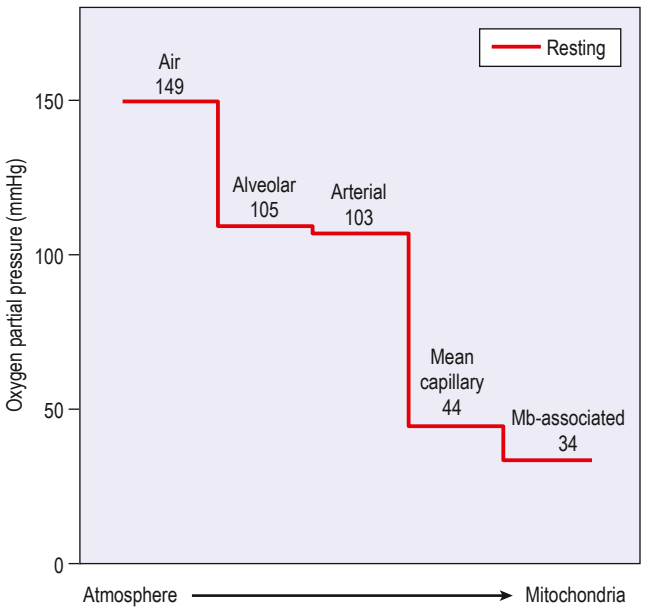

Fig. 13.6 The oxygen cascade. Oxygen levels decrease (shown in graph) as oxygen is unloaded into the tissues and diffuses to the mitochondria. *Mb,* Myoglobin.

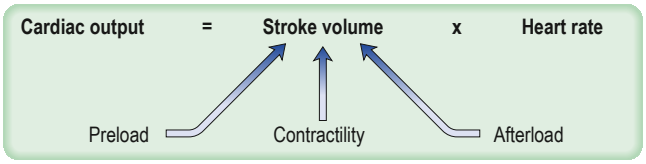

Fig. 13.7 The determinants of cardiac output.

residing at altitude over generations, the hypoxic ventilatory drive and pulmonary vasoconstrictor response evolve to maximize oxygen uptake. In 2007 a series of arterial blood samples were obtained by a group of critical care doctors on the summit of Mount Everest (see 'Further reading'). The project included a 4-month acclimatization period at altitude. The samples were obtained at 8400 m altitude while breathing air. The average P_aO_2 was 3.2 kPa (24.6 mmHg). These figures neatly demonstrate features of both acute (hyperventilation) and chronic (increased haematocrit) acclimatization to hypobaric hypoxia.

Cardiac output

Cardiac output is the product of heart rate and stroke volume (Fig. 13.7). When the heart rate increases, the duration of systole is largely unchanged but diastole, and thus time for ventricular filling progressively shortens and stroke volume eventually falls. In normal hearts this occurs at rates of more than about 160 beats per minute, but in those with cardiac pathology, particularly restricted ventricular filling (e.g., mitral stenosis), it may be seen at much lower rates. Tachycardia increases myocardial oxygen consumption and may precipitate ischemia in areas with restricted coronary perfusion. Conversely, when heart rate falls, the compensatory increase in stroke volume eventually becomes insufficient and cardiac output falls. Furthermore, rhythm disturbances (e.g., atrial fibrillation, complete heart block) may prevent atrial augmentation of ventricular filling, exacerbating the fall in stroke volume.

Stroke volume

The volume of blood ejected in a single contraction is the difference between the ventricular end-diastolic volume (VEDV) and ventricular end-systolic volume (VESV) (i.e., stroke volume = VEDV – VESV). The ejection fraction describes the stroke volume as a percentage of VEDV (i.e., ejection fraction = (VEDV – VESV)/VEDV × 100%) and is an indicator of myocardial performance.

Three interdependent factors determine the stroke volume:

Preload

This is defined as the tension of the myocardial fibres at the end of diastole and is related to the degree of stretch of the fibres by intracardiac volume. As the end-diastolic volume of the ventricle increases, tension in the myocardial fibres is increased and stroke volume rises (Fig. 13.8). Myocardial oxygen consumption ($\dot{V}_mO_2$) increases only slightly with an increase in preload (produced, e.g., by a 'fluid challenge', see later) and this is therefore the most efficient way of improving cardiac output.

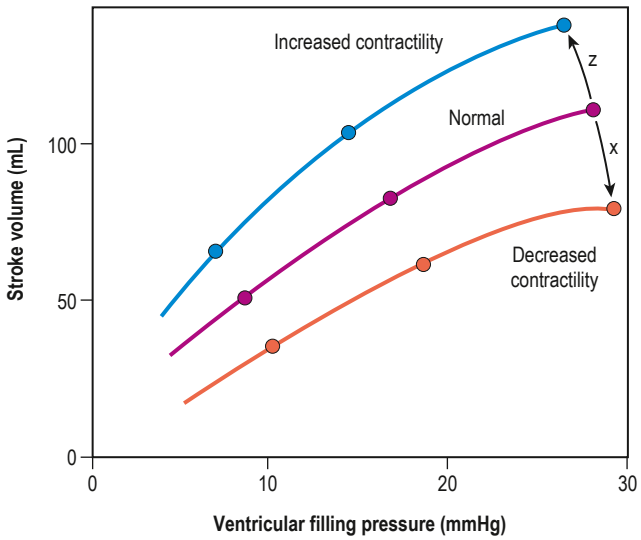

Fig. 13.8 The Frank–Starling relationship: as preload is increased, stroke volume rises. If the ventricle is overstretched, stroke volume will fall (x). In myocardial failure, the curve is depressed and flattened. Increasing contractility, such as that due to sympathetic stimulation, shifts the curve upwards and to the left (z).

Myocardial contractility

This refers to the ability of the heart to perform work, independent of changes in preload and afterload. The state of myocardial contractility determines the response of the ventricles to changes in preload and afterload. Contractility is often reduced in critically ill patients, because of either pre-existing myocardial dysfunction (e.g., ischaemic heart disease) or the acute disease process itself (e.g., sepsis). Changes in myocardial contractility alter the slope and position of the Starling curve; worsening ventricular performance is manifested as a depressed, flattened curve (see Fig. 13.8). Inotropic drugs are used to increase myocardial contractility (see later).

Afterload

This is defined as the myocardial wall tension developed during systolic ejection. In the case of the left ventricle, the resistance imposed by the aortic valve, the peripheral vascular resistance, and the elasticity of the major blood vessels are the major determinants of afterload. Ventricular wall tension will also be increased by ventricular dilation, an increase in intraventricular pressure, or a reduction in ventricular wall thickness.

Decreasing the afterload (through vasodilation due to exercise, sepsis, or vasodilating agents) can increase the stroke volume achieved at a given preload (Fig. 13.9) while reducing $\dot{V}_mO_2$. The reduction in wall tension also leads to an increase in coronary blood flow, improving the myocardial oxygen supply/demand ratio. Excessive reductions in afterload will cause systemic arterial hypotension and potentially an increase in cardiac output.

Increasing the afterload (vasoconstriction due to increased sympathetic activity, vasoconstrictor agents), on the other hand, can cause a fall in stroke volume and an increase in $\dot{V}_mO_2$.

Right ventricular afterload is normally negligible because the resistance of the pulmonary circulation is extremely low but is increased in pulmonary hypertension, the causes of which are multiple and include left-sided heart disease, lung disease, pulmonary emboli, and significant pulmonary emboli. Unlike the left ventricle, the right is poorly tolerant of acute changes in this parameter, and acutely elevated pulmonary vascular resistance may cause shock due to inadequate delivery of blood to the left ventricle, causing falls in cardiac output.

Cardiovascular assessment and monitoring of critically ill patients

Monitoring helps establish or confirm a diagnosis, gauge the severity of a condition, follow its evolution, guide interventions, and assess response to treatment. Invasive monitoring is usually indicated in critically ill patients and those unresponsive to initial resuscitation. These techniques carry a risk of significant complications, are costly, and may lead to patient discomfort. They should be used only when potential benefits outweigh their dangers and for the minimum time necessary.

Assessment of tissue perfusion

- ***Pale, cold skin***, delayed capillary refill, and the absence of visible veins in the hands and feet indicate poor perfusion. Although peripheral skin temperature measurements can help clinical evaluation, the earliest compensatory response to hypovolaemia or low cardiac output, and the last to resolve after resuscitation, is splanchnic vasoconstriction.
- ***Metabolic acidosis with raised lactate concentration*** suggests that tissue perfusion is sufficiently compromised to cause cellular hypoxia and anaerobic glycolysis. Persistent, severe lactic acidosis is associated with an extremely poor prognosis. In addition to serving as a screen for cardiovascular insufficiency and poor tissue perfusion, lactate levels are frequently used to guide the adequacy of resuscitation. High lactate levels that do not respond to resuscitation suggest reduced splanchnic blood flow and bowel ischemia or mitochondria cytopathy. In sepsis, lactic acidosis can also be caused by metabolic disorders unrelated to tissue hypoxia and exacerbated by reduced clearance owing to hepatic or renal dysfunction and the administration of adrenaline (epinephrine) which impairs lactate metabolism.
- ***Urinary flow*** is a sensitive indicator of renal perfusion and haemodynamic performance in the absence of intrinsic renal disease or obstruction.

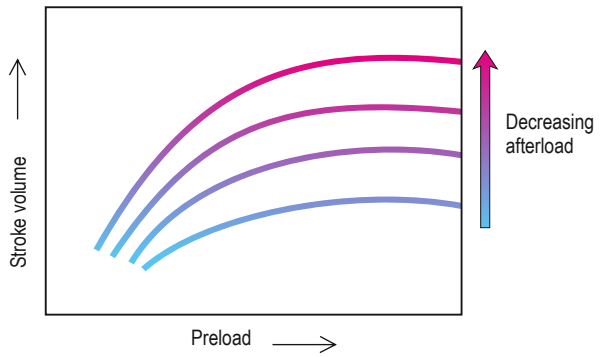

Fig. 13.9 The effect of changes in afterload on the ventricular function curve. At any given preload, decreasing afterload increases the stroke volume.

Blood pressure

Alterations in blood pressure are often interpreted as reflecting changes in cardiac output. However, if there is vasoconstriction with a high peripheral resistance, the blood pressure may be normal, even when the cardiac output is low. Conversely, the vasodilated patient may be hypotensive, despite a very high cardiac output.

Hypotension jeopardizes perfusion of vital organs. The adequacy of blood pressure in an individual patient should always be assessed in relation to the pre-morbid value. Blood pressure is traditionally measured using a sphygmomanometer, but if rapid alterations are anticipated or administration of vasoactive agents is required, continuous monitoring using an intra-arterial cannula is indicated (Box 13.2 and Fig. 13.10).

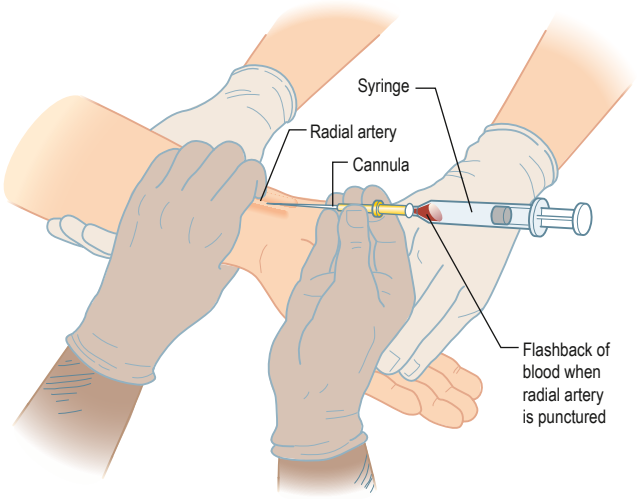

Fig. 13.10 Percutaneous cannulation of the radial artery.

Box 13.2 Radial artery cannulation

Technique

1. Explain the procedure to the patient and, if possible, obtain consent.
2. Ask an assistant to support the patient's arm, with the wrist extended. (Gloves should be worn.)
3. Clean the skin with chlorhexidine. Take sterile precautions throughout the procedure.
4. Palpate the radial artery where it arches over the head of the radius.
5. In conscious patients, inject local anaesthetic to raise a weal over the artery, taking care not to puncture the vessel or obscure its pulsation.
6. Make a small skin incision over the proposed puncture site.
7. Use a small, parallel-sided cannula (20 gauge for adults, 22 gauge for children) in order to allow blood flow to continue past the cannula.
8. Insert the cannula over the point of maximal pulsation and advance it in line with the direction of the vessel at an angle of approximately 30 degrees.
9. Look for 'flashback' of blood into the cannula, which indicates that the radial artery has been punctured.
10. To ensure that the shoulder of the cannula enters the vessel, lower the needle and cannula and advance them a few millimetres into the vessel.
11. Thread the cannula off the needle into the vessel and withdraw the needle.
12. Connect the cannula to a non-compliant manometer line filled with saline. Then connect this via a transducer and continuous flush device to a monitor, which records the arterial pressure.

Possible complications

- Thrombosis
- Loss of arterial pulsation
- Distal ischaemia, e.g., digital necrosis (rare)
- Infection
- Accidental injection of drugs—can produce vascular occlusion
- Disconnection—rapid blood loss

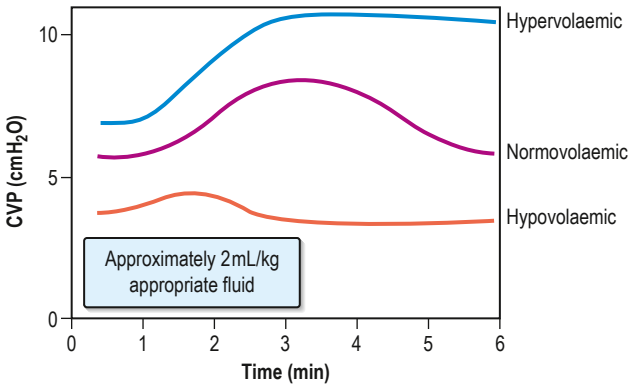

Fig. 13.11 The effects on the central venous pressure (CVP) of rapid administration of a 'fluid challenge' to patients with a CVP within the normal range.

Central venous pressure

Assessment of CVP provides a simple but approximate method of gauging the adequacy of a patient's circulating volume and preload. The absolute value of the CVP is not as informative as its response to a fluid challenge (the infusion of 100–200 mL of fluid over a few minutes; **Fig. 13.11**). The hypovolaemic patient may initially respond to fluid infusion with little or no change in CVP but will exhibit some improvement in cardiovascular function (falling heart rate, rising blood pressure, increased peripheral temperature, and urine output). As the normovolaemic state is approached, the CVP may rise slightly and plateau, while other cardiovascular values stabilize. At this stage, volume replacement should be slowed or even stopped. In cardiac failure, the venous pressure is generally high; the patient will not improve in response to volume replacement, which will cause a further, sometimes dramatic, rise in CVP. However, these numbers cannot be taken in isolation and must be placed against the clinical status. The use of CVP to assess cardiovascular function is controversial, and newer methods, particularly pulse contour analysis and oesophageal Doppler techniques, have largely replaced it (see later).

Central venous catheter placement is described in Chapter 11. Usually, these catheters consist of more than one lumen allowing use for drug or fluid administration in addition to monitoring CVP. The CVP is usually displayed continuously using a transducer and bedside monitor but can also be recorded intermittently using a manometer system. It is essential for the recorded pressure always to be related to the level of the right atrium as a zero point. Various landmarks are advocated (e.g., sternal notch with the patient supine; sternal angle or mid-axilla when the patient is at 45 degrees), but the choice is immaterial, provided the landmark is used consistently in an individual patient.

Left atrial pressure

In uncomplicated cases, careful interpretation of the CVP may provide a reasonable guide to the filling pressures of both sides of the heart. However, in most critically ill patients, there is a disparity in function between the two ventricles related to variation in systemic and pulmonary vascular resistance and differing function. Most commonly, left ventricular performance is worse so that the left ventricular function curve is displaced downwards and to the right (**Fig. 13.12**). High right ventricular filling pressures, with normal or low left atrial pressures, are less common but occur with right ventricular dysfunction and with raised pulmonary vascular resistance (i.e., right ventricular afterload), such as in acute respiratory failure and pulmonary embolism.

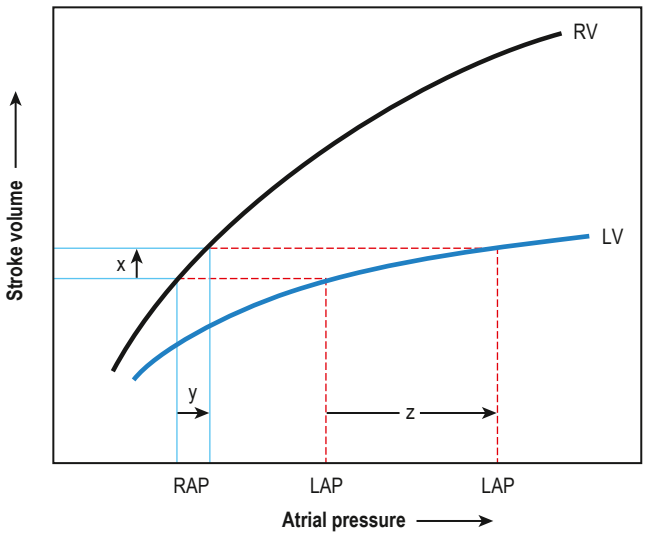

Fig. 13.12 Left ventricular (LV) and right ventricular (RV) function curves in a patient with left ventricular dysfunction. Since the stroke volume of the two ventricles must be the same (except, perhaps, for a few beats during a period of circulatory adjustment), left atrial pressure (LAP) must be higher than right atrial pressure (RAP). Moreover, an increase in stroke volume (x) produced by expanding the circulatory volume may be associated with a small rise in RAP (y) but a marked increase in LAP (z).

Box 13.3 Passage of a pulmonary artery balloon flotation catheter

The catheter is passed through the chambers of the heart into the 'wedged' position.

1. Explain the procedure to the patient and, if possible, obtain consent. Place the patient in a 'head down' position.
2. Insert a balloon flotation catheter through a large vein (see text).
3. Look for respiratory oscillations once the catheter is in the thorax. Advance it further towards the lower superior vena cava/right atrium (see **Fig. 13.13A**), where pressure oscillations become more pronounced. Then inflate the balloon and advance the catheter.
4. When the catheter is in the right ventricle (see **Fig. 13.13B**), there is no dicrotic notch and the diastolic pressure is close to 0. Return the patient to the horizontal or slightly head-up position before advancing the catheter further.
5. When the catheter reaches the pulmonary artery (see **Fig. 13.13C**), a dicrotic notch appears and there is elevation of the diastolic pressure. Advance the catheter further with the balloon inflated.
6. Reappearance of a venous waveform indicates that the catheter is 'wedged'. Deflate the balloon to obtain the pulmonary artery pressure. Inflate the balloon intermittently to obtain the pulmonary artery occlusion pressure (also known as pulmonary artery or capillary 'wedge' pressure; see **Fig. 13.13D**).

Pulmonary artery pressures

A 'balloon flotation catheter' enables reliable catheterization of the pulmonary artery. These are often called 'Swan–Ganz' catheters after their inventors and are inserted through the central veins. Passage of the catheter from the major veins, through the chambers of the heart into the pulmonary artery and into the wedged position, is monitored and guided by the pressure waveforms recorded from the distal lumen (**Box 13.3** and **Fig. 13.13**). A chest X-ray should always be obtained to check the final position of the catheter (**Fig. 13.14**).

Once in position, the catheter measures pulmonary artery mean, systolic, and end-diastolic pressures (PAEDP). The pulmonary artery occlusion pressure (PAOP, or capillary 'wedge' pressure) is

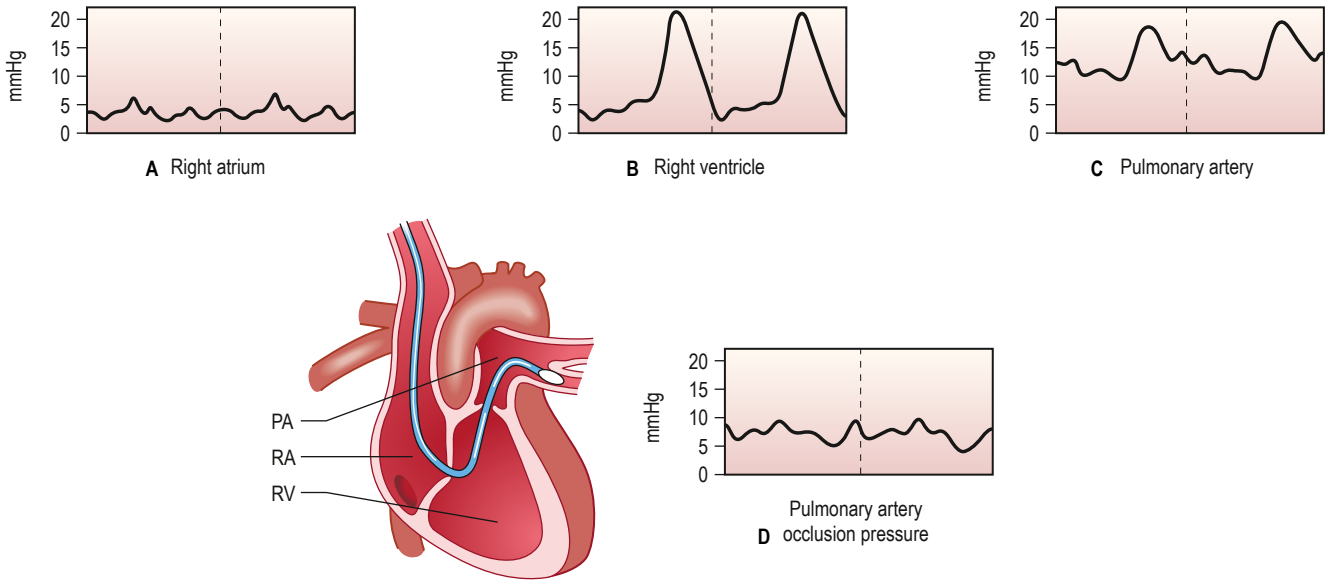

Fig. 13.13 Passage of pulmonary artery balloon flotation catheter through the chambers of the heart. The catheter is passed into the 'wedged' position to measure the pulmonary artery occlusion pressure (see **Box 13.4**). *PA,* Pulmonary artery; *RA,* right artery; *RV,* right ventricle.

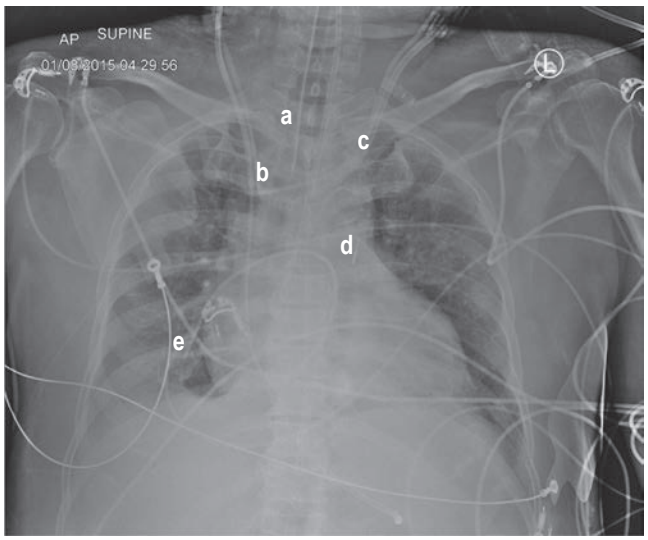

Fig. 13.14 Chest X-ray of a critically ill, mechanically ventilated patient. The X-ray shows **(a)** endotracheal tube; **(b)** end of central venous line seen here medial to the proximal end of the pulmonary artery catheter; **(c)** double-lumen catheter for continuous renal replacement therapy placed via the left internal jugular vein; **(d)** tip of the intra-aortic balloon pump travelling superiorly from a femoral artery; and **(e)** pulmonary artery catheter. Note that the tip of the catheter is too distal; it was therefore subsequently withdrawn by a few centimetres.

measured by inflating the balloon at the tip of the catheter. This creates a continuous column of fluid between the distal lumen of the catheter and the left atrium so that the PAOP is usually a reasonable reflection of left atrial pressure.

The technique is generally safe; the majority of complications, such as 'knotting', valve trauma, and pulmonary artery rupture (which can be fatal), are related to user inexperience. However, they have largely been superseded by less invasive technologies.

Cardiac output

The gold standard cardiac output monitor uses a modified pulmonary artery catheter that transmits low-energy heat from a heating element in the catheter into the surrounding blood. A 'thermodilution curve' is constructed by measuring dissipation of the heat using a thermistor located distal to the heating coil. The dissipation of heat is directly proportional to the cardiac output. These catheters also optically measure and continuously display S_VO_2.

In general, pulmonary artery catheters may help the clinician optimize cardiac output and oxygen delivery while minimizing the risk of volume overload. They guide the rational use of inotropes and vasoactive agents, particularly in patients with pulmonary hypertension. The unselective use of this monitoring device in the absence of evidence-based haemodynamic goals does not, however, lead to improved outcomes, and less invasive techniques such as oesophageal Doppler and pulse contour analysis devices are preferred, except in the most complex cases (e.g., high-risk cardiac surgery) or where there are significant differences in ventricular performance such as an isolated right ventricular infarct.

Less invasive techniques for assessing cardiac function and guiding volume replacement

Arterial pressure variation as a guide to hypovolaemia

Systolic arterial pressure decreases during the inspiratory phase of intermittent positive pressure ventilation (IPPV) (see 'Respiratory support' section). The magnitude of this cyclical variability has been shown to correlate more closely with hypovolaemia than other monitored variables. Systolic pressure (or pulse pressure) variation during mechanical ventilation can be used as a simple and reliable guide to the circulatory volume's adequacy. The response to fluid loading can

also be predicted simply by observing the changes in pulse pressure during passive leg-raising.

Oesophageal Doppler

Stroke volume, cardiac output, and myocardial function can be assessed non-invasively using Doppler ultrasonography. A probe is passed into the oesophagus to monitor velocity waveforms from the descending aorta continuously (**Fig. 13.15**). Although reasonable estimates of stroke volume, and hence cardiac output, can be obtained, the technique is best reserved for trend analysis rather than for making absolute measurements. It is particularly valuable for perioperative optimization of the circulating volume and cardiac performance in the unconscious patient. It is contraindicated in patients with oropharyngeal/oesophageal pathology.

Arterial waveform analysis

Lithium dilution/pulse contour analysis does not require pulmonary artery catheterization or instrumentation of the oesophagus and is suitable for use in conscious patients. A bolus of lithium chloride is administered via a central venous catheter and the change in arterial plasma lithium concentration is detected by a lithium-sensitive electrode. This sensor can be connected to an existing arterial cannula via a three-way tap. The cardiac output determined in this way can be used to calibrate an arterial pressure waveform ('pulse contour') analysis programme that will continuously monitor changes in cardiac output. Devices that employ uncalibrated pulse contour analysis to estimate cardiac output are also available.

Other devices utilize a thermodilution technique, where a small volume of cold fluid is injected into a large central vein and a temperature washout curve is detected via a sensor in a modified arterial line. Following this calibration, beat-to-beat cardiac output is generated by computer-based analysis of the arterial pressure waveform.

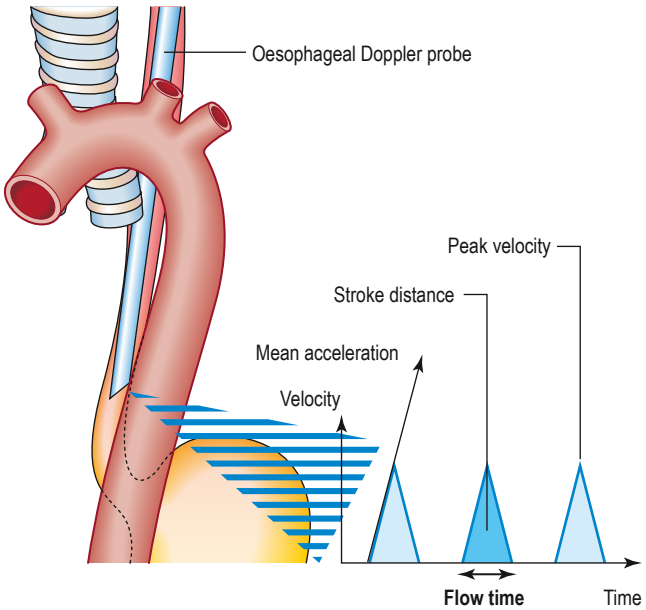

Fig. 13.15 Doppler ultrasonography. Velocity waveform traces are obtained using oesophageal Doppler ultrasonography. *(Reproduced from Singer M, Bennett, ED. Noninvasive optimization of left ventricular filling using esophageal Doppler*. Crit Care Med *1991;19:1132–1137, with permission. © 1991 The Williams & Wilkins Co., Baltimore.)*

As with pulse pressure variation, stroke volume variation, determined by oesophageal Doppler or arterial waveform analysis, can be used to guide fluid replacement.

Echocardiography

Focused transthoracic echocardiography (TTE) is increasingly used to provide immediate diagnostic information about cardiac structure and function (myocardial contractility, ventricular filling) in the critically ill patient. Although transoesophageal echocardiography (TOE) may offer superior image clarity (**Fig. 13.16**), TTE is non-invasive, more readily available, and can easily guide haemodynamic queries, with TOE reserved for complex structural assessment or where there are poor acoustic echo windows.

Key points in monitoring cardiac function

These are shown in **Box 13.4**.

i Box 13.4 Key points in monitoring cardiac function

- If there is disagreement between clinical signs and a monitored variable, assume that the monitor is incorrect until all sources of potential error have been checked and eliminated.
- Remember that changes and trends in monitored variables are more informative than a single reading.
- Use non-invasive monitoring where possible.
- Remove invasive devices as soon as possible

Box 13.5 Arterial blood gas and acid–base values

Analyte	Normal reference range
H^+	35–45 nmol/L (pH 7.35–7.45)
PO_2 (breathing room air)	10.6–13.3 kPa (80–100 mmHg)
PCO_2	4.8–6.1 kPa (36–46 mmHg)
Base deficit	±2.5
Plasma HCO_3^-	22–26 mmol/L
O_2 saturation	95–100%

Both acidosis and alkalosis can occur, each of which is either metabolic (primarily affecting the bicarbonate component of the system) or respiratory (primarily affecting P_aCO_2). Compensatory changes may also be apparent. In clinical practice, pH values outside of 6.9–7.7 (arterial $[H^+]$ values 20 to 126 nmol/L) are rarely encountered.

Blood gas and acid–base values (normal ranges) are shown in Box 13.5. (For blood gas analysis, see 'Respiratory failure' section.)

Respiratory acidosis

This is caused by retention of carbon dioxide. The P_aCO_2 and $[H^+]$ rise. A chronically raised P_aCO_2 is compensated by renal retention of bicarbonate and the $[H^+]$ returns towards normal. A constant arterial bicarbonate concentration is then usually established within 2 to 5 days. This represents a primary respiratory acidosis with a compensatory metabolic alkalosis. Common causes of respiratory acidosis include ventilatory failure (e.g., patients in coma or those with neuromuscular disorders) and COPD (type II respiratory failure, where there is a high P_aCO_2 and a low P_aO_2, see Chapter 20).

Respiratory alkalosis

This results from an increase in minute ventilation (higher respiratory rate and/or tidal volumes) in which there is a fall in P_aCO_2 and $[H^+]$, often with a small reduction in bicarbonate concentration. If hypocarbia persists, some degree of renal compensation may occur, producing a metabolic acidosis, although in practice, this is unusual. A respiratory alkalosis may be produced, intentionally or unintentionally, when patients are mechanically ventilated; it may also be seen in patients with hypoxaemic (type I) respiratory failure (see Chapter 20), those with spontaneous hyperventilation, and those living at high altitudes.

Metabolic acidosis

Metabolic acidosis (see Chapter 27) may be due to excessive acid production, often lactic acid (lactic acidosis), as a consequence of anaerobic metabolism during an episode of shock or following cardiac arrest or after a prolonged seizure. A metabolic acidosis may develop as a consequence of chronic renal failure or in diabetic ketoacidosis. It can also follow the loss of bicarbonate from the gut or from the kidney in renal tubular acidosis. Respiratory compensation for a metabolic acidosis occurs when the patient hyperventilates and 'blows off' carbon dioxide to produce a compensatory respiratory alkalosis. However, there is a limit to this respiratory compensation since, in practice, values for P_aCO_2 of less than 1.4 kPa (11 mmHg) are rarely achieved. Spontaneous respiratory compensation cannot occur if the patient's ventilation is controlled or if the respiratory centre is depressed, for example, by drugs or head injury.

Metabolic alkalosis

This can be caused by loss of acid—for example, from the stomach with excessive vomiting or with nasogastric suction, or in high intestinal obstruction, or excessive administration of absorbable or intravenous alkali. Respiratory compensation for a metabolic alkalosis is often slight, and it is rare to encounter a P_aCO_2 above 6.5 kPa (50 mmHg), even with severe alkalosis.

Box 13.6 Causes of shock

Hypovolaemic
- Exogenous losses (e.g., haemorrhage, burns)

Cardiogenic
- 'Myocardial failure' (e.g., ischaemic myocardial injury)

Obstructive
- Obstruction to cardiac outflow (e.g., pulmonary embolus)
- Restricted cardiac filling (e.g., cardiac tamponade, tension pneumothorax)

Distributive
- Vascular dilation (e.g., sepsis, anaphylaxis)
- Sequestration
- Arteriovenous shunting
- Maldistribution of flow

SHOCK, SEPSIS, AND ACUTE DISTURBANCES OF HAEMODYNAMIC FUNCTION

Shock is the term used to describe acute circulatory failure with inadequate or inappropriately distributed tissue perfusion, resulting in generalized cellular hypoxia and/or an inability of the cells to utilize oxygen.

Aetiology of shock

Abnormalities of tissue perfusion can result from:
- failure of the heart to act as an effective pump
- mechanical impediments to forward flow
- loss of circulatory volume
- abnormalities of the peripheral circulation.

The causes of shock are shown in Box 13.6; see also Chapter 12 for definitions of sepsis. Often, shock can result from a combination of these factors (e.g., in sepsis, distributive shock is frequently complicated by hypovolaemia and myocardial depression).

Pathophysiology

The sympatho-adrenal response to shock

Hypotension stimulates baroreceptors and, to a lesser extent, chemoreceptors, causing increased sympathetic nervous activity with 'spill-over' of noradrenaline (norepinephrine) into the circulation. Later, this is augmented by the release of catecholamines (predominantly adrenaline [epinephrine]) from the adrenal medulla. The resulting vasoconstriction, together with increased myocardial contractility and heart rate, helps to restore blood pressure and cardiac output (Fig. 13.17).

Reduced perfusion of the renal cortex stimulates the juxtaglomerular apparatus to release renin. This converts angiotensinogen to angiotensin I, which, in turn, is converted in the lungs and by the vascular endothelium to the potent vasoconstrictor angiotensin II. Angiotensin II also stimulates secretion of aldosterone by the adrenal cortex, causing sodium and water retention (see Chapter 26). This helps to restore the circulating volume.

The neuroendocrine response

- ***Release of pituitary hormones*** includes adrenocorticotrophic hormone (ACTH), vasopressin (arginine vasopressin, AVP), and

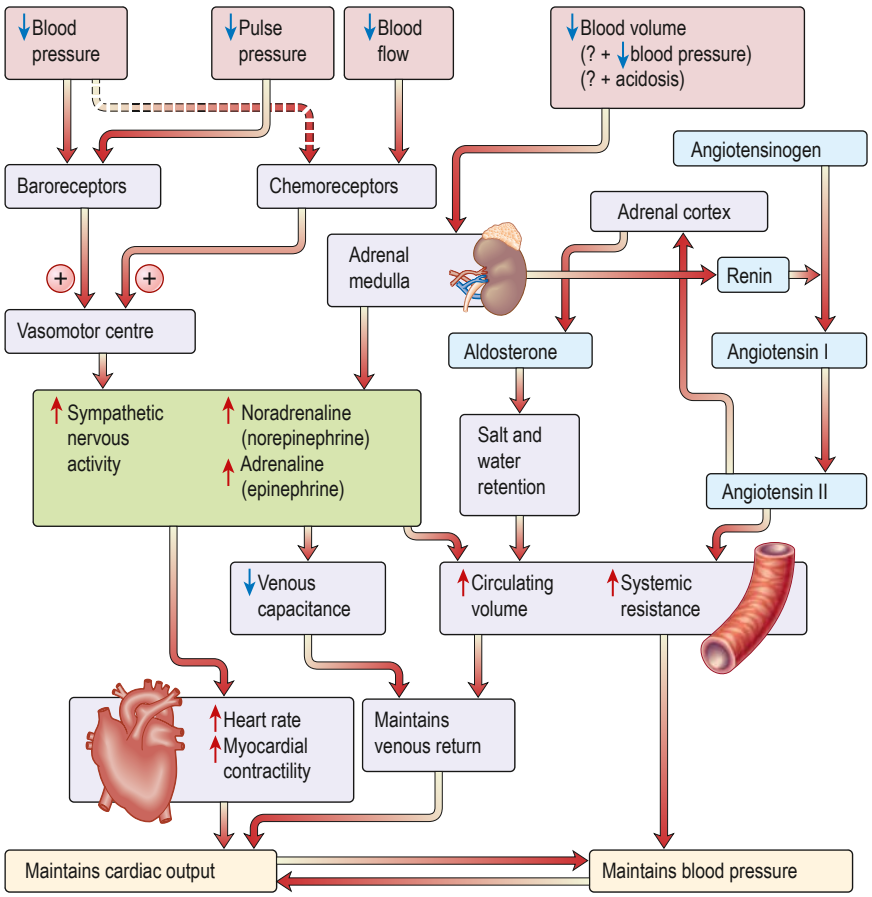

Fig. 13.17 The sympatho-adrenal response to shock. The effect of increased catecholamines is shown on the left and the release of angiotensin and aldosterone on the right. Both mechanisms help to maintain cardiac output and blood pressure in shock.

endogenous opioid peptides. (In septic shock, there may be a relative deficiency of vasopressin.)

- ***Release of cortisol*** causes fluid retention and antagonizes insulin.
- ***Release of glucagon*** raises the blood sugar level.

Although absolute adrenocortical insufficiency (e.g., due to bilateral adrenal haemorrhage or necrosis in meningococcal infection) is rare, a blunted response to exogenous ACTH (so-called ***'relative'*** or ***'occult' adrenocortical insufficiency***) has been observed in septic shock patients with impaired vasoconstrictor response to noradrenaline (norepinephrine). Steroid supplementation improves vasomotor response with a rise in blood pressure but without mortality benefit.

Release of immune mediators

Severe infection (often with bacteraemia or endotoxaemia), the presence of large areas of damaged tissue (e.g., following trauma or extensive surgery), hypoxia, or prolonged/repeated episodes of hypoperfusion can all trigger a dysfunctional immune response with alterations in leucocyte activation and release of a variety of potentially damaging 'mediators' (see also Chapter 6). Although an appropriate immune response is clearly beneficial, the disseminated, dysregulated response observed in some patients can lead to shock and organ failure. This immune response is complex, with upregulation and downregulation of both the innate and the adaptive immune pathways at different stages of the illness. Characteristically, the later phase is typified by a period of immune suppression, during which the patient is at increased risk of developing secondary infections.

Microorganisms and their toxic products

In sepsis/septic shock, the innate immune response (Fig. 13.18) and inflammatory cascade are triggered by the recognition of pathogen-associated molecular patterns (PAMPs), including bacterial and fungal DNA, cell-wall components (e.g., endotoxin), and/or exotoxins (antigenic proteins produced by bacteria such as staphylococci, streptococci, and *Pseudomonas*) (see also Chapter 12).

Endotoxin is a lipopolysaccharide (LPS) derived from the cell wall of Gram-negative bacteria and a potent trigger of the immune response. The lipid A portion of LPS is bound by a serum protein known as lipopolysaccharide-binding protein (LBP). The LBP–LPS complex attaches to the cell surface marker CD14 and, combined with a secreted protein (MD2), then binds to a member of the Toll-like receptor family (TLR4), which transduces the activation signal into the cell. Activation of these receptors promotes the synthesis of a wide variety of immune mediators. Gram-positive bacteria have cell-wall components that are similar in structure to LPS (e.g., lipoteichoic acid) and can also trigger an inflammatory response through similar pathways (see Fig. 13.18).

Toxic products of tissue injury (surgery and trauma)

Following traumatic or surgical tissue injury, inflammatory pathways may be triggered by damage-associated molecular

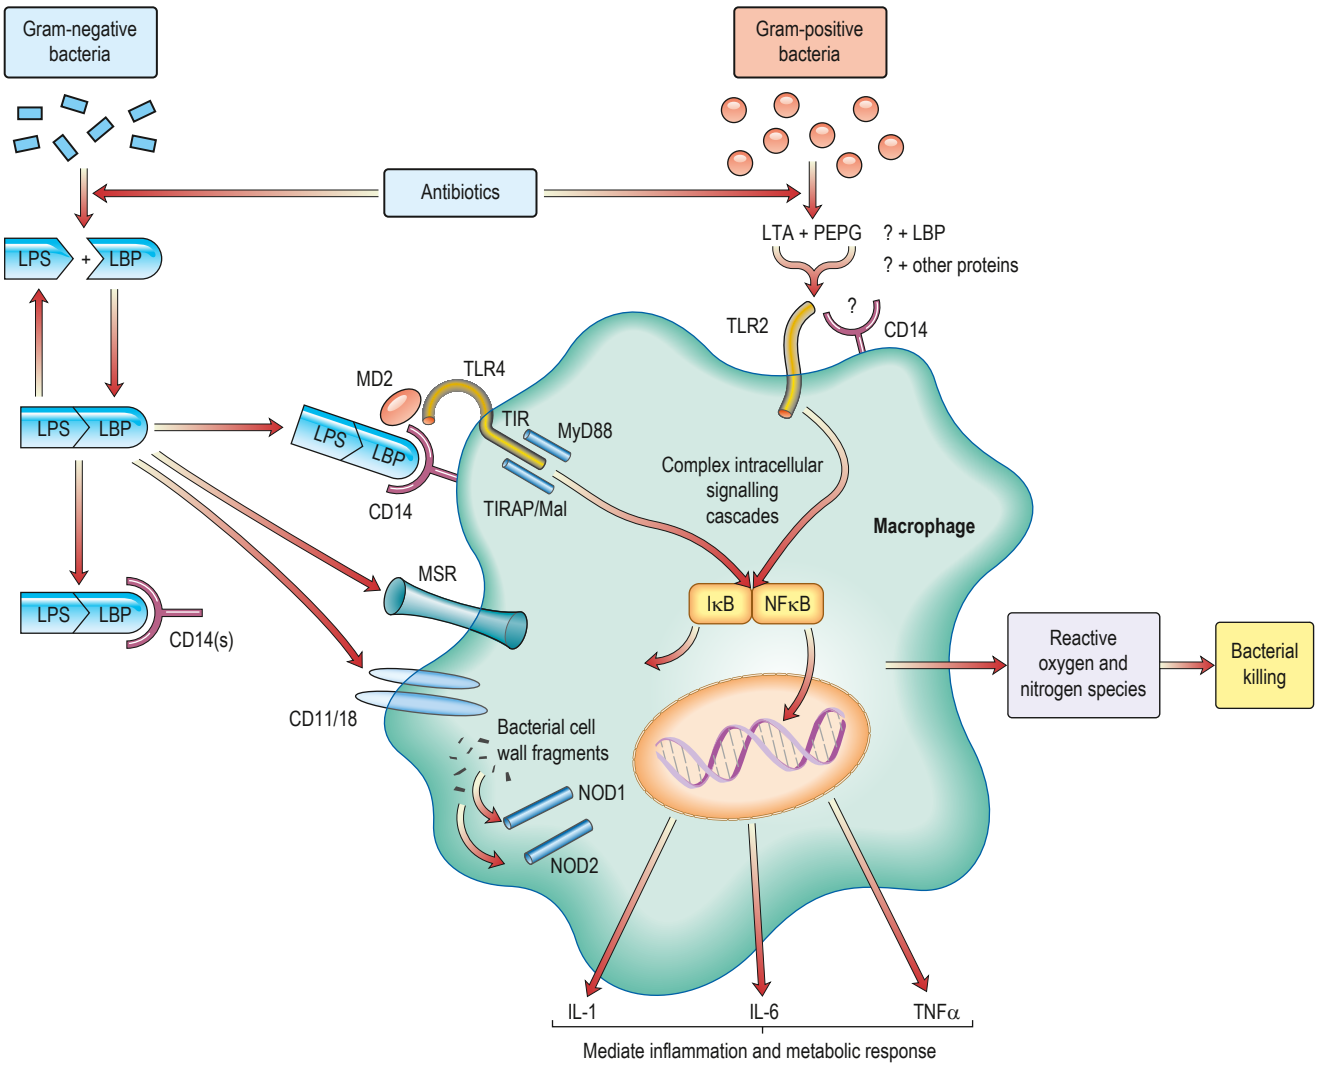

Fig. 13.18 Induction of the innate immune response by the lipopolysaccharide–lipopolysaccharide-binding protein (LPS–LBP) complex. The intracellular events (simplified) initiated by Gram-negative and Gram-positive bacteria, which eventually lead to bacterial killing. *IκB,* Inhibitory factor kappa B; *IL,* interleukin; *LTA,* lipoteichoic acid; *MD2,* a secreted protein involved in binding liposaccharide with TLR4; *MSR,* macrophage scavenger receptor; *MyD88,* myeloid differentiation factor 88; *NFκB,* nuclear factor kappa B; *NOD,* nucleotide-binding oligomerization domain; *PEPG,* peptidoglycan-N; *TIR,* Toll-interleukin receptor; *TIRAP,* Toll-interleukin 1 receptor adaptor protein; *TIRAP/Mal,* an adaptor protein for TLR2 and TLR4; *TLR,* Toll-like receptors; *TNF-α,* tumour necrosis factor-alpha.

patterns (DAMPs), such as DNA fragments. Of particular importance is circulating mitochondrial DNA (mtDNA), which is similar to bacterial DNA and can be 'mistaken' by the immune system for bacteria. This initiates an immune response identical to that observed following bacterial invasion. This is why distributive shock secondary to infection can be difficult to distinguish clinically from that caused by a 'sterile' insult such as severe trauma or surgery.

Cytokines and other immune mediators

An array of cytokines and chemokines (small proteins that orchestrate immune cell behaviour), prostaglandins, leukotrienes, heat shock proteins, adhesion molecules, and endothelial-derived vasoactive factors are induced, particularly during distributive shock. These include pro-inflammatory cytokines (tumour necrosis factor-alpha [TNF-α] and interferon-gamma [IFN-γ]), anti-inflammatory cytokines (interleukin 10 [IL-10]), mediators promoting extracellular extravasation (intracellular adhesion molecule 1 [ICAM-1]), and vasodilation (inducible nitric oxide synthase [iNOS], Fig. 13.19). Although there was initial enthusiasm for treatments that dampened the immune response in septic shock (e.g., high-dose steroids and anti-TNF-α compounds), these strategies failed to improve survival and some worsened it.

Activation of the complement cascade

Fragments of C3 act as opsonins and co-stimulatory molecules that assist lymphocytes with the adaptive immune response, while small peptides derived from C3, C4, and C5 cause leucocyte chemotaxis, release of cytokines, and increased vascular permeability (see Chapter 6).

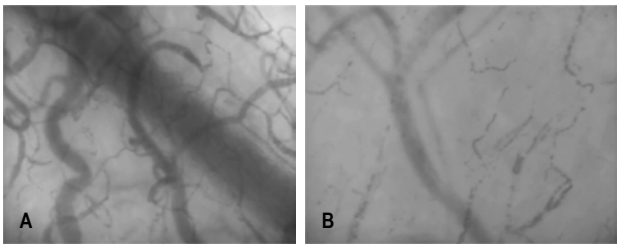

Fig. 13.20 Still side-stream dark field (SDF) images of the microcirculation. (A) Normal subject. **(B)** Septic shock.

