Dermatology is primarily an outpatient specialty, although inpatient treatment is sometimes needed for severe inflammatory or infectious skin disease when associated with systemic symptoms. The demand for specialist care exceeds supply, and teledermatology has become an important means of triaging referrals and offering remote access to specialist advice. Dermatologists work in multidisciplinary teams with oncologists, pathologists, radiotherapists, and plastic or maxillofacial surgeons to provide diagnosis and treatment.

Key skills include:

- Examining the skin and describing common skin lesions and rashes accurately
- Understanding the management of common skin conditions, including acne, eczema, psoriasis, skin infections, and malignancies
- Recognizing life-threatening skin conditions, including skin cancers, severe drug reactions, and aggressive skin and soft tissue infections
- Understanding the role of topical therapies, phototherapy, and systemic drugs in the treatment of patients with skin diseases.

Dermatology is best learned by interviewing and examining patients in outpatient clinics and on surgical lists or in phototherapy and daycare units.

CLINICAL SKILLS

Skin conditions generally consist of ***lesions*** (lumps and bumps) and ***rashes***. Diagnosis is by taking a detailed history (Box 45.1) and examining the whole skin surface, as well as the hair, nails, and mucosal sites. Diagnostic accuracy can be increased by palpation (to assess depth of lesions) and by use of a ***dermatoscope*** (a handheld magnifying device with strong and sometimes polarized light). A dermatoscope (Fig. 45.1) can be used to assess the pigment and blood vessel components of skin conditions (Box 45.2). Irregular pigmentation and irregular or tortuous blood vessels can be seen in skin cancers. Benign conditions usually have regular pigment and blood vessels. Rashes are less often assessed by dermoscopy, but some specific features of rashes are described.

Box 45.1 Taking a history in dermatology

History of the presenting complaint

- Time course: duration, changes in distribution or appearance over time
- Local symptoms: itching, pain and tenderness, bleeding
- Involvement of mouth, nails, hair, or genitalia
- Provoking factors: temperature, sunlight, medication, stress
- Features of systemic inflammatory disease: malaise, fever
- Symptoms in other systems: eyes, joints, internal organs

Risk factors

- History of autoinflammatory or autoimmune disease
- Current and recent medications including supplements and recreational substances, previous history of drug allergy
- Family history of skin disease (e.g., psoriasis, skin cancer) and atopy
- Skin type, cumulative sunlight exposure, use of sunbeds
- Time spent in tropical countries or history of travel

Psychological factors[a]

- Depression and anxiety. Stressful events.
- Disturbed body image; effect on relationships and self-confidence

[a]Screening tools for psychological distress, such as the Patient Health Questionnaire-9 and Generalized Anxiety Disorder 7-Item, may be useful in assessment.

Box 45.2 Dermatoscopy terms

Dermoscopic terms	Seen in these conditions
Lines	Melanocytic naevi and melanoma
Reticular	Dermatofibroma, melanoma, and BCC
White	BCC
Leaf-like	Seborrhoeic keratosis
Cerebriform	Lentigo maligna
Angulated	
Clods	Growing naevi
Circumferential	Seborrhoeic keratosis
Brown, yellow, or orange	BCC
Blue	Melanoma
Pink	Haemangioma
Red/purple	
Dots	Melanoma, lentigo maligna
Grey	Seborrhoeic keratosis, actinic keratosis
White	
Circles	**Circles**
White	SCC, lentigo maligna
Pseudopods	Reed naevus
Structureless	**Structureless**
Brown-black	Dysplastic naevus, melanoma
Blue	Melanoma
Pink	Melanoma
White	Melanoma, dermatofibroma
Red	Actinic keratosis

BCC, Basal cell carcinoma; *SCC,* squamous cell carcinoma.

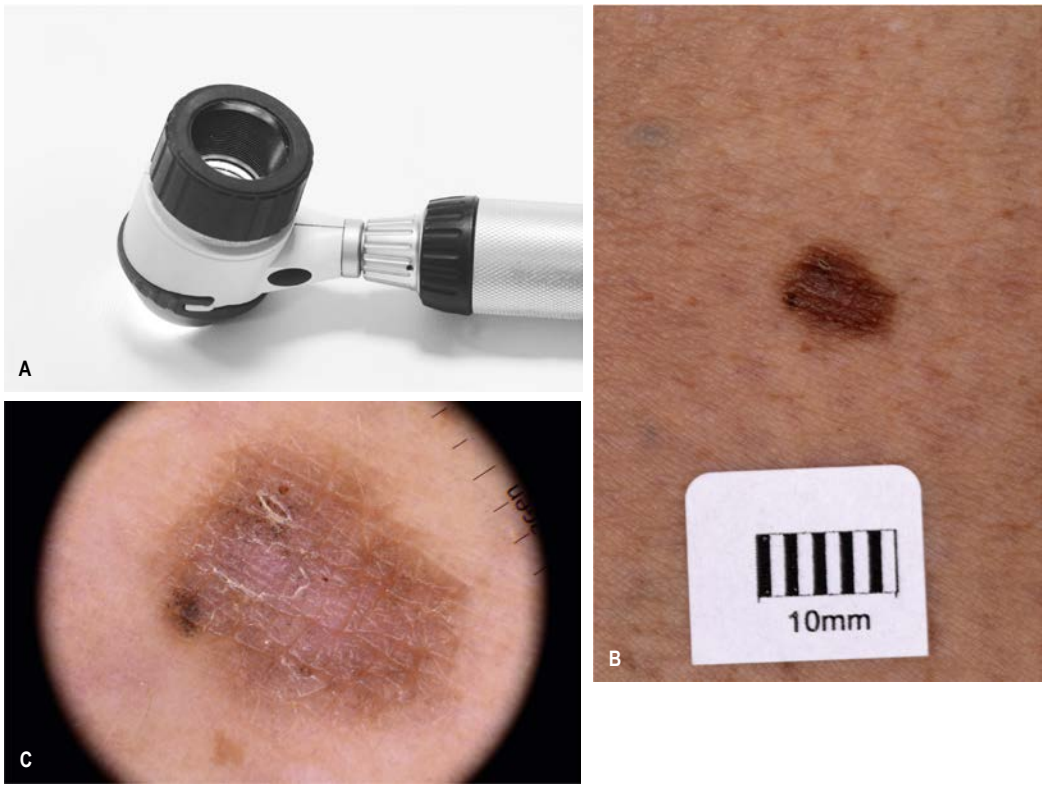

Fig. 45.1 **(A)** A dermatoscope. **(B)** Lesion without use of dermatoscope. **(C)** Same lesion seen through a dermatoscope. (*With kind permission from NHS Lanarkshire Medical Illustration Service.*)

The ***distribution*** (Box 45.3 and Fig. 45.2) and ***pattern*** (Fig. 45.3) of disease should be described. An algorithmic approach can be used to describe lesions and rashes (Fig. 45.4). Terminology used to describe the ***appearance*** of various types of rashes and lesions is discussed in Fig. 45.5.

- **Unilateral** or **bilateral**
- **Symmetrical** or **asymmetrical**
- **Acral** (primarily affecting the extremities, i.e., fingers, toes, nose, ears, and penis) or **truncal** (primarily affecting the torso)

BACKGROUND

Skin diseases affect people of all ages and are among the most common human ailments. Although rarely fatal, many are chronic and constitute a leading cause of disability worldwide. The World Health Organization (WHO) International Classification of Disease (ICD) 10 lists more than 1000 skin or skin-related diseases, but most burden comes from a few diseases (Fig. 45.6). These include eczema or dermatitis; acne; psoriasis; urticaria; and superficial fungal, bacterial (impetigo, cellulitis, abscesses), and viral infections (warts, molluscum contagiosum).

People with skin conditions might seek advice from various sources, including online resources, pharmacists, primary care practitioners, and specialists in intermediate or secondary care. The estimated number of people in European countries with skin conditions and the commonest of those skin conditions are summarized in Box 45.4.

The psychosocial impact of chronic skin disease should not be underestimated, including its effect on the family, work, education, recreation, and relationships. The dermatology life quality index (DLQI) is a simple validated tool for assessing health-related quality

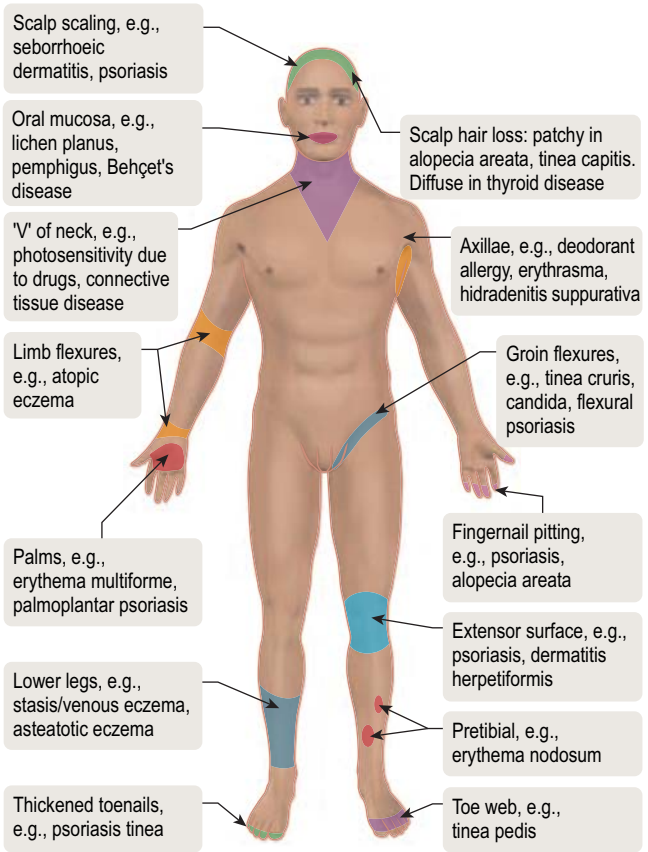

Fig. 45.2 Pattern of disease in different dermatological conditions.

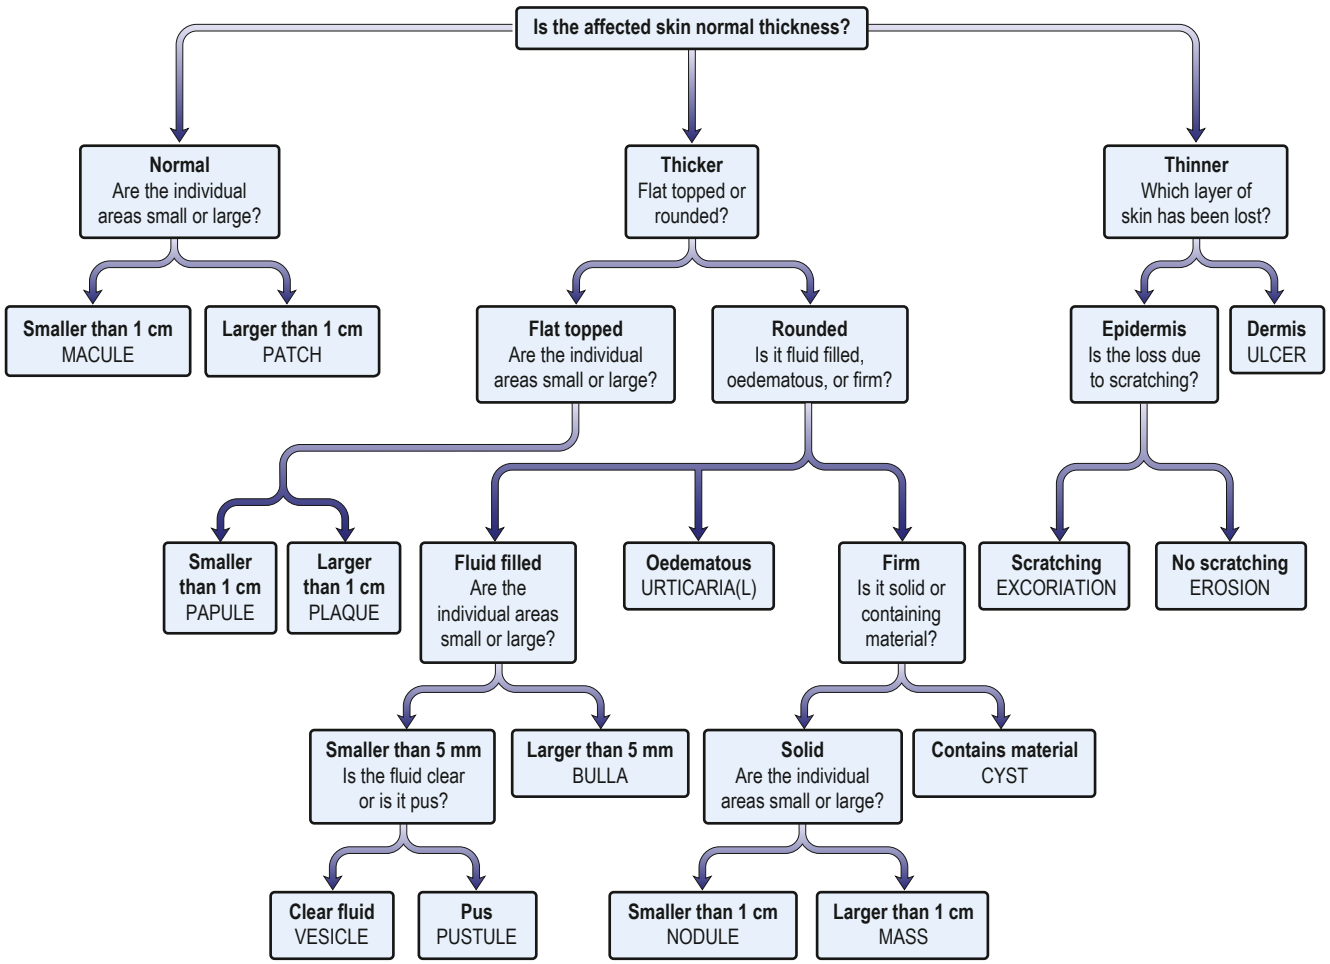

Fig. 45.4 Diagnostic approach to skin disease.

Nodule: a circumscribed, elevated lump in the skin greater than 1 cm. It can arise from the epidermis or dermis. This example is of nodular prurigo.

Papule: a circumscribed, slightly elevated lesion smaller than 1 cm diameter. This example is dermatosis papulosa nigra.

Macule: a completely flat lesion, altered in colour and smaller than 1 cm. This example is of solar lentigines.

Weal: a weal is due to localised dermal oedema. It is typically seen in urticaria.

Purpura: the extravasation of blood into the dermis. It is often due to injury to the blood vessels from inflammation.

Ecchymosis: bruising in the skin related to skin fragility or blood clotting disorders.

Crusting: a combination of an exudate (serous fluid) in combination with scaling. This example is impetigo.

Scaliness: looks like dry skin and indicates that the epidermis is affected by the condition. This example is seborrhoeic dermatitis.

Lichenification is the exaggeration of skin markings as a result of rubbing or scratching the skin. It is typically seen in chronic eczema.

Plaque: a circumscribed, palpable, raised lesion larger than 1 cm. It can arise from either epidermis or dermis. This example is of psoriasis.

Hyperpigmentation is darkening of the skin and is most often due to excessive melanin. It can also be due to deposition of iron or other pigments in the dermis.

Hypopigmentation is partial loss of skin colour. Depigmentation is total loss of colour as in this example of vitiligo.

Fig. 45.5, cont'd

A pustule is a circumscribed lesion containing pus. The pus can be infectious or it can be sterile and due to inflammation as in this example of pustular psoriasis.

A vesicle is a fluid-filled blister smaller than 5 mm. Vesicles can be solitary but are more likely to be multiple. This example is pompholyx.

A bulla is a fluid-filled blister bigger than 5 mm. This example is due to extreme insect bite reactions.

Ulcers typically involve loss of epidermis and dermis. This example is of pyoderma gangrenosum.

Erosions occur when the epidermis is damaged and lost but the dermis is intact.

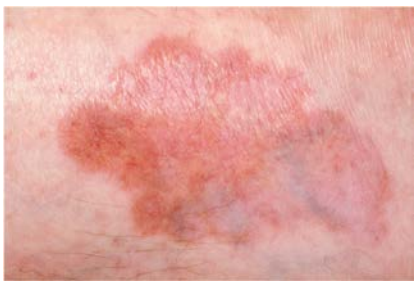
Excoriation is skin erosion due to scratching. In skin of colour there is loss of epidermal colour in the excoriated areas.

Petechiae are tiny red marks due to leakage from small blood vessels in the dermis. They do not blanche on pressure. This example is due to infective endocarditis.

Fissures are splits or cracks in epidermis and can be most commonly seen in the thick stratum corneum of the palms and soles.

Erythema is redness due to increased dermal blood flow. It blanches on pressure.

Telangiectasia are blood vessels which have enlarged enough to be visible. They may be part of a solitary lesion or be multiple as part of a systemic condition.



Atrophy is thinning of the dermis. In this example it is due to necrobiosis lipoidica with blood vessels visible through the atrophic dermis.

of life for patients with skin disease. Some skin diseases can have a greater impact on quality of life than even cardiovascular disease and cancers.

SKIN'S STRUCTURE AND FUNCTION

Understanding the structure and function of the skin helps make sense of the signs and symptoms of skin disease and can help to guide treatment.

The skin is composed of three distinct layers: the epidermis, dermis, and subcutis (**Fig. 45.7**). An overview of the functions of the skin is provided in **Box 45.5**.

Epidermis

The epidermis is the outermost layer. It functions as a renewable dynamic barrier against the environment and pathogens and plays an essential role in homeostasis. Its thickness ranges from 0.05 to 1.5 mm, depending on body site, and it is tethered to the underlying dermis by the dense protein network of the basement

membrane zone (BMZ; see Fig. 45.45). Inherited or autoimmune-induced deficiencies of BMZ proteins lead to fragility and blistering of the skin and mucous membranes (see 'Blistering and bullous skin disease' section). The epidermis is the source of the melanin that gives rise to skin colour.

Barrier functions of the epidermis

The epidermis is a ***stratified squamous epithelium*** composed mostly of ***keratinocytes*** (keratin-synthesizing cells) that originate from a proliferating ***basal layer***. They differentiate and migrate out to the surface to be shed as dead, flattened ***squames***. Epidermal differentiation is a highly complex process involving 'switching on and off' genes that regulate protein and lipid synthesis. Basal keratinocytes synthesize the ***keratin*** filaments of the cytoskeleton and desmosomal proteins (desmoplakin, desmoglein) for cell-to-cell cohesion. ***Lipids*** are synthesized in the granular layer and secreted to form a watertight intercellular layer. ***Filaggrin*** is expressed in the outer stratum corneum, where it acts as a 'natural moisturizing factor', keeping the skin hydrated and pliable.

The stratum corneum provides most of the skin's barrier function, and deficiency in filaggrin leads to 'leaky', dry skin that cracks, allowing entry of allergens and pathogens. Filaggrin gene mutations are common and have been identified as a major risk factor for atopic eczema and other atopic diseases. Changes in lipid and protease activity in the outermost epidermis lead to shedding (desquamation). The keratinocyte's journey from basal cell to skin surface normally takes about 30 days but is considerably faster in people with psoriasis and other conditions, leading to thickened, scaly skin.

Melanin-synthesizing ***melanocytes*** reside in the basal layer and transfer ultraviolet (UV)-protecting pigment to adjacent keratinocytes. The epidermis also contains nerve endings and sensory cells ***(Merkel cells)***.

Box 45.4 Prevalence of skin disease in European countries, including the UK

	12-month prevalence (%)
At least one skin complaint	50.9
Fungal infection	8.9
Eczema	5.5
Acne	5.4
Psoriasis	3.9
Rosacea	2.0
Urticaria	1.0
Non-melanoma skin cancer	1.1
Vitiligo	0.8
Malignant melanoma	0.6

Box 45.5 Functions of the skin

- Physical barrier against friction and shearing forces
- Protection against allergens, chemicals, and ultraviolet radiation
- Protection against infection (innate and acquired immunity)
- Prevention of excessive water loss or absorption
- Temperature regulation
- Ultraviolet-induced synthesis of vitamin D
- Wound healing
- Social and interpersonal function

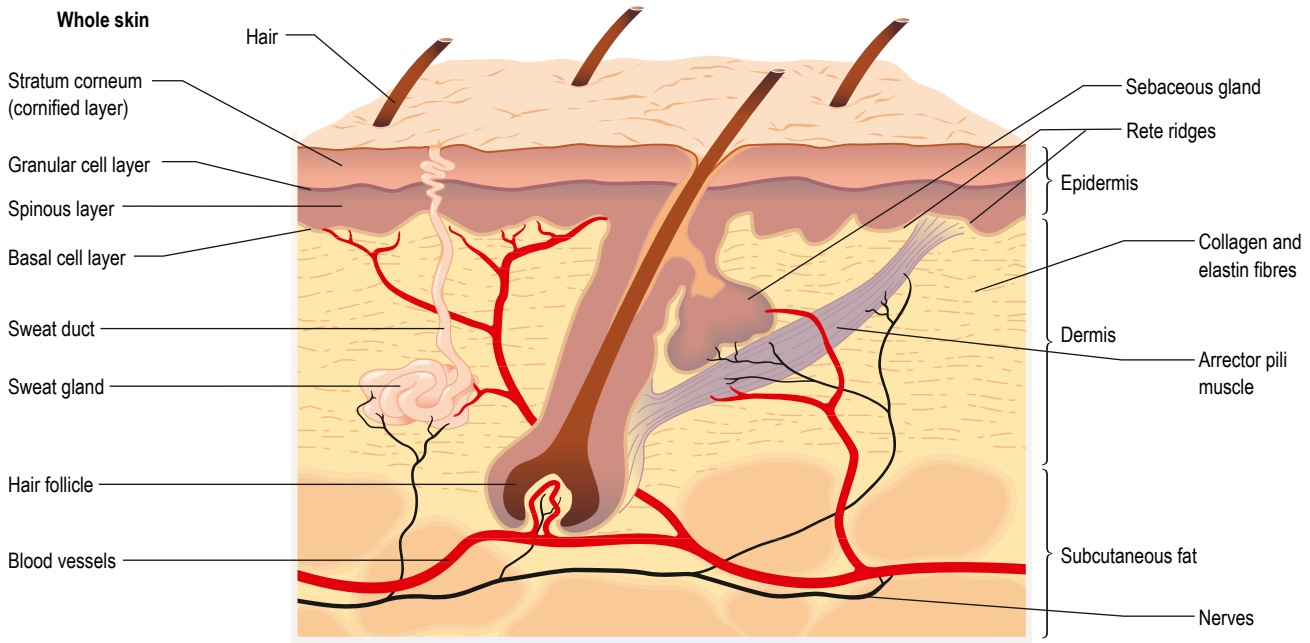

Fig. 45.7 The structure of the skin.

Immune functions of the epidermis

Keratinocytes also secrete cytokines, such as interleukins (ILs), interferon-gamma, and tumour necrosis factor-alpha (TNF-α), in response to injury; these cytokines stimulate wound healing and protect against microbial invasion. They also produce antimicrobial peptides that form part of the innate immune system. Deficiency of these peptides may increase susceptibility to staphylococcal and viral infection in people with atopic eczema. The epidermis contains a network of ***Langerhans cells*** (dendritic cells) that capture and process antigens for presentation to T lymphocytes.

Dermis

The dermis is a tough matrix of ***collagen*** and ***elastin fibres***, which give it strength, surrounded by a gel-like ground substance containing hyaluronic acid, proteoglycans, and glycoproteins, which forms a water-based environment that allows diffusion of molecules and provides compressive strength. It also contains cells (fibroblasts, mast cells, lymphocytes, and dendritic cells), blood and lymphatic vessels, nerves, muscle, and ***appendages*** (sweat glands, sebaceous glands, and hair follicles). The upper ***papillary dermis*** has finger-like projections that contain terminal capillary networks. The lower ***reticular dermis*** is thicker and denser.

Eccrine sweat glands are found throughout the skin, except for the mucosal surfaces, and carry out thermoregulatory sweating. ***Apocrine sweat glands*** are found in the axillae and anogenital area and do not function until puberty. ***Sebaceous glands*** are also inactive until puberty, when they excrete the oily substance sebum, under the influence of androgens. They are most numerous on the 'greasy' (seborrhoeic) sites of the central face, scalp, and upper torso. Sebum flows on to the skin surface via the pilosebaceous duct of the hair follicle. It contributes to skin barrier function and has antimicrobial actions.

The skin is richly innervated with ***sensory fibres*** (transmitting touch, pain, itch, vibration, pressure, and temperature) and ***autonomic fibres*** that innervate sweat glands, blood vessels, and arrector pili for thermoregulation.

Hair and nails

The skin surface is covered with ***hair***, except for the mucous membranes, palms, and soles. Hair grows from follicles, which are modified epidermal structures deeply rooted in the dermis. The lower portion of the hair follicle (bulb) surrounds a richly innervated and vascularized dermal papilla. Hair grows from the stem cells in the bulb, and if this area is damaged by an inflammatory process or trauma, it leads to permanent hair loss. Follicles go through a cycle of anagen (growth), catagen (involution), and telogen (shedding). At any one time, most hairs (>90%) will be in the anagen phase, which is usually 3 to 5 years for scalp hair. Miniaturization of coarse terminal scalp hairs with age leads to hair thinning, or baldness.

Nails are modified epidermal structures that contain specialized tough keratin proteins. It takes about 6 months to grow a fingernail and 1 year to grow a toenail.

Subcutis

The subcutaneous layer consists of lobules of adipose tissue separated by fibrous septa with sparse blood vessels and nerves. This layer provides insulation and cushioning against trauma.

INVESTIGATION OF SKIN DISEASE

The most common dermatology investigations used in dermatology are microbiological: microscopy and culture of microbial swabs, as well as fungal tests (mycology) of skin, hair, or nail clippings (**Box 45.6**). Histology is also carried out, when skin lesions are removed by shaving, curetting, or excision, depending on their depth and the suspected diagnosis. This can be done under local anaesthetic as an outpatient procedure. Immunofluorescence (IMF) tests on skin and serum are indicated in patients with suspected immunobullous diseases.

PRINCIPLES OF DERMATOLOGICAL THERAPY

Topical therapy

The skin is easily accessible to topical therapy, and this is an effective and generally safe way of treating many rashes (and some low-grade malignancies) with a reduced risk of systemic adverse effects compared with oral therapy. Attention to cosmetic acceptability, clear instructions about how and when to apply (**Box 45.7**), duration of treatment, and anticipated effects (including how quickly the condition should settle and the likely side-effects) optimize patient adherence. It is helpful to specify quantities in simple terms, such as a 'pea-sized' portion to treat half a face or the 'fingertip unit' for topical corticosteroids in eczema management.

Box 45.6 Common dermatological investigations

- Microbial swabs: bacterial and fungal (impetigo, folliculitis, candida); viral swab (herpes simplex virus, varicella zoster virus)
- Mycology (fungal studies) of plucked hair or scalp brushings (tinea capitis)
- Mycology of nail clippings (onychomycosis)
- Mycology of skin scrapings (tinea, pityriasis versicolor)
- Skin biopsy (histology, immunohistochemistry, direct immunofluorescence, culture)
- Blood tests (routine bloods, inflammatory markers, autoantibodies, indirect immunofluorescence)
- Urinalysis (glucose, red cells) and urine microscopy (red cells, casts)
- Patch tests for allergic contact dermatitis

Box 45.7 How to use topical treatment

Topical treatment instructions	Examples of instructions	Example of treatment type
What to apply	Ointment on trunk and limbs Lotion on scalp Shampoo on body for 1 minute	Emollient Topical steroid Antifungal shampoo
Where to apply	On the affected skin On the affected zone From the neck down On the whole skin	Topical steroid Acne treatment Scabies treatment Emollients
How much to apply	A fingertip unit covers an area the size of a palm Until the skin is shiny	Topical steroid Emollients
How often to apply	Once daily Two to four times daily As often as needed	Topical steroid Emollients Anti-itch creams
When to apply	Last thing at night After bathing When going outside	Topical steroid Emollients Sunblock
Specific instructions	Apply in direction of hair growth 30 minutes before going to bed Keep away from dogs Leave on for 2 hours Avoid touching mucosal sites	Ointments Benzoyl peroxide 5-Fluorouracil cream Topical psoriasis treatment Capsaicin cream

Topical medicaments consist of an ***active ingredient***, in a ***vehicle*** or ***base***, and ***excipients*** such as ***preservatives*** or ***emulsifiers*** to maintain stability and efficacy. The following formulations exist:

- ***Creams (oil-in-water emulsions)*** are light and easily absorbed. They usually contain preservatives, such as parabens (hydroxybenzoates), which can sometimes cause allergic contact dermatitis (see later). Aqueous cream is a popular and inexpensive soap substitute (but should not be used as a 'leave-on' emollient).
- ***Ointments*** are greasy preparations based in vehicles such as polyethylene glycol (water soluble) or petrolatum (insoluble). They feel sticky and are useful for treating dry, flaky rashes. Some have an emulsifying wax added to allow them to be used as soap substitutes.
- ***Lotions*** contain water or alcohol that evaporates after application, giving a cooling effect. They are useful for weeping skin conditions and on hairy sites (e.g., the scalp). Alcohol-based lotions should be avoided on broken skin because they sting.
- ***Gels*** are semi-solid preparations of high-molecular-weight polymers. They are non-greasy and liquefy on contact with the skin. They are used to treat oily or hairy areas (e.g., scalp).
- ***Pastes*** are thick, adherent ointments containing a powder (e.g., Lassar paste). They are rarely used now because of poor cosmetic acceptability.

Adverse effects of topical therapies

- ***Systemic absorption*** may occur when large areas of inflamed skin are treated, especially with occlusive bandages or dressings. Neonates are particularly susceptible because of their relatively high body surface area and immature skin barrier, and topical steroids can cause adrenal suppression in this age group.
- ***Contact allergy*** may develop to the drug (e.g., hydrocortisone, neomycin), vehicle (e.g., lanolin, cetearyl alcohol), or excipients (e.g., chlorocresol, parabens). It should be considered in any patient with an unresponsive dermatitis or new dermatitis after topical treatment. Ointments contain fewer excipients and so are less likely to cause contact allergy.
- ***Folliculitis*** can occur because of blockage of hair follicles, especially with ointments in hot weather and on sweaty, occluded skin (bandages, tight clothing). It can also occur as a side-effect of topical steroids.
- ***Corticosteroids*** can cause a range of adverse effects but have a very good safety profile when used correctly.

Phototherapy

Phototherapy with natural sunlight has been used to treat people with skin diseases since ancient times. Modern phototherapy uses specific wavelengths in the UV spectrum for anti-inflammatory or pigment-inducing effects. The conditions that are most commonly treated with phototherapy are psoriasis, eczema, polymorphic light eruption, cutaneous T-cell lymphoma, and vitiligo. Narrow-band UVB (311 nm/TL01) was developed specifically to treat patients with psoriasis and is the treatment of choice in most cases. UVA therapy is given with systemic or topical psoralens (psoralen + UVA = PUVA) to enhance its photobiological effects. Commercial tanning beds predominantly deliver low doses of UVA and have limited effectiveness in treating skin disease but carry a risk of inducing melanoma and other skin cancers.

Narrow-band UVB therapy is given two or three times a week for 20 to 25 treatments. It has superseded broadband UVB because it is more effective. PUVA is usually given twice a week for 20 to 25 treatments. If the psoralen is taken orally, UV-protective glasses must be worn for the day of treatment to protect the retinas. PUVA is used less widely nowadays because it is associated with an increased risk of skin cancer, especially SCC. The maximum recommended lifetime dose of PUVA is 200 treatments.

Unaffected regions of skin or high-risk areas such as the scrotum should be covered during phototherapy. To avoid adverse effects, patients should be carefully selected and their skin cancer risk assessed. Phototherapy is generally avoided in those who have already had a skin cancer. People with very fair skin and freckles are at increased risk of burning, and the UV dosage has to be carefully adjusted and escalated according to skin type or based on phototesting to look for the lowest dose that causes just perceptible redness (minimal erythema dose).

Systemic therapy

A wide range of systemic drugs are used to treat skin disease. Some are used off-licence, especially for uncommon diseases where no licensed option exists. The risks and benefits should be carefully considered and discussed with the patient so they can share in treatment decisions. Selected examples of the types of systemic drugs include:

- Antibiotic, antiviral, and antifungal therapies
- Antiandrogens (e.g., cyproterone acetate, spironolactone, minoxidil)
- Anti-inflammatories (antihistamines, antimalarials, colchicine, corticosteroids, dapsone, Janus kinase (JAK) inhibitors, methotrexate, phosphodiesterase inhibitors, thalidomide)
- Anti-scabetics, e.g., ivermectin or anti-helminths (e.g., albendazole)
- Immunosuppressants (azathioprine, ciclosporin, cyclophosphamide, mycophenolate mofetil)
- Retinoids (e.g., acitretin for psoriasis, alitretinoin for hand dermatitis, isotretinoin for acne, bexarotene for cutaneous T-cell lymphoma)
- Monoclonal antibodies (for psoriasis, eczema, urticaria, prurigo, pemphigus).
- Anticancer therapies including small molecule targeted therapy (e.g., vismodegib for basal cell carcinoma [BCC]; dabrafenib and trametinib for melanoma) and immunotherapies (e.g., checkpoint inhibitor therapy for melanoma and Merkel cell carcinoma)

DERMATOLOGICAL EMERGENCIES

Although most skin diseases are dealt with in an outpatient setting, occasionally, they can be life-threatening and require intensive inpatient treatment. Dermatological emergencies are covered in the acute medicine chapter (see Chapter 11) and include:

- ***Erythroderma*** (see Chapter 11, 'Erythroderma and loss of skin function ['skin failure']' section), describing extensive skin inflammation (affecting most or all of the body surface). Patients can become seriously unwell as a result of transdermal fluid losses, alterations in peripheral vascular resistance, thermal dysregulation, and secondary infection. Causes include primary skin diseases such as eczema or psoriasis, allergic reactions, and malignancies.
- ***Necrotizing fasciitis*** (see Chapter 11, 'Necrotizing fasciitis' section), a severe form of bacterial soft tissue infection, often associated with gas formation, extensive tissue destruction, and a high mortality rate.
- ***Severe drug reactions*** (see Chapter 11, 'Severe cutaneous adverse drug reactions' section), including ***Stevens-Johnson syndrome*** (SJS), ***toxic epidermal necrolysis*** (TEN) and ***drug reaction with eosinophilia and systemic symptoms*** (DRESS syndrome). Milder drug eruptions are discussed toward the end of this chapter.

COMMON RASHES

Acne and related disorders

Acne

Acne is one of the most common skin conditions globally, affecting more than 85% of adolescents and often persisting into adulthood. In females, a late-onset chronic variant starting in the 20s is increasingly recognized. Acne can have a profound effect on self-esteem and mood, leading to anxiety, depression, and even suicidal ideation. This may have little correlation with apparent disease severity.

Lesions arise in the pilosebaceous follicle, which becomes blocked because of abnormal keratinization and increased production of altered sebum, leading to comedones (open comedones are 'blackheads', and closed comedones are 'whiteheads'). Microcomedones (microscopic comedones) can be found in biopsies of normal-looking acne-prone skin. Blockage of the pilosebaceous duct is followed by alteration in its microbiome, especially involving *Cutibacterium acnes* (formerly *Propionibacterium acnes*), leading to activation of innate immunity (Fig. 45.8A). This causes an inflammatory response with influx of neutrophils that release elastase, causing connective tissue damage. Scarring may follow with profound long-term psychological consequences. Post-inflammatory hyperpigmentation (see 'Post-inflammatory hyperpigmentation' section) is also a common sequela in darker-skinned people.

Clinical features

Acne affects the face and upper torso, where the sebaceous glands are dense and affected skin is usually greasy (seborrhoea). Lesions are classified as:

- ***Non-inflammatory:*** open comedones (blackheads) or closed comedones (whiteheads)
- ***Inflammatory:*** papules, pustules (Fig. 45.8B), nodules, and cysts
- ***Scars:*** raised (hypertrophic) or depressed or pitted (box, rolling, and ice-pick)
- ***Post-inflammatory hyperpigmentation*** (especially in patients with skin of colour (Fig. 45.8C)

Uncommon acne variants are shown in Box 45.8.

Severe acne may be associated with various autoinflammatory syndromes characterized by fever and aseptic inflammation (Box 45.9).

Management

The diagnosis of acne is usually straightforward. Treatment should target the primary pathogenic lesion: the ***microcomedone*** and associated inflammatory response. The choice depends on whether lesions are predominantly non-inflamed or inflamed, disease severity or scarring, response to previous treatment, and degree of psychological upset (Box 45.10).

- Topical retinoids (adapalene and tretinoin), azelaic acid, salicylic acid, and benzoyl peroxide (BPO) are ***keratolytic*** and help unblock pores but also cause dry, flaky skin. This can be managed with a non-comedogenic, oil-free moisturizer.
- Topical antibiotics including clindamycin are also used and topical fixed combinations are usually recommended (e.g., adapalene/benzoyl peroxide, tretinoin/clindamycin, benzoyl peroxide/clindamycin). Treatment usually takes 6 to 8 weeks to have a noticeable positive effect.
- ***Oral tetracyclines*** and ***erythromycin*** are licensed for acne, but their prolonged use may encourage the emergence of resistant bacteria. They should not be prescribed for the long term or

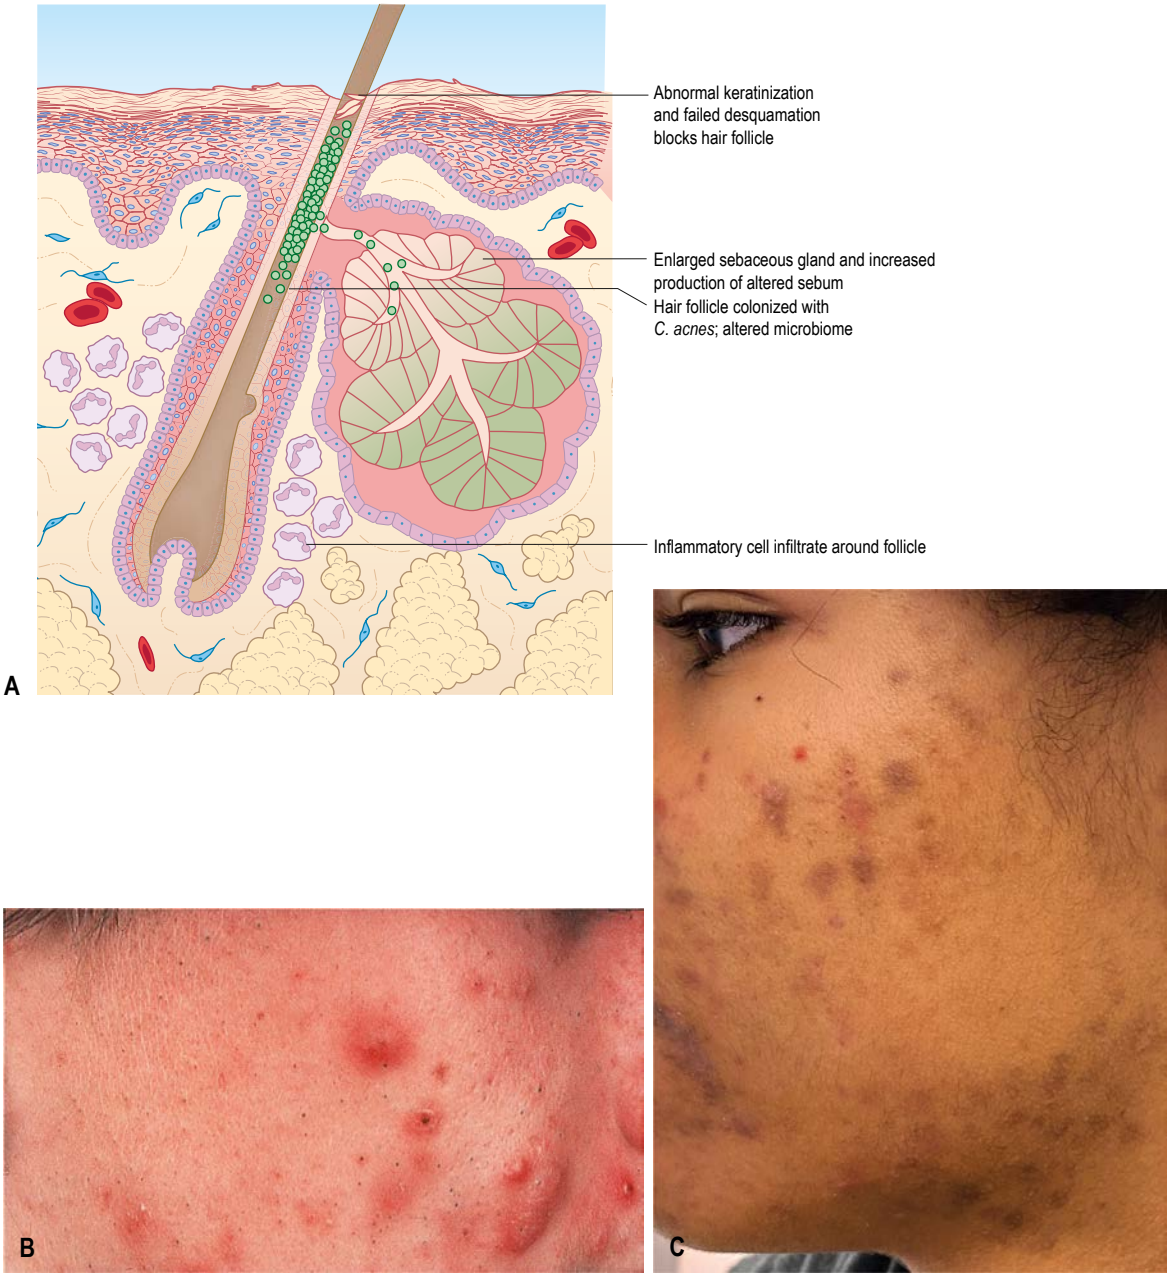

Fig. 45.8 Acne. (A) Pilosebaceous unit, which becomes blocked in acne. **(B)** Comedones and inflammatory lesions in facial acne. **(C)** Post-inflammatory hyperpigmentation secondary to acne. Such pigmentary changes are common in people with darker skin tones. (*A, From Eichenfield LF, Frieden IJ, Mathes EF et al.* Neonatal and Infant Dermatology, *3rd edn. Elsevier Inc.; 2015; Fig. 2.1. Courtesy of Randall Hayes.*)

without non-antibiotic topical therapy because the latter reduces the emergence of resistant bacteria (Box 45.11).

- In females, the ***combined oral contraceptive pill*** and a formulation containing additional ***cyproterone acetate*** (a mild antiandrogen) may be of benefit because of a reduction in sebum excretion. Low-dose spironolactone is another useful option. Progesterone-only pills ('mini-pills') may aggravate acne.
- ***Oral isotretinoin*** is a highly effective treatment licensed for severe inflammatory acne, especially with scarring. It is also used in milder recalcitrant cases associated with severe psychological upset. It causes dryness of the mucous membranes and has a range of other potential adverse effects. A major concern is its potent teratogenicity, so females of childbearing age must use highly effective contraception and follow a specific pregnancy prevention programme. Oral isotretinoin has been associated with depression and rare cases of suicide, so mood should be carefully monitored. There is now a programme in the UK whereby all patients requiring treatment with isotretinoin need documented monitoring of the psychosocial co-morbidities associated with acne, and for patients younger than 18 years of age, two signatories are required for prescriptions.
- High-intensity light treatment (blue light, intense pulsed light) has also been reported to lessen inflammatory lesions, and ablative laser therapy and physical treatment, such as dermabrasion,

Box 45.8 Clinical variants of acne

Infantile acne
- Typically starts between 3 and 12 months of age
- Triggered by maternal androgens

Acne excoriée
- Mainly affects young females who pick mild acne spots, leaving prominent excoriations
- There is usually underlying psychological upset

Drug-induced acneiform eruptions
- May be caused by corticosteroids, vitamin B_{12}, isoniazid, and epidermal growth factor receptor inhibitors
- Comedones are absent

Pomade acne
- Caused by oily scalp cosmetics
- Typically affects the forehead

Oil acne
- Caused by prolonged (e.g., occupational) contact with oils
- Usually affects the legs

Chloracne
- Caused by exposure to toxins (e.g., dioxin)
- Widespread comedones and large, straw-coloured, non-inflamed cysts

Acne conglobata
- A severe form of cystic acne with abscesses and interconnecting sinuses
- Usually affects young males

Acne fulminans
- Associated fever, weight loss, and musculoskeletal pain
- Systemic steroids and oral isotretinoin are required

Follicular occlusion triad
- Severe cystic acne with cellulitis of the scalp and hidradenitis suppurativa

Box 45.9 Acne-associated autoinflammatory syndromes

- SAPHO syndrome: synovitis, acne, pustulosis, hyperostosis, osteitis
- PAPA: pyoderma gangrenosum, acne, pyogenic arthritis
- PASH: pyoderma gangrenosum, acne, suppurative hidradenitis (hidradenitis suppurativa)
- PAPASH: pyoderma gangrenosum, psoriatic arthritis, suppurative hidradenitis (hidradenitis suppurativa)
- PASS: pyoderma gangrenosum, acne, seronegative spondyloarthritis

Box 45.10 Treatment of acne

Mild or physiological acne
- Step 1: Provide oil-free skin care for acne-prone skin, including salicylic acid washes (keratolytic).

Comedonal acne
- Step 2: Add topical retinoid or azelaic acid (keratolytic).

Inflammatory acne
- Step 3: Give topical retinoid + benzoyl peroxide.
  - Benzoyl peroxide ± topical or oral antibiotic (antimicrobial).

Severe acne
- Step 4: Consider oral isotretinoin.
  - Anti-androgen therapy (cyproterone acetate, spironolactone) may be useful in females with moderate acne and seborrhoea.

Box 45.11 Prescribing antibiotics for acne

- Avoid long-term prescription (>6 months) of oral antibiotics
- Do not use topical antibiotic monotherapy (co-prescribe with topical retinoid or benzoyl peroxide)
- Avoid prescribing dissimilar oral and topical antibiotics

may improve the appearance of scars. However, a key goal of acne treatment is to *prevent* scar formation.
- Treatment of scarring and post-inflammatory pigmentation disorders may involve topical retinoids, dermabrasion, 'peels', laser treatments, and sometimes aesthetic surgical interventions.

Acne itself is associated with significant psychological disease, including body dysmorphic disorder, suicidal ideation, changes in self-perception, and skin picking (acne excoriee). However, for most people with acne, emotional wellbeing improves as their acne clears.

Hidradenitis suppurativa ('acne inversa')

Hidradenitis suppurativa is a chronic inflammatory disorder that affects the apocrine pilosebaceous follicles of the axillae, the inguinal area, and around the breasts ('apocrine acne'). It is characterized by recurrent abscesses, draining sinuses, and scarring and is associated with the metabolic syndrome, obesity, and smoking. Patients are often disabled by pain and malodorous discharging lesions; there is no definitive treatment. Bacterial biofilms within the occluded follicles may explain the disappointing results of antibiotic therapy.

Treatment options include oral tetracycline, combined rifampicin and clindamycin, acitretin, adalimumab (anti-TNF), and IL-17 blockers (secukinumab). Surgery (usually marsupialization of affected areas, or excision and grafting) may be required to drain abscesses and to excise the affected areas of skin.

Rosacea

Rosacea (Fig. 45.9) is a common inflammatory rash predominantly affecting the central face. It usually starts in mid-adult life and is more common in fair-skinned people. The cause is unknown, but the pathogenesis probably involves vasodilation of cutaneous facial microvasculature (which may become fixed telangiectasia, i.e., non-blanching on pressure) with or without chronic sun damage and an increased innate immune response triggered by the commensal mite *Demodex folliculorum* and leading to synthesis of pro-angiogenic and pro-inflammatory mediators.