Influence of genetic variation

Individuals vary considerably in their susceptibility to infection, as well as their ability to recover from apparently similar infections, illnesses, or traumatic insults; this is explained in part by genetic variations.

Haemodynamic and microcirculatory changes

The dominant haemodynamic feature of severe sepsis/septic shock is peripheral vascular failure with:

- vasodilation;
- maldistribution of regional blood flow; and
- abnormalities in the microcirculation (Fig. 13.20):
  1. 'stop-flow' capillaries (flow is intermittent)
  2. 'no-flow' capillaries (capillaries are obstructed)
  3. failure of capillary recruitment
  4. increased capillary permeability with interstitial oedema.

Although these ***vascular and microvascular abnormalities*** may partly account for the reduced oxygen extraction seen in septic shock, there is also a ***primary defect of cellular oxygen utilization*** caused by mitochondrial dysfunction (see earlier). These changes may be associated with impaired oxygen consumption, a reduced arteriovenous oxygen content difference, an increased $S_{\bar{v}}O_2$, and a lactic acidosis (so-called ***'tissue dysoxia'***). The rise in lactate levels is partly due to tissue hypoxia as well as the stress response leading to increased glucose metabolism and lactate formation. Similar vasodilation and increased vascular permeability also occur in anaphylactic shock.

The glycocalyx consists of a tight, negatively charged, extremely thin meshwork of proteoglycans on the luminal surface of the vascular endothelium. Oxidative stress, free radicals, and endotoxaemia all have specific detrimental effects on the glycocalyx that promote fluid movement into the tissues. Hence, 'pitting' peripheral oedema is often seen in the most seriously ill patients.

Activation of the coagulation system

The immune response to shock, tissue injury, and infection is frequently associated with systemic activation of the clotting cascade, leading to platelet aggregation and widespread microvascular thrombosis, resulting in turn in reduced tissue perfusion.

Initially, the production of prostaglandin I_2 (PGI_2) by the capillary endothelium is impaired. Vascular endothelial injury leads to exposure to tissue factor (see Chapter 38), which triggers coagulation. In severe cases, these changes are compounded by impairment of fibrinolysis, as well as by deficiencies in physiological inhibitors of coagulation (including antithrombin, proteins C and S, and tissue factor-pathway inhibitor). This procoagulant state can lead to end-artery thrombosis and digital and mesenteric ischaemia. Following clot formation, plasminogen is converted to plasmin, which breaks down thrombus, liberating fibrin/fibrinogen degradation products (FDPs). These processes continue in parallel, leading to a 'consumptive' coagulopathy known as ***disseminated intravascular coagulation (DIC)***. Circulating levels of FDPs and D-dimers are therefore increased; the thrombin time, partial thromboplastin time (PTT), and prothrombin time (PT) are prolonged; and platelet and fibrinogen levels fall. Clinically, the patient will bleed from trivial venepuncture sites but, paradoxically, may still be at risk of thrombosis. The development of DIC is often associated with multiorgan failure. In some cases, a microangiopathic haemolytic anaemia develops. DIC is relatively uncommon but is associated particularly with septic shock, especially when due to meningococcal infection. Management targets the ***underlying cause***, as well as supportive treatment with fresh frozen plasma, platelets, and cryoprecipitate when fibrinogen levels are low and the patient is bleeding.

Clinical features of shock and sepsis

Although many clinical features are common to all types of shock, the causes may be distinguished by the associated haemodynamic changes (Box 13.7) and by examination.

Hypovolaemic shock

- ***Inadequate tissue perfusion:***
  1. Skin: cold, pale, slate-grey, slow capillary refill, 'clammy'
  2. Kidneys: oliguria, anuria
  3. Brain: drowsiness, confusion, and irritability
- ***Increased sympathetic tone:***
  1. Tachycardia, narrowed pulse pressure, 'weak' or 'thready' pulse
  2. Sweating
  3. Blood pressure: may be maintained initially (despite up to a 25% reduction in circulating volume if the patient is young and fit) but hypotension later supervenes
- ***Lactic acidosis:*** compensatory tachypnoea.

Extreme hypovolaemia may be associated with bradycardia.

Cardiogenic shock

The signs in cardiogenic shock are the same as those in hypovolaemic shock, with the addition of myocardial failure: for example, raised jugular venous pressure (JVP), pulsus alternans, 'gallop' rhythm, basal crackles, and pulmonary oedema.

Obstructive shock

Again, the signs are as in hypovolaemic shock with the following additions:

- Elevated JVP
- Pulsus paradoxus and muffled heart sounds in cardiac tamponade
- Signs of pulmonary embolism (see Chapter 11).

Box 13.7 Haemodynamic changes in shock

Hypovolaemic shock

Low central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP)

- Low cardiac output
- Increased systemic vascular resistance

Cardiogenic shock

Signs of myocardial failure

- Increased systemic vascular resistance
- CVP and PAOP high (except when hypovolaemic)

Cardiac tamponade

Parallel increases in CVP and PAOP

- Low cardiac output
- Increased systemic vascular resistance

Pulmonary embolism

Low cardiac output

- High CVP, high pulmonary artery pressure but low PAOP
- Increased systemic vascular resistance

Anaphylaxis

Low systemic vascular resistance

- Low CVP and PAOP
- High cardiac output

Septic shock

Low systemic vascular resistance

- Low CVP and PAOP
- Cardiac output usually high
- Myocardial depression—low ejection fraction
- Stroke volume maintained by ventricular dilation
- Cardiac output maintained or increased by tachycardia

Distributive shock: anaphylactic shock

(See Chapter 11).

- Signs of profound vasodilation:
  1. Warm peripheries
  2. Low blood pressure
  3. Tachycardia.
- Erythema, urticaria, angio-oedema, pallor, cyanosis.
- Bronchospasm, rhinitis.
- Oedema of the face, pharynx, and larynx.
- Pulmonary oedema.
- Hypovolaemia due to vascular leak.
- Nausea, vomiting, abdominal cramps, diarrhoea.

Ideally, 10 mL of clotted blood should be taken within 45 to 60 minutes of the reaction for confirmation of the diagnosis by measurement of mast cell degranulation (tryptase levels). Immunology follow-up of these patients is essential.

Distributive shock: sepsis and septic shock

Sepsis and ***septic shock*** are defined in Chapter 12. The ***Sequential Organ Failure Assessment (SOFA) score***, used to identify organ dysfunction, is shown in **Box 12.2**.

Symptoms and signs of sepsis include:

- Pyrexia and rigors, or hypothermia (unusual, but more common in the elderly and associated with worse prognosis)
- Nausea, vomiting
- Vasodilation, warm peripheries
- Bounding pulse
- Rapid capillary refill
- Hypotension, low diastolic pressure, widened pulse pressure

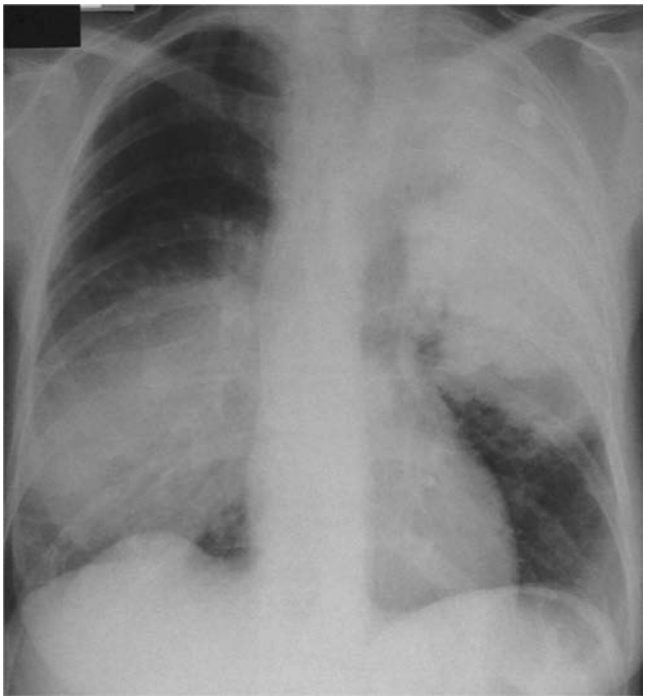

Fig. 13.21 Bilateral pneumococcal pneumonia. Community-acquired pneumonia is the most common cause of sepsis requiring admission to intensive care. *(From Hinds CJ, Watson JD. Intensive Care: A Concise Textbook, 3rd edn. Edinburgh: Saunders; 2008. Courtesy of Dr SPG Padley.)*

- Occasionally, signs of cutaneous vasoconstriction
- Other signs:
  1. Coma, stupor
  2. Bleeding due to coagulopathy (e.g., from vascular puncture sites, gastrointestinal tract, and surgical wounds)
  3. Rash and meningism
  4. Hyperglycaemia; in more severe cases, hypoglycaemia
  5. Jaundice

The ***diagnosis of sepsis*** is easily missed, particularly in the elderly. Clues include mild confusion, tachycardia, tachypnoea, unexplained hypotension, a reduction in urine output, a rising plasma creatinine, and glucose intolerance.

Sepsis and multiple organ failure (multiple organ dysfunction syndrome)

Sepsis is being diagnosed with increasing frequency and is now the most common cause of death in non-coronary adult ICUs. The estimated incidence of severe sepsis is 77 to 300 cases per 100 000 of the population. The most common cause is community-acquired pneumonia (**Fig. 13.21**). Mortality rates are high (between 20% and 60%) and are closely related to the severity of illness and the number of organs that fail. Although some early deaths are caused by cardiovascular collapse, advances in ICU care and supportive therapy have reduced early deaths, and most of those who die are overwhelmed by persistent or recurrent sepsis, with fever, intractable hypotension, and failure of several organs.

Sequential failure of vital organs occurs progressively over days or weeks, although the pattern of organ dysfunction is variable. In many cases, the lungs are the first to be affected (acute respiratory distress syndrome, ARDS; see later) in association with cardiovascular instability and deteriorating renal function. Central

Box 13.8 The metabolic response to trauma, major surgery, and severe infection

- ↑ Energy expenditure
- ↑ Gluconeogenesis
- ↑ Mobilization of glucose from glycogen
- Insulin resistance and hyperglycaemia
- ↑ Free fatty acid synthesis
- ↑ Protein breakdown
- ↑ Liver synthesis of acute phase reactants

nervous system (CNS) dysfunction is also an early feature, including impaired consciousness, disorientation, and coma, and is included in the qSOFA score (see Box 12.3) commonly used to identify septic patients outside of the ICU. Liver dysfunction may develop later. Gastrointestinal failure, with an inability to tolerate enteral feeding and paralytic ileus, is common. Ischaemic colitis, acalculous cholecystitis, pancreatitis, and gastrointestinal haemorrhage may also occur. Characteristically, these patients initially have a hyperdynamic circulation with vasodilation and a high cardiac output, associated with an increased metabolic rate. Eventually, however, cardiovascular collapse supervenes. It is often possible to support such patients for weeks or months; most die following a decision to withdraw or not to escalate treatment (see 'Withholding and withdrawing treatment' section).

Metabolic response to trauma, major surgery, and severe infection

This is initiated and controlled by the neuroendocrine system and various cytokines (e.g., IL-6) acting in concert and is characterized initially by an increase in energy expenditure ('hypermetabolism'; **Box 13.8**). Gluconeogenesis is stimulated by increased glucagon and catecholamine levels, while hepatic mobilization of glucose from glycogen is increased. Catecholamines inhibit insulin release and reduce peripheral glucose uptake. Combined with elevated circulating levels of other insulin antagonists such as cortisol and downregulation of insulin receptors, these changes mean that the majority of patients are hyperglycaemic ('insulin resistance'). Later, hypoglycaemia may be precipitated by depletion of hepatic glycogen stores and inhibition of gluconeogenesis. Free fatty acid synthesis is also increased, leading to hypertriglyceridaemia.

Protein breakdown is initiated to provide energy from amino acids, and hepatic protein synthesis is preferentially augmented to produce the 'acute phase reactants'. The amino acid glutamine (which is indispensable in this situation) is mobilized from muscle for use as a metabolic fuel in rapidly dividing cells such as leucocytes and enterocytes. Glutamine is also required for hepatic production of the free radical scavenger glutathione. When severe and prolonged, this catabolic response can lead to considerable weight loss. Protein breakdown is associated with wasting and weakness of skeletal and respiratory muscle, prolonging the need for mechanical ventilation and delaying mobilization. Tissue repair, wound healing, and immune function are also compromised.

Management of shock and sepsis

Delays in recognizing sepsis and initiating resuscitation and treatments (**Fig. 13.22**) (particularly antibiotics when infection is the underlying cause) are associated with substantially increased morbidity and mortality.

A patent airway must be maintained and oxygen given, as is standard for any acutely ill patient. Some may require endotracheal intubation and those with impending respiratory arrest will require immediate mechanical ventilation.

The underlying cause of shock should be sought and corrected where possible; for example, haemorrhage should be controlled or infection treated. In patients with septic shock, every effort must be made to identify the source of infection and isolate the causative organism. A thorough history, clinical examination, and imaging (X-ray, ultrasonography, or computed tomography [CT] scanning) should be undertaken. Appropriate samples (blood, urine, sputum, cerebrospinal fluid [CSF], pus drained from abscesses) should be taken for microscopy, culture, and sensitivities. Empirical, broad-spectrum antibiotic therapy (see Chapter 12) should be commenced *within the first hour* of recognition of sepsis. If an organism is isolated later, therapy can be adjusted accordingly. The choice of antibiotic depends on the likely source of infection, previous antibiotic therapy, and known local resistance patterns, as well as if the infection was acquired in hospital or in the community. Sources of sepsis such as abscesses and collections must be drained, and infected indwelling catheters removed.

Whatever the aetiology of the haemodynamic abnormality:

- ***Tissue perfusion*** must be restored promptly by resuscitation and re-establishment of the circulation and cardiac output, as well as haemoglobin levels (oxygen carrying capacity).
- ***Arterial blood pressure*** should be restored to maintain perfusion of vital organs.
- ***Published guidelines*** for adult patients suffering septic shock should be followed. These advocate targeting a mean arterial pressure (MAP) of >65 mmHg, a CVP of 8–12 mmHg (>12 mmHg if mechanically ventilated), a urine output of >0.5 mL/kg per hour, and an $S_{CV}O_2$ of ≥70% as the initial goals of resuscitation.
- The ***aim of current sepsis guidelines*** (see 'Further reading') is to combine evidence-based interventions with early effective resuscitation (aimed especially at achieving an adequate circulating volume, combined with the rational use of inotropes and/or vasoactive agents to maintain blood pressure, cardiac output, and oxygen transport), in order to create 'bundles of care' delivered within specific time limits.

Preload and volume replacement

Optimizing preload is the most efficient way of increasing cardiac output. Volume replacement is obviously essential in hypovolaemic shock but is also required in anaphylactic and septic shock because of vasodilation, sequestration of blood, and loss of circulating volume because of vascular leak.

In obstructive shock, high filling pressures may be required to maintain an adequate stroke volume. Even in cardiogenic shock, careful volume expansion may, on occasion, lead to a useful increase in cardiac output. On the other hand, patients with severe cardiac failure, in whom ventricular filling pressures are markedly elevated, often benefit from measures to reduce preload (and afterload), such as the administration of vasodilators and diuretics (see later). Adequate perioperative volume replacement also reduces morbidity and mortality in high-risk surgical patients.

The circulating volume must be replaced quickly in order to reduce tissue damage and prevent acute kidney injury (AKI). Continuous observation of clinical signs, biochemical variables (acid–base and lactate levels), and stroke volume is vital for management and avoidance of volume overload. Pulmonary and peripheral oedema is more likely in seriously ill patients receiving large-volume fluid resuscitation because of a low colloid osmotic pressure (usually due to a low serum albumin), disruption of the alveolar–capillary

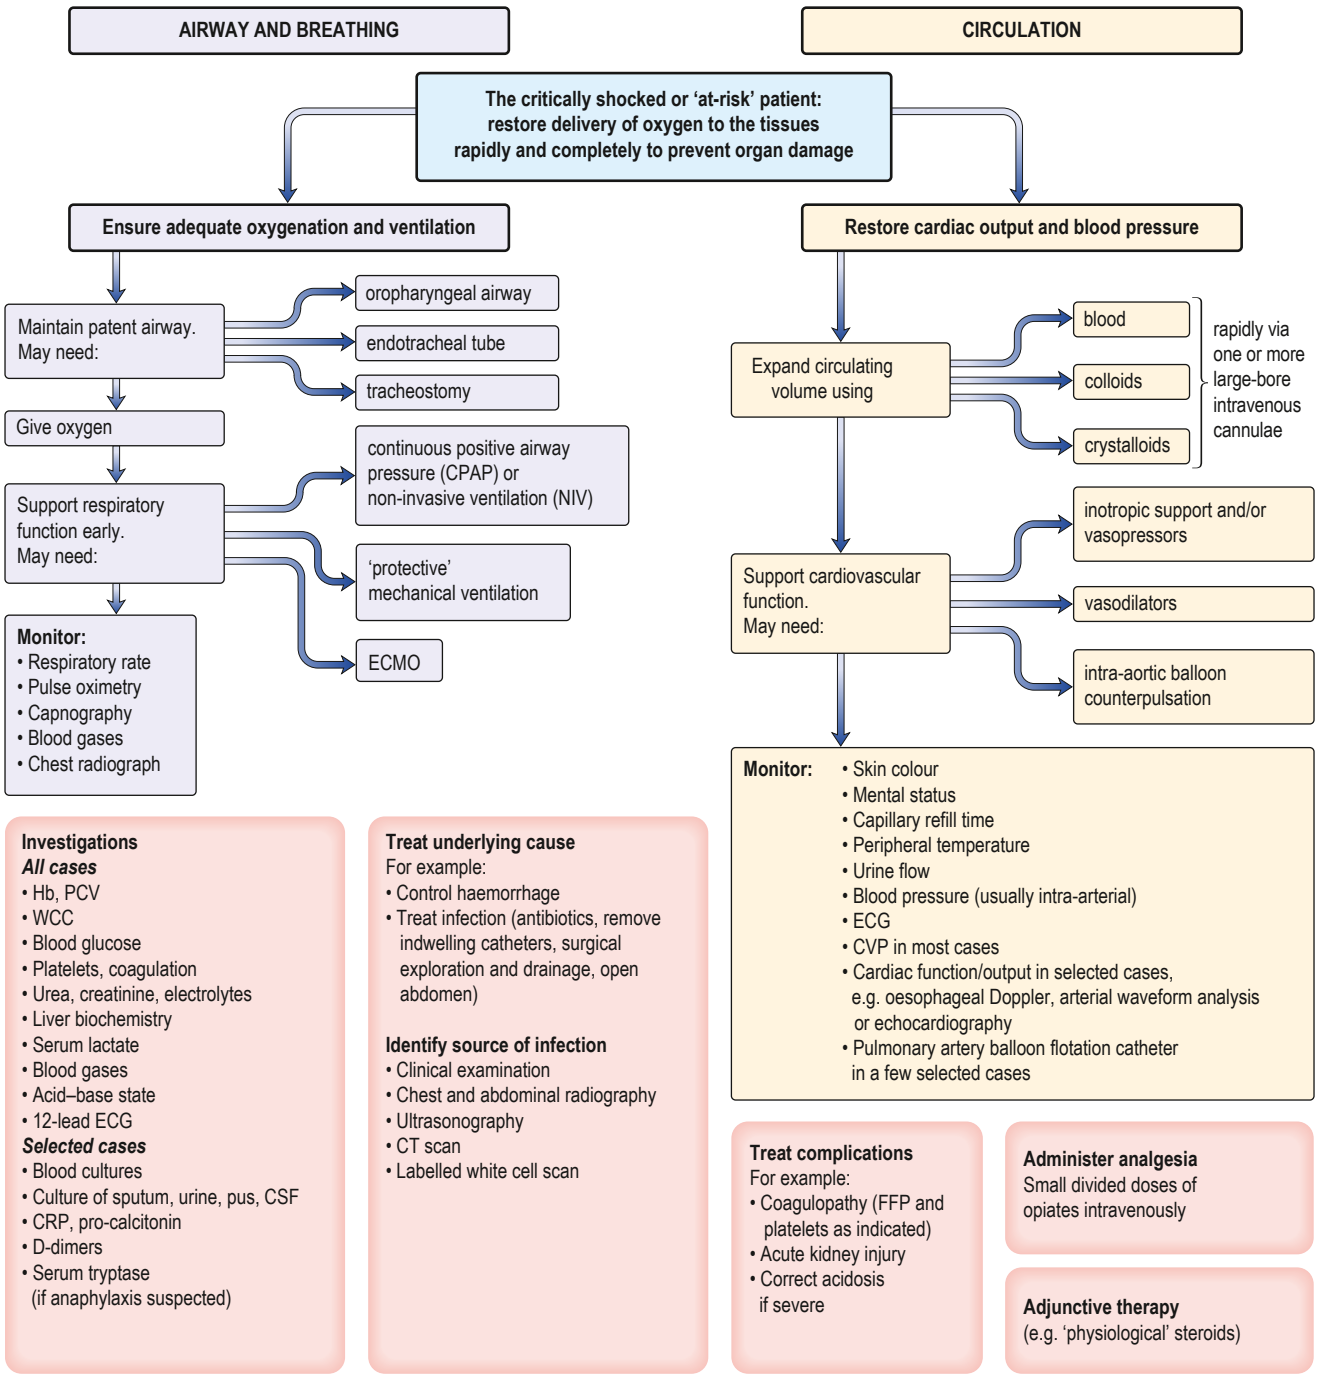

Fig. 13.22 Management of the critically ill, shocked, or 'at-risk' patient. *CRP,* C-reactive protein; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *CVP,* central venous pressure; *ECG,* electrocardiogram; *ECMO,* extracorporeal membrane oxygenation; *FFP,* fresh frozen plasma; *Hb,* haemoglobin; *PCV,* packed cell volume; *WCC,* white cell count.

membrane, microcirculatory changes, and destruction of the endothelial glycocalyx.

Choice of fluid for volume replacement

Blood

This is conventionally given for haemorrhagic shock as soon as it is available. In extreme bleeding emergencies, blood group O Rhesus D negative (universal donor) red cells can be used, although group-specific crossmatch can be performed in minutes (see Chapter 38). When available and not contraindicated, blood salvage may be employed for those with severe ongoing bleeding.

Transfusion of whole blood has largely been replaced by that of red cell concentrates. The use of leucodepleted blood is considered to be safer in terms of immune-mediated transfusion reactions, disease transmission, and immune suppression. Although red cell transfusion can augment oxygen-carrying capacity, and hence global oxygen delivery, transfusion of old stored red blood cells, which become spherical rather than biconcave and poorly

deformable with increased adhesiveness, can compromise microvascular flow. In the case of traumatic or intraoperative haemorrhagic shock, many now favour 'hypotensive resuscitation' with blood and blood products until surgical control of the bleeding has been achieved. This partial resuscitation has been shown to reduce the rate of bleeding and allows the surgeon a greater chance of achieving definitive haemostasis. Once the patient is stable, higher haemoglobin and blood pressure targets may be pursued.

The absolute haemoglobin target in critically ill patients has changed with increasing awareness of the subtle detrimental immune effects associated with transfusing blood. In patients not actively bleeding and without significant cardiovascular risk factors, it is usual to transfuse in order to achieve a target haemoglobin level of 70 g/L or more ('restrictive transfusion strategy'). In patients with significant coronary artery disease or limited respiratory reserve, a target level of 90 g/L ('liberal transfusion strategy') may be more appropriate but remains controversial. Healthy individuals can tolerate haemoglobin levels as low as 40 g/L before displaying signs of cardiac ischaemia.

Massive blood transfusion can be defined as a volume of more than 8 to 10 units of red cells transfused within a 24-hour period, and ***massive haemorrhage*** as a loss of 50% or more of blood volume within 3 hours or a rate of blood loss exceeding 150 mL/min.

Complications of blood transfusion are discussed in Chapter 38. Special problems arise as a result of massive transfusion:

- ***Temperature changes.*** Bank blood is stored at 4°C; transfusion may result in hypothermia, peripheral venoconstriction, and arrhythmias. Blood should be warmed during massive transfusion and in those at risk of hypothermia (e.g., prolonged major surgery with open body cavity).
- ***Coagulopathy.*** Stored blood has virtually no effective platelets or clotting factors. Massive blood transfusions are now accompanied by administration of fresh frozen plasma and platelet concentrates in a balanced ratio of 1:1:1, especially in the treatment of severe traumatic haemorrhage. Cryoprecipitate also plays a key role in securing haemostasis. Recombinant factor VIIa is rarely indicated in those with uncontrollable bleeding, and prothrombin complex concentrates have the advantage that they do not need to be crossmatched or thawed but are expensive. There is significant evidence to support the use of tranexamic acid in patients following major haemorrhage as a result of trauma, postpartum, and major surgery and should be administered early.
- ***Hypocalcaemia.*** Citrate is used to stop coagulation in stored blood by binding calcium ions. As a result, during large transfusion, total body ionized calcium levels often drop, causing myocardial depression and exacerbating coagulation defects. This is corrected by administering intravenous calcium chloride.
- ***Increased oxygen affinity.*** In stored blood, the red cell 2,3-diphophoglycerate (2,3-DPG) content is reduced so that the oxyhaemoglobin dissociation curve is shifted to the left. The oxygen affinity of haemoglobin is therefore increased and oxygen unloading is impaired. Red cell levels of 2,3-DPG are substantially restored within 12 hours of transfusion.
- ***Hyperkalaemia.*** Plasma potassium levels rise progressively as blood is stored. However, hyperkalaemia is rarely a problem, as rewarming of the blood increases red cell metabolism and reactivates the sodium/potassium membrane pumps resulting in uptake of potassium by the red cells. However, there is the occasional need for managing hyperkalaemia with insulin dextrose boluses.
- ***Microembolism.*** Microaggregates in stored blood may obstruct the pulmonary capillaries. This process is thought by some to contribute to acute lung injury.
- ***Immunity.*** Blood transfusion has subtle detrimental effects on the host immune system and has been implicated in a greater susceptibility to nosocomial infections and an increase in the risk of cancer recurrence.

Crystalloids and colloids

The choice of intravenous fluid for resuscitation and the relative merits of crystalloids or colloids have long been controversial. Crystalloid solutions are cheap and convenient to use. However, they are not completely free of side-effects, as large volumes of solutions with high chloride content, such as 0.9% saline, can cause a hyperchloraemic acidosis and are associated with a greater risk of renal impairment. Balanced solutions, such as compound sodium lactate or Plasma-Lyte 148, are preferred.

Crystalloid solutions are made up of small molecules, and due to the increased capillary leak seen in conditions such as sepsis, larger volumes are required to achieve the end points of resuscitation. As a result, colloid solutions (gelatin or hydroxyethyl starch based), with larger molecules, were previously more extensively used as they were more efficient at stabilizing resuscitation end points with lower volumes required to do so. However, recent evidence has suggested higher mortality rates, as well as more AKI and clotting disorders. Furthermore, colloid solutions are more expensive to make and can cause anaphylactic reactions. As a result, their use is no longer recommended.

Human albumin solution (HAS) is a natural colloid that has been used for volume replacement in shock and burns and for the treatment of hypoproteinaemia. In critically ill patients, resuscitation with equivalent volumes of either 0.9% saline or the colloid 4% albumin has been shown to result in similar outcomes. As a result, HAS is not generally recommended for routine volume replacement because supplies are limited, and other cheaper solutions are equally effective. However, it may have a role in the treatment of hepatorenal syndrome in patients with liver cirrhosis or low albumin.

Myocardial contractility and inotropic agents

Myocardial contractility can be impaired by many factors, such as hypoxaemia and hypocalcaemia, as well as by some drugs (e.g., beta-blockers, antiarrhythmics, and sedatives).

Severe metabolic acidosis is conventionally said to depress myocardial contractility and limit the response to vasopressor agents. Attempted correction of acidosis with intravenous sodium bicarbonate, however, generates additional carbon dioxide, which diffuses across cell membranes, producing or exacerbating intracellular acidosis. Other disadvantages of bicarbonate therapy include sodium overload and a left shift of the oxyhaemoglobin dissociation curve. Ionized calcium levels may be reduced and, combined with the fall in intracellular pH, this may impair myocardial performance. Treatment of lactic acidosis should therefore concentrate on correcting the cause. Bicarbonate should be administered only to correct ***extreme persistent metabolic acidosis*** (see Chapter 27).

If the signs of shock persist, despite adequate volume replacement, and perfusion of vital organs is jeopardized, inotropic/vasopressor agents should be administered to improve cardiac output and blood pressure. Vasopressor therapy may also be required to maintain perfusion in those with life-threatening hypotension, even when volume replacement is incomplete. All inotropes increase myocardial oxygen consumption, particularly if a tachycardia develops, and this can lead to an imbalance between myocardial

oxygen supply and demand, with the development or extension of ischaemic areas. Inotropes should therefore be used with special caution, particularly in cardiogenic shock following myocardial infarction and in known ischaemic heart disease.

Many of the most seriously ill patients become increasingly resistant to the effects of pressor agents, an observation attributed to 'downregulation' of adrenergic receptors and nitric oxide-induced 'vasoplegia' (see later).

All inotropic agents should be administered via a large central vein and their effects continually monitored (**Box 13.9**).

Adrenaline (epinephrine)

Adrenaline stimulates both α- and β-adrenergic receptors, but β effects predominate at low doses. Heart rate and cardiac index increase while peripheral resistance is reduced. If there is an associated increase in perfusion pressure, urine output may improve. Adrenaline at higher doses can cause excessive (α-mediated) vasoconstriction with reductions in splanchnic flow, and cardiac output may fall. Prolonged high-dose administration can cause peripheral gangrene and lactic acidosis. The minimum effective dose of adrenaline should therefore be used for as short a time as possible.

Noradrenaline (norepinephrine)

This is predominantly an α-adrenergic agonist. It is particularly useful in patients with hypotension and a low systemic vascular resistance, such as is seen in septic shock. There is a risk of producing excessive vasoconstriction with impaired organ perfusion and increased afterload, particularly if noradrenaline is administered when fluid resuscitation is inadequate, and the circulating volume is reduced.

Dopamine

The haemodynamic effects of dopamine are dose dependent. At low doses, dopamine is a positive inotrope with vasodilator actions on the renal and splanchnic circulation. Higher doses may be complicated by tachycardia, arrhythmias, and vasoconstriction. Compared to noradrenaline, the use of dopamine is associated with increased risk of death and arrhythmic events in patients with septic shock and is no longer recommended.

Dopexamine

Dopexamine is an analogue of dopamine that activates β_2 receptors, as well as DA_1 and DA_2 receptors. Dopexamine is a weak positive inotrope but a powerful splanchnic vasodilator, reducing afterload and improving blood flow to vital organs, including the kidneys. It has been used as an adjunct to the perioperative management of high-risk surgical patients (see below).

Dobutamine

Dobutamine is closely related to dopamine and has predominantly β_1 activity. Dobutamine has no specific effect on the renal vasculature, but urine output often increases as cardiac output and blood pressure improve. It reduces systemic vascular resistance, as well as improves cardiac performance, thereby decreasing afterload and ventricular filling pressures. Dobutamine is therefore useful in patients with cardiogenic shock and cardiac failure.

Box 13.9 Receptor actions of sympathomimetic and dopaminergic agents

Phosphodiesterase inhibitors (e.g., milrinone, enoximone)

These agents have both inotropic and vasodilator properties. Because the phosphodiesterase type III inhibitors bypass the β-adrenergic receptor, they may cause less tachycardia and fewer arrhythmias than β agonists. They are useful in patients with receptor 'downregulation', those receiving beta-blockers, those being weaned from cardiopulmonary bypass, and those with cardiac failure.

Vasopressin

Low-dose vasopressin can increase blood pressure and systemic vascular resistance in patients with vasodilatory septic shock and a high cardiac output unresponsive to other vasopressors ('vasoplegia'). Low-dose vasopressin is often added to treatment of patients with septic shock with escalating doses of conventional vasopressors such as noradrenaline.

Levosimendan

Levosimendan is a myofilament calcium sensitizer. Unlike other inotropes, levosimendan does not exert its action through increases in intracellular Ca^{2+} and, as a result, does not impair diastolic relaxation of the heart. Levosimendan has phosphodiesterase inhibitor actions, but these are not thought to be clinically significant. The dose is usually infused over 24 hours but, significantly, a long-acting metabolite of levosimendan has similar calcium-sensitizing actions, maintaining the inotropic effect of levosimendan once an infusion is stopped. Adverse cardiovascular effects of levosimendan include tachycardia and hypotension; as a consequence, the addition of a vasopressor may be required.

Summary for use of inotropic and vasopressor agents

- In ***vasodilated septic patients*** with an adequate cardiac output, noradrenaline (norepinephrine) is often used alone to augment the blood pressure during and following fluid resuscitation. A combination of dobutamine and noradrenaline (norepinephrine) can be used for those showing signs of low cardiac output: Dobutamine is given to achieve optimal cardiac output.
- Vasopressin is used to supplement escalating doses of noradrenaline in the patient with vasodilatory shock.

There is evidence to suggest that adrenaline (epinephrine) may be equally safe and effective as a dobutamine/noradrenaline combination. Because of its potency, adrenaline is particularly useful in patients with ***refractory hypotension***. Phosphodiesterase inhibitors can be used in the management of cardiac failure, especially when associated with pulmonary hypertension, and perioperatively in those undergoing cardiac surgery. Dobutamine is an alternative that is also used in septic patients with fluid overload or myocardial failure. The role of levosimendan in the management of shock is less clear due to high cost and lack of mortality benefit, but it may be useful in resistant cardiogenic shock.

Targeting haemodynamics and oxygen transport

Critically ill patients who survive often have raised values for cardiac output and oxygen delivery, DO_2 and VO_2. However, elevation of DO_2 and VO_2 to these 'supranormal' levels following admission to intensive care may in fact be harmful. Despite its initial promise, early goal-directed therapy to resuscitate patients in the emergency room aimed at maintaining a central venous oxygen saturation of more than 70% with augmentation of cardiac output and haemoglobin concentration does not appear to improve outcome in patients with severe sepsis or septic shock. However, the principles of optimization of cardiac output through fluid resuscitation and targeting mean arterial blood pressures of 65 mmHg or more are the basis of early management of patients with septic shock.

Box 13.10 Patients at risk of developing perioperative multiorgan failure

- The elderly
- Patients with co-morbidity, especially limited cardiorespiratory reserve
- Patients with trauma to two body cavities requiring multiple blood transfusions
- Patients undergoing surgery involving extensive tissue dissection, e.g., oesophagectomy, pancreatectomy, aortic aneurysm surgery
- Patients undergoing emergency surgery for intra-abdominal or intrathoracic catastrophic states, e.g., faecal peritonitis, oesophageal perforation

High-risk surgical patients

These patients benefit from intensive perioperative monitoring and circulatory support in a critical care area (**Box 13.10**), in particular, maintenance of oxygenation, adequate circulating volume, and blood pressure. Circulating volume replacement and administration of inotropes or vasopressors should be guided by monitoring of stroke volume/cardiac output. The value of the routine use of inodilators such as dopexamine remains unclear.

Vasodilator therapy

In selected cases, afterload reduction is used to increase stroke volume and decrease myocardial oxygen requirements by reducing the systolic ventricular wall tension. Vasodilation also decreases heart size and the diastolic ventricular wall tension so that coronary blood flow is improved. Vasodilators also improve microcirculatory flow.

Vasodilator therapy can be particularly helpful in patients with cardiac failure in whom the ventricular function curve is flat (see **Fig. 13.8**) so that falls in preload have only a limited effect on stroke volume. This form of treatment, combined in selected cases with inotropic support, is therefore useful in the management of patients with cardiogenic shock and in those with cardiogenic pulmonary oedema or mitral regurgitation.

Nitroglycerine (NTG), at low doses, is predominantly a venodilator, but as the dose is increased, it also causes arterial dilation, thereby decreasing both preload and afterload. Nitrates are particularly useful in the treatment of cardiac failure with pulmonary oedema and are usually given in combination with intravenous furosemide. NTG reduces pulmonary vascular resistance, an effect that can be exploited in patients with a low cardiac output secondary to pulmonary hypertension.

Sodium nitroprusside (SNP) dilates arterioles and venous capacitance vessels, as well as the pulmonary vasculature, by donating nitric oxide. SNP therefore reduces the afterload and preload of both ventricles and can improve cardiac output and the myocardial oxygen supply/demand ratio. The effects of SNP are rapid in onset and spontaneously reversible within a few minutes of discontinuing the infusion. Cyanide poisoning is a risk with high-dose, prolonged infusions.

Mechanical support of the myocardium

Intra-aortic balloon pump counterpulsation (IABP) is the technique used most widely for mechanical support of the failing myocardium. It is discussed in Chapter 17. In specialized centres, ventricular

assist devices and veno-arterial ECMO (see below) may be used in the treatment of cardiac failure.

RESPIRATORY FAILURE

(See also Chapter 20).

Classification and aetiology

The respiratory system consists of a gas-exchanging organ (the lungs) and a ventilatory pump (respiratory muscles/thorax), either or both of which can fail and precipitate respiratory failure. Respiratory failure occurs when pulmonary gas exchange is sufficiently impaired to cause hypoxaemia with or without hypercarbia. In practical terms, respiratory failure is present when the P_aO_2 is below 8 kPa (60 mmHg) or the P_aCO_2 is above 6.7 kPa (50 mmHg). It can be divided into:

- type I respiratory failure, in which the P_aO_2 is low and the P_aCO_2 is normal or low
- type II respiratory failure, in which the P_aO_2 is low and the P_aCO_2 is high.

Type I or 'acute hypoxaemic' respiratory failure often occurs as a result of right-to-left shunts or $\dot{V}/\dot{Q}$ mismatch. Common causes include pneumonia, ARDS, cardiogenic pulmonary oedema, pulmonary embolism, and lung fibrosis.

Type II or 'ventilatory failure' occurs when alveolar ventilation is insufficient to remove the volume of carbon dioxide being produced by tissue metabolism. Inadequate alveolar ventilation may be due to reduced ventilatory effort, inability to overcome an increased resistance to ventilation, failure to compensate for an increase in dead space and/or carbon dioxide production, or a combination of these factors. The most common cause is COPD. Other causes include chest-wall deformities, respiratory muscle weakness (e.g., Guillain–Barré syndrome), and depression of the respiratory centre (e.g., drug overdose).

Deterioration in the mechanical properties of the lungs and/or chest wall increases the work of breathing and the oxygen consumption/carbon dioxide production of the respiratory muscles. Respiratory muscle fatigue is a factor in the pathogenesis of respiratory failure.

Clinical features

A clinical assessment of respiratory distress should be made on the following criteria:

- The use of accessory muscles for respiration
- Intercostal recession
- Tachypnoea
- Tachycardia
- Sweating
- Pulsus paradoxus (rarely present)
- Inability to speak, unwillingness to lie flat
- Agitation, restlessness, diminished conscious level
- Asynchronous respiration (a discrepancy in the timing of movement of the abdominal and thoracic compartments)
- Paradoxical respiration (abdominal and thoracic compartments move in opposite directions)
- Respiratory alternans (breath-to-breath alteration in the relative contribution of the intercostal/accessory muscles and the diaphragm).

Investigations

The ***most sensitive clinical indicator*** of increasing respiratory difficulty is a rising respiratory rate. ***Vital capacity*** is a better guide to deterioration, particularly in patients with respiratory inadequacy due to neuromuscular problems such as the Guillain–Barré syndrome or myasthenia gravis, where the vital capacity decreases as weakness worsens. Measurement of ***forced expiratory volume in 1 second (FEV_1)*** is useful in the assessment of patients suffering from acute asthma or COPD. ***Blood gas analysis*** should be performed to guide oxygen therapy and to provide an objective assessment of the severity of the respiratory failure.

Monitoring

Pulse oximetry

Pulse oximeters applied to a finger or earlobe measure the changing amount of light transmitted through the pulsating arterial blood and provide a continuous, non-invasive measurement of arterial oxygen saturation (S_pO_2). These devices are reliable and easy to use and do not require calibration.

Pulse oximetry is not a sensitive guide to *changes* in oxygenation. An S_pO_2 within normal limits in a patient receiving supplemental oxygen does not exclude the possibility of hypoventilation with carbon dioxide retention. Readings can be inaccurate in those with poor peripheral perfusion.

Blood gas analysis

Normal values of blood gas analysis are shown in **Box 13.5**. Disposable pre-heparinized syringes are available for blood gas analysis.

- The sample should be analyzed immediately. Alternatively, the syringe should be put on ice to prevent the continuing metabolism of white cells from causing a reduction in PO_2 and a rise in PCO_2.

- Air almost inevitably enters the sample and air bubbles should be ejected immediately. The gas tensions within these air bubbles will equilibrate with those in the blood, thereby lowering the PCO_2 and usually raising the PO_2 of the sample.

Interpretation of the results of blood gas analysis can be considered in two separate parts:

- Disturbances of acid–base balance (see Chapter 27)
- Alterations in oxygenation.

Correct interpretation requires a knowledge of the patient's clinical history and age, the inspired oxygen concentration, patient temperature, and any other relevant treatment (e.g., the ventilator settings for those on mechanical ventilation or the administration of sodium bicarbonate). The oxygen content of the arterial blood is determined by the percentage saturation of haemoglobin with oxygen. The relationship between the latter and the P_aO_2 is determined by the oxyhaemoglobin dissociation curve (see **Fig. 13.3**).

P_aO_2/F_iO_2 ratio

This calculated variable, the ratio of partial pressure of oxygen in arterial blood to the fractional inspired oxygen, is a simple approximation to the alveolar-arterial oxygen difference ($P_{A-a}O_2$) and can be used to assess the severity of respiratory failure, particularly in patients with ARDS (see 'Acute respiratory distress syndrome' section). It is calculated by taking the arterial PO_2 in mmHg and dividing by the F_iO_2 expressed as a fraction of 1.

Capnography

Continuous breath-by-breath analysis of the expired carbon dioxide concentration can be used to:

- confirm tracheal intubation (standard of care for in-hospital practice);
- continuously monitor end-tidal PCO_2, which approximates to P_aCO_2 in normal subjects and is used to assess effectiveness of ventilation;
- detect acute airway problems, e.g., blocked or dislodged tracheal tube/tracheostomy, in all mechanically ventilated patients (essential when transporting the critically ill); and
- detect acute alterations in cardiorespiratory function (e.g., a sudden fall in cardiac output).

Management

Standard management of patients with respiratory failure includes:

- Administration of supplemental oxygen through a patent airway
- Treatment for distal airway obstruction
- Measures to limit pulmonary oedema
- Control of secretions
- Treatment of pulmonary infection.

The load on the respiratory muscles should be reduced by improving lung mechanics. Correction of abnormalities that may lead to respiratory muscle weakness, such as hypophosphataemia and malnutrition, is also necessary.

Oxygen therapy

Methods of oxygen administration

Oxygen is initially given via a face mask. In the majority of patients (except those with COPD with chronically elevated P_aCO_2), the precise concentration of oxygen given is not vital and oxygen can therefore be delivered by a 'variable performance' device such as a simple face mask or nasal cannula (**Fig. 13.23**).

With these devices, the inspired oxygen concentration varies from about 35% to 55%, with oxygen flow rates of 6 to 10 L/min. Nasal cannulae are often preferred because they are less claustrophobic and do not interfere with feeding or speaking, but they can cause ulceration of the nasal mucosa and the inspired oxygen concentration is diluted by mouth breathing. Higher concentrations of oxygen can be administered by using a mask with a reservoir bag attached (**Fig. 13.23C**). **Fig. 13.23** should be compared with the fixed-performance mask shown in **Fig. 13.24**. The latter allows the oxygen concentration to be controlled and is used in patients with COPD and chronic type II failure who rely on their hypoxic drive to stimulate respiration. The hazards of reducing hypoxic drive can at times be overemphasized and are less dangerous when the patient is in a critical care unit. *Remember*, severe hypoxaemia is more dangerous than hypercapnia.

Oxygen toxicity

Hyperoxia can cause pulmonary damage due to increased oxygen free radicals and oxidative damage to the lung tissue. Although dangerous hypoxia through fear of pulmonary oxygen toxicity should never be tolerated, oxygen saturations between 90% and 92% are probably adequate for most patients and there is some suggestion that targeting higher oxygen saturations using greater concentrations of inspired oxygen may be detrimental (e.g., post-myocardial infarction). Recent evidence suggests that even a brief period of hyperoxia may increase mortality compared with normoxia, even hyperoxia following emergency intubations for any cause in the emergency department.

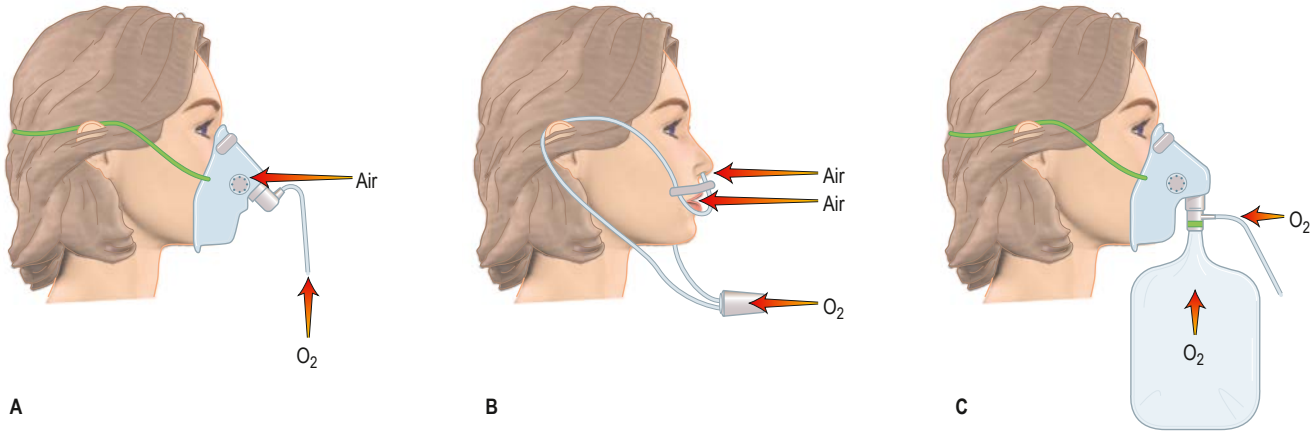

Fig. 13.23 Methods of administering supplemental oxygen to the unintubated patient. (A) Simple face mask. **(B)** Nasal cannulae. **(C)** Mask with reservoir bag and non-rebreathing valve.

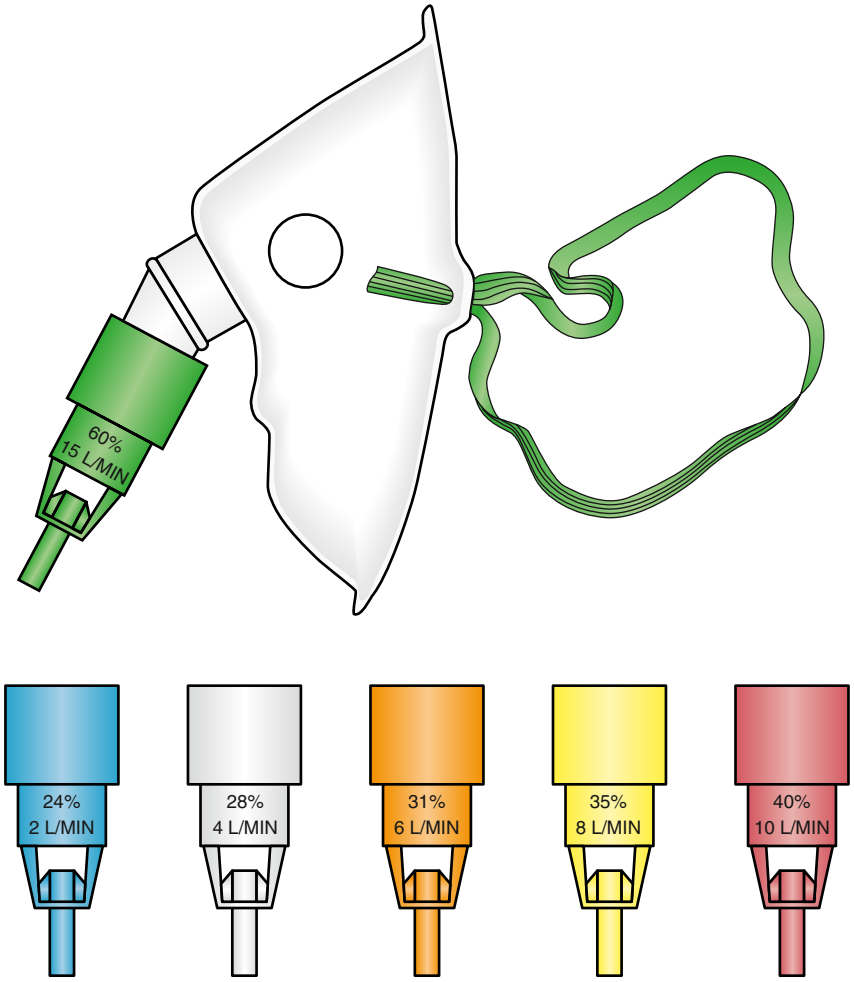

Fig. 13.24 **Fixed-performance Venturi valves attached to a face mask to deliver a fixed percentage of oxygen.**

Respiratory support

If, despite the above measures, the patient continues to deteriorate or fails to improve, the institution of some form of respiratory support is necessary (**Box 13.11**). ***Non-invasive ventilation (NIV)*** via a mask or hood (see 'Non-invasive ventilation' section and also Chapter 11) can be used, but in many critically ill patients ***invasive ventilation*** through an endotracheal tube or tracheostomy is required.

Invasive mechanical ventilation is achieved by intermittently inflating the lungs with positive pressure delivered by a mechanical ventilator through an endotracheal or tracheostomy tube, commonly carried out in the absence of spontaneous breaths. This is called ***IPPV*** or controlled mechanical ventilation (CMV). However, technological development has meant that it is now more commonly carried out by augmenting the patient's own spontaneous breaths (see 'Techniques for respiratory support' section). This has the advantage of maintaining the patient's own respiratory muscle activity and function, thereby avoiding muscle atrophy.

Indications for mechanical ventilation

Acute respiratory failure, with signs of severe respiratory distress (e.g., respiratory rate >40 breaths/min, inability to speak, patient exhaustion) persisting despite maximal therapy, requires mechanical ventilation. Confusion, restlessness, agitation, a decreased conscious level, a rising P_aCO_2 (>8 kPa, >60 mmHg), and extreme hypoxaemia (<8 kPa, <60 mmHg), despite oxygen therapy, are further indications.

In ***acute ventilatory failure*** due, for example, to myasthenia gravis, Guillain–Barré syndrome, or high spinal cord injuries, mechanical ventilation should usually be instituted when the vital capacity has fallen to 10 mL/kg or less. This will avoid complications such as atelectasis and infection, as well as preventing respiratory arrest. The tidal volume and respiratory rate are relatively insensitive indicators of respiratory failure in these conditions and change late in the course of the disease. A high P_aCO_2 (particularly if rising) is an indication of urgent mechanical ventilation.

Not all patients with respiratory failure and/or a reduced vital capacity require ventilation; clinical assessment of each individual case is essential. The patient's general condition, degree of exhaustion, level of consciousness, and ability to protect the airway are often more useful than blood gas values. However, such patients require very close observation of signs of deterioration.

Other indications include:

- Postoperative ventilation in high-risk patients
- Head injury: to avoid hypoxia and hypercarbia, which increase cerebral blood flow and intracranial pressure (ICP, see later)

Box 13.11 Techniques for respiratory support

Technique	Delivery	
Intermittent positive-pressure ventilation (IPPV)		
Controlled mechanical ventilation (CMV) (volume-controlled or pressure-controlled) Synchronized intermittent mandatory ventilation (SIMV)	Usually with	Positive end-expiratory pressure (PEEP) *Lung protective ventilation* Pressure-limited or volume-controlled pressure-limited (peak airway pressure <35–40 cmH_2O) Low tidal volume 6–8 mL/kg (±'permissive hypercarbia') maintain alveolar volume with PEEP and, in some cases, prolonged inspiratory phase
Pressure support ventilation (PSV)		
Biphasic positive airway pressure (BiPAP)		
Non-invasive ventilation	Nasal mask Face mask Hood	
Continuous positive airway pressure (CPAP)	Endotracheal tube, tracheostomy, mask or hood, high-flow nasal prongs	
Extracorporeal techniques	Extracorporeal membrane oxygenation (ECMO), extracorporeal CO_2 removal ($ECCO_2$-R)	

- Trauma: chest injury with lung contusions and high spinal cord injuries
- Severe left ventricular failure with pulmonary oedema
- Coma with airway compromise or breathing difficulties, e.g., following drug overdose.

Institution of invasive respiratory support

This requires tracheal intubation, which should be performed under anaesthesia only by experienced staff. If the patient is conscious, the procedure should be fully explained and consent obtained. The complications of tracheal intubation are given in **Box 13.12**.

Intubating a critically ill patient is very different from intubating a patient in the operating theatre for elective surgery. The patient is usually hypoxic and hypercarbic, with increased sympathetic activity; the stimulus of laryngoscopy and intubation can precipitate dangerous arrhythmias, bradycardia, and even cardiac arrest. In extreme emergencies, it may be necessary to ventilate the patient by hand using a bag-valve-mask (supplemented with high-flow oxygen) and an oropharyngeal airway or a laryngeal mask airway, until experienced help arrives.

The ECG and oxygen saturation should be monitored, and the patient pre-oxygenated with 100% oxygen before intubation. Resuscitation drugs should be immediately available. If time allows, the circulating volume should be optimized and, if necessary, inotropes commenced before intubation is attempted. In some cases, it is appropriate to establish intra-arterial and CVP monitoring before instituting mechanical ventilation, although many patients will not tolerate the supine or head-down position. In some deeply comatose patients, no sedation may be required, but in the majority, a short-acting intravenous anaesthetic agent, usually with an opiate followed by muscle relaxation, will be necessary. Capnography must be used to confirm tracheal intubation.

Box 13.12 Complications of tracheal intubation

Complication	Comments
Immediate	
Trauma to the upper airway Tube in oesophagus	Affects lips, teeth, gums, trachea Gives rise to hypoxia and abdominal distension Detected by absence of capnography trace Requires immediate removal, bag-mask ventilation with oxygen, and re-insertion of tracheal tube
Tube in one or other (usually the right) main bronchus	Avoid by checking both lungs are being inflated, i.e., both sides of chest move, and air entry is heard bilaterally on auscultation Obtain chest X-ray to check position of tube and to exclude lung collapse
Early	
Migration of tube out of trachea Leaks around tube Obstruction of tube because of kinking or secretions	These are dangerous complications Patient becomes distressed and cyanosed and has poor chest expansion The following should be performed immediately: Manual inflation with 100% oxygen Tracheal suction Check position of tube Deflation of cuff Check tube for 'kinks' or blockage with secretions or blood (common) If no improvement, remove tube, ventilate with face mask, and then insert new endotracheal tube
Late	
Sinusitis Mucosal oedema and ulceration Laryngeal injury Tracheal narrowing and fibrosis Tracheomalacia	

Sedation, analgesia, and muscle relaxation

Most critically ill patients require analgesia and many will receive sedatives. The combination of an opiate with propofol or a benzodiazepine is often used to facilitate mechanical ventilation. Heavy sedation is indicated in those with severe respiratory failure, especially since 'lung-protective' ventilatory strategies (see later) are inherently uncomfortable. A few may require neuromuscular blockade. It is recognized, however, that minimizing sedation levels using 'sedation scores' and 'daily wakening', or even the avoidance of sedatives altogether, often in combination with spontaneous breathing modes of respiratory support (see later), is associated with reductions in the duration of mechanical ventilation and more rapid discharge from the ICU and hospital.

Tracheostomy

Tracheostomy may be required for long-term control of the airway in some patients with persistent reduced conscious state, to manage excessive bronchial secretions, facilitate respiratory weaning, reduce sedation requirements, and improve patient comfort.

Tracheostomy is now performed most commonly on the ICU by the intensivist, adopting a percutaneous dilational approach. This

approach is quicker, less resource intensive, safe, and associated with a greatly reduced wound infection rate than surgical tracheostomy performed in the operating theatre. Surgical tracheostomy is reserved for when anatomical factors preclude a percutaneous approach or when there are concerns regarding abnormal coagulation that may require surgical haemostasis.

A life-threatening obstruction of the upper respiratory tract that cannot be bypassed with an endotracheal tube can be relieved by a ***cricothyroidotomy***, which is safer, quicker, and easier to perform than a formal tracheostomy.

Tracheostomy has a small but significant mortality rate. Complications associated with the technique are shown in **Box 13.13**.

Complications associated with mechanical ventilation

Airway complications

See **Boxes 13.12 and 13.13**.

Disconnection, failure of gas or power supply, and mechanical faults

These are unusual but dangerous. A method of manual ventilation, a face mask, and oxygen must always be available by the bedside.

Cardiovascular complications

The application of positive pressure to the lungs impedes venous return and distends alveoli, thereby 'stretching' the pulmonary capillaries and causing a rise in pulmonary vascular resistance. Both of these mechanisms can produce a fall in cardiac output.

Respiratory complications

Mechanical ventilation can be complicated by a deterioration in gas exchange because of $\dot{V}/\dot{Q}$ mismatch, fluid retention, and collapse of peripheral alveoli. Traditionally, the latter was prevented by using high tidal volumes (10–12 mL/kg) but high inflation pressures, with over-distension of compliant alveoli, perhaps exacerbated by the repeated opening and closure of distal airways, can disrupt the alveolar–capillary membrane. There is an increase in microvascular permeability and release of inflammatory mediators, leading to ***'ventilator-associated lung injury'***. This ***'barotrauma'*** and ***'volutrauma'*** can result in rupture of the alveoli and may be complicated by pneumomediastinum, subcutaneous emphysema, pneumothorax, and intra-abdominal air. The risk of pneumothorax is increased in those with destructive lung disease (e.g., necrotizing pneumonia, emphysema), asthma, or fractured ribs.

A ***tension pneumothorax*** can be rapidly fatal in ventilated patients. Signs include the development or worsening of hypoxia, hypercarbia, respiratory distress, and an unexplained increase in airway pressure, as well as hypotension and tachycardia, sometimes accompanied by a rising CVP. Examination may reveal unequal chest expansion, mediastinal shift away from the side of the pneumothorax (deviated trachea, displaced apex beat), and a hyper-resonant hemithorax. Although breath sounds are often diminished over the pneumothorax, this sign can be misleading in ventilated patients. If there is time, the diagnosis can be confirmed by chest X-ray. In a rapidly deteriorating patient with a high index of suspicion for a tension pneumothorax, a needle decompression into the second intercostal space in the mid-clavicular line may be indicated, followed by insertion of a definitive chest drain.

Ventilator-associated pneumonia

Hospital-acquired pneumonia occurs in as many as one-third of patients receiving mechanical ventilation and is associated with a significant increase in length of stay and mortality. The diagnosis can be controversial, as pyrexia and infiltrates on the chest X-ray that may not be infective in origin are common. Organisms commonly isolated are aerobic Gram-negative bacilli (e.g., *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Escherichia coli*, *Acinetobacter* spp.) and *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA). Deciding whether an organism that has been isolated is causing ventilator-associated pneumonia or is simply colonizing the respiratory tract can also be difficult. Leakage of infected oropharyngeal secretions past the tracheal tube cuff is thought to be largely responsible for ventilator-associated pneumonia, and many ICUs now utilize endotracheal tubes with modern tube cuffs and subglottic aspiration ports to minimize the risk. Bacterial colonization of the oropharynx may be promoted by regurgitation of colonized gastric fluid, so the risk of ventilator-associated pneumonia can be reduced by nursing patients in the semi-recumbent position and by oropharyngeal decontamination. Treatment is with an appropriate broad-spectrum antibiotic, which can be modified if a causative organism is isolated.

Techniques for respiratory support

(See **Box 13.11**).

Controlled mechanical ventilation

CMV is used when respiratory efforts are absent or have been abolished. It involves one of two types:

- ***Volume-controlled ventilation.*** The tidal volume and respiratory rate are preset on the ventilator. The airway pressure varies according to both the ventilator setting and the patient's lung mechanics (airway resistance and compliance).
- ***Pressure-controlled ventilation.*** Both the inspiratory pressure and the respiratory rate are preset but the tidal volume varies according to the patient's lung mechanics.

Positive end-expiratory pressure

A positive airway pressure can be maintained at a chosen level throughout expiration using a threshold resistor valve in the

Box 13.13 Complications of tracheostomy

The complications for tracheal intubation shown in **Box 13.12** *plus:*

Early

- Death
- Pneumothorax
- Haemorrhage
- Hypoxia
- Hypotension
- Cardiac arrhythmias
- Tube misplaced in pretracheal subcutaneous tissues
- Subcutaneous emphysema

Intermediate

- Mucosal ulceration
- Erosion of tracheal cartilages (can cause tracheo-oesophageal fistula)
- Erosion of innominate artery (occasionally leads to fatal haemorrhage)
- Stomal infection
- Pneumonia

Late

- Failure of stoma to heal
- Tracheal granuloma
- Tracheal stenosis at level of stoma, cuff, or tube tip
- Collapse of tracheal rings at level of stoma
- Cosmetic factors

expiratory limb of the circuit. Positive end-expiratory pressure (PEEP) re-expands under-ventilated lung units and redistributes lung water from the alveoli to the perivascular interstitial space, thereby reducing shunt and increasing P_aO_2. The inevitable rise in mean intrathoracic pressure associated with the application of PEEP may, however, further impede venous return, increase pulmonary vascular resistance, and reduce cardiac output. The fall in cardiac output can be ameliorated by expanding the circulating volume, although inotropic or vasopressor support is required in some cases. Thus, although arterial oxygenation is often improved by the application of PEEP, a simultaneous fall in cardiac output can lead to a reduction in total oxygen delivery.

Low levels of PEEP (5–8 cmH_2O) are used in the majority of mechanically ventilated patients in order to maintain lung volume, as well as in those with basal atelectasis and in selected cases with airways obstruction.

Continuous positive airway pressure

The application of continuous positive airway pressure (CPAP) achieves for the spontaneously breathing patient what PEEP does for the ventilated patient. Oxygen and air are delivered under pressure via an endotracheal tube, a tracheostomy, a tightly fitting face mask, or a hood (Fig. 13.25). Not only can CPAP improve oxygenation, but also the lungs can become more compliant and the work of breathing is reduced.

An alternative is to use a very high flow of oxygen and air delivered via large-diameter nasal prongs to create a modest amount of CPAP. This high-flow nasal oxygen (HFNO) system is often better tolerated, as the patient is able to cough, expectorate, communicate, and eat. Commencing therapy with HFNO in patients with type I respiratory failure may be equivalent to, and in some circumstances more effective than, NIV in preventing patient deterioration and avoiding subsequent invasive ventilation.

Pressure support ventilation

In pressure support ventilation (PSV), spontaneous breaths are augmented by a preset level of positive pressure (usually between 5 and 20 cmH_2O), triggered by the patient's spontaneous respiratory effort and applied for a given fraction of inspiratory time or until inspiratory flow falls below a certain level. Tidal volume is determined by the set pressure, the patient's effort, and pulmonary mechanics. The level of pressure support can be reduced progressively as the patient improves.

Fig. 13.25 Use of a continuous positive airway pressure (CPAP) hood.

Intermittent mandatory ventilation

The intermittent mandatory ventilation (IMV) technique allows the patient to breathe spontaneously between the 'mandatory' tidal volumes delivered by the ventilator. These mandatory breaths are timed to coincide with the patient's own inspiratory effort (synchronized IMV, or SIMV). The spontaneous breaths are usually assisted with PSV.

'Lung-protective' ventilation

This is an ideal method of mechanical ventilation that avoids overdistension of alveoli, as well as repeated energetic opening and closing of distal airway and alveoli. Alveolar volume is maintained with PEEP, and sometimes by prolonging the inspiratory phase, while tidal volumes are limited to 4 to 8 mL/kg ideal body weight (ideally, 6 mL/kg). Plateau pressures (P_{Plat}) should not exceed 30 cmH_2O. Respiratory rate can be increased to improve CO_2 removal and avoid severe acidosis (pH >7.2), but permissive hypercarbia is common and acceptable. Ventilation with low tidal volumes has been shown to improve outcome in patients with ARDS (see later). Lung-protective ventilation should be used in almost all patients undergoing mechanical ventilation.

High-frequency oscillation

High-frequency oscillation (HFO) is administered using a purpose-designed ventilator. With HFO, there is no bulk flow of gas; rather, gas oscillates to and fro at rates of 4 to 15 Hz in a CPAP circuit set at a high mean airway pressure (often 20–30 cmH_2O). The mechanism of gas exchange is not fully understood, but lung volume is well maintained and oxygenation may be improved. While it is still used in paediatric ICUs, recent evidence in adult patients has not shown any mortality benefit, and one trial reported increased mortality, and consequently HFO is no longer advocated.

Extracorporeal gas exchange

In patients with severe refractory respiratory failure, pumped, high-flow, veno-venous blood flow through an artificial lung is used in specialized centres to achieve adequate oxygenation and CO_2 removal (ECMO; Fig. 13.26). ECMO provides respiratory support while the underlying lung disease improves and allows avoidance of excessive injury by mechanical ventilation. Extracorporeal carbon dioxide removal ($ECCO_2R$) is a simpler device with lower blood flows to allow CO_2 removal (and hence lower tidal volumes) with only marginal oxygenation, but recent trials have not shown outcome benefits.

Adjuncts and newer ventilation modes

Lung recruitment manoeuvres are transient, sustained increased airway pressure to open up collapsed airless alveoli. They can improve oxygenation in patients with refractory hypoxaemia but can be associated with significant morbidity and need to be carried out by clinical experts. Newer modes of ventilation such as airway pressure release ventilation (APRV), an inverse ratio, and pressure-controlled, intermittent mandatory mode of ventilation with unrestricted spontaneous breathing have shown promise in clinical trials to improve oxygenation.

Non-invasive ventilation

Non-invasive ventilation (NIV) is suitable for patients who are conscious, cooperative, and able to protect their airway; they must also

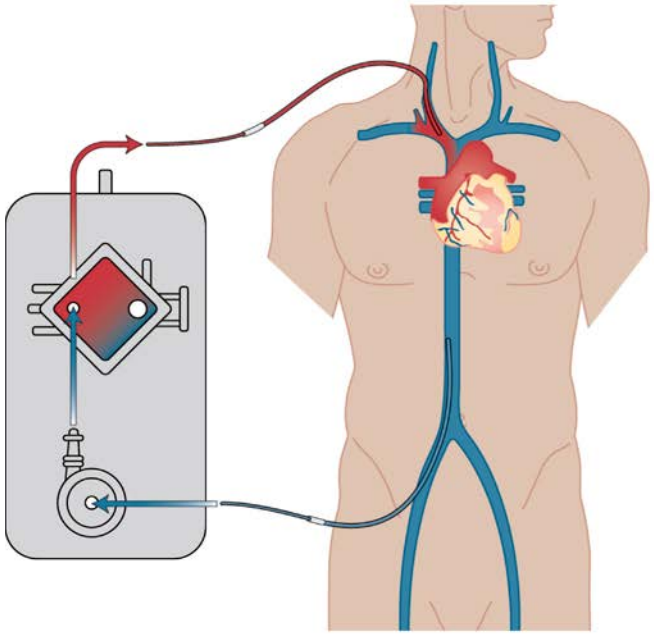

Fig. 13.26 Veno-venous extracorporeal membrane oxygenation (ECMO). A pump pulls blood off the patient through a large cannula with tip in the inferior vena cava. The blood then passes through a membrane oxygenator and is returned to the superior vena cava fully oxygenated and with CO_2 removed.

be able to expectorate effectively. Positive pressure is applied to the airways using a tight-fitting full-face/nasal mask or a hood. Modern ventilators are cheap, easy to use, and flexible. They deliver bi-level positive airway pressure (BiPAP) with inspiratory (IPAP) and expiratory (EPAP) pressure levels, and times are set independently. Unrestricted spontaneous respiration is possible throughout the respiratory cycle. BiPAP can also be patient triggered. There is a reduced risk of ventilator-associated pneumonia and improved patient comfort, with preservation of airway defence mechanisms, speech, and swallowing (which allows better nutrition). Spontaneous coughing and expectoration are not hampered, permitting effective physiotherapy, and sedation is usually unnecessary. Institution of non-invasive respiratory support can reduce respiratory muscle fatigue, reduce respiratory acidosis and breathlessness, improve clearance of secretions, and re-expand collapsed lung segments. The intubation rate, length of ICU and hospital stay, and, in some categories of patient, mortality may all be reduced. NIV is particularly useful in acute hypercapnic respiratory failure associated with COPD, provided the patient is not profoundly hypoxic or obtunded. NIV is also valuable in immunocompromised patients with acute respiratory failure and following extubation of hypercapnic patients with respiratory disorders to reduce the risk of subsequent respiratory failure and mortality. **Box 13.14** lists some indications and contraindications for the use of NIV when standard medical treatment has failed.

Box 13.14 Indications for/contraindications to use of non-invasive ventilation

Some indications

- Acute exacerbation of chronic obstructive pulmonary disease (H^+ >44 nmol/L; pH <7.35)
- Cardiogenic pulmonary oedema
- Chest wall deformity/neuromuscular disease (hypercapnic respiratory failure)
- Obstructive sleep apnoea
- Severe pneumonia (with caution)
- Asthma (occasionally)
- Weaning patients from invasive ventilation

Some contraindications

- Facial or upper airway surgery
- Reduced conscious level
- Inability to protect the airway

Weaning

Weakness and wasting of respiratory muscles are inevitable consequences of the catabolic response to critical illness and the disuse atrophy that will occur as a result of mechanical ventilation. Often, abnormalities of gas exchange and lung mechanics persist. Not surprisingly, therefore, many patients experience difficulty in resuming unsupported spontaneous ventilation.

Neuromuscular weakness complicating critical illness

Polyneuromyopathies have most often been described in association with persistent sepsis and multiple organ failure.

Critical illness polyneuropathy is characterized by a primary axonal neuropathy involving both motor and, to a lesser extent, sensory nerves. Clinically, the initial manifestation is often difficulty in weaning the patient from respiratory support. There is muscle wasting, the limbs are weak and flaccid, and deep tendon reflexes are reduced or absent. Cranial nerves are relatively spared. Nerve conduction studies confirm axonal damage. The CSF protein concentration is normal or minimally elevated. These findings differentiate critical illness neuropathy from Guillain–Barré syndrome, in which nerve conduction studies nearly always provide evidence of demyelination and CSF protein is usually high.

The cause of critical illness polyneuropathy is not known and there is no specific treatment. Weaning from respiratory support and rehabilitation are likely to be prolonged. With resolution of the underlying critical illness, recovery can be expected after 1 to 6 months but weakness and fatigue frequently persist.

Critical illness myopathies can also occur, often in association with a neuropathy. A severe quadriplegic myopathy has been associated in particular with the administration of steroids and muscle relaxants to mechanically ventilated patients who have acute, severe asthma.

Criteria for weaning patients from mechanical ventilation

Clinical assessment is the best way of deciding whether a patient can be weaned from the ventilator. A key part of the assessment is deciding whether the precipitating need for mechanical ventilation is no longer present or has vastly improved, to allow a trial without ventilation. The patient's conscious level and cardiovascular performance, as well as the effects of drugs, must all be taken into account. A subjective evaluation by an experienced clinician of the patient's response to a short period of spontaneous breathing (spontaneous breathing trial) is the most reliable predictor of weaning success or failure. Objective criteria are based on an assessment of pulmonary gas exchange (blood gas analysis), lung mechanics, and muscular strength.

Techniques for weaning

Patients who have received mechanical ventilation for less than 24 to 48 hours—after elective major surgery, for example—can usually resume spontaneous respiration immediately and no weaning process is required. This procedure can also be adopted for those who have been ventilated for longer periods but who tolerate a spontaneous breathing trial and clearly fulfill objective criteria for weaning.

Techniques of weaning include the following:

- The traditional method is to allow the patient to breathe entirely spontaneously for a short time, following which respiratory support is resumed. These periods of spontaneous breathing are gradually increased and the periods of respiratory support are progressively reduced. Initially, it is usually advisable to ventilate the patient throughout the night. This method can be stressful and tiring for both patients and staff, although it is sometimes successful when other methods have failed.
- SIMV (see earlier) involves a progressive reduction in the frequency of mandatory breaths. Spontaneous breaths are usually pressure supported.
- Gradual reduction of the level of pressure support is thought to be the preferred technique.
- CPAP (see above) can prevent alveolar collapse, hypoxaemia, and fall in compliance that might otherwise occur when patients start to breathe spontaneously. It is therefore used during weaning with SIMV or pressure support, during spontaneous breathing trials, and in spontaneously breathing patients prior to extubation.
- Tracheostomy can be used to facilitate weaning from mechanical ventilation and is better tolerated by patients than endotracheal tubes allowing sedation weaning and comfort.
- Non-invasive respiratory support (BiPAP, CPAP) can be used following extubation to prevent respiratory failure and re-intubation.

Extubation and tracheostomy decannulation

These should not be performed until patients can cough, swallow, and protect their own airway and are sufficiently alert to be co-operative. Together with spontaneous breathing trials to show adequate respiratory function, these parameters are used to make the decision to extubate patients. Similar considerations guide the elective removal of tracheostomy tubes.

The 'rapid shallow breathing index'—the ratio of spontaneous respiratory rate (in breaths/minute) to tidal volume (in litres)—of less than 100 is another relatively good predictor of extubation success and represents a patient who breathes slowly and comfortably with adequate tidal volumes.

ACUTE RESPIRATORY DISTRESS SYNDROME

Definition and aetiology

The acute respiratory distress syndrome (ARDS, **Box 13.15**) can be defined as follows:

- Respiratory distress with hypoxaemia
- Chest X-ray, CT, or lung ultrasound findings of new bilateral, diffuse, patchy, or homogeneous pulmonary infiltrates
- Pulmonary oedema not due to cardiogenic oedema or fluid overload
- Gas exchange abnormalities, all with a PEEP ≥ 5 cmH_2O **(Berlin definition):**
  1. Mild: P_aO_2/F_iO_2 ratio 300–200 mmHg (40–26.6 kPa)
  2. Moderate: P_aO_2/F_iO_2 200–100 mmHg (26.6–13.3 kPa)
  3. Severe: P_aO_2/F_iO_2 ratio <100 mmHg (<13.3 kPa).

Stiff lungs with reduced pulmonary compliance resulting in high inflation pressures are often a feature of ARDS but not a defining element. ARDS can occur as a non-specific reaction of the lungs to a wide variety of direct pulmonary and indirect non-pulmonary insults. Approximately 10% of admissions to critical care fit the Berlin definition for ARDS, and the classifications above predict mortality which ranges from 27% in mild, 32% in moderate, and 45% in severe ARDS. By far, the most common predisposing factor is

Box 13.15 Disorders associated with acute respiratory distress syndrome

Direct lung injury	Indirect lung injury
Common causes	
Pneumonia COVID-19 Aspiration of gastric contents	Sepsis Severe trauma with shock and multiple transfusions
Less common causes	
Pulmonary contusion Blast injury Fat embolism Near-drowning Inhalational injury (smoke or corrosive gases) Reperfusion lung injury after lung transplantation or pulmonary embolectomy Amniotic fluid embolism	Cardiopulmonary bypass Drug overdose (heroin, barbiturates) Acute pancreatitis Transfusion-associated lung injury (TRALI) Eclampsia High altitude Severe burns Pulmonary vasculitis

sepsis, and 20% to 40% of patients with severe sepsis will develop ARDS.

Pathogenesis and pathophysiology

ARDS can be viewed as an early manifestation of a generalized inflammatory response with endothelial dysfunction and therefore is frequently associated with the development of multiple organ dysfunction syndrome (MODS, see 'Sepsis and multiple organ failure [multiple organ dysfunction syndrome]' section).

Non-cardiogenic pulmonary oedema

This is the cardinal feature of ARDS and is the first and clinically most evident sign of a generalized increase in vascular permeability, caused by the microcirculatory changes and release of immune mediators described earlier, with activated neutrophils playing a key role. The pulmonary epithelium is also damaged in the early stages, reducing surfactant production and predisposing to alveolar collapse.

Pulmonary hypertension

Pulmonary hypertension, sometimes complicated by right ventricular failure (see Chapter 17), is a common feature of ARDS. Initially, mechanical obstruction of the pulmonary circulation may occur as a result of vascular compression by interstitial oedema, while local activation of the coagulation cascade leads to thrombosis and obstruction in the pulmonary microvasculature. Later, pulmonary vasoconstriction may develop in response to increased autonomic nervous activity and circulating substances such as catecholamines and thromboxane. Those vessels supplying alveoli with low oxygen tensions constrict (the 'pulmonary hypoxic vasoconstrictor response'), diverting pulmonary blood flow to better-oxygenated areas of lung and thus limiting the degree of shunt.

Haemorrhagic intra-alveolar exudate

This exudate is rich in platelets, fibrin, fibrinogen, and clotting factors and may inactivate surfactant and stimulate inflammation, as well as promote hyaline membrane formation and the migration of fibroblasts into the air spaces.

Resolution, fibrosis, and repair

Within days of the onset of lung injury, formation of a new epithelial lining is underway and activated fibroblasts accumulate in the interstitial spaces. However, in some cases, there is progressive interstitial fibrosis. In those who recover the lungs are substantially remodelled.

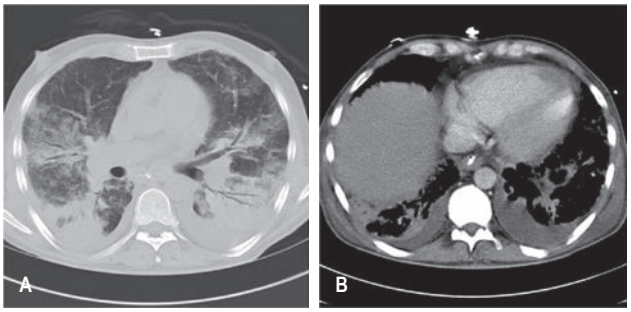

Fig. 13.27 Acute respiratory distress syndrome. **(A)** Computed tomography scan of the lung showing ground-glass opacification in non-dependent regions, with atelectasis and consolidation in dependent regions. There are small pleural effusions. **(B)** The same patient as shown in (A) using soft tissue window settings to demonstrate small bilateral effusions layering in the dependent region of both haemithoraces. *(From Hinds CJ, Watson JD. Intensive Care: A Concise Textbook, 3rd edn. Edinburgh: Saunders; 2008, with permission. Courtesy of Dr SPG Padley.)*

Physiological changes

Shunt and dead space increase, compliance falls, and there is evidence of airflow limitation. Although the lungs in ARDS are diffusely injured, the pulmonary lesions, when identified as densities on a CT scan, are predominantly located in dependent regions (Fig. 13.27). This is partly explained by the effects of gravity on the distribution of extravascular lung water and areas of lung collapse. Pleural effusions are common.

Clinical features

The first sign of the development of ARDS is often an unexplained tachypnoea, followed by increasing hypoxaemia and breathlessness. Fine crackles are heard throughout both lung fields. Later, the chest X-ray shows bilateral diffuse shadowing, interstitial at first, but subsequently with an alveolar pattern and air bronchograms (Fig. 13.28). The differential diagnosis includes cardiac failure and lung fibrosis.

Management

This is based on treatment of the underlying condition (e.g., eradication of sepsis), supportive measures, and avoidance of complications such as ventilator-induced lung injury and ventilator-associated pneumonia.

Mechanical ventilation

This is the cornerstone of management; strategies designed to minimize ventilator-induced lung injury and encourage lung healing should be used (see earlier).

Pulmonary oedema limitation

While most patients require an initial period of resuscitation, it is important to limit pulmonary oedema formation. Fluid restriction strategies and the use of diuretics may be required to prevent fluid overload with the aim of achieving a consistently neutral to negative fluid balance.

Prone position

When the patient is changed from the supine to the prone position, collapsed alveoli in the dependent region are redistributed and

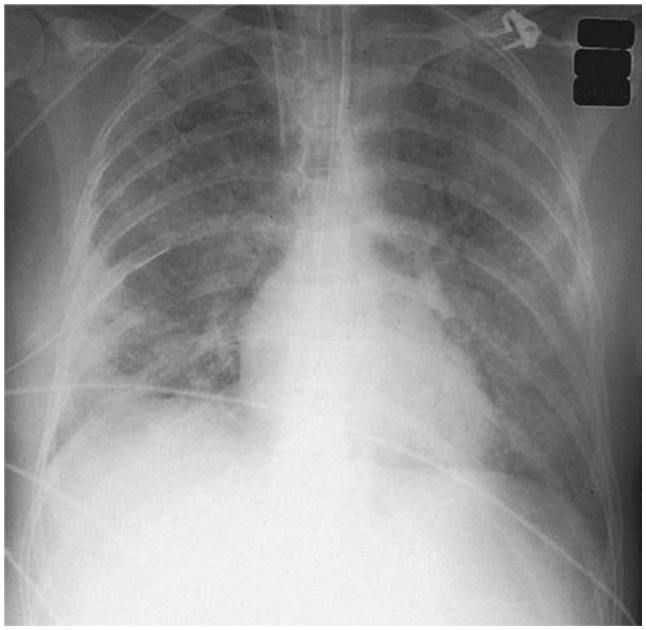

Fig. 13.28 Chest X-ray appearances in acute respiratory distress syndrome. Bilateral diffuse alveolar shadowing with air bronchograms and no cardiac enlargement.

shunt fraction is reduced. More uniform alveolar ventilation, caudal movement of the diaphragm, redistribution of perfusion, and recruitment of collapsed alveoli all contribute to the improvement in gas exchange. Recent findings suggest that proning early in the course of the disease process and spending longer periods prone than supine are associated with substantial mortality benefits.

Inhaled nitric oxide

This vasodilator, when inhaled, may improve ventilation-perfusion matching by increasing perfusion of ventilated lung units, as well as reducing pulmonary hypertension. It has been shown to improve oxygenation in so-called 'responders' with ARDS but has not been shown to enhance survival and may lead to higher rates of AKI.

Aerosolized prostacyclin

This appears to have similar effects to inhaled nitric oxide and is easier to deliver. As with inhaled nitric oxide, the response to aerosolized prostacyclin is variable: although it improves oxygenation, its effect on outcome is unclear.

Steroids

Administration of steroids to patients with persistent ARDS may improve lung function but does not appear to improve outcome. Their use remains controversial.

Prognosis

Mortality from ARDS has fallen over the last two decades, from around 60% to 20% to 40%, perhaps as a consequence of improved general care, lung-protective ventilation strategies, the increasing use of management protocols, and attention to infection control and nutrition. Prognosis is, however, still very dependent on aetiology. When ARDS occurs in association with intra-abdominal sepsis, mortality rates remain very high, whereas much lower mortality is to be expected in those with 'primary' ARDS (pneumonia, aspiration, lung contusion). Mortality rises with increasing age and failure of other organs. Most of those dying with ARDS do so as a result of MODS and haemodynamic instability rather than impaired gas exchange.

COVID-19

ARDS secondary to viral pneumonitis can be particularly challenging to treat. Critical care units around the world were required to grapple with this problem during the COVID-19 pandemic. Pneumonitis due to SARS-CoV-2 (see Chapter 20) proved slow to heal, with patients requiring aggressive ARDS management (paralysis, prone ventilation, or extra-corporeal support) for far longer than had generally been the case with 'classical' ARDS. These clinical features probably reflect differences in the inflammatory response to bacterial sepsis and SARS-CoV-2; initial inflammation is less severe in the latter but more prolonged, with accelerating immunosuppression leaving patients particularly vulnerable to secondary bacterial infection. Early multicentre RCT evidence did demonstrate a mortality benefit for corticosteroid treatment in these patients. The greatest impact of COVID-19 on critical care, however, was the organizational response required to care for far greater than usual patient numbers, as well as the psychological effect of a protracted surge on staff in the specialty.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is a common and serious complication of critical illness and is strongly associated with increased morbidity and mortality. The presence and severity of AKI are now formally classified by relative increases in serum creatinine and/or a persistent reduction in urine output (see Chapter 11).

The importance of preventing renal injury with rapid and effective resuscitation, the avoidance of nephrotoxic drugs (especially non-steroidal anti-inflammatory drugs [NSAIDs]), and control of infection cannot be overemphasized. While shock and sepsis are the most common causes of AKI in the critically ill, causes requiring specific treatment should be excluded, especially urinary tract obstruction

and acute intrinsic renal disease such as rapidly progressive glomerulonephritis (see Chapter 11).

Acutely, oliguria often accompanies shock and renal hypoperfusion and should prompt attempts to optimize cardiovascular function by expanding the circulating volume and restoring blood pressure; restoration of urine output is a good indicator of successful resuscitation. However, when AKI is established, urine output is often normal or high due to impaired concentrating capacity, so the development of oliguria then implies almost complete loss of renal function; in this case, continued fluid resuscitation will be ineffective and potentially harmful.

There is no evidence to support specific pharmacological interventions to prevent or treat AKI; in particular, low-dose dopamine is ineffective for preventing or reversing renal impairment in sepsis. Thus, treatment of those developing or at risk of AKI should focus on prompt resuscitation with fluid and/or vasopressor therapy, as well as treatment of the underlying causes of shock and sepsis. If these measures fail to reverse oliguria, loop diuretics such as furosemide may be used to treat or prevent fluid overload. However, there is no evidence that diuretics alter the clinical course of AKI, and renal replacement therapy (RRT) should not be delayed if indicated.

In AKI, RRT is indicated for refractory fluid overload, major electrolyte disturbances (especially hyperkalaemia), severe acidosis, and, less often, uraemia. There is no evidence to support commencement of RRT for less severe AKI in the absence of these indications. Continuous RRT (e.g., haemofiltration) is associated with greater haemodynamic stability and better control of fluid balance than intermittent haemodialysis, while the use of peritoneal dialysis is unsatisfactory in critically ill patients (although this may be an option in resource-limited environments). Thus, continuous RRT is now the preferred method of renal support in the critically ill.

In critical illness complicated by AKI, if the underlying problems resolve, renal function usually recovers over a period of a few days to several weeks. However, there is good evidence to suggest that, after recovery, subtle defects in renal function persist, so patients requiring RRT in the ICU have a significantly increased risk of developing chronic kidney disease in the months and years after critical illness and should ideally be followed up.

NEUROCRITICAL CARE

Care of patients with a critically injured CNS can be provided in a general ICU but is also sometimes delivered in dedicated neurocritical care units. Examples of lesions found in such patients include traumatic brain injury, acute intracranial haemorrhage (usually subarachnoid bleeding from a berry aneurysm or a hypertensive intraparenchymal haemorrhage), severe ischaemic stroke, and spinal cord injury, as well as medical lesions such as Guillain–Barré syndrome.

Physiology

Neurones are particularly susceptible to acute ischaemic/hypoxic insults, as they have very limited capacity for anaerobic metabolism and are irreversibly lost when blood flow is restricted for as little as 3 to 8 minutes.

The intracranial contents—brain parenchyma, blood, and CSF—are contained in the rigid skull vault. ICP (pressure within the skull) is approximately 7 to 15 mmHg in a resting, supine adult. Changes in intra-abdominal and intrathoracic pressures, such as occurring during coughing or a Valsalva manoeuvre, may result in transient increases in ICP that are of no consequence. The ***Monro–Kellie doctrine*** states that because the intracranial volume is fixed, any increase in the volume of one of the intracranial constituents must be compensated by a decrease in the volume of the others. As space-occupying lesions expand or brain tissue swells, the rise in ICP is limited by displacement of CSF and venous blood from the intracranial compartment. Once these compensatory mechanisms are exhausted, further increases in intracranial volume cause exponentially greater increases in ICP (**Fig. 13.29**).

In health, ***autoregulation*** maintains constant cerebral blood flow over a range of blood pressures. However, these mechanisms are lost following significant intracranial injury, and cerebral blood flow then becomes directly dependent on cerebral perfusion pressure (CPP). CPP is calculated as the MAP minus the ICP. Occasionally, a very high CVP, greater than the ICP, will also reduce CPP (**Fig. 13.30**).

Clinical features and investigations

The causes of coma are listed in 'The unconscious patient' section, Chapter 11. Conscious level should be documented regularly. The Glasgow Coma Scale (GCS) score (see also Chapter 11) is widely used as a semi-quantitative, yet crude, means of gauging the level of consciousness. Assessment of the airway is of particular importance. Patients with airway obstruction due to lax oropharyngeal musculature should be managed as discussed in Fig. 13.22. Patients without a cough or gag reflex may need to be intubated in order to protect the airway. Pupillary size and reactivity is a crucial part of the assessment. A unilaterally dilated pupil that reacts sluggishly or not at all is frequently a sign of increasing ICP. This is caused by compression of the third cranial nerve by herniating brain; if untreated, it can be rapidly fatal. Immediate measures to decrease ICP (see **Box 13.16**) are required while a CT scan of the brain is obtained. In some situations, patients may be taken directly to the operating theatre in order to alleviate the raised ICP and to

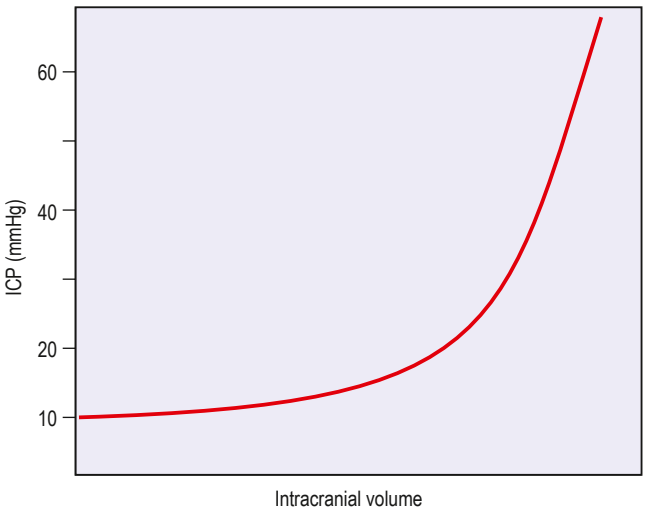

Fig. 13.29 Intracranial compliance curve. *ICP,* Intracranial pressure. *(From Hinds CJ, Watson JD.* Intensive Care: A Concise Handbook, *3rd edn. Edinburgh: Saunders; 2008, with permission.)*

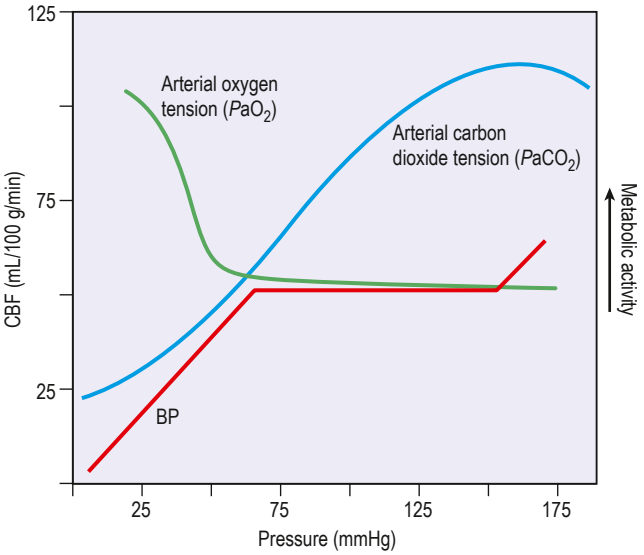

Fig. 13.30 Factors influencing cerebral blood flow (CBF). *BP,* Mean arterial blood pressure.

Box 13.16 Measures to control raised intracranial pressure and prevent secondary brain injury

- Control/restoration of blood pressure
- Control of intracranial pressure:
  - Reduction of intracranial blood volume
  - Mechanical ventilation
  - Sedation
  - Unobstructed venous drainage
  - Control of cerebral oedema
  - Osmotic diuretics (e.g., mannitol)
  - Loop diuretic (e.g., furosemide)
- Other measures:
  - Removal of cerebrospinal fluid via intraventricular catheter
  - Decompressive craniectomy
  - Excision of brain tissue
- Control of seizure activity

remove expanding space-occupying lesions such as a haematoma. Small or pinpoint pupils may be a sign of mid-brain injury or opioid overdose. New focal neurological signs should be sought, such as cranial nerve palsies, limb weakness, or hemiparesis. Seizures should be recognized and treated appropriately (see Chapter 11).

Monitoring

Regular clinical assessments by the bedside nurse are essential, including GCS score and pupillary size and reaction to light at least every hour. Assessment for focal neurological signs and evolving weakness (e.g., regular forced vital capacity measurement) may also be indicated. Neurological assessments are inevitably limited in patients requiring sedation and mechanical ventilation. In these individuals, invasive monitoring of ICP may be necessary.

Invasive ICP monitoring devices may be extradural, subdural, subarachnoid, intraparenchymal, or intraventricular (**Fig. 13.31**). The external ventricular drain (EVD) is the most difficult to insert, particularly when increased ICP causes the ventricles to collapse. EVDs are normally placed through the non-dominant (usually right) hemisphere into the lateral ventricle in the operating theatre. Their main advantage over the other monitoring devices is that they can also be used to treat raised ICP by draining CSF from the ventricular system. They are more prone to infection, however.

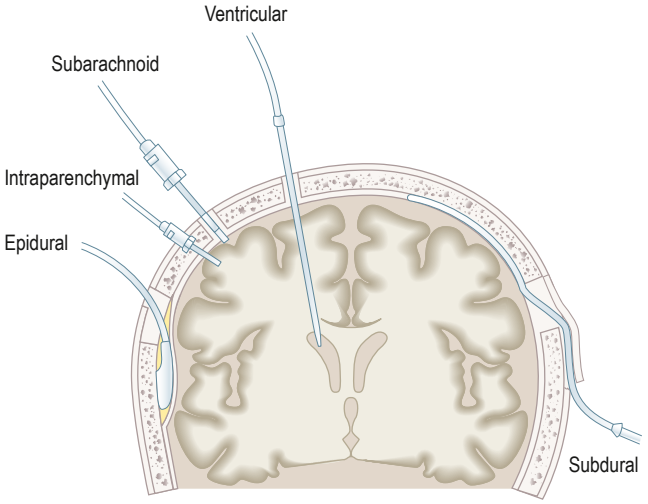

Fig. 13.31 Methods for measuring intracranial pressure.

Multi-electrode electroencephalography (EEG) monitors give both a waveform and an analogue display that can help in the diagnosis of non-convulsive seizures and are also useful in monitoring the depth of sedation.

Oximeter-tipped catheters can be placed via the internal jugular vein and advanced in a cranial direction to lie in the jugular bulb just external to the skull. These 'jugular bulb oximetry' catheters monitor venous saturation in blood leaving the brain and give an indication of the balance between cerebral oxygen supply and demand. Measurements can be interpreted similarly to the mixed venous oxygen content (see 'Mixed venous oxygen tension and saturation' section).

Cerebral oximetry uses near-infrared spectroscopy (NIRS) technology to estimate the oxygenation of a small portion of the cerebral cortex. Adhesive pads that both emit and capture near-infrared light waves are placed over the frontal cortex. Cerebral oximetry can provide an early warning of decreased cerebral oxygen delivery.