Clinical features

The main features are diffuse erythema and inflammatory papules and pustules. Flushing and telangiectasia may be early features and can be aggravated by hot drinks, alcohol, sunlight, and changes in temperature *(erythemato-telangiectatic rosacea)*. This may be

Fig. 45.9 Rosacea. Papules and pustules on background erythema. There are no comedones.

followed by papules and pustules *(papulopustular rosacea)*, but unlike with acne, there are no comedones. Ocular involvement can lead to blepharitis, keratitis, and conjunctivitis. Later complications include sebaceous gland and soft tissue overgrowth *(phymatous rosacea)*, especially of the nose in males, causing rhinophyma and facial lymphoedema. Use of topical steroids can exacerbate or trigger rosacea.

Management

Treatment is suppressive rather than curative. Avoidance of agents that make the skin flush (alcohol, saunas, steam rooms, capsaicin [the 'hot' component of chilli]-containing foods) together with topical metronidazole, azelaic acid, or ivermectin may be used for long-term control, with intermittent courses of oral tetracyclines. Subantimicrobial doses of doxycycline are effective because of an anti-inflammatory effect.

Flushing and erythema do not respond to antibacterial drugs, and treatment options include cosmetic concealers, topical brimonidine, and vascular laser therapy. Rhinophyma can be debulked surgically or with an ablative laser (e.g., CO_2 laser). Lasers may be useful for fixed telangiectasia or erythrotelangiectatic rosacea.

Perioral dermatitis

Perioral dermatitis is a distinctive rosacea-like rash that typically affects the nasolabial fold and area around the mouth in young females in a 'diamond' distribution. It is characterized by small inflammatory papules and pustules with overlying scaling. Topical steroids may trigger the condition in susceptible individuals and are often continued inadvertently because the rash flares when they are discontinued. Treatment is with an oral tetracycline, as for rosacea, and with weaning off topical steroids.

Other rarer causes of facial rashes

These include autoimmune rheumatic diseases and lymphocytic and granulomatous infiltrates.

Eczema and dermatitis

The terms 'eczema' and 'dermatitis' are used interchangeably to describe an extremely common type of inflammatory rash. In the developed world, eczema may affect about 10% of the population at any one time, with up to 40% experiencing an episode of eczema during their lifetime.

Eczema is classified as ***constitutional*** or ***endogenous*** and ***contact*** or ***exogenous*** (Box 45.12). It can also be classified according to duration (***acute, subacute,*** or ***chronic***). The term 'eczema' is used to refer to a number of separate clinical conditions with overlapping clinical features, including:

- Atopic eczema
- Seborrheic eczema
- Venous eczema
- Discoid eczema
- Contact of irritant eczema

Box 45.12 Classification of eczema

Endogenous
- Atopic eczema
- Seborrhoeic eczema
- Venous ('gravitational') eczema
- Discoid eczema
- Asteatotic eczema
- Chronic hand or foot eczema
- Lichen simplex or nodular prurigo

Exogenous
- Irritant contact eczema
- Allergic contact eczema

- Chronic forms of eczema, including lichen simplex and nodular prurigo.

The cardinal features of inflammation are manifest in all forms of eczema, including

- Erythema
- Swelling
- Itch or soreness
- Loss of normal skin barrier function

In acute eczema, oedema is prominent, and tiny vesicles or larger bullae may be seen within inflamed skin. Skin swelling subsides to leave dry, flaky skin. Scratching leads to excoriations with serosanguinous exudate. Repeated scratching or rubbing causes thickened skin with the prominent lines ***(lichenification)*** of chronic eczema. The thickened skin is not supple and cracks easily, predisposing to fissures, especially on the hands and feet. Secondary bacterial infection may occur and cause crusts, papules, and pustules.

The histology of eczema correlates with the clinical features: whereas in acute eczema, the keratinocytes are swollen with increased intercellular fluid (spongiosis), in chronic disease, there is little oedema but prominent thickening of the epidermis (acanthosis) and scaling (hyperkeratosis). Inflammatory cells are present around the upper dermal vessels in all patterns.

Atopic eczema

This type of constitutional eczema is extremely common, affecting 5% to more than 20% of children worldwide (numbers vary widely between countries and ethnicities). It usually starts before the age of 5 years, and the disease course is chronic and relapsing with periods or flare and remission over many years. The majority (~80%) of children with early-onset atopic eczema spontaneously improve and 'clear' the disease before the teenage years. Recurrence may occur in adulthood, especially as a localized hand eczema. Onset in later childhood or adulthood is often associated with a more chronic relapsing course. It is often associated with other atopic diseases.

Aetiology

The pathogenesis of atopic dermatitis represents an interplay between genetic factors, Th2 cell–skewed immune dysregulation, epidermal barrier dysfunction, environmental triggers, an altered skin microbiome, and neuroimmune interaction. It is debated which mechanisms are the main drivers and which combinations of mechanisms accounts for the variable disease phenotypes.

A positive family history of atopic disease is often present: there is 90% concordance in monozygotic twins but only 20% in dizygotic twins. If one parent has atopic disease, the risk of a child developing eczema is about 20% to 30%. If both parents have atopic eczema, the risk is more than 50%.

Activation of Th2 CD4 lymphocytes in the skin drives atopic eczema, with increased IL-4, IL-15, and IL-13 production that lead to raised levels of immunoglobulin E (IgE) and IL-31, a key mediator of itch. Scratching leads to further epidermal damage. The later chronic inflammatory phase is more complex and involves Th1, Th17/IL-23, Th22 cells, and the JAK/STAT pathway. Th2 immune cell activation impairs epidermal antimicrobial peptides in the skin, leading to a partial immunodeficiency and predisposition to cutaneous infection, particularly with *Staphylococcus* spp. and herpes simplex virus (HSV).

An altered skin microbiome has been demonstrated in patients with eczema with a loss of diversity and a predominance of *Staphylococcus* spp. in acute and chronic eczematous skin. It is currently unknown if the microbial changes predispose to an eczema flare or are secondary.

Epidermal skin barrier dysfunction is a further key finding in atopic eczema. Multiple factors have been shown to contribute, including a reduction in filaggrin production, an imbalance in stratum corneum proteases, an abnormality in tight junction function, and microbial colonialization. Filaggrin deficiency is of major importance, and Th2 cytokines have been shown to reduce its production in the skin. Loss of function variants in the filaggrin gene are the strongest genetic predictor of atopic dermatitis with an associated three- to fourfold increase of developing the disease.

Chronic itch is the leading symptom of atopic dermatitis, but it is unknown if it drives inflammation. Itch is in part mediated by Th2 cytokines IL-4, IL-13, TSLP, and IL-31 blockade, which have been used therapeutically in the management of eczema and asthma and itch.

Exacerbating factors

Exposure to soap and detergent skin cleansers dries and damages the epidermis and promotes inflammation. In some patients, repeated infections with *Staphylococcus aureus* induce flares, which may be mediated by superantigen exotoxins that cause widespread T-cell activation. Teething, dribbling, and lip licking may trigger facial eczema in infancy and childhood. Severe anxiety or stress may exacerbate eczema in some individuals. Pet dander can aggravate eczema. The role of house dust mites and diet is less clear-cut.

Immediate or type 1 hypersensitivity to food allergens (cow's milk, egg, soya, wheat, fish, and nuts) is common in young children with severe atopic eczema. Ingestion of food causes perioral and sometimes generalized urticaria (hives) and gastrointestinal (GI) symptoms (reflux, vomiting, and diarrhoea). Rarely, there may be a delayed hypersensitivity to foods such as cow's milk that manifests with an eczema flare after 12 to 24 hours. This cannot be investigated with prick tests or blood tests, and the mechanism is unclear. The diagnosis is made by taking a careful dietary history followed by oral food challenge tests.

Clinical features

Atopic eczema has a variable clinical presentation. The characteristic sites involved are the flexures of the elbows, knees, ankles, and wrists (Fig. 45.10) and around the neck. In infants, eczema often starts on the cheeks, while impacting the flexures in childhood. In adulthood, the hands and feet, nipples, and lateral eyebrows are more likely to be affected. Clinical features of acute or chronic eczema (see earlier) may predominate, and the pattern can change with time. Pruritus is always present and is usually severe, leading to excoriations, lichenification, and dyspigmentation.

In darker skin tones, the erythema of acute eczema may be difficult to appreciate. The distribution may be different, with an 'inverse pattern' predominantly affecting the extensor surfaces, and follicles can be prominent. Pigmentary changes (hyper- and hypopigmentation) may follow the inflammatory phase of eczema and are often

Fig. 45.10 Atopic eczema. Infantile atopic dermatitis on the extensor arms. **(A)** Chronic diffuse involvement of the extensor arms with scaling and hyperpigmentation. Note the follicular prominence on the trunk. **(B)** Nummular lesions on the extensor aspect of the arm and nipple eczema. (*B, Courtesy of Julie V. Schaffer, MD.*)

slow to resolve. Hypopigmented patches over the cheeks termed ***pityriasis alba*** are common.

In some atopic individuals, the skin of the upper arms and thighs feel rough because of follicular hyperkeratosis (keratosis pilaris). Prominent skin creases on the palms (hyperlinear palms) and dry, 'fish-like' scaling of the skin of the lower legs (ichthyosis vulgaris) point to underlying deficiencies in filaggrin. Centrofacial pallor with characteristic nasal sparing is a typical sign of atopic eczema.

Secondary infection

Secondary bacterial infection with *S. aureus* or streptococci is common, especially in moist flexural areas such as the neck and groin. Pustules, oedema, and golden-crusted inflamed papules strongly suggest secondary infection.

Cutaneous viral infections (e.g., viral warts and molluscum) may be more widespread in atopic eczema. HSV can cause extensive infection of the skin, termed ***'eczema herpeticum'***. This appears as multiple small blisters or painful, punched-out crusted papules (Fig. 45.11) that are associated with malaise and pyrexia. Urgent systemic antiviral therapy is indicated to reduce the risk of disseminated life-threatening infection. An extensive form of hand, foot, and mouth disease may also occur in children with eczema, with blisters and crusted lesions extending over large areas of the limbs and face ('eczema coxsackium'). Ocular complications of atopic eczema include conjunctival irritation and, less commonly, keratoconjunctivitis and cataract.

Fig. 45.11 Eczema herpeticum. Grouped punched-out monomorphic erosions with haemorrhagic crusts on the arm **(A)** and posterior neck **(B)**. Vesicles are rarely evident. (*B, Courtesy of Julie V. Schaffer, MD.*)

Investigations

Atopic eczema is diagnosed on the history and clinical features. About 80% of patients also have laboratory features of atopy (raised total IgE and allergen-specific IgE and mild eosinophilia).

Management

General measures include a patient-centered approach avoiding common or proven allergens and irritants (especially bar and liquid soap). Clothing should be made of soft, 'breathable' fabric such as cotton (see Box 45.13). Manipulating the diet (e.g., following a dairy-free or egg-free diet) may help a minority of infants with moderate to severe eczema. However, this should be done only under expert guidance to ensure adequate intake of nutrients such as calcium. Dermatology nurse-led education of people living with eczema and their families provides psychological support and improves adherence to treatment.

Topical therapies

Topical therapies are sufficient to control atopic eczema in most people. The key components are moisturizers or emollients and topical anti-inflammatories such as corticosteroids and calcineurin inhibitors.

Fragrance-free moisturizers should be used liberally on all dry skin areas and reapplied as often as needed. Some can also be used as soap substitutes. Moisturizers with or without topical steroids can be applied under occlusive damp tubular gauze bandages ('wet wraps'). These can improve efficacy but are time consuming to apply. Paste bandages containing ichthammol can also be useful for resistant or lichenified eczema of the limbs.

Topical corticosteroids remain the bedrock of eczema treatment, and for most patients, they provide reasonable disease control. They are applied once a day to inflamed skin. Topical corticosteroids are classified into four groups, according to potency (Box 45.14). An appropriate potency should be selected according to the body site, surface area, and patient age to minimize the risk of adverse effects (Box 45.15) and allow safe, intermittent, long-term treatment. 'Steroid phobia' is common among patients or their carers and should be appropriately addressed to improve adherence. ***Topical steroid withdrawal syndrome*** is increasingly recognized as a rare rebound flare associated with prolonged use of potent steroids characterized by a burning and stinging sensation, skin pain, and flushing. Potent steroids should be used for short periods only and weaned down to milder steroids or used intermittently as the eczema settles. Regular use of emollients may reduce steroid usage.

Box 45.13 Management of atopic eczema

- Education and explanation
- Avoidance of irritants and allergens
- Emollients
- Bath oils, soap substitutes
- Topical therapies
  - Steroids
  - Calcineurin inhibitors
- Adjunct therapies
  - Oral antibiotics
  - Sedating antihistamines
  - Bandaging
- Phototherapy
- Systemic therapy, e.g., oral prednisolone, ciclosporin, methotrexate, dupilumab, tralokinumab, lebrikizumab, JAK inihibitors (baricitinib, abrocitinib, upadacitinib)

Box 45.14 Classification of topical corticosteroids by potency

Very potent
- 0.05% clobetasol propionate
- 0.3% diflucortolone valerate

Potent
- 0.1% betamethasone valerate
- 0.025% fluocinolone acetonide

Moderately potent
- 0.05% clobetasone butyrate
- 0.05% alclometasone dipropionate

Mild
- 2.5% hydrocortisone
- 1% hydrocortisone

Box 45.15 Adverse effects of topical steroids

- Cutaneous atrophy and telangiectasia
- Striae
- Topical steroid withdrawal syndrome
- Steroid-induced rosacea, perioral dermatitis, and folliculitis
- Tinea incognito (a tinea infection modified by a topical steroid applied inappropriately)
- Ocular adverse effects (cataract, glaucoma)
- Adrenal suppression (from systemic absorption with long-term use of potent steroids)

Mild steroids rarely cause skin atrophy, but this is a significant risk with potent and super-potent steroids, especially if applied under occlusion or with a keratolytic such as salicylic acid. Mild to moderate steroids are used to treat eczema on the face and flexures. Potent and super potent steroids are usually required to treat palmoplantar eczema because of the thick stratum corneum at this site. The 'fingertip unit' can be used to guide topical steroid dosage.

Topical calcineurin inhibitors (TCIs) (tacrolimus and pimecrolimus) are licensed for the treatment of atopic eczema in adults and children older than the age of 2 years. They do not cause skin atrophy and are therefore useful for delicate areas such as the face and eyelids. They are less effective on thick skin because of poor penetration. The main adverse effect is a burning or prickling sensation that usually improves with continued treatment. Initial concerns that the immunosuppressant effects of TCIs would increase the risk of skin cancer have not proved well-founded, but patients are advised to photoprotect.

New topical treatments, including the topical PDE4 (phosphodiesterase isozyme 4) inhibitor crisaborole and the JAK1/2 inhibitor ruxolitinib, have shown efficacy in the treatment of patients with eczema but are not currently licensed in the UK.

Antibiotics and antiseptics

Antibiotics are indicated if there are clinical signs of infection and are usually given orally for 7 to 10 days. High-dose flucloxacillin is the treatment of choice for patients with staphylococcal and streptococcal skin infections. Erythromycin is an alternative for those with penicillin allergy. Topical antiseptics are often used as emollient washes or bath additives or in the form of 'bleach baths'. They may cause irritation.

Sedating antihistamines

These may be useful at before bedtime, but because histamine is not a key mediator in the itch of eczema, they are often of limited benefit.

Second-line therapy and new drugs

These are used in severe, unresponsive eczema, especially if it is interfering with an individual's life (e.g., growth, sleeping, schoolwork, or job). ***UV phototherapy*** and ***systemic immunosuppressants*** (ciclosporin, azathioprine, methotrexate) can be helpful. Short, tapering courses of oral prednisolone usually provide rapid disease control, but relapse is common on withdrawal. The risks and benefits of long-term systemic therapy require careful evaluation and are chosen based on shared decision-making.

Recent years have seen a breakthrough in the treatment of patients with severe eczema through the development of new ***therapies that target type 2 immunity***. The monoclonal antibody dupilumab blocks anti-IL4Ra, the shared receptor of IL-4 and IL-13. It is the first approved biologic shown to be an effective and safe treatment for atopic eczema in adults and children. It is given by subcutaneous injection every 2 weeks. The suggestion that IL-13 plays a major role in disease pathogenesis led to the development of tralokinumab, the first anti–IL-13 monoclonal antibody that shows effective disease control with a lower incidence of conjunctivitis than reported for dupilumab.

In addition, three ***small molecule inhibitors of JAK*** have been licensed for the treatment of patients with atopic eczema in the UK. Abrocitinib (JAK1 selective) and upadacitinib (JAK1 selective) are approved in adults and children aged 12 year and older. Baricitinib (JAK1 and 2 selective) is approved for the use in adults only. They have been shown to be a rapid and highly effective treatment and have the advantage of being administered orally. However, data from safety trials in patient with rheumatoid arthritis showed a potential increased risk of serious infections, major cardiovascular events, cancer, thrombosis, and death, but these have not been noted in clinical trials for atopic eczema, and long-term data are awaited.

Prevention

Maintenance regimens using topical steroids or calcineurin inhibitors twice weekly have been shown to reduce the frequency of eczematous flares. Studies are exploring if early treatment with targeted therapy can change the overall disease course.

Seborrhoeic eczema

Clinical features

Seborrhoeic eczema is extremely common in adults and in its mildest form is often overlooked. As the name implies, it affects greasy areas of skin because of its high density of sebaceous glands. On the face, it presents with greasy yellow-looking scale and erythema around the nose and nasolabial folds (Fig. 45.12), medial eyebrows, scalp, and retroarticular folds. Itch is variable. Dandruff is thought to be a mild variant of scalp seborrhoeic dermatitis. More severe scalp involvement can look like psoriasis (sebopsoriasis). The presternal area may be affected, particularly in males, as well as upper back, axillae, and anogenital area. A generalized form of seborrhoeic eczema presents as erythroderma in older adults. Children are not affected until puberty. Cradle cap and a non-itchy napkin dermatitis may represent infantile variants of seborrhoeic eczema.

Aetiology

The precise cause of seborrheic eczema is not known. It is thought that a lipophilic commensal yeast, *Malassezia* spp., triggers the inflammatory skin changes of seborrhoeic dermatitis in susceptible individuals. Host immunity is also involved, and seborrhoeic dermatitis is one of the earliest skin manifestations of human

Fig. 45.12 Seborrhoeic dermatitis. Note the hypopigmented plaques over seborrhoeic sites. (*From James WD, et al.* Andrews' Diseases of the Skin, *12th edn. Philadelphia: Elsevier; 2016.*)

Fig. 45.13 Chronic atopic dermatitis. (A) Hand eczema. **(B)** Thick eczematous plaques with lichenification and excoriation on the dorsal hands and wrists. (*B, Courtesy of Julie V. Schaffer, MD.*)

immunodeficiency virus (HIV) infection (see Chapter 44). Its prevalence is also increased in those with Parkinson's disease and other neurological disorders.

Management

Seborrhoeic dermatitis usually runs a chronic relapsing course, and treatment is suppressive rather than curative. Stress and cold weather are frequent triggers. Topical azole antifungal creams, with short-term use of mild- to moderate-potency steroids according to body site, are usually helpful. TCIs are an effective option but are unlicensed for this form of dermatitis. Ketoconazole-containing shampoo is useful to treat scalp involvement and as maintenance therapy.

Venous eczema (varicose eczema, stasis, gravitational eczema)

Venous eczema usually affects older adults and those with varicose veins or a history of venous thrombosis. The inner calf is involved, and there are usually coexistent signs of venous hypertension, including haemosiderin deposition, lipodermatosclerosis, and varicose ulceration. The eczematous changes range from mild erythema and scaling to an acute exudative inflammatory rash. It may be complicated by allergic contact dermatitis to medicated creams or bandages, and patch tests should be done if there is an inadequate response to treatment.

Management

This includes use of bland (perfume-free) emollients such as a 50:50 liquid paraffin:white soft paraffin mix and short-term prescription of a moderately potent topical steroid. Underlying venous hypertension should be managed with compression hosiery or vascular surgery. Caution should be exercised over prolonged used of paraffin-containing emollients because they pose a fire hazard by impregnating clothes and bedding, making them highly flammable.

Discoid eczema (nummular eczema)

Discoid eczema is characterized by well-demarcated, inflamed scaly patches, sometimes with tiny vesicles. It usually affects the limbs and torso and is intensely itchy, which helps differentiate it from psoriasis. Lesions may be secondarily infected with *S. aureus*. The cause is unknown. Potent topical steroids are usually required to clear individual lesions. Management of severe cases follows general atopic dermatitis treatment protocols as described earlier.

Asteatotic eczema (winter eczema, eczema craquelé)

This form of eczema often affects older people in the wintertime and can be intensely pruritic. It involves the lower legs, lower back, and other areas that have few sebaceous glands. These areas are particularly vulnerable to the drying effects of soap and water. The rash resembles 'crazy paving' with dry scales and inflamed fissures. Frequent use of a bland moisturizer and soap substitute is usually all that is needed.

Hand eczema

Hand eczema (Fig. 45.13) is a common problem that has a significant impact on quality of life. It often runs a chronic relapsing course for

many years, with a reported lifetime prevalence of up to 15%. Different clinical patterns are recognized, and the morphology may be mixed and can vary with time in an affected individual.

Aetiology

The underlying causes are:

- ***Contact dermatitis or eczema*** caused by an external harsh substance ***(irritant)*** or allergy-provoking substance ***(allergen)***
- ***Endogenous dermatitis or eczema*** in which no external factors can be identified. There may also be involvement of the feet.

Hand eczema often has a complex and mixed aetiology because of an inherent endogenous eczema tendency and an additional irritant or allergic component.

Mild ***irritant hand eczema*** typically causes dry, sore skin on the dorsal hands and finger webs. It is extremely common in cold, dry weather and in people who wash their hands frequently, either at home (especially when caring for young children) or in occupations such as catering, healthcare, and hairdressing. Hand eczema is a common finding in people with ***atopic eczema***, and the hand may be the only site involved in adulthood. ***Vesicular hand eczema (pompholyx)*** is characterized by multiple intensely itchy blisters, especially on the lateral fingers and palms, and can similarly affect the feet (Fig. 45.14). ***Hyperkeratotic eczema*** is characterized by dry, scaly plaques and fissures on the palms and soles and shares similarities with psoriasis at these sites. Localized eczema of the finger pulps is called ***pulpitis***.

Severe chronic hand eczema may be associated with increased sickness leave and job loss. It is a considerable financial and societal burden because it impairs the ability to work and to carry out the tasks of daily living. ***Patch testing*** should be considered in all patients with chronic hand eczema to identify relevant contact allergens because it is often not possible to distinguish which patients have an allergic contact dermatitis from the clinical appearances. A careful history of occupation and recreational activities may indicate the need to test with extra allergens beyond the standard battery of common allergens (e.g., specific plants in a gardener or gloves in a healthcare provider).

Management of chronic hand eczema includes use of emollients and moderate to potent topical corticosteroids, minimizing contact with irritants, and avoiding exposure to allergens (Box 45.16).

Fig. 45.14 Pompholyx eczema. (A) Acute pompholyx-like palmar vesicles. **(B and C)** Crusted papules from dried up pompholyx-like vesicles. (*Courtesy of Dr A. Bewley, London.*)

Box 45.16 Common contact allergens

- ***Fragrance*** ('parfum'): in fine fragrances, toiletries, moisturizers, household products
- ***Rubber chemicals:*** in household and examination gloves and footwear
- ***Metals:*** in jewellery; buckles; spectacle frames; and gadgets, including mobile phones
- ***Chemical hair dye:*** in permanent and semi-permanent colorants
- ***Preservative chemicals:*** in cosmetics, toiletries, and household and industrial products
- ***Topical antibiotics and antiseptics:*** prescribed and over-the-counter products
- ***Other ingredients in medicated creams:*** e.g., lanolin, hydrocortisone
- ***Adhesives:*** in footwear, acrylic nails, superglue
- ***Leather and textile dyes***

This may involve wearing protective gloves and sometimes even a change of occupation. The oral retinoid alitretinoin is an effective treatment for topical steroid-refractory severe chronic hand eczema. It leads to clearance or significant improvement in more than half of all patients over a 6-month course. Like all oral retinoids, it is a teratogen, and a pregnancy prevention programme must be followed.

Allergic and irritant contact eczema

Allergic contact eczema is an example of a delayed-type hypersensitivity. The rash does not usually appear until at least 12 to 24 hours after skin contact and may even be delayed by several days, so the cause is often unsuspected. The hands, face, and neck (Fig. 45.15) are commonly involved because of their frequent contact with allergens. Other body sites that are often affected by allergic contact dermatitis include the lower leg, external auditory canal, and anogenital area (from medicaments) and the feet (from footwear). Patch testing should be considered in all patients with suspected allergic contact eczema or when this cannot be excluded.

Irritant contact eczema is a common condition that mainly affects the hands. People with a history of atopic eczema are at significantly increased risk. The most common cause is frequent contact with soap or detergents and water at work ('wet work'). Occupations with increased risk include hairdressing, catering, and healthcare.

Lichen simplex

This is a chronic form of eczema in which the skin is thickened with increased skin markings (lichenified) in response to repeated rubbing or scratching (Fig. 45.16). Common sites are the nape of the neck, lateral calves, and anogenital area. Short-term use of a potent or super-potent topical steroid and topical anti-pruritics (e.g., menthol) often helps to break the ***itch–scratch cycle***, along with habit reversal techniques. There may be underlying emotional stress, hence the alternative name, 'neurodermatitis'.

Nodular prurigo

This is a chronic, widespread, intensely itchy, nodular eruption that is perpetuated by picking and scratching. It develops on a background of chronic pruritus and is often associated with a history of atopic eczema. Scattered, firm, dome-shaped, and hyperkeratotic nodules are typically found on the upper trunk and the extensor surfaces of the limbs. The upper middle back is typically spared (butterfly sign). The diagnosis is made by exclusion of other pathologies and may require a skin biopsy. Medical causes of pruritus should be excluded (see Box 45.23). Topical corticosteroids, sedating antihistamines, and antipruritics have limited effectiveness. Narrowband UVB and methotrexate can be useful for widespread disease. Dupilumab has shown promising results in clinical trials and has been approved in some countries for this indication.

Fig. 45.15 Contact eczema secondary to perfume allergy.

Fig. 45.16 Lichen simplex chronicus. (A) Lichen simplex from chronic rubbing. **(B)** Lichen simplex chronicus of the posterior neck. (*B, Courtesy of Ronald P. Rapini, MD.*)

Chronic actinic dermatitis

This uncommon form of eczema mainly affects older males and is caused by excessive sensitivity to UV radiation in sunlight. The

rash is prominent on sun-exposed sites and worse in the summer, but patients may not be aware of their underlying photosensitivity. A clear cut-off can usually be found between clothed (unaffected) and exposed (affected) sites. Specialist assessment is needed. Monochromator phototesting across the solar spectrum can be done to confirm UVB sensitivity and other causative wavelengths.

Psoriasis

Psoriasis is a common chronic inflammatory skin disease that affects 2% to 3% of the total population. Various clinical patterns are recognized, and the severity is highly variable. Psoriasis can appear at any age but has two peak ages of onset: early disease (age 20–30 years) is more common and is often associated with a positive family history, and late-onset disease peaks around 50 to 60 years.

Psoriasis is associated with an inflammatory arthritis, metabolic syndrome, cardiovascular disease, inflammatory bowel disease, and autoimmune disorders. Depression and impaired body image are common co-morbidities.

Aetiology

The condition appears to be polygenic, with epigenetic, environmental, and behavioural triggers. Forty percent of individuals with psoriasis or psoriatic arthritis have a positive family history. Twin studies show 73% concordance in monozygotic twins compared with 20% in dizygotic pairs. Multiple genetic psoriasis susceptibility loci have been identified including *PSORS1* (which accounts for 35%–50% of the heritable component).

The pathogenesis of psoriasis is complex and involves an interplay between keratinocytes, immune cells, and other skin-resident cells. Plasmacytoid dendritic cells induce the maturation of myeloid dendritic cells and the production of TNF-α, IL-12, and IL-23, which leads to the activation of the pro-inflammatory T17 axis and secretion of TNF-α, IL-17, IL-21, and IL-22 and keratinocyte activation. This causes overproduction of antimicrobial peptides, inflammatory cytokines, and chemokines, amplifying the immune response and driving abnormally rapid keratinocyte proliferation and abnormal differentiation of the epidermis. The result is thickened, inflamed skin (plaques) with thick overlying scale. Biologic therapy targeting TNF-α, IL-23, and Il-17 have revolutionized psoriasis management.

Exacerbating factors

Multiple medical and behavioral conditions have been identified as risk factors, including smoking, obesity, alcohol use, stress, UV light exposure, and trauma. Drugs including beta-blockers, lithium, and anti-malarial drugs and more recently immune checkpoint inhibitors can exacerbate psoriasis.

Infections including bacterial and viral infection may induce acute flares, and post-streptococcal flares of ***guttate psoriasis*** are well recognized.

Clinical features

Different patterns of psoriasis are recognized, and many can occur together.

Chronic plaque psoriasis is the most common variant and is characterized by pink-red, well-demarcated plaques with silver-white scales, seen especially on extensor surfaces of the knees (Fig. 45.17A) and elbows (Fig. 45.17B). The lower back, ears, and scalp are often also involved. New plaques of psoriasis occur

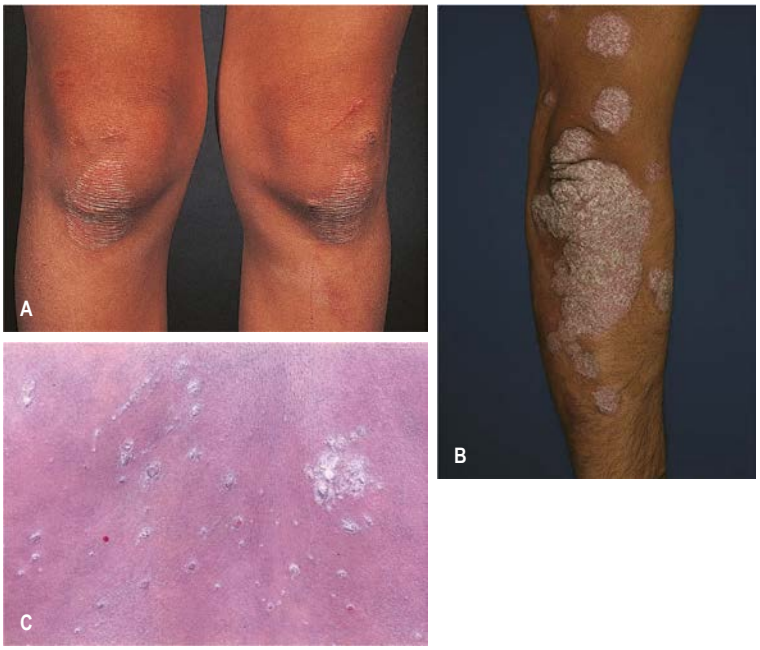

Fig. 45.17 Psoriasis. (A) Chronic plaque psoriasis of the knees. **(B)** Chronic plaque psoriasis on the elbows of an Indian patient. **(C)** Guttate psoriasis in an African patient. (*Courtesy of Dr P Matondo, Lusaka, Zambia.*)

at sites of skin trauma. The lesions can become itchy or sore and bleed easily when scales are removed. The palms and soles can develop painful fissures. The extent of involvement can vary between localized disease and almost full-body surface involvement.

Flexural psoriasis tends to affect older adults with a raised body mass index. It is characterized by well-demarcated, shiny plaques with little, if any, scaling affecting the large flexures of the groin, natal cleft, axillae, and submammary area. The rash is often misdiagnosed as *Candida* intertrigo (see '*Candida* infections' section), but it has a sharp margin and lacks satellite lesions. Anogenital involvement is common and can cause considerable psychosexual upset.

Guttate psoriasis is the term given to a 'raindrop-like' pattern of psoriasis, most commonly seen in children and young adults (**Fig. 45.17C**) with no previous history of psoriasis. The rash develops over days and consists of very small circular or oval plaques on the torso. It is usually triggered by a streptococcal throat infection. Guttate psoriasis resolves spontaneously and in up to one-third of individuals does not recur. However, the remainder experience recurrent guttate attacks or develop chronic plaque psoriasis.

Erythrodermic and pustular psoriasis are the most severe variants and are manifestations of extensive inflammatory skin disease. They may occur together and may be preceded by unstable widespread chronic plaque disease. There is often associated systemic upset with malaise, fever, and circulatory disturbance, which can be life-threatening. The pustules are sterile and can be triggered by sudden withdrawal of potent topical or systemic corticosteroids, pregnancy (impetigo herpetiformis), or infection.

Palmoplantar pustulosis is a more common localized, pustular rash on the palms and soles, and it is controversial whether it is a variant of psoriasis or a separate entity.

Acrodermatitis continua of Hallopeau with involvement of the distal digits is considered a further variant.

Associated features

Nail changes affect up to 50% of people with psoriasis (**Fig. 45.18**). Features include:

- Pitting of the nail plate (most common)
- Distal separation of the nail plate (onycholysis) and, rarely, loss of the nail plate
- Pink- (salmon patch) to yellow brown (oil-drop) discoloration
- Subungual hyperkeratosis (accumulation of scales under distal portion of the nail).

Toenail psoriasis can be difficult to distinguish from nail tinea, and the two diseases may coexist.

Fig. 45.18 Psoriasis of the nail. Yellowish brown discoloration and distal nail plate separation (onycholysis).

Psoriatic arthritis and enthesitis (see Chapter 32, 'Psoriatic arthritis' section) may affect up to 40% of individuals, although the prevalence varies widely. Joint symptoms can present before skin disease, but most individuals have scalp or nail psoriasis. People with psoriasis should be asked specifically about joint symptoms, and the Psoriasis Epidemiology Screening Tool (PEST) score can be used as a guide for rheumatological referral.

Management

There is no curative treatment, and the choice of therapy is determined on an individual basis, according to the site and severity of disease, its psychological impact, co-morbidities such as cardiovascular or liver disease, and the individual's wishes (**Fig. 45.19**). Most people with chronic plaque psoriasis have the condition for life, though it may fluctuate in severity. A supportive and empathic approach is needed because people with psoriasis often feel stigmatized by their skin disease.

Topical therapy

This is given for limited chronic plaque psoriasis, usually as a vitamin D analogue (calcipotriol, calcitriol, tacalcitol) and an emollient to reduce scaling. Moderate or potent corticosteroids may also be used in combination with vitamin D (e.g., calcipotriol with betamethasone) for short-term control. Other topical agents include coal tar and calcineurin inhibitors (tacrolimus and pimecrolimus) for facial and flexural areas. Dithranol is seldom used nowadays because it stains the skin and clothing. Salicylic acid can help remove scales but increases steroid potency when used concurrently.

Topical therapy is usually applied once or twice daily to skin plaques. Vitamin D analogues should be limited to less than 100 g per week because higher doses may cause hypercalcaemia. Topical therapy is often not practical for widespread plaque psoriasis and the next option is usually narrowband UVB phototherapy. Treatment of difficult-to-treat sites is outlined in **Box 45.17**. Topical therapy of nail disease is usually ineffective because of the difficulty of absorption of topical medication at the levels of the nail plate. Systemic medication and biologics can improve nail dystrophy.

Phototherapy

Patients with guttate psoriasis are usually treated with topical therapies, UVB phototherapy, or both. Chronic plaque psoriasis may also respond to phototherapy with UVB or PUVA. Topical PUVA

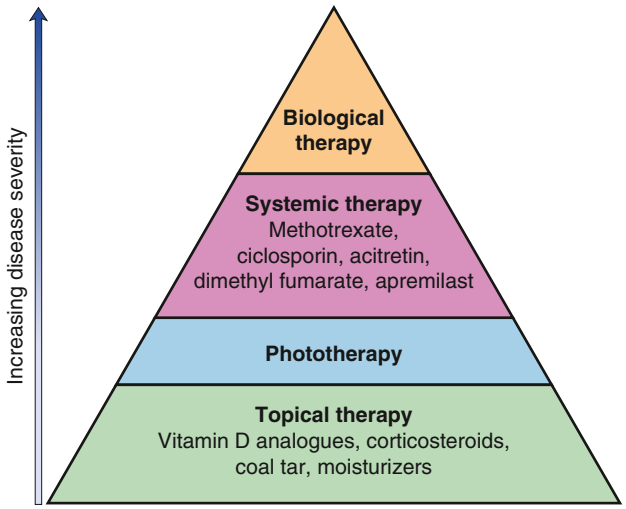

Fig. 45.19 Management of psoriasis.

Box 45.17 Difficult-to-treat sites in psoriasis

- The scalp is considered a 'difficult-to-treat' site because thick scales build up, hindering penetration of topical drugs. Scaling needs removal with keratolytic agents (e.g., silicone lotion or coconut oil and salicylic acid ointment). These can be applied overnight and washed out with a coal tar shampoo.
- Flexural and genital psoriasis requires special consideration because the skin is easily irritated and prone to secondary infection and steroid atrophy. Treatment usually consists of intermittent mild to moderate steroids used alone or in combination with antimicrobial agents. Calcitriol and 0.1% tacrolimus ointment can also be effective.
- Nail psoriasis responds poorly to topical therapy and usually requires systemic drugs.

can be helpful for palmoplantar psoriasis, including palmoplantar pustulosis.

Systemic therapy

Systemic therapy is usually indicated for widespread disease that has failed to respond to topical agents and phototherapy. It may also be needed to manage associated psoriatic arthritis and milder disease with psychological upset. All medication has potential adverse effects and toxicities, and patients should be provided with user-friendly information, such as the British Association of Dermatologists patient information leaflets.

Methotrexate is given orally or by subcutaneous injection in low dose (up to 25 mg) once a week, with folic acid on other days to reduce GI upset. It is a teratogen, so pregnancy must be avoided. Regular blood tests are needed to check liver function and monitor for bone marrow suppression. Measurement of serum procollagen 3 peptide levels and fibrosis-4 (FIB-4) and assessment by liver fibroelastography (see Chapter 23, 'Hepatic stiffness [transient elastography]' section) have evolved as routine non-invasive alternatives to liver biopsy to monitor for hepatotoxicity. Non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided, especially in older adults, because they reduce renal excretion of methotrexate metabolites and may cause toxicity.

Ciclosporin is a selective immunosuppressant that inhibits T lymphocytes. It has been widely used in the acute treatment of patients with severe psoriasis and is a useful drug in unstable or erythrodermic disease because of its rapid onset of action. However, long-term use is often complicated by nephrotoxicity and hypertension and is not recommended.

Acitretin is an oral retinoid used to treat patients with psoriasis and rarer inherited scaly skin diseases (e.g., Darier disease, congenital ichthyosis). It is less effective than ciclosporin or methotrexate but lacks immunosuppressant effects and may be used in combination with UVB and PUVA. All oral retinoids are potent teratogens. Acitretin metabolites have an extremely long half-life, and pregnancy must be avoided for 3 years after completing treatment, so this drug is generally not suitable for females of childbearing potential.

Immunomodulator drugs licensed for use in patients with severe psoriasis include the phosphodiesterase-4 inhibitor ***apremilast*** and ***dimethyl fumarate***. Other drugs include the newly licensed oral selective inhibitor of tyrosine kinase 2 ***deucravacitinib***.

Biological therapy

Advances in understanding the immunopathogenesis of psoriasis have led to development of an expanding and increasingly effective group of targeted biological drugs that block pro-inflammatory cytokines or their receptors. The UK's National Institute for Health and Care Excellence restricts use of these drugs to patients with severe psoriasis (defined by a Psoriasis Area Severity Index [PASI] of >10 and DLQI of >10), in whom phototherapy and conventional systemic drug therapy have failed, are contraindicated, or are not tolerated.

Anti–TNF-α drugs (infliximab, etanercept, adalimumab, certolizumab) were the first group of biologics licensed for use in psoriasis. These have been followed by ***IL-12/23 inhibitors*** (ustekinumab), ***IL-17 inhibitors*** (secukinumab, brodalumab, ixekizumab), and ***selective IL-23 inhibitors*** (guselkumab, tildrakizumab, risankizumab). The more recent allow the majority of patients to achieve a 90% reduction in PASI score (PASI-90), and improvement can be observed within weeks. However, biologic drugs remain expensive despite the launch of several cheaper biosimilars, and they have the potential to lose efficacy over time.

Other common papulosquamous rashes

Pityriasis rosea

Pityriasis rosea is an acute, self-limiting exanthem, which is thought to be caused by a viral infection, possibly human herpesvirus (HHV)-6 and HHV-7. It usually affects older children or young adults, and there is an increased incidence in spring and autumn. The rash is most prominent on the torso and proximal limbs and consists of circular or oval pink macules with a collarette of fine scale. It is usually preceded by a larger solitary 'herald patch' a few days prior. Lesions tend to run along dermatomal lines of the back, giving a 'Christmas tree' pattern. The rash is usually asymptomatic or mildly itchy and resolves within 4 to 8 weeks. Treatment is not usually required, but emollients and a mild steroid cream may be used for pruritus. Severe pityriasis rosea in the first trimester of pregnancy has been associated with fetal loss, and off-label use of aciclovir may be considered.

Polymorphic light eruption

Polymorphic light eruption (PLE) is a sun-induced rash is common in young females and is usually triggered by unusually intense exposure to strong sunshine on holiday. In most cases, it is mild and wrongly attributed to heat ('prickly heat'). Typically, an itchy papular rash develops on sun-exposed areas, particularly the anterior neck, shoulders, and arms, several hours to days after sun exposure and persist for several days. Papules, plaques, and vesicles may occur, hence the term 'polymorphic'. A minority of people with PLE are severely affected and develop the rash in temperate zones, starting in spring or early summer. It is thought to be caused by a delayed-type hypersensitivity to an endogenous antigen that occurs in the skin after UV exposure (photoantigen). Mild cases can be managed by avoiding the sun (with high sun protection factor [SPF] sunscreens and clothing) and gradually building up tolerance to sunlight. Short courses of oral corticosteroids can be given for prophylaxis or treatment. People who are troubled by severe PLE can be desensitized with a short course of UVB phototherapy in early spring, which enables them to tolerate subsequent sun exposure.

Lichen planus

Lichen planus (LP) is a chronic inflammatory skin disease that can affect the skin, scalp, nails, oral mucosa, anogenital area, and oesophagus.

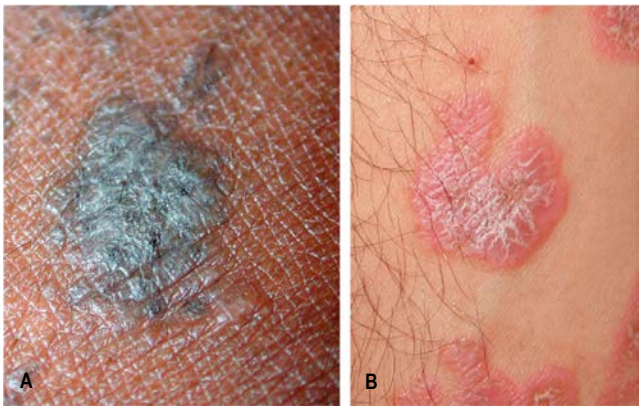

Fig. 45.20 Lichen planus. Lichen planus on pigmented skin **(A)** has a much darker appearance than on lightly pigmented skin **(B)**. Erythema and striae are less obvious. The lesion and surrounding skin become more heavily melanin-pigmented because of the chronic inflammation, producing a very different appearance.

Aetiology is thought to be a an immune-mediated mechanism involving CD8+ T cells against basal keratinocytes with a potential association with the hepatitis C virus (HCV). LP-like (lichenoid) rashes may be caused by drugs (e.g., antihypertensives, antimalarials, NSAIDs) and contact allergens. However, in most cases, there is no identifiable cause.

Clinical features

Cutaneous LP appears as clusters of intensely pruritic, flat-topped, purple-pink (violaceous), polygonal papules (Fig. 45.20) that usually affect the flexural aspect of the extremities such as the wrists, forearms, and lower legs but may be widespread. Close inspection of the papules shows fine white streaks (Wickham striae). Lesions can fuse into plaques, especially on the lower legs, where they become hyperkeratotic. After resolution, marked post-inflammatory hyperpigmentation is common, especially in people with skin of colour. LP may köbnerize, that is, localize to areas of superficial trauma. Scalp and nail involvement may lead to scarring alopecia and permanent nail damage or loss.

Mucosal LP is seen in about 50% of patients with cutaneous LP, and the oral and genital mucosae may also be affected in isolation. Involvement ranges from asymptomatic, reticulate white streaks on the buccal mucosa and lateral tongue (Wickham striae) to a severe, painful, erosive gingivitis and glossitis (erosive LP). Delayed-contact allergy to metals in amalgam fillings may cause localized LP-like changes on the oral mucosa. The anogenital mucosa may be affected by LP and lesions on the penis are often annular. A severe erosive variant can affect the vulva and vagina in females. Genital LP can result in significant scarring.

Diagnosis and treatment

Histology of LP is usually diagnostic and shows a dense infiltrate of lymphocytes along the dermo-epidermal junction (DEJ), which becomes damaged with degenerate (apoptotic) basal keratinocytes. Cutaneous LP usually resolves within 1 to 2 years, though it may relapse. Hypertrophic disease and mucosal, genital, and scalp disease are usually more persistent. Malignant change with development of SCC may rarely complicate chronic ulcerated LP.

Skin and mucosal lesions usually respond to potent or super-potent topical corticosteroids and topical tacrolimus. Widespread skin disease may require tapering courses of oral steroids, phototherapy, oral retinoids, anti-malarials, methotrexate, or systemic immunosuppressants such as azathioprine.

Granuloma annulare

Granuloma annulare usually affects children and young adults. It is often asymptomatic and characterized by clusters of small flesh-coloured or slightly erythematous papules (with no scaling) in an annular shape with a dusky centre. These typically affect the dorsal hands or feet (or both) but can be generalized in 15% of cases. The cause is unknown, but several systemic associations have been reported, including diabetes mellitus and dyslipidaemia and thyroid disease. Localized granuloma annulare is usually self-limiting and resolves after a few years, but potent topical or intralesional steroids can be tried if necessary.

Lichen sclerosus

Lichen sclerosus (LS) is a common chronic inflammatory dermatosis of the genital area. The cause is unknown, but it may be autoimmune and preceding infection or trauma, and an occluded, moist environment may act as triggers.

Clinical features

In females, the usual age of onset is before puberty or after menopause. Males may develop LS at any age. Lesions are intensely pruritic or sore, and appear as shiny, ivory-white, fissured plaques on the vulva, glans penis, distal foreskin, or penile shaft. Additional perianal involvement is common in females, leading to a 'figure-of-8' distribution. Telangiectasia may be evident, and early lesions in young females can present with haemorrhagic blisters that are occasionally mistaken for signs of sexual abuse.

The scarring and atrophy that accompany longstanding LS cause changes in the vulval structure, with loss and fusion of the labia minora and scarring of the clitoral hood. Involvement of the foreskin can cause phimosis, and urethral disease may cause strictures and impaired micturition. Profound sexual dysfunction can result from LS in both males and females.

Management

The diagnosis is usually made by the clinical appearance. Histology shows thickened (hyalinized) dermal collagen and a thin, flat (atrophic) epidermis.

Short-term courses of potent or super-potent topical corticosteroids improve the signs and symptoms of LS. TCIs may also be helpful. The condition may remit spontaneously after several years, especially in children. Unresponsive phimosis may necessitate circumcision. Longstanding anogenital LS is associated with an increased risk of SCC in affected sites.

Urticaria and angio-oedema

Urticaria (hives, 'nettle rash') is common (10% of the population will have urticaria at some stage in their life) and is characterized by short-lived (<24 hours), itchy swellings or 'weals' with a surrounding redness (flare) (Fig. 45.21). The short-lived nature of individual swellings and lack of skin surface changes help distinguish urticaria from other inflammatory rashes, especially eczema.

Fig. 45.21 Urticaria.