Management

Little can be done to reverse the immediate primary brain injury and irreversible loss of neurones that occur as a direct consequence of intracerebral haemorrhage, infarct, or traumatic brain injury. ICU care is focused on minimizing secondary brain injury (**Box 13.16**). This commonly occurs as a result of decreases in oxygen delivery secondary to hypoxaemia or reduced CPP due to systemic hypotension and/or raised ICP. Cerebral oedema, expanding mass lesions (e.g., haemorrhage), prolonged seizure activity, and hypercarbia (which causes cerebral vasodilation) are all examples of mechanisms leading to secondary injury. Neurocritical care has therefore focused on monitoring ICP and maintaining CPP. The Brain Trauma Foundation (BTF) guidelines state that an ICP of 22 mmHg or less and a CPP of between 60 and 70 mmHg should be the aim, with vasopressors and fluid given as required in conjunction with supportive care; the latter should include airway protection, maintenance of oxygenation and normocarbia, reduction of the risk of nosocomial infections, and prevention of thromboembolic complications.

OUTCOMES

Withholding and withdrawing treatment

(See also Chapter 50).

For many critically ill patients, intensive care is undoubtedly life-saving, and resumption of a normal lifestyle is to be expected. It is also widely accepted that the elective admission of high-risk patients into an ICU or HDU, particularly in the immediate post-operative period, can minimize morbidity and mortality and lower costs, as well as reduce the demands on medical and nursing personnel on general wards. In the most seriously ill patients, however, mortality rates are high, and a significant number die soon after discharge from the ICU. Mortality rates are particularly high in those who require re-admission to intensive care. Moreover, patients surviving a prolonged ICU admission often do not regain their premorbid functional status, and longer-term mortality rates (for at least 10 years post discharge) remain higher than in a general population matched for age and illness severity.

Inappropriate use of intensive care facilities has other implications. The patient may experience unnecessary suffering and loss of dignity, while relatives may also have to endure considerable emotional pressures. In some cases treatment may simply prolong the process of dying, and in others, the risks of interventions outweigh the potential benefits. Lastly, intensive care is expensive, particularly for those with the worst prognosis, and resources are limited.

To ensure both a humane approach to the management of critically ill patients and the appropriate use of limited resources, it is necessary to:

- avoid admitting patients who cannot benefit from intensive care; and
- limit further aggressive therapy when the prognosis is clearly hopeless.

Such decisions are extremely difficult; each case is assessed individually, taking into account previous health and quality of life, the patient's expressed wishes, the primary diagnosis, medium- and long-term prognosis of the underlying condition, and survivability of the acute illness. Age alone should not be the sole consideration. When in doubt, active measures should continue but with regular review in light of response to treatment and any other changes.

Decisions to limit therapy, not to resuscitate or to withdraw treatment should be made jointly by the ICU medical staff, the primary physician or surgeon, nursing staff, and, if possible, the patient, normally in consultation with the patient's family. Limitation of active treatment is *not* the cessation of medical or nursing care; rather, a caring approach must be adopted to ensure a dignified death, free of pain and distress, with support for family and friends.

Scoring systems

A variety of scoring systems have been developed to evaluate the severity of critical illness. Some include an assessment of the patient's previous state of health and the severity of the acute disturbance of physiological function (***acute physiology, age, chronic health evaluation***, or ***APACHE II***; the ***simplified acute physiology score***, or ***SAPS II and the SOFA score***). Other systems have been designed for particular categories of patient (e.g., the Injury Severity Score [ISS] for trauma victims).

The APACHE II (**Box 13.17**), SAPS II (**Box 13.18**), and SOFA (**Box 12.2**) scores are widely applicable and have been extensively validated. They can accurately quantify the severity of illness and predict the overall mortality for large groups of critically ill patients and are therefore useful for defining the 'case mix' of patients when auditing a unit's clinical activity, for comparing results nationally or internationally, and for characterizing groups of patients in clinical studies.

APACHE II is measured in the first 24 hours of admission. It has a maximum score of 71. A score of 25 represents a predicted mortality of 50% and a score of over 35 to 80%.

SAPS II is also measured in the first 24 hours of critical care admission and gives a mortality prediction.

SOFA score should also be undertaken in the first 24 hours of admission but can also be recalculated at every 24-hour period of admission. Although the APACHE II, SAPS II, and SOFA methodologies can also estimate mortality risk, no scoring system has yet been devised that can predict with certainty the outcome in an individual patient. They must not, therefore, be used in isolation as a basis for limiting or discontinuing treatment.

Death by neurological criteria

Traditionally, death is thought of as cessation of breathing and the heartbeat. Death by neurological criteria, sometimes referred to as brain death, means 'the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe'. Both of these are essentially functions of the brainstem. With the advent of mechanical ventilation, it became possible to support such a dead patient temporarily, although, in all cases, cardiovascular failure eventually supervenes and progresses to asystole.

Before deciding on a diagnosis of death by neurological criteria, it is essential for certain preconditions and exclusions to be fulfilled. Two doctors need to agree on these preconditions—one consultant and one doctor who has been fully registered with the GMC for more than 5 years. These same two doctors will then perform the tests once the preconditions have been met.

Preconditions

- The patient must be in apnoeic coma (i.e., unresponsive and on a ventilator, with no spontaneous respiratory efforts).
- Irremediable structural brain damage due to a disorder that can cause brainstem death must have been diagnosed with certainty (e.g., head injury, intracranial haemorrhage).

Exclusions

- The possibility that unresponsive apnoea is the result of poisoning, sedative drugs, or neuromuscular blocking agents must be excluded.
- Hypothermia must be excluded as a cause of coma (core temperature >34°C).
- There must be no significant circulatory, metabolic, or endocrine disturbance that could produce or contribute to coma or cause it to persist (including acid–base, electrolyte, and glucose abnormalities).

Diagnostic tests for the confirmation of death by neurological criteria

All brainstem reflexes are absent to confirm death by neurological criteria.

The following tests should not be performed in the presence of seizures or abnormal postures.

- The pupils are fixed and unresponsive to bright light. Both direct and consensual light reflexes are absent. The size of the pupils is irrelevant, although most often, they will be dilated.

Box 13.17 The APACHE II scoring system

Physiologic variable	+4	+3	+2	+1	0	+1	+2	+3	+4

Yes, and admitted after emergency surgery or any reason other than elective surgery	5

A-aDO_2, Alveolar-arterial oxygen gradient, calculated as A-aDO_2 = (FIO_2 × 710) − ($PaCO_2$ × 1.25) − PaO_2

- Corneal reflexes are absent.
- There are no vestibulo-ocular reflexes on caloric testing.
- There is no motor response within the cranial nerve territory to painful stimuli applied centrally or peripherally. Spinal reflex movements may be present.
- There is no gag or cough reflex in response to pharyngeal, laryngeal, or tracheal stimulation.
- Spontaneous respiration is absent. The patient should be ventilated with 100% O_2 for 10 minutes and then temporarily disconnected from the ventilator for 5 minutes. Oxygenation is maintained by insufflation with 100% oxygen via the endotracheal tube. The patient is observed for any signs of spontaneous respiratory efforts. A blood gas sample should be obtained during this period to ensure that the P_aCO_2 is sufficiently high to stimulate spontaneous respiration (starting P_aCO_2 ≥ 6.0 kPa and pH < 7.4, with P_aCO_2 rise of >0.5 kPa after 5 minutes).

The examination should be performed twice; the completion of the first set of tests is the legal time of death, and the second set of tests is confirmatory.

In the UK, it is not considered necessary to perform routine confirmatory tests, such as EEG or cerebral angiography; however, there are some 'red flags' listed on the faculty of intensive care guidance for brainstem testing that suggest performing CT angiography to confirm loss of blood flow is advisable. These include decompressive craniectomy, inability to perform all tests due to severe facial injuries, ongoing metabolic derangement that cannot be remedied, and situations where families are finding diagnosis difficult to accept and understand by neurological testing alone. The primary purpose of establishing a diagnosis of death by neurological criteria is to demonstrate beyond doubt that ongoing treatment is futile.

Organ donation

Organ donation may be possible in situations where ongoing life-sustaining treatment is deemed futile and a decision is reached in conjunction with the family (and, in rare circumstances, the patient) to withdraw treatments such as invasive ventilation and inotropes that are simply delaying an inevitable death. Organ donation can occur after death by neurological criteria—known as donation after brain death (DBD) or after withdrawal of life-sustaining therapies such as ventilation and inotropes and subsequent cardiac death, known as donation after cardiac death (DCD). In the circumstance of DCD, the withdrawal of life-sustaining therapies usually occurs in a planned fashion and

Box 13.18 The SAPS II score

often in the operating department suite. If death occurs relatively quickly, then organ retrieval may proceed immediately following cardiac death. In DBD mechanical ventilation continues during organ retrieval.

Both of these situations require rapport and trust to be established with the family. In the UK, there are separate teams of nurse specialists to help the families through these very difficult situations and coordinate organ retrieval. A local and regional transplant coordinator can help with the process, as well as provide information, training, and advice about organ donation. The medical teams involved in the ICU care of the patient and those involved in the organ retrieval process must remain completely independent. The role of the intensive care physician once a patient has been identified as a donor and consented for organ donation is to optimize the donor physiology in order that the donor's organs are in the best possible condition at the point of donation. This may require escalation of some therapies and includes correcting hypovolaemia, treating AVP-deficiency (AVP-D, formerly cranial diabetes insipidus), administration of steroids, and use of vasopressors to maintain organ perfusion. NHS Blood and Transplant has a donor optimization care bundle to guide physicians through the management of this phase.

The UK now operates an opt-out policy for the presumed consent to organ donation. This means that a person is presumed to consent to donation unless they have actively opted out of the organ donor register. The final consent still lies with the next of kin.

Follow-up and care after discharge

Critical care survivors often have ongoing health problems that can last for many years, and a full recovery to their premorbid state is not always possible. Many patients will require months of inpatient rehabilitation before being able to return home. Both the patients

and their families/carers can experience something called post-intensive care syndrome (PICS). PICS is a combination of physical, psychological, cognitive, and socioeconomic problems that can be seen in critical care survivors and their loved ones. Approximately 30% of critical care patients that survive to discharge exhibit some signs of PICS.

Physical symptoms may include chronic pain, weakness, fatigue, breathlessness, and a reduction in mobility and exercise tolerance. Psychological problems such as post-traumatic stress, depression, and anxiety are common. Cognition deficiencies can manifest as memory loss, concentration difficulties, and slow mental processing. There are often employment issues and a lot of patients do not return to work and family members take on the role of caregiver which can have huge financial implications for families.

In order to identify PICS and help these patients and their families, it is recommended that critical care survivors are offered a multidisciplinary assessment approximately 3 months after hospital discharge. This usually occurs in a critical care follow-up outpatient clinic. A detailed assessment of the patient's pre-morbid and current state is undertaken including screening for physical, psychological, cognitive, and socioeconomic problems that the patient may be experiencing since their illness. Following this, patients are often referred to other services which may include therapies and rehabilitation, psychological support in the form of counselling, peer support groups, one-to-one psychological support, and other medical or surgical specialties for ongoing management of physical issues.

CORE SKILLS AND KNOWLEDGE

Every year, more than 300 million operations are performed around the world. As global life expectancy increases, so too does the complexity of procedures that surgeons are able to perform. As a result, as time passes, patients presenting for surgery will be older, with multiple co-morbidities and having increasingly complex surgery. Therefore, the risk of poor outcomes after surgery is elevated and perioperative medicine has emerged as a multidisciplinary subspecialty focused on improving surgical outcomes. Anaesthetists form a central part of perioperative teams and often have oversight and influence over the entire surgical pathway, working closely with surgeons, physicians, nurses, and other allied health professionals.

Key skills to learn in anaesthesia and perioperative medicine include:

- Understanding the process of risk assessment, shared decision-making, and consent in the preparation of a patient for surgery
- Knowledge of the spectrum of anaesthetic agents and principles of intraoperative monitoring
- Recognizing common postoperative complications and understanding how to prevent and treat them.

Opportunities to learn skills in anaesthesia and perioperative medicine include attending surgical and anaesthetic pre-assessment clinics and multidisciplinary teams (MDTs), 'shadowing' an anaesthetist during an operating list, and joining specialist postoperative ward rounds (e.g., orthogeriatrics).

CLINICAL SKILLS

The preoperative anaesthetic assessment:

The preoperative assessment is a key step in patient preparation for surgery, providing opportunities to pre-empt or avoid predictable complications, evaluate and optimize chronic health conditions ahead of surgery, and provide a bespoke estimate of 'risk', to better inform and counsel both the patient and other health professionals involved in their care (**Box 14.1**).

The perioperative checklist:

All hospitals should have a localized perioperative checklist based on the World Health Organization Surgical Safety template to minimize risks due to human error and oversight and avoid 'never events' such as 'wrong site surgery' (**Fig. 14.1**).

BACKGROUND

Perioperative medicine is a medical subspeciality dedicated to comprehensive care of patients undergoing surgery, encompassing the assessment, optimization, and management of patients in the period spanning the decision to undergo surgery, through the surgical procedure itself and into the postoperative recovery phase (**Fig. 14.2**). This discipline is essential for ensuring the safety, well-being, and optimal outcomes of patients having surgery.

Perioperative medicine specialists include doctors trained in anaesthesia, surgery, or medicine working collaboratively alongside allied health professionals, such as psychologists, physiotherapists, and dietitians to provide patients contemplating surgery with integrated and personalized care throughout their surgical pathway.

Box 14.1 The preoperative anaesthetic assessment

Preoperative assessment		Implications/further actions
Anaesthetic history	Previous anaesthetics? Any problems? Any family problems with anaesthesia?	Explore events further. Review previous anaesthetic charts. Consider rare inherited problems with volatile anaesthetics and muscle relaxants.
	Fasting status	Allowed to drink clear fluids until 2 hours preop. Allowed food until 6 hours preop.
	History of acid reflux Controlled or symptomatic?	Implications for risk of pulmonary aspiration of gastric contents and airway management.
Medical history	Hypertension Ischaemic heart disease Heart failure Cerebrovascular disease Diabetes Asthma/COPD Snoring/obstructive sleep apnoea Obesity Liver disease Renal impairment Venous thromboembolism Anaemia	Contribute to risk assessment and optimization. Influence delivery and choice of anaesthetic care.
Drug history	**Allergies** Regular medications Any issues taking NSAIDs	Influence delivery and choice of anaesthetic care.
	Specific medicines—steroids, anticoagulation, insulin, SGLT-2 inhibitors	Perioperative management of specific medicines.
Social history	Alcohol intake	Influences delivery and choice of anaesthetic care.
	Smoking including vaping or cannabis use Other recreational drug use	Increased risk of laryngospasm, bronchospasm, postoperative pulmonary complications.
	Home environment	Planning for rehabilitation and postoperative care.
Functional assessment	Subjective assessments	Contribute to risk assessment and optimization.
	Objective tests, for example, CPET	
Physical examination	Airway assessment	Implications for airway management
	Cardiorespiratory examination	
Investigations	ECG Echocardiogram Blood tests Respiratory function tests CPET	Depends on age, ASA status, and surgical complexity. Guided by hospital and NICE guidelines (Routine preoperative tests for elective surgery).
Summary	ASA status Risk assessment tools Frailty assessment	Contribute to risk assessment and optimization, shared decision-making, and resource planning.
Communication with patient, families, or carers	Explain conduct of anaesthetic options Explain the expected pre/intra/postoperative journey Allow time for questions, concerns, or clarifications	Describe the advantages/benefits and disadvantages/risks of options for anaesthesia. Facilitate shared decision-making.
Multidisciplinary communication	Request additional investigations Refer for optimization of co-morbidities, nutrition, physical fitness, lifestyle interventions (prehabilitation) Arrange additional perioperative resources including critical care admission	Optimize progress through perioperative journey. Reduce or modify risk of perioperative complications or mortality. Reduce cancellations at short notice or on the day of surgery.

Over the past two decades, the landscape of medical care for surgical patients has undergone a marked transformation. Evidence that pre-existing medical conditions and development of complications following surgery significantly impact long-term outcomes has driven development of perioperative medicine teams, breaking traditional silos that separated surgical, anaesthetic, and medical care. For example, while preoperative assessments have traditionally focused on surgical fitness and procedural planning, the perioperative medicine approach places a stronger emphasis on *optimizing patients' overall health and individual needs before surgery*. This involves meticulous evaluation of medical co-morbidities, nutritional status, and psychosocial factors to identify and address potential risks, ensuring patients are in the best possible condition before surgery.

Advances in technologies including real-time data on vital signs, tissue oxygenation, and anaesthesia depth allow for immediate intervention and optimization of patient physiology. Adoption of minimally invasive surgical techniques has revolutionized many procedures, enabling smaller incisions, reduced tissue trauma, and quicker recovery times minimizing surgical stress on the patient. Postoperative management has evolved beyond immediate recovery to focus on long-term outcomes, with enhanced

Surgical Safety Checklist

World Health Organization | Patient Safety
A World Alliance for Safer Health Care

Before induction of anaesthesia (with at least nurse and anaesthetist)	Before skin incision (with nurse, anaesthetist and surgeon)	Before patient leaves operating room (with nurse, anaesthetist and surgeon)
Has the patient confirmed his/her identity, site, procedure, and consent? ☐ Yes	☐ **Confirm all team members have introduced themselves by name and role.**	**Nurse Verbally Confirms:** ☐ The name of the procedure
Is the site marked? ☐ Yes ☐ Not applicable	☐ **Confirm the patient's name, procedure, and where the incision will be made.**	☐ Completion of instrument, sponge and needle counts
Is the anaesthesia machine and medication check complete? ☐ Yes	**Has antibiotic prophylaxis been given within the last 60 minutes?** ☐ Yes ☐ Not applicable	☐ Specimen labelling (read specimen labels aloud, including patient name)
Is the pulse oximeter on the patient and functioning? ☐ Yes	**Anticipated Critical Events** **To Surgeon:** ☐ What are the critical or non-routine steps? ☐ How long will the case take? ☐ What is the anticipated blood loss?	☐ Whether there are any equipment problems to be addressed
Does the patient have a: **Known allergy?** ☐ No ☐ Yes **Difficult airway or aspiration risk?** ☐ No ☐ Yes, and equipment/assistance available **Risk of >500ml blood loss (7ml/kg in children)?** ☐ No ☐ Yes, and two IVs/central access and fluids planned	**To Anaesthetist:** ☐ Are there any patient-specific concerns? **To Nursing Team:** ☐ Has sterility (including indicator results) been confirmed? ☐ Are there equipment issues or any concerns? **Is essential imaging displayed?** ☐ Yes ☐ Not applicable	**To Surgeon, Anaesthetist and Nurse:** ☐ What are the key concerns for recovery and management of this patient?

This checklist is not intended to be comprehensive. Additions and modifications to fit local practice are encouraged.

Revised 1 / 2009

pain management, early mobilization, and proactive rehabilitation integral components.

This more holistic and proactive approach to the surgical patient enables greater efficiency and targeted allocation of expensive resources, such as postoperative critical care best enhances patient safety, minimizes the impact of complications, and improves surgical outcomes.

PATHOPHYSIOLOGY

Major surgery constitutes a significant injury to the body. Surgery causes acute inflammation both local to and distant from the site of surgery. This is known as the 'surgical stress response' and is mediated by:

- ***Inflammatory cells***, including macrophages, monocytes and neutrophils
- ***Cytokines and other inflammatory mediators***, such as tumour necrosis factor-alpha (TNF-α) and various interleukins
- ***Activation of the endothelium*** with production of kinins, prostaglandins, and nitric oxide, leading to vasodilation and increased vessel permeability
- ***Release of stress hormones***, mediated primarily via:
  1. the sympathetic nervous system, through noradrenaline (norepinephrine) from sympathetic nerve endings and adrenaline (epinephrine) from the adrenal glands
  2. activation of the hypothalamic–pituitary axis with release of arginine vasopressin (AVP) and adrenocorticotrophic hormone (ACTH), leading to direct effects, as well as the subsequent release of other hormones such as glucagon and aldosterone.

This inflammation presents a significant challenge to organ systems in terms of metabolic supply and demand. **In particular, oxygen supply/demand mismatch may occur:** delivery of oxygen to metabolically active tissue can fail to meet requirements, which have dramatically increased, leading to disrupted cell function. This can affect any tissue or organ, but incision/wound sites, the heart, lungs, kidneys, and brain are often affected. For this reason, the perioperative physician focuses on assessing and optimizing a patient's ability to deliver oxygen to tissues when presented with a surgical stress. Cardiac, lung, and circulatory performance are the main determinants of oxygen delivery. **Patients presenting for surgery with existing organ dysfunction or co-morbid disease are therefore at significant risk of morbidity and mortality.**

The need for energy to support inflammation and tissue repair triggers a catabolic state in the surgical patient. This is characterized by:

- ***Sodium and water retention*** mediated by AVP and the renin–angiotensin–aldosterone pathway
- ***An increase in carbohydrate, fat, and protein catabolism***, mediated by catecholamines and cytokines, with increased glucose and fat turnover
- ***The breakdown of adipose tissue and catabolism of skeletal muscle proteins*** to provide amino acids for both gluconeogenesis and acute-phase proteins by the liver
- ***Hypercoagulability***, typically in the first 24 to 48 hours after surgery and mediated via endothelial injury and activation, which increases the risk of thromboembolism.

This may be on top of existing malnutrition and metabolic deficit, for example, in the elderly or patients with cancer.

Postoperative complications (such as sepsis) can increase inflammation, energy demand, and catabolism yet further.

Our understanding of the pathophysiology of surgical stress, oxygen delivery, and metabolic supply/demand is developing. Newer work includes focus on dysfunction at the level of the mitochondria and genetic drivers of an individual's response to surgery.

PREOPERATIVE CARE

Preoperative care of the surgical patient can be thought of as occurring in three phases:

First, the assessment and diagnosis of the presenting surgical disease, usually by a surgeon. This involves relevant examination (e.g., of the abdomen, or limb), imaging (e.g., CT scanning), and further investigation (e.g., blood tests).

Second, medical (i.e., non-operative) treatments, administered by a multidisciplinary team of surgeons, physicians, anaesthetists, and allied health professionals (e.g., physiotherapists). Measures can include analgesia if the patient is in pain, resuscitation, and organ support if the patient is significantly unwell and is hospitalized in an emergency, and chemotherapy or radiotherapy if appropriate for a patient's cancer.

Third, preparation for surgery, by surgeons, anaesthetists, and other perioperative teams. This requires careful assessment of the patient's pre-existing disease (whether chronic co-morbidity, or acute related to the active surgical pathology) and functional state. Optimization of a patient's physiology, timing of surgery, planning the surgery itself (e.g., open vs. laparoscopic, anatomical approach, availability of equipment and resources), and careful consent and shared decision-making are all fundamental.

These phases can be interrupted at any time to delay or even cancel surgery if the patient's condition changes, or if they withdraw their consent.

Emergency versus elective surgery

Surgery can be elective (i.e., planned in advance) or emergency. Certain conditions (e.g., rapidly advancing cancer) require surgery that is both elective and urgent.

The phases of preoperative care detailed above are similar for elective and emergency surgery but may be delivered in a different setting and in a different time frame (**Box 14.2**). Time to prepare for surgery may be limited if the patient needs an emergency procedure, and resuscitation may occur simultaneous to the operation itself. Optimization of existing disease may not be possible at all—hours before an emergency surgery, a patient's exercise capacity or lung function, for example, are unlikely to be modifiable. For these reasons, emergency surgery is understood to be higher risk in terms of morbidity and mortality.

Consent

All surgery requires informed consent from the person undergoing the operation and in the UK, this must be written. The principles of obtaining informed consent, including assessment of mental capacity, are discussed in Chapter 3. If a patient requires emergency surgery but is unable to provide consent (e.g., if they are unconscious as a result of trauma), clinicians and patient representatives (e.g., family) can consider options based on the best interests of that person.

Information provided during the consent process must be detailed and include risks, benefits, and alternatives. Risks must be those that are common, those that are significant or major (e.g.,

Box 14.2 Emergency versus elective surgery: differences in preoperative care

	Elective	Emergency
Example	Knee replacement	Laparotomy and Hartmann's procedure for perforated bowel
Diagnosis and investigation	Outpatient *Orthopaedic clinic, X-ray/CT/MRI scans, repeat appointments for reassessment*	Emergency department, inpatient *Urgent examination and CT scan, vital sign monitoring*
Non-surgical treatment	Usually outpatient, often multiple steps/stages *Weight loss, physiotherapy, analgesia*	Resuscitation, simultaneous bundles of care alongside operation *i.v. antibiotics, i.v. fluid resuscitation, vasopressors*
Preparation for surgery	Outpatient, over weeks *'Prehabilitation' programmes, nutrition and fitness, 'surgery school', blood tests, functional tests, referral to other clinics for management of existing chronic diseases*	Inpatient where possible, rapid *Resuscitation as above, blood tests and blood gas analysis, minimal delay of surgery for optimization of chronic diseases*

death or serious disability, even if rare), and those that are relevant to the particular patient (e.g., a risk that, while rare, might impact the person significantly because of their particular job). Individualized descriptions of risk are essential after the key legal case of Montgomery versus Lanarkshire Health Board (2015).

A description of the planned surgery must also be given, along with relevant additional steps that may become necessary as the operation progresses. A common example is consent for a laparoscopic procedure, with simultaneous consent for conversion to an open approach if required.

Best practice is to provide information much in advance of the proposed date of surgery, so that a patient can discuss it with trusted friends and family and come to a measured decision. Clearly, in the setting of emergency surgery, this may not be possible, but care should be taken not to rush or pressure a person, even if time to surgery is short.

Site of surgery is an important detail not to be missed during consent. Laterality (i.e., left- or right-sided surgery) or level (e.g., in spinal surgery) in particular should be noted. On the day of surgery, patients should have a mark (usually an arrow) drawn on their skin by a surgeon to indicate where on the body the operation will take place (Fig. 14.3). A patient needing a right nephrectomy should have an arrow on the right side of their abdomen, even if a midline incision is planned. Wrong-site surgery is catastrophic for the patient.

Multiperson checks, performed separately at multiple times during the journey from admission to operation, are essential. These confirm consent and ensure the correct surgery for the correct patient at the correct time.

A consent form is not a binding contract. A person can withdraw their consent for a surgery or procedure at any time.

Shared decision-making

Shared decision-making describes a collaborative process of actively involving people in their care, moving beyond informed consent to reach more patient-centred decisions. In the UK, *recently updated General Medical Council (GMC) and National Institute for Health and Care Excellence (NICE) guidance highlight the legal, ethical, and regulatory frameworks underpinning this approach to decision-making*. Every test or intervention has advantages and disadvantages, and how these are balanced will be different for each patient. Choosing Wisely, an international initiative aims to improve communication around decision-making and advocates for use of the BRAN model:

Fig. 14.3 The left leg has been marked with an upward arrow pointing to the left knee in this patient prepared for arthroscopic meniscectomy.

- **B**enefits—what are the intended benefits of the proposed investigation or treatment?
- **R**isks—what are the risks of each option, individualized to a person's specific circumstances?
- **A**lternatives—are there any alternatives to the proposed intervention? What would be the relative benefits and risks?
- The option to do **N**othing—what would happen if we chose not to proceed? What might the consequences involve over the short term and longer term?

Risk assessment

'Risk' is a concept that describes the likelihood of developing a specified outcome in either an individual or population. The term is often used and interpreted differently by clinicians and patients, making communication about risk related to surgery challenging. Risk is also subjective: what is considered 'low' risk to one person may not be for another.

Historically, short-term mortality has been considered an important outcome in both surgery and perioperative medicine, due to its significance and ease of measurement. However, short-term mortality is highly limited as a quality measure and of little relevance to patients wanting to understand how surgery will impact their quality of life and longer-term health. As a consequence, greater weight is now being given to *predicting postoperative morbidity and effects on long-term survival after surgery*.

From the perspective of a perioperative physician, accurate risk assessment is a key step in preparing and counselling patients for surgery and planning individualized perioperative care.

In general terms, perioperative risk can be assessed using several methods:

1. **Scoring systems and prediction models:**
   a. Population-based risk scores, for example, American Society of Anesthesiologists Physical Status score (ASA Score)
   b. Organ-specific risk scores, for example, Lees Cardiac Risk Index
   c. Individualized risk prediction models, for example, Surgical Outcome Risk Tool (SORT) and American College of Surgeons National Surgical Quality Improvement tool
2. **Functional capacity assessments:**
   a. Pulmonary function testing (PFT)
   b. Echocardiography
   c. Cardiopulmonary exercise testing (CPET)
3. **Serum biomarkers:**
   a. High-sensitivity Troponin-T (hsTnT)
   b. Brain natriuretic peptide (BNP)

Scoring systems and prediction models

Appraisal and categorization of underlying fitness is the most fundamental component of predicting outcomes following surgery. The American Society of Anesthesiologists Physical Status score (ASA Score, **Box 14.3**) is a simple and easily replicable system for achieving this, and despite limitations, correlates surprisingly well with outcomes in multiple surgical patient settings.

Urgency of surgery also impacts rates of postoperative morbidity with **emergency surgery being consistently higher risk for both anaesthetic and surgical-related complications**. Non-elective surgical cohorts differ markedly from populations undergoing planned procedures in key aspects: the presence of acute physiological and organ system derangements, differences in innate compensatory capacity, and the limited potential for preoperative modification of patient risk. The effects of variations in the delivery of healthcare in non-elective settings also play a role.

More sophisticated risk prediction tools involve inputting preoperative parameters about patients, including planned surgical procedure, age, co-morbidity status, and basic investigation results. Computer models used to generate risk estimates are based on comprehensive data from thousands of patients undergoing surgery. This data powers tools, such as the American College of Surgeons, National Surgical Quality Improvement Program, which include freely available online calculators that allow clinicians to estimate risk of various postoperative complications for individual patients.

All risk prediction tools have limitations, most importantly that they are technically only valid for the specific patient population whose data was used to design and validate them.

Functional capacity assessments

Functional capacity assessments help gauge a patient's ability to withstand the physiological stress of surgery. These can be subjective, including structured self-reports on exercise tolerance or graded ability to carry out a variety of daily activities, or objective assessments based on clinical investigations and measurements.

Common tests of cardiorespiratory function include echocardiography and pulmonary function tests. Such assessments are non-invasive, relatively cheap, and provide information about cardiorespiratory health, but are best considered diagnostic tools to determine the presence of abnormal function or disease, with opportunities for targeted optimization prior to surgery. Echocardiography, in particular, provides limited information about dynamic performance when the heart is under stress and can therefore be misleading when used to estimate perioperative risk.

In contrast, **cardiopulmonary exercise testing (CPET)** is an objective measure of a patient's aerobic capacity and cardiopulmonary function (**Fig. 14.4**). CPET quantifies variables such as oxygen consumption (VO_2), carbon dioxide production (VCO_2), and the anaerobic threshold during exercise. Patients with reduced aerobic

Box 14.3 The American Society of Anaesthesiologists Physical Status Score

ASA grade[a]	Assessment	Description
I	A normal healthy patient	Healthy, non-smoking, no or minimal alcohol use
II	A patient with mild systemic disease	Mild diseases only without substantive functional limitations. Examples include current cigarette smoking, social alcohol drinking, pregnancy, obesity (BMI 30–40), well-controlled diabetes or hypertension, mild lung disease
III	A patient with severe systemic disease	Substantive functional limitations; one or more moderate to severe diseases. Examples include poorly controlled diabetes or hypertension, COPD, morbid obesity (BMI ≥40), active hepatitis, alcohol dependence or abuse, moderate reduction of ejection fraction, end-stage renal failure undergoing regular dialysis, recent (but >3 months) myocardial infarction or stroke
IV	A patient with severe systemic disease that is a constant threat to life	Examples include recent (<3 months) myocardial infarction, stroke or coronary intervention (such as coronary angioplasty), ongoing cardiac ischaemia or severe valve dysfunction, severe reduction of ejection fraction, sepsis, advanced renal impairment not on dialysis
V	A moribund patient who is not expected to survive without the operation	Examples include ruptured abdominal/thoracic aortic aneurysm, massive trauma, intracranial bleed with mass effect, ischaemic bowel, multiple organ/system dysfunction
VI	A declared brain-dead patient whose organs are being removed for donor purposes	

[a]The addition of 'E' denotes emergency surgery (when delay in treatment would lead to a significant increase in the threat to life or body part).
BMI, Body mass index; *COPD*, chronic obstructive pulmonary disease.

Fig. 14.4 A patient undergoing cardiopulmonary exercise testing (CPET).

capacity are at higher risk for postoperative complications, including adverse cardiac events, respiratory failure, and longer hospital stays.

Identifying patients as high-risk for surgery helps guide decisions about surgical candidacy and procedural planning and may prompt further interventions, such as cardiac rehabilitation, pulmonary rehabilitation, or nutritional support. CPET data can also be used to facilitate informed consent discussions with patients by providing a quantitative and objective way of describing fitness.

Serum biomarkers

A relatively new and still controversial approach to help predict risk after surgery is by monitoring for serum biomarkers indicating early end-organ damage to vital organs, such as the heart (via serial troponin or BNP concentration changes) or kidneys. An increase in troponin levels indicates myocardial injury or strain, which is most frequently due to imbalance between myocardial oxygen demand and supply during the perioperative period (rather than coronary artery plaque rupture). Identifying troponin rises early and optimizing cardiovascular status to minimize further injury to the heart may improve patient outcomes.

Frailty

Frailty is a state of vulnerability leading to poor restoration of homeostasis after a stressor event. It is a result of cumulative functional decline of the body's organ systems with age, leading to reduced physiological reserve. Frailty assessment is a comprehensive evaluation that considers multiple domains, including physical function (e.g., grip strength, gait speed), nutritional status, cognitive function, and psychosocial factors. A detailed description of frailty, including tools for diagnosis and grading of severity, is provided in Chapter 49.

Frailty assessments are highly predictive of adverse perioperative outcomes, including postoperative delirium (POD), prolonged hospital stays, falls, disability, and mortality.

Anaesthetic assessment and perioperative clinics

The preoperative anaesthetic assessment is a comprehensive evaluation of the patient conducted by the anaesthetist before surgery to ensure the safety and well-being of a patient before they have their operation and incorporates anaesthetic, surgical, and medical history, focused clinical examination and outputs from relevant clinical investigations, functional assessments, and risk calculations (Box 14.1).

Preoperative fasting status should be determined. Fasting is required to minimize the risk of regurgitation and pulmonary aspiration of gastric contents under anaesthesia. In general, patients should be fasted for 6 hours for solid foods and 2 hours for clear liquids. Non-clear liquids, such as milk, should be treated as solids.

Airway assessment

The anaesthetic airway assessment ensures safe and effective management of a patient's airway during surgery. It involves a thorough examination of anatomical factors, such as neck mobility, mouth opening, and the presence of any abnormalities that may impede safe airway access. Assessing factors like Mallampati score (Fig. 14.5), thyromental distance, and the ability to protrude the mandible helps predict ease of intubation. This assessment guides the choice of airway management techniques and equipment, minimizing the risk of complications and ensuring adequate oxygenation and ventilation throughout the surgical procedure.

Specific common diseases in the perioperative patient

Any patient with any pre-existing disease can present for surgery at any time. The student or early career doctor learning about a condition should ask themselves: 'What if this patient needed an operation?'.

A number of conditions merit special attention because they are common and associated with morbidity and mortality across surgical populations.

Diabetes mellitus

Diabetes is common and predisposes to other conditions requiring surgery (e.g., abscesses, vascular pathology). Perioperative priorities are to optimize chronic glucose control where time allows or acute control if surgery is emergent. Any patient normally using insulin (whether type 1 or type 2 diabetic) should have their blood ketones monitored perioperatively—surgical stress is a trigger of ketoacidosis—and may require variable-rate insulin infusion. Preoperative fasting can cause problems for diabetic patients, and common practice is to schedule their surgery at the start of an operating list, to minimize fasting duration.

Targets: HbA1c < 69 mmol/L to proceed for elective surgery. Blood glucose 6 to 12 mmol/L throughout surgical journey. Minimize fasting time preoperatively, restore diet as quickly as possible postoperatively.

Drugs: Most can be continued as normal (including metformin), although any agents that predispose to hypoglycaemia should be stopped if the patient is not eating at the time of their normal dose. This includes sulphonylureas such as gliclazide. Insulin doses may need to be adjusted down or doses omitted if not eating (although basal insulins should continue in those with type 1 diabetes). Sodium/glucose cotransporter 2 (SGLT2) inhibitors (e.g., dapagliflozin) can cause euglycaemic ketoacidosis in patients undergoing starvation and surgical stress and should be omitted on the day before and day of surgery. Ketones should be checked regularly.

Risks and complications: Hypoglycaemia, hyperglycaemia. Increased risk of acute kidney injury (AKI). Predisposition to local (wound) and systemic infection postoperatively. Diabetic ketoacidosis (more likely in type 1 diabetes), hyperosmolar hyperglycaemic state, euglycaemic ketoacidosis (if taking SGLT-2 inhibitors).

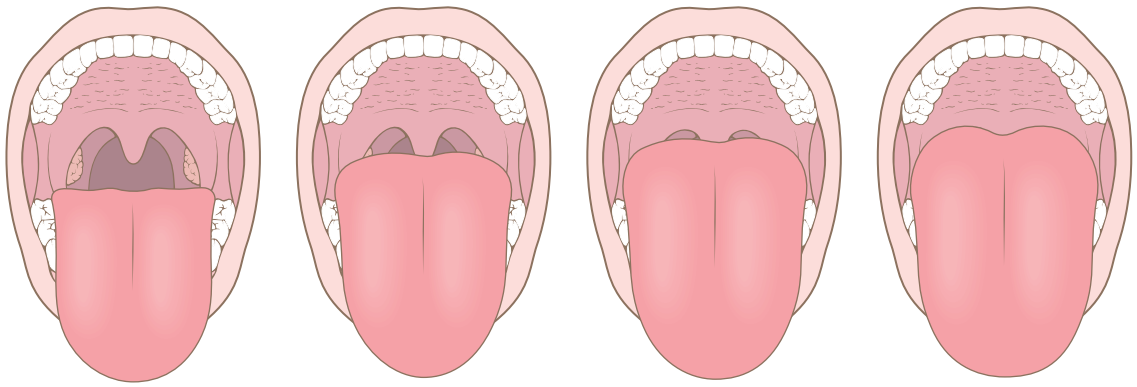

Fig. 14.5 The Mallampati score. Scores of ≥3 are associated with more difficult endotracheal intubation.

Key investigations: HbA1c, capillary blood glucose, blood ketones, renal function, fluid balance assessment.

Hypertension

High blood pressure (BP) affects approximately one in four adults. It is associated with other medical and surgical diseases, in particular vascular pathology. Cardiovascular risk related to hypertension is the major perioperative concern. Hypertension is a chronic condition, and management occurs over months to years, usually in the primary care setting. Acute perioperative BP treatment is therefore only advised in the setting of severe hypertension, that is, BPs high enough to present significant risk of end-organ damage (e.g., stroke). The most common cause of hypertension postoperatively is pain, including pain caused by urinary retention. Exclude triggers for high BP before treating the hypertension directly.

Targets: Aim BP < 160/100 mmHg in primary care, prior to referral for surgery. BP < 180/110 mmHg in hospital pre-assessment clinic or on day of elective surgery. BP reduction in the setting of emergency surgery is unlikely to be beneficial unless a hypertensive crisis is suspected. Maintaining intraoperative mean arterial pressure > 60 mmHg and systolic BP > 100 mmHg in a hypertensive patient may reduce risk—the usually hypertensive patient can be *relatively* hypotensive with a BP that would not normally be considered low.

Drugs: ACE inhibitors (e.g., lisinopril) and angiotensin receptor blockers (e.g., losartan) should be stopped 24 hours prior to surgery to reduce risk of AKI and refractory hypotension under anaesthesia and restarted within 48 hours of operation. Thiazides, calcium channel blockers, and beta-blockers should be continued. Beta-blockers should not be newly started preoperatively.

Risks and complications: Stroke, myocardial infarction, heart failure, increased risk of AKI, hypotension secondary to treatments.

Key investigations: Serial BP measurement, electrocardiogram (ECG), renal function

Anaemia

Anaemia (low haemoglobin) has a variety of causes and is always associated with increased perioperative risk. Low haemoglobin equates to a reduced capacity for oxygen carriage and delivery to tissues, which can lead to organ dysfunction, impaired healing, and other complications. The preoperatively anaemic patient has less capacity to accommodate a fall in haemoglobin caused by intra- or postoperative bleeding. Modern approaches aim to avoid excessive blood transfusion—the traditional multi-unit transfusion to target haemoglobin > 100 g/L is incorrect. Patients who refuse blood products (commonly on religious grounds) present a perioperative challenge, and additional advice should be sought.

Targets: Anaemia in the non-pregnant adult patient is defined by Hb < 130 g/L. Blood transfusion is indicated if Hb is below 70 g/L, or 80 g/L in patients with ischaemic heart disease. Post-transfusion targets are 70 to 90 g/L and 80 to 100 g/L, respectively.

Drugs: Oral iron—can take up to four weeks to be effective. i.v. iron can be used if surgery is less than four weeks away or oral iron fails. B12 and folate replacement based on blood tests. Oral therapies should be continued throughout the perioperative period. Erythropoietin is often given in patients with renal disease and should be continued. Tranexamic acid should be given intraoperatively during major surgery.

Risks and complications: Untreated anaemia increases risk of local (wound) and systemic infection, cardiovascular complications (stroke, myocardial infarction), and death. Anaemic patients will tolerate bleeding poorly.

Key investigations: Full blood count, iron studies (iron level, ferritin, transferrin saturation), B12 and folate levels, C-reactive protein, renal function, urinalysis, referral for endoscopy if GI bleed suspected as cause of anaemia.

Ischaemic heart disease

Ischaemic heart disease is defined by acute or chronic failure of oxygen delivery to meet myocardial demand. This is normally because of partial or complete occlusion of one or more coronary arteries. Surgery leads to increased myocardial work and can unmask latent disease or worsen existing disease. Minimizing surgical stress is therefore essential, and approaches to anaesthesia and surgery must be planned accordingly. Patients with ischaemic heart disease are at high risk of perioperative cardiovascular complications, principally myocardial infarction, dysrhythmia, and death. In addition, many patients (with or without existing ischaemic heart disease) experience **m**yocardial **i**njury after **n**on-cardiac **s**urgery (MINS), an ischaemic episode not meeting criteria for myocardial infarction. Investigations and treatments for MINS are the subject of ongoing debate. The Lee Revised Cardiac Risk Index is a scoring system that can be used to predict cardiac complications after non-cardiac surgery.

Targets: Reduce risk of perioperative cardiovascular event by avoiding sustained hypo/hypertension, uncontrolled pain, anaemia, tachycardia and using goal-directed haemodynamic therapy. Optimize associated risk factors preoperatively (BP, haemoglobin, cholesterol). Delay elective non-cardiac surgery for 6 months after elective percutaneous coronary intervention (PCI) and 12 months after an acute coronary syndrome event.

Drugs: After elective PCI, delay urgent non-cardiac surgery until a minimum of one month of dual antiplatelet therapy (DAPT) has been given. Continue aspirin throughout the perioperative period unless surgery is neurosurgical (including spine) or vitreal ophthalmology. Clopidogrel and ticagrelor should be stopped for 5 days prior to surgery; prasugrel should be stopped for 7 days. Direct oral anticoagulants (DOACs, e.g., dabigatran, rivaroxaban) should be stopped for at least 2 days (longer if a patient has impaired renal function). In patients at very high risk of thrombosis (e.g., mechanical heart valves), a 'bridging' plan may be commenced, using low molecular weight heparin (e.g., enoxaparin) to provide anticoagulation while a patient is not taking a direct oral anticoagulant. Secondary prevention drugs for patients with ischaemic heart disease (e.g., statins, beta blockers) should not be discontinued.

Risks and complications: Myocardial infarction, MINS, dysrhythmia, heart failure. Thrombosis due to stopping anticoagulants, or bleeding when continuing.

Key investigations: Based on patient and surgical risk. ECG, troponin if myocardial injury or ACS suspected, echocardiography, stress imaging (e.g., myocardial perfusion scintigraphy), BNP.

Chronic obstructive pulmonary disease (COPD)

Patients with chronic respiratory diseases such as COPD are at high risk of perioperative complications. They are more likely to develop postoperative pneumonia, particularly if surgery is prolonged, involves the abdomen (since abdominal pain due to surgery impairs deep breathing), or involves the thoracic cavity. COPD itself is almost always caused by smoking, and hence, patients are at risk of additional complications (myocardial infarction [MI], stroke) or surgical disease (cancers) related to this. Severe COPD makes intraoperative and postoperative ventilation more difficult and may be an indication to avoid general anaesthesia.

Targets: Smoking cessation is vital, and patients should be referred to relevant support services. Patients should also have up-to-date pneumococcal and influenza vaccinations. Although spirometry is used for diagnosis of COPD, preoperative pulmonary rehabilitation is better guided by symptom assessment and functional tests (see below).

Drugs: Inhalers should be continued and should be used on the morning of surgery as normal. Most patients will be using inhaled steroids and may be at risk of adrenal suppression—additional i.v. or oral steroids should be given perioperatively if so.

Risks and complications: Pneumonia, pneumothorax, prolonged and difficult ventilation, bronchospasm, respiratory failure, death.

Key investigations: Spirometry (forced expiratory volume in 1 second [FEV1], forced vital capacity [FVC]), functional assessment (e.g., Chronic Respiratory Questionnaire, 6-minute walk test, CPET), arterial blood gases in major surgery, chest X-ray.

Optimization and prehabilitation

Screening and risk assessment to identify patients at increased risk of perioperative complications presents an opportunity to optimize modifiable risk factors and plan care.

Preoperative optimization describes a holistic approach to preparing patients physically and psychologically for surgery. In addition to optimizing common co-morbidities described above, preoperative preparation includes identifying and addressing additional modifiable risk factors such as:

- Smoking and vaping
- Alcohol use
- Recreational drug use
- Nutritional state and obesity
- Physical fitness

'Prehabilitation' is an umbrella term describing multidisciplinary interventions to help patients prepare for surgery, reduce complications, and improve outcomes. The most common interventions include:

- **Psychological interventions:** signposting patient information resources, support groups, counselling, and other therapeutic techniques such as motivational interviewing and coaching.
- **Exercise and fitness interventions:** delivered virtually or in-person, most often led by physiotherapists, sports and exercise therapists, or personal trainers. Improving cardiorespiratory fitness through group or individual exercise sessions, particularly high-intensity interval training, may be associated with reduced perioperative complications.
- **Nutritional screening and interventions:** led by dietitians to optimize energy reserves and metabolic status before surgery, particularly during neoadjuvant cancer therapy.

High-quality evidence supporting the use of prehabilitation has yet to be established. Interventions and outcome measures in the available evidence are heterogenous, leading to low-certainty conclusions in recent meta-analyses.

Preoperative optimization and prehabilitation offer the opportunity for 'teachable moments' regarding a patient's long-term health. Improvements to chronic health problems and risk factors such as smoking or cardiorespiratory fitness may have long-term benefits for patients beyond the perioperative period.

Fasting and nutrition

Surgical pathology and systemic illness are associated with malnutrition. Patients have inadequate energy reserves in the context of increased energy demands and/or impaired fuel utilization associated with cancer, cancer treatments, infection, and inflammation. Nutritional deficits may be further exacerbated in hospital by restricted intake, intestinal malabsorption, and systemic catabolism.

Daily requirements after surgery range from 30 to 40 kCal/kg and 1 to 2 g/kg of protein per day. Assessment of nutritional status and screening for malnutrition is discussed in Chapter 25.

Patients at risk of malnutrition warrant early specialist input from a dietitian, with nutritional supplementation.

Preoperatively, patients undergoing both elective and emergency surgery are instructed to avoid eating and consuming dairy products for 6 hours before surgery and to stop drinking fluids 2 hours before, to reduce the risk of aspirating gastric contents into the airway and lungs during anaesthesia. Increasingly, hospitals are introducing 'sip until send' policies which allow patients to sip water until surgery to avoid excessive periods of time 'nil by mouth' (NBM). Many elective surgical pathways utilize carbohydrate drinks before surgery to minimize periods of nutritional deficit as part of **e**nhanced **r**ecovery **a**fter **s**urgery (ERAS): multicomponent bundles of care which seek to reduce complications and length of hospital stay.

Postoperatively, patients may be unable to meet the increased energy requirements associated with healing and postoperative inflammation through oral intake alone. Malnutrition adversely affects patients' recovery after surgery through reduced mobility and wound healing, in addition to increased risk of complications such as wound infection. Options for supplementation include energy-dense drinks or enteral nutrition via nasogastric, nasojejunal, or percutaneous feeding tubes. In patients with significant gut dysfunction, total parenteral nutrition (TPN) may be delivered intravenously via central venous lines or peripherally inserted central catheters (PICC). TPN requires intensive monitoring of fluids and electrolytes and patients are at increased risk of infection.

INTRAOPERATIVE CARE

Types of anaesthesia

Anaesthesia exists to make safe and painless surgery possible and can be administered in three main ways, which can also be combined: general anaesthesia, neuraxial anaesthesia, and regional or local anaesthesia.

General anaesthesia

General anaesthesia, or 'GA', is the administration of drugs to a patient to render them unconscious. This is often described to patients as 'going to sleep' for an operation, although brain activity in sleep states is markedly different from that under anaesthetic. GA can involve inhalation of volatile gases (e.g., sevoflurane) or giving intravenous medications (e.g., propofol). Patients can be given a 'push' of i.v. drugs to render them unconscious, prior to maintenance of anaesthesia with gas, have inhalational induction and maintenance (e.g., in small children), or have i.v. induction and maintenance using infusions (known as total intravenous anaesthesia). A variety of agents are available for each technique. All will suppress respiratory drive and airway reflexes, meaning that patients must have airway support (e.g., intubation or supraglottic airway insertion) and ventilation provided. Most will cause a fall in blood pressure and myocardial contractility to some degree. GA can also involve muscle relaxation (with, e.g., atracurium or rocuronium), but this is not a requirement.

Neuraxial anaesthesia

Neuraxial anaesthesia is the blockade of the central nervous system below the brain. This involves passing a needle intrathecally (i.e., into the cerebrospinal fluid) for a spinal anaesthetic, or into the epidural space for an epidural anaesthetic, and administering local anaesthetic drugs (e.g., lidocaine, bupivacaine) to bathe the spinal cord and/or nerve roots. These techniques can be truly anaesthetic (i.e., surgery can be completed without any additional anaesthesia) or analgesic (used in combination with a general anaesthetic for postoperative pain relief, e.g., in laparotomy). As sole techniques, they are used for surgery below the umbilicus of short to medium duration (e.g., caesarean section, knee replacement). Spread of local anaesthetic to high thoracic or cervical spinal levels can cause bradycardia, respiratory depression, and coma. Spinal anaesthetic, in particular, causes a loss of vascular tone through blockade of sympathetic fibres and falls in blood pressure are likely.

Regional anaesthesia

Regional anaesthesia is the blockade of specific nerves (or their roots) by needle injection of local anaesthetic into the anatomical area around those nerves. The aim is to interrupt sensory signals from relevant areas distal to the blockade. For example, an interscalene brachial plexus block involves injection of local anaesthetic around the C5, C6, and C7 roots of the brachial plexus in the neck between the scalene muscles, such that the shoulder and arm become numb, and a procedure (e.g., shoulder surgery) can be performed. Again, this could be used as a sole technique (i.e., with an awake patient) or in combination with general anaesthesia, as pain relief. Historically, nerve blocks were done using landmark anatomy only, but modern practice is to use ultrasound to guide the path of the needle towards neurologic structures of interest. Some nerve blocks do not target specific structures, but rather fill a space or potential space with local anaesthetic, with action on fibres passing through, such as the rectus sheath block for midline abdominal incisions. These are analgesic rather than anaesthetic. Field blocks, or simple wound infiltration, involve injection of local anaesthetic without targeting a specific nerve or plane. This provides analgesia to a small area of tissue and allows minor surgery (e.g., lipoma excision) or postoperative analgesia at the surgical site.

Anaesthetic drugs

The anaesthetic pharmacy is large and varied, but some agents in regular use merit brief introduction.

Volatiles—anaesthetic gases

Volatile gases are used to induce and maintain anaesthesia by inhalation. In modern practice they include sevoflurane, desflurane, and isoflurane, but historically have covered a multitude of compounds, including ether, cyclopropane, and halothane. A vaporizer mounted on the anaesthetic machine is used to produce a precisely controlled mixture of anaesthetic and life support gases (i.e., oxygen and air) to be delivered to the patient. The percentage of anaesthetic gas within this mixture can be altered by the anaesthetist to control depth of anaesthesia. The partial pressure of anaesthetic gas in the alveoli dictates the amount in the patient's bloodstream and hence the amount reaching the brain to exert the anaesthetic effect. Mechanism of action is likely via lipophilic protein binding, but a variety of theories remain under review—no individual target channel or receptor has been identified conclusively. Volatiles cause dose-dependent hypotension, myocardial depression, and postoperative nausea and vomiting. They form a significant part of healthcare-related greenhouse gas emissions.

Propofol

Propofol is an intravenous anaesthetic, formulated as a milky-white lipid emulsion, at 10 mg/mL or 20 mg/mL. It was first described in 1980 and has rapidly become the most commonly used anaesthetic drug in the UK. Propofol can be used as a bolus dose to induce anaesthesia, an infusion to maintain anaesthesia, or for sedation delivered in either way at lower doses. It has a rapid onset and offset, with relatively little accumulation when infused for a long time (known as a short context-sensitive half time). This makes it excellent for use in anaesthesia and intensive care for longer procedures or sedation of the critically ill intubated patient. In these settings, it is almost always used alongside an infusion of opioid, for example, remifentanil. Propofol also reliably and rapidly blunts airway reflexes, making insertion of supraglottic airway devices (e.g., a laryngeal mask or iGel) straightforward and allowing swift progress between cases on a surgical list. It does not cause nausea and vomiting but does cause a fall in blood pressure

due to vasodilation, which can be severe and dangerous in the elderly or shocked patient.

Opioids

Derived from *Papaver somniferum*, the opium poppy, opioids are effective analgesics. The class includes morphine (the reference compound to which all other opioids are compared), fentanyl, remifentanil, alfentanil, oxycodone, codeine, and diamorphine, among others. All act on the mu opioid receptor, found throughout the CNS. Naloxone is a competitive antagonist at this receptor, used to reverse the effects of opioids. Most agents can be used i.v. (as a bolus or infusion) and orally, while some are also used intrathecally or epidurally. Speed of onset and offset and potency vary significantly between compounds. Remifentanil is used as a component of total intravenous anaesthesia because of its rapid onset and offset, non-hepato-renal metabolism, and because it does not accumulate when infused for long durations. Morphine, fentanyl, and oxycodone are commonly used to treat acute postoperative pain but should be avoided in the chronic pain setting due to risk of addiction. Opioids can cause sedation, respiratory depression, nausea, itching, and constipation.

Muscle relaxants

Muscle relaxants, or neuromuscular blocking drugs (NMBDs), are used to temporarily paralyse a patient. This can be for anaesthetic reasons (to improve conditions when instrumenting the airway), surgical reasons (to improve operating conditions, e.g., in laparoscopy or when closing an abdominal incision), or in critical care to improve ventilation in severe respiratory failure. They are always given alongside general anaesthetic drugs. Agents include atracurium, rocuronium, and suxamethonium. All are chemical derivatives of curare, found in several plant species native to South America and used on the tips of arrows for hunting. NMBDs act by competitive antagonism at the neuromuscular acetylcholine receptor, except suxamethonium which acts as an agonist, depolarizing the neuromuscular end-plate and rendering it refractory to further stimulus. Speed of onset and offset, alongside duration of action, usually drive the choice of a specific agent for a given task. Level of paralysis is monitored by delivering small currents transcutaneously, to stimulate a nerve and observe the extent of muscle contraction ('twitches') that follows (e.g., the ulnar nerve, causing movement of the hand). Non-depolarizing NMBDs (those other than suxamethonium) are reversed by increasing the concentration of acetylcholine at the neuromuscular junction, such that they are out-competed. This is achieved by administering neostigmine, which blocks the metabolism of acetylcholine by acetylcholinesterase. Rocuronium and vecuronium can be reversed rapidly by sugammadex, a drug which chemically envelops the muscle relaxant. NMBDs cause voluntary respiration to cease and obtund airway reflexes. They are important triggers for anaphylaxis.

Local anaesthetics

Local anaesthetics are used to block transmission of action potentials along a nerve, such that sensation (pain) is not felt in the area supplied by that nerve. They cross neuronal cell membranes and block sodium channels. Examples include lidocaine, bupivacaine, and prilocaine. Choice of agent is driven by duration of action, speed of onset and offset, and route of administration. Local anaesthetics can be given via ultrasound-guided needle injection around a nerve or nerve root (e.g., popliteal sciatic nerve block, Fig. 14.6), into a plane or potential space (e.g., erector spinae plane block), into a wound or tissue area (including the eye), intrathecally or

Fig. 14.6 **Popliteal sciatic nerve block performed by the supine position lateral approach under ultrasound guidance.**

epidurally. Toxicity is seen at high doses when significant absorption into the bloodstream occurs. This is characterized initially by excitatory phenomena such as tingling lips, visual disturbance, tinnitus, and tremor, followed by seizure, then coma. Cardiac dysrhythmia may also occur, particularly with bupivacaine.

Additional drugs

Antiemetics

Antiemetic drugs are designed to prevent and treat nausea and vomiting, common symptoms associated with anaesthesia. These drugs exert their effects by targeting neurotransmitter pathways involved in the emetic (vomiting) reflex.

Commonly used anti-emetics, their mechanisms of action, and potential adverse effects are described in Box 22.7.

Non-opioid analgesia

Non-opioid analgesic drugs play a crucial role in managing pain during and after surgery, offering effective pain relief with fewer opioid-related side-effects. Common non-opioid analgesics include:

Non-Steroidal Anti-Inflammatory Drugs (NSAIDs): Drugs like ibuprofen, parecoxib, and ketorolac are commonly used to reduce inflammation and alleviate pain. They work by inhibiting enzymes (COX-1 and COX-2) involved in prostaglandin synthesis, thereby reducing pain and inflammation.

Paracetamol: Widely used for its analgesic and antipyretic properties, paracetamol works centrally to modulate pain perception. It is often combined with NSAIDs for synergistic pain relief.

Local Anaesthetics: Administered through injections or topical applications, local anaesthetics like lidocaine provide targeted pain relief by blocking nerve signals in specific areas.

N-methyl-D-aspartate Receptor Antagonists: Drugs like ketamine act on the N-methyl-D-aspartate receptors in the central nervous system, modulating pain perception. They are used as adjuncts to other analgesics to enhance pain control.

Emergency drugs

Anaesthetic emergency drugs are essential components of any medical facility, ready to address unforeseen complications during surgery. Key drugs include:

Adrenaline: Acts rapidly to counteract severe allergic reactions (anaphylaxis) and cardiac arrest by increasing heart rate and blood pressure.

Atropine: Reverses bradycardia and counters excessive vagal stimulation.

Vasopressors: Raise blood pressure by constricting blood vessels, counteracting anaesthesia-induced hypotension.

Suxamethonium (Succinylcholine): A neuromuscular blocking agent used for rapid sequence intubation to secure the airway.

Intraoperative fluids

Intravenous (i.v.) fluids are vital during surgery to maintain hydration and electrolyte balance and support physiological haemodynamics, such as blood pressure and heart rate. The choice of i.v. fluids depends on the patient's needs and the surgical context.

Crystalloids: These are solutions containing water, electrolytes, and, sometimes, sugar. Normal saline (0.9% sodium chloride) is a common crystalloid used to replace extracellular fluid losses and restore electrolyte balance. Balanced crystalloids, like Ringer's lactate or Plasma-Lyte, mimic the body's electrolyte composition and are often preferred.

Colloids: These solutions contain larger molecules, such as starches or albumin, which tend to stay in the intravascular space longer, helping to maintain blood volume. However, the use of colloids has been debated due to concerns about adverse effects, including allergic reactions and acute kidney injury.

Blood and Blood Products: In certain scenarios, there may be a need for transfusions of whole blood, packed red blood cells, platelets, or fresh frozen plasma to address significant blood loss and maintain adequate oxygen-carrying capacity.

Dextrose Solutions: Solutions with varying concentrations of dextrose are used to prevent hypoglycaemia, especially during prolonged surgeries.

The choice of i.v. fluids is carefully considered based on the patient's co-morbidities, the extent of surgery, and specific fluid requirements. Maintaining fluid balance is crucial to prevent complications such as electrolyte imbalances, fluid overload, or inadequate tissue perfusion during and after surgery.

Airway management

Almost all hypnotic anaesthetic drugs can suppress ventilatory drive and airway reflexes and relax muscles supporting the mouth and tongue. This process is carefully controlled and monitored by anaesthetists, but without intervention can cause airway obstruction. Airway management involves procedures and techniques aimed at establishing and maintaining a clear and secure airway. In turn, this ensures adequate oxygenation and ventilation while patients receive GA.

Preoperative airway assessment is discussed earlier. Proper positioning of the patient is crucial to maintain airway patency. The head-tilt, chin-lift manoeuvre, or the use of specialized devices (e.g., Guedel airways) may be employed to open and align the airway during induction of GA.

During GA, airway patency is secured using specialist devices categorized according to their positioning relative to patient anatomy. **Endotracheal tubes** are inserted beyond a patient's vocal cords into the trachea, where a balloon is inflated to protect the lungs from potential gastric content regurgitation. **Supraglottic airway devices (SGAs)**, which include laryngeal masks and iGels, are simpler to insert and less invasive, being situated above the vocal cords, but do not provide definitive protection against aspiration. Other airway devices are used for certain surgeries, including double-lumen endotracheal tubes, which can isolate lungs for thoracic surgery, or small or armoured tubes that can be used when surgeons need to operate around a patient's airway. Airway devices are most commonly inserted using a technique called laryngoscopy, in which an instrument is used to visualize the larynx and vocal cords. Laryngoscopy can offer direct views or involve cameras, mirrors, or fibreoptic scopes to provide indirect inspection of airway structures.

After securing the airway, anaesthetists ensure proper mechanical ventilation to maintain oxygenation and prevent hypercarbia. Ventilator settings are adjusted to individual patient needs. Continuous monitoring of oxygen saturation (pulse oximetry), end-tidal carbon dioxide (capnography), and other vital signs helps detect changes in the patient's respiratory status promptly. Anaesthetists are trained to respond quickly to unexpected airway emergencies, such as laryngospasm, bronchospasm, or tube dislodgement and have a range of techniques and equipment at their disposal to manage these situations.

At the end of surgery, anaesthetists oversee the safe extubation of the patient. This includes assessing the patient's readiness to breathe independently and ensuring a smooth transition to spontaneous breathing and wakefulness.

The anaesthetic machine

The anaesthetic machine is a piece of equipment found in all areas where anaesthesia is delivered including operating theatres, diagnostic and therapeutic radiology suites, and some emergency departments. The machine is connected to piped supplies or large cylinders of oxygen and air. The machine consists of a combination of essential equipment for delivering anaesthesia including:

- **Physiological monitoring** including pulse oximetry (SpO_2), non-invasive blood pressure monitoring (NIBP), three-lead ECG. Additional monitoring may include invasive blood pressure monitoring via an arterial cannula, cardiac output monitoring, temperature, processed electroencephalogram (pEEG) to monitor depth of anaesthesia and neuromuscular monitoring to assess the effect of NMBDs.
- **Ventilator monitoring** including pressures and flow of gases. Gas analysers measure inspired and expired gases including oxygen, carbon dioxide, and volatile anaesthetic gases. End-tidal carbon dioxide monitoring ($etCO_2$) is essential for any patient undergoing GA or sedation.
- **A mechanical ventilator** similar to those found in critical care settings but with fewer advanced modes of ventilation. Positive pressure ventilation maintains delivery of oxygen ± anaesthetic gases because anaesthetic agents cause hypoventilation and apnoea. Depending on the mode selected, the anaesthetist may select the pressure, volume, number of breaths per minute, and concentrations of different gases delivered to the patient.
- **A breathing circuit** which comprises tubing inside and outside the machine to deliver oxygen, air, and volatile anaesthetic gases to the patient. The most used in modern practice is the circle system which facilitates efficient recycling of anaesthetic gases and helps to maintain moisture and humidity of inspired gases. Expired carbon dioxide, the product of aerobic respiration, is absorbed by granules of soda lime to remove it from the circuit.
- **Vaporisers** which deliver volatile anaesthetic gases into the breathing circuit and subsequently to the patient. The anaesthetic gases may be carried along with oxygen and air or directly injected into the breathing circuit. The concentration added to the circuit is controlled by the anaesthetist.
- **Other supplemental equipment** including suction, additional oxygen ports, and emergency equipment including a self-inflating bag for use in case of a power or gas supply failure.

Ensuring that the anaesthetic machine is functioning normally is an essential component of routine safety checks before delivering any form of anaesthesia to a patient.

Theatre safety and human factors

Human factors play a crucial role in ensuring safety within the operating theatre, significantly influencing the overall quality of patient care. Communication, teamwork, and situational awareness are pivotal aspects of these factors.

Clear and effective communication among members of the surgical team is paramount. Miscommunication can lead to errors, compromising patient safety. Open lines of communication, including briefings before surgery and timely updates during the procedure, are vital. The collaborative efforts of the perioperative team are essential for safety. Well-coordinated teamwork helps prevent errors and promotes a culture of safety. Each team member's role and responsibilities should be clearly defined to avoid misunderstandings.

Maintaining situational awareness of the surgical environment and anticipating potential challenges is critical. This involves constant vigilance and attention to detail, ensuring that the team is prepared to respond effectively to unexpected developments, for example, awareness of ongoing blood losses.

Healthcare professionals working in the operating theatre often experience high levels of stress and fatigue. Acknowledging these factors is essential for maintaining concentration and decision-making abilities. During long operations, surgeons may take short breaks and anaesthetists may handover patient care to a colleague to take a short break. Ongoing training and education contribute to the continuous improvement of skills and knowledge among the perioperative team. Regular drills and simulations can enhance preparedness for emergency situations in the operating theatre environment.

Encouraging a culture where all team members feel empowered to voice concerns or question decisions, regardless of hierarchy, is crucial. This fosters a climate where patient safety is prioritized over traditional hierarchies. By recognizing and addressing these human factors, perioperative teams can create a safer and more efficient operating theatre environment, ultimately improving patient outcomes and reducing the likelihood of adverse events.

POSTOPERATIVE CARE

Location of postoperative care

The most appropriate location for postoperative care is based on several factors, including the time point after surgery, type and complexity of the operation, the patient's medical history and comorbidities, and any procedure-specific monitoring and treatment requirements.

Immediate recovery:

- Patients are transferred to the recovery unit directly from the operating theatre, where they are closely monitored as they emerge from anaesthesia.
- Key responsibilities in recovery include assessing vital signs, oxygen saturation, consciousness level, surgical site condition, and pain management.
- Nurses and anaesthetists oversee this phase and ensure patients are stable and comfortable before discharge to a higher level of care or the surgical ward.

Surgical ward care:

- Patients who are stable and have recovered sufficiently may be transferred to a surgical ward.
- Nurses on the surgical ward continue to monitor vital signs, assess wound healing, administer pain medications, manage drains and tubes, and provide patient education on postoperative care.
- Physiotherapists may assist with early ambulation and mobility.

High dependency unit (HDU) or Level 2 care:

- Patients with more complex surgical procedures or higher acuity may be admitted to an HDU or enhanced recovery unit.
- In these units, patients receive more intensive monitoring, including continuous ECG, more frequent vital sign assessments, and specialized care for complex medical conditions.
- The nursing staff-to-patient ratio is often lower in HDUs to provide a higher level of care.

Intensive care unit (ICU) Care or Level 3 care:

- Patients with the most complex surgeries, major co-morbidity, or those who experience severe postoperative complications may require admission to an ICU.
- ICU care involves continuous monitoring of vital signs, invasive hemodynamic monitoring, mechanical ventilation if needed, and management of organ support.
- A multidisciplinary team, including intensivists, critical care nurses, and physiotherapists, manages care in the ICU. Nursing support is often provided at a 1:1 ratio.

Home Recovery Care:

- After being discharged from the hospital, many patients continue their recovery at home.
- Home recovery care involves following instructions for wound care, pain management, medication administration, and any physical therapy or exercises as prescribed by the surgical team.
- Patients and caregivers play an active role in managing home recovery care, with regular follow-up appointments scheduled with the surgeon.

Rehabilitation and Follow-Up:

- Some patients, especially those who have undergone orthopaedic, neurological, or major reconstructive surgeries, may require rehabilitation services.
- Rehabilitation can include physical therapy, occupational therapy, and speech therapy, depending on the specific surgical procedure and patient needs.
- Long-term follow-up appointments with the surgeon may be necessary to monitor progress and address any complications or concerns.

It is vital that a continuum of care is maintained across each different area as patients progress through the postoperative recovery process. Surgical teams provide overriding continuity, with effective communication and comprehensive handover processes by other parts of the perioperative team, ensuring that transition from one care setting to another (e.g., from operating theatre to recovery or ICU) involves sharing of all relevant patient information and ongoing care needs. Checklists are frequently used to minimize human factor errors.

Important and common complications after surgery

Bleeding

Bleeding usually occurs in the acute phase, in the first 12 to 24 hours after surgery. Effects depend on the volume and location of the bleed. Rapid large volume loss leads to shock, with hypotension and tachycardia. This is more likely when blood loss is into a major body cavity, for example, the abdomen, as a haematoma is unlikely to form and tamponade the damaged vessel. A normal haemoglobin in this setting is not necessarily reassuring—it is a poor marker of acute haemorrhage. In confined spaces, for example the brain, spine, or fascial compartments in the limbs, compressive effects may predominate, revealed as pain and derangement of function of the compressed tissues (e.g., altered neurology).

Treatment is with transfusion of red cells and other blood products to stabilize and resuscitate, as a bridge to definitive surgical (or radiological) control of the bleed.

Venous thromboembolism

Venous thromboembolism (VTE) comprises deep vein thrombosis (DVT) and pulmonary embolism (PE). Surgical patients are at higher risk of VTE because of their procoagulant state (due to the inflammatory response to surgery) and immobility (whether during or after surgery). Specific risk factors include prolonged surgery (>90 minutes), abdomino-pelvic procedures, lower limb orthopaedic surgery, and cancer. DVT presents as limb swelling and pain and is usually unilateral. PE presents as pleuritic chest pain, breathlessness, tachycardia, and, if massive, hypoxia and shock. These normally occur more than 72 hours after surgery and can present after more than a week. Prevention is mechanical (compression stockings or intermittent pneumatic compression devices) or pharmacological (commonly low molecular weight heparin). Both prevention and treatment can be complex because using anticoagulants after surgery can cause bleeding. Risk/benefit discussions are essential and should include anaesthetists, surgeons, haematologists, and patients/family. Diagnosis and treatment of VTE is discussed in Chapter 11.

Pneumonia/postoperative pulmonary complications

Postoperative pulmonary complications (PPCs), including pneumonia, are among the most common adverse events after surgery. Prevalence of postoperative pneumonia can vary widely depending on several factors, typically ranging from 1% to 5% of surgical cases. Factors predicting risk include the type of surgery, the patient's baseline respiratory function, and preventive measures employed. Proximity of surgical incision to the thorax, where pain disrupts the performance of respiratory muscles, is a strong predictor of PPCs, as is age, with even healthy older patients being at higher risk of PPCs. PPCs are also predictors of short-term and long-term health outcomes after surgery and are associated with increased risk of admission to critical care and prolonged length of hospital stay.

Atelectasis describes partial collapse or compression of lungs and is the most common PPC, occurring due to depressant effects of anaesthesia and mechanical ventilation causing small airway collapse within lungs and impairment to normal mucociliary clearance. Failure to reverse atelectasis can lead to a worsening cycle of ventilatory impairment, leading to trapped sputum, increased oxygen requirements, and respiratory infection.

Interventions aimed at preventing PPCs include pre-emptive strategies to optimize respiratory physiology (such as respiratory muscle training before surgery) and intraoperative and postoperative interventions to minimize the adverse effects of surgery and anaesthesia. Early mobilization, supervised respiratory physiotherapy, and ambulation help prevent atelectasis and promote normal lung function. Effective pain management to encourage coughing and deep breathing are also vital.

Pain

Acute postoperative pain is common: up to 20% of patients experience severe pain in the first 24 hours after surgery. Pain should be pre-empted and prevented, with appropriate analgesia given before and during surgery. The WHO pain ladder (Fig. 50.3) is an appropriate starting point to manage pain. Additional options include intravenous strong opioids (perhaps in the form of patient-controlled analgesia, or PCA), gabapentinoids, alpha-2 agonists (clonidine), ketamine, magnesium, and regional anaesthetic techniques. Uncontrolled pain leads to further morbidity, both physical and psychological. Increased sympathetic drive adds to surgical stress and challenges the myocardium and circulation through hypertension and tachycardia, with MI and stroke possible. Surgery to the abdomen or thorax can cause pain, which prevents

adequate deep breathing or coughing, leading to atelectasis and pneumonia.

Chronic post-surgical pain is defined as pain persisting beyond the healing process, that is, beyond 3 months postoperatively. Knee replacement, thoracotomy, amputation, and mastectomy all have notably high rates of chronic post-surgical pain. Neuropathic type features may develop, and treatment should be multidisciplinary, along the bio-psycho-social model of care. Strong opioids should be avoided where possible in chronic pain settings.

Delirium and perioperative neurocognitive disorders

Perioperative delirium (POD) is a common and potentially serious condition that affects individuals after surgery. It is characterized by acute confusion, disorientation, and altered cognitive function, often occurring within the first few days following an operation. While the exact causes are multifactorial, factors such as age, pre-existing cognitive impairment, type of surgery, and anaesthesia can contribute to its onset. POD poses risks, including prolonged hospital stays, increased morbidity, and higher healthcare costs. Preventative measures include careful medication management, minimizing sedatives, and promoting early mobilization. Timely recognition and management are crucial. The approach to a delirious patient is discussed further in Chapter 49.

Postoperative cognitive dysfunction (POCD) is a condition marked by a longer-term decline in cognitive function following surgery, with symptoms such as memory problems, reduced attention, and impaired information processing. It is particularly prevalent in older adults and can persist for weeks to months, affecting the patient's daily life and quality of life. The exact cause of POCD is not fully understood but is thought to involve factors like anaesthesia, surgery-related stress, and inflammation. Prevention and management strategies include careful anaesthesia selection, minimizing surgical trauma, and promoting early postoperative mobilization.

Myocardial infarction and myocardial injury

Postoperative myocardial infarction (POMI) is a critical, albeit rare, complication that occurs following surgery. It refers to the occurrence of a myocardial infarction in the immediate postoperative period or within 30 days of surgery. POMI is a multifactorial condition, often associated with underlying heart disease, atherosclerosis, and the stress of surgery. Patients with risk factors like hypertension, diabetes, or a history of heart disease are more susceptible. Early diagnosis (ECG, cardiac biomarkers) and intervention are essential, as POMI can be life-threatening. Preventative measures include preoperative cardiac evaluation, careful monitoring during and after surgery, and optimizing patient management to reduce the risk of cardiac events in the postoperative setting.

Myocardial injury after non-cardiac surgery (MINS) is a condition characterized by damage to the heart muscle during surgery unrelated to heart procedures. MINS often goes unnoticed but can lead to complications. It is most commonly seen in individuals with existing heart disease or risk factors but is thought to occur primarily as a result of a supply and demand mismatch in myocardial perfusion rather than as a direct result of underlying cardiac disease.

Acute kidney injury

Postoperative AKI is a common (up to 30% of surgical patients) and often avoidable complication. Like many other postoperative complications, even lesser grades of AKI are associated with longer-term impact, including increased hospital stay after surgery, mortality, and risk of developing chronic kidney disease. AKI is recognized through either reduced urine output or an elevation in serum creatinine on postoperative blood testing. Reduced urine volumes are common immediately after surgery due to adaptive neurohumoral responses (including AVP secretion and activation of the renal-angiotensin-aldosterone axis) and do not necessarily indicate AKI, but recognition should trigger patient assessment to include review of haemodynamic parameters and fluid balance and exclude post-renal factors (e.g., urinary retention or a blocked catheter). The STOP mnemonic (Sepsis and hypovolaemia, Toxins, Obstruction, Parenchymal) is a useful *aide memoire* to potential causes of AKI.

Attention to fluid balance is key to avoiding AKI after surgery. These measures include maintaining haemodynamic stability and avoiding intraoperative hypotension and extremes of fluid administration. Both too much and too little fluid may be deleterious, the former resulting in oedema or hyponatraemia, and the latter prerenal 'stress' to the kidneys, which are highly metabolically active organs and are particularly susceptible to impaired oxygen delivery and AKI is often hence an early sign of inadequate global tissue oxygen delivery. NSAIDs should be avoided or used sparingly in patients with pre-existing renal disease.

Patients are commonly monitored by measuring urine output and serial plasma creatinine after surgery. For high-risk patients, this should occur in a critical care environment. Specialized devices, including cardiac output monitors, may be employed to specifically guide fluid management during the perioperative period.

Direct complications of surgery

Anastomotic leak

Leaks from surgically created anastomoses, created using sutures or automated stapling devices during gastrointestinal or other luminal surgery, may result in contents from the gastrointestinal tract leaking into the peritoneal space. This may lead to sepsis, abscess, and fistulae. Investigation and management may involve CT imaging, treatment with antimicrobials, initiation of TPN and delayed restoration of enteral nutrition, drainage by interventional radiology, or unplanned return to theatre.

Ileus

Paralytic ileus occurs after intraperitoneal surgery associated with handling or instrumentation of the bowel. Clinical features are similar to mechanical bowel obstruction including vomiting, abdominal distension, and constipation. Management comprises gastric drainage and decompression via a wide bore nasogastric (NG) tube, intravenous fluid replacement and maintenance, optimization of electrolytes, and where possible, withdrawal or dose reduction of medications which may slow gastrointestinal motility such as opioids.

Wound infection

Localized infection may cause superficial or deep wound dehiscence, prompt return to theatre for exploration and washout, impair wound healing, and delay patients' recovery and hospital discharge.

Flap/graft failure

Surgery involving transfer of skin or tissue to another location relies on delivery of oxygen and venous drainage, often via surgically formed anastomoses of small blood vessels. Complications include infection and reduced perfusion which may require washout, unplanned return to theatre, or revision of the graft.

Other morbidity and mortality

Functional recovery/morbidity

Recovering from the physiological insult of surgery may be associated with a delay or failure to return to previous levels of function. Delayed recovery and rehabilitation are influenced by several patient factors including pre-existing functional capacity and co-morbidities, advanced age, and frailty. Surgical factors include unplanned or major surgery, critical care admission, or other postoperative complications.

Patients may experience new morbidity such as chronic pain, anaemia, or deterioration in renal function. Patients may take longer than expected to leave the hospital and may require additional support including carers at home or moving to a residential or nursing care institution.

Mortality

Overall mortality in the 30 days after surgery is estimated between 0.5% and 3.6%. High-risk patients represent 80% of postoperative deaths. Developing postoperative complications is also associated with increased mortality at 1 year after surgery. This highlights the importance of preoperative risk assessment (discussed earlier) to facilitate:

- Planning of treatment options
- Optimization of modifiable risk factors
- Shared decision-making with patients, families, and carers
- Resource planning including postoperative critical care admission

Enhanced recovery after surgery and day-case surgery

Patients recovering from surgery would traditionally expect long hospital stays and extended periods of bed rest. Modern approaches emphasize rapid return to normal function and avoid prolonged admission.

Enhanced recovery pathways (also known as fast-track pathways) map a patient's surgical journey. The aim is to achieve the earliest possible return to drinking, eating, and mobilizing ('DrEaMing') by focusing on streamlined, standardized, and protocolized care. An emphasis on patient-centred outcomes like these has translated into reduced surgical stress and hence complications, reduced hospital length of stay, and reduced cost. Enhanced recovery guidelines are designed for specific surgical procedures (e.g., cystectomy, hemicolectomy) but some core principles are shared:

- Minimize preoperative starvation time, avoid dehydration
- Laparoscopic rather than open surgery where possible
- Multimodal analgesia, with regional anaesthetic techniques where appropriate
- Minimize use of systemic (i.v.) opioids
- Use goal-directed fluid therapy, avoid excess i.v. fluid administration
- Avoid use of drains, NG tubes, and urinary catheters
- Early physiotherapy and mobilization
- Early restoration of diet
- Use appropriate antimicrobial prophylaxis, for the minimum required duration
- Use antiemetics and appropriate anaesthetic techniques to minimize risk of postoperative nausea and vomiting
- Use mechanical or chemical thromboprophylaxis where appropriate

Many surgical procedures can be completed as **day cases**, that is, without admitting the patient to hospital overnight. This approach allows patients to return rapidly to their own home and their normal function and routines. It implicitly includes the principles of enhanced recovery detailed above. Day surgery also avoids potential cancellations when inpatient beds are full due to high emergency caseload and, for this reason, day surgery units are often physically separate from inpatient areas within a hospital. Rapid turnover and elective work are prioritized, although emergency procedures are not excluded from the day case approach (e.g., superficial plastic surgery, drainage of some abscesses). Successful day surgery requires high-quality preoperative assessment to avoid unplanned conversion to an inpatient case.

There is no single list of procedures that are/are not suitable for day surgery, nor a list of particular patient groups. However, major surgery with expected bleeding, opening a major body cavity, prolonged surgery, and patients without suitable home support in the 24 hours following GA are usually excluded. Perhaps counter-intuitively, elderly or co-morbid patients may benefit from day surgery, through reduced risk of VTE and nosocomial infection linked to hospital admission, and can resume normal medication and care routines quickly. The best centres would consider day surgery the default approach and ask, 'what benefit is offered to this patient through inpatient admission?' rather than simply allocating an overnight bed automatically. Frontier models include remote home monitoring of postoperative patients and intensive recovery in non-hospital facilities.

Orthogeriatrics

An orthogeriatric service is a specialized healthcare approach that combines the expertise of orthopaedic and elderly care medicine to provide comprehensive care for older adults with fractures and complex medical needs. The principles of medicine for the older adult are discussed in Chapter 49. This model of care recognizes the unique needs of elderly patients who may have multiple co-morbidities and emphasizes a multidisciplinary and holistic approach.

Orthogeriatrics employs a multiprofessional approach to recognize, prevent, and treat common postoperative complications including delirium and pressure ulceration, navigate polypharmacy and drug-drug interactions, reduce falls risk, and facilitate smooth transitions of care from the hospital to rehabilitation centres or home. The orthogeriatric model has served to drive up quality and safety of care in this vulnerable population and improve patient satisfaction.

Perioperative fluid balance

Perioperative fluid management seeks to maintain physiological homeostasis of water, glucose, and electrolytes. The aims of fluid management are to maintain perfusion pressure and oxygen delivery to tissue capillaries in order to facilitate aerobic respiration (see also Chapter 27).

Fluid replacement is often described in terms of:

- Resuscitation: replacing acute fluid losses to restore physiological homeostasis
- Replacement: replacing fluid and electrolyte deficits
- Maintenance: providing weight-based daily requirements of water, glucose, and electrolytes.

In practice in the perioperative setting, these three indications for fluid are managed simultaneously.

Maintenance intravenous fluid therapy may be required in patients fasting for protracted periods or unable to consume fluid orally due to acute illness. The UK NICE Guidelines for intravenous fluid therapy in adults in hospital highlight core principles for safe prescription of maintenance fluids to address baseline requirements. Prescriptions of maintenance fluid should comprise:

- **25 to 30 mL/kg/day of water** (so a 70 kg patient would require approximately 2000 mL/24 hours).
- Approximately **1 mmol/kg/day of potassium, sodium, and chloride** (round potassium prescriptions to commonly available fluids which contain 20 mmol or 40 mmol of potassium; adding potassium to bags of i.v. fluid should be avoided to diminish the chance of dangerous errors).
- Approximately **50 to 100 g/day of glucose** to limit starvation ketosis.
- For patients living with obesity, adjust maintenance i.v. fluid prescriptions to their ideal body weight (patients rarely require more than 3000 mL/24 hours).

Exercise additional caution or consider lower volumes (e.g., 20–25 mL/kg/day) for patients who are older, frail, have renal impairment or cardiac failure, or are malnourished.

Regardless of initial prescription choice, monitoring of fluid balance and electrolytes is pivotal and the ongoing regimen should be tailored accordingly.

Resuscitation and replacement fluid requirements are determined by the clinical status of the patient (i.e., symptoms and signs of hypovolaemia) and fluid losses due to the underlying pathology or surgical procedure, respectively. Potential losses may include:

- Bleeding
- Loss of other body fluids via vomiting, diarrhoea, sweating, urine
- Shifts in extracellular fluid from the intravascular space to the interstitial space leading to functional reduction in circulating volume

Fluid balance is assessed through balancing measurable inputs and outputs and clinical assessment (heart rate, BP, urine output, etc.) ± blood gas sampling (serum lactate, point of care haemoglobin, creatinine, and electrolytes). Advanced perioperative haemodynamic monitoring includes cardiac output monitoring using medical devices which analyze arterial waveforms, Doppler ultrasound of blood flowing through the aorta, or temperature difference in blood samples from different parts of a patient's circulation. Devices and techniques include arterial waveform pulse contour analysis, oesophageal Doppler, transthoracic or transoesophageal echocardiography, and pulmonary artery flotation catheters. Each device has a different profile of invasiveness, accuracy, cost, and variables measured.

The most common intravenous fluids used for resuscitation and replacement are balanced crystalloid solutions. Bolus administration (e.g., 250–500 mL of Hartmann's solution) is preferred for resuscitation and response gauged by continuous reassessment of clinical and haemodynamic parameters. Repeated boluses may be required, although a requirement for volumes in excess of 30 mL/kg should generally trigger escalation to critical care services, as additional pharmacological treatments of shock may be required.

Administering too little or too much fluid are both associated with perioperative complications: hypovolaemia may contribute to hypoperfusion, acidosis, hypotension, and AKI while hypervolaemia may be associated with pulmonary complications, venous congestion, and anastomotic leak. Regular reassessment of fluid status and monitoring of electrolytes and renal function remains the best defence against fluid-related complications. The best method of assessing fluid requirements remains a debated topic; anaesthetists aim to deliver individualized fluid management to administer a 'Goldilocks' level of just enough but not too much fluid.

SPECIAL POPULATIONS

Emergency laparotomy

Emergency laparotomy is a common operation worldwide and is associated with a mortality risk of almost 10% in the UK. Indications for emergency laparotomy are broad, spanning acute abdominal trauma, bowel obstruction, perforations, and vascular emergencies. The complexity of surgery varies with indication and is one important determinant of outcomes. Surgery is often time-sensitive necessitating swift decision-making and leaving little time for detailed risk assessment or patient preparation, with perioperative resuscitation proceeding in parallel.

Mortality rates, reflecting the severity of underlying conditions, are higher than those observed in elective surgeries. Complications such as surgical site infections, wound dehiscence, respiratory issues, intra-abdominal collections, and sepsis pose additional challenges and prolonged hospital stays are common. Resource utilization is substantial, with emergency laparotomies demanding significant operating theatre time, intensive care unit resources, and postoperative care.

In the UK, the National Emergency Laparotomy Audit (NELA) allows institutions to report and benchmark outcomes at a national level and has led to reduced variations in the quality of care between institutions and a reduction in mortality and complications.

Hip fracture

Hip fractures are a serious and relatively common injury in the UK, with approximately 76 000 fractured neck-of-femurs occurring each year. Frail and older patients, particularly those over the age of 65 years, are most vulnerable. Approximately 75% of hip fracture patients are females, in part due to the higher prevalence of osteoporosis. Hip fractures are associated with increased mortality rates, particularly in the first year following the fracture. Approximately 10% to 30% of hip fracture patients in the UK do not survive the first year after the injury, with advanced age and underlying health conditions contributing to higher mortality rates.

In response to the high incidence of hip fractures, fall prevention programs and initiatives have been implemented in various regions of the UK (see Chapter 49 for further discussion). Treatment to reduce the risk of future fracture is discussed in Chapter 33.

Surgical recovery can be challenging for hip fracture patients, and orthogeriatric services help provide a holistic and 'joined-up' approach to care (see earlier). Analgesic nerve block injections (e.g., fascia iliaca blocks) are now widely used for pain control after hip fracture and help both ensure patient comfort and reduce the risk of complications such as delirium.

As surgical repair to hip fractures can offer pain benefits, surgery should not be delayed for more than 36 hours after hospital admission. Spinal anaesthesia is preferred over general anaesthesia and may have benefits for reducing delirium risk.

Early rehabilitation to restore mobility and function is crucial to patient outcomes.

Cancer

The incidence of cancer is increasing: one in three people in the UK will be diagnosed with cancer in their lifetime and one in four will die from it. More than 60% of patients with cancer require surgery

during their treatment and therefore high-quality perioperative care is a fundamental component of cancer care.

Patients with cancer are discussed in ***multidisciplinary meetings*** which combine the different expertise of radiologists, pathologists, oncologists, surgeons, palliative care physicians, anaesthetists, clinical nurse specialists (CNSs) and allied health professionals to consider the individualized risks and benefits of different treatment options (see Chapter 41).

The main ***role of surgery*** in cancer is to completely remove the primary tumour with clear margins of normal tissue around it. Depending on the tumour type and Tumour, Node, Metastasis (TNM) stage, surgical resection of a cancer presents a potentially curative intervention. Surgery may also play a role in cancer which has spread locally or metastasized to distant sites including removing large tumours causing symptoms due to mass effect or bleeding or resection of metastases.

Surgery is often supplemented by ***systemic anticancer therapy*** (including chemotherapy, immunotherapy, or targeted therapies) and/or radiotherapy to optimize conditions for surgery or reduce the risk of recurrence and metastases. Oncological therapies may be delivered before surgery (neoadjuvant) and/or after surgery (adjuvant). Multidisciplinary teams consider the optimal timing of systemic anticancer therapy in relation to surgical intervention: on one hand, neoadjuvant treatment aims to reduce the size or extent of the tumour to make surgery possible or more successful; on the other hand, systemic anticancer therapy is associated with reduced cardiorespiratory fitness. As discussed above, prehabilitation seeks to improve outcomes by optimizing or maintaining patients' cardiorespiratory fitness throughout the perioperative period including while undergoing neoadjuvant or adjuvant treatment.

The ***goals of the perioperative team*** are to minimize early morbidity and complications in order to improve survival and patient-reported outcome measures (PROMs) such as health-related quality of life and functional status. An additional priority is recovery from surgery to continue adjuvant oncological treatment, sometimes described as **r**eturn to **i**ntended **o**ncologic **t**reatment (RIOT).

Complications from cancer depend on the tumour type and location but may include anaemia, pleural and pericardial effusions, ascites, and VTEs. Cancer therapies are also associated with complications including bone marrow suppression, neuropathies, fatigue, and renal impairment. Patients from distant geographical areas may be referred to specialist centres for cancer surgery requiring a high standard of communication and clinical data-sharing to ensure adequate and timely preoperative assessment.

Obstetrics

Performing surgery on obstetric patients, whether it is for obstetric or non-obstetric reasons, involves care of not just one but two patients: mother and fetus. This situation presents unique perioperative considerations and implications to ensure the safety and well-being of all involved. In addition, maternal physiology undergoes adaptations across most organ systems from the first trimester, driven by a combination of progesterone release from the placenta and the increased metabolic demands associated with pregnancy (see Chapter 48). Such changes are vital adaptations to accommodate the growing fetus and prepare for delivery but can make perioperative care more challenging. Later in pregnancy, as the gravid uterus increases in size and weight, it exerts mechanical effects causing further potential challenges to safely performing surgery.

Cardiac output and blood volume both increase by approximately 30% during pregnancy. This can affect drug distribution and metabolism, potentially altering the effects of anaesthesia agents. The enlarging uterus pushes the diaphragm upward, restricting ventilatory capacity and leading to a higher risk of rapid desaturation after induction of GA. Delayed gastric emptying and increased intra-abdominal pressure during pregnancy can lead to a higher risk of aspiration of gastric contents during induction of anaesthesia. As the uterus enlarges, it can compress the inferior vena cava when the patient is in the supine position, potentially causing hypotension. Left lateral tilt or wedge positioning is often used to alleviate this. Finally, weight gain and increased breast size can make airway management more difficult, alongside affecting positioning of the patient for regional anaesthesia techniques like epidurals and spinals.

Surgery in obstetric patients involves close collaboration between surgical teams, obstetricians, anaesthetists, midwives, and neonatologists to ensure comprehensive care that addresses both the surgical and obstetric aspects. Timing of surgery is crucial. Whenever possible, non-emergency surgeries should be delayed until after delivery, especially during the first trimester when the fetus is most vulnerable. However, sometimes surgical interventions are necessary during pregnancy, such as for appendicitis or acute gynaecological conditions.

Anaesthesia choices should prioritize the safety of the mother and fetus. Regional anaesthesia (epidural or spinal) is often preferred over GA to avoid potential risks to the fetus.

Postoperatively, it is important to consider how medications used during surgery may affect breastfeeding. Consultation with a lactation specialist or obstetrician is often necessary to guide postoperative breastfeeding practices. Recognition of the potential emotional stress that pregnant patients may experience when undergoing surgery is also important. Providing psychological support and clear communication about the risks and benefits of the procedure is essential.

Trauma

Major trauma can be caused by accident, violence, or even a fall from standing in vulnerable patients. Perioperative care includes initial assessment and resuscitation (commonly in the emergency department), immediate surgery, secondary surgery, and rehabilitation.

The 'ABCDE' approach used in critically ill patients elsewhere in medicine is adapted to trauma, recognizing the physiological consequences of different types of traumatic injury:

- The ***airway*** is assessed while also ***protecting the cervical spine***, which may have been injured during the incident that led to the trauma.
- ***Breathing*** may be compromised by massive haemothorax or tension pneumothorax, requiring urgent chest drain insertion.
- ***Circulatory compromise*** from haemorrhagic shock or cardiac tamponade may occur, and ***haemorrhage control*** is undertaken before proceeding to further evaluation.
- ***Disability*** may occur from traumatic brain or spine injury.
- ***Exposure and environmental control*** is carried out to exclude other injuries not immediately obvious on initial assessment, and steps are taken to warm the patient and prevent hypothermia.

The metabolic response to injury is aggravated in major trauma by what has been termed the 'triad of death': ***hypothermia***, ***acidosis***, and ***coagulopathy***. Together, these can have devastating consequences for a rapidly exsanguinating, severely injured patient. While massive blood transfusion is often required, emergency surgery to

achieve control of a catastrophic bleed and '***turn off the tap***' is an immediate and life-saving intervention. A degree of hypotension can be permitted until surgical control can be achieved, in order to limit the loss of blood. Excessive crystalloid resuscitation must be avoided in the severely injured patient as this may exacerbate coagulopathy; instead, use of antifibrinolytics such as tranexamic acid, transfusion of packed red cells, fresh frozen plasma, and platelets in 1:1:1 ratios form part of major transfusion protocols in trauma.

Care has been revolutionized by a focus on early transfusion in the management of massive haemorrhage in trauma, in combination with damage control surgery. The availability of less invasive but equally effective interventional radiology angio-embolization techniques has facilitated a more conservative approach to blunt trauma in particular. The outcomes for severely injured patients continue to improve.

The key principles of major trauma are based around ***damage control***—operating early to avert life-threatening complications, leaving definitive surgical management until the patient is more stable.

Poisons in the natural world 370

CORE SKILLS AND KNOWLEDGE

Poisoning is a significant global health problem most commonly seen in the context of deliberate self-harm but with a substantial proportion of inadvertent poisoning globally. Patients who have taken a drug overdose, a substance of abuse, or who have been accidentally poisoned will usually present to a hospital emergency department. Fortunately most can be managed with supportive care alone, although a few require critical care admission. Poisoning with rare agents may require the expertise of clinical toxicologists in a specialist poisons unit.