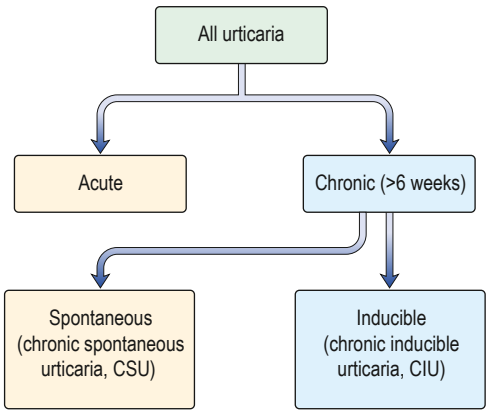

Fig. 45.22 Classification of urticaria. *CSU,* Chronic spontaneous urticaria.

Angio-oedema is a similar disorder involving deeper tissues and usually affecting the lips, tongue, and eyelids. Urticaria and angio-oedema may occur together or separately and have a range of causes. Angioedema by itself may be a feature of chronic spontaneous urticaria or may be a side-effect of angiotensin-converting enzyme (ACE) inhibitor or of an underlying hereditary angioneurotic oedema (HAE).

Aetiology and clinical features

Urticaria and angio-oedema with weals are caused by dermal mast cell degranulation and release of a range of pro-inflammatory mediators (including histamine), together with release of neuropeptides from cutaneous nerves, which together cause vasodilation and increased capillary permeability. Mast cell degranulation may be triggered by various stimuli, including ***drugs*** (opiates, aspirin), ***physical triggers*** (friction, pressure, sweating), ***allergens***, and ***autoantibodies***. Urticaria is classified as acute or chronic (>6 weeks' duration). Chronic urticaria is divided into spontaneous and inducible types (Fig. 45.22).

Acute urticaria (urticaria lasting up to 6 weeks) is often triggered by infections or (more commonly an allergic response to a foodstuff, e.g., peanuts). It may also be the presenting feature of immediate (type 1) allergy, especially in young children with atopic eczema. Common causes include food (nuts, egg, milk), drugs (penicillin), and natural rubber latex. Allergic urticaria may be localized to an area of skin (contact urticaria), such as caused by latex gloves, or take the form of a more widespread reaction that can evolve to anaphylaxis (see Chapter 11, 'Anaphylaxis' section). Measurement of allergen-specific IgE or skin prick tests and allergen challenge tests can be done to confirm an allergic cause.

Chronic inducible urticaria has a range of causes, including friction (symptomatic dermographism), pressure (delayed pressure urticaria), cold (cold urticaria), sunshine (solar urticaria), and sweating (cholinergic urticaria). Physical tests, such as lightly scratching the skin for dermographism or an ice cube test for cold urticaria, are helpful in demonstrating the cause.

Chronic spontaneous urticaria (CSU) is thought to have an underlying autoimmune basis, and in some individuals, functional autoantibodies against the high-affinity IgE receptor on mast cells and basophils or against IgE antibodies can be identified. There is also an association with autoimmune thyroid disease. Chronic urticaria is seldom caused by food allergy, and food allergy tests are not indicated.

Angio-oedema without weals is classified into hereditary and acquired variants:

- ***HAE*** is a rare autosomal dominant condition that can cause recurrent and severe swellings of the skin, upper airways, and intestinal tract. Laryngeal involvement may be life-threatening. Attacks usually start in childhood and can be spontaneous or triggered by minor trauma. Skin swellings are not itchy and usually last for several days. HAE types I and II are caused by mutations in the *SERPING1* gene that result in decreased plasma levels of functional C1 esterase inhibitor (C1NH). This allows unchecked activation of the complement cascade. Serum complement C4 can be measured as a screening test. C1NH activity is normal in type III HAE. All forms of HAE are caused by increased levels of bradykinin.
- ***Acquired angio-oedema*** may be idiopathic or associated with lymphoproliferative or autoimmune disorders. Drugs can also cause angio-oedema, especially ACE inhibitors and angiotensin II receptor antagonists. The rate is up to four times higher in Afro-Caribbean patients, and the onset may be delayed by months or years after starting therapy, so a careful drug history is essential.

Management

Acute urticaria is usually self-resolving. Allergic urticaria and angio-oedema may require emergency treatment with intramuscular adrenaline (epinephrine) and intravenous steroids (see Chapter 6, 'Allergic disease [immediate hypersensitivity]' section). ***Chronic urticaria*** is managed with nonsedating antihistamines such as loratadine 10 mg/day; the dose may be increased fourfold if needed for symptom control. Montelukast may also be helpful in those with aspirin sensitivity. NSAIDs and opiate analgesics should be avoided because they can aggravate urticaria. The biological anti-IgE drug omalizumab is licensed for antihistamine-refractory CSU.

Management of ***HAE*** used to be limited to prophylaxis with attenuated androgens (stanozolol, danazol), which were poorly tolerated, and treatment of acute attacks was with fresh-frozen plasma. Newer selective therapies include plasma-derived and recombinant C1NH, a kallikrein inhibitor (ecallantide), and a bradykinin B2 receptor antagonist (icatibant). These newer products can be used for treatment of acute attacks of HAE, and C1NH is also used for prophylaxis.

Urticarial vasculitis

If urticarial weals are painful and last for more than 24 hours, leaving bruising or a blemish, this may indicate an underlying vasculitis rather than ordinary urticaria. The patient should be thoroughly assessed with blood tests, skin biopsy, and urinalysis.

SKIN INFECTIONS

The skin is the largest organ in the body and is home to an enormous and diverse population of microbial organisms—the skin microbiome. The skin microbiome includes a vast array of bacteria, viruses, and fungi, most of which are commensals (permanent non-pathogenic residents) or transients (temporary residents). Considerable variation in the composition of the skin microbiome exists both across different body sites and between individuals.

Disruption of host–microbiome interactions can cause an organism to transition from commensal to pathogen, causing skin disease, and may occur as a result of alterations in environmental exposures, trauma, changes in host immunity, and host genetic variations. In addition to its role in skin infections, there has been intense interest in recent years in the role of the skin microbiome across a range of other inflammatory and malignant skin diseases.

Bacterial infections

See also Chapter 11 ('Acute skin infections' section).

Impetigo

Impetigo is a common and highly contagious skin infection affecting the superficial epidermis which is typically caused by *S. aureus* or less commonly by group A beta-haemolytic *Streptococcus pyogenes* (or sometimes by both organisms together). Although it is most common in children, impetigo can occur at any age and is transmitted by direct skin contact.

Two forms of impetigo are recognized:

- ***Nonbullous impetigo*** is most common on the face and the extremities. Infected areas initially appear as red macules (which may be more difficult to see in darker skin tones) and pustules evolving into characteristic golden (honey-coloured), crusted, and eroded plaques (Fig. 45.23). It can spread rapidly and may be itchy with associated regional lymphadenopathy, but patients are usually well.
- ***Bullous impetigo*** is caused by exfoliative toxins produced by *S. aureus*, which target intracellular adhesion molecules in the epidermal granular layer, resulting in blister formation. Lesions appear as superficial, thin-roofed blisters that rupture and ooze yellowish fluid, leaving a rim of scale, and patients may have malaise, fever, and lymphadenopathy.

The term 'impetiginization' is also used to describe secondary infection of skin lesions with similar clinical appearances to impetigo.

Fig. 45.23 Impetigo. Yellowish, crusted lesions on the chin with areas of blistering (bullous impetigo).

Predisposing factors include skin diseases such as atopic eczema, skin trauma, immunosuppression, crowded environments, and warm and humid climates. Complications include cellulitis, bacteraemia, staphylococcal scalded skin syndrome, post-streptococcal glomerulonephritis, and post-inflammatory hyper- or hypopigmentation.

Management

The diagnosis is usually based on clinical features, and a skin swab may be helpful if impetigo is recurrent or widespread. Nasal swabs can identify staphylococcal nasal carriage, which may be a source of recurrent infection.

Treatment of localized nonbullous impetigo is with topical antiseptics and topical antibiotics (fusidic acid as first line, mupirocin in cases caused by methicillin-resistant *S. aureus* [MRSA]).

Oral antibiotics are used in widespread (more than 3 lesions) nonbullous impetigo and bullous impetigo and for patients at risk of complications. Flucloxacillin is usually the first-line treatment (or erythromycin or clarithromycin in penicillin-allergic patients). Nasal staphylococcus nasal carriage should be treated in patients with recurrent infections.

Affected individuals should avoid close contact with others (e.g., school or work) until the lesions have crusted over or after at least 24 hours of treatment.

Ecthyma and ecthyma gangrenosum

Ecthyma is considered a deeper form of impetigo and is usually caused by the same bacteria. It presents as chronic, well-demarcated, deep ulcers with overlying, adherent necrotic crust and exudate. Lesions are up to 3 cm in diameter and may heal with scarring. It is most common in children, older people, and immunocompromised people and often affects the lower limbs and buttocks. Predisposing factors include poor hygiene, crowded living conditions, high temperature and humidity, malnutrition, immunocompromise, and the presence of minor skin injuries of other skin conditions. Complications include more widespread infection, scarring, and post-streptococcal glomerulonephritis. Management is with topical antiseptics, topical and systemic antibiotics, improved hygiene, and addressing predisposing factors.

Ecthyma gangrenosum is characterized by distinctive necrotic ulcers with a central thick, black-brown eschar, and surrounding redness that evolve rapidly through initial red macules and subsequent haemorrhagic pustules. It particularly affects axillae and anogenital areas. It is most frequently caused by *Pseudomonas aeruginosa* bacteraemia in an immunocompromised or neutropenic patient, with bacterial invasion of the subcutaneous vasculature causing haemorrhagic occlusive vasculitis. Other bacterial, viral, and fungal pathogens may also be implicated.

Management requires prompt diagnosis of the causal infection for which swabs, blood cultures, and skin biopsy and culture may be needed. Treatment is with the appropriate parenteral antibiotics for the causal underlying bacteraemia.

Cellulitis

Cellulitis describes bacterial infection of subcutaneous tissue and is dealt with elsewhere (see Chapter 11, 'Cellulitis and erysipelas' section). Necrotizing bacterial infection extending into deeper soft tissue structures or muscle (***necrotizing fasciitis*** or ***myonecrosis***; see Chapter 11, 'Necrotizing fasciitis' section) is a clinical emergency with a high mortality rate.

Folliculitis

Folliculitis is a common superficial infection of the hair follicle by a range of pathogens, but non-infective causes are also recognized.

- *S. aureus* is the most common cause of infective folliculitis and presents as itchy or tender small papules and pustules. Predisposing factors include friction, occlusion, humidity, diabetes, immunodeficiency, and underlying skin disease (e.g., atopic dermatitis). A deeper variant affecting hair follicles in the beard area (sycosis barbae) causes multiple papules that may coalesce to form pustule-studded plaques. The main differential diagnosis is pseudofolliculitis barbae, which is caused by ingrowth of curly hairs.
- *P. aeruginosa* folliculitis is caused by inadequately disinfected hot tubs or spas and lesions tend to cluster under swimming costumes.
- *Malassezia (pityosporum)* folliculitis caused by *Malassezia* yeast infection causes papules and pustules mainly on the trunk.
- *Extensive, itchy folliculitis* may also be a manifestation of HIV infection (see Chapter 44).
- *Non-infective folliculitis* may be caused by trauma (e.g., shaving and waxing), chemicals (e.g., coal tar), and occlusion (e.g., emollient use).

Management

Topical antiseptics, topical or oral antibiotics, or antifungals are used in bacterial and *Malassezia* folliculitis, respectively. Management should address underlying predisposing factors.

Boils (furuncles) and carbuncles

Boils (furuncles) are deeper infections of hair follicles and surrounding subcutaneous tissue and appear as painful, red, pus-containing nodules. Multiple boils may coalesce to form carbuncles, which are larger swellings with multiple pus-discharging openings and may cause systemic symptoms. The term 'skin abscess' refers to a collection of pus within the dermis and deeper skin tissue and therefore includes furuncles and carbuncles, which are usually caused by *S. aureus* infection. Factors predisposing to formation of boils include diabetes, metabolic syndrome, iron deficiency, malnutrition, and immunocompromise.

Most people with boils are otherwise healthy but may carry *S. aureus* on their skin or in their upper respiratory tract, and up to 20% of the population are staphylococcal carriers. Person-to-person spread may be facilitated by poor hygiene or overcrowding. Enhanced transmission and increased virulence is also caused by *S. aureus* strains (both MRSA and non-MRSA), which secrete an exotoxin called ***Panton–Valentine leukocidin (PVL)***. PVL *S. aureus* (PVL-SA) has been associated with outbreaks of severe recurrent furuncles, carbuncles, and skin abscesses in healthy adults.

Management

Skin and nasal swabs should be taken in severe or recurrent folliculitis, furuncles, and carbuncles to determine antibiotic sensitivities and to screen for staphylococcal carrier status and PVL-SA strains. Other predisposing causes should be addressed.

Small, isolated boils can be treated with hot compresses alone. Oral antibiotics are required for larger or more widespread infection, and intravenous antibiotics may be required for severe infections. Larger abscesses may require incision and drainage. PVL-positive strains required prolonged therapy with a combination of antibiotics such as rifampicin and clindamycin. Screening of family contacts and decolonization measures (including nasal mupirocin ointment and antiseptic washes, e.g., with chlorhexidine) are recommended as part of prevention in recurrent disease.

Erythrasma and pitted keratolysis

Erythrasma is a common superficial skin infection caused by gram positive *Corynebacterium minutissimum*. Corynebacteria are part of the normal skin microbiome but can also act as pathogens.

Fig. 45.24 Erythrasma. (A) Erythrasma of the axilla. **(B)** Pink fluorescence under a Wood lamp.

Erythrasma presents as well-defined, pink-brown plaques with fine scaling most commonly in the axillae, groin, and toe webs (Fig. 45.24), and it is often misdiagnosed as fungal infection. The diagnosis is supported by the characteristic coral-pink fluorescence of affected areas when examined with Wood lamp light (long wavelength UVA radiation), which is caused by coproporphyrin III released by the bacteria.

Corynebacteria are also implicated in ***pitted keratolysis***. This superficial skin infection appears on weight-bearing plantar skin of the feet as multiple punched-out 1- to 3-mm-diameter pits and maceration that fluoresces coral-pink with Wood lamp examination. There is usually associated malodour. The clinical features are caused by production of protease enzymes by the bacteria, which cause stratum corneum destruction. Predisposing factors include hyperhidrosis, keratoderma, wearing occlusive footwear, diabetes, and immunocompromise.

Management

Patients with erythrasma can be treated with topical antiseptics or antibiotics (fusidic acid and clindamycin) or oral antibiotics (erythromycin or tetracycline). Pitted keratolysis responds to astringents such as potassium permanganate soaks, antiperspirants, and topical imidazoles or fusidic acid combined with adequate foot hygiene.

Borrelia infection: Lyme disease

Lyme disease (see Chapter 42, 'Lyme disease' section) is caused by infection with the spirochaete *Borrelia burgdorferi* transmitted by tick bites. The main hosts for the ticks are animals, including deer, often in grass and woodlands. The skin is one of the most common organs to be affected, but infection can also involve the central nervous system (CNS), joints, heart, eyes, and liver. Depending on the infecting subspecies, *Borrelia* infection may present in the skin in two main patterns:

- ***Erythema chronicum migrans*** occurs in 70% to 80% of cases and is the most characteristic sign of Lyme disease. It appears 1 to 2 weeks after the initial tick bite as a gradually expanding, pink to purple plaque often with central clearing, which is asymptomatic, but may become itchy and associated with flu-like symptoms and lymphadenopathy. It usually resolves after 3 to 4 weeks, but if untreated, infection disseminates and joint, CNS, and cardiac involvement may occur months later.
- ***Acrodermatitis chronica atrophicans*** is the most common skin condition in the late stage of disease, occurring months to years after infection as violaceous discoloration over the dorsum of the hands, elbows, knees, and ankles followed by fibrosis and atrophy. The diagnosis is based on positive serology, consistent

histological features on skin biopsy, and positive *Borrelia* polymerase chain reaction (PCR) results. Treatment is with antibiotics, including doxycycline.

Mycobacterial infections

Leprosy (Hansen disease)

Leprosy (see Chapter 42, 'Leprosy [Hansen's disease]' section) is a chronic bacterial infection usually caused by the intracellular acid-fact bacillus *Mycobacterium leprae*. Worldwide prevalence is more than 5 million; most endemic cases are in India, Myanmar, Indonesia, Brazil, and Nigeria. Spread is probably by inhalation of airborne droplets with an incubation period of 6 months to 20 years. It typically affects the skin and peripheral superficial nerves because of its predilection for cool temperatures. The clinical features depend on the host immune response to *M. leprae*. However, in most cases, the first symptom is numbness, which may precede the appearance of skin lesions by years.

Initial skin lesions are often those of ***indeterminate leprosy***, with a few small, hypopigmented or red, scaly patches with reduced sensation. Biopsy reveals a perineural granulomatous infiltrate and scant acid-fast bacilli. It may resolve spontaneously or progress to tuberculoid or lepromatous types.

In ***tuberculoid leprosy***, there is a strong immune response and consequently fewer organisms (paucibacillary). It presents with a few hypopigmented patches or well-defined red plaques. Sensation is absent within lesions, which are also dry and hairless. Nerves may be enlarged, palpable, and tender. Biopsy shows a granulomatous infiltrate around nerves but no organisms. In ***borderline tuberculoid leprosy***, lesions are more numerous and less well defined, and anaesthesia is less prominent.

Lepromatous leprosy is a multibacillary form caused by a low or limited immune response to *M. leprae*. It presents with nasal stuffiness, discharge, and bleeding with multiple poorly defined hypopigmented and red macules with normal sensation, which progress to inflammatory plaques, nodules, and widespread skin infiltration. A characteristic 'leonine facies' is described with thickening and distortion of the forehead, nose, and earlobes and loss of the eyebrows and eyelashes (madarosis). Skin swelling and thickening and trophic ulceration of the limbs with severe disfigurement may follow. Multiple other organs may also be involved, including the eyes, liver, kidney, testes, and bones. Skin biopsy shows numerous acid-fast bacilli. In ***borderline lepromatous leprosy***, skin lesions are widespread, and symmetrical and sensation and hair growth remain normal, but there is a glove-and-stocking peripheral neuropathy with widespread peripheral nerve involvement.

Skin involvement is also a feature of ***'lepra' reactions*** during treatment. Type I lepra reactions usually occur in patients with borderline leprosy and cause increased erythema, induration, and ulceration of existing lesions and in severe reactions; nerve involvement also occurs. Type 2 reactions (erythema nodosum leprosum) occur in patients with borderline lepromatous leprosy and lepromatous leprosy and is an acute immune complex vasculitis. It causes multiple painful red nodules, sterile pustules, and ulcers and may cause systemic symptoms and affect multiple other organs.

Further clinical details, diagnosis, and management are discussed in Chapter 42 ('Leprosy [Hansen's disease]' section).

Skin manifestations of tuberculosis

Tuberculosis (TB) caused by *Mycobacterium tuberculosis* (see Chapter 20, 'Tuberculosis' section) can cause skin manifestations caused by:

- Cutaneous infection: either direct inoculation or re-inoculation of bacilli into the skin or direct extension or haematogenous spread to the skin from an underling infective focus
- Hypersensitivity reactions to underlying infection, including *tuberculides* and *erythema nodosum.*

A variety of skin lesions are caused by direct cutaneous TB infection of the skin:

- ***Primary cutaneous TB*** is caused by direct inoculation of bacilli into the skin. It usually appears 1 to 4 weeks after a penetrating injury such as tattooing or piercing, often occurs on the face, hands, or legs. An initial painless, firm red papule becomes ulcerated, and may be associated with sporotrichoid spread (along the lines of the lymphatic drainage) and local lymphadenopathy. Rarely it may follow BCG vaccination, particularly in people with STAT1 mutation or on TNF-alpha inhibitors.
- ***Lupus vulgaris*** results from re-infection, particularly on the head and neck. It presents with red–brown nodules that merge into plaques with a gelatinous 'apple jelly' appearance when pressed under a glass slide (diascopy). These heal with scarring, which may be disfiguring, and persistent lesions may predispose to cutaneous SCC (cSCC) 25 to 30 years later in up to 10% of people.
- ***TB verrucosa cutis (warty TB)*** also occurs after further inoculation in people who have previously been infected and have developed good immunity. It appears as brown, red or purple warty plaques often on the hands, feet, knees, elbows, and buttocks.
- ***Orificial TB*** is caused by autoinoculation of bacilli from internal disease, with shallow ulcers appearing at mucocutaneous junctions such as nose, mouth, and perianally.
- ***Scrofuloderma*** occurs because of invasion of the skin from an affected lymph node or bone, particularly around the jaw and neck. Firm painless lesions eventually ulcerate and heal with disfiguring scars and may also predispose to cSCC.
- ***Cutaneous miliary TB*** results from haematogenous spread of TB in patients with an active internal focus of infection. It causes multiple red papules which become ulcerated, necrotic and form abscesses and has a poor prognosis.

Cutaneous hypersensitivity reactions seen in TB infection include:

- ***Tuberculids***, which are skin lesions from which *M. tuberculosis* cannot be isolated as they represent a type III or IV hypersensitivity reaction to an underlying infection. The reaction is probably caused by haematogenous spread of mycobacterial antigens to the skin. ***Erythema induratum (Bazin disease)*** is the most common tuberculid and presents as tender red nodules and plaques on the posterior calves, particularly in females, which may ulcerate and scar.
- ***Erythema nodosum***, not strictly classified as a tuberculid, may also occur as a hypersensitivity reaction to underlying *M. tuberculosis* infection (see 'Erythema nodosum' section).

The diagnosis and treatment of patients with TB are discussed in Chapter 20 ('Tuberculosis' section).

Atypical mycobacterial infections

These are infections caused by mycobacterial species other than *M. tuberculosis* and *M. leprae*. Of more than 30 species, those most often associated with skin and soft tissue infections are *Mycobacterium marinum, Mycobacterium ulcerans* (Buruli ulcer), *Mycobacterium fortuitum,* and *Mycobacterium chelonae*. Skin infection often causes plaques, crusted nodules, and abscesses. Skin biopsy and culture are important for diagnosis.

M. marinum infection ('fish tank' or 'swimming pool granuloma') is one of the more common types and is usually acquired through recreational or occupational exposure with contaminated,

non-chlorinated water, for example, after cleaning a fish tank without gloves. The initial lesion is usually a single painless inflammatory nodule or abscess on the dorsum of the fingers or hands. Further lesions may appear in a sporotrichoid distribution and are more widespread in immunocompromised patients. The diagnosis is usually made from the history and clinical features. A skin biopsy shows granulomatous inflammation, and *M. marinum* may be identified by prolonged culture at low temperature or PCR of skin lesions.

Treatment is with combination oral antibiotics (e.g., clarithromycin and ciprofloxacin) for 8 to 12 weeks, according to microbiological guidance.

Viral infections

Viral exanthems

The most common cutaneous manifestation of viral infections is a widespread maculopapular rash or exanthem that predominantly affects the torso and proximal limbs and is usually associated with systemic symptoms. It is probably caused by deposition of antibody–viral antigen immune complexes within dermal blood vessels. Many viruses cause exanthems, including echovirus, measles, HHV-6, Epstein–Barr virus, and erythema infectiosum (fifth disease) (see Chapter 42, 'Maculopapular viral rashes' section). The rash generally resolves spontaneously in 7 to 10 days.

Herpes simplex virus

Herpes simplex is a common viral infection that causes localized blistering. HSV-1 is mainly associated with orofacial infections and HSV-2 with anogenital infections, but both viruses can affect any mucocutaneous site. HSV remains latent in spinal dorsal root nerves between recurrences. It is transmitted by direct or indirect contact with active HSV and less commonly by asymptomatic shedding in saliva or genital secretions.

Most people are infected with HSV type 1 in childhood. Primary infection is often subclinical but may cause clusters of painful blisters on the face (**Fig. 45.25**) or an ulcerative gingivostomatitis associated with fever and lymphadenopathy. Minor trauma may facilitate inoculation at other sites, such as the cheek and neck in people who play contact sports or the fingers in healthcare workers (herpetic whitlow). After a primary infection, some individuals experience recurrent attacks of HSV at approximately the same site. This usually consists of smaller, umbilicated blisters and 'punched-out' ulcers on a red base that are closely grouped and usually preceded by burning or pain. They heal without scarring, although there may be post-inflammatory hypo- or hyperpigmentation at the site, which often are more apparent in darker skin tones. Factors that may trigger recurrences include illnesses such as upper respiratory tract infections ('cold sores'), UV exposure, menstruation, and emotional stress.

HSV-2 infection (see Chapter 42, 'Herpes simplex virus infection' section) is usually sexually acquired and associated with anogenital ulceration (although HSV-1 causes genital infection in 30% of cases and HSV-2 also causes lesions at non-genital sites such as the buttock and lower back). Infection can result in significant pain and difficulty passing urine, particularly during a primary infection. Recurrences are more frequent with HSV-2, and in immunocompromised patients, recurrences of both HSV-1 and 2 may be more frequent and episodes more severe with chronic ulceration. Other complications of HSV infection include corneal ulceration, eczema herpeticum, and erythema multiforme.

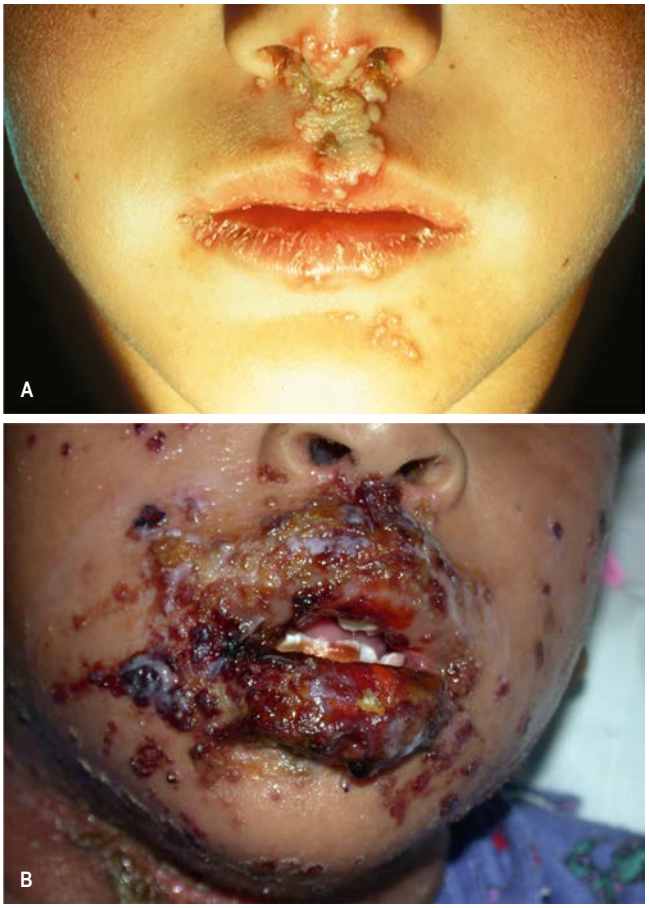

Fig. 45.25 Herpes simplex infection. (A) Labelled primary herpes simplex infection. **(B)** More extensive primary herpes simplex infection with probable bacterial superinfection.

Management

Oral antiviral therapy (e.g., aciclovir, valaciclovir) may be given for patients with severe primary HSV. Topical aciclovir started as soon as burning or discomfort is felt may shorten an episode of recurrence. However, if recurrence is more severe, oral antivirals are required as 'attack-initiated' treatment. Patients with frequent recurrences can be treated with prophylactic low-dose oral therapy. Eczema herpeticum, neonatal infection, and infection in immunocompromised patients require intravenous antiviral therapy with aciclovir or with foscarnet if resistance to aciclovir develops.

Varicella zoster virus

Varicella zoster virus (VZV, HHV-3) causes the common childhood infection varicella (chickenpox; see Chapter 42, 'Varicella [chickenpox] and herpes zoster [shingles]' section) which may reactivate later in life as herpes zoster.

Herpes zoster (shingles)

VZV remains latent in dorsal root ganglia after primary varicella infection. Herpes zoster results from reactivation of latent VZV infection, usually in adulthood. Triggers include infection, injury, radiotherapy, and contact with varicella or herpes zoster. It may be preceded by a prodromal phase of itch, tingling, or pain and may be associated with fever, headache, and feeling unwell. Within 1 to 3 days, a painful, unilateral, blistering eruption appears in the area and is in a characteristic dermatomal distribution (**Fig. 45.26**; see also **Fig. 42.10**). New lesions occur in crops over several days as initial

Fig. 45.26 Herpes zoster in an African male. (*Courtesy of Dr P Matondo, Lusaka, Zambia.*)

red papules, which then blister and may become purulent before crusting. Thoracic, cervical, and lumbosacral dermatomes are most often affected, and ophthalmic dermatomal involvement increases with age. Involvement of dermatomes affecting the mouth, ears, and genital areas can also occur. The rash lasts 2 to 4 weeks and is usually more severe in older adults or immunocompromised patients with involvement of more than one dermatome.

Complications include ocular disease (if the ophthalmic nerve is involved); motor neuropathy (e.g., facial nerve palsy in Ramsay-Hunt syndrome); and disseminated disease involving internal organs (e.g., encephalitis), which is more common in the immunocompromised patients. Severe blistering may leave post-inflammatory pigmentary changes and scarring. The risk of severe, persistent pain or burning sensation more than 1 month after the onset of herpes zoster (post-herpetic neuralgia) increases with age and is more common with facial infection.

Management

Oral antiviral therapy should be started within 72 hours of the onset of the rash and continued for 7 to 10 days to reduce pain, severity, and viral shedding. Parenteral therapy is indicated in immunocompromised patients. General measures include adequate analgesia and antibiotics if secondary bacterial infection is present. Treatment of patients with post-herpetic neuralgia includes topical capsaicin, tricyclic antidepressants, gabapentin, and pregabalin.

Recombinant and live-attenuated shingles vaccines are available to boost immunity against VZV in older adults (in the UK, adults older than 65 years of age) and people who are severely immunocompromised to reduce the risk of developing herpes zoster. Only recombinant vaccines are used in immunocompromised patients because of the risk of infection from live-attenuated vaccines.

Human papillomavirus

There are more than 200 known human papillomavirus (HPV), types and they have specific tropisms for the skin and mucosae. HPV is part of the normal skin microbiome, and infection may be asymptomatic. Viral warts caused by HPV infection are common, benign hyperproliferative mucocutaneous lesions. Persistent mucocutaneous HPV infection is occasionally associated with malignant transformation, particularly in anogenital sites (cervical cancer and some penile, vulval, and anal cancers), in the oropharynx (including some types of tonsillar cancer), and causing some types of cSCCs (including periungual cSCC). Transmission is by direct contact and is facilitated by trauma. Severe mucocutaneous HPV infection may be a feature of immunocompromise.

- ***Common warts*** (verruca vulgaris) are single or multiple papules with a hyperkeratotic, warty (papillomatous) surface, most often seen on the hands and feet and in periungual sites may be painful and cause nail dystrophy (**Fig. 45.27A**).
- ***Plantar warts*** (verruca plantaris) occur on the soles of the feet as endophytic lesions with a papillomatous surface. Small black dots (thrombosed capillaries) may be visible and cause pinpoint bleeding if the skin is pared down, distinguishing them from callosities (**Fig. 45.27B**). Plantar warts may be tender if they affect pressure points and can affect walking.
- ***Mosaic warts*** are clusters of multiple, confluent, more superficial and less tender plantar warts.
- ***Filiform warts*** are warts with elongated, 'digitate' fronds that occur most frequently on the face (**Fig. 45.27C**). Children and adolescents are usually affected. They may also affect the beard area in males and spread by shaving.
- ***Plane warts*** are less common and caused by specific HPV subtypes. They are small, flat-topped papules and may be skin-coloured or lightly pigmented; they are best seen with side-on lighting. They are usually multiple and are frequently found on the face or the backs of the hands and may exhibit the Köbner phenomenon (**Fig. 45.27D**).
- ***Anogenital warts*** are described in Chapter 43 ('Human papillomavirus [anogenital warts]' section).

Epidermodysplasia verruciformis is a genodermatosis (a hereditary condition causing a particular skin phenotype) that causes a predisposition to widespread cutaneous infection with beta HPV types. It is characterized by disseminated hypo- and hyperpigmented plane warts, pityriasis versicolor-like lesions, and red plaques. Progression to cSCC on UV exposed sites may occur. Similar features may be seen in acquired immunocompromise such as HIV infection.

Management

The diagnosis is usually clinical and can be assisted by dermoscopy. Skin biopsy is only required if lesions such as SCC cannot be excluded clinically. In most cases, spontaneous resolution occurs over 12 to 24 months, and treatment is not required. However, warts may persist for months or years, particularly in immunocompromised patients such as solid organ transplant recipients, and can cause significant discomfort and psychosocial effects. There is no available treatment that kills HPV infection, and most available treatments work by stimulating an immune response to the virus. Regular use of a topical keratolytic agents (e.g., 10%–26% salicylic acid) after removal of hyperkeratotic skin may hasten resolution and is the mainstay of treatment. Liquid nitrogen cryotherapy can also be effective but is painful and can cause dyspigmentation, and repeated cycles are usually required. Other destructive treatments include surgery and laser therapy, which may also cause pain and scarring. Treatment of patients with anogenital warts is discussed in Chapter 43 ('Human papillomavirus [anogenital warts]' section).

Molluscum contagiosum

Molluscum contagiosum is a common childhood skin infection caused by a pox virus. Lesions appear as small (1–3 mm), translucent, firm skin-coloured papules with a central indentation (umbilicated) (**Fig. 45.28**). They may have surrounding eczematous changes. They contain soft, white, keratinous matter that can be extruded by squeezing. They often occur in clusters, particularly in flexures; may spread by autoinoculation; exhibit the Köbner phenomenon; and can affect any body site. They are more common in children with atopic dermatitis. Occasionally, larger ('giant') lesions of up to 1 cm in diameter may occur, and widespread infection should raise the possibility of immunocompromise, especially HIV infection. Lesions usually appear in crops over 6 to 12 months. They may become

Fig. 45.27 Viral warts. (A) Common wart (verruca vulgaris). **(B)** Mosaic plantar warts. **(C)** Filiform wart. **(D)** Plane warts: multiple, skin-colored papules. Note pseudo-Koebner phenomenon.The *black dots* represent thrombosed capillaries within the wart. (*B, From Bolognia JL, Jorizzo JL, Schaffer JV.* Dermatology, *3rd edn. St. Louis: Saunders; 2012, with permission.*)

inflamed and crusted before resolving spontaneously and may heal with a pitted scar.

The diagnosis is usually based on typical clinical and dermatoscopic appearances. There is no specific antiviral treatment, and treatment is not usually required, particularly in children. Destructive therapies such as cryotherapy or curettage may be helpful. Potassium hydroxide 5% lotion can be used in younger children. Genital mollusca are usually sexually transmitted in adults.

Orf

Orf is a zoonotic pox virus infection acquired by direct inoculation from infected lambs and goats. Those most often affected include farm workers and children exposed, for example, on city farms. Lesions appear as solitary 1- to 2-cm red-blue papules, nodules, and plaques on the fingers, hands, and forearms with inflamed borders. They evolve into blisters or pustules and may be larger and atypical in immunocompromised people. They may be complicated by lymphangitis and lymphadenopathy. Lesions resolve spontaneously within 4 to 6 weeks, conferring immunity, and although subsequent infection may occur, it is usually less severe. Infection is diagnosed on swab, skin biopsy, or PCR of vesicular fluid. Occasionally, orf is complicated by secondary bacterial infection and erythema multiforme.

Mpox (formerly monkeypox)

Mpox is caused by the MPX orthopox virus. It produces a pustular rash with systemic symptoms similar to, but milder than, smallpox (see Chapter 42, 'Mpox [formerly known as monkeypox]' section). It is endemic in Central and West Africa with increasing outbreaks since 2010 possibly caused by waning of cross-protection from cessation of smallpox vaccination or possible environmental factors changing the interface between humans and the Mpox animal reservoir. In May 2022, a global outbreak was reported, particularly affecting Europe and disproportionately affecting males who have sex with males (MSMs). Spread is particularly associated with close person-to-person or sexual contact.

A prodrome with fever, headache, fatigue, sore throat, myalgia, and lymphadenopathy is followed by the appearance of multiple macules and papules, which evolve into vesicles and pustules. These become umbilicated or centrally eroded and are most prominent on the face but also hands and feet. After 2 to 4 weeks, the

Fig. 45.28 Molluscum contagiosum. Inoculation around the eye, a typical presentation in children.

lesions become crusted and may leave atrophic or pitted scarring. In the 2022 outbreak, lesions were more often localized to the anogenital area, were fewer in number than in previous outbreaks, and were characterized by pseudopustules. These are firm papules with a central ulceration that simulate pustules but are composed of inflammatory keratinocytic debris and not pus. Anorectal and pharyngeal involvement is also common and may be complicated by pain and lymphoedema. Lesions may heal with scarring and can be more severe in immunocompromised people, including those living with HIV.

The diagnosis and treatment of patients with Mpox are discussed in Chapter 42 ('Mpox [formerly known as monkeypox]' section).

SARS-CoV-2 infection and COVID-19

COVID-19 disease is discussed in detail in Chapter 42 ('Coronavirus infections' section).

Mucocutaneous manifestations are experienced by approximately 6% to 8% of those with COVID-19. A spectrum of presentations has been described spanning early viral exanthems to later cutaneous vasculopathies (**Box 45.18**) and in around 20% may be the only sign of infection. Maculopapular or morbilliform, urticarial, and papulovesicular eruptions and vaso-occlusive presentations are seen in older age groups and associated with more severe disease.

- ***Urticarial and morbilliform rashes*** are common, occur early in COVID-19 infection, and are generally associated with less severe disease. They may be red in lighter skin tones but grey or brown in darker skin tones.
- ***Papulovesicular and vesiculobullous rashes*** may be generalized or localized and can simulate varicella but tend to be more truncal and less itchy.
- ***Chilblain-like lesions (pseudo-pernio; 'Covid toes' or 'Covid fingers'):*** Perniosis (chilblains) is an inflammatory disorder in which pink-red-violaceous macules, papules, plaques, or nodules (with less pronounced redness in darker skin tones) present at sites of cold exposure, usually the toes, fingers, and other acral sites such as the ear. They may blister and ulcerate and are associated with pain or a burning sensation. Chilblain-like lesions are seen early in COVID-19, particularly in children and young adults who have otherwise asymptomatic or mild disease. They are thought to be caused by vascular damage by the SARS-CoV-2 virus.
- ***Livedo reticularis*** occurs concurrently or late relative to COVID-19 symptoms and consists of symmetrical, annular, violaceous patches involving trunk and limbs caused by partial or intermittent blood flow reduction to the skin resulting from SARS-CoV-2–associated endothelial cell damage.
- ***Vaso-occlusive skin lesions*** are rare, occur late, and are most often seen in older patients with severe COVID-19, often with systemic thromboembolic complications, and have the highest mortality rate of all COVID-associated skin manifestations.
- ***Multisystem inflammatory syndrome*** may occur in children and adults, and cutaneous manifestations include a polymorphic rash associated with redness and swelling of the hands and feet, conjunctivitis, and mucositis.

Box 45.18 Skin manifestations described in COVID-19

Category	Morphology
Inflammatory or exanthematous	• Urticarial rash • Maculopapular or morbilliform exanthem • Papulovesicular or vesiculobullous exanthem
Vasculopathic	• Chilblain-like acral pattern (COVID-19 toes and fingers) • Livedo reticularis • Purpura or petechiae • Vaso-occlusive (livedo racemosa; retiform purpura; acro-ischaemia; pressure-associated ulceration and necrosis)
Other rashes	• Multisystem inflammatory syndrome (children, adults) • Erythema multiforme–like rash • Pityriasis rosea–like rash • Herpes zoster reactivation • Neutrophilic dermatoses (Sweet syndrome) • Erythema nodosum or panniculitis • Vitiligo • Bullous pemphigoid
Hair and nails	• Alopecia (telogen or anagen effluvium; androgenic; alopecia areata) • Trichodynia • Beau's lines; onychomadesis; red-white discoloration with distal onycholysis
Mucosal	• Oral: Aphthous-like ulcers, angular cheilitis, white plaques, hyperpigmentation • Genital: acute genital ulcers

Many other mucocutaneous disorders have been described in association with COVID-19, including hair and nail disorders (examples are listed in **Box 45.18**), although definitive confirmation of a causative association can be challenging. COVID-19 vaccination has also been linked to a range of mucocutaneous disorders. In addition, exacerbation of pre-existing mucocutaneous disease by SARS-CoV-2 is described for conditions, including psoriasis, atopic dermatitis, alopecia areata, systemic lupus erythematosus (SLE), and bullous pemphigoid.

Fungal infections

Fungal skin diseases are very common human skin infections. In most cases, infection is *superficial* and limited to the stratum

corneum, which elicits no inflammation, or the deeper layers of the epidermis, including the hair and nails, where inflammation may be triggered by the fungus or its products. *Subcutaneous mycoses* include a range of infections of the subcutaneous tissues, usually after traumatic inoculation from environmental sources such as soil and vegetation. *Systemic fungal infections* may result from inhalation or are opportunistic and occasionally because of secondary spread from skin infection, particularly in immunocompromised patients.

Superficial mucocutaneous fungal infections

There are three groups of pathogenic fungi that commonly affect the keratinizing epidermis:

- Dermatophytes
- *Candida albicans*
- *Malassezia* spp. (formerly *Pityrosporum* spp.)

Dermatophyte infections

Dermatophyte (tinea) fungi invade and grow in keratin. The three main genera that affect humans are *Trichophyton*, *Microsporum*, and *Epidermophyton* spp. In the skin, they tend to form an expanding annular plaque caused by progressive peripheral growth, hence the name 'ringworm', and infect hair and nails.

Transmission may be human to human (anthropophilic), from animals (zoophilic), or from the environment (geophilic). The clinical appearances depend on the infecting organism, the body site affected, and the host reaction to infection.

Tinea infections are classified according to body site and include tinea corporis (body), tinea facei (face), tinea barbae (beard), tinea cruris (groin), tinea manuum (hand), tinea pedis (foot), tinea capitis (scalp), and tinea unguium (nails).

Tinea corporis: Tinea affecting the body usually presents with itchy, asymmetrical, scaly, inflamed plaques with central clearing and a scaly, raised border that may be red in lighter skin tones or violaceous to brown in darker skin tones. Occasionally, vesicles or pustules may be seen. Treatment with topical or oral steroids reduces inflammation and pruritus and masks clinical signs while allowing spread of the infection ***(tinea incognito)***. The rash typically flares when steroids are stopped, which often prompts further use of steroids and may lead to widespread infection.

Tinea cruris is more common in males than females and presents with an intensely itchy rash in the groin, with a scaly border that extends on to the thighs (Fig. 45.29A).

Tinea pedis (athlete's foot) (Fig.45.29B) is extremely common in adults and is often confined to the toe webs, where the skin looks white, macerated, and fissured. It often starts between the fourth and fifth toes and may extend more widely on to the soles and lateral borders of the feet, causing dryness, scaling, and erythema ('moccasin feet'), and the toenails are also often affected (see later). Annular lesions are rarely seen on palmoplantar skin. Tinea pedis frequently flares in hot weather, causing pustules or blisters, and this can be misdiagnosed as eczema, including pompholyx eczema.

Fig. 45.29 Dermatophyte infections. (A) Tinea cruris. **(B)** Tinea capitis. **(C)** Tinea pedis. **(D)** Onychomycosis: dermatophyte infection of the nail with white, crumbling dystrophy. (*BC, From Callen et al, 2000.*)

Infection may also spread to the palm ***(tinea manuum)***, especially in manual workers, and causes redness and scaling. ***Tinea manuum*** is often unilateral rather than bilateral and is usually associated with bilateral involvement of the feet.

Tinea capitis (Fig. 45.29C) is the most common dermatophyte infection in young children, especially those of Black African origin, in whom hair and scalp seem more susceptible to fungal invasion. Adults are rarely affected. Dermatophyte infection may be restricted to the hair shaft (endothrix) or spread over the hair surface (ectothrix), where it fluoresces under Wood lamp (UV light). Scalp ringworm is spread by close contact, particularly in schools and households, and by sharing of brushes or clippers.

The majority of UK cases are caused by *Trichophyton tonsurans* (which does not fluoresce under Wood light). Migration has led to changing patterns of fungal infections in Europe (e.g., *Trichophyton tonsurans* from Central America, *Trichophyton violaceum* from India and Pakistan).

The clinical appearance of scalp ringworm varies from mild diffuse scaling with no hair loss (similar to seborrhoeic dermatitis) to the more typical appearance of bald, scaly patches with broken hairs. An increased host response causes pustules and an inflammatory exudate, and certain types of tinea can trigger a severe inflammatory reaction with a swollen purulent mass or 'kerion'. This may be mistaken for a bacterial infection and inappropriately treated with antibiotics alone or even attempted incision and drainage.

Extensive infection is occasionally accompanied by a widespread papulopustular rash most prominent on the trunk. This so-called 'id reaction', which probably relates to the host immune response to the fungus. It resolves when the infection is treated.

Tinea unguium and onychomycosis: 'Onychomycosis' is a broad term for fungal nail infection. Tinea unguium refers to a dermatophyte infection of the fingernails or toenails (Fig. 45.29D). *Trichophyton rubrum* is the most common pathogen.

Tinea toenail infection is a common finding in older adults and is usually asymptomatic. Fingernail infection is less common. Affected nails are dystrophic, thick (subungual hyperkeratosis), and discoloured (white, yellow, or beige). Infection usually starts at the distal or lateral nail edges and then spreads proximally. The whole nail plate may be destroyed in advanced disease. The differential diagnoses include nail psoriasis and traumatic nail dystrophy (which may coexist with fungal infection).

Diagnosis and management

Asymmetrical scaly rashes should be investigated for fungal infection by mycology of skin scrapings. Multiple sites may be affected, and the skin, hair, and nails should be examined. The diagnosis should be confirmed with skin scrapings taken from the active margin or across the affected area. Clippings should be taken from the proximal crumbly, white area of affected nails, and plucked hairs or scrapings for diagnosis of scalp tinea. Specimens are transported in folded paper to keep them dry and prevent bacterial contamination. Microscopy and mycological culture confirm the diagnosis and identify the organism. Molecular diagnostic techniques, including PCR analysis, are gaining in popularity because they can offer high sensitivity and rapid results.

Localized tinea of the body or flexures is treated with an antifungal cream (clotrimazole, miconazole, or terbinafine for 1–2 weeks). Nystatin is ineffective. More widespread infection, tinea pedis, tinea manuum, and tinea capitis require oral antifungal therapy with itraconazole or terbinafine for 1 to 2 months.

Toenail tinea infection requires prolonged oral antifungal therapy. Oral terbinafine for 3 to 6 months can clear up to 80% of cases, but relapses are common. Itraconazole may be given as a continuous or pulsed regimen. Griseofulvin is a less effective drug but is still used for childhood tinea capitis.

Antifungal drug resistance of dermatophyte fungi to both topical and systemic medication is rising globally and should be suspected in extensive, treatment-resistant dermatophyte infection. This appears to be most common with terbinafine because of mutation in the squalene epoxidase gene; resistance has been particularly recognized in the Indian subcontinent and is becoming increasingly prevalent in Europe. Resistance to griseofulvin and triazole antifungals (e.g., itraconazole, fluconazole, voriconazole) is also becoming more common.

Candida infections

Candida is a common species of yeast that causes a variety of skin infections. *Candida albicans* (see Chapter 42, 'Candidiasis' section) is a commensal in the GI tract and vagina. It can overgrow on occluded moist skin, causing nappy rash, intertrigo of the large flexures in obese people (Fig. 45.30), and vulvovaginal candidiasis or 'thrush'. The glans penis may be affected in uncircumcised males (candidal balanitis). Other species of *Candida* may be isolated from vaginal infections and immunocompromised hosts.

Candidal intertrigo causes irritation and soreness; affected areas are glazed and inflamed, with a ragged, peeling edge that may contain a few small pustules. Multiple red papules (satellite lesions) may extend beyond the affected red border.

Candida may also affect the moist interdigital clefts of the toes and mimic tinea pedis. In people who frequently immerse their hands in water (e.g., cleaners, caterers), *Candida* may cause chronic infection of the nail folds (paronychia) and nail infection (candida onychomycosis).

Candida can also infect the oral mucosa, especially after broad-spectrum antibiotics and in immunocompromised people and some denture wearers. Affected mucosal surfaces are inflamed with superficial white or creamy pseudomembranous plaques, which can easily be scraped away. The diagnosis can be confirmed with microscopy and culture of a specimen taken with a routine microbial swab.

Fig. 45.30 Intertrigo with satellite lesions typical of candidiasis.

Management

Predisposing factors should be treated. Diabetes should be excluded. Topical therapy (azoles or nystatin) is usually adequate, except for nail infection, and may take the form of creams, pessaries, lozenges, or powder, depending on body site. Recurrent vulvovaginal candidiasis (see Chapter 43, 'Candidiasis' section) is a common condition in females and may require oral azole antifungal therapy.

Malassezia infection

This lipophilic yeast family (formerly called *Pityrosporum*; is part of the normal skin microbiome. Colonization is prominent at areas rich in sebaceous glands: the scalp, large flexures, and the upper trunk. More than a dozen different species of *Malassezia* have been identified, and there is increasing evidence of their causal role in three common dermatoses:

- Pityriasis (or tinea) versicolor
- Seborrhoeic eczema
- *Pityrosporum (Malassezia)* folliculitis.

Pityriasis (tinea) versicolor is a common condition in young adults, especially in warm climates. It causes widespread pink-beige slightly scaly macules on the torso. Variable pigmentation is characteristic, with pale areas developing after tanning and in individuals with darker skin tones because the yeast impairs melanin synthesis. The diagnosis is usually made clinically but can be confirmed by microscopy of skin scrapings, which shows spherical yeast and short pseudohyphae ('meatballs and spaghetti'). Treatment is with topical azoles or oral itraconazole for resistant cases. Anti-dandruff shampoos containing selenium sulphide or ketoconazole may also be used as a body wash. The pigment changes take months to resolve, and recurrences are common.

Pityrosporum folliculitis is also common in young males and causes small, itchy, monomorphic papules and pustules on the upper back, shoulders, and face and may simulate acne. Topical and oral azole antifungals can be effective, but the condition often relapses quickly.

Subcutaneous mycoses

Subcutaneous mycoses (see Chapter 45, 'Subcutaneous fungal infections' section) are a rare group of localized infections of the skin and subcutaneous tissues that follow traumatic implantation of the fungal agent, often a soil saprophyte. The causative organisms vary geographically and disease examples include sporotrichosis (worldwide), chromoblastomycosis and mycotic mycetoma (tropical and subtropical). Sporotrichosis, or 'rose gardener's disease', usually causes a slowly growing, inflamed nodule at the site of skin inoculation, with new lesions developing along lymphatics and blood vessels (sporotrichoid spread). Treatment is with oral itraconazole.

Parasites and infestations

Scabies

Scabies is an ectoparasite infestation with the mite *Sarcoptes scabiei*. There are approximately 450 million cases of scabies in the world each year, and at any one time, approximately 130 million cases are untreated, representing a huge global burden of disease. It affects people of all races and socioeconomic groups although is more common in resource-poor communities and countries, especially sub-Saharan Africa. Risk factors include social overcrowding, poor hygiene, malnutrition, and immunocompromise. It is most common in children and young adults but can affect any age group. Although scabies is considered a trivial condition, infectious complications include neonatal septicaemia, post-streptococcal glomerulonephritis, and rheumatic fever.

Scabies is spread by close or prolonged physical contact, such as within families, households, and care homes and by sexual contact. The mite survives only a few hours of leaving the host and so spread by fomites (e.g., clothing, bed linen, towels) is uncommon. Sites of predilection for the initial infestation in which the mite burrows into the stratum corneum and lays eggs are the finger webs, palms, soles, flexor wrists, elbows, axillae, male genitalia, and around the nipples and umbilicus. Fine linear or curved burrows a few millimetres long may be seen, though they are not always visible, and dermoscopy may be helpful. Small red papules, vesicles, and occasionally pustules occur anywhere on the body but rarely on the face, except in neonates (**Fig. 45.31A**).

After 4 to 6 weeks, a secondary widespread, intensely itchy, excoriated, and often eczematous rash develops that is triggered

Fig. 45.31 Scabies. (A) Itchy papules and pustules centred on the web spaces of the hand. **(B)** Crusted scabies in a patient with chronic myeloid leukaemia.

Box 45.19 Treatment of scabies

- Treat all skin below the neck, including the genitalia, palms and soles, and under the nails. Treat the head and neck regions in infants (up to 2 years of age).
- Treat all close contacts at the same time *even if asymptomatic.*
- Reapply scabicide to the hands if they are washed during the treatment period.
- Wash or clean recently worn clothes (preferably at 60°C) to avoid re-infection.
- Repeat the application after 1 week.

by a TH1 hypersensitivity response to mite antigens. Pruritus is usually worse at night and disturbs sleep. With chronic infection, skin-coloured, red-brown, or violaceous nodules can, for example, around the axillae and in the male genital area. The rash may be complicated by secondary bacterial infection with pustular lesions, blistering, and impetigo and globally is one of the most common causes of acute glomerulonephritis. Sleep disturbance and psychological distress may be significant.

Diagnosis and management

Scabies is common, and a high index of suspicion is required in patients presenting with new and widespread itchy rashes. The diagnosis is usually based on clinical features (including dermoscopic identification of burrows or mites) and risk factors, particularly contact history. It can be confirmed by demonstrating the mites or eggs or on microscopy of potassium hydroxide–treated skin scrapings from the tip of a burrow, although this is time consuming.

Treatment is based on overnight application of a topical scabicide. For the treatment to be successful, the measures listed in **Box 45.19** should be followed. Five percent permethrin cream or lotion is first-line therapy, and malathion can be used if permethrin is unavailable; 25% benzyl benzoate is use occasionally, but it is an irritant and should not be used in children. Two doses of oral ivermectin, 2 weeks apart, is effective if topical treatment has failed and in communal outbreaks (e.g., residential homes). However, it is unlicensed for this indication. Resistance to topical treatment has been increasingly recognized in recent years, and treatment with ivermectin may be required in this situation. Pruritus takes several weeks to settle after treatment and can be managed with antihistamines, cooling creams such as 2% menthol, and topical steroids for eczematous reactions.

Crusted (Norwegian) scabies

Crusted scabies is a variant in which there is uncontrolled proliferation of mites, and thousands to millions rather than usual 10 to 20 mites are present (**Fig. 45.31B**). Risk factors include increased age, immunocompromise, reduced peripheral sensation (e.g., leprosy), dementia, Down syndrome, and institutional accommodation. Pruritus may be mild or absent. Individuals are highly infectious and may be the source of outbreaks if the diagnosis is delayed. Hyperkeratotic crusted lesions characteristically affect the hands and feet. There may be more widespread inflammatory rash with scaly, crusted plaques resembling infected eczema or psoriasis. Meticulous barrier nursing is needed to protect staff against infestation. Hyperkeratotic scales should be removed with a keratolytic agent before application of a scabicide. Oral ivermectin is often required for effective eradication of all mites.

Lice

Lice are ectoparasites that feed on human blood and cause three patterns of infestation in humans.

Head lice (pediculosis capitis) is the most frequent form of infestation by lice and is extremely common in children, particularly females. Head lice spread by close head-to-head contact, and risk factors include sharing hairbrushes, beds, and clothing. Lice attach to hairs and inject anticoagulant saliva to suck up scalp blood, and they can survive a few days away from the scalp. Infestation causes pruritus, leading to excoriations and papules, particularly around the hairline of the neck and ears. The diagnosis is made by identifying transparent or whitish hatched egg cases ('nits'), which are firmly adherent to the hair shaft, or unhatched brown eggs, which are harder to detect. Adult lice are most easily detected between the teeth of a fine comb and can also be seen on dermoscopy. Complications include dermatitis, impetigo, and lymphadenopathy.

Management aims at eradication, but re-infestations are common. Lotions containing topical insecticides, such as malathion, carbaryl, permethrin, and phenothrin, are now used less widely because of increasing resistance and low cure rates. They are being supplemented or replaced by physical approaches such as application of 4% dimethicone or isopropyl myristate (suffocating agents that kill adults and nymphs) on two occasions 1 week apart and fine combing of wet hair after applying conditioner to remove young lice before they mature. This should be repeated until all eggs have hatched.

Body lice (pediculosis corporis) is less common than head lice, and infestation is associated with poverty and personal neglect, particularly if individuals are unable to wash and wear the same clothes for extended periods. Transmission is by direct contact or by sharing of infested clothing or bedding and is more common in crowded living conditions. The body louse is 2 to 4 mm in size and does not live on the skin but moves there to feed. Lice and eggs are therefore not usually seen on the skin but can be found on close inspection of clothing, particularly seams. Infestation presents with itchy papules and excoriations. Complications include secondary bacterial infections and spread of diseases such as typhus.

Management consists of malathion or permethrin application if infestation is widespread, but environmental measures are the main treatment approach and include high temperature washing and drying or ironing of clothing and bed linen. Topical insecticide spraying of clothing can also be considered.

Pubic lice (phthiriasis pubis) are often referred to as 'crabs' because of the appearance of their physical appearance. They are transmitted by direct contact, usually sexual (see Chapter 43, 'Pediculosis pubis' section). Infestation presents with itching, especially at night. Lice can be seen near the base of the hair with eggs somewhat farther up the shaft. They are most often found in pubic hair, but eyebrows, eyelashes, beard, chest, and thigh hair may also be affected. Live lice can be seen on examination or dermoscopy, and pinpoint bleeding spots associated with louse bites may also be evident.

Management is as for head lice, with use of insecticides; all sexual contacts, even if asymptomatic, should be treated and patients screened for other sexually transmitted diseases.

Papular urticaria (persistent insect bite reactions)

Papulovesicular reactions may develop to bites from airborne insects (e.g., mosquitoes) or fleas *(Cheyletiella)* from an infested animal (particularly dogs and cats). Papular urticaria presents as itchy, urticated papules that may blister and are often grouped in clusters or lines and can leave post-inflammatory hyperpigmentation. Legs and other uncovered areas are most frequently affected sites.

It probably represents an immunological reaction to bites, and some individuals react more severely than others. It is more common in children. Complications include secondary bacterial infection.

The diagnosis is usually based on clinical features, but skin biopsy may occasionally be required. Insect repellents and appropriate clothing help reduce bites from airborne insects. Topical steroids and antihistamines may reduce the size and severity of lesions and associated itching. Animals infested with fleas usually scratch vigorously, leading to scaly, thickened skin. Insect eggs can lie dormant in soft furnishings (e.g., carpets) for many months, hatching when disturbed by vibrations. Anti-flea treatment of the animal and furnishings is therefore required.

Bed bug infestation

'Bed bugs' are small, flat, brown-black, parasitic insects 5 to 15 mm in length from the Cimicidae family (including *Cimex lectulatius* and *Cimex hemipterus*). They are an increasing problem worldwide, particularly in urban populations. They do not live on human skin but emerge from the seams of bedding and bedframes at night when attracted to the warmth and carbon dioxide emissions of a sleeping human body, and they feed on human blood one to two times a week. They are attracted to warm environments; can travel in furniture, luggage, and clothing; and can live up to 12 months without feeding.

Bed bug bite reactions occur in only a subgroup of people as intensely itchy red papules on exposed areas, including the face and neck, and often appear in a linear pattern. They may be more violaceous or brown in people with darker skin tones. A punctum may be seen at the site of a bite, and vesicles or bullae, pustules, urticaria, petechiae, and post-inflammatory hyperpigmentation may occur. Complications include secondary bacterial infection and significant psychological distress.

Eradication is the key to management (see **Box 45.20**). Attempts should be made to identify the presence of bed begs in bedding, mattresses, and so on. Expert professional pest control is usually required, and resistance to pesticides is being increasingly reported. If treatment is required for bed bug bites, topical steroids and oral antihistamines may be helpful.

Tropical dermatoses

Skin diseases that feature among the 'neglected tropical diseases' defined by the WHO include scabies, leprosy, leishmaniasis, dracunculiasis (guinea worm), lymphatic filariasis, onchocerciasis, mycobacterium ulcerans (Buruli ulcer), mycetoma, tungiasis, and yaws. These are endemic in low-income countries and constitute a huge physical and financial burden on societies. These are covered in more detail in Chapter 42.

Box 45.20 Eradication and prevention of bed bugs

- Use of covers to seal mattresses (for at least 12 months).
- Removal of bed bugs with vacuum cleaners incorporating high-efficiency particulate air (HEPA) filters
- Heat and cold treatment: washing, tumble drying, or use of steam cleaners that reach 60°C will usually kill bed bugs, as will temperatures of −20°C.
- Check second-hand furniture for the possible presence of bed bugs before use
- Care to minimize exposure of luggage to bedding, carpeting, and so on while travelling
- Professional pest control companies are often required to eradicate infestations

Travellers who have visited tropical or subtropical countries may also be affected by skin diseases, especially cutaneous leishmaniasis, cutaneous larva migrans, and myiasis. Rashes may also be a feature of systemic tropical infections such as ***dengue, schistosomiasis,*** and ***rickettsial diseases***.

Leishmaniasis (see Chapter 42, 'Leishmaniasis' section) is caused by a protozoon, *Leishmania*, and is acquired from the bite of sandfly vectors. It affects approximately 12 million people worldwide. Cutaneous, mucocutaneous, and visceral disease (kala azar) may occur, and clinical features depend on the infecting organism (which varies geographically—American or 'New World' vs non-American or 'Old World') and host response. ***Cutaneous leishmaniasis*** is the most common form and initially presents as small red papules that enlarge and form a chronic ulcer ('oriental sore'), usually on non-exposed areas such as the face and limbs. The ulcer heals slowly over many months with scarring.

Cutaneous larva migrans is caused by direct contact with the larvae of one of the many types of hookworms, which may be present in faeces from dogs, cats, and other animals. It is usually acquired by walking or lying on sandy beaches. Larvae penetrate the skin—often the feet, hands, knees, and buttocks—and cause an intensely itchy serpiginous track, which migrates as the larva burrows within the epidermis (**Fig. 45.32**). It usually resolves without treatment within 8 weeks. Treatment includes topical thiabendazole, cryotherapy, or laser to destroy the larvae.

Myiasis is an infestation of the skin with developing fly larvae (maggots). Species that can penetrate intact skin to cause boil-like lesions include botflies and tumbu flies.

Human immunodeficiency virus and the skin

HIV infection is associated with a range of infective, inflammatory, and malignant skin diseases. As in the case of other immunocompromised patients, such as organ transplant recipients, people living with haematologic malignancy, and people receiving long-term immunosuppressive medication for immune-mediated inflammatory conditions, these skin disorders in people living with HIV (PLWH) may be severe, atypical,

Fig. 45.32 Cutaneous larva migrans. (*Habif T.* Clinical Dermatology, *6th edn. Oxford: Elsevier; 2016.*)

and recalcitrant (see Chapter 44). Advances in highly active antiretroviral therapy (ART) have dramatically reduced the prevalence of these diseases in recent years in countries with early access to therapy. However, awareness must be maintained because they may be a presenting feature of undiagnosed HIV infection.

Seroconversion rash

This non-specific maculopapular exanthem affects up to 75% of individuals a few weeks after becoming infected with HIV. There may be associated fever, malaise, myalgia, lymphadenopathy, and mouth ulceration (or oral candidiasis). Symptoms usually resolve within a few weeks and are often dismissed as 'flu' and the diagnosis missed. Patients are highly infectious during this time because of very high viral loads.

Cutaneous infections

Susceptibility to bacterial, viral, fungal, and parasitic infections, including opportunistic infections, is increased because of HIV-induced immune deficiency, and infections are often more severe and atypical. Skin biopsy and culture can play an important role in accurately diagnosing some infections and should be considered in any immunocompromised person presenting with atypical rash or skin lesions.

- *Bacterial infections:* Staphylococcal and streptococcal infections may be more severe; atypical mycobacterial infections are more common as are syphilis and bacillary angiomatosis (caused by *Bartonella* spp.)
- *Viral infections:* Many viral infections are seen that are typically more severe or widespread than in immunocompetent patients, including:
  - Molluscum contagiosum, especially on the face, with lesions that are large (>1 cm in diameter) and extensive (a pattern rarely seen in immunocompetent adults)
  - HSV (with increased frequency of recurrences and chronic ulceration)
  - Herpes zoster (severe shingles may be a presenting sign of HIV infection, and disseminated infection is more common)
  - HPV (causing common and anogenital warts and acquired epidermodysplasia verruciformis)
  - HHV-8 (always consider HIV infection in people presenting with Kaposi's sarcoma [KS])
  - EBV (associated with oral hairy leukoplakia; see later)
  - Cytomegalovirus (a cause of anogenital ulceration).
- *Fungal infections:* dermatophyte and candidal infections may occur early and recalcitrant and recurrent oropharyngeal candidiasis is a particular problem with low CD4 counts. Systemic fungal infections with skin manifestations include cryptococcus, aspergillus, and histoplasma (see Chapter 42, 'Systemic fungal infections' section).
- *Parasitic:* leishmaniasis (see Chapter 42, 'Leishmaniasis' section), strongyloides (see Chapter 42, 'Strongyloidiasis' section).

Inflammatory dermatoses

Severe, extensive seborrhoeic eczema is common and may be the presenting sign of HIV infection. Psoriasis is often more severe, may be atypical, and may be treatment resistant in PLWH. Management may require close liaison between dermatologist and HIV physicians, especially in patients with low CD4 counts (<200/mm^3), because of the risk of further immunocompromise if immunosuppressive systemic therapy (e.g., ciclosporin) is required or to prevent harmful drug interactions with ART.

Other inflammatory dermatoses reported to be overrepresented in PLWH include nodular prurigo and granuloma annulare.

Drug rashes

Cutaneous adverse drug reactions are significantly more common in PLWH. Reactions to co-trimoxazole and dapsone (used in *Pneumocystis* prophylaxis) and anti-retroviral drugs appear to be particularly frequent. Drug rashes may be severe (especially with nevirapine and efavirenz), resulting in erythroderma or toxic epidermal necrolysis (TEN; see Chapter 11 'Stevens–Johnson syndrome and toxic epidermal necrolysis' section). Other unusual conditions include nail or mucosal pigmentation from zidovudine, paronychia from indinavir, and lipodystrophy of the face and abdomen or buttocks with protease inhibitors.

Cutaneous malignancy

The risk of malignancy is increased in PLWH because of impaired immune surveillance, and those associated with oncogenic viruses are particularly increased.

- KS (caused by HHV-8 infection; see Chapter 44, 'Kaposi's sarcoma' section) was one of the earliest recognized manifestations of HIV infection and led to the description of the acquired immune deficiency syndrome (AIDS). KS is much more common in MSMs than in other groups of PLWH.
- Cutaneous B- and T-cell lymphomas (EBV) are also more prevalent in PLWH.
- Anogenital premalignancies caused by HPV infection (prostatic [PIN], vulval [VIN], anal [AIN], or cervical intraepithelial neoplasia [CIN]) are more frequent, and the risk of malignant transformation is high and should be assessed by screening.
- Merkel cell carcinoma (caused by Merkel cell polyomavirus or UV exposure) is increased more than 10- to 15-fold, and outcomes are worse.
- Cutaneous keratinocyte cancers (SCC and BCC) are increased 2- to 5-fold and are frequently multiple. Melanoma risk is increased 1.5- to 3-fold.

HIV-specific dermatoses

- ***Itchy folliculitis and HIV folliculitis*** (papular pruritic eruption and eosinophilic folliculitis) are commonly found in association with declining CD4 counts. It presents with intensely itchy papules and excoriations around hair follicles and occurs most commonly over the upper trunk and upper arms (**Fig. 45.33**).

Fig. 45.33 Itchy folliculitis of human immunodeficiency virus infection on the upper trunk and proximal limbs.

- ***Oral hairy leucoplakia*** presents with fixed, white plaques with vertical ridges on the sides of the tongue. Unlike candidiasis, the lesions cannot be scraped off. It was first recognized in HIV disease and associated with low CD4 counts but can rarely occur in other forms of immunosuppression and is thought to be caused by co-infection with EBV.

Immune reconstitution inflammatory syndrome

Several infections can be unmasked or can paradoxically worsen 2 to 4 months after initiation of ART as CD4 lymphocyte counts recover—the immune reconstitution inflammatory syndrome (IRIS). This is most frequently described for anogenital HSV infection, viral warts, tinea folliculitis, and molluscum contagiosum. IRIS affects up to 25% of patients on ART and is thought to reflect the response of a recovering immune system against pathogens that were already present. IRIS may also be responsible for an increase in inflammatory rashes, such as folliculitis and subacute lupus erythematosus.

SKIN SIGNS OF SYSTEMIC DISEASE

Most skin diseases are isolated conditions, but some are associated with underlying systemic disease and may even be the presenting feature.

Multisystem inflammatory disorders

Erythema nodosum

Erythema nodosum has multiple disease associations (**Box 45.21**). It presents as painful or tender, dusky bruise-like swellings over the shins, which fade over several weeks (**Fig. 45.34**). It is most common in young females. There may be associated arthralgia, malaise, and fever. Inflammation occurs in the deeper dermis and the subcutaneous fat (panniculitis) and can be confirmed on skin biopsy.

Management includes symptomatic relief with NSAIDs, light compression socks and rest. Any underlying cause should be treated. It usually resolves spontaneously, but persistent cases can be treated with anti-inflammatory drugs (dapsone, colchicine) or prednisolone.

Box 45.21 Causes of erythema nodosum

- Streptococcal infection[a]
- Drugs (e.g., sulphonamides, oral contraceptive pill)
- Sarcoidosis[a]
- Idiopathic[a]
- Bacterial gastroenteritis, e.g., *Salmonella*, *Shigella*, *Yersinia* spp.
- Fungal infection (histoplasmosis, blastomycosis)
- Tuberculosis
- Leprosy
- Inflammatory bowel disease
- *Chlamydia* infection

[a]Common causes.

Erythema multiforme

Erythema multiforme is an acute self-limiting rash characterized by distinctive 'target lesions' on the distal limbs, palms, and soles (acral sites). These are concentric rings of erythema with a dusky centre, which can blister. There is variable inflammation or ulceration of the mouth, lips, and other mucosal sites. In erythema multiforme major, mucosal ulceration is severe, and there may be fever and systemic upset (**Fig. 45.35**). Infections, specifically HSV, are the most common triggers. Fewer than 10% of cases are caused by drugs (e.g., anticonvulsants). In 50% of cases, there is no identifiable cause. *Mycoplasma pneumoniae* infection may trigger severe erythema multiforme–like mucosal ulceration with minimal skin changes: *M. pneumoniae*–associated mucositis (MPAM).

Management is supportive, with analgesia and parenteral fluids until dysphagia has resolved. MPAM requires antimicrobial

Fig. 45.34 Erythema nodosum in a patient with human immunodeficiency virus taking co-trimoxazole.

Fig. 45.35 Erythema multiforme major. (A) Target lesions of the palm. **(B)** Mucosal involvement around the mouth.

therapy. Infection can be confirmed by HSV or *M. pneumoniae* serology.

The clinical features of erythema multiforme and SJS are shown in **Box 45.22** and are discussed in more detail in Chapter 11 ('Stevens–Johnson syndrome and toxic epidermal necrolysis' section). The role of systemic steroids in this condition remains controversial.

Pyoderma gangrenosum

Pyoderma gangrenosum (PG) is a rare ulcerating skin disease of unknown cause, often associated with systemic inflammatory conditions, especially inflammatory bowel disease. It may also be associated with inflammatory arthritis and haematological malignancies. It is classified as a neutrophilic disease and shares clinicopathological similarities with autoinflammatory diseases in which there is an infection-like host response in the absence of a microbial trigger.

The most common presentation is with painful inflammatory nodules that rapidly turn into enlarging purulent ulcers (pyoderma) with purple undermined edges. PG may occur spontaneously or postoperatively in a surgical wound or stoma, when it can be misdiagnosed as a wound infection. Skin lesions are rich in neutrophils but histological features are non-specific, so the diagnosis is made on clinical features.

Super-potent topical corticosteroids may help in very mild cases. Systemic therapy with moderate- to high-dose systemic corticosteroids, ciclosporin, or both is usually needed. Anti-TNF therapy, such as infliximab or adalimumab, may be used for refractory cases. The clinical course is unpredictable and unrelated to underlying inflammatory bowel disease activity. PG ulcers heal with mesh-like (cribriform) scars (**Fig. 45.36**).

Sweet syndrome (acute febrile neutrophilic dermatosis)

Sweet syndrome is a rare disorder characterized by fever; malaise; and an acute eruption of tender, red-purple plaques and nodules on the head, neck, and upper body (**Fig. 45.37**). As in PG, the skin lesions contain abundant neutrophils (neutrophilic dermatosis). There is usually no underlying illness, but the syndrome may be associated with haematological malignancy and can be induced by drugs, including granulocyte colony-stimulating factor. It is usually treated with systemic corticosteroids or antineutrophil drugs (dapsone, colchicine).

Behçet syndrome

Behçet syndrome (see Chapter 32, 'Behçet's disease' section) is an inflammatory disorder characterized by recurrent oral ulcers and eye lesions, genital ulcers, or skin lesions. Skin changes include erythema nodosum, papulopustular acne-like lesions, thrombophlebitis, and skin pathergy (prolonged inflammation or pustulation at the site of needle-prick or other minor skin injuries). The syndrome is probably a vasculitis affecting blood vessels of all sizes, and many organs can be involved. Patients with milder disease and skin lesions may respond well to colchicine or dapsone.

Sarcoidosis

Sarcoidosis (see Chapter 20, 'Sarcoidosis' section) is a multisystem granulomatous disorder of unknown aetiology. Skin involvement occurs in 20% to 30% of cases and usually presents with red-brown papules, nodules, and plaques. The nose may be extensively involved ***(lupus pernio)***. Lesions may hypo- or hyperpigmented, especially in people with darker skin tones. Erythema nodosum is sometimes seen in acute sarcoidosis. Although sarcoidosis may be localized to the skin, all patients should be investigated for systemic involvement (see Chapter 20, 'Sarcoidosis' section).

Patients with cutaneous sarcoid respond poorly to topical therapy, but super-potent or intralesional corticosteroids or

Fig. 45.36 Bullous pyoderma gangrenosum. This patient had ulcerative colitis. (*Habif T.* Clinical Dermatology, *6th edn. Oxford: Elsevier, Inc.; 2016.*)

Box 45.22 Clinical spectra of erythema multiforme, Stevens–Johnson syndrome, and toxic epidermal necrolysis

Diagnosis	Skin lesions	Mucosal lesions	Other signs and symptoms
Erythema multiforme (EM)	Three-ring target lesions, often on the hands and feet	EM major only	Recent infection (herpes simplex virus, *Mycoplasma* spp.)
Stevens-Johnson syndrome (SJS)	Scattered macules or blisters scattered over the face, trunk, and proximal limbs (<10% body surface area) Occasional two-ring target lesion	Always	Fever Skin tenderness and pain Recent drug exposure
Toxic epidermal necrolysis (TEN)	As for SJS but >30% body surface area involved	Always	As for SJS Respiratory, gastrointestinal, and genitourinary lesions Hypotension Decreased consciousness
SJS–TEN overlap	As for SJS (10%–30% body surface area involved)	Always	

Fig. 45.37 Sweet syndrome. Lesions are tender erythematous papules and plaques that can also be pseudovesicular or pustular. Lesions tend to be multiple but isolated lesions are seen. topical tacrolimus may help. Systemic therapy with antimalarials and methotrexate may also be required for those with extensive disease.

Pruritus

The pathophysiology of pruritus (itch) is complex and incompletely understood. It may be caused by peripheral mechanisms (as in skin disease), central or neuropathic mechanisms (as in multiple sclerosis), neurogenic mechanisms (as in cholestasis or μ-opioid receptor stimulation), or psychogenic mechanisms (e.g., parasitophobia). Evidence suggests that low stimulation of unmyelinated peripheral C-fibres is associated with the sensation of itch; high stimulation produces pain. Histamine, tachykinins (e.g., substance P), gastrin-releasing peptide, cathepsin, proteases, opioids, nerve growth factors, prostaglandins, and cytokines (e.g., IL-31) may also play a role. In the CNS, μ-opioid receptors may regulate the perception and intensity of itch.

Pruritus is a characteristic feature of many inflammatory rashes, especially atopic eczema, scabies, and LP. It also occurs with asteatotic eczema and cholinergic urticaria, in which the rash may be subtle and overlooked. Pruritus is common in older adults and usually caused by skin dryness (xerosis). ***Generalized pruritus*** without a rash can be caused by a number of medical conditions (**Box 45.23**) or drug reactions. ***Localized pruritus*** may be caused by neurological dysfunction such as in brachioradial pruritus or notalgia paraesthetica.

Management involves use of soap substitutes and symptomatic measures (as for asteatotic eczema). Phototherapy, low-dose amitriptyline, or gabapentin may help in intractable cases. If a pruritic skin disease is not evident, patients should be fully investigated for underlying systemic disease.

Fig. 45.38 Necrobiosis lipoidica on the shin in a patient with type 1 diabetes mellitus.

Box 45.23 Medical conditions associated with pruritus

- Iron-deficiency anaemia
- Malignancy (especially lymphoma)
- Diabetes mellitus
- Chronic kidney disease
- Chronic liver disease (especially primary biliary cholangitis)
- Thyroid disease
- Human immunodeficiency virus infection
- Polycythaemia vera

Endocrine disease

Thyroid disease

Individuals with ***hypothyroidism*** have cold, dry skin and brittle hair with diffuse thinning and loss of the outer third of the eyebrows. There may be a jaundice-like appearance caused by carotene excess with firm, gelatinous (myxoedematous) skin (see also Chapter 34, 'Hypothyroidism' section).

Hyperthyroidism may be associated with hyperhidrosis, onycholysis, and diffuse alopecia. The extrathyroid manifestations of Graves' disease include dermopathy (pretibial myxoedema), which classically presents with non-pitting infiltration; plaques on the shins; and in severe cases, thyroid acropachy, characterized by clubbing and soft tissue swelling of the fingers and toes with periosteal reaction of the bones.

Diabetes mellitus

Patients with diabetes mellitus (see Chapter 35) can have a range of skin manifestations and complications, mediated mainly by hyperglycaemia and hyperinsulinaemia. They include:

- Fungal infection (e.g., candidiasis)
- Bacterial infections (e.g., recurrent boils)

Fig. 45.39 Acanthosis nigricans in the axilla of an individual with a high body mass index.

- Arterial and neuropathic ulcers
- Poor or delayed healing
- Xanthomas

Specific dermatoses of diabetes include:

- ***Necrobiosis lipoidica*** (a patch of spreading erythema over the shin, which becomes yellowish and atrophic in the centre and may ulcerate; Fig. 45.38)
- Diffuse ***granuloma annulare***
- Diabetic stiff skin or ***cheiroarthropathy*** (tight, waxy skin over the fingers with limitation of joint movement owing to thickened collagen).

Cushing syndrome

Skin manifestations caused by high cortisol include hirsutism; central obesity; a full, round face ('moon face'); and dorsocervical fat pad ('buffalo hump'). Florid purple striae distensae (or 'stretch marks') skin atrophy, telangiectasia, and increased susceptibility to folliculitis and candidiasis may occur. Hyperpigmentation also occurs in cases with increased circulating adrenocorticotropic hormone (ACTH; ectopic ACTH syndromes or Cushing disease; see Chapter 34, 'Cushing's syndrome' section).

Striae distensae are caused by ruptures in dermal collagen and elastic tissue. They are a common finding over the abdomen, hips, and breasts in normal female puberty and pregnancy and in obesity and over the lumbosacral area in adolescent males. The cause is unclear, but they are associated with rapid growth and genetic susceptibility. There is no effective treatment, but they fade from pink-purple to pale silvery lines with time. Striae are also seen in those with Marfan's syndrome.

Addison disease

Generalized hyperpigmentation occurs secondary to raised circulating ACTH levels (see Chapter 34, 'Addison's disease' section). This may be prominent in the palmar creases, oral mucosa, lips, large flexures, genitals, and nail beds.

Acanthosis nigricans

Acanthosis nigricans presents with thickened, hyperpigmented, velvet-textured skin around the large flexures (Fig. 45.39). It can appear warty when advanced. The most common and mildest form is associated with obesity and insulin resistance. Late-onset, severe disease with mucosal involvement is usually a paraneoplastic phenomenon caused by underlying malignancy, especially GI tumours. Acanthosis nigricans may also be triggered by niacin therapy. If an underlying cause is present, it should be treated. Some improvement may be achieved with topical tretinoin or a vitamin D analogue such as calcipotriol.

Flushing

Facial flushing in response to emotional stimuli (blushing) is a normal physiological response that can cause embarrassment and may be associated with social phobia. Pathological causes include carcinoid syndrome, other neuroendocrine tumours, and drugs. Treatment of idiopathic flushing includes cosmetic camouflage, beta-blockers, and clonidine. Cognitive therapy and selective serotonin reuptake inhibitors may help with associated depression and anxiety.

Metabolic disease

Hyperlipidaemias

Patients with hyperlipidaemia (see Chapter 19) may present with xanthomas, which are abnormal lipid deposits in the skin. A fasting lipid profile should be checked in all patients, though it may be normal in those with the most common type, ***xanthelasma***, which presents with asymptomatic yellow plaques around the eyes. There are a number of other clinical variants of ***xanthoma***, including:

- ***Tuberous xanthoma*** (firm orange-yellow nodules and plaques on extensor surfaces)
- ***Tendon xanthoma*** (firm subcutaneous swellings attached to tendons)
- ***Plane xanthoma*** (orange-yellow macules often affecting palmar creases)
- ***Eruptive xanthoma*** (numerous small, yellowish papules, commonly on the buttocks).

Porphyria cutanea tarda

Porphyria cutanea tarda (PCT; see Chapter 36, 'Porphyrias' section) is a rare metabolic disorder associated with liver disease; it is usually precipitated by alcohol excess or HCV infection, and 20% of patients have underlying haemochromatosis (see Chapter 23, 'Hereditary haemochromatosis' section). PCT presents with sun-induced blisters, fragile skin, scarring and milia (especially on the dorsal hands), and hypertrichosis.

Management is with repeated venesection to reduce iron overload, alcohol avoidance, and low-dose antimalarial drugs. HCV infection should be treated.

Haematological disease

Anaemia (especially iron-deficient), iron overload, polycythaemia vera, and lymphoproliferative diseases such as lymphoma can present with generalized pruritus. Those with iron deficiency can also present with hair loss, glossitis, angular cheilitis, and brittle or spoon-shaped nails (koilonychia).

Amyloidosis

Amyloid may be deposited in the skin in localized cutaneous forms, including macular amyloid, lichen amyloid, nodular amyloid, and familial primary localized cutaneous amyloidosis, and is most commonly seen in South American, Asian, and Middle Eastern individuals. It may also present in association with underlying systemic

disease. About 50% of patients with systemic amyloid have skin involvement, usually in the context of an underlying monoclonal plasma cell disorder.

Macular amyloid presents with hyperpigmented plaques of 'rippled' grey-tan streaks. The upper back, chest, and upper arms are most involved. Lichen amyloid presents as skin-coloured or hyperpigmented papules that coalesce into plaques often seen on the shins. Amyloid deposits in the oral cavity present with macroglossia and mucosal papules. Deposition in and around blood vessels causes fragility with petechiae and purpura, especially in the periocular skin and large flexures. Multidisciplinary treatment of the underlying disease is required.

Chronic liver disease

Chronic liver disease may present with jaundice, palmar erythema, spider naevi, white nails (leukonychia), onycholysis, hyperpigmentation, and xerosis. Pruritus is common in cholestatic disease, including cholestasis of pregnancy (see Chapter 48).

Chronic kidney disease

End-stage kidney disease (ESKD; see Chapter 26) is commonly associated with intractable pruritus, which can lead to excoriations and nodular prurigo. Treatment involves careful management of serum phosphate levels; optimization of dialysis; and symptomatic therapy, including emollient creams and gabapentin. The selective kappa opioid receptor agonist difelikefalin has been shown to reduce itch in patients receiving haemodialysis.

Reactive perforating collagenosis is seen in up to 10% of patients with ESKD and diabetes and presents with umbilicated papules and nodules with central crusting; skin biopsy shows transepidermal elimination of collagen from the dermis. Pallor, hyperpigmentation, and ecchymoses also occur. It may rarely be associated with non-inflammatory, PCT-like blistering and fragility ***(pseudo-porphyria)***.

Calciphylaxis is a rare, life-threatening disorder caused by vascular calcification and occlusion, generally seen in patients with a long history of chronic kidney disease with suboptimal management of hyperparathyroidism. It is characterized by extremely painful, ulcerating plaques, and the associated mortality rate is high and usually caused by secondary infection (see Chapter 26, 'Calciphylaxis' section).

Nephrogenic systemic fibrosis is a severe, scleroderma-like skin disease that affects people with severe renal impairment after exposure to older gadolinium-containing magnetic resonance imaging (MRI) contrast agents. No cases have been reported in the past 15 years as newer agents have been used.

Kidney transplant recipients are at high risk of skin infections (including atypical and opportunistic infections) and skin cancers (particularly SCCs) because of immunosuppression.

Millington GW, Collins A, Lovell CR et al. British Association of Dermatologists' guidelines for the investigation and management of generalized pruritus in adults without an underlying dermatosis 2018. *Br J Dermatol.* 2018; 178:34–60.

Autoimmune rheumatic disease

Dermatomyositis

The rash of dermatomyositis (see Chapter 32, 'Polymyositis and dermatomyositis' section) often includes prominent, periocular lilac discoloration, likened to that of the heliotrope flowering plant (heliotrope rash), and periocular oedema. The rash is usually in a photosensitive, cape-like distribution, and may be pruritic and associated with poikiloderma (reticulate pigmentation, atrophy, and telangiectasia). Purple nodules or plaques appear over the knuckles (Gottron papules; see **Fig. 32.38**) and macular pink-violaceus erythema over the extensor surfaces (Gottron sign). In individuals with darker skin tones, the rash may be hyperpigmented. A scaly scalp with associated pruritus and alopecia may be present. The nail folds and c uticles are ragged with dilated capillaries. Skin involvement only occur in amyopathic dermatomyositis on extensor surfaces. Nail folds and cuticles are ragged with dilated capillaries.

Investigations include serum muscle enzymes, myositis-specific antibodies, MRI scan, muscle biopsy, and electromyography. Skin biopsy changes are non-specific. Myositis-specific antibody tests predict the clinical disease phenotype and include:

- Anti–Mi-2 associated with mainly skin presentation and mild myositis
- Anti-SAE associated with severe skin presentation
- Anti–MDA-5 associated with interstitial lung disease and skin ulceration
- Anti–TIF1-gamma associated with malignancy-associated disease
- Anti-NXP2 associated with pronounced muscle symptoms and calcinosis.

Treatment of patients with skin disease includes photoprotection, topical corticosteroids, TCIs, and the antimalarial drug hydroxychloroquine. Patients with myositis usually require high-dose corticosteroids and steroid-sparing immunosuppressant drugs (methotrexate, tacrolimus, mycophenolate mofetil, azathioprine); intravenous immunoglobulin and biological treatments (including rituximab, anti-TNF, and anti-IL6) may also be used. This is discussed further in Chapter 32 ('Polymyositis and dermatomyositis' section).

Scleroderma

The term ***scleroderma*** refers to a thickening of the skin caused by fibrosis from abnormal dermal collagen, but the term is not a diagnostic entity in itself. Systemic sclerosis (SSc) and morphea both show sclerodermatous changes but are distinct conditions:

- ***SSc*** (systemic scleroderma) has cutaneous and systemic features and is discussed in Chapter 32 ('Systemic sclerosis [scleroderma]' section). Skin changes may occur as ***diffuse cutaneous SSc*** or ***limited cutaneous SSc*****.** The latter was previously referred to as CREST variant (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, telangiectasia), and skin changes may be the presenting feature.
- ***Morphea*** (localized cutaneous scleroderma) is confined to the skin or subcutis and usually presents in children or young adults. It is more common in females, and the cause is unknown. Lesions usually appear on the trunk as bluish-red thickened plaques with shiny white indurated or atrophic centres (**Fig. 45.40**). A severe linear variant in childhood is associated with atrophy of underlying deep tissues and can lead to unequal limb growth or scarring alopecia.

Rarely, scleroderma-like skin changes may occur in patients with chronic *Borrelia* infection (acrodermatitis chronica atrophicans), chronic graft-versus-host disease, and eosinophilic myalgia syndrome (caused by tryptophan therapy).

Patients with skin involvement may respond to potent topical steroids and calcineurin inhibitors, phototherapy, antimalarial drugs, oral (or pulsed intravenous) corticosteroids, methotrexate, and

Fig. 45.40 Morphea. Hyperpigmentation and scarring on the trunk.

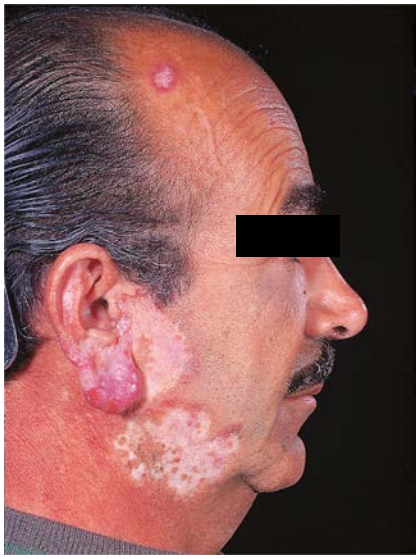

Fig. 45.41 Chronic discoid lupus erythematosus. Scaling, atrophy, and hypopigmentation.

mycophenolate mofetil. Additional systemic treatments (including cyclophosphamide, rituximab, intravenous immunoglobulin, anti–IL-6 drugs) may be indicated for those with severe subcutaneous disease to minimize scarring.

Lupus erythematosus

Lupus is a chronic multisystem autoimmune inflammatory disease (see Chapter 32, 'Systemic lupus erythematosus' section). Skin involvement falls into three broad categories:

- Chronic discoid lupus erythematosus (CDLE)
- Subacute cutaneous lupus erythematosus (SCLE)
- SLE

The cause is unknown, but inherited factors, UV exposure, and drugs may be relevant. All forms of lupus are more common in females.

Chronic discoid lupus erythematosus

CDLE is characterized by chronic red, scaly, atrophic plaques with telangiectasia, especially on the face and other sun-exposed sites (Fig. 45.41). Lesions are often hypopigmented, and close examination may show plugged follicles. Scalp involvement leads to patchy scarring alopecia. Oral involvement (red plaques or ulcers) occurs in 25% of cases. A minority of patients also have Raynaud phenomenon or chilblain-like lesions (chilblain lupus). About 30% of patients have positive antinuclear antibodies, and about 5% develop overt systemic disease.

Skin biopsy shows a dense infiltration of lymphocytes around the hair follicles and damage to the basal layer of the epidermis. Direct IMF may demonstrate granular deposits of IgM and C3 at the DEJ ('lupus band'). CDLE usually lasts for many years, with fluctuations in severity before burning out.

Treatment includes careful photoprotection and high-factor sunscreens, potent topical corticosteroids, occasionally intralesional steroids, and TCIs (tacrolimus, pimecrolimus). Widespread or unresponsive disease and associated arthritis may require antimalarial therapy (hydroxychloroquine, mepacrine), systemic steroids, methotrexate, oral retinoids, andante-proliferative immunosuppressants (mycophenolate mofetil, azathioprine), dapsone, intravenous immunoglobulins, thalidomide, and biologic treatments (rituximab).

Subacute cutaneous lupus erythematosus

SCLE is an uncommon non-scarring variant that presents with widespread annular, papulosquamous plaques on the upper trunk and upper limbs. It typically flares a few weeks after sun exposure. Systemic symptoms, such as arthralgia and mouth ulceration, are seen, but significant organ involvement is uncommon. It may be drug induced, and proton pump inhibitors, terbinafine, calcium channel blockers, and thiazide diuretics are known culprits. Anti-Ro and anti-La antinuclear antibodies are usually positive.

Treatment is similar to that used in DLE.

Systemic lupus erythematosus

In SLE (see Chapter 32, 'Systemic lupus erythematosus' section), organ involvement such as arthritis and nephritis usually predominates, but 80% of individuals will have cutaneous involvement. The classical 'butterfly' rash affects the central face in a rosacea-like distribution (Fig. 45.42). Palmar erythema, dilated nail-fold capillaries, splinter haemorrhages, digital infarcts, purpura, and livedo reticularis (see later) may be evident because of vascular inflammation or occlusion. CDLE and SCLE may overlap.

Treatment is described in Chapter 32 ('Systemic lupus erythematosus' section).

Disorders of blood vessels and lymphatics

Vasculitis

Vasculitis (see Chapter 32, 'Systemic inflammatory vasculitis' section) is an inflammatory disorder of blood vessels that causes endothelial damage. Cutaneous vasculitis may be an isolated problem or part of a multisystem disease with involvement of other organs. The most used classification is based on the size of blood vessel involved (see Box 32.39) and the presence or absence of antineutrophil cytoplasmic antibody.

The features of cutaneous vasculitis are haemorrhagic papules, pustules, nodules, or plaques, which may erode and ulcerate. Lesions are purpuric and do not blanch with pressure. Erythema in a broken livedo or reticulate pattern (see next section) may be seen, with areas of infarction and necrosis. Pyrexia and arthralgia are common associated features. Other clinical features depend on the underlying cause. A thorough clinical evaluation will determine the likely causes and guide further investigations. Routine blood tests and urinalysis should be carried out to exclude renal involvement.

Fig. 45.42 Systemic lupus erythematosus. Macular erythema on the cheeks ('butterfly rash').

Leucocytoclastic vasculitis is the most common cutaneous vasculitis and involves small vessels. It usually affects the lower legs as a symmetrical palpable purpura and is rarely associated with systemic involvement. It can be caused by drugs (15%), infection (15%), inflammatory disease (10%), or malignant disease (<5%), but often no cause is found (55%–60%). Histology of an early lesion confirms blood vessel inflammation (rather than primary occlusion) and indicates the size of the blood vessel involved, as well as the presence of additional diagnostic features such as granulomas. Treatment is with analgesia, support stockings, and oral prednisolone or dapsone to control inflammation and heal ulceration.

Livedo reticularis

The term ***livedo reticularis*** describes a net-like (reticulate), purple-red discoloration of the skin. It usually affects the lower limbs and is more noticeable in the cold but does not disappear on rewarming (unlike physiological livedo). The colour change is because of sluggish blood flow in dermal venules. This may be caused by abnormalities of the blood (high viscosity, coagulopathy, cryoglobulinaemia) or vessel wall (vasculitis such as polyarteritis nodosa or mural calcification). If the network pattern is broken and irregular ***(livedo racemosa)***, underlying systemic disease is likely. ***Livedoid vasculopathy*** is characterized by broken livedo, painful leg ulcers and *atrophie blanche* (see later). It may be associated with antiphospholipid syndrome and SLE.

Leg ulcers

Leg ulcers are common and can have many causes (**Box 45.24**). Venous ulcers are the most common type in high-income countries (**Fig. 45.43**).

Venous ulcers

Venous ulcers are the result of sustained venous hypertension in the superficial veins, usually caused by incompetent valves in the deep or perforating veins or previous deep vein thrombosis. The increased pressure causes extravasation of fibrinogen through the capillary walls, giving rise to perivascular fibrin deposition, which leads to poor oxygenation of the surrounding skin.

Venous ulcers are common in later life, affecting 1% of the population older than the age of 70 years. They are often chronic or recurrent and create a significant burden on healthcare resources.