Key skills related to toxicology include:

- Understanding common feature clusters in acute poisoning
- Understanding treatment algorithms for patients poisoned by one of the 'top ten poisons' described in this chapter.
- Understanding features and management of poisoning with other important drugs, toxins, and chemicals.

The initial assessment and management of patients who have been poisoned, either intentionally or accidentally, is best observed in the emergency department. Subsequent management may be observed in the intensive care setting or on medical wards.

CLINICAL SKILLS

History

More than 80% of adults are conscious on arrival at hospital and the diagnosis of self-poisoning can usually be made from the history (Box 15.1). Acute poisoning should be considered in the differential diagnosis of any patient presenting with impaired consciousness.

Box 15.1 History-taking in poisoning (record in notes)

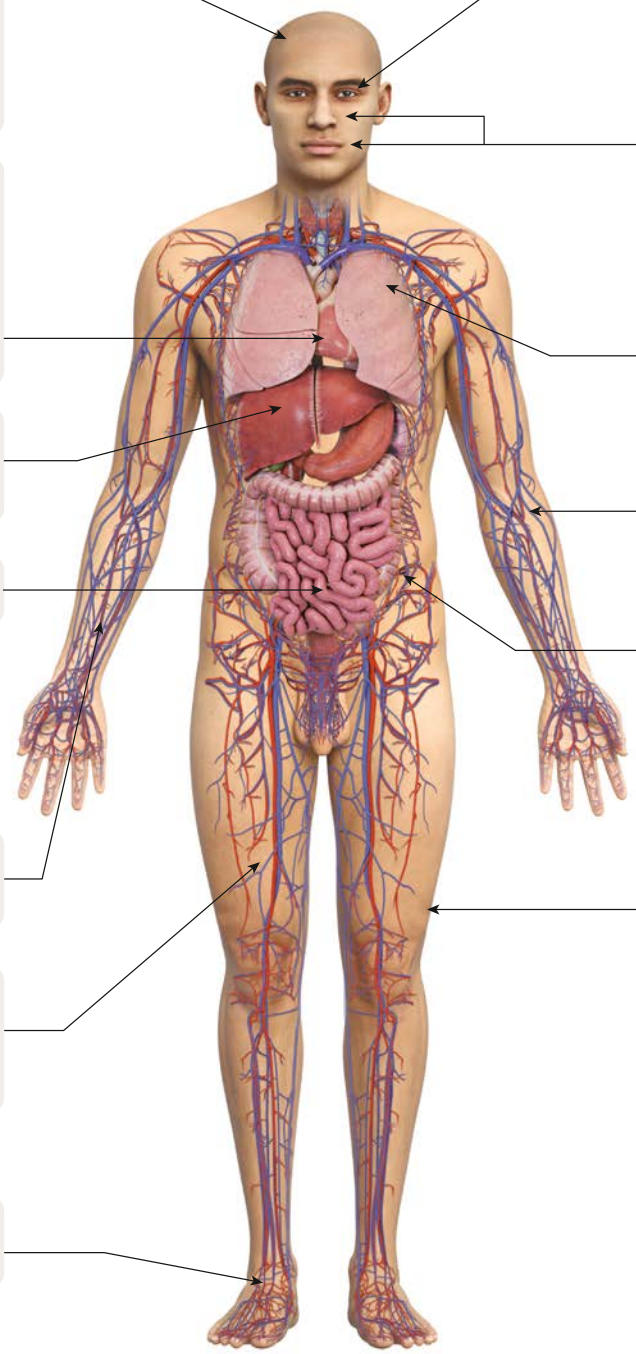
- Obtain history (if possible) from patient, relatives, friends, paramedics, witnesses
- Seek evidence of overdose
- Establish whether suicide note was left
- Ascertain what drugs/poisons were taken
- Establish time/route taken
- Ask about additional drugs, e.g., alcohol
- Seek details from general practitioner, e.g., prescribed medicines
- Assess suicide risk
- Assess capacity to make decisions
- Record a general history—past history, allergies, family history, social history

Examination

Box 15.2 provides a quick examination guide. The 'cluster of features' on presentation may be distinctive and diagnostic; for example, sinus tachycardia, fixed dilated pupils, exaggerated tendon reflexes, extensor plantar responses, and coma suggest tricyclic antidepressant poisoning (Box 15.3).

Box 15.2 Quick examination guide for the poisoned patient

- A B C D E (see Chapter 11)
- Level of consciousness (Glasgow Coma Scale; see Chapter 11)
- Ventilation—pulse oximetry
- Blood pressure and pulse rate
- Pupil size and reaction to light
- Temperature
- Head injury complicating poisonings
- If patient is unconscious, check cough and gag reflex



Brain
Coma – benzodiazepines, opioids, anticonvulsants, tricyclic antidepressants
Agitation – tricyclic antidepressants, synthetic cannabinoids, stimulants such as amfetamines and cathinones;
Seizures – tramadol, mefenamic acid, SSRIs, anticonvulsants, synthetic cannabinoids

Heart
Tachycardia – stimulants such as amfetamines, cathinones, cocaine, synthetic cannabinoids
Bradycardia – beta-blockers, calcium channel blockers, digoxin
QT prolongation – citalopram, amisulpride

Liver
Acute liver failure – paracetamol, mushroom poisoning (e.g. amanita phalloides)

Abdomen
Vomiting – ethanol, opioids

Forearm
Linear scars suggest previous deliberate self-harm

Thigh
Rhabdomyolysis – stimulants such as amfetamines, cathinones, cocaine, synthetic cannabinoids; long lie during period of coma

Ankle
Clonus – serotonin syndrome (e.g. SSRI + ecstasy)

Eyes
Miosis – opioids, organophosphorus and carbamate insecticides, nerve agents
Mydriasis – tricyclic antidepressants, ecstasy and other amfetamines, cathinones, cocaine

Mouth/Nose
Hypersalivation, rhinorrhea, bronchorrhoea – organophosphorus and carbamate insecticides, nerve agents

Lungs
Reduced respiratory rate – opioids
Hyperventilation – salicylates
Tachypnoea – may indicate aspiration pneumonitis

Antecubital fossa
'Track marks' suggest previous intravenous drug use (e.g. heroin, 'crack' cocaine)

Kidneys
Acute renal failure – ethylene glycol

Skin
Hyperthermia – stimulants such as ecstasy and other amfetamine derivatives, dinitrophenol (DNP); serotonin syndrome (e.g. SSRI + ecstasy)

Risk assessment

Risk assessment should be carried out following initial treatment and stabilization of the patient. The clinical course may be predictable based on the substance involved, the dose (e.g., in mg/kg), the timing, the clinical features observed, and the results of initial investigations. This can help guide decisions on the optimal location for on-going management of the patient.

Resources

If specialist advice is required for the management of a poisoned patient, regional or national poison centres should be the first port of call. In the UK, the National Poisons Information Service operates a 24-hour telephone advice service, Internet database, and app (Toxbase®). Toxbase® is continually updated and contains information on over 20000 products, together with generic advice on the management of poisoning.

Box 15.3 Common feature clusters in acute poisoning

Feature clusters	Poisons
Coma, hypertonia, hyper-reflexia, extensor plantar responses, myoclonus, strabismus, mydriasis, sinus tachycardia	Tricyclic antidepressants; less commonly, antihistamines, particularly diphenhydramine
Coma, hypotonia, hyporeflexia, plantar responses flexor or non-elicitable, hypotension	Benzodiazepines, with or without alcohol
Coma, miosis, reduced respiratory rate	Opioid analgesics
Nausea, vomiting, tinnitus, deafness, sweating, hyperventilation, vasodilation, tachycardia	Salicylates
Hyperthermia, tachycardia, delirium, agitation, mydriasis	Ecstasy (MDMA) or other amfetamines, cathinones, cocaine
Miosis, hypersalivation, rhinorrhoea, bronchorrhoea	Organophosphorus and carbamate insecticides, nerve agents

Box 15.4 Prevention of self-poisoning

Patients usually take what is readily available at home:

- Only small amounts of drugs should be sold in chemists/shops
- Foil-wrapped drugs are less likely to be taken in overdose
- Drugs should always be kept in a safe place
- Drugs and liquids should be kept in their original containers
- Child-resistant drug containers should be used
- Care should be taken in prescribing all drugs
- Prescriptions for any susceptible patient (e.g., the depressed) must be monitored
- Household products should be labelled and kept safely away from children

Box 15.5 Investigations that may be helpful in poisoned patients

- Serum creatinine and electrolytes, estimated glomerular filtration rate
- Creatine kinase activity
- Acid–base assessment (arterial gas, unless no concern regarding ventilation)
- Blood for specific poisons (see later)
- Electrocardiography (see Chapter 17)
- Urine saved (plain tube) for possible drug screen
- Radiology (see Chapter 8)

BACKGROUND

In high-income countries, poisoning is responsible for approximately 10% of acute hospital medical presentations and 1% of admissions. Most cases involve self-administration of prescribed or over-the-counter medicines and/or illicit drugs.

- ***Poisoning in children*** aged <6 months is usually iatrogenic. Children between 8 months and 5 years of age may ingest poisons accidentally (due to inappropriate storage of prescribed or illicit medicines intended for use by an older family member/carer). Drugs may also be administered deliberately to cause harm (abuse by proxy).
- ***Self-poisoning in adults*** is commonly a form of care-eliciting behaviour without fatal intent, particularly among females <35 years old who are otherwise in good physical health. The overdose is taken in circumstances where they are likely to be found, often in the presence of others. In the over-55s, there is a preponderance of males who are suffering from mental and/or physical ill health.
- ***Occupational poisoning*** due to dermal or inhalational exposure to chemicals is more common in the developing world.
- Poisoning may be ***iatrogenic*** and common in drugs with a narrow therapeutic window, for example, lithium, digoxin, theophylline, or phenytoin.
- The ***type of agent*** taken in overdose is influenced by availability and culture. In the UK, paracetamol poisoning remains the most common drug taken, whereas in Sri Lanka, for example, the agents ingested are more often pesticides (e.g., organophosphorus [OP] insecticides) or plants (e.g., oleander). In addition, ingestion of heating fuels, antimalarials, anti-tuberculous drugs, and traditional medicines is common in the developing world. Poisoning from snake venoms is also a problem in rural areas.

Most patients taking an overdose reach for a drug, or a combination of drugs, that is easily available. To this end, **Box 15.4** lists some significant aspects of poisoning prevention. Acute overdoses often involve more than one agent, particularly alcohol. There is often a poor correlation between the patient's history (which itself may change over time) and subsequent analytical findings.

The majority of patients do not require intensive medical management, but all require a sympathetic and caring approach, with a psychiatric and social assessment. Fatalities in the UK are due predominantly to antidepressants, paracetamol, or analgesic combinations containing paracetamol and an opioid, heroin, methadone, or cocaine. In North America there has been a substantial increase in recent years in fatal poisonings from prescription and illicit opioids (including fentanyl).

APPROACH TO THE POISONED PATIENT

The approach to history taking and examination of the poisoned patient are summarized in Boxes 15.1 and 15.2.

Investigations

Box 15.5 (and see also **Box 15.7**) sets out investigations that may be helpful in poisoned patients. On admission, or at an appropriate time post overdose, a timed blood sample should be taken if it is suspected that aspirin, digoxin, ethylene glycol, iron, lithium, methanol, paracetamol, paraquat, quinine, or theophylline has been ingested (**Box 15.6**). The determination of the concentrations of these drugs will be valuable in management. Drug screens on blood and urine are occasionally indicated in severely poisoned patients in whom the cause of coma is unknown. A poison information service will advise.

Some routine investigations (**Box 15.7**) are of value in the differential diagnosis of coma or the detection of poison-induced hypokalaemia, hyperkalaemia, hypoglycaemia, hyperglycaemia, hepatic or renal failure, or metabolic acidosis (**Box 15.8**). Measurement of carboxyhaemoglobin, methaemoglobin, and cholinesterase activities are of assistance in the diagnosis and management of cases

Box 15.6 Laboratory analysis for toxins

- Carbon monoxide (carboxyhaemoglobin) and methaemoglobin concentrations are available on most blood gas analysers
- Digoxin
- Ethanol (when monitoring treatment in glycol and methanol poisoning)
- Ethylene glycol
- Iron
- Lithium
- Methanol
- Paracetamol
- Salicylate
- Theophylline

Box 15.7 Relevant non-toxicological investigations with examples

Investigation	Situation
Serum sodium concentration	Hyponatraemia in ecstasy (MDMA) poisoning
Serum potassium concentration	Hypokalaemia in theophylline poisoning Hyperkalaemia in digoxin poisoning
Serum creatinine concentration	Acute kidney injury in ethylene and diethylene glycol poisoning
Acid–base disturbances	Including metabolic acidosis (see Box 15.8)
Blood glucose concentration	Hypoglycaemia in insulin poisoning Hyperglycaemia in salicylate poisoning
Serum calcium concentration	Hypocalcaemia in ethylene glycol poisoning
Liver function (prothrombin time)	In paracetamol poisoning
Carboxyhaemoglobin concentration	In carbon monoxide poisoning
Methaemoglobin concentration	In nitrite poisoning
Cholinesterase activity	Organophosphorus insecticide and nerve agent poisoning
ECG	Wide QRS in tricyclic antidepressant poisoning
X-ray	Detection of radio-opaque toxins, e.g., elemental mercury

Box 15.8 Some poisons that induce metabolic acidosis

- Carbon monoxide
- Cyanide
- Ethanol
- Ethylene glycol
- Iron
- Metformin
- Methanol
- Paracetamol
- Salicylates
- Tricyclic antidepressants

of poisoning due to carbon monoxide, methaemoglobin-inducing agents, such as nitrites, and organophosphorus insecticides, respectively.

ECG

Routine ECG is of limited diagnostic value, but continuous ECG monitoring should be undertaken in those ingesting potentially cardiotoxic drugs. Sinus tachycardia with prolongation of the PR and QRS intervals in an unconscious patient suggests tricyclic antidepressant overdose. QT interval prolongation is an adverse effect of several drugs (e.g., citalopram).

Radiology

Routine radiology is of little diagnostic value. It can confirm ingestion of metallic objects (e.g., coins, button batteries) or injection of globules of metallic mercury. Some enteric-coated or sustained-release drugs or ingested packets of illicit substances may be seen on plain abdominal X-rays. Radiology can confirm complications of poisoning, such as aspiration pneumonia, non-cardiogenic pulmonary oedema (salicylates), and acute respiratory distress syndrome (ARDS).

PRINCIPLES OF MANAGEMENT OF POISONING

Most people with self-poisoning require only general care and support of the vital systems (**Box 15.9**). However, for a few poisons, additional therapy is required.

Care of the unconscious patient

(See also Chapter 11.) In all cases, the initial priority is to ensure that basic resuscitative measures are instituted promptly, establishing a clear airway and supporting breathing as necessary. Remember that pulse oximetry alone will not detect hypercapnia. Loss of the cough or gag reflex is the prime indication for intubation. In many severely poisoned patients, the reflexes are depressed sufficiently to allow intubation without the use of sedatives or relaxants.

Immediate catheterization of the bladder is not usually required. Insertion of a venous cannula is usual, but administration of intravenous fluids is unnecessary unless the patient has been unconscious for more than 12 hours, is dehydrated, or is hypotensive.

Box 15.9 Management strategy in acute poisoning

Immediate decisions

- Supportive treatment
- Is an antidote appropriate? (see **Box 15.10**)
- Is it appropriate to try to reduce poison absorption?
- Is it appropriate to perform toxicological investigations?
- Is it appropriate to try to enhance elimination?

Practical points—contact with poison

Eyes

- Remove contact lenses
- Wash eyes with 0.9% saline or water for about 15 min
- Assess corneal damage (if necessary) with slit lamp and fluorescein stain

Skin

- Remove clothing
- Wash thoroughly with soap and water if, for example, chemical exposure

Cardiovascular support

Severe hypotension and shock are unusual in the acutely poisoned patient but may be caused by:

- ***a direct cardio-depressant action*** of the poison (e.g., beta-blockers, calcium-channel blockers, tricyclic antidepressants)
- ***vasodilation and venous pooling*** in the lower limbs (e.g., ACE inhibitors, phenothiazines)
- ***a decrease in circulating blood volume*** because of gastrointestinal losses (e.g., profuse vomiting), increased sweating, increased renal losses, and/or increased capillary permeability.

Hypotension may be exacerbated by coexisting hypoxia, acidosis, and dysrhythmias. Volume expansion with intravenous crystalloids is usually sufficient to restore blood pressure. Volume replacement and the use of inotropes are discussed in Chapter 13. All patients with cardiogenic shock should have ECG monitoring.

Systemic hypertension may occur in poisoning with drugs such as amfetamines and cocaine. If this is mild and associated with agitation, treatment with a benzodiazepine may suffice. In more severe cases there may be a risk of arterial rupture, particularly intracranial. To prevent this, intravenous nitrates such as glyceryl trinitrate can be given, starting at a dose of 1 to 2 mg/h, gradually increasing the dose to a maximum of 12 mg/h until blood pressure is controlled. Calcium antagonists, such as verapamil 240 to 480 mg daily in divided doses, are an alternative second-line therapy. Sodium nitroprusside 0.5 to 1.5 μg/kg/min (to a maximum of 8 μg/kg/min) is an option for patients with increased blood pressure when there is no evidence of cardiac ischaemia but caution is required as it may cause a rapid fall in blood pressure.

Arrhythmias can occur, such as tachyarrhythmias following ingestion of a tricyclic antidepressant or bradyarrhythmias with digoxin poisoning. Known arrhythmogenic factors, such as hypoxia, acidosis, and hypokalaemia, should be corrected.

Other problems

Hypothermia

A rectal temperature below 35°C is a recognized complication of poisoning, especially in older patients or in those who are comatose. The patient should be covered with a 'space blanket' and, if necessary, given intravenous fluids at normal body temperature. The administration of heated (37°C), humidified oxygen delivered by face mask is also useful.

Hyperthermia

Body temperature can, rarely, increase to being potentially fatal after poisoning with central nervous stimulants, such as cocaine, and amfetamines, including 'ecstasy' (MDMA) and the weight-loss/body-building agent dinitrophenol. Muscle tone is often increased and convulsions and rhabdomyolysis are common. Cooling measures, sedation with diazepam, and, in severe cases, intravenous dantrolene (a skeletal muscle relaxant) 2.5 mg/kg body weight should be given.

Skin blisters

Skin blisters may be found in poisoned patients who are, or have been, unconscious and do not move. Such lesions are not diagnostic of specific poisons but are sufficiently common in poisoned patients (and sufficiently uncommon in patients unconscious from other causes) to be of diagnostic value.

Rhabdomyolysis

Rhabdomyolysis can occur from pressure necrosis in drug-induced coma, or it may complicate poisoning in the absence of coma, such as in ecstasy (MDMA) abuse. People with rhabdomyolysis are at risk of developing acute kidney injury from myoglobinuria, particularly if they are hypovolaemic and have a metabolic acidosis. Severe rhabdomyolysis may lead to the development of a compartment syndrome (see Chapter 32), which can cause serious tissue damage if not treated promptly.

Convulsions

These may occur in poisoning from many drugs, including tricyclic antidepressants, mefenamic acid, and opioids such as tramadol. Usually, seizures are short-lived but, if they are prolonged, intravenous diazepam 10 to 20 mg or lorazepam 4 mg should be administered. Persistent fits must be controlled rapidly to prevent severe hypoxia, brain damage, and laryngeal trauma. If diazepam or lorazepam in repeated dose is ineffective, second-line treatments include intravenous levetiracetam (loading dose 60 mg/kg, maximum dose 4500 mg over 10 minutes) or intravenous phenobarbital sodium (10 mg/kg at not more than 100 mg/min). Phenytoin is contraindicated in cases of poisoning with sodium channel-blocking drugs (such as tricyclic antidepressants) and is relatively contraindicated in all cases of poisoning with cardiotoxic drugs.

Stress ulceration and bleeding

An intravenous proton pump inhibitor should be given to prevent stress ulceration of the stomach in the elderly and patients with a previous history of ulceration.

Body 'packers' and body 'stuffers'

Body 'packers' (sometimes called 'mules' or 'swallowers') are those who swallow a substantial number of packages containing illicit drugs as a means of smuggling. Heroin used to be the drug of choice but this has been superseded by cocaine. Although each package contains a potentially lethal amount of drug, packets are now usually machine manufactured using a material that does not leak. Body packers may ingest up to 100 to 200 packages.

Body 'stuffers' swallow a small number of packages containing an illicit drug, usually heroin, cocaine, cannabis, or an amfetamine, in an unplanned attempt to conceal evidence when on the verge of being arrested. These drugs are usually either unpackaged or poorly packaged and, as a consequence, leakage may occur over the ensuing 3 to 6 hours and cause significant symptoms. Some also hide illicit drug packages in their rectum or vagina with the same intent (these are sometimes known as ***body 'pushers'***).

The ***role of imaging*** is usually confined to body packers; imaging has little role in the care of body stuffers or pushers. Low-dose computed tomography (CT) is now considered the gold standard imaging investigation of choice for locating body packages. A urine screen for drugs of misuse should be performed. A screen that is positive for one or more drugs of misuse suggests that either the patient has used the drug in the previous few days or at least one packet is leaking. A negative screen strongly suggests that no packet is leaking. Screens should be repeated daily, or immediately if the patient develops features of intoxication, to confirm the diagnosis.

Management

Packages can be removed most expeditiously in body stuffers by employing whole-bowel irrigation (see 'Gut decontamination' section). Indications for urgent surgery in body packers include evidence of acute intestinal obstruction, radiological confirmation of many packets, and clinical or analytical evidence to suggest package leakage, particularly if the drug involved is cocaine.

Packets in the vagina can usually be removed manually.

Specific management of the poisoned patient

Antidotes

Specific antidotes are available for a small number of poisons only (Box 15.10).

Antidotes may exert a beneficial effect by:

- ***forming an inert complex*** with the poison (e.g., desferrioxamine, dicobalt edetate, digoxin-specific antibody fragments, dimercaprol, HI-6, hydroxocobalamin, obidoxime, pralidoxime, sodium calcium edetate, succimer (dimercaptosuccinic acid; [DMSA]), unithiol (dimercaptopropanesulphonate; [DMPS])
- ***accelerating detoxification*** of the poison (e.g., acetylcysteine, sodium thiosulphate)
- ***reducing the rate of conversion*** of the poison to a more toxic compound (e.g., ethanol, fomepizole)
- ***competing with the poison*** for essential receptor sites (e.g., oxygen, naloxone, phytomenadione)
- ***blocking essential receptors*** through which the toxic effects are mediated (e.g., atropine)
- ***bypassing the effect*** of the poison (e.g., oxygen, glucagon).

Gut decontamination

Although it seems logical to assume that removal of unabsorbed drug from the gastrointestinal tract will be beneficial (gut decontamination), the efficacy of gastric lavage and syrup of ipecacuanha (to induce vomiting) remains unproven and efforts to remove small amounts of non-toxic drugs are clinically not worthwhile or appropriate.

Gastric lavage should only be performed if a patient has ingested a potentially life-threatening amount of a poison, for example, iron, and the procedure can be undertaken within 60 minutes of ingestion. Ensure the airway is protected. Lavage is contraindicated if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested.

Syrup of ipecacuanha to induce vomiting should not be used, as the amount of drug recovered is highly variable and diminishes with time; there is no evidence that it improves outcome.

Single-dose activated charcoal can adsorb a wide variety of compounds. Exceptions are strong acids and alkalis, ethanol, ethylene glycol, iron, lithium, mercury, and methanol. In studies in volunteers given 50 g activated charcoal, the mean reduction in absorption was 40%, 16%, and 21%, at 60, 120, and 180 min, respectively, after ingestion. Administration of oral activated charcoal (50 g for an adult, 1 g/kg for a child) should be considered following ingestion of a potentially toxic amount of a poison (except those listed above) if this is possible within 1 hour of ingestion. There are insufficient data to support or exclude its use after 1 hour. There is no evidence that administration of activated charcoal improves clinical outcome.

Cathartics have no role in the management of the poisoned patient.

Whole-bowel irrigation requires the insertion of a nasogastric tube into the stomach and the introduction of polyethylene glycol electrolyte solution 1500 to 2000 mL/h in an adult, which is continued until the rectal effluent is clear. Whole-bowel irrigation may be used for potentially toxic ingestions of sustained-release or enteric-coated drugs or to remove illicit drug packets.

Box 15.10 Antidotes of value in poisoning

Poison	Antidotes
Aluminium	Desferrioxamine
Arsenic	Succimer (DMSA), dimercaprol
Benzodiazepines	Flumazenil
β-Adrenoceptor-blocking drugs	Atropine, glucagon
Calcium-channel blockers	Atropine
Carbamate insecticides	Atropine
Carbon monoxide	Oxygen
Cyanide	Oxygen, hydroxocobalamin, sodium thiosulphate
Digoxin and digitoxin	Digoxin-specific antibody fragments
Ethylene glycol	Fomepizole, ethanol
Hydrogen sulphide	Oxygen
Iron salts	Desferrioxamine
Lead (inorganic)	Succimer (DMSA), sodium calcium edetate
Methaemoglobinaemia	Methylthioninium chloride (methylene blue)
Methanol	Fomepizole, ethanol
Mercury (inorganic)	Unithiol (DMPS)
Nerve agents	Atropine, HI-6, obidoxime, pralidoxime
Opioids	Naloxone
Organophosphorus insecticides	Atropine, HI-6, obidoxime, pralidoxime
Paracetamol	Acetylcysteine
Warfarin and similar anticoagulants	Phytomenadione (vitamin K)

Increasing poison elimination

Multiple-dose activated charcoal (MDAC) involves the repeated administration of oral activated charcoal to increase elimination of a drug that has already been absorbed. Most absorbed drugs re-enter the gut from the villi capillaries by passive diffusion (a few by an active process) if the concentration in the gut is lower than that in the blood (this is called the entero-enteric circulation). Some drugs are also secreted in the bile (enterohepatic circulation). Activated charcoal will bind any drug that is in the gut lumen, so keeping the concentration in the gut low and favouring further diffusion from blood to gut lumen.

Elimination of drugs with a small volume of distribution (<1 L/kg), low p*K*a (which maximizes transport across membranes), low binding affinity, and prolonged elimination half-life following overdose is particularly likely to be enhanced by MDAC. MDAC also improves total body clearance of the drug when endogenous processes are compromised by liver and/or renal failure.

Although MDAC has been shown to increase elimination significantly for a small number of drugs (e.g., carbamazepine, dapsone, phenobarbital, quinine, theophylline), it has not been shown to reduce morbidity and mortality in controlled studies.

In *adults*, charcoal should be administered in an initial dose of 50 to 100 g and then at a rate of not less than 12.5 g/h, preferably via a nasogastric tube; usually, 200 g is sufficient. Intravenous ondansetron 4 to 8 mg is an effective antiemetic and facilitates MDAC administration if vomiting is a problem.

Urine alkalinization enhances elimination of salicylate, phenobarbital, and chlorophenoxy herbicides (e.g., 2,4-dichlorophenoxyacetic acid) by mechanisms that are not clearly

understood. Urine alkalinization is a metabolically invasive procedure requiring frequent biochemical monitoring and medical and nursing expertise. Advice should be sought from those familiar with the procedure before urine alkalinization is commenced. Plasma volume depletion, electrolytes (notably plasma potassium since sodium bicarbonate exacerbates pre-existing hypokalaemia), and metabolic abnormalities should be corrected first. Sufficient bicarbonate is then administered to ensure that urine pH is over 7.5 and preferably close to 8.5. In one study, sodium bicarbonate 225 mmol was the mean amount required initially. This can be administered intravenously as 225 mL of an 8.4% solution (1 mmol bicarbonate/mL) over 1 hour but great care must be taken to avoid extravasation if given via a peripheral line.

Haemodialysis and haemodiafiltration are of little value in patients poisoned with drugs that have large volumes of distribution (e.g., tricyclic antidepressants) because the plasma contains only a small proportion of the total amount of drug in the body. These methods are indicated in patients with severe clinical features and high plasma concentrations of ethanol, ethylene glycol, isopropanol, lithium, methanol, and salicylate: that is, drugs with small volumes of distribution.

Lipid emulsion therapy involves the intravenous administration of 20% Intralipid (fractionated soya oil) 1.5 mL/kg, followed by 0.25 to 0.5 mL/kg per minute for 30 to 60 minutes to an initial maximum of 500 mL. Use of lipid emulsion as an antidote for severe poisoning with highly lipid-soluble drugs is based on experience of its efficacy in local anaesthetic poisoning. It is believed to increase the intravascular lipid phase, so creating a 'lipid sink' to reduce the amount of active drug in plasma. Other proposed mechanisms of benefit include increasing myocardial fatty acid energy substrate and improving the function of cell membrane-bound ion channels (particularly Ca^{2+} and Na^{+}). The role of Intralipid in the management of poisoning with highly lipid-soluble drugs is not well defined but case reports suggest some benefit in life-threatening cardiotoxicity that is resistant to other measures.

SPECIFIC POISONS

- All patients must be reviewed by senior medical staff.
- All patients should have relevant blood tests and monitoring when appropriate.
- The general principles of management of self-poisoning outlined earlier will always need to be applied.

In this section, only the specific treatment regimens are outlined. The first section covers the 'top ten' drug types encountered in poisoning: paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs), opiates/opioids, antidepressants, benzodiazepines, stimulants (including cocaine), ethanol, neuroleptics, cannabis/synthetic cannabinoids, and anticonvulsants. All doctors working in an acute setting should be familiar with the clinical presentation and principles of management of poisoning with these agents.

The top ten

Paracetamol (acetaminophen)

In ***therapeutic doses***, paracetamol is conjugated with glucuronide and sulphate. A small amount of paracetamol is metabolized by mixed-function oxidase enzymes to form a highly reactive toxic compound (*N*-acetyl-*p*-benzoquinoneimine; NAPQI), which is then immediately conjugated with glutathione and subsequently excreted as cysteine and mercapturic conjugates.

In ***overdose***, large amounts of paracetamol are metabolized by oxidation because of saturation of the sulphate conjugation pathway. Liver glutathione stores become depleted so that the liver is unable to deactivate NAPQI. Paracetamol-induced kidney injury probably results from a mechanism similar to that responsible for hepatotoxicity.

Clinical features

Following the ingestion of an overdose of paracetamol, patients usually remain asymptomatic for the first 24 hours or, at the most, develop anorexia, nausea, and vomiting. Liver damage is not usually detectable by routine liver function tests until at least 18 hours after ingestion of the drug. Liver damage usually reaches a peak, as assessed by measurement of alanine aminotransferase (ALT) activity and prothrombin time (or INR), at 72 to 96 hours after ingestion. Without treatment, a small percentage of patients will develop fulminant hepatic failure. Acute kidney injury due to acute tubular necrosis occurs in 25% of patients who have severe hepatic damage and in a few without evidence of serious disturbance of liver function.

Management

Acetylcysteine is an effective protective agent, provided that it is administered within 8 to 10 hours of ingestion of the overdose. It acts by replenishing cellular glutathione stores, though it may also repair oxidation damage caused by NAPQI.

There are now two main approaches to treatment worldwide. In the UK, following a decision by the Medicines and Healthcare products Regulatory Agency in 2012 to abandon a detailed risk assessment in the decision to treat, it is deemed that patients with concentrations above a 'treatment line' starting at 100 mg/L 4 hours after ingestion (**Fig. 15.1**) should be given treatment with acetylcysteine. In most other countries, a parallel line starting at 150 mg/L 4 hours after ingestion is used. The treatment lines are uncertain if the patient presents 15 hours or more after ingestion or has taken a modified-release preparation of paracetamol. Although these lines are often extended to 24 hours (dotted lines), the concentrations are not based on clinical trial data.

A summary of single acute paracetamol overdose management at different times post ingestion is given in Box 15.12. Note that patients whose paracetamol overdose is staggered over more than 1 hour or who take repeated therapeutic excess are at greater risk of liver damage, and decisions to treat are generally based on the dose ingested/24 hours. In the UK, treatment with acetylcysteine is considered if more than 75 mg/kg has been ingested in 24 hours.

Up to 15% of patients treated with intravenous acetylcysteine develop a rash, angio-oedema, hypotension, and/or bronchospasm. These reactions, which are histamine-mediated and related to the initial bolus, are seldom serious, and pausing the infusion is usually all that is required. In more severe, adult cases, intravenous chlorphenamine 10 to 20 mg should be given.

The Royal College of Emergency Medicine and The National Poisons Information Service in the UK both now formally advocate use of SNAP (Scottish and Newcastle Acetylcysteine Protocol), a 12-hour, 2-bag regimen (**Box 15.11**), instead of the standard 21-hour, 3-bag regimen. SNAP has been shown to be as efficacious as the

Box 15.11 SNAP regimen for acetylcysteine

- Acetylcysteine 100 mg/kg in 200 mL 5% glucose over 2 h
- Then 200 mg/kg in 1000 mL 5% glucose over 10 h
- Total dose 300 mg/kg over 12 h

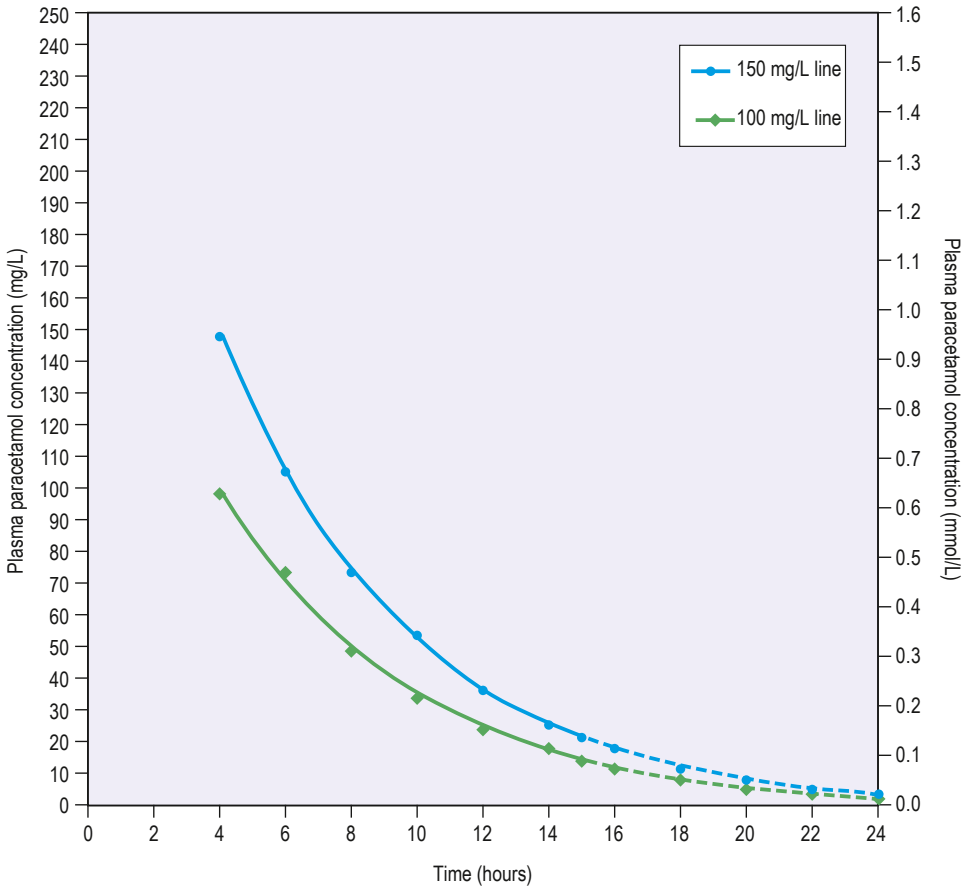


Fig. 15.1 Nomogram for treatment of paracetamol poisoning. In the UK, patients with concentrations above a 'treatment line' starting at 100 mg/L 4 hours after ingestion should be given treatment with acetylcysteine. In most other countries, a parallel line starting at 150 mg/L 4 hours after ingestion is used. Note that the treatment lines are uncertain if the patient presents 15 hours or more after ingestion or has taken a modified-release preparation of paracetamol. Although these lines are often extended to 24 hours (dotted lines), the concentrations are not based on clinical trial data.

Box 15.12 Summary of management of single acute paracetamol overdose

All patients

- Clarify date, time, formulation, and dose of paracetamol taken
- Weigh the patient
- Calculate the paracetamol dose ingested in mg/kg

Patients presenting 0–8 hours since last paracetamol ingestion

- Wait until 4 h post ingestion then take venous blood for plasma paracetamol concentration, serum creatinine and electrolytes, bicarbonate, liver function, and INR
- If the blood results will not be available until after 8 h post ingestion *AND* patient has ingested >150 mg/kg, commence acetylcysteine immediately
- When the plasma paracetamol concentration is available, assess need for antidotal treatment with acetylcysteine using the treatment nomogram (see **Fig. 15.2**)
- Administer acetylcysteine if required. If already commenced but not required, acetylcysteine can be discontinued at this stage
- Seek specialist advice if plasma paracetamol concentration is below the treatment line but liver function tests (LFTs) or clotting are abnormal
- At end of acetylcysteine course, take venous blood for serum creatinine and electrolytes, paracetamol, bicarbonate, liver function, and INR
- Consider need for further acetylcysteine if post-treatment bloods are abnormal

Patients presenting between 8 h and 24 h after paracetamol ingestion

- Take venous blood for urgent measurement of plasma paracetamol concentration, serum creatinine and electrolytes, bicarbonate, liver function, INR
- Commence acetylcysteine immediately if ingested paracetamol dose is >150 mg/kg
- If ingested dose <150 mg/kg, await blood results and assess need for acetylcysteine using treatment nomogram
- Administer acetylcysteine if required. If already commenced but not required, acetylcysteine can be discontinued at this stage
- BEWARE that for patients presenting >12 h after ingestion, the plasma paracetamol concentration at which treatment is required may be close to the laboratory's limit of detection. If borderline, treat with acetylcysteine
- Seek specialist advice if plasma paracetamol concentration is below the treatment line but LFTs or clotting are abnormal
- At end of acetylcysteine course, take venous blood for serum creatinine and electrolytes, paracetamol concentration, bicarbonate, liver function, and INR
- Consider need for further acetylcysteine if post-treatment bloods are abnormal

Patients presenting more than 24 h post overdose

- Commence acetylcysteine if the patient is jaundiced or has hepatic tenderness
- Measure the plasma paracetamol concentration (before NAC is administered if possible), serum creatinine and electrolytes, bicarbonate, LFTs, glucose, full blood count, and INR
- Treat with acetylcysteine if the ALT is above the upper limit of normal, *OR* INR is >1.3 (in the absence of another cause, e.g., warfarin) *OR* paracetamol concentration is detectable
- If the paracetamol concentration is not detectable, the INR and ALT are normal, and the patient is asymptomatic, no treatment with an antidote is indicated. If acetylcysteine has been started, it may then be discontinued
- At end of acetylcysteine course, take venous blood for serum creatinine and electrolytes, bicarbonate, liver function, and INR
- Consider need for further acetylcysteine if post treatment bloods are abnormal

21-hour regimen, has a reduced risk of anaphylactoid reactions, and is more convenient.

If liver or renal failure ensues, this should be treated conventionally, although there is evidence that a continuing infusion of acetylcysteine (continue 200 mg/kg in 1000 mL of 5% glucose infused at a rate of 100 mL/h until recovery) will improve the morbidity and mortality. Liver transplantation has been performed successfully in patients who have paracetamol-induced acute hepatic failure (see Chapter 23).

Non-steroidal anti-inflammatory drugs

Self-poisoning with NSAIDs, other than salicylates, has increased, particularly now that ibuprofen is available without prescription, over the counter, in many countries. Poisoning with salicylates is considered in Box 15.3.

Clinical features and management

In most cases, minor gastrointestinal disturbance is the only feature but in more severe cases, coma, convulsions, and acute kidney injury have occurred. Transient renal impairment is common after ibuprofen overdose. Poisoning with mefenamic acid commonly results in convulsions, though these are usually short-lived.

Treatment is symptomatic and supportive.

Opiates and opioids

Clinical features

Cardinal signs of opiate poisoning are pinpoint pupils, reduced respiratory rate, and coma. Hypothermia, hypoglycaemia, and convulsions are occasionally observed in severe cases. Non-cardiogenic pulmonary oedema has been reported in severe heroin overdose. See Chapter 50 for more information about the worldwide opioid crisis.

Management

Intravenous naloxone will reverse respiratory depression and coma, at least partially. In severe poisoning, an initial dose of 1.2 mg is likely to be required and repeat doses necessary. Lower doses (0.4–0.8 mg) may suffice in less severe cases and if precipitating opioid withdrawal is a concern. The duration of action of naloxone is often less than the drug taken in overdose, for example, methadone, which has a very long half-life. For this reason, an infusion of naloxone is often required. Non-cardiogenic pulmonary oedema should be treated with mechanical ventilation.

Antidepressants: tricyclics and selective serotonin reuptake inhibitors

Tricyclic antidepressants block the reuptake of monoamines (e.g., norepinephrine (noradrenaline) and serotonin) into peripheral and intracerebral neurones, thereby increasing the concentration of these neurotransmitters in these areas. They also have antimuscarinic actions and class 1 antiarrhythmic (quinidine-like) sodium-channel-blocking activity.

Selective serotonin reuptake inhibitors (SSRIs) (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) lack the antimuscarinic and sodium-channel-blocking actions of tricyclic antidepressants.

Clinical features

Tricyclic antidepressants. Mild poisoning commonly causes drowsiness, sinus tachycardia, dry mouth, dilated pupils, urinary retention (all antimuscarinic effects), and increased reflexes and extensor plantar responses. Severe intoxication leads to coma, convulsions, and, occasionally, divergent strabismus. Plantar, oculocephalic, and oculovestibular reflexes may be abolished temporarily. An ECG will often show a wide QRS interval (due to sodium channel blockade) and there is a reasonable correlation between the width of the QRS complex and the severity of poisoning. Life-threatening arrhythmias may ensue. Metabolic acidosis and cardiorespiratory depression are observed in severe cases.

Selective serotonin reuptake inhibitors. Even in large overdoses, SSRIs appear to be relatively safe unless potentiated by ethanol. Most patients will show no signs of toxicity but drowsiness, nausea, diarrhoea, and sinus tachycardia have been reported. Rarely, junctional bradycardia, seizures, and hypertension have been encountered and influenza-like symptoms may develop.

Serotonin syndrome occasionally occurs (see Chapter 30).

Other antidepressants. Venlafaxine is a serotonin-norepinephrine reuptake inhibitor with a similar toxicity profile to the SSRIs but with greater risk of cardiac arrhythmias and convulsions. Mirtazapine, an antidepressant that acts via presynaptic alpha blockade to increase central serotonin release, is probably the safest antidepressant in overdose, causing mainly only sedation.

Management

The majority of patients recover with supportive therapy alone (adequate oxygenation, control of convulsions, and correction of acidosis), although a small percentage who ingest a tricyclic will require assisted ventilation for 24 to 48 hours. Widening of the QRS interval, the onset of supraventricular tachycardia and ventricular tachycardia should be treated with ***intravenous sodium bicarbonate*** (8.4%) 50 mmol, even if there is no acidosis present; a second bolus may be required. The benefit of sodium bicarbonate in the setting of tricyclic antidepressant (TCA) overdose is thought to be due to both an increase in serum pH and the increase in extracellular sodium. Alkalinization increases protein binding of the drug and the high sodium load increases the electrochemical gradient across cardiac cell membranes, potentially attenuating the TCA-induced blockade of sodium channels. A serum pH of 7.5 to 7.55 should be aimed for.

Benzodiazepines

Benzodiazepines are commonly taken in overdose but rarely produce severe poisoning, except in the elderly or those with chronic respiratory disease.

Box 15.13 Clinical features of ethanol poisoning

Blood (ethanol)		Clinical features
mg/L	*mmol/L*	
500–1500	11.0–32.5	Emotional lability Mild impairment of coordination
1500–3000	32.5–65.0	Visual impairment Incoordination Slowed reaction time Slurred speech
3000–5000	65.0–108.5	Marked incoordination Blurred or double vision Stupor Occasionally, hypoglycaemia, hypothermia, and convulsions
>5000	>108.5	Depressed reflexes Respiratory depression Hypotension Hypothermia Death (from respiratory or circulatory failure, or from aspiration)

Clinical features

Benzodiazepines produce drowsiness, ataxia, dysarthria, and nystagmus. Coma and respiratory depression develop in severe intoxication.

Management

If respiratory depression is present in patients who have severe benzodiazepine poisoning, ***intravenous flumazenil*** 0.5 to 1.0 mg is given in an adult and this dose often needs repeating. Flumazenil use often avoids the need for assisted ventilation. It is relatively contraindicated in patients with mixed proconvulsant (e.g., tricyclic antidepressants)/benzodiazepine poisoning and those with a history of epilepsy because it may cause convulsions.

Stimulants

The most commonly abused stimulants are the amfetamines, cocaine, and the synthetic cathinones.

Amfetamines are central nervous system (CNS) and cardiovascular stimulants. These effects are mediated by increasing synaptic concentrations of adrenaline (epinephrine) and dopamine. The *N*-methylated derivative, metamfetamine (the crystalline form of this salt is known as 'crystal meth' or 'ice'), and 3,4-methylenedioxymetamfetamine (MDMA), known as ecstasy, are common examples.

Cocaine hydrochloride ('street' cocaine, 'coke') is a water-soluble powder or granule that can be taken orally, intravenously, or intranasally ('snorting'). 'Freebase' or 'crack' cocaine comprises crystals ('rocks') of relatively pure cocaine without the hydrochloride moiety. Crack cocaine is more suitable for smoking in a pipe or mixed with tobacco; it can also be heated on foil and the vapour inhaled (approximately 35 mg of drug per 'line' or a 'rail'). The effects of cocaine are experienced almost immediately after intravenous administration or smoking, about 10 minutes following intranasal administration, and 45 to 90 minutes after ingestion. The effects start to resolve in about 20 minutes but may last up to 90 minutes. In severe poisoning, death occurs in minutes, and death rarely occurs more than 3 hours after exposure.

Cocaine blocks the reuptake of biogenic amines:

- Inhibition of dopamine reuptake is responsible for psychomotor effects.
- Blockade of noradrenaline (norepinephrine) reuptake produces tachycardia.
- Inhibition of serotonin reuptake induces hallucinations.
- CNS arousal is enhanced by potentiating the effects of excitatory amino acids.
- Cocaine is a powerful local anaesthetic and vasoconstrictor.

Cathinone (khat) is a naturally occurring stimulant derived from the plant *Catha edulis*. The drug is released during prolonged chewing of plant leaves. An increasing number of synthetic cathinone derivatives are available, the best-known of which is mephedrone (4-methyl methcathinone). While originally sold as 'plant foods' or 'bath salts', these substances are purchased for their recreational abuse potential. Synthetic cathinones may be taken by mouth, nasal insufflation, or injection.

Clinical features

Stimulants cause dilated pupils, tachycardia and hypertension, sweating, euphoria, extrovert behaviour, and a lack of desire to eat or sleep. More severe intoxication is associated with agitation, paranoid delusions, hallucinations, and violent behaviour. Convulsions, rhabdomyolysis, hyperthermia, metabolic acidosis, and cardiac arrhythmias may develop. Rarely, dissection of the aorta, myocarditis, myocardial infarction, dilated cardiomyopathy, subarachnoid haemorrhage, or cerebral haemorrhage or infarction may occur and can be fatal. Disseminated intravascular coagulation and acute kidney injury are recognized. If a young person presents with a stroke or myocardial infarction, poisoning with a stimulant should be considered in the differential diagnosis.