? Box 45.24 Causes of leg ulceration

- Venous hypertension
- Arterial disease (e.g., atherosclerosis)
- Neuropathic disease (e.g., diabetes, leprosy)
- Neoplastic disease (e.g., squamous or basal cell carcinoma)
- Vasculitis (e.g., rheumatoid arthritis, systemic lupus erythematosus, pyoderma gangrenosum)
- Infection (e.g., ecthyma, tuberculosis, deep mycoses, Buruli ulcer, syphilis, yaws)
- Haematological disease (e.g., sickle cell disease, spherocytosis)
- Drugs (e.g., hydroxycarbamide)
- Others (e.g., necrobiosis lipoidica, trauma, artefact)

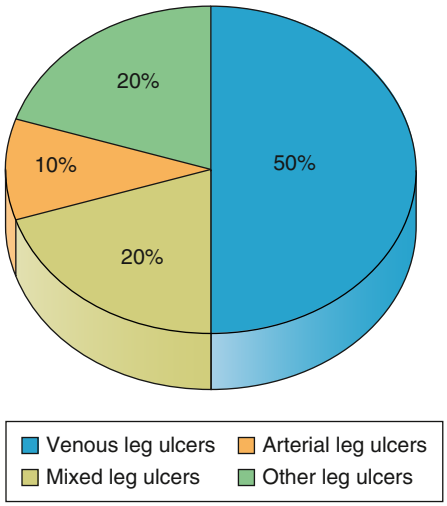

Fig. 45.43 Types of leg ulcers. (*From Griffiths C, Barker J, Bleiker T et al. eds.* Rook's Textbook of Dermatology, *9th edn. Chichester: John Wiley & Sons; 2016.*)

Fig. 45.44 Venous leg ulcer.

Ulceration is most common on the lower leg above the medial malleolus (**Fig. 45.44**). Dilated foot, leg, and thigh veins are usually evident. Other signs include:

- Oedema of the lower legs
- Venous (stasis or gravitational) eczema
- Hyperpigmentation caused by haemosiderin deposition
- Lipodermatosclerosis (fibrosing panniculitis of subcutaneous tissue), a combination of subcutaneous induration, reddish-brown pigmentation, and inflammation

- Atrophie blanche (white atrophy), which includes angular, ivory-white, depressed atrophic plaques with prominent red dots caused by dilated capillaries.

Management is with graduated multilayer (two- to four-layer) compression bandaging and leg elevation to improve venous return. Doppler studies (ankle:brachial pressure index) should be performed before compression to exclude significant arterial disease. Treatment can be delivered effectively in the community by appropriately trained healthcare professionals. Non-adherent dressings are used to keep the ulcer moist. Alternative dressings (alginate, hydrogel, hydrocolloid) may be helpful for heavy exudate and slough.

With adequate compression, up to 80% of ulcers can be healed within 6 months. Slower healing rates occur in patients with poor mobility, bilateral disease, and very large ulcers that have been present for more than 6 months. Diuretics are sometimes indicated to reduce oedema. Microbial swabs and antibiotics are indicated only when there are clinical signs of infection or cellulitis.

Painful venous leg ulcers require adequate analgesia. Split-thickness skin grafting can aid healing in resistant cases. Support stockings (individually fitted) should be worn for life after healing to lessen recurrence. Underlying venous disease should be assessed. Modern vascular surgical interventions may accelerate healing and reduce the risk of ulcer recurrence.

Arterial ulcers

Arterial ulcers present as punched-out, painful lesions on the legs or feet in people with underlying peripheral vascular disease, particularly smokers. The affected leg is usually cold and pale with loss of hair. Peripheral pulses are absent or weak. Doppler ultrasound studies can confirm underlying arterial disease.

Management depends on keeping the ulcer clean and covered, adequate analgesia, and vascular surgical intervention if appropriate. Compression bandaging must be avoided.

Neuropathic ulcers

These ulcers usually occur over pressure areas of the feet, such as the metatarsal heads, owing to repeated trauma. They are usually associated with diabetes and peripheral neuropathy. In some countries, leprosy is a common cause (see 'Leprosy [Hansen disease]' section).

Management involves keeping the ulcer clean and reducing pressure or trauma to the affected area. People with diabetes need meticulous foot care and correctly fitting shoes (see Chapter 35, 'Management of diabetes-related foot problems' section).

Pressure ulcers (decubitus ulcers, bedsores)

Pressure ulcers or sores are a severe manifestation of pressure-induced skin and soft tissue injury. They affect older, immobile, unconscious, and paralysed patients and are caused by skin and soft tissue ischaemia from sustained pressure over a bony prominence, most commonly the heel and sacrum.

Healthy individuals feel the discomfort of continued pressure, even during sleep, and relieve pressure by changing body position.

There are numerous risk factors for the development of pressure ulcers (**Box 45.25**). The majority arise in hospital, with approximately 70% appearing in the first 2 weeks of hospitalization and 70% occurring in patients with orthopaedic disorders, especially those receiving traction.

Pressure injuries may be graded and range from non-blanchable erythema of intact skin (stage 1) to deep ulcers extending to the bone (stage 4). Deep ulcers are associated with a high mortality rate. The early sign of red-blue skin discoloration can lead rapidly to ulcers within hours. Leaving patients on hard emergency room trolleys or sitting them in chairs for prolonged periods must be avoided.

Box 45.25 Risk factors for the development of pressure ulcers

Prolonged immobility
- Paraplegia
- Arthritis
- Severe physical disease
- Apathy
- Surgery and postoperative states
- Plaster casts
- Treatment on the intensive care unit

Decreased sensation
- Coma
- Neurological disease
- Diabetes mellitus
- Drug-induced sleep

Vascular disease
- Atherosclerosis
- Diabetes mellitus
- Scleroderma
- Vasculitis

Poor nutrition
- Anaemia
- Hypoalbuminaemia
- Vitamin C or zinc deficiency

Box 45.26 Management of pressure ulcers

- Ensure bed rest with pillows and fleeces to keep pressure off bony areas (e.g., sacrum and heels) and prevent friction.
- Provide special pressure-relieving mattresses and beds.
- Maintain regular turning and avoid pressure on hips.
- Provide air-filled cushions for patients using wheelchairs.
- Provide adequate nutrition.
- Apply non-irritant occlusive moist dressings (e.g., hydrocolloid).
- Prescribe adequate analgesia (e.g., may need opiates).
- Consider plastic surgery (debridement and grafting in selected cases).
- Treat the underlying condition.

Management

See **Box 45.26**.

Prevention

A risk assessment should be undertaken on newly admitted patients. The best-known risk assessment tools are the Norton Scale and Waterlow Pressure Ulcer Risk Assessment, which yield a numerical score (**Box 45.27**). Specialist tissue viability nurses help assess risk, deliver care, and train other clinical staff.

Lymphatic disease

Lymphoedema

Impaired lymphatic fluid drainage leads to chronic non-pitting oedema with impaired tissue immunity and increased fat deposition. It most commonly affects the legs and tends to progress with age. It is associated with an increased risk of cellulitis, which often becomes recurrent. The subcutaneous tissues become thickened and indurated, and the overlying skin develops a warty texture. Affected limbs may become grossly enlarged.

Box 45.27 Pressure ulcer risk assessment tools

Norton Scale for pressure ulcers[a]

Physical		Neurology		Activity		Mobility		Incontinence	
4	Good	4	Alert	4	Ambulant	4	Full	4	None
3	Fair	3	Apathetic	3	Walks with help	3	Slightly	3	Occasionally incontinent
2	Poor	2	Confused	2	Not bound	2	Limited	2	Usually incontinent
1	Very poor	1	Stupor	1	Bedfast	1	Very limited; immobile	1	Doubly incontinent

Waterlow Pressure Ulcer Risk Assessment[b]

Build/weight for height		Visual skin type		Continence		Mobility		Sex/Age		Appetite	
Average	0	Healthy	0	Complete	0	Fully mobile	0	Male	1	Average	0
Above average	2	Tissue paper	1	Occasionally incontinent	1	Restricted or difficult	1	Female	2	Poor	1
Below average	3	Dry	1	Catheter or incontinent of faeces	2	Restless or fidgety	2	14–18	1	Anorectic	2
		Oedematous	1	Doubly incontinent	3	Apathetic	3	50–64	2		
		Clammy	1			Inert/ traction	4	65–75	3		
		Discoloured	2					75–80	4		
		Broken or spot	3					81+	5		

Special risk factors		Assessment value	
1. Poor nutrition, e.g., terminal cachexia	8	At risk	10
2. Sensory deprivation, e.g., diabetes, paraplegia, cerebrovascular disease	6	High risk	15
3. High-dose anti-inflammatory or steroid in use	3	Very high risk	20
4. Smoking 10+ per day	1		
5. Orthopaedic surgery or fracture below waist	3		

[a]Low scores carry a high risk.
[b]See assessment value, bottom right of table.

Lymphoedema can be primary (and present early in life) and caused by an inherited abnormality of lymphatic vessels (e.g., Milroy disease) or can be secondary and caused by obstruction of lymphatic vessels (e.g., filarial infection or malignant disease).

Management is with compression stockings and physical massage. Causes of high central venous pressure, low albumin, and local inflammation should be treated. Long-term antibiotics are indicated for patients with recurrent cellulitis (see Chapter 11, 'Cellulitis and erysipelas' section) because each episode of cellulitis causes further damage to the lymph vessels. Surgery should be avoided.

Systemic malignant disease

Certain skin disorders may be a non-metastatic manifestation of an underlying malignancy; these are the ***paraneoplastic dermatoses*** (Box 45.28). Rarely, internal malignancies can metastasize to the skin, where they usually present as papules or nodules that may ulcerate.

Genetic disease

Neurofibromatosis type 1

Type 1 neurofibromatosis (von Recklinghausen disease) is an autosomal dominant condition caused by mutations in the *NF1* gene on chromosome 17. It often presents in childhood with more than five ***café-au-lait*** macules (light brown, well-demarcated, round or oval macules >5 mm in diameter) and axillary freckling. Learning difficulties and skeletal dysplasia can occur. Lisch nodules in the iris may be seen on slit-lamp examination. Neurofibromas appear in adulthood as fleshy skin polyps and smooth, soft dermal tumours, and can be extensive. Several endocrine disorders are rarely associated, including

Box 45.28 Non-metastatic cutaneous manifestations of underlying malignancy

Dermatosis	Tumour
Dermatomyositis	Lung, gastrointestinal tract, genitourinary tract
Acanthosis nigricans	Gastrointestinal tract, lung, liver
Paget disease of the nipple (localized eczema-like changes on nipple and areola)	Ductal breast carcinoma
Erythroderma	Lymphoma, leukaemia
Tylosis (thickened palms/soles)	Oesophageal carcinoma
Tripe palms (velvet palms)	Pulmonary, gastric
Ichthyosis (dry flaking of skin)	Lymphoma
Sign of Lesar-Trelat (sudden eruption of multiple seborrheic keratoses)	Lymphoproliferative, gastrointestinal
Erythema gyratum repens (concentric rings of erythema, which change rapidly)	Lung, breast
Necrolytic migratory erythema (burning, geographic and spreading annular areas of erythema)	Glucagonoma
Paraneoplastic pemphigus	Lymphoproliferative
Pyoderma gangrenosum	Myeloproliferative
Acute febrile neutrophilic dermatosis (Sweet syndrome)	Lymphoproliferative

phaeochromocytoma, acromegaly, and Addison disease (see Chapter 34, 'Addison's disease' section).

Tuberous sclerosis

Tuberous sclerosis complex (TSC) is an autosomal dominant multisystem disorder characterized by a range of benign hamartomas in multiple organs. It is caused by mutations in either *TSC1* gene on chromosome 9q, which produces the protein hamartin (10%–30%), or TSC2 on chromosome 16p, which produces tuberin. The main clinical features are learning and behavioural difficulties, epilepsy, and skin lesions:

- Angiofibromas: pink or red papules around the nose and cheeks
- Periungual fibromas: nodules arising from the nail bed
- Shagreen patches: connective tissue naevi present as flesh-coloured plaques on the trunk
- Ash-leaf hypopigmentation: pale macules best seen with a Wood UV lamp
- Forehead plaque: indurated, flesh-coloured plaques
- *Café-au-lait* macules

Hamartomas can also arise in the heart, lung, kidney, retina, and CNS. Inhibition of the mammalian target of rapamycin (mTOR) signalling pathway with drugs such as rapamycin may help to shrink TSC-associated tumours.

Ehlers–Danlos syndrome

Ehlers–Danlos syndrome (EDS; see Chapter 32, 'Hypermobile Ehlers–Danlos syndrome and hypermobility spectrum disorders' section) is a group of inherited disorders of connective tissue that affect the structure and function of the skin, eyes, ligaments, joints, blood vessels, and internal organs. At least 13 subtypes of EDS are recognized with different molecular genetic defects, inheritance, and clinical features. The underlying genetic defects involve abnormalities of collagen and other extracellular matrix molecules, affecting connective tissue synthesis and structure. These lead to:

Box 45.29 Differential diagnosis of photosensitive rashes

Photoexacerbated or provoked rashes

Autoimmune rheumatic disorders
- Lupus erythematosus
- Dermatomyositis

Metabolic disease
- Porphyrias (see Chapter 36, 'Porphyrias' section)
- Pellagra (see Chapter 25, 'Pellagra' section)

Drugs
- Thiazides
- Phenothiazines
- Tetracyclines
- Amiodarone

Plant phototoxins
- Phytophotodermatitis (photosensitivity induced by contact of the skin with certain plants, e.g., celery, hogweed, rue, lime, fig tree)

Skin disease
- Rarely, atopic eczema, psoriasis, lichen planus (these usually improve in sunlight)

Idiopathic photodermatoses
- Polymorphic light eruption
- Chronic actinic dermatitis
- Solar urticaria

- Fragile, hyperelastic and lax skin that heals with tissue paper scars
- Fragile bloods vessels with easy bruising
- Hypermobile (unstable and hyperextensible) joints.

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum is a group of rare autosomal recessive diseases caused by mutations in the *ABCC6* gene encoding a protein involved in inhibition of mineralization. It causes abnormal calcification and consequent fragmentation of elastic fibres, particularly in the reticular dermis of skin, tunica or media intima of blood vessels, and Bruch membrane of the choroid. Skin changes include laxity and wrinkling and yellow papules and plaques (resembling 'plucked chicken' skin), and the changes are most evident in the flexures and lateral neck. Non-cutaneous features include angioid streaks on the retina, recurrent GI bleeding, vascular occlusion, and aneurysms.

PHOTOSENSITIVITY DISORDERS

Photosensitivity disorders are characterized by abnormal sensitivity to UV radiation and sometimes the visible range of the solar spectrum. Several skin diseases are primarily caused by sunlight ***(primary or idiopathic photodermatoses)*** including polymorphic light eruption, chronic actinic dermatitis, and solar urticaria. A larger number are exacerbated by sun exposure ***(photo-aggravated photodermatoses)***, including some connective tissue diseases (dermatomyositis and cutaneous lupus). The rashes of pellagra (see Chapter 25, 'Pellagra' section) and the porphyrias (see Chapter 36, 'Porphyrias' section) and certain drug hypersensitivities may also be triggered by UV exposure (**Box 45.29**).

BLISTERING AND BULLOUS SKIN DISEASE

There are many causes of skin blisters, the most common being ***infection*** (HSV, chickenpox, impetigo, cellulitis), ***insect bites*** (especially on the lower legs), and ***trauma*** (burns and friction). Blistering

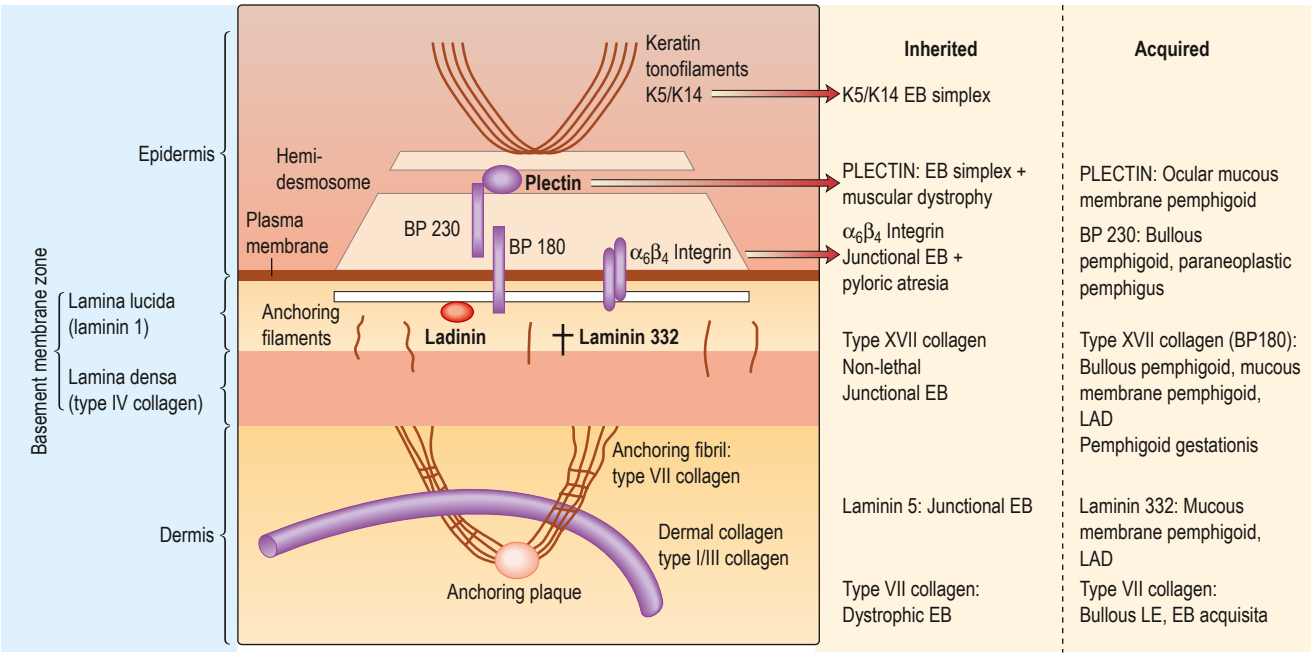

Fig. 45.45 Section of the basement membrane zone. The structural sites of damage in bullous disorders. *EB,* Epidermolysis bullosa; *K,* keratin; *LAD,* linear IgA disease; *LE,* lupus erythematosus.

may also be a feature of eczema, especially on the hands and feet (pompholyx).

Very rarely, blistering is from skin fragility caused by genetically determined abnormalities in the structural proteins of the DEJ and basal keratinocytes ***(mechanobullous diseases)*** or their destruction by antibodies in autoimmune ***(immunobullous)*** disease. The level at which fragility and blistering occur varies according to disease and affects the clinical presentation (Fig. 45.45). It can be demonstrated by light and electron microscopy and IMF studies. Autoantibody deposits (at the basement zone or between keratinocytes) can be identified by direct IMF of affected (perilesional) skin; indirect IMF identifies circulating autoantibodies in serum.

Immunobullous diseases

Pemphigus

This is a disorder affecting the upper (epidermal) layer of skin, characterized by fragile, flaccid blisters that burst easily.

- ***Pemphigus vulgaris*** is a rare and potentially life-threatening autoimmune blistering disease. It is more common in Ashkenazi Jews and people from the Indian subcontinent. It may affect all ages but usually starts in adulthood. Pathogenic IgG4 antibodies against desmosomal proteins (desmoglein 1 and 3) lead to loss of keratinocyte adhesion in the skin and mucous membranes, causing superficial (intraepidermal) blisters, erosions, and mucosal ulcers.

  Oral involvement is common and is the presenting sign in up to 50% of patients. Skin lesions appear as flaccid blisters that rupture easily, leaving weeping and crusted erosions. Blisters can be extended with gentle lateral pressure or rubbing of the skin (Nikolsky sign).
- ***Pemphigus foliaceus*** is a rarer variant, in which the target antigen is desmoglein 1. This antigen is not expressed in the oral mucosa, which is therefore unaffected. Desmoglein 1 is predominantly expressed in the upper epidermis, which detaches, leaving crusts and erosions rather than blisters. It usually affects the seborrhoeic areas before becoming more widespread. Endemic pemphigus foliaceus (fogo selvagem) occurs in rural areas of Brazil and is thought to be triggered by an infectious agent carried by biting insects. A pemphigus foliaceus–like rash can be induced by drugs (e.g., captopril, penicillamine).
- ***Paraneoplastic pemphigus*** is a rare malignancy-associated disorder characterized by painful, hemorrhagic oral erosions and a polymorphic inflammatory rash. It is usually associated with an underlying lymphoproliferative neoplasm.

Investigations

Direct IMF of perilesional skin in pemphigus shows intercellular IgG deposition. Circulating anti-epidermal antibodies can also be detected, and their titre correlates with disease activity. Histology of affected skin shows intraepidermal cleavage above the basal cell layer with separation of individual keratinocytes (acantholysis) in pemphigus vulgaris. The split occurs higher in the epidermis in pemphigus foliaceus.

Management

Topical and systemic corticosteroids are usually effective in controlling pemphigus followed by longer-term, steroid-sparing immunosuppressive drugs, including mycophenolate mofetil, azathioprine, methotrexate, cyclophosphamide, and rituximab (anti-CD20 monoclonal antibody).

Bullous pemphigoid

Bullous pemphigoid is more common than pemphigus in Western Europe and usually affects adults older than 60 years of age. Blisters form in the dermis (deeper than in pemphigus); are usually itchy; and present as large, tense, serous, or haemorrhagic blisters (bullae) with inflamed (urticated) bases. In some cases, intensely itchy, urticated plaques are the presenting feature and precede blistering. Blistering may be widespread, affecting the trunk and limbs, especially the lower abdomen and thighs (Fig. 45.46) but in some cases remain localized.

Fig. 45.46 Bullous pemphigoid: bullous presentation. (A) Typical presentation with multiple tense bullae arising on normal and erythematous skin. Several of the bullae have ruptured, leaving circular erosions. **(B)** Multiple tense bullae that contain serous fluid arising within an area of erythema in addition to haemorrhagic crusts.

Mucosal ulceration is not prominent, except in the rare variant ***mucous membrane pemphigoid*** (formerly called cicatricial pemphigoid). This presents with erosions and ulceration of the mucosal surfaces and scarring eye disease, with fusion of the eyelids, corneal damage, and visual loss. ***Pemphigoid gestationis*** is a rare variant that occurs in pregnancy and the postpartum period.

Investigations

Autoantibodies against a 230- or 180-kDa hemidesmosomal protein (bullous pemphigoid antigen 1 and type 17 collagen, respectively) play a pathogenic role and cause a split through the epidermal BMZ. This can be seen on routine histology as a subepidermal split. Direct IMF shows deposition of IgG and complement at the DEJ.

Management

Oral corticosteroids (prednisolone 0.5 mg/kg per day) are usually initiated for disease control, with a steroid-sparing drug such as azathioprine, mycofenolate mofetyl, or rituximab for long-term management. These drugs require careful monitoring in older adults because of their increased risk of adverse drug effects, which contributes to the increased mortality associated with pemphigoid. Oral tetracyclines are also used for their anti-inflammatory actions. Mild localized pemphigoid can be managed by daily application of a very potent topical steroid to drained blisters. Treatment can usually be withdrawn after a few years, but the disease may relapse.

Linear IgA disease

Linear IgA disease (LAD) is a rare pemphigoid-like disorder of adults and children caused by pathogenic IgA autoantibodies that target various BMZ proteins, including type XVII collagen and laminin-332 (see **Fig. 45.45**). The cause is unknown, but LAD may be induced by drugs, especially vancomycin. Direct IMF of skin shows linear IgA deposition along the DEJ. LAD characteristically presents with circular clusters of golden blisters, described as a 'string of jewels' (**Fig. 45.47**). It usually responds to treatment with dapsone (see later).

Fig. 45.47 Linear IgA disease: typical circular clustering of blisters.

Dermatitis herpetiformis

Dermatitis herpetiformis (DH) is a cutaneous manifestation of coeliac disease (see Chapter 22, 'Coeliac disease [gluten-sensitive enteropathy]' section). Both conditions are genetically determined and triggered by dietary gluten. DH presents with an intensely itchy, eczematous rash that predominantly affects the elbows, knees, scalp, and buttocks. Small blisters may be visible but are often scratched away, leaving excoriations and crusted erosions.

DH is more common in males (whereas coeliac disease has a female predominance); it can present at any age but usually appears in early adulthood. Nearly all patients with DH have small intestinal changes of coeliac disease (villous atrophy/inflammation) but lack GI symptoms. Autoantibodies against tissue transglutaminase (TG) 2 occur in the serum and bowel in patients with DH and coeliac disease, with additional IgA antibodies against TG3 occurring in DH. The latter can be demonstrated in the skin by direct IMF, which reveals granular IgA deposits in the dermal papillae and along the BMZ. Histology of DH shows subepidermal blistering and a florid infiltrate of neutrophils causing micro-abscesses in the dermal papillae.

Management

Patients should avoid all dietary gluten. Treatment with dapsone or sulphonamides, sometimes at low doses, usually gives rapid relief from itch. If a strict gluten-free diet is followed, oral medication can usually be withdrawn after 2 years. Dapsone causes mild dose-related haemolysis, which is usually well tolerated except in those with cardiorespiratory disease. It is contraindicated in people with glucose-6-phosphate dehydrogenase deficiency because they are at risk of severe drug-induced haemolysis. Other rare adverse effects of dapsone include hepatitis, drug hypersensitivity syndrome (including DRESS; see Chapter 11, 'Drug reaction with eosinophilia and systemic symptoms/drug hypersensitivity syndrome' section), and peripheral neuropathy.

Mechanobullous diseases (epidermolysis bullosa)

This rare group of inherited skin diseases is caused by defective or absent structural skin proteins, leading to fragile skin that blisters with minimal trauma. Blisters and erosions usually appear at or shortly after birth. The degree of skin fragility is highly variable, ranging from mild friction blisters to severe, extensive, and life-limiting skin loss. There are three broad groups of disorders:

- ***Epidermolysis bullosa simplex*** is the mildest form and causes localized blisters on the hands and feet that heal without scarring. It is inherited as an autosomal dominant trait and caused by synthesis of abnormal cytoskeleton proteins (e.g., keratins 5 and 14) in the basal epidermis.
- ***Dystrophic epidermolysis bullosa*** is a debilitating, life-limiting disease characterized by deep erosions, blisters, and scarring. The underlying abnormality is mutations in the type 7 collagen gene that cause impaired or absent synthesis of anchoring fibrils in the deep part of the BMZ. Mucosal involvement can affect the larynx and oesophagus, causing voice loss and dysphagia. Nails are absent, and the digits may become fused by the scarring, causing mitten-like deformities. Affected individuals have a high risk of developing aggressive SCCs within chronically inflamed skin. There is no curative therapy at present, and management is supportive.
- ***Junctional epidermolysis bullosa*** is the most severe form and is characterized by a split in the lamina lucida of the BMZ caused by mutations in genes controlling synthesis of various structural proteins (laminin-332, $\alpha_6\beta_4$ integrin, type 17 collagen). It presents at birth with widespread blistering and areas of absent skin and is usually fatal in early childhood.

Investigations and management

Investigation and treatment of patients with epidermolysis bullosa should be carried out in a specialist centre. Ultrastructural skin tests and genetic testing provide a precise diagnosis and prognosis and are required for genetic counselling. Prenatal diagnosis and preimplantation diagnosis are available for those with severe forms of epidermolysis bullosa.

Treatment options have been limited to supportive care, pain management, and skin grafting. More recently, topical birch bark triterpenes for dystrophic and junctional epidermolysis bullosa and topical gene therapy for dystrophic epidermolysis bullosa have shown effectiveness in promoting wound healing. Gene therapy and bone marrow transplantation are further new approaches that are undergoing clinical trials.

SKIN TUMOURS

Benign skin tumours

Melanocytic naevi

Melanocytic naevi are the most common benign neoplasms in humans and are caused by a proliferation of melanocytes. They are usually diagnosed based on clinical and dermatoscopic appearances.

- ***Congenital melanocytic naevi*** are present at birth in 1% to 2% of newborns and may be classified by actual or predicted adult size: small naevi are smaller than 1.5 cm, medium are 1.5 to 19.9 cm, and large (giant) are more than 20 cm, including bathing trunk naevi, which cover large areas of the trunk and proximal limbs. Small solitary lesions are common and harmless. Larger lesions and multiple smaller naevi may be associated with neurological complications, including epilepsy and an increased risk of melanoma. Specific types of congenital naevi also recognized include ***hairy congenital naevus*** (which grows long, thick hairs), ***speckled lentiginous naevus*** (naevus spilus, which is a flat, tan coloured patch with darker papules), ***naevus of Ota*** (brown-blue macule around the eye or cheek), and ***Mongolian spot*** (bluish macule over the sacral and buttock areas of newborns).
- ***Acquired melanocytic naevi (moles)*** appear in childhood, adolescence, and early adult life, increasing in size and number with age. Benign naevi may arise on any location and appearances may differ by body site. They are usually round or oval, vary in size from a few millimetres to a few centimetres, and usually have even pigmentation and regular borders. Colours vary and are often pale, pink, or tan-coloured in those with lighter skin tones and darker brown or black in darker skin tones.

Initially, melanocytic naevi may appear as flat, brown macules because of proliferation of melanocytes at the DEJ ***(junctional naevus)***. With later downward growth of melanocytes into the dermis as well as the DEJ, the mole becomes raised and palpable ***(compound naevus)***. Eventually, melanocytes may completely migrate into the dermis, and the mole becomes dome shaped with progressive loss of pigment ***(intradermal naevus)***. Some melanocytic naevi may gradually involute later in life, particularly those acquired in later childhood and adulthood. They may also change during pregnancy and after sun exposure when they can increase in size, regress, or involute.

Additional types of benign acquired melanocytic naevi with characteristic clinical appearances are summarized in **Box 45.30**. Dermatoscopic classifications of moles are also used to describe their different pigment patterns (see **Box 45.2**).

Factors influencing the number of acquired melanocytic naevi present include genetic predisposition, UV exposure, and immunosuppressive medication.

Although the risk of malignant transformation of a benign melanocytic naevus is extremely low, the presence of more than 100 common naevi is associated with a sevenfold increase in the risk of melanoma. Warning signs of possible malignant transformation are summarized in **Fig. 45.1**. Most acquired melanocytic naevi do not require treatment.

- ***Atypical naevi*** are acquired melanocytic naevi that are clinically atypical or histologically dysplastic. They may occur sporadically

Box 45.30 Types of acquired melanocytic naevi

Acquired melanocytic naevus	Clinical appearance
Acral naevi	Moles on the palm or sole; often irregular in shape; more common type in darker-skinned individuals
Subungual or nail unit naevi	Usually present as a longitudinal pigmented band beneath a nail; may affect multiple nails
Blue naevus	Dome-shaped, blue-grey lesions, often located on the forehead or dorsal hands and feet, with a characteristic dermatoscopic appearance of dark blue, structureless lesion caused by a deeper proliferation of melanocytes in the mid-dermis
Spitz naevus (epithelioid cell naevus)	Dome-shaped moles rising in children and young adults that may be pink (classic Spitz) or brown (pigmented Spitz)
Reed naevus	Flat and darkly pigmented type of Spitz naevus with a 'starburst' pattern on dermoscopy
Halo naevi (Sutton naevi)	Symmetrical, round or oval, white 'halo', which is probably caused by autoimmune depigmentation; usually seen in children and young adults; may be multiple and associated with benign melanocytic naevi that gradually regress
Meyerson naevus	Melanocytic naevi affected by a halo of eczema, which appears red and scaly and may be itchy and usually resolved spontaneously

or may be familial. Clinically, atypical features include larger size (>5 mm), irregular pigmentation, and irregular or ill-defined borders. Dysplastic histological features include lentiginous proliferation of naevus cells, cytological atypia, spindle or epithelioid melanocytes, fibrosis in the dermis, inflammatory infiltrate, and increased or enlarged blood vessels. Atypical clinical features and histological dysplasia are not always correlated. They particularly affect people with lighter skin tones and may be more numerous with increased UV exposure.

Atypical naevi that lack features of melanoma, do not warrant excision on presentation, and can be photographed and reviewed at 3- to 4-month intervals to detect early features of malignant change. Patients should be advised on self-examination and photoprotection.

- ***Atypical mole syndrome (AMS)*** refers to the presence of multiple (>5) atypical and dysplastic naevi and multiple benign naevi (>50), which are often located on atypical sites (scalp, buttocks, dorsal hands and feet, irises). The lifetime risk of melanoma is increased approximately sixfold. Familial atypical multiple mole and melanoma (FAMMM) syndrome describes AMS with a family history of melanoma (one or more first- or second-degree relatives diagnosed with melanoma) and is associated with a significantly increased risk of melanoma. People with AMS and a personal history of melanoma or FAMMM usually require long-term self-monitoring and clinical surveillance, which may be supported using dermoscopy of atypical lesions and serial photographic imaging ('mole mapping'), which may be automated and may include dermoscopy.

Epidermal naevi

These are benign overgrowth of epidermal components that appear at birth or early childhood because of mosaic genetic mutations in skin cells during ectodermal development. Epidermal naevi follow the lines of Blaschko (embryological tracks taken by genetically identical developing cells).

- The most common type is a ***linear epidermal naevus***, which usually occurs on trunk and limbs, is unilateral, is a flat and tan-brown colour at birth, and becomes raised and warty with age.
- ***Organoid naevi*** ('naevus sebaceous') also involve proliferation of skin appendages (e.g., sebaceous glands, sweat glands, hair follicles). Initially, they appear as single oval or linear smooth orange-yellow patches, often in the scalp, and become more raised during puberty. In a small proportion, a secondary tumour may occur, usually in adulthood, the most common of which is BCC.
- ***Becker naevus*** is a distinct type of epidermal naevus that usually occurs in males during adolescence in any skin type and unilaterally affects the shoulders or upper trunk. It includes the epidermis, hair follicles, and melanocytes and becomes increasingly thickened, pigmented, and hairy after puberty. Rarely, epidermal naevi may be part of syndromes, which also involve eyes, nervous system, or skeleton.

Fig. 45.48 Seborrhoeic keratoses (seborrheic warts, basal cell papillomas).

Basal cell papillomas ('seborrhoeic keratoses' or 'seborrheic warts')

These are very common, benign lesions caused by hyperproliferation of basal keratinocytes. They increase in number with age (~90% of adults older than 60 years of age have one or more) and are frequently multiple. They appear anywhere on the skin other than palms and soles as papules and plaques and range from flesh-coloured to yellow, grey, light brown, very dark brown to black, or have mixed colours. They have a greasy, 'stuck-on' appearance, and the surface may rough and warty or relatively smooth and waxy. Tiny yellow-white keratin cysts may be visible (Fig. 45.48).

Dermoscopy can be very helpful in distinguishing them from other pigmented skin lesions. They are usually asymptomatic but may be itchy. Treatment is not usually required, but cryotherapy or surgery by curettage and cautery can be used. Eruptive seborrheic keratoses may very rarely be associated with an underlying malignancy (sign of Lésar-Trelat).

Dermatosis papulosa nigra is a term used to describe multiple, small, heavily pigmented basal cell papillomas that may appear with increasing age on the head and neck of some people with darker skin tones (see Fig. 45.5). ***Stucco keratoses*** are another variant that

appear as white or yellow papules on the legs. Treatment is not needed unless the lesions are causing problems, and methods used include cryotherapy, curettage and cautery, and shave biopsy.

Dermatofibroma (benign fibrous histiocytoma)

Dermatofibromas are common, benign fibrous nodules that are most frequently found on the legs and particularly in females. The cause is unclear, but there is sometimes a history of minor trauma or an insect bite. They appear as firm, smooth, pink-red or brown dermal papules or nodules (which may be darker brown or black in darker skin tones), 0.5 to 1.5 cm in diameter, often have a peripheral pigmented margin, and exhibit dimpling of overlying skin when pinched. Although usually asymptomatic, they may be itchy or tender. Histologically, they consist of proliferating fibroblasts histiocytes, blood vessels, and varying degrees of fibrosis. The diagnosis is usually straightforward clinically, and dermoscopy may be helpful. Excision is not needed unless lesions are symptomatic or there is diagnostic uncertainty, and recurrence is common if excision is incomplete.

Lipoma

These benign subcutaneous tumours consist of fat cells, are very common, and are often multiple. They usually appear in adulthood, and there is often a family history when multiple. At presentation, they are often ovoid or round, 2 to 10 cm in size and soft, rubbery, smooth, and mobile. They are most common on the trunk and limbs but can develop wherever fat is present. They are generally asymptomatic, but those with an increased number of blood vessels ***(angiolipomas)*** may be tender on palpation. Surgical treatment is rarely required.

Epidermoid cyst ('sebaceous cyst') and pilar cyst

Epidermoid cysts are benign cysts derived from occluded pilosebaceous units. 'Sebaceous' cyst is a misnomer in that they do not arise in sebaceous glands or contain sebum. They are more common in adults and in males. They are flesh-coloured or yellowish, 1 to 3 cm in diameter, and are fixed to skin but are mobile from deeper structures. They have a central punctum and contain keratin and lipid-rich, often malodorous 'cheesy' debris, which may discharge. They are most common on the trunk but can occur anywhere and may be multiple. They may rupture, causing inflammation with redness and tenderness, and can become secondarily infected. ***Pilar cysts*** are similar but occur on the scalp. Both may be multiple and familial. Uncomplicated cysts do not need treatment, but surgical excision may be considered if the cysts is particularly symptomatic, for example, if infection has occurred.

Pyogenic granuloma

Pyogenic granulomas are acquired, benign vascular proliferations of capillary vessels that present as rapidly growing, friable, red nodules that bleed easily. They may follow minor trauma and often occur on the fingers, face, lips, and oral mucosa. They may also be linked to pregnancy and certain drugs, including retinoids. They rarely resolve spontaneously, except those associated with pregnancy. Excision is the most frequently used treatment, and lesions should be sent for histology to exclude amelanotic melanoma, which is the most important differential diagnosis.

Cherry angioma (Campbell de Morgan spots)

Cherry angiomas are benign haemangiomas that appear as asymptomatic red, purple, or blue papules and may become black if thrombosed. They occur anywhere on the skin, especially on the trunk, and vary in size from pinpoint to 0.5 to 1 cm diameter and are usually multiple. They increase in number with age, and an estimated 75% of people older than 40 years of age have at least one. No treatment is required.

Keloid and hypertrophic scars

Abnormal wound healing with excessive dermal fibrosis leads to hypertrophic scars and keloid formation.

- In ***hypertrophic scars***, thickening remains confined to the borders of the original wound, is usually slightly raised and pink-red (more pigmented in darker skin tones), and occurs within weeks of an injury. They are common in all age groups and races and ages and tend to develop if there is significant tension on a wound. They may regress spontaneously.
- In contrast, in ***keloid scars***, the excessive scar formation extends beyond the original wound margins and may develop months or even years after minor injury such as minimal trauma, acne, shingles, insect bites, immunization, and occasionally spontaneously. They tend to affect young adults with darker skin tones and are more common in those of African and Chinese heritage. They are usually red-purple (or brown in darker skin tones), firm, and may be itchy and tender, and sites of predilection are areas of high skin tension, including the shoulders, upper back and chest, earlobes, and chin (Fig. 45.49).

Both hypertrophic and keloid scars can be associated with significant cosmetic disfigurement, functional problems, and adverse psychosocial impact. Treatment options include use of silicone gel or dressings, pressure garments, topical steroids, steroid-impregnated tapes, intralesional corticosteroids, cryotherapy, and intralesional 5-fluorouracil (5-FU). Occasionally, surgical excision of keloid scars may be undertaken and followed by superficial radiotherapy. Non-essential surgery should be avoided.

Dysplastic and premalignant skin lesions

Actinic (solar) keratoses

Actinic keratoses (AKs) are common premalignant skin lesions with partial-thickness epidermal dysplasia and are considered to be

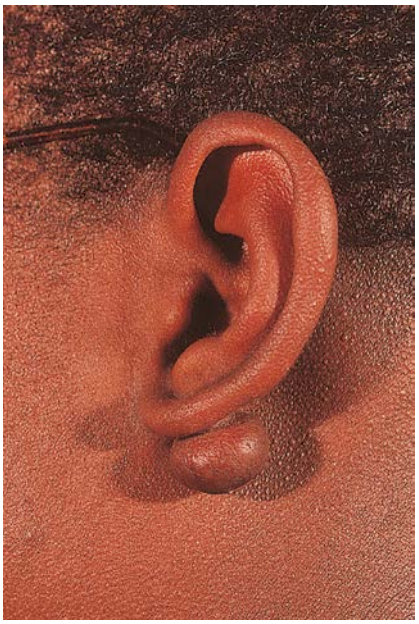

Fig. 45.49 **Keloid scar on the lobe of the ear.**

Box 45.31 Fitzpatrick skin phototype classification

Fitzpatrick classification[a]	Clinical features (skin tone, hair colour, eye colour)	Reaction to UV radiation
I	Pale white skin; light blonde or red hair; blue or green eyes	Always burns; does not tan; freckles
II	Lighter white skin; blue, green, or hazel eyes	Usually burns; tans with difficulty; freckles
III	Darker white skin; blonde or brown hair; dark blue, hazel, or brown eyes	Initially burns moderately; tans gradually to light brown; may freckle
IV	Light to moderate brown or olive skin; brown-black hair; light brown eyes	Rarely burns; tans easily to moderate brown
V	Brown skin; brown-black hair; dark brown eyes	Very rarely burns; tans easily
VI	Dark brown or black skin; brown-black hair; brown eyes	Never burns; tans very easily and deeply; never freckles

[a]This classification estimates the sunburning and tanning ability of skin to ultraviolet (UV) radiation. Although widely used, its representation of global skin colour diversity in people of colour is recognized to be limited.

precursors for cSCC. They are the result of chronic UV radiation (UVR) exposure and are most common on UV-exposed sites, particularly the ears, nose, cheeks, forehead, lips, scalp (particularly in balding males), and dorsal hands and forearms. Risk factors include lighter skin tones (particularly Fitzpatrick skin phototypes I and II; Box 45.31), a history of sunburn, immunocompromise, and a history of high UV exposure (e.g., outdoor occupation or recreational activities, residence in geographic locations with high ambient UV, increasing age). They appear as asymptomatic or tender papules or plaques, which may be white, yellow, red, or pigmented. They usually feel scaly and rough and may be palpated more easily than seen. Some become more hyperkeratotic, and cutaneous horns may also arise from AKs. AKs may be multiple and confluent and coexist with chronic photodamage (Fig. 45.50), to form areas of 'field cancerization' or 'field change'.

AKs are usually diagnosed clinically and on dermoscopy, although occasionally, a skin biopsy may be required to exclude cSCC, particularly if an AK becomes tender, enlarges, or ulcerates. Malignant transformation of an individual AK is rare, occurring in an estimated 0.1% of AKs. However, approximately 10% of patients with 10 or more AKs eventually develop cSCC. Because AKs are associated with UV damage, they are also a sign of an increased risk for other skin cancers, including BCC and melanoma.

Treatment is usually indicated for symptomatic AKs and to reduce the risk of cSCC development (although the evidence for this is limited). Strict photoprotection can reduce the numbers of AKs and cSCC. Other treatments that are often used in combination or sequentially include:

- *Lesion-directed treatments* for individual AKs, including cryotherapy, curettage and cautery, and excision
- *Field treatments* aimed at clearing multiple visible and subclinical lesions in areas of field change. These include topical treatments with different modes of action, including 5-FU (cytotoxic agent), imiquimod (immune response modifier), diclofenac (cyclo-oxygenase-2 inhibitor) and tirbanibulin (inhibitor of tubulin polymerization and protein kinase signalling). Photodynamic therapy using the topical photosensitiser 5-aminolaevulinic acid or its methyl ester followed by exposure to a source of red or blue light or daylight is another option.

Bowen disease (squamous cell carcinoma *in situ*, intraepidermal carcinoma)

This is also an cSCC premalignant lesion with full-thickness intraepidermal dysplasia histologically. It is estimated to progress to invasive cSCC in approximately 5% of cases. It is usually caused by chronic UV exposure in people with Fitzpatrick skin phototype type I or II; other risk factors include immunocompromise, arsenic ingestion (e.g., from contaminated well water is some parts of the world), human papillomavirus (HPV) infection (see later), and ionizing radiation.

Fig. 45.50 Actinic (solar) keratoses with background actinic damage ('field change').

Bowen disease lesions present as slowly enlarging, well-demarcated scaly plaques that may be pink-red, purple, or pigmented. When related to UV exposure, they typically affect the lower legs in females (Fig. 45.51A); the trunk in males and the ears, face, and hands in both sexes. They may resemble plaques of psoriasis, eczema, or tinea. They may be contiguous with AKs in areas of field cancerization or field change. The diagnosis is usually based on clinical features and supportive dermoscopy, but a skin biopsy may be required for confirmation.

Variants of Bowen disease affecting the genital mucosa are referred to as ***VIN, PIN,*** or ***AIN*** and usually result from infection with high-risk alpha HPV (e.g., HPV-16 and 18). Lesions present with nonspecific red or brown plaques (erythroplasia; Fig. 45.51B) or warty papules and plaques ***(Bowenoid papulosis)***. Anogenital disease may also be associated with periungual Bowen disease. Anogenital Bowen disease is more common in immunocompromised individuals, including PLWH. Management is discussed in Chapter 43 ('Human papillomavirus [anogenital warts]' section).

Treatment for patients with Bowen disease is similar to that for AK and includes physical destructive treatments (e.g., cryotherapy, curettage and cautery, excision, laser), topical treatments (5-FU, imiquimod), and photodynamic therapy.

Keratoacanthoma

Keratoacanthomas are rapidly growing epidermal tumours that develop as nodules with a central crater-like, keratinous plug

Fig. 45.51 **Cutaneous squamous cell carcinoma *in situ* (intra-epidermal carcinoma, Bowen's disease).** **(A)** The lower leg is a common site, and lesions are often treated non-surgically. **(B)** Erythroplasia of glans penis (penile intraepithelial neoplasia).

Fig. 45.52 **Keratoacanthoma.**

(Fig. 45.52). They typically develop on chronically sun-exposed skin in males with lighter skin tones older than the age of 60 years. They characteristically grow rapidly over 3 to 6 weeks, often reaching 2 to 3 cm in diameter, and may regress spontaneously after about 3 months, leaving a crateriform scar, although they are generally excised because they can be difficult to distinguish from well-differentiated SCC. Keratoacanthomas are usually associated with chronic UV exposure but are also more common in immunocompromised patients and occur in people with some rare genetic cancer syndromes (e.g., Ferguson-Smith syndrome and Muir Torre syndrome) and secondary to some drugs (e.g., vemurafenib and dabrafenib).

Lentigo maligna (Hutchinson melanotic freckle)

Lentigo maligna is a precursor to lentigo maligna melanoma and is a slow-growing intraepidermal *(in situ)* form of melanoma. The main risk factor is chronic UV exposure. It is more common in males aged 60 to 80 years, and patients often also have a history of AKs and keratinocyte cancers. It typically presents as a pigmented macule on chronically sun-damaged skin (usually the face) and may initially resemble a solar lentigo but grows slowly over many years, often becoming increasingly atypical (Fig. 45.55C).

Invasive lentigo maligna melanoma (see later) occurs in approximately 3% to 10% of cases. It should be suspected if thickening, increasing numbers of colours, ulceration, bleeding, and suspicious dermoscopic features develop. Skin biopsy can confirm the diagnosis, but there is a risk of sampling error, which misses an invasive focus if large lesions are biopsied.

Treatment of lentigo maligna is by excision if possible, but margins may be difficult to define clinically, and recurrence rates are approximately 20%. Confocal microscopy or excision by Mohs' micrographic surgery (see later) can help improve margin control. Because complete excision may have adverse cosmetic and functional outcomes, non-surgical approaches include topical imiquimod and radiotherapy. In some cases, particularly in very frail or older patients with large lesions and multiple co-morbidities, close observation may be a reasonable alternative.

Malignant skin tumours

Keratinocyte cancers

Keratinocyte cancers account for more than 90% of all skin cancers and are the most common human malignancies. They arise in the epidermis and include BCC and cSCC. Tumours are frequently multiple, and the AK, Bowen disease, field change, and keratinocyte cancer spectrum is often regarded as a chronic condition. 'Non-melanoma skin cancer' is a broader term that includes both keratinocyte cancers and other skin cancers, including Merkel cell carcinoma, appendageal cancers, sarcomas, and lymphomas.

Basal cell carcinoma

BCCs are the most common form of keratinocyte skin cancer and overall are two- to threefold more common than cSCC. Incidence is increasing by 5% to 10% a year. BCC probably arise from pluripotent cells in the basal epidermis or follicular structures. UV-induced DNA mutations in *PTCH* tumour suppressor gene involved in regulation of the Hedgehog intracellular signalling pathway are detected in sporadic BCCs (usually UV induced) and in Gorlin syndrome, a familial cancer syndrome characterized by the development of multiple BCCs. Risk factors for BCC include:

- Age and sex (more common with increasing age and in males)
- UVR exposure (previous episodes of sunburn; use of artificial tanning beds)
- Lighter skin tones that burn easily (Fitzpatrick phototype I and II), although they also occur in people with darker skin tones
- Previous skin cancer (BCC, cSCC, melanoma)
- Immunocompromise (e.g., risk is increased 5 to 10-fold in organ transplant recipients and PLWH or haematological malignancy)
- Genetic predisposition (family history of BCC)

Fig. 45.53 Clinical basal cell carcinoma (BCC) subtypes. (A) Nodular. **(B)** Superficial. **(C)** Morphoeic. **(D)** Nodulo-ulcerative BCC.

- Rare genodermatoses (e.g., Gorlin syndrome [naevoid basal cell carcinoma syndrome], xeroderma pigmentosum)
- Exposure to arsenic, ionizing radiation, or other drugs (including immunosuppressive agents, hydrochlorothiazide).

Clinical features

BCCs are locally invasive and typically appear as a slowly enlarging plaques or nodules that may be skin coloured, pink-red, or pigmented. They are most common on the head and neck and are frequently multiple. Several distinct clinical types are recognized:

- Nodular or nodulocystic BCC (70%): pearly or shiny plaques and nodules that bleed easily with minor trauma and fail to heal. They may have a central ulceration, making the borders appear rolled, with a pearly appearance (Fig. 45.53A), and overlying, branch-like (arborizing) telangiectasia.
- Superficial BCC is the most common type on the upper trunk and presents as a pink, red, or pigmented; scaly; irregular plaque with a thin, cord-like rolled border and microerosions (Fig. 45.53B).
- Morphoeic (infiltrative) variants present as scar-like plaques with ill-defined borders and are most prevalent on the face (Fig. 45.53C). They may have significant subclinical extension and perineural invasion; both of these features make incomplete excision and recurrence more likely with this subtype.

Although BCCs have minimal metastatic potential, they may cause extensive local tissue destruction if untreated (hence the common term 'rodent ulcer'), resulting in significant cosmetic and functional morbidity (Fig. 45.43D).

Management

The diagnosis is based on clinical and dermatoscopic appearances and a skin biopsy if the diagnosis is uncertain or non-surgical treatment is planned. Non-invasive skin imaging technologies such as optical coherence tomography (OCT) and reflectance confocal microscopy (RCM) are also increasingly being used to assist diagnosis and monitor treatment, although their availability is currently limited in most centres.

The treatment depends on the subtype, size, location, number of BCCs, and patient factors.

- The treatment of choice for most BCCs is surgical excision with histology to ensure complete removal of the tumour with adequate margins.
- *Mohs micrographic surgery* is a form of margin-controlled surgery in which tumours are excised in layers and processed so that 100% of the margins are evaluated (compared with standard 'breadloaf' histology, which evaluates a much smaller proportion of margins). Further layers are removed if excision is incomplete, ensuring that complete excision is achieved before reconstruction, while minimizing tissue removal. It is preferred for morphoeic BCCs (which are more likely to recur), BCCs in locations where tissue sparing is a priority (e.g., nose, periorbital), and recurrent BCC.
- Superficial BCCs can be managed with excision; curettage and cautery; or non-surgical treatments, including cryotherapy, photodynamic therapy, topical imiquimod cream, and topical 5-FU creams.
- Radiotherapy is an option if surgery is not appropriate or for patients who are unsuitable for surgery.
- Targeted therapy with the oral hedgehog inhibitors vismodegib and sonidegib is indicated for locally advanced and metastatic BCC not amenable to surgery or radiotherapy, but adverse effects result in a significant number of patients stopping treatment.

- Anti–programmed cell death-1 (PD-1) immunotherapy with cemiplimab has shown benefit in locally advanced and metastatic BCC when hedgehog inhibitors have been unsuccessful.

After a first BCC, approximately 30% to 50% of people develop another keratinocyte cancer within 5 years and are also at increased risk of other skin cancers. Regular self-examination and ongoing photoprotection should be advised as part of long-term management.

Cutaneous squamous cell carcinoma

cSCC is the second most common skin cancer. Like BCC, it is derived from keratinocytes but has a higher metastatic potential than BCC and can arise in pre-existing AKs or Bowen disease (cSCC in-situ). The incidence is increasing by 5% to 6% per year. UVR exposure (both solar and artificial from tanning beds) is the most important cause of cSCC, and there is a clearer correlation with chronic cumulative UV-induced skin damage compared with BCC. cSCCs have a high tumour burden of UV-induced genetic mutations in multiple genes, including *TP53*, *NOTCH1* and *NOTCH2*, *CDKN2A*, and *N-RAS*.

Risk factors for cSCC include:

- Age and sex (average age higher than for BCC; more common in males)
- UVR exposure (solar and sunbeds)
- Lighter skin tones that burn easily (Fitzpatrick phototypes I and II), but it can also occur in people with darker skin tones
- AKs, Bowen disease, and previous skin cancer (BCC, cSCC, melanoma)
- Immunocompromise (e.g., risk increased 65- to 100-fold in organ transplant recipients and 5-fold in PLWH or haematologic malignancy; cSCCs in immunocompromised people are often more aggressive with a higher rate of metastasis)
- Genetic predisposition (family history of skin cancer; specific genetic polymorphisms; rare genodermatoses, e.g., xeroderma pigmentosum, albinism, epidermodysplasia verruciformis, Muir Torre syndrome)
- Exposure to arsenic, ionizing radiation, smoking, other drugs (including immunosuppressive agents, hydrochlorthiazides, voriconazole, BRAF inhibitors, JAK inhibitors, and anti-TNF agents)
- Chronic inflammation (e.g., thermal burns, lupus vulgaris, lupus erythematosus, LP, leg ulceration)

Clinical features

cSCC mainly affects the UV-exposed sites of older people with lighter skin tones, particularly the face, ears, lips, balding scalp, dorsal hands, and lower legs. cSCCs present as enlarging, ill-defined, keratotic or warty, inflamed plaques or nodules that may ulcerate and bleed easily (Fig. 45.54). They grow more rapidly than BCC and are often painful and tender. It can also occasionally complicate areas of chronic inflammation such as ulcers (Marjolin ulcer). Metastasis risk is associated with specific high-risk features (Box 45.32) and overall is 2% to 3%, but it is higher in immunocompromised individuals. The most common site of metastasis are the lymph nodes and parotid gland (80%) but also the skin, bone, liver, lung, and brain. Most cSCC-specific deaths are caused by locoregional recurrence rather than distant metastasis.

Management

Diagnosis is based on clinical and dermatoscopic appearances and a diagnostic skin biopsy if required. Non-invasive skin imaging technologies (e.g., OCT and reflectance confocal microscopy) may also be useful when available. Staging investigations including imaging (e.g., ultrasonography, computed tomography, MRI) and biopsies of lymph nodes and other tissues may be required to assess the extent of locoregional and distant spread in high-risk tumours.

Fig. 45.54 **Squamous cell carcinoma.**

Box 45.32 High-risk features of primary cutaneous squamous cell carcinoma (cSCC)

- Tumour diameter >2 cm
- Immunosuppression
- Recurrent SCC
- SCC on ear (lips, eyelid, and scalp may also carry an increased risk)
- Histological features: tumour >4 mm thick, poor differentiation, extending into fat, perineural invasion

Patients with suspected and confirmed cSCC should be managed by a multidisciplinary skin cancer team.

- Treatment is usually complete surgical excision with a margin ranging from 4 to 10 mm depending on the risk status of the cSCC.
- *Mohs' micrographic surgery* may be used for high-risk cSCC in locations and when tissue sparing is important.
- Radiotherapy may be used as a primary treatment if surgery is not possible or unsuitable. It is also used as adjuvant treatment postoperatively for some high-risk tumours.
- Anti–PD-1 inhibitor immunotherapy (e.g., cemiplimab, pembrolizumab) is used for locally advanced and metastatic disease not amenable to surgery or radiotherapy and has significantly superior response rates to conventional chemotherapy and targeted epidermal growth factor receptor (EGFR) inhibitor therapy.

As for BCC, the risk of further cSCC is increased after a first cSCC, and patients should be advised on self-examination and photoprotection. Treatment of AKs and field change with sunscreen and 5-FU reduce cSCC risk in randomized controlled trials. Oral nicotinamide (a form of vitamin B3) reduces the risk of further cSCC in immunocompetent patients, and the oral retinoid acitretin reduces cSCC risk in immunocompromised patients.

Melanoma

Melanoma is a malignancy of melanocytes and most commonly arises in the skin, but it can also develop in non-cutaneous sites

Box 45.33 Risk factors for melanoma

- Increasing age
- Lighter skin tones (Fitzpatrick skin phototype I or II)
- High ultraviolet exposure (including sunbed use) and history of sunburn
- Multiple (more than five) atypical melanocytic naevi
- Large congenital melanocytic naevi (>20 cm in diameter)
- Family history of melanoma: mutations described in CDK4 (20%–40% of familial melanoma), *MC1R, MITF, TERT, ACD, BAP1, POT1,* and *TERF2IP*
- Immunocompromise (e.g., risk increased two- to fivefold in organ transplant recipients)
- Immunosuppressive medication, e.g., azathioprine
- Genodermatoses, e.g., xeroderma pigmentosum, albinism

(e.g., ocular, mucosal, meningeal). Although it represents only 4% of all skin cancers, melanoma is responsible for 80% of skin cancer-related deaths. The incidence increases with age, but it also disproportionately affects young people and in Australia is the most common cancer in people aged 15 to 29 years. The increasing incidence in recent years is thought to be attributable to more extensive recreational sun exposure, especially intermittent intense exposure (sunbathing in particular); sunburn in childhood; and use of artificial tanning beds, particularly in children and young adults. About 75% of cutaneous melanomas arise *de novo* from normal skin, the remainder arising from a pre-existing acquired or congenital melanocytic naevi. Risk factors for melanoma are summarized in **Box 45.33**.

Multiple oncogenes and tumour suppressor proteins have been implicated in the pathogenesis of melanoma and specific genotypes correlate with clinical phenotypes and have therapeutic implications. For example, activating mutations in the BRAF V600E protein kinase is the most common mutation in melanoma and is a therapeutic target for which treatments were first approved in 2011 (see Chapter 41, 'Malignant melanoma' section). The tumour mutational burden of cutaneous melanoma is also high, and as with cSCC and BCC, this is because of the highly mutagenic properties of UV radiation. This high mutational burden makes melanoma a good candidate for response to immunotherapy, and melanoma was the first cancer for which immune checkpoint inhibitor immunotherapy was approved in 2012 (see Chapter 6, 'T lymphocyte development and activiation' section).

Classification and clinical features

The conventional morphologic classification of melanoma recognizes four main types (**Fig. 45.55**):

- ***Lentigo maligna melanoma*** (10%–15%) is an invasive tumour that develops within pre-existing lentigo maligna. It is usually apparent as a new nodule.
- ***Superficial spreading melanoma*** (55%–60%) is a large, flat, irregularly pigmented lesion that grows laterally before vertical invasion develops.
- ***Nodular melanoma*** (10%–15%) is the most aggressive type. It presents as a rapidly growing pigmented nodule, which bleeds or ulcerates. Rarely, it is amelanotic (non-pigmented) and can mimic pyogenic granuloma.
- ***Acral lentiginous melanomas*** (<5%) arise as pigmented lesions on the palm or sole or under the nail and usually present late. They may not be related to sun exposure and are the most common skin type in people with skin of colour.

The WHO also now classifies melanoma by associated cumulative solar damage, anatomic location, epidemiology, and genotype (**Box 45.34**).

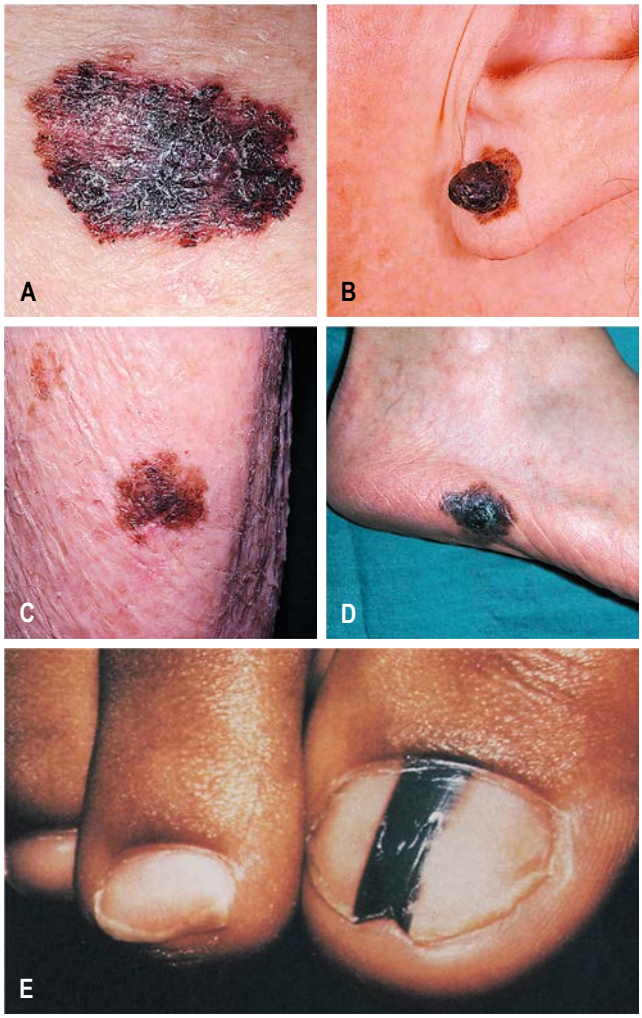

Fig. 45.55 Types of cutaneous melanoma. (A) Superficial spreading melanoma. **(B)** Nodular melanoma arising in a benign compound nevus. **(C)** Lentigo maligna, which may progress to lentigo maligna melanoma. **(D)** Acral lentiginous melanoma on the sole of the foot. **(E)** Subungual acral lentiginous melanoma. (*A–D: From Callen JP, et al:* Color atlas of dermatology, *ed 2, Philadelphia, 2000, Saunders. D, Courtesy Dr. Neil A. Fenske, Tampa, FL. E: From Habif, T. P., Campbell, J. L., Chapman, M. S., et al. [2011].* Skin disease: Diagnosis and treatment *[3rd ed.]. St Louis: Saunders.*)

Diagnosis

The diagnosis of melanoma is not always easy because many other pigmented cutaneous lesions may simulate melanoma, but a history of change, the clinical signs listed in **Box 45.35**, and recognition of the 'ugly duckling' sign (i.e., a mole that stands out as significantly different from the others) may all help distinguish melanoma from benign melanocytic naevi. ***Dermatoscopic examination*** is a key aid to clinical diagnosis, and dermoscopy is an essential skill for clinicians who assess pigmented lesions. Specific dermoscopic features of melanoma include atypical pigment network, multiple colours (five or six), brown-black dots or globules, an irregular vascular pattern, blue-white veil, and depigmentation. Other skin imaging techniques such as ***reflectance confocal microscopy (RCM)*** may be helpful in supporting the diagnosis.

Teledermatology is playing and increasingly important role in the diagnostic pathway for melanoma and other skin cancers. Artificial

Box 45.34 Classification of melanoma

Relationship with cumulative sun damage (CSD)	Melanoma type (WHO, 2018)	Examples of genetic changes
Melanomas typically associated with CSD	Cutaneous, low CSD (e.g., superficial spreading melanoma on trunk)	*BRAF* V600E mutations
	Cutaneous high CSD, (e.g., lentigo maligna on face)	Mutually exclusive mutations in *NRAS*, *NF1*, non-V600E *BRAF*
	Desmoplastic	Inactivating mutations in *NF1*; activating mutations in MAPK pathway
Melanomas not consistently associated with CSD	Acral	Amplifications of *c-KIT*, *TERT*, *CCND1*; *c-KIT* mutations
	Uveal	*GNAQ*, *GNA11*
	Mucosal	Copy number and structural variations
	Spitz	*HRAS*, kinase fusions
	Arising in congenital naevus	*NRAS*
	Arising in blue naevus	*GNAQ*, *GNA11*

Modified from WHO Classification, 2018.

Box 45.35 Clinical criteria for the diagnosis of melanoma

ABCDE criteria (USA)

- **C**olour variegation
- **D**iameter >6 mm
- **E**levation

Glasgow seven-point checklist

Major criteria

- Change in size
- Change in shape
- Change in colour

Minor criteria

- Diameter >6 mm
- Inflammation
- Oozing or bleeding
- Mild itch or altered sensation

Box 45.36 Visible and ultraviolet radiation

Type	Wavelength (nm)	Properties
Visible radiation (visible light)	400–700	Visible light
Ultraviolet A	400–315	Long wave, black light, not absorbed by the ozone layer
Ultraviolet B	315–280	Medium wave, mostly absorbed by the ozone layer
Ultraviolet C	280–100	Short wave, germicidal, completely absorbed by the ozone layer and atmosphere

intelligence–based diagnostic approaches are also being widely investigated and are likely to play an increasingly important supportive role in the future. However, currently, the definitive diagnosis is made on biopsy and histological confirmation.

Management

In the UK, all people with suspected melanoma should be referred urgently (2-week wait pathway) to the local multidisciplinary skin cancer team. Suspicious lesions should be completely and promptly excised with a narrow (2-mm) margin for review by a dermatopathologist experienced in melanoma diagnosis. Further management of melanoma is discussed in Chapter 41 ('Malignant melanoma' section). In people with skin of colour, identification of melanoma may be more challenging: melanomas may be more advanced at presentation, acral lentiginous melanomas are more common as are non-cutaneous melanomas, and outcomes tend to be worse.

Ultraviolet exposure and photoprotection

UV radiation is the most important carcinogen in both keratinocyte cancers and melanoma. The solar spectrum at the earth's surface includes visible light and medium- and long-wave UV (i.e., UVB and UVA). Short-wavelength UVC is highly carcinogenic but is filtered out by the atmosphere (**Box 45.36**). UVB and UVA are also potentially mutagenic and carcinogenic, especially in fair-skinned people. They cause sunburn (predominantly UVB) and premature ageing or photodamage (predominantly UVA). UV radiation also has immunosuppressive effects that enhance skin cancer development.

Additional adverse effects of UV radiation include cooperation in the direct carcinogenic effects of some systemic medications such as azathioprine, ciclosporin, voriconazole, and hydrochlorthiazides, the mechanisms responsible include drug-associated photosensitivity to UV and phototoxicity.

The wavelength of visible light is longer (400–750 mn), and it can trigger or exacerbate photodermatoses including solar urticaria and porphyria cutanea tarda (see Chapter 36, 'Porphyrias' section).

Sunscreens and photoprotection

Although sunscreens protect against UVA and UVB radiation, they are no substitute for use of protective clothing (including sunhats and sunglasses). Restriction of exposure, especially in young children, avoidance of artificial tanning beds and the 'Slip, slop, slap, seek, slide' approach should be advised (**Box 45.37**). The widely available WHO UV Index provides information on intensity of UV on a daily basis for specific geographic locations at different times of day (**Box 45.38**).

Box 45.37 Recommended approaches to photoprotection (SunSmart Australia)

Slip: Slip on protective clothing.
Slop: Slop on some sunscreen.
Slap: Slap on a sunhat.
Seek: Seek out some shade.
Slide: Slide on some sunglasses.

Box 45.38 World Health Organization ultraviolet (UV) index

UV index 1–2: No protection needed; safe to be outside
UV index 3–7: Protection needed: seek shade around midday hours; wear protective clothing
UV index 9–11: Extra protection: avoid being outside around midday hours; seek shade; wear protective clothing

Sunscreens work by using ***chemical sunscreens*** (organic filters or 'absorbers') that absorb or filter UV radiation (e.g., benzophenones, cinnamates, salicylates) or ***physical (mineral) sunscreens*** that reflect it (e.g., zinc, titanium dioxide). New sunscreen chemicals have been developed to give better protection, and the particle size of physical sunscreens can be reduced (micronized or ultrafine 'nanoparticles') to improve their cosmetic acceptability. Modern sunscreens are formulated to provide broad-spectrum protection against UVA and UVB. The SPF is a measure of UVB protection and the degree to which exposure can be prolonged before burning. The star rating (one to five stars) is an indication of UVA protection. Generally, an SPF30+ with four or five UVA stars is recommended (particularly for people with a history of skin cancer). However, in many cases, sunscreens are not applied in adequate amounts and are estimated on average to provide one-third of the SPF as labelled. UV-absorbing chemicals may occasionally cause allergic contact dermatitis and, in rare instances, photoallergic contact dermatitis (in which the sunscreen becomes allergenic with UV exposure).

Photoprotection and vitamin D deficiency

Sunlight on the skin is the source of approximately 90% of our vitamin D (which is difficult to obtain in food, being present only in a limited range of food, e.g., oily fish and some fortified butters and cereals). Individuals who do not have photosensitivity or a history of skin cancer benefit from short-term sun exposure (without burning) to maintain cutaneous vitamin D production. This is particularly necessary for people with darker skin colours (particularly Fitzpatrick phototypes V and VI) living in temperate climates, who are at risk of vitamin D deficiency. In those requiring photoprotection, oral vitamin D supplementation may be required. Advice about sun protection therefore needs to consider skin type.

Cutaneous lymphomas: primary cutaneous T-cell lymphoma (mycosis fungoides)

Cutaneous lymphomas are rare. Two main classes affect the skin: cutaneous T-cell lymphoma (CTCL) and cutaneous B-cell lymphoma.

CTCL (mycosis fungoides) accounts for 50% of primary cutaneous lymphomas. It is a rare form of non-Hodgkin lymphoma and usually follows an indolent course. It is more common in males, and its incidence increases with age with median age of onset of 55 to 60 years (although this can be younger in Black and Asian patients). It presents with pruritic, scaly patches, which typically start on the buttocks and thighs and can resemble eczema, psoriasis, or fungal infection; asymmetry and atrophy (thin, wrinkled skin) are useful clues (Fig. 45.56). Hypopigmented variants are seen in people with skin of colour and in children. Patches of mycosis fungoides may evolve into plaques, nodules, and red-violaceous tumours, which may ulcerate and become necrotic and may be complicated by secondary bacterial infection. Extracutaneous spread to the lymph nodes and internal organs occurs in 10%, and transformation into large cell lymphoma is a rare complication. The 5-year survival rate is 87%.

Fig. 45.56 Patch-stage mycosis fungoides.

The diagnosis may often require multiple skin biopsies over time to confirm the characteristic invasion of the epidermis by atypical T lymphocytes (exocytosis). T-cell receptor gene rearrangement studies show that the infiltrate is clonal.

Sézary syndrome (see Chapter 39, 'Mycosis fungoides and Sézary's syndrome' section) is an erythrodermic variant of CTCL with peripheral lymphadenopathy and atypical malignant Sézary cells in the blood. The onset is often rapid and characterized by severe itch and diffuse eczematous changes. Palmoplantar keratoderma, ectropion, nail dystrophy, and alopecia may also occur. It is seen mostly in older males and is more common in people with skin of colour who are often younger than White patients. The 5-year survival rate is less than 30%.

Treatment

Mycosis fungoides and Sézary syndrome usually run chronic relapsing courses. Treatment choices depend on disease stage and extent. Patch and plaque stage mycosis fungoides usually responds to topical treatment with potent corticosteroids, nitrogen mustard, or retinoids (bexarotene gel). Phototherapy can also be helpful. Treatment options for patients with advanced disease include localized radiotherapy or electron-beam therapy, oral bexarotene, denileukin diftitox, histone deacetylase inhibitors, chemotherapy, and brentuximab vedotin (anti-CD30 monoclonal antibody) for CD30+ disease.

Patients with Sézary syndrome are treated with extracorporeal photopheresis (in which leucocytes are mixed with psoralen

and irradiated with UVA *ex vivo*), total skin electron-beam therapy, methotrexate, bexarotene, or monoclonal antibody therapy (alemtuzumab and mogalizumab). The only potential cure is allogeneic stem cell transplantation.

Kaposi sarcoma

This tumour of vascular and lymphatic endothelium is caused by infection with human herpes virus-8 (HHV-8), also known as KS herpes virus. The incidence of KS is associated with the seroprevalence of HHV-8 globally: 30% to 50% of the population in sub-Saharan Africa is seropositive compared with 10% to 20% in the Mediterranean, Middle East, and Caribbean and fewer than 5% in Northern Europe and the USA. Transmission may be vertical, sexual, or via blood products and saliva.

Four types of KS are recognized:

- ***Classic KS*** occurs in older males, especially people of Mediterranean, Middle or Eastern European, and Jewish descent. It presents as slow-growing macules, plaques, or nodules on the foot and lower limb.
- ***Endemic KS*** occurs in sub-Saharan Africa in children and young adults and has more widespread skin and lymph node involvement with lymphoedema as a prominent feature.
- ***HIV-associated KS*** affects PLWH, most commonly MSMs in whom sexual transmission of HHV-8 may occur. Cutaneous lesions may be widespread (**Fig. 45.57**) with additional involvement of the oral cavity, bowel, and lungs. Antiretroviral therapy (see Chapter 44) has significantly reduced the incidence of KS.
- ***Iatrogenic KS*** affects people receiving immunosuppressive medication, particularly organ transplant recipients who were born in countries with a high seroprevalence of HHV-8 and in whom KS usually develops because of reactivation of latent virus.

Clinical features

KS usual presents with skin involvement as red to purplish macules, patches, papules, plaques, and nodules, which may appear dark brown-black in darker skin tones (see **Fig. 45.57**). These are usually asymptomatic initially but can enlarge, ulcerate, bleed, and become painful. Oral and nasopharyngeal mucosal involvement is common. KS lesions frequently affects the legs and feet in classic and endemic types and are associated with lymphoedema, and the latter may sometimes be the presenting symptom before the appearance of cutaneous lesions. Progression may result in involvement of lymph nodes, GI tract, and lungs.

Skin biopsy confirms the diagnosis, with slit-like spaces containing red cells, which are formed by atypical spindle cell proliferation of endothelial cells and are HHV-8 positive on immunohistochemistry. HHV-8 DNA and antibodies may also be detected in the blood.

Treatment

In localized disease, individual lesions may require treatment if they are symptomatic. Options include surgery, radiotherapy and cryotherapy. In PLWH, starting antiretroviral therapy will often result in regression of lesions. In immunosuppressed patients, reduction of immunosuppressive drugs or—in the case of organ transplant recipients—switching from calcineurin inhibitor to mTOR inhibitor immunosuppressive agents may also result in regression.

In advanced KS, treatment is with radiotherapy, chemotherapy (e.g., liposomal doxorubicin, paclitaxel), or immunotherapy (e.g., interferon-alpha), and there are ongoing clinical trials with immune checkpoint inhibitor immunotherapy.

Fig. 45.57 Kaposi's sarcoma. (A) Hyperpigmented macules and plaques. **(B)** Violaceous plaques and nodules.

Other rare skin tumours

Almost any structure in the skin can be affected by benign and malignant tumours. Rarer tumours that may be included in the differential diagnosis of the more common skin cancers include:

- ***Merkel cell carcinoma***, an aggressive neuroendocrine skin cancer that is much less common than melanoma but has a higher rate of metastasis and a 50% 5-year survival rate. It presents as an asymptomatic, enlarging, solitary, red-purple nodule (and may initially simulate other skin cancers such as cSCC but grows more rapidly; **Fig. 45.58A**). It is more common with increasing age, immunocompromise, and high UV exposure. Merkel cell polyomavirus infection is present in approximately 80% of cases. Treatment of the primary tumour usually includes combined surgery and radiotherapy. The anti–programmed death-ligand 1 checkpoint inhibitor avelumab is used in patients with metastatic disease.
- ***Appendageal tumours*** derive from epidermal appendages (hair follicles, sweat glands) and may be benign or malignant. Clinical appearances vary widely, but they often present as solitary nodules that may ulcerate (e.g., eccrine porocarcinoma). They are only infrequently diagnosed before excision.

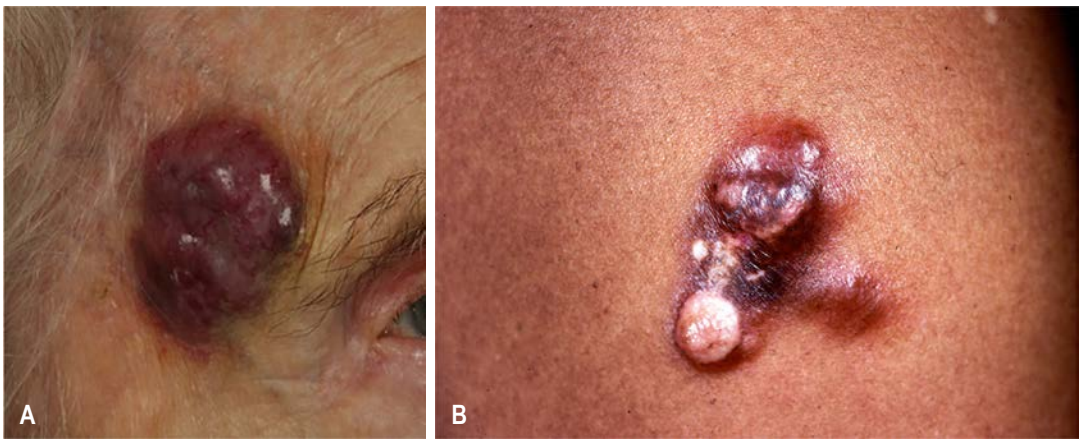

Fig. 45.58 **(A)** Merkel cell carcinoma: rapidly growing, large purple nodule of the face. **(B)** Dermatofibrosarcoma protuberans on the trunk.

- ***Dermatofibrosarcoma protuberans (DFSP)*** is a rare sarcoma arising in the dermis that presents as a rubbery, firm plaque or nodule and may be pigmented in darker skin tones in which it is also more common (Fig. 45.58B). It is most often located on the shoulder and chest areas and may simulate a hypertrophic or keloid scar. It grows slowly and often recurs after surgery but rarely metastasizes. Treatment includes surgery and radiotherapy, and in advanced disease, the tyrosine kinase inhibitor imatinib has a 50% response rate.
- ***Cutaneous angiosarcomas*** are rare and aggressive tumours of endothelial cells that occur most frequently on the head and neck of older people. They may initially present as bruise-like patches but rapidly evolve into multifocal, ulcerated, bleeding plaques and nodules. Treatment is usually with surgery or radiotherapy, but the prognosis is poor.

DISORDERS OF PIGMENTATION

Hypopigmentation

Vitiligo

Vitiligo is a chronic depigmenting skin disorder that affects 1% to 2% of the world population; about one-third of all cases start in childhood. It is caused by autoimmune T cell–mediated destruction of melanocytes and is associated with other autoimmune disease, especially that of the thyroid. Vitiligo presents with asymptomatic, symmetrical, well-demarcated macules of complete pigment loss and typically affects the face, hands and feet, genitalia, and bony prominences (Fig. 45.59). Pigment may be lost from overlying hair, which is a poor prognostic sign because the stem cells for melanocytes (the source of repigmentation) are located in the hair follicles. Lesions are not inflamed.

Fig. 45.59 **Vitiligo of the hands.** Areas of depigmentation.

Management

Treatment is often unsatisfactory (because repigmentation is slow to occur) and has no impact on the long-term outcome. Potent topical corticosteroids, topical tacrolimus, and UV phototherapy may stimulate repigmentation, and this usually starts around hair follicles, giving a speckled appearance. Repigmentation is less likely in established lesions and acral sites because they lack hair follicles. Sunscreens should be used to prevent burning, although, paradoxically, there is no increased risk of skin cancer in vitiligo-affected skin (in contrast to oculocutaneous albinism; see later), possibly the result of increased immunosurveillance caused by autoimmunity. Patients may benefit from psychological support and skin camouflage advice.

Post-inflammatory hypopigmentation

Pale patches may be left after resolution of an inflammatory condition, especially eczema and psoriasis. They are more noticeable in people with darker skin tones or who are tanned and can be mistaken for vitiligo, but lesions are *hypo*pigmented rather than *de*pigmented. Pigmentation recovers over several months if the underlying condition has been treated. It can coexist with post-inflammatory hyperpigmentation (see later). ***Pityriasis alba*** is a common hypopigmented variant of atopic eczema seen on the cheeks and arms of

dark-skinned children, in whom there is little inflammation but prominent pallor. Hypopigmented patches are also common in ***pityriasis versicolor*** and may occur in ***mycosis fungoides***.

Leprosy

Tuberculoid leprosy and indeterminate leprosy (see Chapter 42, 'Leprosy [Hansen's disease]' section) can present with anaesthetic hypopigmented patches and should always be considered in people from endemic regions. Lesions may also show hair loss and decreased sweating.

Oculocutaneous albinism

This rare group of autosomal recessive disorders is caused by reduced or absent pigment synthesis in the melanocytes in the skin, hair, and eyes. It can affect all ethnic groups. Individuals have pale skin, white or yellow hair, and pink irises. Ocular manifestations include photophobia, nystagmus, and a squint. Meticulous UV protection is required to prevent sunburn and reduce the risk of skin cancer (in contrast to vitiligo; see earlier).

Hyperpigmentation

Freckles (ephelides)

These extremely common pigmented macules appear in childhood after sun exposure. They fade in the winter. They are commonly associated with red hair and easy sunburning and can be a clinical sign of higher skin cancer risk.

Lentigines

These persistent pigmented macules look similar to freckles, but they do not fade in winter. They may rarely be associated with systemic syndromes (e.g., Peutz–Jeghers; see Chapter 22, 'Peutz–Jeghers syndrome' section; Noonan syndrome or LEOPARD [*l*entigines, *E*CG abnormalities, *o*cular hypertension, *p*ulmonary stenosis, *a*bnormalities of genitalia, *r*etardation of growth and *d*eafness]). Solar lentigines ('age spots', 'liver spots') are common on the dorsal hands and face and on bald scalps in older people.

Café-au-lait macules

These are common flat brown birthmarks and may occur as an isolated abnormality with no clinical significance. Multiple lesions (five or more) can be a feature of some genodermatoses such as neurofibromatosis types 1 and 2, tuberous sclerosis, ataxia telangiectasia, multiple endocrine neoplasia type 1, and McCune–Albright syndrome.

Melasma (chloasma if it occurs in pregnancy)

This is a common condition in pregnant females and in females taking hormonal contraception. Asymptomatic beige-brown patches develop on the forehead, temples, and cheeks. Topical azelaic acid, retinoic acid, or 2% to 5% hydroquinone may help reduce pigmentation. Meticulous sun protection, including protection against the high-energy visible blue part of the spectrum (using sunscreen containing iron oxide), is needed to prevent relapse.

Post-inflammatory hyperpigmentation

This phenomenon occurs in dark-skinned individuals at the sites of skin trauma or inflammatory rashes, such as acne, psoriasis, LP, and eczema. It improves slowly over many months. It can occur at the same time as post-inflammatory hypopigmentation (see earlier) but is more common.

Metabolic and endocrine effects

Generalized skin darkening can occur with chronic liver disease, especially haemochromatosis (see Chapter 23, 'Hereditary haemochromatosis' section), and endocrine disease such as Addison disease.

Urticaria pigmentosa (cutaneous mastocytosis)

This disorder is caused by a benign proliferation of cutaneous mast cells. It presents most commonly in childhood as multiple pigmented macules that become red, itchy, and urticated if they are rubbed (Darier sign), and they occasionally blister. Extensive mast cell degranulation can lead to systemic symptoms, such as wheeze; flushing; syncope; diarrhoea; and, very rarely, anaphylaxis.

This may be triggered by drugs, including aspirin and opiates, and allergens. Childhood urticaria pigmentosa usually resolves spontaneously, but adult-onset disease is often persistent. Histology of skin lesions shows increased numbers of mast cells. Most cases are caused by somatically acquired activating mutations of the *KIT* receptor that controls mast cell proliferation and apoptosis. Rarely, in adult and neonatal disease, mast cell infiltration may involve the internal organs (bone, GI tract, liver, spleen—***systemic mastocytosis***). There is a small risk of developing mast cell leukaemia. Treatment of cutaneous mastocytosis is aimed at controlling the symptoms of mast cell mediator release with antihistamines and cromoglicate and minimizing the risk of anaphylaxis.

NAIL DISORDERS

- ***Psoriasis***, ***fungal infection***, and ***trauma*** are the most common causes of abnormal nail growth (dystrophy).
- ***Pitting*** can be associated with psoriasis, alopecia areata, atopic eczema, and trauma.
- ***Trachyonychia*** is roughening of the nails and can be seen in inflammatory conditions and in so-called 20-nail dystrophy.
- ***Onycholysis*** (distal nail plate separation) is caused by psoriasis; thyrotoxicosis; trauma; and, rarely, a phototoxic drug reaction (e.g., with tetracyclines).
- ***Onychoschizia*** is splitting of the distal end of brittle nails. It is cause by damage from wet work, heat, or chemicals such as nail varnishes. It is made worse with vitamin D deficiency.
- ***Koilonychia*** (thin, spoon-shaped nails) can be caused by iron-deficiency anaemia.
- ***Leuconychia*** (white nails) is seen in hypoalbuminaemia (e.g., in chronic liver disease).
- ***Beau lines*** (transverse lines) are horizontal grooves in the nail caused by a temporary growth arrest associated with an acute severe illness.
- ***Yellow-nail syndrome*** is a rare disorder based on the triad of thickened, slow-growing, yellow nails; pulmonary manifestations (cough, bronchiectasis, pleural effusion); and lower limb lymphoedema.
- ***Subungual hyperkeratosis*** is thickening of the nail plate, usually caused by tinea infection, psoriasis, trauma, or a combination of these. Occasionally, it can be the presenting feature of nail bed SCC.

- ***Onychogryphosis*** is severe nail thickening and curvature (resembling a ram's horn), which is common in older adults, especially in the big toenail, where trauma from ill-fitting footwear may be relevant.
- ***Longitudinal melanonychia*** (hyperpigmented streaks) in multiple nails is a common finding in darker-skinned people. An acquired solitary pigmented streak may be caused by a melanocytic naevus and needs to be differentiated from subungual melanoma, especially if the pigmentation spreads on to the adjacent nail fold **(Hutchinson sign)** or if it causes destruction of the nail plate.
- ***Subungual haemorrhage*** is common in the great toenails after trauma (football, running downhill, tight footwear). The red-brown pigmentation in located under the nail plate and grows out with the nail over several months with clear proximal growth. It might be persistent if the trauma continues.
- ***Clubbing*** is discussed in Chapter 17 ('Examination of the cardiovascular system' section).
- ***Nail dystrophy*** is also a feature of various genodermatoses, including ***nail patellar syndrome, ectodermal dysplasias*** (abnormal hair, teeth, and nails), and ***pachyonychia congenita***.
- Benign tumours around the nail (e.g., **myxoid cyst**) can exert pressure on the nail matrix and cause a longitudinal groove in the nail.

HAIR DISORDERS

Hair loss (alopecia)

There are many causes of hair loss (alopecia) (Box 45.39). They are broadly divided into localized and diffuse patterns and into ***non-scarring alopecia*** (in which follicles are preserved) and ***scarring alopecia*** (in which an inflammatory process causes permanent destruction of follicles). Some forms of alopecia start as non-scarring but can become scarring with time. Patients may complain of increased hair shedding or thinning. Dermoscopic (trichoscopic) examination can help to identify whether follicles are still present, and histology of scalp biopsies is helpful when there is diagnostic uncertainty.

Box 45.39 Causes of alopecia

Scarring alopecia
- Discoid lupus erythematosus
- Trauma
- Traction (pulling) alopecia
- Lichen planus
- Sarcoidosis
- Dissecting cellulitis
- X-irradiation
- Idiopathic ('pseudopelade')

Non-scarring alopecia
- Androgenic alopecia (can scar in late stages)
- Telogen effluvium
- Alopecia areata
- Trichotillosis (self-induced hair-pulling)
- Tinea capitis and kerion
- Metabolic (iron deficiency, hypothyroidism)
- Drugs (e.g., heparin, isotretinoin, chemotherapy)

Male pattern and female pattern alopecia

Pattern alopecia is the most common cause of non-scarring hair loss and may be regarded as a feature of normal human ageing. It is thought to be caused by a genetically determined increased sensitivity to androgens (usually with normal blood androgen levels), and there is often a positive family history. It may present in adolescence with a receding frontal hairline followed by thinning over the vertex. Females may be similarly affected but usually later in life, with milder loss and preservation of the frontal hair margin. If acne, hirsutism, and menstrual disturbance are also present, there may be underlying polycystic ovary syndrome or an androgenic disorder.

Treatment options include topical or oral minoxidil or anti-androgens, including spironolactone (in female patients) or oral 5-alpha-reductase inhibitors such as finasteride in male patients. These can halt progression and may induce modest regrowth if used early in disease and continued indefinitely. Approximately one-third of patients do not respond to either therapy. Finasteride is well tolerated but may cause sexual adverse effects, such as loss of libido in about 1% of males; it should not be taken or handled by pregnant females because it can cause feminization of a male fetus. In stable pattern alopecia, hair transplantation may be helpful in restoring areas of hair loss using occipital hair units (which are not affected by hormonal influences).

Alopecia areata

Alopecia areata is a non-scarring hair loss disorder with a lifetime prevalence of about 2%. It is thought to be an organ-specific autoimmune disease of the hair follicle that occurs because of loss of hair follicle immune privilege. It is associated with other organ-specific autoimmune diseases and runs an unpredictable course ranging in severity from a temporary small, solitary patch of scalp hair loss ***(alopecia areata)*** to total loss of scalp hair ***(alopecia totalis)*** and rarely, scalp and body hair ***(alopecia universalis)***. Hair loss can have a major impact on body image and quality of life, with associated depression and social isolation.

Clinical features

Alopecia areata usually presents in children or young adults with patches of baldness (Fig. 45.60). There is very often psychological stress that triggers the hair loss. These areas of hair loss may regrow spontaneously and in mild disease (<25% scalp involvement), there is an 80% chance of regrowth within 2 years. However,

Fig. 45.60 Alopecia areata.

it is not unusual for regrowth to be followed by new areas of hair loss. The presence of broken hairs and ***exclamation mark hairs*** (narrow at the scalp and wider and more pigmented at the tip) at the edge of a bald area is diagnostic. The nails may be pitted or roughened. The diagnosis is usually based on clinical features and trichoscopy (dermoscopic imaging of the scalp and hair). Skin biopsy may occasionally be required if there is any diagnostic uncertainty.

Management

Treatment has no effect on the long-term disease course. Potent topical corticosteroids in children or injected steroids in adults may trigger regrowth of localized patchy hair loss. TCIs may also be helpful. PUVA phototherapy or repeated application of a contact sensitizer (contact immunotherapy) such as diphencyprone can be helpful in more extensive disease. Oral JAK inhibitors can reverse the hair loss in 60% of moderate to severe alopecia areata, but the rate of relapse is around 50% when treatment is stopped. In the UK, patients with extensive hair loss are eligible for prescribed wigs and may benefit from joining patient support groups such as Alopecia UK.

Traction alopecia

This form of scarring hair loss is caused by mechanical damage to the hair follicle from pulling the hair back into a bun or tight plaits. It can be reversible initially, but continued mechanical damage can cause permanent scarring.

Telogen effluvium

This type of diffuse, non-scarring hair loss is associated with increased hair shedding and usually presents 2 or 3 months after pregnancy, severe illness, sudden weight loss, or severe psychological stress. It occurs when a larger percentage of scalp hairs enters the telogen phase of hair shedding at the same time. Spontaneous recovery is usual after a few months, though a chronic variant is recognized, particularly if the trigger is unresolved.

Metabolic causes of hair loss

Iron deficiency may be associated with increased hair shedding and hair thinning and is a common finding in menstruating females who do not eat red meat. The exact relationship between serum iron or ferritin levels and optimum hair growth is unclear. Untreated hypothyroidism is also associated with hair loss, particularly of the outer third of the eyebrows ***(madarosis)***.

Dissecting cellulitis

This is a chronic scarring folliculitis of the scalp that predominantly affects males with afro-textured hair and may sometimes be associated with severe acne and hidradenitis suppurativa ***(follicular occlusion syndrome)***. Crusted papules and pustules with underlying diffuse swelling cause scarring on the scalp (Fig. 45.61). Prolonged courses of anti-staphylococcal oral antibiotics such as rifampicin and clindamycin may be helpful. Oral isotretinoin can help control the disease (after antibiotic treatment has been completed), but there is a high rate of recurrence after stopping it.

Increased hair growth

Hirsutism

Hirsutism refers to a male pattern of hair growth in females. Ethnic variation in hair growth must be considered because people of certain ethnicities (e.g., African, Caribbean, and Asian) commonly have more male-pattern hair growth than Northern European females. If virilizing features (deep voice, clitoromegaly, dysmenorrhoea, acne) are present, a full endocrine assessment is necessary. Hirsutism may cause severe psychological distress in some individuals.

Management involves physical methods, such as bleaching, waxing, electrolysis, intense pulsed light, and laser therapy. Oral anti-androgen therapy is occasionally helpful.

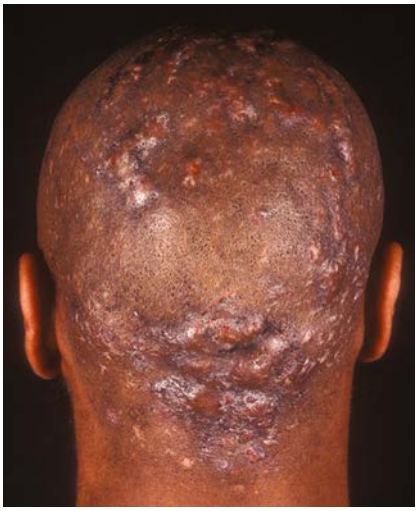

Fig. 45.61 Dissecting cellulitis of the scalp in an African-Caribbean male patient.

Hypertrichosis

Hypertrichosis refers to excessive hair growth at any site and occurs in both sexes. It can be seen in anorexia nervosa, PCT, and underlying malignancy. It is also caused by certain drugs (e.g., ciclosporin, minoxidil) and can be a side-effect of potent topical steroids

BIRTH MARKS AND NEONATAL RASHES

Various skin lesions may be present at birth or during infancy; most resolve during childhood, although ***congenital melanocytic naevi*** persist lifelong.

Port-wine stain (naevus flammeus)

Port-wine stain ('capillary haemangioma') is not a true haemangioma but an abnormal dilation of dermal capillaries. It presents at birth as a flat, red area and is commonly found on the face. It does not improve and may become thickened with age. If the lesion occurs in the distribution of the first division of the trigeminal nerve, it may be associated with ipsilateral meningeal vascular anomalies that can cause epilepsy and even hemiplegia (Sturge–Weber syndrome). Periocular lesions may be associated with glaucoma, so ophthalmological follow-up is required.

Box 45.40 Severe cutaneous adverse drug reactions

- Stevens–Johnson syndrome and toxic epidermal necrolysis
- Drug reaction with eosinophilia and systemic symptoms
- Acute generalized exanthematous pustulosis
- Erythroderma or exfoliative dermatitis
- Serum sickness–like reactions

Fig. 45.62 Morbilliform drug rash caused by penicillin allergy.

Treatment of port-wine stains is with a vascular laser, for example, a pulsed-dye laser. Facial lesions respond best, but lesions can darken after several years and require retreatment.