Management

- Agitation is best controlled by intravenous diazepam 10 to 20 mg.
- Hypertension and tachycardia also usually respond to sedation but if hypertension persists, consider intravenous glyceryl trinitrate starting at 1 to 2 mg/h and gradually increase the dose (maximum 12 mg/h) until the blood pressure is controlled. The peripheral sympathomimetic actions of amfetamines can be antagonized by β-adrenoceptor-blocking drugs but these are rarely required. The use of beta-blockers in cocaine poisoning is controversial.
- Active external cooling should be employed for hyperthermia and, if uncontrolled, intravenous dantrolene 2.5 mg/kg body weight should be considered (see 'Hyperthermia' section).
- Early use of a benzodiazepine is often effective in relieving stimulant-associated non-cardiac chest pain. Myocardial ischaemia/infarction should be treated conventionally.

Ethanol

Ethanol is commonly ingested in beverages and deliberately with other substances in overdose. It is also present in many cosmetic and antiseptic preparations. Following absorption, ethanol is oxidized to acetaldehyde and then to acetate. Ethanol is a CNS depressant and the features of ethanol intoxication are generally related to blood concentrations (**Box 15.13**).

Clinical features

In children, in particular, severe hypoglycaemia may accompany alcohol intoxication due to inhibition of gluconeogenesis. Hypoglycaemia is also observed in those who are malnourished or who have fasted in the previous 24 hours. In severe cases of intoxication, coma and hypothermia are often present, and lactic acidosis, ketoacidosis, and acute kidney injury have been reported.

Management

Supportive care is paramount. Intravenous glucose may be required to treat hypoglycaemia. Haemodialysis should be considered if the blood ethanol concentration exceeds 5000 mg/L and if a severe metabolic acidosis is present, which has not been corrected by fluids and intravenous bicarbonate.

Neuroleptics and atypical neuroleptics

Neuroleptic (antipsychotic) drugs are thought to act predominantly by blockade of dopamine D_2 receptors. The ***first-generation neuroleptics*** include the phenothiazines (chlorpromazine), the butyrophenones (haloperidol), and the substituted benzamides (sulpiride). More ***selective second-generation (or 'atypical') antipsychotics*** include amisulpride, aripiprazole, clozapine, olanzapine, quetiapine, and risperidone.

Clinical features

These include impaired consciousness, hypotension, respiratory depression, hypothermia or hyperthermia, antimuscarinic effects

such as tachycardia, dry mouth and blurred vision, occasionally seizures, rhabdomyolysis, cardiac arrhythmias (both atrial and ventricular), and ARDS. Extrapyramidal effects, including acute dystonic reactions, occur but are not dose related. Most 'atypical' antipsychotics have less profound sedative actions than the older neuroleptics. QT interval prolongation and subsequent ventricular arrhythmias (including torsades de pointes) have occurred following overdose with the atypical neuroleptics (especially amisulpride). Unpredictable fluctuations in conscious level, with variations between agitation and marked somnolence, have been particularly associated with olanzapine overdose.

Management

Intravenous procyclidine 5 to 10 mg in an adult can occasionally be required for the treatment of dyskinesia and oculogyric crisis. After acidosis has been corrected with sodium bicarbonate, the preferred treatment for arrhythmias caused by antipsychotic drugs (including torsades de pointes) is intravenous magnesium (see Chapter 17) or cardiac pacing (Chapter 11).

Cannabis (marijuana) and synthetic cannabinoids

Cannabis is usually smoked but may be ingested as a 'cake' or made into a tea. The major psychoactive constituent is δ-9-tetrahydrocannabinol (THC). THC possesses activity at the benzodiazepine, opioid, and cannabinoid receptors.

Synthetic cannabinoids emerged onto the drug scene around 2009, initially sold as herbal incense or 'spice'. There are now hundreds of derivatives and most are considerably more potent than THC (common street name 'mamba').

Clinical features

Cannabis intoxication initially causes euphoria followed by distorted and heightened images, colours and sounds, altered tactile sensations, and sinus tachycardia. Visual and auditory hallucinations and acute psychosis are particularly likely to occur after substantial ingestion in naive users. Heavy users suffer impairment of memory and attention and poor academic performance. There is an increased risk of anxiety and depression. Regular users are at risk of dependence. Cannabis use results in an overall increase in the relative risk for later schizophrenia and psychotic episodes (see Chapter 30). Cannabis smoke is probably carcinogenic.

The clinical features observed following intoxication with synthetic cannabinoids are variable and unpredictable, reflecting the numerous derivatives available. Tachycardia and agitation are the most consistent effects but psychosis, seizures, respiratory failure, coma, acute kidney injury, stroke, and myocardial infarction have all been reported and fatalities have occurred.

Management

Reassurance is usually the only treatment required, although sedation with intravenous diazepam (10–20 mg in an adult) or intramuscular or oral haloperidol (2–5 mg in an adult) is sometimes required if agitation is severe. Occasionally, agitation is sufficiently severe for patients to require sedation in a critical care environment.

Anticonvulsants

Clinical features

The clinical features of poisoning with anticonvulsant drugs are summarized in **Box 15.14**.

Box 15.14 Clinical features of poisoning with anticonvulsant drugs

Anticonvulsant drug	Clinical features of poisoning
Carbamazepine and oxcarbazepine (a prodrug of carbamazepine)	Dry mouth, coma, convulsions, ataxia, incoordination, hallucinations (particularly in the recovery phase) Ocular: nystagmus, dilated pupils (common), divergent strabismus, complete external ophthalmoplegia (rare)
Phenytoin	Nausea, vomiting, headache, tremor, cerebellar ataxia, nystagmus, loss of consciousness (rare)
Sodium valproate	Most frequent: drowsiness, impairment of consciousness, respiratory depression Uncommon complications: liver damage, hyper-ammonaemia, metabolic acidosis Very severe poisoning: myoclonic jerks, seizures, cerebral oedema
Gabapentin and pregabalin	Lethargy, ataxia, slurred speech, gastrointestinal symptoms
Lamotrigine	Lethargy, coma, ataxia, nystagmus, seizures, cardiac conduction abnormalities
Levetiracetam	Lethargy, coma, respiratory depression
Tiagabine	Lethargy, facial grimacing, nystagmus, posturing, agitation, coma, hallucinations, seizures
Topiramate	Lethargy, ataxia, nystagmus, myoclonus, coma, seizures, metabolic acidosis (secondary to carbonic anhydrase inhibition)

Management

Elimination of carbamazepine can be significantly increased by MDAC.

If hepatotoxicity and encephalopathy develop in severe valproate poisoning, early intravenous supplementation with L-carnitine will reduce the formation of ammonia and other toxic metabolites of valproic acid. Haemodialysis increases the elimination of valproate and should be instituted if severe hyper-ammonaemia and electrolyte and acid–base disturbances occur.

Other drugs of importance in poisoning

For ease of reference, these are arranged in alphabetical order and include antidiabetic drugs, antimalarial drugs, beta-blockers, calcium-channel blockers, digoxin, iron salts, lithium salts, nitrous oxide, and salicylates.

Antidiabetic drugs

Insulin (if injected but not if ingested) and ***sulphonylureas*** cause hypoglycaemia. This is not seen with ***metformin***, since its mode of action is to increase glucose utilization, but lactic acidosis is a potentially serious complication of metformin poisoning.

Clinical features

Features of severe hypoglycaemia include drowsiness, coma, convulsions, depressed limb reflexes, extensor plantar responses, and cerebral oedema. Hypokalaemia also occurs. Cranial (neurogenic) diabetes insipidus and persistent vegetative states are possible long-term complications if hypoglycaemia is prolonged.

Management

The blood or plasma glucose concentration should be measured urgently and intravenous glucose given, if necessary. Glucagon produces only a slight rise in blood glucose, although it can reduce the amount of glucose required (see Chapter 11).

Severe insulin poisoning

A continuous infusion of 10 to 20% glucose (with K^+ 10–20 mmol/L) is required, together with carbohydrate-rich meals, though there may be difficulty in maintaining normoglycaemia. For refractory cases, corticosteroids can be used (e.g., i.v. hydrocortisone 100 mg up to 4 times a day).

Sulphonylurea poisoning

The administration of glucose increases already high circulating insulin concentrations. Intravenous octreotide (50 μg), which inhibits insulin release, should be given as well as glucose.

Antimalarials

Chloroquine

Severe poisoning may present with hypotension, cardiac failure, pulmonary oedema, and cardiac arrest. Agitation, acute psychosis, convulsions, and coma may occur. Hypokalaemia is common and is due to chloroquine-induced potassium-channel blockade. Bradyarrhythmias and tachyarrhythmias are common, and ECG conduction abnormalities are similar to those seen in quinine poisoning.

Quinine

Cinchonism (tinnitus, deafness, vertigo, nausea, headache, and diarrhoea) is common. In more severe poisoning, convulsions, hypotension, pulmonary oedema, and cardiorespiratory arrest are seen (due to ventricular arrhythmias that are often preceded by ECG conduction abnormalities, particularly QT prolongation). Quinine cardiotoxicity is due to sodium channel blockade. Patients may also develop ocular features, including blindness, which can be permanent.

Primaquine

The main concern is primaquine's propensity to cause methaemoglobinaemia and haemolytic anaemia.

Management

- MDAC increases quinine and probably chloroquine clearance.
- Hypokalaemia should be corrected.
- Intravenous sodium bicarbonate 50 to 100 mmol is given if the ECG shows QRS prolongation but it will exacerbate hypokalaemia, which should be corrected first.
- Mechanical ventilation, the administration of an inotrope (see Chapter 13), and high doses of diazepam (1 mg/kg as a loading dose and 0.25 to 0.4 mg/kg per hour maintenance) may reduce the mortality in severe chloroquine poisoning.
- Overdrive pacing may be required if torsades de pointes occurs in quinine poisoning and does not respond to intravenous magnesium sulphate (see Chapter 17).
- If clinically significant methaemoglobinaemia (generally above 30%) develops in primaquine poisoning, methylthioninium (methylene blue) 1 to 2 mg/kg body weight should be administered.

Beta-adrenoceptor–blocking drugs

In mild poisoning, sinus bradycardia is the only feature, but if a substantial amount has been ingested, coma, convulsions, and hypotension develop. Less commonly, delirium, hallucinations, and cardiac arrest supervene. Bronchospasm and hypoglycaemia are rare complications.

Management

- ***Glucagon*** 50 to 150 μg/kg (typically 5–10 mg in an adult), followed by an infusion of 5 to 10 mg/h, is the most effective agent. It acts by bypassing the blocked beta-receptor, thus activating adenylyl cyclase and promoting formation of cyclic adenosine monophosphate from adenosine triphosphate; cyclic adenosine monophosphate, in turn, exerts a direct beta-stimulant effect on the heart.
- ***Intravenous atropine*** 0.6 to 1.2 mg can be used to treat bradycardia but is usually less effective.
- ***High-dose insulin*** (initial intravenous bolus of 1.0 IU/kg, followed by 1–10 IU/kg per hour) with hypertonic glucose to avoid hypoglycaemia has been shown to improve myocardial contractility and systemic perfusion.

Calcium-channel blockers

Calcium-channel blockers all act by blocking voltage-gated calcium channels. Dihydropyridines (e.g., amlodipine, felodipine, nifedipine) are predominantly peripheral vasodilators, while verapamil (a phenylalkylamine) and diltiazem (a benzothiazepine) also have significant cardiac effects. Poisoning, particularly with verapamil and diltiazem, causes heart block and hypotension; in severe poisoning, there is a substantial fatality rate. When a sustained-release preparation has been ingested, the onset of severe features is delayed, sometimes for more than 12 hours. Overdose with even small amounts can have profound effects.

Clinical features

Hypotension occurs due to peripheral vasodilation, myocardial depression, and conduction block. The ECG may progress from sinus bradycardia through first, then higher, degrees of block to asystole. Cardiac and non-cardiac pulmonary oedema may ensue in severely poisoned patients. Other features include nausea, vomiting, seizures, and a lactic acidosis.

Management

- ***Intravenous atropine*** 0.6 to 1.2 mg, repeated as required, should be given for bradycardia and heart block. The initial dose can be repeated every 3 to 5 min, but if there is no response in pulse rate or blood pressure after three doses, it is unlikely that further boluses will be helpful. The response to atropine is sometimes improved following intravenous 10% calcium chloride, 5 to 10 mL (at 1–2 mL/min). If there is an initial response to calcium, a continuous infusion is warranted as 10% calcium chloride, 1 to 10 mL/h.
- ***Cardiac pacing*** has a role if there is evidence of atrioventricular conduction delay but failure to capture occurs.
- Hypotension that persists despite volume replacement may respond to ***i.v. glucagon***, which activates myosin kinase independent of calcium. An initial bolus of 50 to 150 μg/kg can be repeated as necessary or an infusion of 5 to 10 mg/h can be commenced.
- Insulin–glucose euglycaemia has been shown to improve myocardial contractility and systemic perfusion and should be considered in cases of resistant hypotension. ***Insulin*** is given as a bolus dose of 1 IU/kg, followed by an infusion of 1 to 10 IU/kg per hour with hypertonic glucose and frequent monitoring of blood glucose and potassium.

Digoxin

Toxicity occurring during chronic administration is common, though acute poisoning is infrequent.

Clinical features

These include nausea, vomiting, dizziness, anorexia, and drowsiness. Rarely, confusion, visual disturbances, and hallucinations occur. Initial sinus bradycardia may be followed by supraventricular arrhythmias with or without heart block, ventricular premature beats, and ventricular tachycardia. Hyperkalaemia occurs due to inhibition of the sodium–potassium activated ATPase pump.

Management

- ***Intravenous atropine*** 1.2 to 2.4 mg is given to reduce sinus bradycardia, atrioventricular block, and sinoatrial standstill.
- ***Digoxin-specific antibody fragments*** (digoxin-Fab) should be given intravenously for significant hyperkalaemia, marked arrhythmias (usually severe bradycardia compromising the cardiac output), and asystole. In both acute and chronic poisoning, only half the estimated dose required for full neutralization (calculated from amount of drug taken or serum digoxin concentration) needs to be given initially; a further dose is given if clinically indicated.

Iron salts

Unless more than 20 mg of elemental iron per kg of body weight is ingested (a ferrous sulphate tablet contains 60 mg of iron), features are unlikely to develop. As a result, poisoning is seldom severe but deaths still occur. Iron salts have a direct corrosive effect on the upper gastrointestinal tract.

Clinical features

Initial features include nausea, vomiting (the vomit may be grey or black in colour), abdominal pain, and diarrhoea. Severely poisoned patients develop haematemesis, hypotension, coma, and shock at an early stage. Usually, however, most patients suffer only mild gastrointestinal symptoms. A small minority deteriorate 12 to 48 hours after ingestion and develop shock, metabolic acidosis, acute tubular necrosis, and hepatocellular necrosis. Rarely, up to 6 weeks after ingestion, intestinal strictures occur due to corrosive damage. The serum iron concentration should be measured some 4 hours after ingestion; if the concentration exceeds the predicted normal iron-binding capacity (usually >5 mg/L; 90 μmol/L), free iron is circulating and treatment with desferrioxamine should be considered.

Management

The majority of patients ingesting iron do not require desferrioxamine therapy. If a patient develops coma or shock, ***desferrioxamine*** should be given without delay in an intravenous dose of 15 mg/kg per hour (the total amount of infusion usually not to exceed 80 mg/kg in 24 h). If the recommended rate of administration is continued for several days, adverse effects, including pulmonary oedema and ARDS (see Chapter 13), have been reported.

Lithium salts

Lithium poisoning usually results from impaired renal elimination in an individual on lithium therapeutically; that is, chronic toxicity rather than deliberate self-poisoning (acute toxicity). Lithium has a narrow therapeutic index (target plasma range 0.8–1.2 mmol/L).

Clinical features

Features of intoxication include diarrhoea and vomiting, tremor, thirst, polyuria, and, in more serious cases, impairment of consciousness, hypertonia, and convulsions; irreversible neurological damage may occur. Measurement of the serum lithium concentration confirms the diagnosis. However, in chronic poisoning the plasma lithium concentration may not be markedly above the upper end of the therapeutic range despite the presence of severe neurological features (which are due to accumulation of lithium in the CNS). Conversely, acute massive overdose may produce high plasma concentrations with few toxic features.

Management

The plasma lithium concentration must always be interpreted in association with the clinical features present. Since lithium is eliminated unchanged via the kidneys, diuresis with sodium chloride 0.9% is effective in increasing clearance. Haemodialysis is far superior and is used if neurological features are present and/or if renal function is impaired. It is employed particularly in cases of chronic toxicity.

Nitrous oxide

Nitrous oxide (N_2O), also known as 'laughing gas', is a general anaesthetic agent with a long history of recreational misuse preceding use as an anaesthetic. It is usually inhaled from balloons filled with N_2O-containing canisters. The small steel canisters are also known as 'whippets'.

Clinical features

Inhalation produces a short-lived feeling of euphoria or relaxation. Hypoxia, asphyxiation, and injuries secondary to acute intoxication are possible. Cold burns to the lips or thighs can occur as the canister becomes ice cold as it discharges. Chronic misuse over weeks and months can lead to N_2O-induced myeloneuropathy, a syndrome ranging from mild damage to peripheral nerves to severe spinal cord damage, known as subacute combined degeneration of the cord. N_2O irreversibly inactivates vitamin B12, resulting in functional B12 deficiency, which leads to a failure in the production of myelin. An increasing number of cases of N_2O-induced myeloneuropathy have been reported in recent years. Patients usually present with paraesthesia in the upper and lower limbs and gait ataxia.

Management

There is no specific toxicological management for acute intoxication and patients should be treated with symptomatic and supportive care. N_2O-induced myeloneuropathy should be treated with ***intramuscular B12 injections*** (e.g., 1 mg hydroxocobalamin i.m. initially on alternate days) regardless of the measured B12 concentration in the blood, which may be normal. Treatment duration depends on symptom improvement and can also be guided by biomarkers of functional B12 deficiency such as methylmalonic acid and homocysteine, which are often raised at the point of diagnosis.

Salicylates

Aspirin is metabolized to salicylic acid (salicylate) by esterases present in many tissues, especially the liver, and subsequently to salicyluric acid and salicyl phenolic glucuronide (**Fig. 15.2**); these two pathways become saturated, with the consequence that the renal excretion of salicylic acid increases after overdose; this excretion pathway is extremely sensitive to changes in urinary pH.

Clinical features

Salicylates stimulate the respiratory centre, increase the depth and rate of respiration, and induce a respiratory alkalosis. Compensatory mechanisms, including renal excretion of bicarbonate and

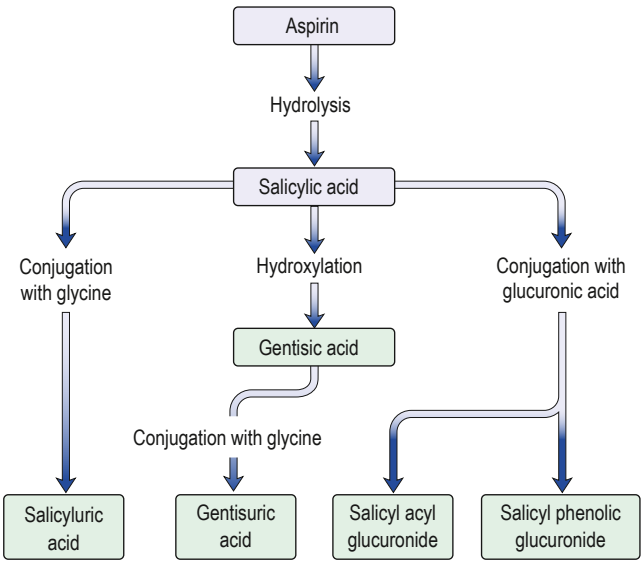

Fig. 15.2 The metabolism of aspirin.

potassium, result in a metabolic acidosis. Salicylates also interfere with carbohydrate, fat, and protein metabolism and disrupt oxidative phosphorylation, producing increased concentrations of lactate, pyruvate, and ketone bodies, all of which contribute to the acidosis.

Common features of poisoning include tachypnoea, sweating, vomiting, epigastric pain, tinnitus, and deafness. Respiratory alkalosis and metabolic acidosis supervene and a mixed acid–base disturbance is typical. Rarely, in severe poisoning, non-cardiogenic pulmonary oedema, coma, and convulsions ensue.

The severity of salicylate toxicity is dose related.

Management

Fluid and electrolyte replacement are required with prompt correction of dehydration and hypokalaemia.

- Mild cases of salicylate poisoning are managed with parenteral fluid and electrolyte replacement only.
- Patients whose plasma salicylate concentrations are in excess of 500 mg/L (3.6 mmol/L) should receive urine alkalinization (see 'Increasing poison elimination' section).
- ***Haemodialysis*** is the treatment of choice for severely poisoned patients (plasma salicylate concentration >700 mg/L; >5.1 mmol/L), particularly those with coma and metabolic acidosis.

Poisoning with chemicals

Included in this section, in alphabetical order, are arsenic, carbamate insecticides, carbon monoxide, copper sulphate, corrosives, cyanide, ethylene glycol, household agents, lead, mercury, methanol, nerve agents, OP insecticides, and phosphides.

Arsenic

Arsenic poisoning worldwide is commonly caused by contamination of the ground water by inorganic arsenates, particularly in Asia. Occasionally, arsenic is found in Chinese and Indian traditional remedies.

Clinical features

Acute ingestion causes abdominal pain, vomiting, and diarrhoea. Hypovolaemic shock and acute tubular necrosis occur in severe cases.

Chronic exposure to lower doses produces gastrointestinal effects, accompanied by skin changes (hyperkeratosis of palms and soles, 'raindrop' pattern of hyperpigmentation, and alopecia), neurological features (headache, sensorimotor neuropathy), abnormal liver biochemistry (non-cirrhotic portal hypertension is recognized), peripheral vascular arteriosclerosis, and haematological abnormalities (pancytopenia).

Management

The identification of, and removal from, the source of exposure to arsenic is vital. Chelation therapy with oral DMSA 30 mg/kg per day or intravenous DMPS 30 mg/kg per day may be indicated.

Carbamate insecticides

Carbamate insecticides inhibit acetylcholinesterase but the duration of this inhibition is comparatively short-lived in comparison with OP insecticides (see 'Organophosphorus insecticides' section), since the carbamate–enzyme complex tends to dissociate spontaneously.

Clinical features

Although carbamate insecticide poisoning is generally less severe than OP insecticide poisoning, acute poisoning with a carbamate can be severe and fatal. Cholinergic symptoms usually develop within a few minutes. In the most severe cases, muscle twitching, profound weakness, profuse sweating, incontinence, mental confusion, and progressive cardiac and respiratory failure ensue. In less severe cases, cholinergic symptoms are usually evident within 2 hours and typically resolve within 24 hours. Seizures are relatively uncommon, since carbamate penetration into the CNS is limited.

Management

Mild cases require no specific treatment other than the removal of soiled clothing. ***Intravenous atropine*** 2 mg should be given every 3 to 5 minutes, if necessary, to reduce increased secretions, rhinorrhoea, and bronchorrhoea. If this measure fails, the patient should be intubated and mechanical ventilation instituted. Since carbamates have a shorter duration of action than OP insecticides, pralidoxime should be used only rarely in carbamate poisoning. If intoxication is life-threatening, give ***intravenous pralidoxime chloride*** 30 mg/kg body weight over 5 to 10 minutes, followed by an infusion of 8 to 10 mg/kg per hour.

Carbon monoxide

The most common source of carbon monoxide is an improperly maintained and poorly ventilated heating system. In addition, inhalation of methylene chloride (found in paint strippers) may also lead to carbon monoxide poisoning, as methylene chloride is metabolized *in vivo* to carbon monoxide. Carbon monoxide has a greater affinity for haemoglobin and forms carboxyhaemoglobin (COHb), thereby reducing the oxygen-carrying capacity. The affinity of the remaining haem groups for oxygen is increased. This shifts the oxyhaemoglobin dissociation curve to the left, impairing liberation of oxygen to the cells and leading to tissue hypoxia. In addition, carbon monoxide also inhibits cytochrome oxidase a_3.

Clinical features

Symptoms of mild to moderate exposure to carbon monoxide may be mistaken for a viral illness.

- A peak COHb concentration of <10% is not normally associated with symptoms.
- A peak COHb concentration of 10% to 30% usually causes headache and mild exertional dyspnoea.

- Higher concentrations of COHb are associated with coma, convulsions, and cardiorespiratory arrest. Metabolic acidosis, myocardial ischaemia, hypertonia, extensor plantar responses, retinal haemorrhages, and papilloedema also occur.

Neuropsychiatric features may develop after apparent recovery from carbon monoxide exposure.

Management

In addition to removing the patient from carbon monoxide exposure, high-flow oxygen should be administered using a tightly fitting face mask (see Chapter 13). Endotracheal intubation and mechanical ventilation are required in those who are unconscious. Several controlled studies of hyperbaric oxygen have been published but none has shown long-term clinical benefit.

Copper sulphate

Copper sulphate is used in fungicides, algicides, electroplating, dyes, inks, disinfectants, and wood preservatives.

Clinical features

Ingestion causes vomiting, abdominal pain, diarrhoea, headache, dizziness, and a metallic taste. Gastrointestinal haemorrhage, intravascular haemolysis, methaemoglobinaemia, rhabdomyolysis, coma, convulsions, and hepatorenal failure may ensue and fatalities have occurred. Body secretions may be blue/green.

Management

Treatment is supportive with replenishment of lost fluids/blood. Blood copper concentrations correlate with the severity of poisoning; a copper concentration of >8 mg/L is indicative of severe poisoning. Early endoscopy (or CT scan with contrast if endoscopy is not possible) is recommended if corrosive damage is suspected. Methaemoglobinaemia of >30% should be treated with intravenous methylthioninium chloride 1 to 2 mg/kg. Renal failure may require extracorporeal support.

Corrosive agents

Strong acids and alkalis cause chemical burns. Inorganic acids such as hydrochloric and sulphuric acid are generally more toxic than organic acids such as acetic acid. Hydrofluoric acid is considered separately (see 'Hydrofluoric acid and hydrogen fluoride' section). Some household products, such as water-sterilizing tablets, are strong alkalis. Following corrosive ingestion, both CT scan and endoscopy are useful in assessing the severity of injury, risk of mortality, and risk of subsequent stricture formation. Prompt surgical intervention may be required to remove necrotic tissue, if indicated.

Cyanide

Cyanide and its derivatives are used widely in industry. Hydrogen cyanide is also released during the thermal decomposition of polyurethane foams, such as that in mattresses. Cyanide reversibly inhibits cytochrome oxidase a_3, so that cellular respiration ceases.

Clinical features

Inhalation of hydrogen cyanide produces symptoms within seconds and death within minutes. By contrast, the ingestion of a cyanide salt may not produce features for 1 hour. After exposure, initial symptoms are non-specific and include a feeling of constriction in the chest and dyspnoea. Coma, convulsions, and metabolic acidosis may then supervene.

Management

Oxygen should be provided and an antidote administered. ***Dicobalt edetate*** was historically used and is highly efficacious but manufacturing has been discontinued. Dicobalt edetate (and the free cobalt contained in the preparation) complexes free cyanide. An alternative and more widely available antidote is ***intravenous hydroxocobalamin*** (5 g); a second dose may be required in severe cases. Each hydroxocobalamin molecule can bind one cyanide ion to form cyanocobalamin, which is then excreted in the urine. Hydroxocobalamin is now considered first line in cases of moderate and severe cyanide poisoning. ***Intravenous sodium thiosulphate*** 12.5 g, which acts by enhancing endogenous detoxification, can be used as an adjunct in severe cases, or alone in mild or moderate poisoning.

Ethylene glycol

Ethylene glycol is found in a variety of common household products, including antifreeze, windshield washer fluid, brake fluid, and lubricants. The features observed in poisoning are due to metabolites predominantly, not the parent chemical. Ethylene glycol (**Fig. 15.3**) is metabolized to glycolate, the cause of the acidosis. A small proportion of glyoxylate is metabolized to oxalate. Calcium ions chelate oxalate to form insoluble calcium oxalate, which is responsible for renal toxicity.

Clinical features

Initially, the features of ethylene glycol poisoning are similar to those of ethanol intoxication (though there is no ethanol on the breath). Coma and convulsions follow and a variety of neurological abnormalities, including nystagmus and ophthalmoplegias, are seen. Severe metabolic acidosis, hypocalcaemia, and acute kidney injury are well-recognized complications.

Management

If the patient presents early after ingestion, the priority is to inhibit metabolism using either intravenous fomepizole or ethanol; the former does not require monitoring of blood concentrations.

- ***Fomepizole:*** 15 mg/kg body weight should be administered, followed by four 12-hourly doses of 10 mg/kg, then 15 mg/kg every 12 h until glycol concentrations are not detectable. Following a substantial ingestion, haemodialysis or haemodiafiltration should be employed to remove the glycol and metabolites. If dialysis is used, fomepizole should be administered as an infusion

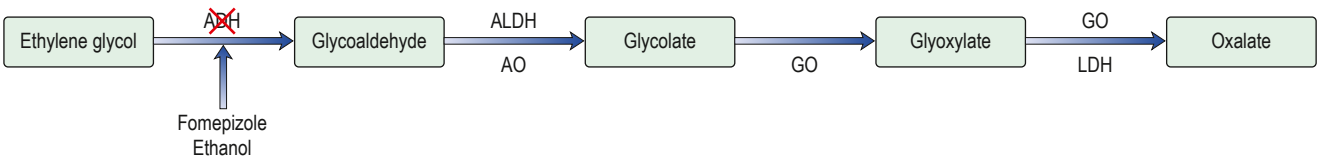

Fig. 15.3 The metabolism of ethylene glycol. Fomepizole and ethanol inhibit ADH. *ADH,* Alcohol dehydrogenase; *ALDH,* aldehyde dehydrogenase; *AO,* aldehyde oxidase; *GO,* glycolate oxidase; *LDH,* lactate dehydrogenase.

of 1 mg/kg/h, or the frequency of fomepizole dosing should be increased to 4 hourly because fomepizole is dialysable.

- ***Ethanol:*** alternatively, a loading dose of ethanol 50 g can be administered, followed by an intravenous infusion of ethanol 10 to 12 g/h to produce blood ethanol concentrations of 500 to 1000 mg/L (11–22 mmol/L). The infusion is continued until the glycol is no longer detectable in the blood. If haemodialysis is employed, the rate of ethanol administration will need to be increased to 17 to 22 g/h, as ethanol is dialysable.

Supportive measures to combat shock, hypocalcaemia, and metabolic acidosis should be instituted.

Household products

The agents most commonly involved are bleach, cosmetics, toiletries, detergents, disinfectants, and petroleum distillates such as paraffin and white spirit. Ingestion of household products is usually accidental and is most common among children less than 5 years of age.

Clinical features

If ingestion is accidental, features very rarely occur, except in the case of petroleum distillates where aspiration is a recognized complication because of their low surface tension. Powder detergents, sterilizing tablets, denture cleaning tablets, and industrial bleaches (which contain high concentrations of sodium hypochlorite) are corrosive to the mouth and pharynx if ingested. Nail polish and nail polish remover contain acetone, which may produce a coma if ingested in substantial quantities. Inhalation by small children of substantial quantities of talcum powder has occasionally given rise to severe pulmonary oedema and death.

Hydrofluoric acid and hydrogen fluoride

Hydrofluoric acid, a solution of hydrogen fluoride in water, is a colourless, fuming liquid that is widely used in industry. It is particularly dangerous because of its unique ability among acids to penetrate tissue.

Clinical features

Dermal exposure to hydrofluoric acid results in rapid liquefactive necrosis and erosion of bone. If more than 1% of the body surface area is contaminated with a 50% or higher solution of hydrofluoric acid, there is a high risk of hypocalcaemia from the formation of calcium fluoride. This may lead to cardiac conduction disturbances, notably QT interval prolongation and an increased risk of ventricular arrhythmias, particularly torsades de pointes (see Chapter 17).

Ingestion of hydrofluoric acid causes severe corrosive injury to the gastrointestinal tract.

Inhalation of hydrogen fluoride causes irritation of the eyes and nose, with sore throat, cough, chest tightness, headache, ataxia, and confusion. Dyspnoea and stridor due to laryngeal oedema may follow, depending on the concentration of hydrogen fluoride. Haemorrhagic pulmonary oedema with increasing breathlessness, wheeze, hypoxia, and cyanosis may take up to 36 hours to develop.

Management

- ***Dermal exposure.*** Immediate irrigation of the skin with copious volumes of water is the priority, followed by the prompt application of calcium gluconate gel to reduce pain and limit skin damage.
- ***Ingestion.*** This is a medical emergency with the need for immediate assessment for surgery after endoscopy or CT.
- ***Inhalation.*** If the patient has clinical features of bronchospasm after inhalation, then treat conventionally with nebulized bronchodilators and steroids. Treat pulmonary oedema and/or ARDS (see Chapter 13) with continuous positive airway pressure or, in severe cases, with intermittent positive pressure ventilation.

Lead

Exposure to lead occurs occupationally, children may eat lead-painted items in their homes (pica), and the use of lead-containing cosmetics or ‘drugs’ has also resulted in poisoning.

Clinical features

Mild intoxication may result in no more than lethargy and occasional abdominal discomfort, though abdominal pain, vomiting, constipation, and encephalopathy (seizures, delirium, coma) may develop in more severe cases. Encephalopathy is more common in children than in adults but is rare in the developed world. Typically, though very rarely, lead poisoning results in foot drop attributable to peripheral motor neuropathy.

Anaemia (normally normochromic normocytic) occurs due both to inhibition by lead of several enzymes involved in haem synthesis and to haemolysis. The latter results from damage to the red cell membrane by aggregates of RNA that accumulate owing to inhibition by lead of pyrimidine-5-nucleotidase, causing characteristic ‘basophilic stippling’ of erythrocytes.

Management

The social and occupational dimensions of lead poisoning must be recognized. Simply giving patients chelation therapy and then returning them to a contaminated environment is of no value.

The decision to use chelation therapy is based not only on the blood lead concentration but also on the presence of symptoms. Parenteral ***sodium calcium edetate*** 75 mg/kg per day or oral ***succimer (DMSA)*** 30 mg/kg per day is of similar efficacy. At least 5 days’ treatment is usually required. As chelation of zinc may occur with sodium calcium edetate, serum zinc concentrations should be checked.

Mercury

Mercury is the only metal that is liquid at room temperature. It exists in three oxidation states (elemental/metallic Hg^0, mercurous Hg_2^{2+}, and mercuric Hg^{2+}) and can form inorganic (e.g., mercuric chloride) and organic (e.g., methylmercury) compounds. Metallic mercury is very volatile; when spilled, it has a large surface area so that high atmospheric concentrations may be produced in enclosed spaces, particularly when environmental temperatures are high. Thus great care should be taken in clearing up a spillage. If ingested, metallic mercury will usually be eliminated per rectum, though small amounts may settle in the appendix and remain there for years. Mercury salts are well absorbed following ingestion, as is mercury vapour following inhalation.

Clinical features

Acute inhalation of mercury vapour causes headache, nausea, cough, chest pain, and, occasionally, a chemical pneumonitis. Proteinuria and nephrotic syndrome are observed rarely.

Ingestion of inorganic or organic mercury compounds causes an irritant gastroenteritis. Mercurous (Hg_2^{2+}) compounds are less corrosive and less toxic than mercuric (Hg^{2+}) salts.

Systemic accumulation of mercury from any source and by any route of exposure leads to characteristic neurological features, including a fine tremor, lethargy, memory loss, insomnia,

personality changes, and ataxia. Peripheral nerve damage has also been observed, as has renal tubular damage.

Management

Unithiol (DMPS) is the antidote of choice and is given in an intravenous dose of 30 mg/kg per day. At least 5 days' treatment is usually required.

Methanol

Methanol is used widely as a solvent and is found in antifreeze solutions. Methanol is metabolized to formaldehyde and formate (**Fig. 15.4**). The concentration of formate increases greatly and is accompanied by accumulation of hydrogen ions, leading to metabolic acidosis.

Clinical features

Methanol causes inebriation and drowsiness. After a latent period, coma supervenes. Blurred vision and diminished visual acuity occur due to formate accumulation. The presence of dilated pupils that are unreactive to light suggests that permanent blindness is likely to ensue. A severe metabolic acidosis may develop and be accompanied by hyperglycaemia and a raised serum amylase activity. A blood methanol concentration of 500 mg/L (15.6 mmol/L) confirms severe poisoning. The mortality correlates well with the severity and duration of metabolic acidosis. Survivors may show permanent neurological sequelae, including parkinsonian-like signs as well as blindness.

Management

Treatment is similar to that of ethylene glycol poisoning (see 'Ethylene glycol' section) with the addition of intravenous folinic acid 30 mg 6 hourly for 48 hours, which accelerates formate metabolism, thereby reducing ocular toxicity.

Nerve agents

Nerve agents are related chemically to OP insecticides (see below) and have a similar mechanism of toxicity but a much higher mammalian acute toxicity, particularly via the dermal route. In addition to inhibition of acetylcholinesterase, a chemical reaction known as 'ageing' also occurs rapidly and more completely than in the case of insecticides. This makes the enzyme resistant to spontaneous reactivation or treatment with oximes (pralidoxime, obidoxime or HI-6).

Several classes of nerve agents are recognized: G agents (named after Gerhard Schrader, who synthesized the first agents) and V agents (V purportedly standing for venomous). G agents include tabun, sarin, soman, and cyclosarin. The V agents, for example, VX, were introduced later. The G agents are both dermal and respiratory hazards, whereas the V agents, unless aerosolized, are contact poisons. The latest class of nerve agents to receive notoriety are the Novichok agents, which are potent contact poisons.

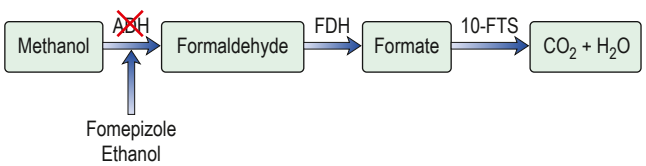

Fig. 15.4 The metabolism of methanol. Fomepizole and ethanol inhibit ADH. *10-FTS,* 10-Formyl tetrahydrofolate synthetase; *ADH,* alcohol dehydrogenase; *FDH,* formaldehyde dehydrogenase.

Clinical features

Systemic features include increased salivation, rhinorrhoea, bronchorrhoea, miosis (which is characteristic) and eye pain, abdominal pain, nausea, vomiting and diarrhoea, involuntary micturition and defecation, muscle weakness and fasciculation, tremor, restlessness, ataxia, and convulsions. Bradycardia, tachycardia, and hypotension occur, depending on whether muscarinic or nicotinic effects predominate. Death occurs from respiratory failure within minutes but individuals with mild or moderate exposure usually recover completely. Diagnosis is confirmed by measuring the erythrocyte cholinesterase activity.

Management

- The administration of ***intravenous atropine*** 2 mg repeated every 3 to 5 min as necessary to patients presenting with rhinorrhoea and bronchorrhoea may be lifesaving.
- An oxime should be given to all those requiring atropine as soon as possible after exposure before 'ageing' has occurred; for example, ***intravenous pralidoxime*** chloride 30 mg/kg, followed by an infusion of pralidoxime chloride 8 to 10 mg/kg per hour. Alternatively, boluses of pralidoxime chloride 30 mg/kg may be given 4 to 6 hourly.
- ***Intravenous diazepam*** 10 to 20 mg, repeated as required, is useful in controlling apprehension, agitation, fasciculation, and convulsions.

Organophosphorus insecticides

OP insecticides are used widely throughout the world and are a common cause of poisoning, leading to thousands of deaths annually in the developing world. Intoxication may follow ingestion, inhalation, or dermal absorption. OP insecticides inhibit acetylcholinesterase, causing accumulation of acetylcholine at central and peripheral cholinergic nerve endings, including neuromuscular junctions. Many OP insecticides require biotransformation before becoming active and so the features of intoxication may be delayed.

Clinical features

Poisoning is characterized by anxiety and restlessness, which is typically followed by nausea, vomiting, abdominal colic, diarrhoea (particularly if exposure is by ingestion), tenesmus, sweating, hypersalivation, and chest tightness. Respiratory failure will ensue in severe cases and is exacerbated by the development of bronchorrhoea and pulmonary oedema. Miosis is characteristic. Muscle fasciculation and flaccid paresis of limb muscles and, occasionally, paralysis of extraocular muscles are observed. Coma and convulsions occur in severe poisoning.

Diagnosis is confirmed by measuring the erythrocyte acetylcholinesterase activity; plasma cholinesterase activity is less specific but may also be depressed.

The ***intermediate syndrome*** usually becomes established 1 to 4 days after exposure, when the symptoms and signs of the acute cholinergic syndrome are no longer obvious. The characteristic features of the syndrome are weakness of the muscles of respiration (diaphragm, intercostal muscles, and accessory muscles, including neck muscles) and of proximal limb muscles. Accompanying features often include weakness of muscles innervated by some cranial nerves.

Delayed polyneuropathy is a rare complication of acute exposure to some OP insecticides not marketed in most countries. It presents with glove and stocking paraesthesiae some 1 to 4 weeks after exposure, followed by an ascending motor polyneuropathy in

many cases. It is initiated by phosphorylation, and subsequent ageing, of at least 70% of an esterase—neuropathy target esterase—in peripheral nerves. Most mild cases improve with time but severe cases can be left with an upper motor neurone syndrome and permanent disability.

Management

Mild cases require no specific treatment other than the removal of soiled clothing. ***Intravenous atropine*** 2 mg should be given every 3 to 5 minutes if necessary, to reduce increased secretions, rhinorrhoea, and bronchorrhoea.

Symptomatic patients should also be given an oxime (pralidoxime, obidoxime) to reactivate inhibited acetylcholinesterase; for example, ***pralidoxime chloride*** 30 mg/kg by slow intravenous injection, followed by an infusion of pralidoxime chloride 8 to 10 mg/kg per hour. There is no specific treatment for the intermediate syndrome apart from supportive care, including prolonged ventilation, though a prospective trial suggested that early treatment with oximes could reduce the likelihood of the syndrome developing. Most patients recover in 2 to 3 weeks.

Phosphides

Aluminium and zinc phosphides are used as rodenticides and insecticides. They react with moisture in the air (and the gastrointestinal tract) to produce phosphine, the active pesticide. Acute poisoning with these compounds may be direct, due to ingestion of the salts, or indirect, from accidental inhalation of phosphine generated during their approved use.

Clinical features

Ingestion causes vomiting, epigastric pain, peripheral circulatory failure, severe metabolic acidosis, acute kidney injury, and disseminated intravascular coagulation, in addition to the features induced by phosphine.

Exposure to phosphine causes lacrimation, rhinorrhoea, cough, breathlessness, chest tightness, dizziness, diplopia, headache, nausea, drowsiness, intention tremor, and ataxia. Acute pulmonary oedema, hypertension, cardiac arrhythmias, convulsions, and jaundice have been described in severe cases.

Management

Treatment is symptomatic and supportive. Gastric lavage should not be used, as it can speed up the rate of disintegration of the product ingested and increase toxicity. Activated charcoal may bind metal phosphides. The mortality is high, despite supportive care.

Poisons in the natural world

Numerous biological organisms produce or contain substances that are toxic to humans, including animals (snakes, insects, spiders, and marine creatures), and some species of plants and fungi. **An online supplement covers these naturally occurring poisons in detail**.

Venomous snakes

Approximately 15% of the 3000 species of snake found worldwide are considered to be dangerous to humans. Snakebite is common in some tropical countries; rural areas of West Africa, South-east Asia, the Indian subcontinent, New Guinea, and the Amazon region are particularly affected. Bites by venomous snakes cause more than 100 000 deaths and many permanent sequelae each year (some 46 000 people are killed each year in India alone).

Clinical features

The main effects of envenoming are:

- local swelling, bruising, blistering, regional lymph node enlargement and necrosis
- anti-haemostatic defects: consumption coagulopathy and spontaneous systemic bleeding from gums, nose, skin, gut, genitourinary tract, and intracranial haemorrhage
- shock (hypotension) and myocardial damage
- descending paralysis: progressing from ptosis and external ophthalmoplegia to bulbar, respiratory muscle, and total flaccid paralysis
- generalized rhabdomyolysis with myoglobinuria
- intravascular haemolysis
- acute kidney injury.

A more detailed account of mechanisms and clinical features of snakebite envenoming, including discussion of the main groups of venomous snakes, can be located in the online supplement.

Management

Following a snakebite, all efforts should be made to transport the patient quickly to a hospital or dispensary. Traditional methods should be discouraged, as they are often ineffective and may harm the patient. Arterial tourniquets should *not* be used, and incision or excision of the bite area should *not* be performed.

As a first aid measure, a firm pressure bandage should be placed over the bite and the limb immobilized, as this may delay the spread of the venom. Local wounds often require little treatment. If necrosis is present, antibiotics should be given. Skin grafting may be required later. Anti-tetanus prophylaxis must be given. The type of snake should be identified, if possible.

In about 50% of cases, no venom has been injected by the bite but, nevertheless, careful observation for 12 to 24 hours is necessary in case envenomation develops. General supportive measures should be carried out, as necessary. These include intravenous fluids with volume expanders for hypotension and diazepam for anxiety. Treatment of acute respiratory, cardiac, and kidney injury is instituted as necessary.

Antivenoms are not generally indicated unless envenomation is present, as they can cause severe allergic reactions. Antivenoms can rapidly neutralize venom, but only if an amount in excess of the amount of venom is given. Large quantities of antivenom may be required; as antivenoms cannot reverse the effects of the venom, they must be given early to minimize some of the local effects and may prevent necrosis at the site of the bite. Antivenoms should be administered intravenously by slow infusion, the same dose being given to children and adults.

Allergic reactions are frequent, and adrenaline (epinephrine) 1 in 1000 solution should be available. In severe cases, the antivenom infusion should be continued even if an allergic reaction occurs, with subcutaneous injections of adrenaline being given as necessary. Some forms of neurotoxicity, such as those induced by the death adder, respond to anticholinesterase therapy with neostigmine and atropine.

POISONS IN THE NATURAL WORLD

This online-only content supplements the more limited information on snake envenomation in the print edition and includes in-depth descriptions of different forms of snake envenomation alongside a range of other toxins present in the natural world. Many of these have particular patterns of geographic distribution, making local knowledge invaluable in assessing regional risks.

Poisonous plants

Poisonous mushrooms

Marine animals

Amnesic shellfish (domoic acid) poisoning

The syndrome should be known more accurately as domoic acid poisoning because amnesia is not always present. In one outbreak, the first symptoms were experienced between 15 minutes and 38 hours after mussel consumption. There are now legal limits on the domoic acid concentrations allowed in mussels.

Clinical features and management

The most common symptoms are nausea, vomiting, abdominal cramps, headache, diarrhoea, and short-term memory loss. Axonal sensory motor neuropathy, seizures, coma, and death have also been reported. Treatment is symptomatic and supportive.

Diarrhoeic shellfish (okadaic) poisoning

Okadaic poisoning occurs worldwide, often after eating bivalve molluscs such as mussels and scallops. Okadaic acid is produced by dinoflagellates belonging to the genus *Dinophysis*. It inhibits the activity of the protein phosphatases 1 and 2a. As a result, increased phosphorylation of intestinal transport proteins, with increased permeability to solutes, leads to diarrhoea.

Clinical features and management

The predominant symptoms are diarrhoea, nausea, vomiting, and abdominal pain. Symptoms tend to occur between 30 minutes and a few hours after shellfish consumption, with patients recovering within 2 to 3 days. Treatment is symptomatic and supportive.

Neurotoxic shellfish (brevetoxin) poisoning

Neurotoxic shellfish poisoning is caused by brevetoxins produced by the dinoflagellate *Gymnodinium breve*. Brevetoxins open voltage-gated sodium ion channels in cell walls and enhance the inward flow of sodium ions into the cell.

Clinical features and management

The symptoms of neurotoxic shellfish poisoning occur within 30 minutes to 3 hours and last a few days; they include nausea, vomiting, diarrhoea, chills, sweats, reversal of temperature sensation, hypotension, arrhythmias, numbness, tingling, paraesthesiae of the lips, face and extremities, cramps, bronchoconstriction, paralysis, seizures, and coma. Treatment is symptomatic and supportive.