DRUG ERUPTIONS

Cutaneous adverse drug reactions are common and range from mild and predictable dose-related effects such as phototoxicity from doxycycline or mucocutaneous dryness from oral isotretinoin to idiosyncratic, severe, and life-threatening eruptions (severe cutaneous adverse drug reactions; **Box 45.40**). These life-threatening diagnoses are described in Chapter 11 ('Severe cutaneous adverse drug reactions' section). The diagnosis of drug eruptions can be challenging because individual drugs can cause different rashes, and these may mimic constitutional inflammatory rashes or viral rashes. The clinical features can also be mixed, and patients may be receiving multiple drugs that are potential culprits.

A high index of suspicion and a detailed drug history are essential. Underlying viral infection, especially HIV, and systemic disease, such as SLE and leukaemia, may also increase the risk of drug rashes. Allergy tests (prick tests and patch tests) have a limited role, especially in the acute setting, and drug challenge tests are time consuming and potentially risky.

Maculopapular (morbilliform) exanthems

These are the most common type of hypersensitivity rash (**Fig. 45.62**). They start on the trunk and spread to the face and limbs but spare the mucosae. They are self-limiting and usually clear within 1 to 2 weeks.

Box 45.41 Dermatoses induced or exacerbated by drugs

Dermatosis	Drugs
Acne	Androgens (e.g., danazol)
Acneiform	Corticosteroids, EGFR inhibitors
Angio-oedema	ACE inhibitors
Urticaria	Penicillin, aspirin, NSAIDs, iodine contrast media
Vasculitis	Gold, hydralazine, NSAIDs, PPIs
Fixed drug eruption	Phenolphthalein in laxatives, tetracyclines, paracetamol
Pigmentation	Minocycline (black), amiodarone (slate-grey)
Vitiligo	Anti–PD-1/PD-L1 immunotherapy
Lupus erythematosus	Minocycline, anti-TNF biologics, isoniazid, interferons, anti–PD-1/PD-L1 immunotherapy
Photosensitivity	Thiazides, quinolones, tetracyclines, diuretics, amiodarone
Pseudoporphyria	Naproxen, diuretics
Leg ulcers	Hydroxyurea
Anogenital ulcers	Nicorandil
Erythema nodosum	Sulphonamides, oral contraceptive
Erythema multiforme	Barbiturates, etravirine
Lichen planus-like (lichenoid)	Antimalarials, thiazides, statins, diuretics, anti–PD-1/PD-L1 immunotherapy
Psoriasiform	Methyldopa, gold, lithium, beta-blockers, anti–PD-1/PD-L1 immunotherapy
Toxic epidermal necrolysis	Penicillin, co-trimoxazole, carbamazepine, NSAIDs, nevirapine, efavirenz
Bullous pemphigoid	Anti–PD-1/PD-L1 immunotherapy
Pemphigus	Penicillamine, ACE inhibitors
Erythroderma	Gold, sulphonylureas, allopurinol, nevirapine, efavirenz

ACE, Angiotensin-converting enzyme; *EGFR,* epidermal growth factor receptor; *NSAID,* non-steroidal anti-inflammatory drug; *PD-1,* programmed cell death-1; *PD-L1,* programmed death-ligand 1; *PPI,* proton pump inhibitor; *TNF,* tumour necrosis factor.

Fixed drug eruptions

These inflamed patches recur at the same site each time a drug is taken. They may blister and often resolve with hyperpigmentation.

Drug-induced and drug-exacerbated dermatoses

Drugs may exacerbate pre-existing skin disease and can also trigger or induce skin disease that resembles a constitutional dermatosis (**Box 45.41**).

Severe cutaneous adverse reactions

SJS, TEN, DRESS, and acute generalized exanthematous pustulosis are discussed in Chapter 11 ('Severe cutaneous adverse drug reactions' section).

PSYCHODERMATOLOGY

Psychodermatlogy is a newer and emerging subspecialty of dermatology. There are two main categories of disorders, as discussed next.

Primary psychiatric disease presenting to dermatology healthcare professionals

For example:

- ***Delusional infestation:*** Patients believe that they have an infestation of the skin when there is no infestation (i.e., a primarily persistent delusional disorder). Commonly, this may be associated with recreational drug usage (e.g., cocaine, cannabis, or amfetamines).
- ***Body dysmorphic disease:*** Patients have an overstated concern about a physical (usually cutaneous) change that may seem very trivial to healthcare professionals but tat for the patient is very much the focus of their attention. Patients may have social avoidance or hide their skin from others. It is usually classified as an obsessive-compulsive disorder.
- ***Dermatitis artefacta:*** Patients harm or neglect themselves in some way, often mimicking a skin disease. This is different from deliberate self-harm because patients with dermatitis artefacta do not know that they are harming themselves.

Primary dermatological disease in which there are psychosocial co-morbidities

For example:

- Changes in self-perception
- Anxiety
- Depression
- Anxiety and depression (more common than anxiety or depression in isolation)
- Suicidal ideation

CORE SKILLS AND KNOWLEDGE

Healthcare professionals providing for the medical needs of young people need effective communication skills. Active listening, motivational interviewing techniques, and a non-judgemental approach are key to putting young people at their ease. Healthcare professionals need to create an environment in which young people feel safe talking about sensitive issues.

A broad understanding of general medicine is essential, with a more detailed knowledge of medical conditions that are more likely to occur in this age group.

Illnesses pertaining to mental health are common healthcare problem and are important co-morbidities complicating other medical conditions. Doctors treating young people in this age group need to be aware of relevant resources that are available to help meet this need in their patients.

When managing chronic conditions, doctors need to consider the way in which maturational development of the brain increases tendency to risk-taking behaviours, which can result in worse long-term outcomes. Adherence is a particular challenge. Doctors need to have strategies to ask about and address this.

Comprehensive care for young people requires collaborative working with other professionals. Psychologists and social workers have major roles in this age group. Doctors need a good understanding of the roles of the wider multiprofessional team and how best to use their skills and services.

Successful care of young people facilitates transition to adult care and the promotion of healthy lifestyle choices that can impact long-term health.

BACKGROUND

Adolescents and young people in early adult life face unique healthcare challenges. Adolescence is typically defined as the period from puberty to 18 years of age and young adulthood from age 18 to 25 years, although individuals mature over different time scales. Young people's health is an area of medicine focusing on the specific needs of these age groups. It is a time of significant physiological and psychological change, compounded by peer pressures and social, romantic, and sexual relationships (**Fig. 46.1**). There is a major reorganization of neural pathways during adolescence that continues into early adult life (**Fig. 46.2**).

A tendency to risk-taking behaviour is common and can result in poor engagement with healthcare and adherence to medical treatment, as well as misadventure. Such behaviours occur at a time of increased autonomy and independence from parents and guardians, including capacity to give informed consent for medical treatments and procedures (**Box 46.1**).

In 2019, young people made up 18% of the UK population. They are more ethnically diverse, less likely to identify as heterosexual, and more gender fluid than older age groups. Socioeconomic and ethnic disparities have a significant impact on their health outcomes. Young people from low-income families and marginalized groups often face barriers accessing healthcare, nutrition, and safe environments.

Healthcare professionals have an important role in helping young people achieve good physical and mental health outcomes. At a societal level, this might include advocating for improvements in housing, education, and employment opportunities. At a patient level, this is best achieved through multidisciplinary teams that have the skills to address the specific health needs of this age group.

Biological	Psychological	Social
• Breast development (stage 2–3 at ages 11–12) • Penis enlargement • Increase in testicular volume (10 mL at ages 13–14) • Development of pubic and axillary hair • Menarche • Growth spurt • Fat deposition • Changes in body shape • Voice maturation in males • Accretion of bone mineral density • Acne • Blushing • Increased need for sleep • Organ maturation	• Thinking changes from concrete to abstract (logic) • A sense of invincibility • Development of sexual identity and increased experimentation • Reassessment of body image • Growing educational abilities and development of vocational ideas • Learning to differentiate between laws and morality • Learning to control impulsivity • The development of passionate views	• Emotional separation from parents • Peer identification • Exploratory risk-taking behaviours (e.g., smoking, violence, sex, illicit drug use) • Romantic/sexual relationships • Vocational plans • Financial independence

Fig. 46.1 Developmental changes during adolescence. Extensive biological, psychological, and social changes occur in adolescence and early adult life.

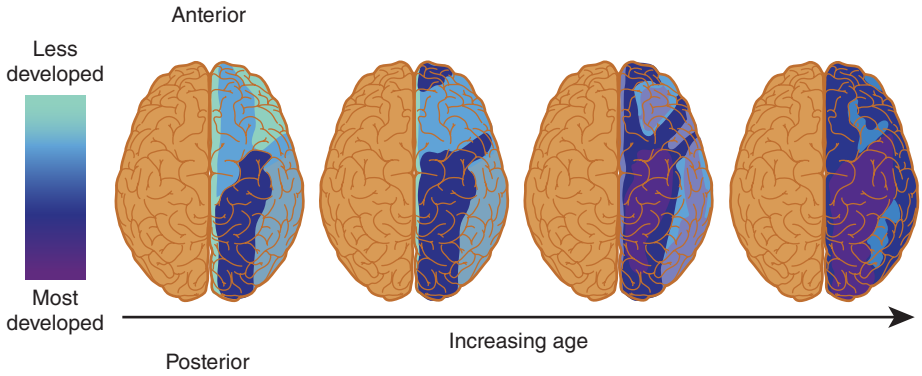

Fig. 46.2 Brain development and maturation after completion of brain growth. Although the brain stops growing by early adolescence (about 11 years old), there is ongoing maturation (from posterior to anterior) and neurological 'fine-tuning', finishing typically after the age of 25 years. The prefrontal cortex, responsible for thought and emotional regulation, is one of the last parts to mature.

Identifying and responding to the specific needs of young people can be challenging. HEeADSSS (**Box 46.2**) is an acronymic interview screening tool for use with young people attending healthcare services. It helps identify a wide range of potential psychosocial protectors and risks that may warrant further enquiry. It can be completed with a healthcare professional during consultation or used as a self-assessment tool before consultation.

MORTALITY AND MORBIDITY

Deaths among young people are fortunately rare and represent less than 1% of all-age deaths. In the UK, mortality rates fell consistently until 2015 before plateauing in all age groups, except in those aged 20 to 25 years, in which it subsequently increased. Males are at greater risk of death than females (**Fig. 46.3**). The most common cause of death is accidents. Death caused by vehicle collisions a particular concern: young people aged 10 to 14 years are at risk as pedestrians and older age groups as drivers and passengers (**Fig. 46.4**). Death by suicide is the second most common cause of death in young people, killing more than 5000 young adults in the UK in 2019. Globally, tuberculosis is a major killer of young people in low-resource settings.

MENTAL HEALTH ISSUES IN YOUNG PEOPLE

Academic pressures, social media influence, financial pressures, and a competitive job market all contribute to anxiety, depression, and stress among adolescents and young adults. Increased isolation, as occurred through SARS-CoV-2 restrictions, has disproportionately affected young people's mental health. Twelve percent of young people aged 16 to 24 years self-report feeling isolated in the past 12 months. This was higher than the 9% reported among those aged older than 85 years. Access to mental health services, school-based counselling programmes, and fostering open conversations to reduce the stigma surrounding mental health illness are supportive approaches to this problem. More recently, medical

Box 46.1 Consent and the law for young people in the UK

Consent in the context of healthcare is the process of agreeing or giving permission to have treatment. It should be achieved as part of shared decision-making. Consent can be non-verbal (e.g., attendance for a low-risk procedures such as radiography, holding out an arm for venepuncture), verbal with documentation of information given and discussion of risk (e.g., blood transfusion), or written by signing a consent form.

Young people younger than 18 years of age might make life choices that conflict with their parents or guardians. For example, they may want to access contraception or seek confidential support for substance misuse but do not want their parents or other carers to know.

The law makes provision to protect young people from making decisions that lead to serious permanent harm. This means that there are specific considerations in relation to age and consent.

Aged older than 16 years old

Gillick competency and Fraser guidelines underpin consent in young people aged younger than 16 years. If judged capable of decision-making, young people younger than 16 years old can consent to treatment, and an agreement to treatment cannot be overruled by someone with parental responsibility. Even if judged competent, refusal of treatment can be overruled by a person with parental responsibility if healthcare professionals think that treatment is in their best interests.

If a person younger than 16 years is judged incapable of deciding because of emotional maturity or learning disabilities, a person with parental responsibility can give permission on their behalf.

Aged 16 or 17 years

For anyone aged 16 years or older, the ability to consent is governed by the Mental Capacity Act 2005. The law states that young adult aged 16 years or older must give consent unless they are not able decide. Those with parental responsibility can give consent on behalf of a 16- and 17-year-olds only if they lack capacity, and an assessment of capacity should be carried out and documented.

If a competent 16- or 17-year-old patient refuses a treatment that can save them from death, severe permanent injury, or irreversible mental or physical harm, refusal can be overridden by a court.

Aged 18 years or older

Young people aged 18 years or older are adults. Parents cannot give consent even the patient cannot consent for themselves. The only exception to this is if parents have applied successfully for an Order from the Court of Protection. In an emergency, the treating team will make a decision according to the person's best interests.

Who has parental responsibility

Parental responsibility includes the legal rights, duties, powers, responsibilities, and authorities parents have in relation to their children and their children's property. A mother automatically has parental responsibility for her child from birth. A father usually has parental responsibility if he is either married to the child's mother or is listed on the birth certificate. Same-sex partners both have parental responsibility if they were civil partners at the time of artificial insemination (after 6 April 2009) but not if conception occurred after intercourse with a male. Others can apply for parental responsibility via legal routes. In safeguarding cases, the local authority may be granted parental responsibility by a court.

What should be discussed in consent

The judgement in *Montgomery v Lanarkshire Health Board* [2015] United Kingdom Supreme Court (UKSC) 11 guides what should be discussed in the consent process: The doctor is under a duty to take reasonable care to ensure that the patient is aware of any material risks involved in any recommended treatment and of any reasonable alternative or variant treatments. Whether a risk is material does not solely depend on how frequently it occurs. Understanding what matters to the patient ensures the patient understands the risk and benefits of treatment for them. For example, for a lung transplant operation, the position of the scar may be important to a young person.

Sharing information

Sharing health information with parents of competent young people younger than 18 years old must be with their explicit agreement. This is particularly relevant to letters automatically sent to a home address.

When a competent young person refuses to allow information to be shared with their parents, there should be evidence that the risks of not sharing the information have been considered. When it is in the young person's best interests to share information, there should be attempts to compromise. If this is unachievable, legal and safeguarding advice should be sought.

An example of how to discuss confidentiality with young people states: 'Everything we talk about today is confidential. That means I cannot tell other people, even your parents, unless you agree to my sharing information with them. The only exceptions would be if I thought you or someone else was at risk of serious harm. In that case, I would need to tell someone else to keep everyone as safe as possible'.

professionals have had the option of prescribing activities such as exercise, music clubs, and social get togethers. This is termed 'social prescribing' and has been shown to have multiple benefits for young people; for example, joining an organized walking group helps both mental and physical wellbeing. The effects also often last beyond the prescribed period and do not have the risks associated with prescribing medication.

Eating disorders

Anorexia nervosa, bulimia nervosa, and binge eating disorder are psychiatric diseases in which there are severe alterations of body image and eating behaviour. Anorexia and bulimia typically occur in the later teenage years and binge-eating disorders in early adult life. Treatment typically includes a combination of medical, nutritional, and psychological interventions. BEAT is a UK-based eating disorder charity with useful resources for those who are affected as well as their families and friends (https://www.beateatingdisorders.org.uk/).

Bullying

One in five secondary school-aged children experiences bullying. Males are more often involved in physical bullying and females in verbal and cyberbullying. Bullying can cause significant physical, psychological, social, and educational harm.

Those with protected characteristics are particularly susceptible; these include ethnic and religious minority groups, people with physically disabilities, LGBTQ+ individuals, travellers, and asylum seekers. Those who are very thin or obese are also at increased risk. Being bullied results in poor school attendance and reduced academic achievement. Victims are more likely to experience depression and anxiety and are at increased risk of suicide. Bullies are more likely to become known to the criminal justice system, abuse drugs and alcohol, conduct antisocial behaviour, and commit domestic violence than those who do not exhibit bullying behaviours.

Young people are particularly susceptible to cyberbullying by email, text messages, or social media. Teaching good Internet etiquette and maintaining open dialogue with young people about their Internet experiences are key.

Screen time and social media

The overwhelming majority of 12- to 15-year-olds own a smartphone. The increasing use of technology and social media has both positive and negative health effects. It provides opportunities for learning and connectivity, but excessive screen time is associated with sleep

Box 46.2 Identification of protective and risk psychosocial factors in young people. Adapted from the HEeADSSS tool, with suggested questions to facilitate use

Establish trust
- Explain the purpose of the assessment.
- Explain rights when receiving care.
- Obtain informed consent.
- Explain confidentiality but include the three safety exceptions: harming self, harming others, or someone else harming them.

HEeADSSS

Home and relationships
- Who lives at home with you?
- Do you have your own room?
- Who do you get on with best or fight with the most?
- Who do you turn to when you're feeling down?

Education and employment
- Are you in school or college? If so, which year?
- What do you like best or least at school or college?
- How are you doing at school?
- Do you have friends at school?
- How do you get along with others at school?
- What do you want to do when you finish school or college?
- Do you work? If so, how much?

Eating
- Are you worried about your weight or body shape?
- Have you noticed any change in your weight recently?
- Have you been on a diet?

Activities and hobbies
- How do you spend your spare time?
- What do you do to relax?
- What kind of physical activities do you do?

Drugs, alcohol, and tobacco
- Does anyone smoke at home?
- Have you been offered cigarettes?
- Do you smoke? If so, how many cigarettes or vapes per day?
- Have you tried or been offered alcohol? How much and how often?
- Have you tried cannabis? How much and how often?
- Have you tried any other drugs, for example, ecstasy and cocaine?

Sex and relationships
- How do you identify: as a boy, girl, other, or not sure?
- Are you seeing anyone?
- Are they male or female, and how do they identify?
- Do you have any intimate relationships? How are you managing this?
- Have you ever had sex?
- What contraception do you use?

Self-harm, depression, and self-image
- How is life going generally?
- What do you do when you feel stressed?
- Do you ever feel sad and tearful?
- Have you ever felt so sad that you feel that life is not worth living?
- Do you think about hurting or killing yourself?
- Have you ever tried to harm yourself?

Safety and abuse
- Do you feel safe at home and at school?
- Is anyone harming you?
- Is anyone making you do things that you do not want to do?
- Have you ever felt unsafe online or when using your phone?

disturbance, cyberbullying, and a lack of physical activity. Engaging with social media represents the largest proportion of screen time use in young people. Regular use of social media is reported by 65% of 8- to 12-year-olds and 91% of 13- to 18-year-olds. Inappropriate content or content that caused worry or upset has been seen by 45% of 8- to 17-year-olds, and in half of cases, this was not reported

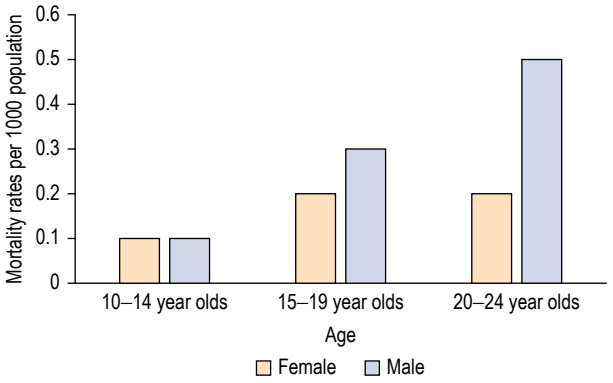

Fig. 46.3 Age- and sex-specific mortality rates in young people in England and Wales in 2019.

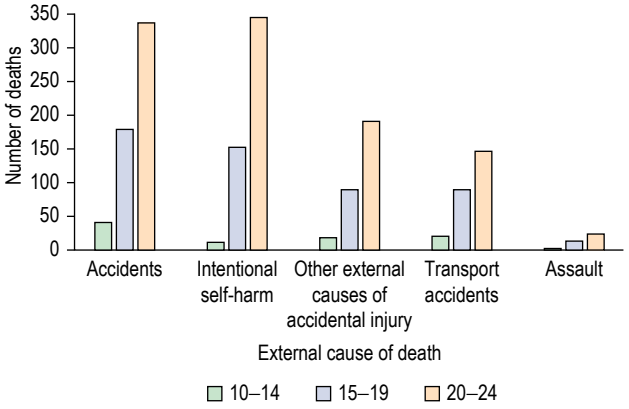

Fig. 46.4 Age-specific causes of death in young people in England and Wales in 2019.

to a responsible adult. More than 10% of 13- to 15-year-olds report receiving a sexual message within the past year.

The Royal College of Paediatrics and Child Health recommends that families should negotiate screen time limits with their children considering disruptions to physical activity, social life, and sleep. Screens should be avoided for 1 hour before a planned bedtime. The National Institute for Health and Care Excellence suggests that children should have days without any TV or have a 2-hour screen time limit.

LIFESTYLE CHOICES IN YOUNG PEOPLE

Achieving and maintaining a healthy lifestyle in young people is important for current health status and the long-term risk of illnesses including cancer, diabetes, and cardiovascular disease.

Nutrition and obesity

Contemporary diets are more likely to be calorie dense and nutrient poor. The average consumption of fruit and vegetables for females

aged 11 to 18 is 2.7 portions per day, with just 7% achieving the recommended five portions per day. Nearly half of all young females are not ingesting the recommended amount of iron. Males aged 11 to 18 years eat an average of 3.1 vegetable portions, but only 13% achieve five-a-day recommendations.

Obesity is an important long-term problem with many potential adverse health consequences. of The prevalence is high: 14% of young people were overweight, and 21% were obese at 17 years of age according to data from 2018 to 2019. A meta-analysis of longitudinal studies identified that obese adolescents are five times more likely to be obese adults than non-obese adolescents. Around 70% of obese adolescents will still be obese after 30 years of age. Early intervention is therefore important. Obesity disproportionately affects those living in deprived areas and is more prevalent among ethnic minority groups and young people with learning disabilities.

Physical activity

Regular exercise has long-term health benefits. Worldwide, only 22% of male and 15% of female adolescents take part in at least 60 minutes of moderate- or vigorous-intensity physical activity a day across the week. Qualitative data show that teenagers value unstructured, local, low-cost, fun, sociable opportunities and the right facilities to be active.

Smoking and vaping

Most adult smokers began in childhood with the risk of nicotine addiction occurring within 4 weeks of starting. Trends for young people smoking traditional cigarettes have progressively declined with only 2% of those aged 11 to 15 years smoking regularly in 2018.

E-cigarettes (vapes, vaporizers, and electronic nicotine delivery systems) heat nicotine-containing solutions with additional flavourings and other additives that are held in a cartridge or tank, with vapour inhaled through a mouthpiece. Since their widespread introduction in the UK in 2007, e-cigarettes can be sold to anyone older the age of 18 years in the UK and are encouraged as a less dangerous product than traditional cigarettes. It is illegal to sell these products to those younger than 18 years of age but not to give or supply them. E-cigarettes are more successful in getting people to stop smoking traditional cigarettes than other nicotine replacement therapies, but it is controversial as to whether they are more effective than discontinuation.

Although considered less harmful than traditional cigarettes, potential dangers are associated with vaping. The long-term effects of toxins in e-cigarette vapours are unknown. E-cigarettes contain nicotine, which is highly addictive. Of relevance to young people, they may have an impact on concentration ability and have toxic effects on developing brains.

Vaping by young people is rapidly increasing. In 2023 in the UK, 20.5% of young people aged 11 to 17 years had tried vaping compared with 15.8% in 2022 and 13.9% in 2020. Regular or occasional vaping occurred in 7.8% in 2023 compared with just 1.4% in 2014. Trends are similar in the USA.

When talking to young people about smoking and vaping:

- Give clear, consistent messages about the known and unknown risks of smoking and vaping. These should include health risks but also the impact on skin condition, ageing, bad breath, and cost.
- Avoid threats and ultimatums.
- Acknowledge that family significantly influences behaviour.
- Discuss early in childhood. Addiction occurs quickly and may occur before the later teen years.
- Discuss whether peers smoke or vape and empower young people to refuse cigarettes and e-cigarettes.
- Explain that most smokers quit smoking successfully without the need for any type of nicotine replacement.
- Ask young people how they might have been targeted and manipulated by tobacco companies. Such understanding can modify views and help motivate smoking cessation.

Action on Smoking and Health (ASH). *Young People and Smoking.* 2019. www.ash.org.uk.

Alcohol

In the UK, it is illegal to sell alcohol and for an adult to purchase alcohol for those younger than 18 years old. From age 16 years, young people can drink beer, wine, or cider with a meal if accompanied by an adult. Despite these legal barriers, consumption of alcohol in young people is common. Experimentation with drinking alcohol occurs as young people explore their environment and socialize.

Alcohol exposure in young people, especially regularly or heavily, is associated with poorer neurological development and poorer scholastic achievement and increases the chance of risk-taking behaviours that may result in antisocial or violent behaviour and unprotected and unsafe sexual behaviours.

NHS data from England show that the number of young people who have ever had an alcoholic drink has fallen from around 60% in 1992 to around 40% in 2021 for school-aged children and that 6% drink alcohol at least once per week and 17% monthly or more frequently. The proportion usually drinking once a week increases with age, from 1% of 11-year-olds to 14% of 15-year-olds. Eight percent of school children report being drunk in the previous 4 weeks.

Further reading

Advice about how to talk about alcohol consumption is available on the Drinkaware website https://www.drinkaware.co.uk/advice.

Recreational drugs

In 2020, more than 280 million people worldwide aged 15 to 64 years old used illicit drugs, with use skewed to younger people. Most commonly, this was cannabis (209 million annual users) followed by opioids (61 million), amfetamines (34 million), cocaine (21 million), and Ecstasy (20 million). Use in school children in 2020 was reported as 18% (12% in the past year), although this was a decrease from 2018, when use was 24% (17% in the previous year). A similar trend was seen in 15- to 16-year-olds in Italy and the USA associated with the SARS-CoV-2 pandemic. Future monitoring will inform whether this trend of reduced use of recreational drugs has continued.

Cannabis use is now legal in many countries, including the USA, and this is associated with an increase in use. Globally, cannabis use continues to increase year on year with 16% of those aged 16 to 24 reported having used the drug in the previous year. In England and Wales, where cannabis use is not legal, use is relatively stable in all age groups and has decreased by 40% in young people since 1995.

Non-prescribed opioid-related deaths are a concern in USA and Canada with more than 100 000 deaths in 2021. More than 61 million used opioids for non-medical reasons in 2020, with a doubling of use between 2010 and 2020. Their use accounts for nearly 70% of drug-related deaths and 40% of illicit drug use treatment costs.

Drug use can have detrimental effects on physical and mental health, with significant adverse long-term consequences, including the increased likelihood of risk-taking behaviours and transmission of blood-borne infections, including human immunodeficiency virus (HIV) and hepatitis B and C. Prevention programmes, early intervention, and public awareness campaigns are essential in curbing substance abuse and supporting those living with addiction.

Gambling

Young people are vulnerable to gambling addiction. Risk factors in this age group include impulsivity, peer pressure, and seeking excitement or escape. The consequences of addiction include adverse effects on mental health, relationships, and financial stability. The ease of access to online gambling platforms and widespread social acceptance of gambling exacerbate risks. Regulation of the gambling industry including reliably imposed age restrictions and the provision of support services can help mitigate against negative effects.

Vaccination

Young people are recommended to receive human papillomavirus and meningitis (Men ACWY) vaccinations as well as booster vaccinations against tetanus, diphtheria, and polio. Outbreaks of bacterial meningitis are reported around the world in young people who remain particularly vulnerable because of bacterial carriage rates and social behaviours. Despite the introduction of routine meningitis ACWY vaccination in the UK in 2015, invasive disease, with a mortality rate of 6%, kills up to 12 people in England every year.

Sleep

Regular and adequate amounts of good-quality sleep are needed for optimal growth, cognitive function, and physical and mental wellbeing. Almost a third of males and half of females aged 15 years report disturbed sleep with more than a third reporting that this interferes with their schooling. Up to 7% of teenagers develop a particular insomnia called delayed sleep phase syndrome. This is because they produce the pineal hormone melatonin later at night than other age groups. This causes them to have difficulties getting to sleep and waking in the morning. Chronotherapy treatment aims to reset circadian biorhythms with interventions including avoiding bright light in the evening and being exposed to bright light in the morning.

Establishing a good sleep routine in early adult life can help prevent diseases in later life, including hypertension, diabetes, obesity, and depression. Good sleep hygiene is key to achieving this. Some of the key components of good sleep hygiene include having a regular sleep routine and avoiding heavy meals, caffeine, and light emitted by screens before bedtime. Encouraging young people to establish a routine that works best for them is most likely to be successful. Referral for more specialist assessment and treatment might be needed for young people with severe sleep-related disorders.

NHS Digital. *Smoking, Drinking and Drug Use among Young People in England*, 2021. Published September 2022. Accessed online at: https://digital.nhs.uk/data-and-information/publications/statistical/smoking-drinking-and-drug-use-among--young-people-in-england.

LONG-TERM HEALTH CONDITIONS

Up to one-third of 16- to 25-year-olds self-report having a health condition (Fig. 46.5). The most reported long-term health conditions in 11- to 16-year-old young people is mental health illness followed by acne, migraine, allergy, and asthma. Healthcare professionals have an important role in providing support, education, and resources to help young people meet the challenges of long-term conditions and to facilitate informed decision-making by young people about their health and wellbeing.

Several studies report an increase in morbidity and mortality when young people with long-term health conditions move from paediatric to adult healthcare services. Young people with long-term conditions are twice as likely to have mental health problems (30% vs 15%) and more likely to be unemployed (25% vs 2%) compared with healthy peers.

Approximately one-third to half (30%–43%) of young people with long-term health conditions fail to attend adult healthcare services 2 years after transfer from paediatric services. Non-attendance is associated with reduced adherence to treatment and worsening disease control. For example, fewer than 30% of those aged younger than 25 years with type 1 diabetes have

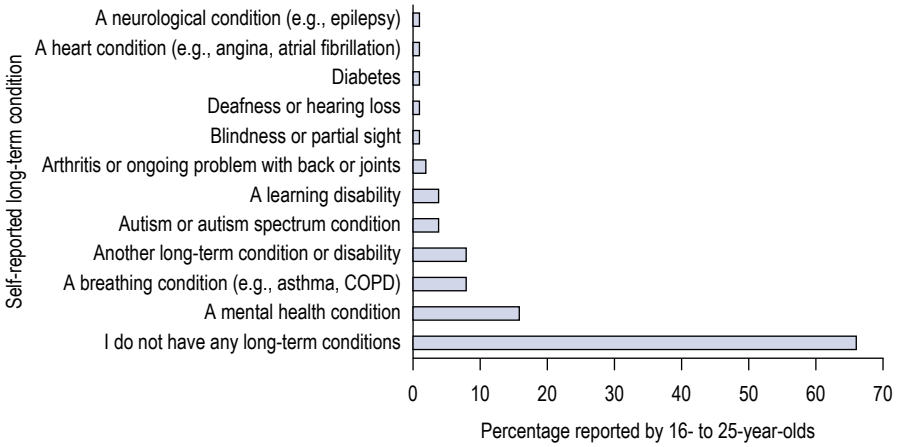

Fig. 46.5 Prevalence of self-reported long-term conditions by 16- to 25-year-olds in England and Wales in 2021. *COPD,* Chronic obstructive pulmonary disease.

an HbA_{1c} within the target range, rates of diabetes-related hospital admissions are increased, and almost one-third live with depression or eating disorders or are distressed about their condition.

The move to adult care can be challenging for many reasons (**Box 46.3**). Despite the availability of resources and evidence highlighting the risks of poorly managed transition to adult care, many young people and their families report unsatisfactory experiences. Several reports and guidelines have sought to mitigate the risks associated with transition from paediatric to adult services. Central to these efforts is the concept of 'transition'. The process of transition aims to empower young people and gradually equip them with the necessary skills and knowledge to confidently manage their healthcare. Transition needs to be structured and holistic and to address young people's medical, psychosocial, and vocational issues.

Features of transitional healthcare that are associated with improved outcomes include:

- A prolonged period of preparation, ideally starting before 13 to 14 years of age
- Accurate and comprehensive referral documentation
- Joint clinics between adult and paediatric specialist teams and a visit to the adult service before transfer of care
- Appropriate parent involvement that facilitates gradual relinquishing responsibility for treatment
- Promotion of young people's knowledge of and confidence in managing their health conditions and wider health (health self-efficacy).

Various transitional programmes have been developed that focus on empowering young people by teaching them self-advocacy and involving them in shared decision-making. One such programme is the 'Ready Steady Go' transition programme (www.readysteadygo.net). Through completion of a series of structured questionnaires, young people's knowledge of their conditions, treatment, the healthcare team, healthy lifestyle practices, sexual health, educational and vocational issues, and psychosocial concerns are assessed and addressed. Specific questions prompt discussion about potentially difficult topics such as sex and mental health (**Fig. 46.6**).

Effective transition programmes improve long-term outcomes. For example, in patients with type 1 diabetes, an effective transition increases attendance in adult services, reduces hospital admissions, and improves diabetic control as evidenced by HbA_{1c} concentrations.

i Box 46.3 Challenges in transition from paediatric to adult healthcare services

- The increased responsibilities of adult healthcare lead to apprehension, anxiety, and disengagement.
- Reluctance from parents to relinquish control over healthcare management hinders development of independence.
- Saying goodbye to trusted paediatric healthcare providers leads to feelings of loss and anxiety about building new connections with an adult team.
- Changes in care protocols between paediatric and adult services cause confusion, concern, and problems in accessing necessary services.
- Young people may worry that new healthcare providers will not fully understand their medical history and specific needs.
- Fear of being judged or stigmatized in adult healthcare settings deters young people from seeking care and support.
- Emotional stress and anxiety make it hard to cope with change.
- A poorly planned transition process results in gaps in medical care.

SHARED DECISION-MAKING

Shared decision-making is the direct involvement of young people in decisions about their healthcare. It is a key part of empowering young people to be actively engaged in managing their healthcare and improves health outcomes and patient satisfaction. It requires consideration of safeguarding, consent and parental involvement in care. The UK NHS constitution, the American Academy of Pediatrics, and the Australian Commission on Safety and Quality in Healthcare all promote shared decision-making in young people. Despite evidence for shared decision-making, fewer than half of young people and their parents feel involved in decisions about healthcare (which are similar to data from adult services).

'Ask 3 Questions' is a shared decision-making tool that provides a structured framework for discussions and resource allocation using a patient-centred approach. This approach empowers patients to become active participants in their healthcare journey and leads to improved patient satisfaction and health outcomes.

HEALTH LITERACY

For young people to be empowered, active participants in their own healthcare, they need to be able to obtain and understand information about their conditions and lifestyle choices. This skill is termed 'health literacy'. Better health literacy can be realized through improving young people's self-confidence and motivation to access information, as well as ensuring that the information provided is engaging, relevant, and appropriate to their needs and ability to understand.

In the UK, the average adult reading level is comparable to that of a 9-year-old. About 42% of English adults struggle to comprehend and use written health information, which rises to 61% when numeracy skills are necessary. These rates are similar worldwide. To address the gap in accessible health information, co-production between healthcare professionals and patients is essential. Involving young people and their parents or other carers in designing resources and services empowers patients and tailors' healthcare to young people's needs.

OTHER CONSIDERATIONS WHEN ADDRESSING THE NEEDS OF YOUNG PEOPLE

Neurodiversity

Brain maturational changes during adolescence reveals variation in brain function and neurodevelopment. Neurodiversity, including autistic spectrum disorders, attention deficit hyperactivity disorder, and dyslexia, may become apparent. Health services have an important role in the diagnosis of those with neurodiversity and signposting to resources such as speech and language, occupational, and behavioural therapists. Access to education and employment support and technologies to facilitate communication may also benefit young people.

Sexual and reproductive health

Sexually transmitted infections (STIs) and unintended pregnancy are preventable. Teenage pregnancy is associated with adverse health and social outcomes, including lower education achievement, deprivation, and higher infant mortality rates, compared with older mothers and birthing people. The highest rates of STIs, HIV, and unintended pregnancy are among adolescents and young adults. Timely sex education, including information about consent, and access to youth-friendly, confidential reproductive health services providing contraception, STI testing, and treatment, are necessary measures toward achieving good sexual health in young people. Non-judgemental, accessible support is required in pregnancy, and many obstetric centres have specialist medical and midwifery teams supporting pregnancies in young people. About 40% to 60% of conceptions among females younger than 25 years of age living in the UK result in termination.

Menstruation

Key concerns in relation to menstruation in young people include ensuring the provision of accurate, timely, and age-appropriate information about menstrual hygiene and the emotional and physical changes that occur. Educational materials should promote positive societal attitudes and challenge cultural taboos when present. Access to affordable hygiene products can be a problem for those in low-income households.

Further reading

Menstrual Hygiene Day: Making Menstruation a Normal Fact of Life by 2030. Menstrual hygiene day Global (menstrualhygieneday.org).

Gender identity

Young people with gender identity concerns have specific needs. These include access to inclusive healthcare and the provision of policies and legislation to help ensure equal rights and opportunities to realize their potential. Careful consideration needs to be given to the needs of transgender and non-binary young people who menstruate and the way in which hormonal changes during the menstrual cycle can impact mood and exacerbate pre-existing mental health conditions. Young transmen should have access to safe and effective contraception and cervical screening programmes.

CORE SKILLS AND KNOWLEDGE

More than 90% of patients presenting to breast clinics have normal breasts or benign breast disease. Benign breast disease includes congenital abnormalities, aberrations of normal development and involution (ANDI), and other benign conditions. Timely, accurate diagnosis is key.

Approximately 1 in 20 females aged 30 to 49 years consults annually with menstrual disorders, 1 in 6 couples experiences subfertility, and 1 in 3 females will have a termination, with considerable global variance. Most gynaecological issues are managed in primary care. Complex gynaecological conditions, red-flag symptoms suggestive of possible malignancy, and symptoms that fail to respond to initial treatments require referral.

Conditions of the human body unique to the male sex include disorders of the male urogenital tract including the prostate, penis, and testes. Compared with females, males have lower health literacy and are less likely to use available health resources. Few countries have addressed the burden of male ill-health through the adoption of male-centred health strategies.

The development of a person's gender identity involves the interplay of psychological, social, and physical factors. Biology, socialization, and cognition contribute to the formation of gender identity. Gender diverse people face discrimination, leading to barriers in accessing healthcare.

Key learning objectives in sex and gender medicine include:

- Establishing gender identity, preferred name, and pronouns for all patients
- History taking in patients presenting with breast, gynaecological, or lower urinary tract symptoms (LUTS)
- Examinations of breast, genitalia, and prostate that are sensitive, efficient, and maintain dignity, with a chaperone present
- Knowledge of benign breast conditions, the menstrual cycle, and factors that impact physiology
- Understanding the benefits, risks, and potential side-effects of available contraceptive methods
- Recognizing red-flag symptoms suggestive of gynaecological and urogenital tract cancers
- Recognizing and managing urological emergencies, including testicular torsion, acute urinary retention, paraphimosis, and priapism
- The assessment of gender, physical health, and mental health in gender diverse patients
- Understanding the diagnostic criteria for gender incongruence and gender dysphoria
- Understanding that assessment and management of gender incongruence and dysphoria requires a multidisciplinary team, including psychological, social, and physical health
- Recognizing that gender diverse people face discrimination and barriers to accessing healthcare.

BREAST DISEASE

History

The primary focus is to assess whether breast cancer could be present. A history of presenting symptoms, risk factors for breast cancer, family history, and current medication is needed. The duration and onset of symptoms can be helpful: cysts can appear overnight, but cancers usually grow slowly. The growth of breast tissue in males (gynaecomastia) is usually self-limiting but can rarely be a sign of underlying systemic disease or drug toxicity.

Examination

Breast inspection should take place in good light with the patient sitting with their arms in three positions: by their side, above their head, and pressed on their hips to contract pectoralis major. Skin dimpling in the lower part of the breast may only be evident with the arms elevated or when the pectoral muscles are contracted. Contraction of the pectoral muscles allows assessment of deep fixation of palpable lumps.

Breast palpation is best performed with the patient lying flat with the arms above or behind the head. The fingertips are used to palpate all areas of the breast. Abnormalities should be assessed for contour, texture, and size. Patients with breast pain should be examined lying on each side, allowing the breast tissue to fall away from the chest wall to differentiate between true breast pain (mastalgia) and chest wall pain. Axillary and supraclavicular lymph nodes should be palpated. Palpable nodes may be palpable in up to 30% of patients without clinically significant disease. Benign causes of enlarged axillary nodes include infection, postvaccination response, and implant silicone leak causing silicone granuloma.

Investigation

Most breast masses or concerning areas of asymmetric nodularity should have *triple assessment* consisting of clinical examination, imaging, and core biopsy. Bilateral two-view (oblique and cranio-caudal) mammography is performed in patients older than 40 years of age with palpable abnormalities or nipple discharge. In patients younger than 40 years, the breasts are relatively radio-dense, and ultrasound scan is preferred. Ultrasonography can characterize benign and malignant features: whereas breast cysts are well demarcated, cancers usually have indistinct outlines. Magnetic resonance imaging (MRI) may be indicated in benign breast disease and is the optimum imaging method when the patient has breast implants. Ultrasound-guided core biopsy is the standard procedure to determine the cause of suspicious or indeterminate lesions or suspicious nodes in the axilla. Fine-needle aspiration cytology is no longer used to assess breast masses, although it may be useful in the assessment of axillary or supraclavicular lymphadenopathy. Large-bore vacuum-assisted biopsy can be used to completely remove lesions such as fibroadenomas and small papillomas. Open biopsy should be used only after imaging and at least one attempt at core biopsy.

Breast cancer

Although most patients presenting to breast clinics have normal breasts or benign breast disease, breast cancer should be excluded in patients presenting with breast symptoms.

Breast cancer may present as:

- **Breast lump or nodularity:** A breast lump is discrete and feels different from the surrounding breast tissue; it has definable borders and is measurable. Nodularity can be bilateral and symmetrical, or localized; it can fluctuate with the menstrual cycle. Localized nodularity is a common presentation of invasive lobular cancer.
- **Skin dimpling or change in contour** are present in up to 25% of symptomatic patients with breast cancer.
- **Nipple changes:** Nipple inversion occurs in both breast cancer and inflammatory breast conditions. Nipple inversion associated with breast cancer may be eccentric with the nipple being distorted. Slit-like central retraction of the nipple (inversion without distortion) is characteristic of benign disease.

Box 47.1 lists breast symptoms that require referral to exclude breast cancer.

Breast masses require triple assessment:

1. Examination
2. Imaging (mammography or ultrasonography)
3. Tissue sample (fine-needle aspiration or core biopsy)

Areas of asymmetrical nodularity require clinical and radiological assessment. A cause for nodularity needs to be identified; if no cause is found and the nodularity is localized, then core biopsy is indicated.

i Box 47.1 Breast symptoms requiring assessment for malignancy

Breast lump
- New discrete lump
- New lump within pre-existing nodularity
- Asymmetrical nodularity after the age of 35 years
- Asymmetrical nodularity that persists after menstruation (review after next menstrual cycle, within 4 weeks)
- Abscess or breast inflammation that does not settle rapidly after one course of antibiotics
- Palpable axillary mass

Pain
- If associated with a lump
- Intractable pain that interferes with a patient's lifestyle or sleep that has failed to respond to reassurance, supportive measures, and anti-inflammatory drugs
- Unilateral persistent breast pain (distinguished from chest wall pain)

Nipple discharge
- In females aged over 50 years
- In females 50 years or younger with any of:
  - Blood-stained discharge
  - Spontaneous single-duct discharge
  - Bilateral discharge sufficient to stain clothes

Nipple retraction or distortion

Nipple eczema

Change in skin contour

Family history
- Genetic testing offered if *BRCA1* and *BRCA2* mutation carrier possibility is 10% or more using available risk assessment tools

Box 47.2 Aberrations of normal breast development and involution

Age (years)	Normal process	Aberration
Younger than 25	Breast development: Stromal or lobular	Fibroadenoma Juvenile hypertrophy (macromastia)
25–40	Cyclical activity	Cyclical mastalgia or cyclical nodularity (diffuse or local)
35–55	Involution: Lobular Stromal Ductal	 Macrocysts Sclerosing lesions Duct ectasia

Adapted from Dixon JM, Thomas J. Congenital problems and aberrations of normal development and involution. In: ABC of Breast Diseases, *4th edn. Blackwell Publishing; 2012.*

Each component of the assessment—clinical examination (E), mammography (R) and ultrasound (U), cytology (C), and core biopsy (B)—is graded:

1. Normal (C1 = acellular)
2. Benign
3. Indeterminate or probably benign (B3 = atypical)
4. Probably malignant (B4 = suspicious)
5. Malignant (B5a = *in situ* carcinoma; B5b = invasive cancer)

Any mass, localized nodularity, or skin change considered clinically E3 or above requires biopsy even in the presence of normal or benign imaging. In the presence of a definite lesion, a normal core biopsy (B1) may be unrepresentative, and further biopsies should be considered by the multidisciplinary team (MDT). In any lesions considered suspicious of malignancy should be marked in the centre of the lesion at the time of biopsy, including suspicious lymph nodes. Management of breast cancer is detailed in Chapter 41.

Congenital abnormalities of the breast

Supernumerary nipple has an incidence of approximately 0.2% to 2.5%, most found inferior to the breast. Supernumerary breasts are less common with an incidence of 0.1% to 1%, most commonly in the lower axilla. Some degree of breast asymmetry is usual, and the left breast is more commonly larger than the right. Absence or hypoplasia of one breast can be associated with defects in one or both pectoral muscles. True unilateral absence of breast tissue is associated with absence or hypoplasia of the pectoral muscles in around 90% of patients. In contrast, 90% of patients with pectoral muscle defects have normal breasts. Tubular breasts have a narrow base and resemble a tubular hourglass structure. Pectus excavatum and scoliosis can result in symmetrical breasts appearing asymmetrical. Correction of asymmetry and tubular breasts involves tissue expansion, autologous fat grafting, or implants.

Aberrations of development and involution

The breast undergoes regular changes in relation to the menstrual cycle passing through phases of development, cyclical activity, and involution. ANDI is an established framework that refers to common benign breast conditions that occur during one specific period and are considered variations of a normal process, not caused by pathology (Box 47.2).

Box 47.3 Management of fibroadenoma

Conservative: If imaging and pathology are concordant with fibroadenoma, the patient can be reassured and discharged.

Excision (surgical excision or vacuum-assisted excision):

- If pathology shows a cellular fibroepithelial lesion that is difficult to confidently distinguish from a phyllodes tumour, open surgical excision is recommended.
- Rapidly growing lesion.
- Large fibroadenoma relative to the breast size or superficial fibroadenoma with significant distortion of the breast.
- Discomfort and pain are relative indications for surgical excision. Pain may not improve after excision.

Fibroadenoma

Fibroadenomas are the most common causes of palpable breast masses before 20 years of age, accounting for 60% of masses. They account for 13% of palpable symptomatic breast masses. Clinically, they are mobile, discrete, rubbery masses. An ultrasound scan can differentiate a fibroadenoma from a cancer. Core biopsy of the lesion should be performed if patients are aged 25 years or older or if there are indeterminate clinical or radiological features. Management is reassurance or excision (Box 47.3). Juvenile fibroadenomas occur in adolescent females and can undergo rapid growth.

Tubular and lactating adenoma

A tubular adenoma is a benign circumscribed lesion managed in a similar way to fibroadenoma. Lactating adenomas occur during pregnancy, usually regress after cessation of breast-feeding, and are managed conservatively.

Juvenile hypertrophy

During puberty or lactation, uncontrolled overgrowth of stromal and ductal breast tissue can occur with no measurable endocrine abnormality. Reduction mammoplasty should be considered within a careful shared decision-making pathway and can improve quality of life.