Paralytic shellfish (saxitoxin) poisoning

This is caused by bivalve molluscs being contaminated with neurotoxins, including saxitoxin, produced by toxic dinoflagellates on which the molluscs graze. Saxitoxin blocks voltage-gated sodium channels in nerve and muscle cell membranes, thereby blocking nerve signal transmission.

Clinical features and management

Symptoms develop within 30 minutes. The illness is characterized by paraesthesiae of the mouth, lips, face, and extremities and is often accompanied by nausea, vomiting, and diarrhoea. In more severe cases, dystonia, dysphagia, muscle weakness, paralysis, ataxia, and respiratory depression occur. In one outbreak involving 187 cases, there were 26 deaths. Treatment is symptomatic and supportive.

Ciguatera fish poisoning

Over 400 fish species have been reported as ciguatoxic (*cigua* is Spanish for poisonous snail), though barracuda, red snapper, amberjack, and grouper are most commonly implicated. Ciguatera fish contain ciguatoxin, maitotoxin, and scaritoxin, which are lipid-soluble, heat-stable compounds that are derived from dinoflagellates such as *Gambierdiscus toxicus*. Ciguatoxin opens voltage-sensitive sodium channels at the neuromuscular junction and maitotoxin opens calcium channels of the cell plasma membrane.

Clinical features and management

The onset of symptoms occurs from a few minutes to 30 hours after ingestion of toxic fish. Typically, features appear between 1 and 6 hours and include abdominal cramps, nausea, vomiting, and watery diarrhoea. In some cases, numbness and paraesthesiae of the lips, tongue, and throat occur. Other features described include malaise, dry mouth, metallic taste, myalgia, arthralgia, blurred vision, photophobia, and transient blindness. In more severe cases, hypotension, cranial nerve palsies, and respiratory paralysis have been reported. Treatment is symptomatic and supportive. Recovery takes from 48 hours to 1 week in the mild form and from 1 to several weeks in the severe form. The mortality in severe cases may be as high as 12%. To prevent ciguatera fish poisoning, consumption of reef fish should be limited and parts of the fish that concentrate ciguatera toxin (e.g., the head, intestines, liver, roe) should be avoided. Ingestion of high-risk fish such as barracuda and moray eel should be avoided altogether.

Scombroid fish poisoning

This is due to the action of bacteria such as *Proteus morgani* and *Klebsiella pneumoniae* in the decomposing flesh of fish such as tuna, mackerel, mahi-mahi, bonito, and skipjack stored at insufficiently low temperatures. The spoiled fish can contain excessively high concentrations of histamine (muscle histidine is broken down by the bacteria to histamine), though the precise role of histamine in the pathogenesis of the clinical syndrome is uncertain.

Clinical features and management

Clinically, the mean incubation period is 30 minutes. The illness is characterized by flushing, headache, sweating, dizziness, burning of the mouth and throat, abdominal cramps, nausea, vomiting, and diarrhoea; it is usually short-lived, the mean duration being 4 hours. Treatment is symptomatic and supportive. Antihistamines may alleviate the symptoms.

Stings from marine animals

Several species of fish have venomous spines in their fins. These include the weaver fish, short-spine cottus, spiny dogfish, and stingray. Bathers and fishermen may be stung if they tread on or handle these species. The immediate result of a sting is intense local pain, swelling, bruising, blistering, necrosis, and, if the poisoned spine is not removed, chronic sepsis (although this is uncommon). Occasionally, systemic symptoms, including vomiting, diarrhoea, hypotension, and tachycardia, occur. Treatment by immersing the affected part in hot water may relieve local symptoms, as this denatures the thermolabile toxin.

Jellyfish stings

Most of the jellyfish found in North European coastal waters are non-toxic, as their stings cannot penetrate human skin. A notable exception is the 'Portuguese man-o'-war' *(Physalia physalis)*, whose sting contains a toxic peptide, phospholipase A, and a histamine-liberating factor. Toxic jellyfish are found more frequently in Australia and some, notably the box jellyfish, *Carukia barnesi*, cause the Irukandji syndrome (see below).

Clinical features and management

Local pain occurs, followed by myalgia, nausea, griping abdominal pain, dyspnoea, and even death. The cluster of severe systemic symptoms that constitute the Irukandji syndrome occur some 30 minutes after the jellyfish sting. The symptoms include severe low back pain, excruciating muscle cramps in all four limbs, abdomen, and chest, sweating, anxiety, restlessness, nausea, vomiting, headache, palpitations, life-threatening hypertension, and cardiogenic pulmonary oedema.

Adhesive tape may be used to remove any tentacles still adherent to the bather. Local application of 5% acetic acid is said to prevent stinging cells adherent to the skin discharging. Local analgesia and antihistamine creams provide symptomatic relief. Other features should be treated symptomatically and supportively.

Berling I, Isbister G. Marine envenomations. *Aust Fam Physician* 2015; 44:28–32.

Venomous animals

Insect stings and bites

Insect stings from wasps and bees, and bites from ants, produce pain and swelling at the puncture site. Following the sting or bite, patients should be observed for 2 hours for any signs of evolving urticaria, pruritus, bronchospasm, or oropharyngeal oedema. The onset of anaphylaxis requires urgent treatment (see Chapter 11).

Scorpions

Scorpion stings are a serious problem in North Africa, the Middle East, and the Americas. Scorpion venoms stimulate the release of acetylcholine and catecholamines, causing both cholinergic and adrenergic symptoms.

Clinical features and management

Severe pain occurs immediately at the site of puncture, followed by swelling. Signs of systemic involvement, which may be delayed for 24 hours, include vomiting, sweating, piloerection, abdominal colic, and diarrhoea. In some cases, depending on the species, cardiogenic shock, respiratory depression, and pulmonary oedema may develop.

Local infiltration with anaesthetic or a ring block will usually alleviate local pain, though systemic analgesia may be required. Specific antivenom, if available, should be administered as soon as possible.

Spiders

The black widow spider *(Latrodectus mactans)* is found in North America, Australia, the tropics, and, occasionally, in Mediterranean countries.

Clinical features and management

The bite quickly becomes painful, and generalized muscle pain, sweating, headache, and shock may occur. No systemic treatment is required except in cases of severe systemic toxicity, when specific antivenom should be given, if this is available.

Venomous snakes

Contributed by C. Ariaranee Gnanathasan
University of Colombo, Sri Lanka

Venomous snakes are found in most parts of the world except in very cold regions such as Antarctica and islands such as Ireland, Iceland, New Zealand and most islands of the Western Mediterranean, Caribbean, and Pacific. Sea snakes (**Fig. E15.1**) inhabit the Indian and Pacific Oceans between latitudes 30°N and 30°S.

Two families of venomous snakes are of major medical importance:

- ***Elapidae:*** African and Asian cobras (**Fig. E15.2**), Asian kraits (Figs. E15.3 and E15.4), African mambas, American coral snakes, most Australo-Papuan venomous snakes and sea snakes
- ***Viperidae:*** that is, vipers (**Fig. E15.5**), adders, pit vipers (**Fig. E15.6**), and rattlesnakes.

Snakebite envenoming is a category A neglected tropical disease of high global impact. The burden of snakebite envenoming has the highest impact on populations and healthcare systems in sub-Saharan Africa, South and South-east Asia, Latin America, and Oceania. The World Health Organization (WHO) estimated that 4.5 to 5.4 million people are bitten by snakes annually, resulting in 1.8 to 2.7 million envenomings, 81 000 to 138 000 deaths, at least 400 000 people suffering from physical or psychological sequelae, and a staggering 400 000 limb amputations. A large number of victims survive with permanent sequelae of envenoming, both physical and psychological (e.g., post-traumatic stress disorder).

Snake venom is not a single toxin. It is a complex mixture of more than 100 different components. More than 90% of the dry weight is protein, comprising a variety of enzymes, non-enzymatic polypeptide toxins, and non-toxic proteins. Non-protein components include carbohydrates and metals (often part of glycoprotein

Fig. E15.1 **Sea snake: *Pelamis platurus*.**

metalloproteinase enzymes), lipids, free amino acids, nucleosides, and biogenic amines such as serotonin and acetylcholine.

- Proteinases act as cytotoxins, causing severe local swelling and tissue damage in the region of the bite.
- Neurotoxins interfere with neuromuscular transmission.
- Some phospholipase A2 toxins also directly damage myocytes and red blood cells (causing rhabdomyolysis and haemolysis).
- Some venoms contain haemorrhagins (metalloproteinases) that damage the vascular endothelium, causing systemic haemorrhage.
- Components of venom can act at many different sites in the coagulation pathways, resulting in anticoagulant or procoagulant effects.
- Venom components can also act directly on platelets.

Snake venoms are capable of producing adverse effects in one or more systems of the body. Most have multisystem effects. There are qualitative or quantitative variations in the chemistry of venoms in different snake species of the same family. Such differences may also occur within a species, depending on their geographical distribution.

Clinical features

The clinical effects of snakebite envenoming will vary with the species of snake, its age, size and geographical origin, the quantity of venom injected, the route of injection, the age, size and previous health of the victim, and past exposure to venom. Accurate identification of the biting species, ideally by examination of the dead snake, is crucial. Care should be taken; however, when examining a dead snake, as a reflex bite can still occur. Careful clinical evaluation of the patient is necessary before treatment is administered because bites by venomous species do not always result in envenoming ('dry bite').

Envenoming may cause both local and systemic effects. Elapid snakes (kraits, cobras) most commonly cause neurotoxicity whereas viperine snakes (vipers, pit vipers, rattlesnakes, adders) cause local tissue damage and coagulopathy. However, this distinction may be blurred; for example, Australasian elapids may cause both neurotoxicity and coagulopathy.

Local effects

- ***Oedema*** at the site of the bite, which may spread to involve the whole limb.
- ***Tissue necrosis*** at the site of the bite (Fig. E15.7).
- ***Painful regional lymph node enlargement***—a common early sign of envenoming.

Systemic effects

- ***Coagulopathy and haemorrhage*** include bleeding from the gums and other sites (Fig. E15.8). Bleeding may occasionally be life-threatening.
- ***Shock*** may occur as a result of loss of fluid into a limb or haemorrhage.
- ***Neurological involvement*** classically causes progressive descending paralysis. Ptosis (Fig. E15.9) occurs initially; this progresses with involvement of bulbar muscles and, ultimately, paralysis of the diaphragm.
- ***Skeletal muscle necrosis*** leads to painful myopathy, myoglobinuria, and paralysis. This complication is especially seen following envenoming by sea snakes.
- ***Renal failure*** occurs due to envenoming by several species, such as Russell's vipers.

Management

First aid

- Reassurance should be given, as even the most venomous species often bite without injecting enough venom to be harmful.
- Immobilization of the patient, especially of the bitten limb, to slow venom spread is the most important component of first aid.
- Pressure immobilization can reduce systemic spread of large-molecular-weight neurotoxins and delay the onset of life-threatening neurotoxicity. The technique requires training and the appropriate equipment in order to avoid aggravating soft tissue injury from local envenoming. The entire limb is bandaged 'as tightly as for a sprained ankle', starting around the fingers or toes and finishing at the axilla or groin using stretch bandages, crepe, and a splint. Pressure immobilization should be used in all cases unless the snake has not been identified or it is clear that the patient was bitten by a large viper, as development of severe local swelling may compromise the circulation.
- Transport of the victim to a medical centre should take place as quickly, safely, and passively as possible.
- Traditional methods, such as incision, suction, tourniquet, electric shock, cryotherapy, instillation of chemicals, and snake stones, are useless and harmful.
- Avoidance of aspirin and NSAIDs is important, as they may aggravate bleeding.
- The biting snake is valuable evidence but should not be pursued or handled carelessly.

Hospital treatment

Hospital treatment involves rapid clinical assessment, resuscitation, and administration of antivenom, the only specific treatment for envenoming. Wherever possible, the priority is to assess critically and stabilize vital systems. Attention to airway, breathing, and circulation should take priority.

Diagnosis

There are three principal diagnostic questions:

- Is this a snakebite?
- If it is, is there significant envenoming?
- What snake species was responsible?

In the history, three preliminary questions should be asked of the victim:

- Which part of your body was bitten?
- How long ago were you bitten?
- Have you brought the snake along, and if not, can anyone describe it?

Look for circumstantial evidence if the answers are not clear.

Immunodiagnostic tests that can identify the offending species by detecting specific snake venom antigens in wound swabs, serum, urine, or other body fluids are not widely available.

Fig. E15.7 **Severe local effects of envenomation.**

Fig. E15.8 **Bleeding following snakebite.**

Fig. E15.9 **Neurological symptoms following snakebite.**

Investigations

The white blood count is commonly elevated and thrombocytopenia is often seen, particularly in patients with coagulopathy. Renal function should be assessed. Creatine kinase levels are elevated when myotoxicity occurs. The 20-minute whole-blood clotting test (20 WBCT) is a good bedside indicator of envenoming by species that cause coagulopathy. Blood left in a clean, dry, glass tube is examined after 20 minutes to see whether clotting has occurred. The test may also be used to assess response to treatment with antivenom.

Antivenom

Antivenom is indicated for the treatment of systemic or severe local envenoming. A delay in administration reduces its efficacy, but antivenom may remain useful for as long as signs of systemic envenoming persist. The antivenom used depends on the biting species. In many parts of the world, polyspecific antivenoms covering locally occurring snake species are employed. This is because the biting species is only rarely identified. Monospecific/monovalent antivenoms can be used only if the snake has been positively identified, either by direct identification if the offending snake is brought to hospital or by detection of venom antigens in body fluids using immunodiagnostic tests.

Indications for antivenom include:

- spontaneous systemic bleeding
- incoagulable blood based on the 20 WBCT or other laboratory tests (e.g., international normalized ratio, INR)
- shock, indicated by low or falling blood pressure or cardiac arrhythmia
- ptosis, diplopia, neck muscle weakness, paralysis of limb muscles, respiratory paralysis, altered sensorium
- black urine positive for blood/haemoglobin/myoglobin (indicating rhabdomyolysis or intravascular haemolysis)
- local swelling involving more than half the bitten limb, swelling after bites on the fingers and toes, or swelling after bites by species likely to cause necrosis.

Antivenom should be administered by slow intravenous infusion. The appropriate dose is dictated by local experience. The initial dose of antivenom depends on the type of antivenom, the offending snake species, and the severity of envenoming. Children require the same dose as adults. Reactions to some preparations of antivenoms are common and include life-threatening anaphylaxis. Test doses of antivenom do not reliably predict these reactions and have no role in management. Adrenaline (epinephrine) must be kept available whenever antivenom is administered, to treat possible anaphylactic reactions.

Antivenom only neutralizes circulatory venom and will not neutralize or combine with venom once the venom is attached to target organs: that is, platelets, red blood cells, vascular endothelium, renal tubules, muscles, or neuromuscular receptors. Effective antivenom treatment should halt the progression of symptoms and reverse coagulopathy within 6 hours of administration. The dose of antivenom should be repeated if life-threatening bleeding, shock, or paralysis persists a few hours after the first infusion, or if the blood remains incoagulable when retested after 6 hours. Most postsynaptic neuromuscular junction neurotoxins (cobra and krait) are neutralized by antivenom, but presynaptic neurotoxins (krait) are less responsive and may need supportive therapy.

Supportive treatment and treatment of complications

- ***Shock*** usually results from hypovolaemia (extravasation of blood into the bitten limb) and should be corrected with intravenous fluids.
- ***Respiratory failure*** from respiratory muscle paralysis should be treated with assisted ventilation (common in krait bite).
- ***Paralysis*** due to postsynaptic neurotoxicity may respond to anticholinesterases such as neostigmine.
- ***Tetanus prophylaxis*** should be given as per requirement.
- ***Acute renal failure*** may need dialysis (common after Russell's viper bites).
- ***Surgical complications*** include necrotic tissue, which should be debrided and split skin grafts should be applied. Compartment syndrome is uncommon. Fasciotomy is seldom necessary, even when there is severe oedema, the only indication being raised intra-compartmental pressure. Surgery should not be performed until coagulopathy has been corrected.

Prevention

Avoid contact with snakes, even harmless or apparently dead ones. Wear protective clothing (boots not open sandals, socks, long

trousers) when walking in the undergrowth or deep sand and carry a light at night. Avoid blindly putting hands or feet into termite holes and crevices in trees, bushes, and under logs. Sleep off the ground and ideally under a mosquito net to prevent nocturnal bites (kraits). Fishermen should not handle sea snakes trapped in fishing nets.

Plants

Life-threatening poisoning from plant ingestion is rare, though many plants contain potentially toxic substances. These include antimuscarinic agents, calcium oxalate crystals, cardiogenic glycosides, pro-convulsants, cyanogenic compounds, mitotic inhibitors, nicotine-like alkaloids, alkylating agent precursors, sodium channel activators, and toxic proteins (toxalbumins). While many plants contain gastrointestinal toxins, these rarely give rise to life-threatening sequelae. In contrast, other botanical poisons may cause specific organ damage, and death may occur from only small ingestions of yew (genus: *Taxus*), oleander (*Thevetia peruviana* and *Nerium oleander*), and cowbane *(Cicuta)*.

Atropa belladonna

Atropa belladonna (deadly nightshade) contains hyoscyamine (atropine) and hyoscine. It causes antimuscarinic effects—a dry mouth, nausea, and vomiting—leading to blurred vision, hallucinations, confusion, and hyperpyrexia.

Cicuta species

Cicuta spp. (water hemlock) and the related genus *Oenanthe* contain cicutoxin, a potent CNS stimulant that produces violent seizure activity. The CNS effects of cicutoxin are similar to those of picrotoxin, a known inhibitor of gamma-aminobutyric acid (GABA). Severe gastrointestinal symptoms, diaphoresis, salivation, and skeletal muscle stimulation may precede the seizure activity.

Conium maculatum

Conium maculatum (poison hemlock) contains a variety of volatile piperidine alkaloids, which have a toxic activity similar to that of nicotine. Large doses produce non-polarizing neuromuscular blockade, which may result in respiratory depression and death.

Datura stramonium

Datura stramonium (jimsonweed) and other *Datura* spp. contain hyoscyamine (atropine) and hyoscine. These alkaloids are potent antagonists of acetylcholine at muscarinic receptors and produce the anticholinergic syndrome. While morbidity is significant, fatalities are rare and are the consequence of hyperthermia, seizures, and/or arrhythmias.

Digitalis purpurea, Nerium oleander, Thevetia peruviana (yellow oleander)

Ingestion of *Digitalis purpurea* (Foxglove) or the common oleander *(Nerium oleander)* or yellow oleander *(Thevetia peruviana)* can produce a syndrome similar to digoxin poisoning (see 'Digoxin' section). A randomized controlled trial has shown that digoxin-specific antibody fragments can rapidly and safely reverse yellow oleander-induced arrhythmias, restore sinus rhythm, and rapidly reverse bradycardia and hyperkalaemia. The administration of multiple doses of activated charcoal is used but the effect on survival is debated.

Singh M, Routledge PA. Poisoning by toxic plants and fungi. *Medicine* 2020; 48(3):218–219.

Mushrooms

Poisoning due to mushrooms is usually accidental, though ingestion of hallucinogenic ('magic') mushrooms is invariably intentional.

Cytotoxic mushrooms

Cytotoxic mushroom poisoning is caused by the amatoxins and orellanin. Amatoxins are found in *Amanita phalloides*, *A. virosa*, and *A. verna*, and in some *Galerina* and *Lepiota* spp. Amatoxins inhibit transcription from DNA to messenger RNA (mRNA) by the blockade of nuclear RNA polymerase II; this results in impaired protein synthesis and cell death.

Clinical features and management

Intense watery diarrhoea starts 8 to 24 hours after ingestion and persists for 24 hours or longer. Patients often become severely dehydrated. Signs of liver damage appear during the second day and hepatic failure may ensue. Impaired kidney function is often seen both because of fluid loss and as a result of direct kidney injury. In all patients, fluid, electrolyte, and acid–base disturbances should be corrected and renal and hepatic function supported. The value of silibinin and benzylpenicillin is not proven. Occasionally, liver transplantation is necessary.

Gyromitrin poisoning

Gyromitrin is found in *Gyromitra* spp., including in particular the false morel *(Gyromitra esculenta)* and *Cudonia circinans*. Gyromitrin decomposes in the stomach to form hydrazines that inhibit pyridoxine kinase and thus produce functional pyridoxine deficiency. GABA deficiency ensues since pyridoxine is an essential co-factor in GABA synthesis. Seizures may result. Hydrazines also cause haemolysis, methaemoglobin formation, and hepatorenal toxicity.

Clinical features and management

Vapours from the mushrooms are irritating to the eyes and respiratory tract. Gastrointestinal symptoms appear 5 to 8 hours after exposure. Vertigo, sweating, diplopia, headache, dysarthria, incoordination, ataxia, and seizures may follow. Symptomatic and supportive care is required. Pyridoxine 25 mg/kg as an infusion over 30 minutes should be given if severe CNS toxicity develops; repeat doses may be required.

Hallucinogenic mushroom poisoning

Psilocybin produces pharmacological effects similar to those of LSD and is found in *Psilocybe* and *Panaeolus* spp.

Clinical features and management

Symptoms occur within 20 to 60 minutes. Effects include altered time and space sense, depersonalization, hallucinations, derealization, and euphoria. Symptoms are usually maximal within 2 hours and disappear within 4 to 6 hours, though 'flashbacks' may recur after weeks or months. Anxiety and agitation should be treated with diazepam, 10 to 20 mg i.v., repeated as necessary.

Isoxazole poisoning

Isoxazoles (e.g., ibotenic acid, muscimol, muscazone) occur in *Amanita muscaria* and *A. pantherina*, and act as GABA agonists.

Clinical features and management

Nausea, vomiting, inebriation, euphoria, confusion, anxiety, visual disturbances, and hallucinations occur often within 30 minutes. Drowsiness is common and a coma-like state may ensue. Severe agitation and violent behaviour are seen occasionally. Other features include myoclonic jerks, muscle fasciculation, and seizures. Symptomatic and supportive care should be given as necessary. Diazepam 10 to 20 mg i.v., repeated as required, should be administered for anxiety, agitation, and seizures.

Neurotoxic mushroom poisoning

Muscarine is found in, for example, *Inocybe* spp., *Clitocybe* spp., and *Mycena pura*. Muscarine stimulates cholinergic receptors in the autonomic nervous system.

Clinical features and management

Diarrhoea, abdominal pain, diaphoresis, salivation, lacrimation, miosis, bronchorrhoea, bronchospasm, bradycardia, and hypotension occur. Atropine 0.6 to 2 mg i.v. should be given to manage the cholinergic syndrome.

Orellanin poisoning

Orellanin is a potent nephrotoxin found in, for example, *Cortinarius orellanus* and *C. speciosissimus*. A metabolite of orellanin inhibits protein synthesis in the kidneys.

Clinical features and management

Symptoms are typically delayed for 2 to 4 days. Some patients suffer a mild gastrointestinal disturbance before developing signs of renal impairment, headache, fatigue, intense thirst, chills, myalgia, and abdominal, lumbar, and flank pain. Transient polyuria with proteinuria, haematuria, and, characteristically, leucocyturia is followed by oliguria and then anuria. Renal function may recover only partially; chronic kidney disease is reported in about 10 to 40% of cases. Management involves careful monitoring and haemodialysis/haemofiltration if renal failure supervenes.

CORE SKILLS AND KNOWLEDGE

Environmental emergency medicine studies the challenge to the human body when it interacts with the physical world. Healthcare professionals operating in these situations should be trained to perform in stressful conditions with minimal support and limited resources. Doctors specializing in this field often have backgrounds in emergency medicine, pre-hospital care, expedition, and military medicine. This chapter explores the physiology, pathophysiology, and management of environmental emergencies. It will consider when adaptation is possible and the nature of illness when the body is subjected to excessive environmental stress. Climate change is causing more extreme weather events, exposing whole populations to heat, cold, and flooding. Many of those most affected live in deprived communities. Ease of global transportation has brought people into environments with which they are unfamiliar.

Key learning outcomes include:

- Understanding how the physical environment impacts normal human physiology.
- Explaining how the body can acclimatize to different environments.
- Recognizing common illness and injury caused by excessive environmental stress.
- Formulating management plans for common environment medical emergencies.

The life-threatening conditions described in this chapter occur with different frequency. For example, drowning is a common worldwide problem, whereas acute high-altitude cerebral oedema (HACE) is rare. **Box 16.1** describes 10 fatal conditions in environmental emergency medicine.

Box 16.1 Fatal conditions in environmental emergency medicine

Environment	Life-threatening condition
Altitude	High-Altitude Cerebral Oedema High-Altitude Pulmonary Oedema
Water	Drowning Arterial Gas Embolus—in divers
Cold	Hypothermia
Heat	Heat Stoke Hyponatraemia—due to excessive water intake
Physical	Lightning Strike
Ionizing Radiation	Acute Radiation Sickness—in high dose exposure Increased risk of malignancy—medical radiation

CLINICAL SKILLS

The conditions seen in environmental medicine affect many body systems and require broad expertise in clinical medicine. Much of the initial management takes place in the pre-hospital outdoor environment. The practitioner must be able to assess the situation for danger and manage the associated risk. Training to work in different austere pre-hospital situations is essential (**Fig. 16.1**).

History

The diagnosis depends on a careful, detailed history. This must consider the environment and the patient's activity, as well as relevant features of the patient's previous medical problems and physical fitness. In a challenging pre-hospital setting, history-taking may be difficult; however (as in other fields of medicine), it is almost always more helpful for diagnosis than examination, and if curtailed by circumstances, it should be completed as soon as possible once the situation allows.

Fig. 16.1 **Rescue of a hypothermic patient.**

Box 16.2 Patient assessment in environmental medicine

Assessment of the scene
- Danger to yourself, others, casualty
- Weather
- Terrain

Primary Survey
- The aim is to identify life-threatening conditions, start initial essential treatment, and obtain baseline observations.
- Safety
- Patient Response: conscious/unconscious
- C—Catastrophic life-threatening bleeding
- A—Airway
- B—Breathing
- C—Circulation
- D—Conscious level
- E—(In this context) Environment protection.

History Taking
- A history of the events leading up to the injury or illness with a chronological account of progress
- Activity profile of the casualty, for example, dive profile, ascent profile
- Nutritional status—recent food and fluids
- Clothing and protective equipment
- Result of any recent acclimatization, for example, heat, altitude
- Previous exposure to the conditions, for example, altitude
- Current medication
- Immunization in foreign countries
- Medical insurance—evacuation, in-country treatment, repatriation
- The examination will focus on the signs most relevant to the case and the context.

Examination

This can be difficult and limited by the situation. Wind masks subtle breath sounds, vasoconstriction inhibits some cardiovascular signs, altitude alters physiological observations, and removing the patient's clothing for examination may not be possible in some situations. Box 16.2 outlines special considerations for patient assessment in environmental medicine.

There are often no investigations or imaging to support initial diagnosis or treatment decisions. Resources may be limited and successful management requires a flexible and pragmatic approach. The time to reach definite care can be hours or days. Good communication and team work are essential.

The integration of skills required for successful management in the outdoors is illustrated in Figs. 16.2 and 16.3.

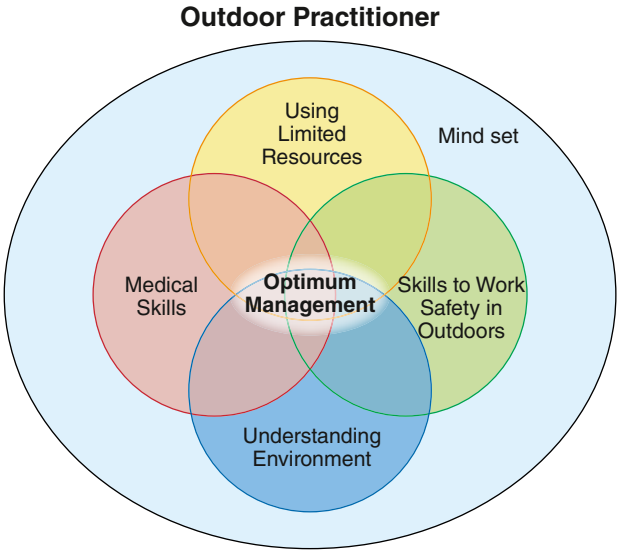

Fig. 16.2 **Skills required for environmental emergency medicine.**

AVIATION AND SPACE

Aviation and space medicine takes a holistic approach to consider the health, performance, and safety of those who travel in air or space. At the heart of aviation and space medicine is the management of human risk in the extreme environments of aviation and spaceflight. The main areas of activity are providing clinical medicine in a flight environment, understanding how flight or space travel may affect human performance, and human factors engineering (designing the human into the system).

The challenges vary between operational settings but include reduced barometric pressure (hypoxia, decompression sickness, gas volume changes), increased forces of acceleration, increased radiation exposure, thermal stress, motion sickness, noise, vibration, spatial disorientation, and circadian dysrhythmia. Additionally, in space, there are challenges associated with weightlessness that affect all body systems and drive a requirement for various countermeasures including regular resistance and aerobic exercise.

Environmental challenges in flight may cause new medical issues or exacerbate pre-existing conditions. As well as managing medical problems in individual patients, an assessment must be made of how a medical emergency might affect others on the flight: ***Flight safety critical emergencies*** describe situations where medical incapacitation of the individual might impact flight safety. They require the definition of acceptable medical risk and standards depending on the individual's role, for instance, as pilots, cabin crew, air traffic controllers, and drone or remotely piloted aerial system operators. ***Non–flight safety–critical emergencies*** affect passengers, aeromedical evacuation patients, and their clinical teams, where there is no threat to the safety of the whole flight.

Fitness to fly

Billions of people fly by air as passengers every year. Therefore, it is useful for all doctors to have some awareness of fitness-to-fly considerations for passengers and patients, although the ultimate decision on fitness to fly is the responsibility of the

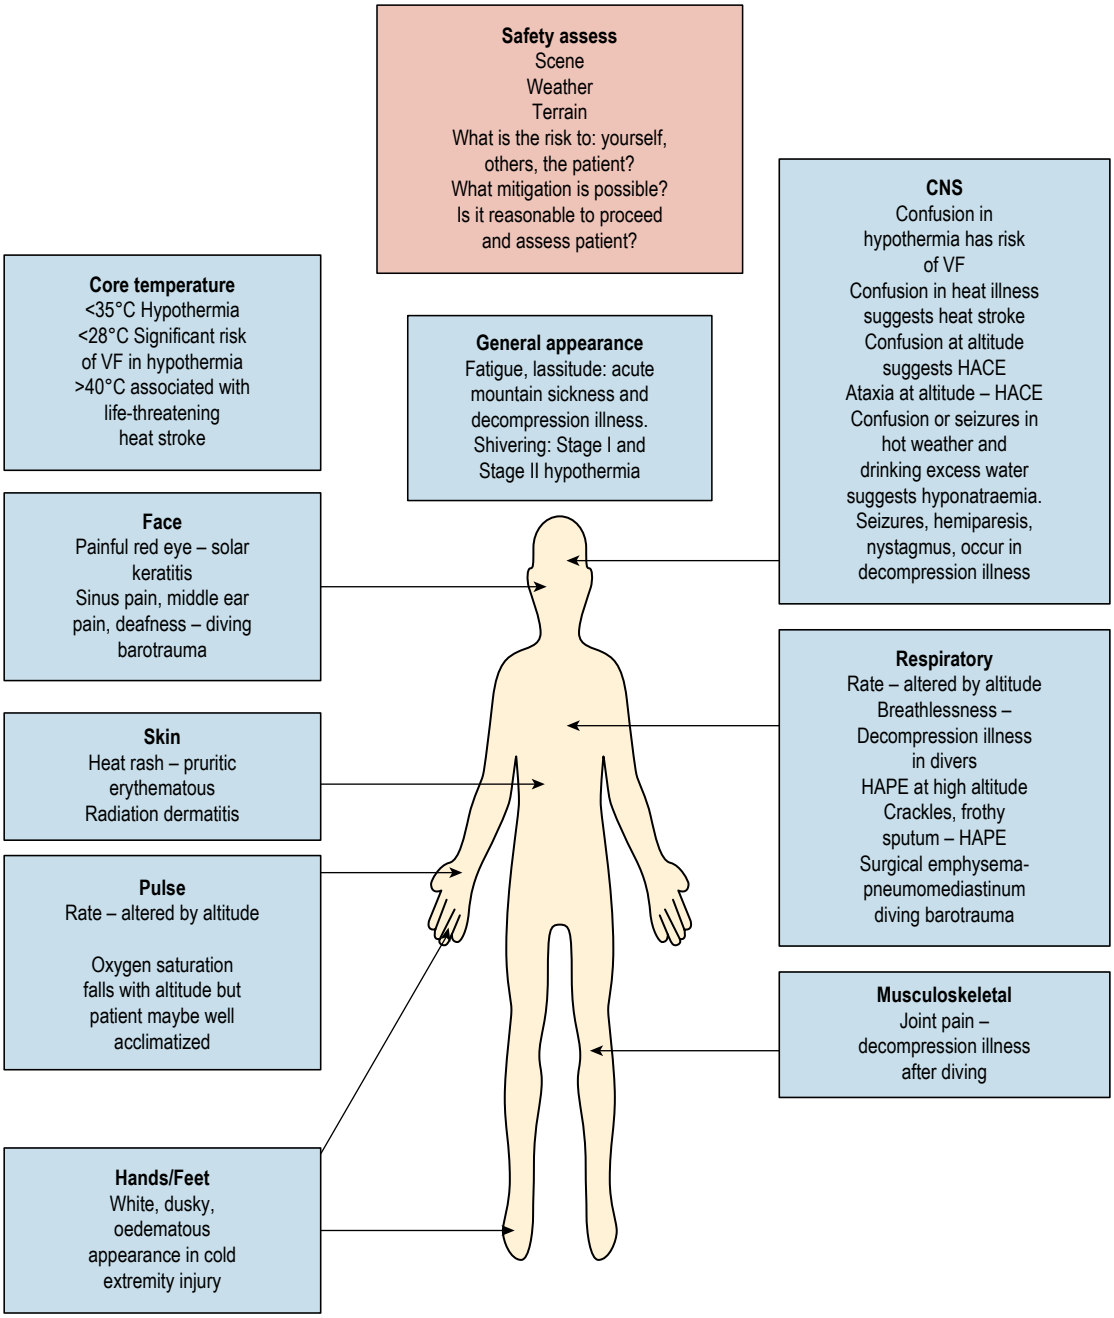

Fig. 16.3 **The examination of a patient in environmental medicine.**

airline, and patients with questions about fitness-to-fly should be directed to contact the airline medical officer. A patient's treating doctor may be asked, subject to patient consent, to complete a Medical Information Form (MEDIF) by the airline medical officer. This form is specific to each airline but describes the patient's clinical condition, course, treatment, and complications and is used to inform the fitness-to-fly decision. The treating doctor does not require any aviation medicine knowledge to fill it in. More information can be obtained by consulting their local aviation authority advice (e.g., UK Civil Aviation Authority website).

Pilots and cabin crew fitness-to-fly considerations are dealt with by doctors with specialist training in aviation medicine, called Aeromedical Examiners (AMEs), who work on behalf of the aviation regulatory authorities.

Specific considerations for air travel

- Standard travel health considerations such as vaccination or malaria prophylaxis should be considered, depending on destination and planned activities.
- Commercial aircraft expose people to an atmospheric pressure equivalent to approximately 1500 to 2500 m (5000–8000 feet). This induces a mild degree of hypoxia, meaning that patients with cardiorespiratory compromise may need to consider flying with supplemental oxygen, and some patients will need to travel with their non-invasive ventilation equipment. It is critical the

battery supply is sufficient to last 1.5 times the flight duration in case of delay or diversion.
- Deep vein thrombosis risk should be considered in passengers in the context of prolonged immobility on long haul flights.
- Patients should carry sufficient medication for the flight and a supply for use on arrival in case their hold luggage is lost. This may require that a doctor's letter be provided to accompany the medication at security checks.
- All travellers should be encouraged to have travel insurance to cover overseas medical costs in the event of a medical problem and to cover the cost of flight home, which might need the inclusion of an aeromedical escort team. Patients must declare pre-existing medical conditions for many of these travel insurance policies to be valid. Travel insurance companies have medical teams that can provide advice and help to arrange flights home.
- Medical conditions may restrict pilots from flying. Some of these will be similar to driving restrictions, for example, around epilepsy or diabetes. It is the pilot's responsibility to discuss new or ongoing medical conditions and treatments with regulatory authorities regarding their fitness to fly.

Astronauts are dealt with by flight surgeons with specialist space medicine training at government agencies such as the European Space Agency or in commercial companies such as SpaceX.

HIGH ALTITUDE

Physiology

The challenges of high altitude are caused by the low partial pressure of gases in the atmosphere, cold, and increased exposure to solar radiation.

The partial pressure of oxygen decreases with a fall in barometric pressure. This is dependent on latitude, the season, and local weather conditions. Although the concentration of oxygen throughout the troposphere is 21%, barometric pressure directly determines the inspired PO_2. At higher altitudes as barometric pressure falls, there are fewer oxygen molecules in each breath, so less available to bind to haemoglobin, and tissues become hypoxic. This decreases exercise performance and increases risk of altitude illness. The general effects on the human body are summarized in **Box 16.3**, which lists the effects of ascent in altitude.

At the summit of Mount Everest (Chomolungma, Sagarmatha) (8848 m) the barometric pressure is 34 kPa (253 mmHg). Arterial blood sampled from climbers near the summit in 2007 demonstrated a PO_2 of 3.3 kPa (24.6 mmHg) in acclimatized climbers and an alveolar PO_2 of 4.0 to 4.7 kPa (30–35 mmHg)—near the limit of human physiology.

Box 16.3 Effects of ascent in altitude

Altitude above sea level	Effect on human body
High altitude, 2500–3500 m (European Alps)	Illness occurs with rapid ascent Decreased exercise performance
Very high altitude, 3500–5800 m (Mt Blanc—4809 m)	Illness will occur without acclimatization Decreased exercise performance Extreme hypoxia possible with exercise and sleep
Extreme altitude, >5800 m Mt Everest (Chomolungma, Sagarmatha)—88849 m	Complete acclimatization is generally not possible Rapid ascent causes severe and life-threatening disease Progressive physical deterioration

Box 16.4 Physiological changes with altitude acclimatization

System	Start duration	Adaptive change during acclimatization
Respiratory	Immediate Days	Increase in ventilation (hypoxic ventilatory response) with a fall in $PaCO_2$ and rise in PaO_2
Renal	24–48 h Days	The kidneys excrete bicarbonate to normalize the pH over 6–8 days
Cardiac	Immediate Days	There is an increased cardiac output; this returns to normal with acclimatization
Haemopoietic	Days Weeks	Increase in red cells and haemoglobin over 2–3 weeks, increase in 2,3 diphosphoglycerate with right shift of oxygen dissociation curve

Acclimatization

There are adaptations in many body systems during acclimatization to altitude that mitigate the effects of hypoxia caused by a fall in the partial pressure of oxygen. Despite this improvement, individuals still do not achieve the level of performance they could achieve at sea level. **Box 16.4** describes the physiological changes with altitude acclimatization.

Accent profiles

Acclimatization is supported by a suitable rate of ascent. The rate should be guided by the principle of ascending to a sleeping height of no more than 300 to 500 m per day (above previous sleeping height) when over 3000 m. Greater height can be gained during the day if the sleeping height is not exceeded. A rest day each 1000 m or 3 to 4 days should be added to allow for acclimatization.

Altitude illness

Clinical features

Acute mountain sickness (AMS), high-altitude cerebral oedema (HACE), and high-altitude pulmonary oedema (HAPE) are the three conditions associated with acute exposure to altitude.

People who normally reside at low altitudes and who ascend for leisure or work can be affected. The incidence depends on many factors including the rate of ascent, previous exposure to high-altitude environments, duration of stay, and genetic factors. Altitude illness usually occurs at more than 2500 m but can affect those with pre-existing conditions at lower altitudes. All these conditions respond to descent in altitude.

Acute mountain sickness

AMS is a clinical syndrome characterized by the symptoms of headache, plus fatigue, nausea, anorexia, lassitude, or poor sleep. This generally starts within 4 to 6 hours of arrival at altitudes above 3000 m and occurs in 10% to 25% of unacclimatized people travelling to areas above 2500 m. Treatment is rest, simple analgesia, and no further ascent. Symptoms usually resolve within 24 to 36 hours. These symptoms can mimic other conditions such as dehydration, carbon monoxide poisoning, and migraine, but at altitude, they should be considered to be AMS until proven otherwise. If symptoms persist or progress, descent is indicated. Prophylactic treatment using acetazolamide has been shown to reduce symptoms but is not a substitute for slow ascent and physiological acclimatization. Acetazolamide is a carbonic anhydrase inhibitor that promotes ventilation by inducing a mild metabolic acidosis through increasing urinary bicarbonate excretion. Dexamethasone prevents AMS and can reduce symptoms but does not facilitate acclimatation. Supplementary oxygen relieves symptoms.

Acute high-altitude cerebral oedema

This is a life-threatening illness with a similar pathophysiology to AMS. It is the least common of the three conditions, but death can occur within hours of onset. There is cerebral dysfunction often with ataxia and a change in the level of consciousness; coma and death may follow. Immediate descent is indicated and is lifesaving. Dexamethasone and oxygen should be administered if available. If descent is impossible (weather, terrain), a portable hyperbaric chamber may be used while rescue is organized. Long-term effects such as ataxia and cognitive impairment have been reported.

Acute high-altitude pulmonary oedema

This is a life-threatening condition of the lungs with raised pulmonary venous pressure and impaired alveolar gas transfer. Some individuals are HAPE susceptible. Untreated HAPE has a 50% mortality. It typically occurs 2 to 5 days after ascent and is characterized by breathlessness at rest, decreased exercise tolerance, tachypnoea, and crackles in the lungs. There may be a dry cough, followed by the production of frothy sputum. Immediate descent is indicated. Oxygen should be given if available. The use of nifedipine, sildenafil, and beta-agonists in the acute phase has been shown to be beneficial.

The portable high-altitude chamber

A portable chamber is made from an air-tight material and fitted with a pressure release valve that can be inflated to higher than external atmospheric pressure (Fig. 16.4). It can be used in high-altitude emergencies as a temporary life saving measure while evacuation to a lower altitude is organized. Pumping the chamber generates a pressure of 13.7 kPa above ambient pressure and simulates a descent of about 900 to 1200 m.

Fig. 16.4 **A portable high-altitude chamber in use in Nepal.**

Other effects of high altitude

Solar keratitis

'Snow blindness' is a painful burn of the cornea caused by exposure to UV light without adequate protection (Fig. 16.5). It renders sufferers 'snow blind' and makes movement impossible on difficult terrain. Recovery is spontaneous over 2 to 3 days and analgesia is likely to be required. Prevention is by wearing sunglasses.

Retinal haemorrhage

Small flame haemorrhages within the retinal nerve fibre layer are common above 5000 m and often asymptomatic. Rarely will a haemorrhage cover the macula, causing painless loss of central vision. Recovery is usual.

Physical deterioration

Prolonged residence between 6000 and 7000 m leads to weight loss, anorexia, and listlessness after several weeks. Over 8000 m, the effects of deterioration become apparent over several days.

Chronic mountain sickness

Chronic mountain sickness occurs in long-term residents at high altitudes, usually after several decades, and is seen in individuals living in the Andes and in Central Asia.

Polycythaemia, lassitude, cyanosis, finger clubbing, congested cheeks and ear lobes, and right ventricular enlargement develop. Chronic mountain sickness is gradually progressive.

COLD ENVIRONMENTS

Physiology

The effects of cold can be divided into hypothermia (cooling of the whole body) and peripheral cold injury. There is limited physiological adaptation to cold, and prevention depends on appropriate clothing, food, and behaviour. Heat is lost to the environment by conduction, convection, radiation, and evaporation. The lowest temperature from which an adult has recovered from accidental hypothermia with good neurological outcome is a core body temperature (T_{Core}) of 13.7°C.

Hypothermia

Hypothermia is a fall in T_{Core} to less than 35°C below which normal muscular and brain function are impaired. It occurs when the cold challenge is greater than heat production and retention. Shivering is effective and increases temperature by 3–4°C per hour. However, it uses energy reserves and oxygen and stops below a T_{Core} of 30°C. Once shivering stops, the patient cannot independently restore their temperature. Brain metabolism falls by approximately 10% for each 1°C decrease in temperature. The faster this occurs, the greater the chance of a good neurological outcome. Hypothermia occurs in both urban and austere environments.

Urban

Hypothermia can occur if there is poor heating, inadequate clothing, and poor nutrition. Depressant drugs, alcohol, or intercurrent illness (such as hypothyroidism) may also contribute. It is commonly seen in social deprivation, as well as in the frail and the elderly. Older people have a diminished sense of cold and may have little insulating fat. Neonates and infants become hypothermic rapidly because of a proportionally larger surface area and less subcutaneous fat.

Austere environments

Accidental hypothermia

This occurs in challenging environmental conditions and is a danger for climbers, skiers, the military, and workers in the outdoors. Wet, cold conditions, with wind chill, physical exhaustion, injuries, and inadequate clothing, are contributory.

Cold water immersion

Hypothermia can develop following immersion for over 30 minutes in temperatures of 15 to 20°C. In water below 12°C the limbs rapidly become numb and weak. Cooling of the muscles and nerves causes weakness and loss of coordination. Drowning occurs from swim failure.

Clinical features of hypothermia

Mild hypothermia (T_{Core} 32–35°C) causes shivering, which can be painful. As the T_{Core} continues to fall, moderate hypothermia (28–32°C) causes impaired judgement, including lack of awareness of cold and drowsiness. In severe cases the risk of ventricular fibrillation increases significantly below T_{Core} of 28°C. Coma follows and death is due to cardiorespiratory arrest from dysrhythmia.

Pulse rate and blood pressure fall in hypothermia, but vital signs change at different absolute temperatures in different individuals. Cardiac output and cerebral blood flow fall, and respiration becomes shallow and slow. Muscles are stiff and there is a loss of coordination. In severe hypothermia, as coma ensues, pupillary and other brainstem reflexes are lost, and pupils become fixed and dilated. There is a shift of the oxygen dissociation curve to the left because of the reduction in the temperature of haemoglobin. An arterial blood sample from a hypothermic patient must be corrected for the patient's temperature prior to analysis. Dysrhythmias are common; atrial fibrillation, prolongation of the PR and QT intervals, and ventricular dysrhythmias all occur. Bradycardia with 'J' waves are pathognomonic of hypothermia but is uncommon.

Diagnosis

In rescue situations, the diagnosis of hypothermia is usually clinical because low-reading thermometers are rarely available and can be unreliable in field conditions. The Swiss Hypothermia Staging method describes clinical features that guide pre-hospital decisions and treatment. In the hospital a low-reading thermometer such as temperature probe placed in the lower third of the oesophagus should be used to measure core temperature. **Box 16.5** outlines the Swiss staging of hypothermia.

Field management

Swiss stage I

The patient is managed in a sheltered environment. Protection from wind and rain must be provided, wet clothing should be removed (if practical), and extra dry clothing should be added for insulation. Food and fluid should be provided, and the patient allowed to rewarm. Warm drinks do not warm the patient but boost morale and provide calories. There is little heat loss from radiation, because of cold vasoconstriction; therefore foil blankets may provide some shelter but do not rewarm the patient. Such patients may be able to self-evacuate to a safer situation.

Swiss stage II

Patients should be encouraged to stop exercise. Without shivering, these people cannot maintain a normal core

Box 16.5 The Swiss staging of accidental hypothermia

Swiss stage	Clinical features	Temperature range	Risk of hypothermic cardiac arrest
Stage I (Mild)	Conscious (GCS = 15, AVPU = A). Shivering	35–32°C	Low
Stage II (Moderate)	Impaired conscious level (GCS < 15, AVPU = Confusion, V or P). Shivering may or may not be present	<32–28°C	Moderate
Stage III (Severe)	Unconscious. Vital signs present on 1 min check	<28°C	High
Stage IV (Severe)	Apparently dead. No vital sign present on 1 min check	Variable <24°C	Very High