Pain and nodularity

Cyclical pain and nodularity are common and regarded as physiological, not pathological. Pain that is severe or prolonged is regarded as an aberration of cyclical change. Nodularity is the most common cause of referral to a breast clinic. Imaging reveals normal breast tissue. Focal, asymmetric nodularity that persists after menstruation requires triple assessment. Repeat review may be required because breast cancer frequently presents as localized asymmetrical nodularity in young females.

Palpable breast cysts

Palpable breast cysts are a common reason for presentation to a breast clinic, affecting 7% of females. They are distended and involuted lobules most commonly in perimenopausal females and less common after the menopause. Presentation is usually as a smooth, mobile, discrete breast mass, which can be firm. Box 47.4 summarizes the investigation and management of palpable breast

Box 47.4 Investigation and management of breast cysts

Investigation

Mammography: in females older than 40 years

Ultrasonography: distinguishes solid and cystic lesions; allows image-guided aspiration

- Simple cyst: smooth outline, posterior enhancement, absent internal echoes
- Complex cyst: thickened or irregular wall, internal echoes or thin septations, absent posterior enhancement

Core biopsy:

- If projections in the cyst wall to exclude intraductal papilloma or carcinoma
- Indeterminate clinical or radiological findings
- Persistence of a palpable mass after aspiration
- Rapid and persistent refilling of a cyst

Management

Simple, asymptomatic: reassure

Large, symptomatic, or complex characteristics:

Aspirate to dryness and send only blood-stained fluid for cytology

Re-examine after aspiration to ensure resolution; perform further imaging and biopsy if the mass persists

Recurrent: repeat aspiration; perform further investigation including imaging and biopsy if there is rapid and persistent refilling

cysts. Although there is a minimally increased risk of breast cancer in females with cysts, especially at younger ages, this does not warrant routine follow-up. Complex cysts are rarely malignant, but aspiration or repeat review and imaging is required.

Duct ectasia

The major subareolar ducts dilate and shorten with age. By age 70 years, 40% of females have duct ectasia. Presentation is with symmetrical, slit-like nipple retraction, cheesy nipple discharge, or a palpable mass that may be hard or doughy. Surgery may be indicated if discharge is troublesome or the patient wishes the nipple to be everted.

Sclerosing lesions

Sclerosing lesions are aberrations of stromal involution and can mimic cancer on mammography, causing diagnostic challenges during breast screening. There are three types: sclerosing adenosis, radial scars, and complex sclerosing lesions (CSLs). Sclerosing adenosis is benign and does not increase the risk of breast cancer. Radial scars and CSLs are associated with malignancy in up to 20% of cases, usually ductal carcinoma in situ (DCIS) or low-grade invasive cancers. Vacuum-assisted large-bore core biopsy usually provides sufficient tissue to exclude malignancy and avoid surgical excision.

Benign neoplasms and proliferations

Epithelial hyperplasia

Epithelial hyperplasia is characterized by an increase in the number of cells lining the terminal duct lobular unit. It is graded as mild, moderate, or florid (severe). If the cells display cellular atypia, the condition is called atypical hyperplasia. There are two types of atypical proliferation of the terminal duct lobular unit:

- **Lobular intraepithelial neoplasia (LIN):** characterized by loss of E-cadherin expression; includes atypical lobular hyperplasia and lobular carcinoma in situ

Fig. 47.1 Large ulcerated borderline phyllodes tumour.

- **Atypical ductal hyperplasia (ADH)** or atypical intraductal epithelial hyperplasia: express E-cadherin

ADH is the only benign breast condition associated with an increased risk of breast cancer. ADH carries a four- to fivefold increased risk of breast cancer, and the risk is doubled with a positive family history of breast cancer. When ADH is diagnosed on core biopsy, large-volume vacuum-assisted core biopsy or excisional biopsy is recommended because DCIS (up to 30%) or invasive carcinoma (9%) can be present in adjacent breast tissue. Tamoxifen 20 mg/day reduces the cancer risk associated with ADH by more than 80%, with more recent data showing that 5 mg/day is also effective, with limited toxicity.

Duct papilloma

Duct papillomas can cause nipple discharge that is often bloody. They are commonly detected through breast screening. Although the epithelial component can range from benign to *in situ* carcinoma, they usually have low malignant potential. Single-duct or total-duct excision is used to establish the diagnosis and stop troublesome nipple discharge. Core biopsy cannot always confidently differentiate between benign and malignant papillomas; therefore, a vacuum-assisted excision or surgery is recommended. Given the low malignant potential of these lesions, small papillomas without atypia can be safely observed.

Phyllodes tumours

These are rare fibroepithelial neoplasms that range from benign to borderline to malignant. The majority are benign in nature. They are commonly seen in patients aged 35 to 55 years. The aetiology is unknown. They feel like large fibroadenomas. They can grow rapidly and rarely cause marked distortion, cutaneous venous engorgement, and ulceration (Fig. 47.1). The diagnosis is with core biopsy. Excision is required to remove benign phyllodes with a clear margin. A wide margin excision is required in malignant lesions. Local recurrence is seen in fewer than 10% of benign phyllodes, and the rate of metastasis is 10% to 20% in malignant lesions.

Box 47.5 Benign nipple conditions

Condition	Features	Investigation	Management
Nipple adenoma	Non-discrete, benign, palpable growth in the nipple papilla Most common at ages 40–50 years Bloody nipple discharge is characteristic Cause nipple mass, discoloration, erosion, or contour change	Punch or core biopsy	Complete surgical excision
Eczema of the nipple	Usually affects areola first	Punch or core biopsy to differentiate from Paget's disease	Remove allergen; use hypoallergenic washing agents Topical steroid
Nipple Raynaud's disease	Vasospasm causes nipple to turn white, then blue, then red Patients usually have Raynaud's disease symptoms elsewhere		Avoid cold Low-dose nifedipine

Lipomas

Lipomas are common, soft, lobulated, radiolucent lesions. They can be confused with pseudolipomas, which are soft masses around a breast cancer caused by indrawing of fat surrounding a spiculated carcinoma. Ultrasound examination establishes the diagnosis. Biopsy or excision is only required if there has been rapid growth.

Granular cell tumours

Granular cell tumours are benign neoplasms that arise from Schwann cells of the peripheral nerve sheath. Although largely benign, malignant lesions have been described.

They can be challenging to differentiate clinically and radiologically from breast carcinoma because of their fibrous consistency, fixation to the pectoral fascia, and skin retraction. Core biopsy confirms the diagnosis. Granular cell tumours should be excised with a narrow clear margin to prevent recurrence.

Other benign conditions of the breast

Nipple conditions

Benign breast conditions of the nipple are summarized in **Box 47.5**.

Haematomas

Breast haematoma occurs most commonly after trauma such as road traffic accidents or surgery. Breast haematoma may occur spontaneously in patients on anticoagulant therapy. Examination reveals bruising or a palpable collection in a post-surgical patient. Management is supportive, including reassurance, educating patients on anticoagulant therapy, and repeat review if the haematoma does not resolve or the patient has any further concerns.

Fat necrosis

Fat necrosis can produce a mass that can feel like a breast carcinoma. Causes include:

- Trauma to the breast
- Surgery: Mammaplasty, lipofilling, and breast reconstruction with lower abdominal flaps can cause areas of fat necrosis.

Management is supportive with reassurance of the benign nature of the palpable breast abnormality. Lipomodelling may be used for significant distortion.

Diabetic mastopathy

This is a form of sclerosis associated with longstanding type 1 diabetes. It can present as one or more hard breast masses that are indistinguishable from malignancy. Histology reveals sclerosis. There is no increased risk of malignancy, and the treatment is reassurance.

Mondor's disease

Mondor's disease is thrombosis of the superficial veins in the skin of the breast, most commonly involving at least one of three venous channels:

- The thoracoepigastric vein
- The lateral thoracic vein
- The superior epigastric vein

It presents as a painful, thickened palpable cord, which may be erythematous. It is self-limiting. Topical non-steroidal anti-inflammatory drugs (NSAIDs) can be used.

Hamartomas

Hamartomas are common benign breast lesions composed glandular epithelium, adipose tissue, and fibrous tissue in variable proportions. They are usually asymptomatic but may present as a soft, smooth, mobile lump indistinguishable from fibroadenoma. Core biopsy confirms the diagnosis and excision is not required.

Mastalgia

Mastalgia is pain originating from within the breast. This needs to be distinguished from chest wall pain, which is the commonest cause of pain presenting to breast clinics (**Boxes 47.6 and 47.7**).

Few patients with breast pain require treatment. Reassurance that there is no serious underlying pathology is the mainstay of treatment. Tamoxifen 10 mg in the luteal phase of the menstrual cycle can be used for cyclical pain, and selective serotonin reuptake inhibitors can be used for premenopausal mastalgia. The fruit extract agnus castus has described benefits but is not widely used. Chest wall pain may be relieved by wearing a soft, supporting bra 24 hours a day. NSAIDs, providing there are no contraindications, can also be effective. Depot prednisolone combined with long-acting

Box 47.6 Breast pain overview

Breast pain alone or painful lumpiness is common and accounts for approximately 50% of new breast clinic referrals.
Breast pain is rarely a symptom of breast cancer.
Pain in the breast can arise from the breast or the underlying chest wall.
Careful examination can differentiate chest wall pain from true breast pain.
Medical treatment rarely needed.

Box 47.7 Breast pain

Clinical features

Most patients with breast pain who reach the breast clinic have pain arising from the chest wall. It is rare for breast carcinoma to present with breast pain.

True breast pain

- Worse before and relieved after menstruation; aetiology unknown
- Exacerbated by fluctuating hormone concentrations (perimenopause) and exogenous hormones (hormone replacement therapy, contraceptive pill); more common with combined oral contraceptive pill use than progesterone methods of contraception but seen in both

Chest wall pain

- Unilateral
- Exacerbated by activity
- Reproduced by direct pressure over a specific area of chest wall

Examination

Sitting up and lying on each side to allow breast tissue to fall away from chest wall

Investigation

Mammography: in females older than 40 years of age to exclude malignancy. The positive predictive value of mammography for malignancy in breast pain is very low (0.17 for age 40–49 years vs 2.8 after 70 years)
Ultrasonography: in all patients with localized area of pain
Triple assessment: in all patients with a palpable lump

local anaesthetic can be effective for patients with localized chest wall pain.

Nipple discharge

Nipple discharge accounts for 5% of referrals to breast clinics. Up to 20% is caused by *in situ* or malignant disease. Serosanguinous or bloody discharge from a single duct raises the suspicion of an underlying malignancy, although it is rare for an invasive cancer to cause nipple discharge in the absence of a palpable lump. The aim is to differentiate physiological causes from ductal pathology. Causes of nipple discharge include:

- Physiological discharge: opalescent, multiple duct discharge
- Galactorrhoea: bilateral, copious, pale milky, multiple duct discharge. This can be caused by prolactinoma or medications that increase prolactin concentrations.
- Duct ectasia: a yellow, thick discharge, usually at older ages
- Papilloma, epithelial hyperplasia, and DCIS: can all present with serosanguinous or bloody discharge from a single duct
- Invasive carcinoma: serosanguinous or bloody discharge from a single duct, often with a palpable lump. The clinical features, investigation, and management of nipple discharge are shown in **Box 47.8**.

Box 47.8 Nipple discharge

Key clinical assessment

Does it arise from a single duct or multiple ducts?
Is it bloodstained?
Induced by squeezing the nipple or spontaneous?
Affecting one or both breasts?
Frequency, colour, and consistency

Examination

Breast examination for lump
Firm digital pressure to allow assessment of site and character of discharge

Investigation

Test discharge for blood by inspection and urinalysis strip testing
Mammogram in patients older than 40 years of age
Ultrasonography of ducts close to the nipple can sometimes identify papillomas and malignant lesions

Management

Spontaneous single-duct discharge requires surgery if it occurs on more than one occasion and has at least one of the following features:

- Blood stained or contains moderate or greater amounts of blood on testing
- Persistent (occurs at least twice per week)
- Associated with a suspicious mass

Microdochectomy, in which a single duct is removed, is considered for single-duct discharge in younger females. This should not damage the surrounding ducts and allows lactation. Total-duct excision is an option for females of non-childbearing age and is less likely to miss underlying malignancy than microdochectomy. Multiple-duct spontaneous discharge is treated by total-duct excision. It is very rare for duct surgery to be indicated in males.

Breast infection

Breast infection most commonly affects females between the ages of 18 and 50 years and can be divided into lactational and non-lactational infection. As with all breast pathology, breast infection is rare in males. Cellulitis in male breast is uncommon but can be seen in the neonatal and pubertal periods. Specific breast infections are summarized in **Box 47.9**. The four guiding principles in treating patients with breast infection are:

1. Provide early appropriate antibiotics to reduce the risk of abscess development.
2. Refer to hospital for infections that do not settle within 48 hours of appropriate antibiotic treatment.
3. Perform ultrasonography if abscess is suspected to confirm a collection before drainage.
4. Exclude breast cancer if there is a solid lesion on ultrasound or if infection fails to resolve with adequate antibiotic treatment.

Peripheral non-lactating breast abscesses

Most of these have no underlying cause. They can be associated with diabetes, rheumatoid arthritis, steroid treatment, granulomatous lobular mastitis, and trauma. If the skin overlying the abscess is not thinned, management is by aspiration and

Box 47.9 Breast infections

Neonatal infection

Presentation: rare, occurring in first few weeks of life when breast bud is enlarged

Organism: usually *Staphylococcus aureus*; occasionally *Escherichia coli*

Management: antibiotics or small peripheral incision of abscess to avoid damage to the breast bud

Lactating infection

Presentation: most commonly seen during first 6 weeks of breast-feeding; history of nipple or skin abrasion causing local oedema and reduced milk flow

Organism: usually *S. aureus*

Management: antibiotic therapy according to sensitivity (e.g., flucloxacillin, erythromycin, co-amoxiclav); avoid tetracyclines and chloramphenicol when possible because of adverse neonatal effects; promote milk drainage; application of gel packs or cold cabbage leaves to the breast

Periareolar infection

Presentation: most common in young females; more common in smokers; periareolar inflammation or abscess with mass, pain, nipple retraction, or discharge; organism: usually anaerobic organisms

Management: antibiotics including anaerobic cover (e.g., co-amoxiclav, erythromycin plus metronidazole); recurrent episodes may be caused by persistence of diseased ducts, and excision may be considered, weighed with risk of further infection and nipple necrosis, particularly in smokers

irrigation with local anaesthesia along the aspiration track and to wash out the abscess until fluid is clear. If the skin overlying the abscess is thinned or necrotic, then pus is drained through a small skin incision through the thinned skin under local anaesthesia without packing. Drainage under general anaesthesia is rarely required. Patients should be reviewed every 2 to 3 days and aspiration or irrigation continued until no further pus is present.

Granulomatous lobular mastitis

This is a rare condition that presents most frequently in young parous females as an irregular mass indistinguishable from a carcinoma or as multiple or recurrent breast abscesses. Pathological features include non-caseating granulomas and microabscesses confined to a breast lobule. The role of specific organisms in the aetiology of this condition is unclear, but an association with *Corynebacterium* spp. is described in some studies. The diagnosis is confirmed on core biopsy. Management has a limited evidence base, and approaches include:

- Treat episodes of infection with antibiotics, aspiration, or drainage and ensure close surveillance.
- Avoid large incisions because of risks of poor wound healing and persistent discharge.
- Steroids and immunosuppressants have been used with varying efficacy in small series.

Mammary duct fistula

This describes an abnormal communication between the skin and a major subareolar breast duct. It occurs as a complication of periductal mastitis after incision and drainage, spontaneous discharge of a peri-areolar inflammatory mass, or core biopsy of a peri-areolar inflammatory mass. Treatment is by opening (fistulotomy) or excising (fistulectomy) the fistula, but recurrence is common.

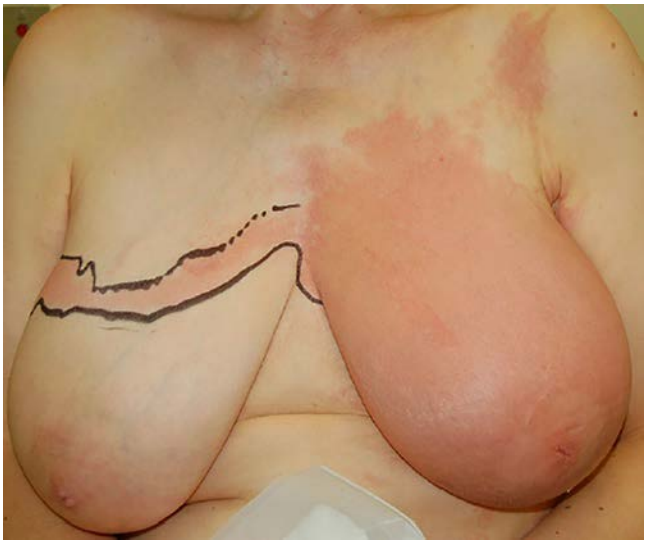

Fig. 47.2 Left breast cellulitis with lymphangitis across the right breast.

Skin-associated infection

Primary infection of the skin of the breast can present as cellulitis or an abscess and most commonly affects the lower half of the breast. Radiotherapy disrupts the blood and lymphatic flow of the breast and increases the risk of skin-associated infection and cellulitis (Fig. 47.2). When inflammation occurs after radiotherapy, it is important to distinguish lymphoedema from cellulitis. Cellulitis of the male breast is rare but is seen in the neonatal and pubertal periods. Beta-haemolytic streptococci and *Staphylococcus aureus*, including methicillin-resistant *S. aureus*, are the most common pathogens. Treatment is with antibiotics according to organism and sensitivity. Outlining the area of cellulitis allows assessment of response to treatment. Epidermoid cysts of the skin of the breast may become infected.

Those who are overweight, have large breasts, or have intertrigo are susceptible to recurrent infections in the skin under the breast. Treatment includes antibiotics if infection is present, weight reduction, and advice on measures to keep the area as clean and dry as possible.

Hidradenitis suppurativa

Hidradenitis suppurativa is a chronic disease of follicular occlusion that can affect the infra-mammary regions. Treatment of secondary infection is with appropriate antibiotics and drainage of pus if required. Excision of the affected skin is associated with a high risk of recurrence despite surgery. Patients should be supported to stop smoking.

Post-surgical infection

Post-surgical infection can occur in the early postoperative period or after wound healing. The most common organisms in the early operative period include skin flora and *S. aureus*. Perioperative prophylaxis with a single dose of a broad-spectrum antibiotic such as co-amoxiclav has

been shown to be beneficial in prevention. Delayed cellulitis may occur months to years after breast-conserving surgery and radiation therapy and should be managed as skin-associated infection as described earlier.

FEMALE HEALTH

History

Direct but sensitive questioning about intimate issues may be required. People may not feel comfortable talking about these in front of their family or friends Ensure you have a confidential area to take a history (**Box 47.10**).

Examination

Consider the preliminaries listed in **Box 47.11**. Ensure a chaperone is available to conduct an examination. Vaginal (bimanual) and speculum examinations (**Fig. 47.3**) are needed as part of the investigation of symptoms including abnormal vaginal discharge, intermenstrual or postmenopausal bleeding, pelvic pain, and dyspareunia. These examinations may be perceived as invasive, intimate, and uncomfortable. It is essential to gain competence in examination techniques using pelvic training simulators before examining patients. Gain informed consent and empower patients to tell you to stop the examination at any point.

Box 47.10 Taking a gynaecological history

Menstruation
- Age when periods began and stopped (if postmenopausal)
- Regularity of periods: usual length of cycle and duration of bleeding
- Any significant changes in menstrual cycle
- First day of the last menstrual period
- Heavy or painful periods:
  - As perceived by the patient, including impact on quality of life
  - Semi-objective measures: days off work, frequency of sanitary product change

Pregnancy
- Number, timing, and outcomes
- Sensitive approach to adverse outcomes and difficult decisions: e.g., miscarriage, termination, stillbirth
- Avoid confusing gravida and parity jargon: a detailed chronological list is more valuable

Medical history
- Medical and surgical history
- Personal and family history of gynaecological and breast disorders
- Current and past medications, including teratogenic or fetotoxic medication, e.g., sodium valproate, warfarin

Cervical cancer risk factors
- Human papillomavirus vaccination
- Uptake of cervical screening
  - Date and outcome of most recent and previous screening
  - Ensure accessible screening for females in same-sex relationships and transgender men

Sexual history
- Sexual partners and types of intercourse in the preceding 6 months
- History of sexually transmitted and pelvic infections
- Current and past use of contraception
- Current and future fertility wishes

As appropriate
- History of non-consensual sexual activity or abuse

Consider referral for forensic medical examination
Support with referral to police
Consider need for psychological support
Female genital mutilation

Box 47.11 Preliminaries to a vaginal examination

- Ensure the environment is comfortable and private.
- Wash your hands.
- Introduce yourself (name and role) and confirm patient details.
- Ensure a chaperone is present (ideally, a female chaperone) and record their name.
- Explain the proposed procedure clearly and answer all questions.
- Obtain explicit consent; explain that the patient may change their mind at any time.
- Ask whether there is any possibility that the patient might be pregnant.
- Wear gloves.
- Provide a sheet or modesty blanket and ensure the door is closed and locked.
- Ask the patient to remove their underwear and lie on the examination couch with the heels drawn to buttocks and the knees out to sides (modified lithotomy position).

Bimanual examination	Speculum examination
	• Inspect vulva: - Ulcers - Vaginal discharge - Masses (malignant or abscesses) • Enter vagina using two lubricated fingers • Assess vagina (including the fornices) for masses or irregularities • Assess cervix: - Masses - Os (open/closed) - Pain on palpation – 'cervical excitation' • Assess uterus: - Place second hand on lower abdomen - Use internal fingers in posterior fornix to push uterus upwards and palpate between hands - Assess size, shape and position • Assess adnexa: - Place internal fingers into left lateral fornix - Place other hand to palpate deeply in left iliac fossa - Move internal fingers towards other hand to assess for tenderness and masses - Repeat on right • Close the encounter: - Stop examination; remove gloves - Offer paper towels and encourage patient to dress - Summarize findings and next steps - Document procedure and chaperone identity	• Inspect vulva (see left) • Insert speculum: - Warn patient you will now insert speculum - Lubricate speculum (if possible, also warm metal speculums) - Part labia using thumb and first finger of non-dominant hand - Insert the speculum sideways; rotate 90 degrees once inside (so handle faces upwards) - Open speculum blades and visualize cervix - Tighten locking nut to hold blades open • Assess cervix: - Os (open/closed) - Ulcers - Masses - Discharge • Perform any necessary diagnostic procedures: - Swabs for conventional culture or nucleic acid amplification tests (NAATs) - Smear test for cytology • Remove speculum: - Loosen locking nut - Partially close blades, taking care not to trap vaginal wall between blades - Rotate 90 degrees and withdraw speculum • Close the encounter (see left) • Ensure all samples are sent for appropriate tests

Fig. 47.3 **Bimanual and speculum examination.**

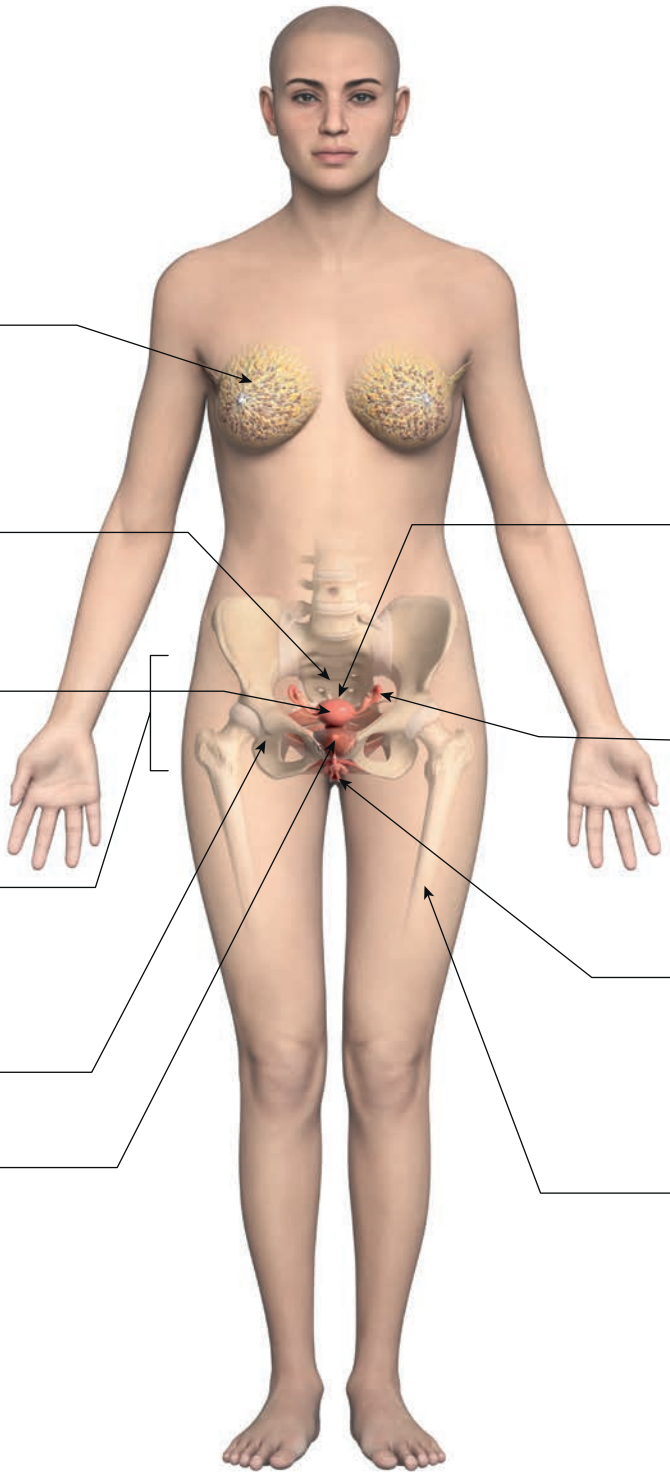
Each patient will have their own experience of menarche and the pre- and postmenopause. Issues during these life phases may result in females interacting more with health services compared with male patients. Female patients have a higher lifetime risk of mental health issues, anaemia, and osteoporosis while also being at risk of complications related to pregnancy and delivery.

Female reproductive and sexual health needs are largely predictable. Most females want to enjoy healthy sexual relationships and control their fertility to prevent unwanted pregnancies. Patients are increasingly choosing to delay conception until later in life, which will likely increase the demand for fertility services in the future. Increased life expectancy means that the postmenopausal period is longer. An understanding of the impact of societal changes on future healthcare needs is warranted. Female patients are more likely to experience sexual and domestic violence than male patients, the latter being even more common in pregnancy and the postnatal period.

Ethnic inequalities in obstetric healthcare are a concern. In the UK, patients of Black ethnicity are 3.7 times more likely to die in pregnancy or the postpartum period (34 per 100 000 giving birth) compared with patients of White ethnicities. Patients of Asian ethnicities are 1.8 times more likely to die (16 per 100 000 giving birth).

Definitions in female health include:

- ***Puberty.*** The process of physical maturation to reach sexual maturity and be capable of reproduction. The mean age of menarche is 12.8 years, but it may take several years for the menstrual cycle to establish a regular pattern. Initial cycles are typically anovulatory and unpredictable.



Breast
Mass: contour, texture, size
Pain (mastalgia)
Nipple: mass, discoloration, discharge, retraction, vasospasm
Skin: contour, infection
Congenital abnormality
Venous thrombosis
Reconstruction
Infection: abscess, cellulitis
Atrophy

Abdominal/pelvic pain
Exclude ectopic pregnancy

Uterus
Fibroid
Amenorrhea
Heavy menstrual bleeding
Intermenstrual bleeding
Post-coital bleeding
Menopause

Gynaecological malignancy
Pain

Termination
Post-partum depression/psychosis
Prediction of future health risk

Premenstrual symptoms
Bloating
Weight gain
Breast tenderness
Headache
Mood changes/irritability

Vagina
Discharge
Dyspareunia
Dryness
Genital mutilation
Skin change: lichen sclerosus

Bone
Reduced bone mineral density

- ***Precocious puberty.*** This is defined as menses or breast development before the age of 8 years.
- ***Delayed puberty.*** This is the absence of secondary sex characteristics after 14 years. Causes may be central (e.g., anorexia, excessive exercise, chronic illness, pituitary tumour) or failure of gonadal function (e.g., Turner's syndrome, XX gonadal dysgenesis).
- ***Primary amenorrhoea.*** This is the absence of menstruation by 16 years of age.
- ***Secondary amenorrhoea.*** This is a new absence of menses for more than 6 months in a female who is not pregnant, lactating, or menopausal.
- ***Menorrhagia.*** This is menses with abnormally heavy or prolonged bleeding affecting quality of life.

- ***Premenstrual syndrome.*** Physical or emotional symptoms before a period are very common and include progesterone-induced bloating, weight gain, mastalgia (breast tenderness), headaches, depression, and irritability. In 5% to 15% of females, severe symptoms affect lifestyle and personal relationships. Treatments, including lifestyle modifications, hormonal preparations, cognitive-behavioural therapy (CBT), selective serotonin reuptake inhibitors, and surgery, are variably effective.
- ***Premature ovarian insufficiency.*** The cessation of periods before age 40 years occurs in 1% of females.
- ***Menopause.*** Menopause is a retrospective diagnosis made 1 year after the final menstrual period in the absence of hormonal suppression or pregnancy. The average age of menopause in high-income countries is 51 years.
- ***Surgical menopause.*** This is a menopausal state induced by surgical removal of both ovaries (oophorectomy).
- ***Postmenopausal bleeding.*** Most cases are caused by benign atrophic vaginitis and respond to topical oestrogens. Approximately 10% are caused by endometrial pathology, including atypical hyperplasia (precancerous changes) or endometrial cancer. Ultrasound examination is used to assess endometrial thickness. Tissue sampling is indicted for patients with endometrial thickness greater than 3 to 5 mm or recurrent bleeding episodes and in high-risk patients. Patients on tamoxifen for breast disease may have an irregular, thickened, and cystic endometrium, which requires hysteroscopy and directed tissue biopsy.

The life course approach

A life course approach examines the effects of biological, social, and behavioral exposures that occur during fetal development, childhood, adolescence, and adulthood, including pregnancy. The different stages of the life course impact health, wellbeing, and disease in later life and across generations. A life course perspective recognizes that the circumstances of pregnancy can affect the health of the offspring, early life events impact long-term outcomes, and early interventions may reduce the risk and severity of disease.

Female adolescence

Sex and relationship education became statutory in primary and secondary schools in the UK in September 2019. It provides information on:

- The constituents of a healthy relationship
- Consent, empowering young people to say no, and how to seek help
- Contraception
- Risks of sexually transmitted infections (STIs)
- Vaccination and screening programmes to prevent and detect early or pre-disease

Human papillomavirus (HPV) vaccination at age 12 to 13 years and *Chlamydia trachomatis* screening for those younger than 25 years aim to prevent cervical cancer, ectopic pregnancy, and tubal infertility. These encounters provide early opportunities to discuss the long-term benefits of a healthier lifestyle before considering pregnancy.

Early sexual health education reduces the incidence of teenage pregnancy. In the UK, the Teenage Pregnancy Strategy is a sustained, coordinated local and national action that has led to the lowest conception rate in those younger than 18 years since 1969. However, England's teenage birth rate remains higher than other Western European countries, and adolescent mothers have poor outcomes: 90% leave education and 20% become pregnant again within their teenage years.

Heavy menstrual bleeding

The menstrual cycle is shown in Fig. 47.4.

Heavy menstrual bleeding (HMB) accounts for one in five gynaecology clinic consultations and is the most common cause of iron-deficiency anaemia in females. Methods to quantify menstrual blood loss are inaccurate; clinical assessment uses the patient's perception of blood loss and impact on quality of life. The passage of large blood clots, severe pain, or flooding that prevents a patient leaving home require investigation and management.

Detailed menstrual and medical histories are required, with special consideration for symptoms of anaemia. Abdominal and pelvic examination is carried out to exclude pelvic masses, visualize the cervix, perform a smear (HPV test) if needed, and take swabs if infection is suspected. Investigations to consider are:

- ***Full blood count and iron studies*** to assess need for iron replacement and, in extreme cases, blood transfusion.
- ***Haematological opinion*** if history is suggestive of a bleeding disorder.
- ***Ultrasound scan*** if a pelvic mass is palpated or the bleeding pattern suggests endometrial pathology.
- ***Endometrial biopsy*** for irregular or intermenstrual bleeding and when drug therapy fails (Fig. 47.5).

Ultrasound and haematological investigations are indicated in young females presenting with menorrhagia from their first period.

The most appropriate treatment for HMB considers patient preference, risks and benefits, fertility and contraceptive requirements, and contraindications to medical or surgical therapies.

Medical treatments

- ***Levonorgestrel intrauterine system*** (Mirena coil). This has revolutionized treatment of patients with HMB. It leads to a 95% reduction in blood loss (30% of females are amenorrhoeic within 1 year of insertion), is an effective contraceptive, improves dysmenorrhoea, and has few side-effects. It should be considered in most females with HMB as an alternative to surgical treatment. Some experience irregular bleeding and persistent spotting for 3 to 9 months after insertion.
- ***Tranexamic acid.*** This is an antifibrinolytic associated with a 50% reduction in HMB.
- ***Mefenamic acid.*** This NSAID is taken during menses and is associated with a 25% reduction in bleeding.
- ***Combined oral contraceptive pill.*** This reduces bleeding and provides effective contraception, but side-effects exist, including an increased risk of venous thromboembolism (VTE).
- ***Oral progestogens.*** Taken on days 6 to 26 of the menstrual cycle, these regulate the bleeding pattern but are not contraceptives, and breakthrough bleeding can occur.
- ***Ulipristal acetate.*** This can be added to other strategies in females with fibroids larger than 3 cm. Severe liver injury is rare.
- ***Gonadotrophin-releasing hormone (GnRH) agonist*** drugs lead to desensitization of the gonadotroph GnRH receptor, resulting in the suppression of luteinizing hormone (LH) follicle-stimulating hormone (FSH) and secretion and amenorrhoea. They are suitable only for short-term use because they produce a hypoestrogenic state predisposing to osteoporosis.

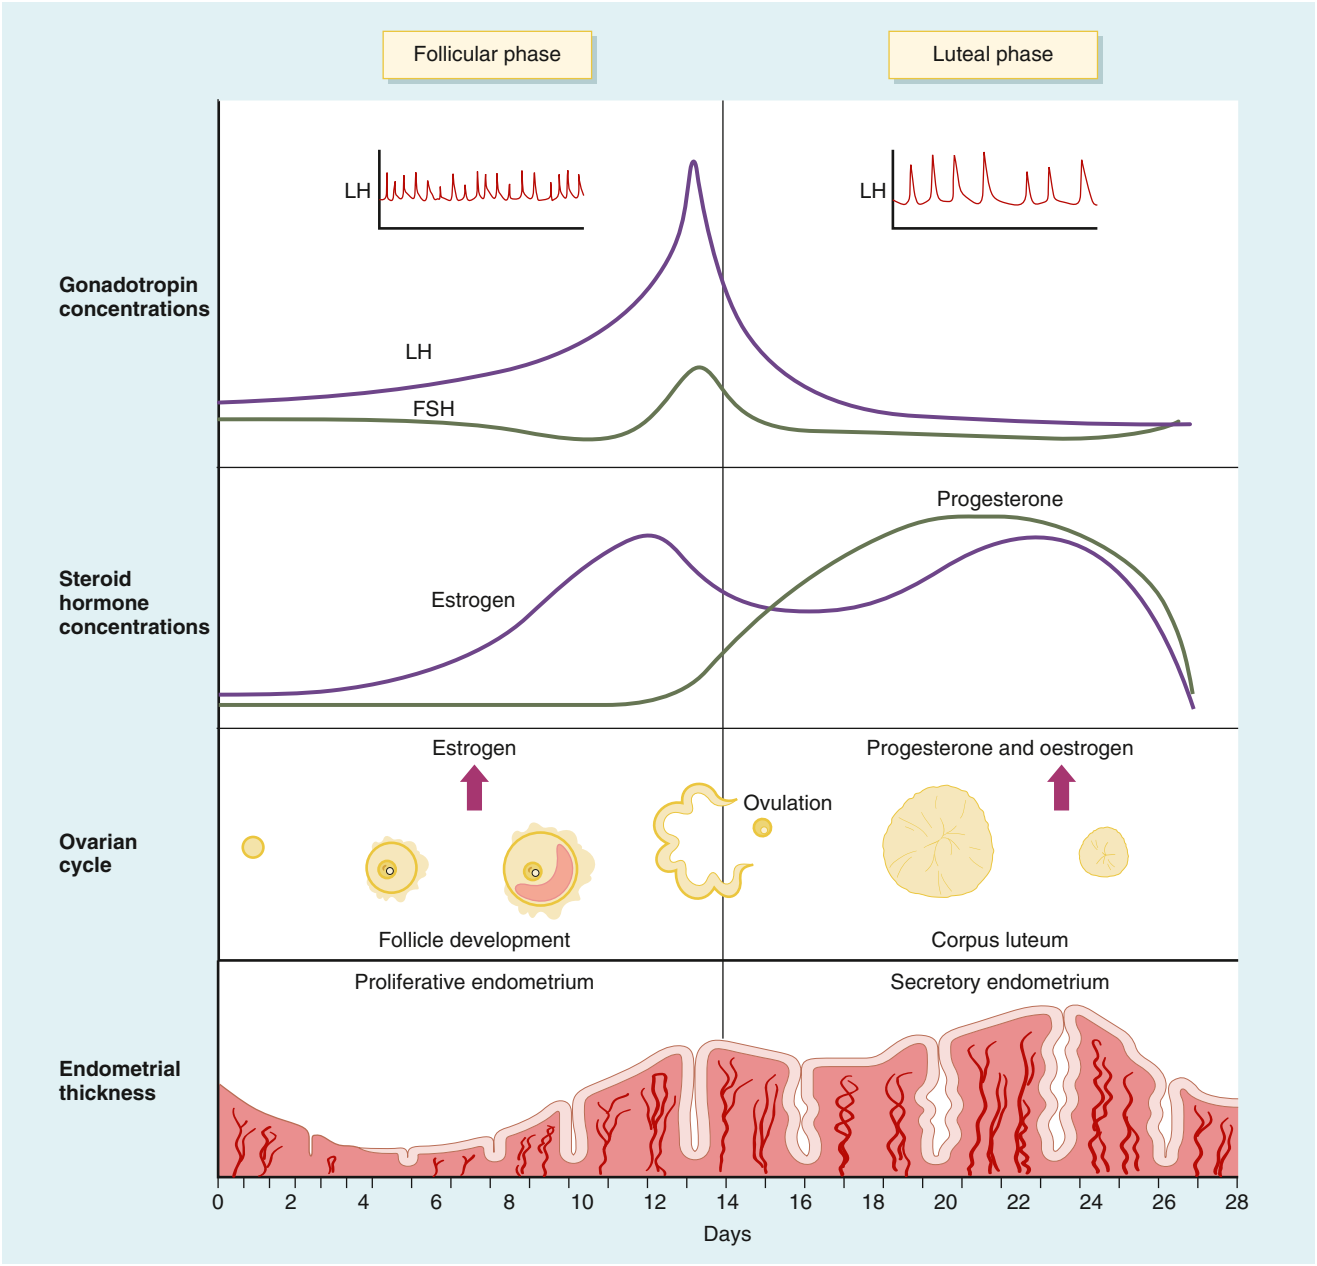

Fig. 47.4 **The menstrual cycle: luteinizing hormone (LH), follicle-stimulating hormone (FSH), oestrogen, and progesterone concentrations during the follicular and luteal phases of the menstrual cycle, with associated endometrial thicknesses and ovulation.**

Surgical treatments

Surgical treatments for patients with HMB are usually offered when medical treatments have failed and patients have completed their families.

- ***Endometrial ablation.*** This destroys the endometrial lining to a depth that prevents cyclical regeneration. Second-generation microwave and thermal ablation techniques are undertaken as day-case procedures.
- ***Hysterectomy.*** Removal of the uterus via an abdominal, vaginal, or laparoscopic method depends on the size of the uterine body, the degree of laxity of the pelvic muscular floor, and surgical expertise. Vaginal or laparoscopic surgical procedures usually mean shorter hospital stays and faster return to normal activities, but a large fibroid uterus may require an open incision.

Pre-pregnancy counselling

Forty percent of pregnancies in the UK are unplanned, and opportunities to provide preconceptual advice on diet, weight, exercise, smoking and alcohol, vaccination, and folic acid intake are often missed before pregnancy. Pre-pregnancy counselling allows a review of general health and medication and ensures that a management plan for pregnancy is in place.

Most maternal deaths in the UK occur in females with medical or mental health co-morbidity. Between 2018 and 2020, 60% of deaths in pregnancy or within the first postpartum year were in females with pre-existing medical problems, and 37% had pre-existing mental health problems. More than 25% of females' deaths were in those living with obesity (body mass index [BMI] ≥30 kg/m^2).

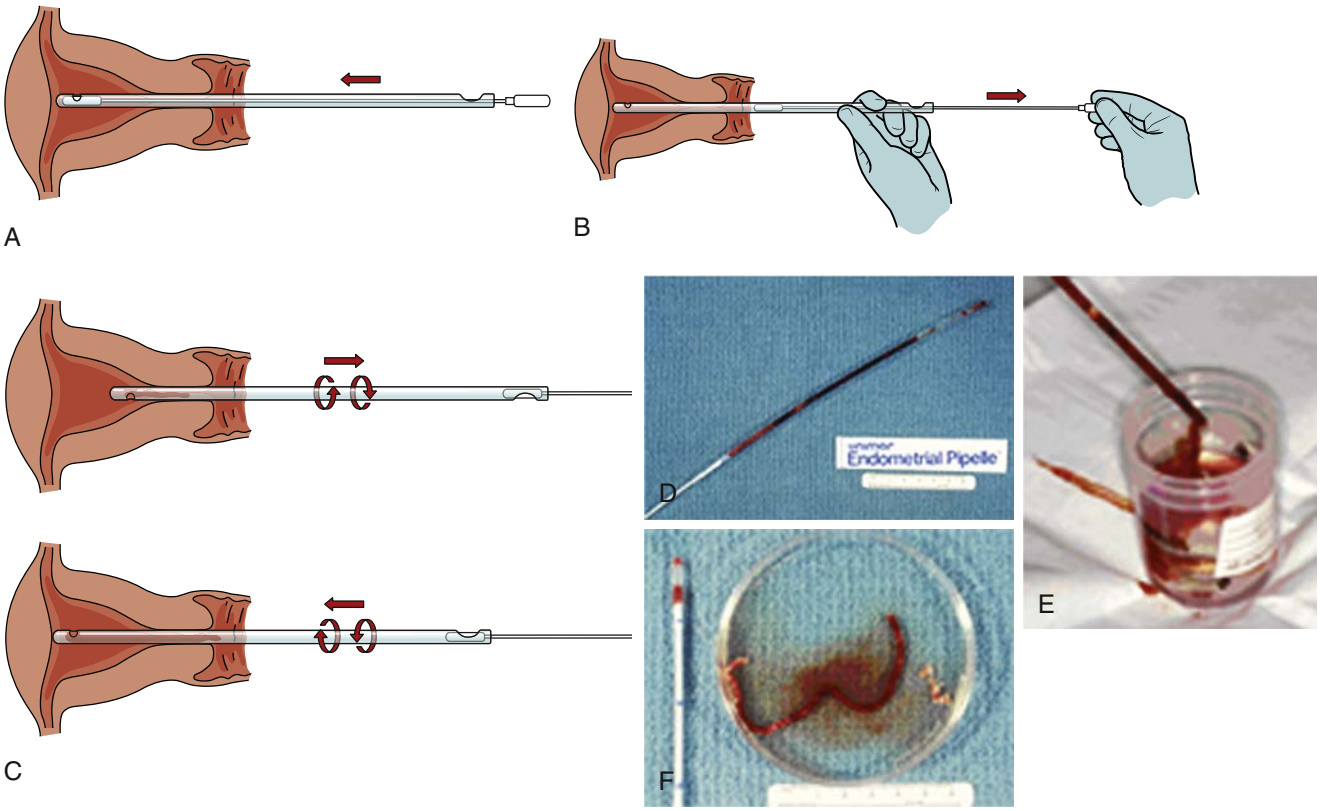

Fig. 47.5 Pipelle endometrial biopsy. The Pipelle is passed through the cervix into the endometrial cavity **(A)**. The plunger is then drawn back to create a small vacuum **(B)**. The Pipelle sampler is then moved through 360 degrees against the endometrium **(C)** to obtain an adequate sample **(D)**. The sample is put into formalin **(E)** and sent for histopathological analysis **(F)**.

Around 20% of females in the UK remain childless, either by choice or otherwise. A smaller but growing number pursue assisted conception, including *in vitro* fertilization, to overcome an age-related decline in fertility, of which the British Fertility Society has highlighted that few females are aware. Older females are more likely to have medical co-morbidities and an increased risk of adverse pregnancy outcomes. Access to fertility treatment in the UK is recommended, but local referral criteria and available funding are a source of inequality.

Miscarriage and stillbirth

Miscarriage is a pregnancy that ends spontaneously before the fetus reaches a viable gestation. The term includes all pregnancy losses between conception and 24 weeks' gestation. Sporadic miscarriage is the most common pregnancy complication; most cases are thought to be caused by random genetic abnormalities in the embryo. The incidence of clinically recognized miscarriage is thought to be 15% to 20% of all pregnancies, but the total number of very early conceptions lost may be as high as 50%. Sensitive home pregnancy testing kits have identified many biochemical pregnancies that fail to implant successfully and resolve spontaneously as a delayed or heavy menstrual period. Miscarriage incidence decreases with advancing gestation, with rates of second trimester loss between 1% and 2%.

Maternal age at conception and reproductive history are independent risk factors for miscarriage. The risk of fetal loss rises steeply after 35 years of age, reaching 75% by 45 years presumed to be because of poor-quality oocytes leading to chromosomally abnormal conceptions. Delayed childbearing not only leads to increased rates of miscarriage, but also ectopic pregnancy, and later pregnancy complications, including stillbirth. Less common factors contributing to early pregnancy loss are uterine abnormalities, infection, endocrine disorders, and exposure to teratogenic drugs and chemicals.

Different types of miscarriage are classified by clinical presentation and the results of investigations (Box 47.12). Vaginal bleeding in early pregnancy is common and does not always indicate miscarriage (Box 47.13). A detailed clinical history is needed. Clinical assessment includes:

- ***Speculum examination*** assesses the cervix and excludes other lower genital tract pathology (e.g., cervical polyp, ectropion). A closed cervix in the context of miscarriage means either a 'complete miscarriage' or a 'missed miscarriage' has occurred in which the pregnancy has stopped growing but the patient has not yet had pain or bleeding. An open cervix represents either a 'threatened miscarriage' if the pregnancy remains in the uterus or an 'incomplete miscarriage' often with products of conception seen in the cervical os.
- ***Transvaginal ultrasonography*** determines pregnancy location, gestation, and viability. It offers valuable reassurance if fetal heart activity is seen.
- **Serial serum beta-human chorionic gonadotrophin (β-hCG) concentrations** are measured when a conceptus cannot be visualized and the site of pregnancy is therefore unknown.

Box 47.12 Classification of miscarriage

Type of miscarriage	Uterus ultrasonography	Clinical presentation
Biochemical pregnancy	Empty uterus	PV bleeding; 'late period' after positive pregnancy test result
Threatened miscarriage	Intrauterine pregnancy	PV bleeding and pain; cervical os closed
Inevitable miscarriage	Intrauterine pregnancy	PV bleeding and pain; cervical os open
Incomplete miscarriage	Retained products of conception	PV bleeding and pain; cervical os open ± products in cervical os
Complete miscarriage	Uterus empty; no retained products	Pain and PV bleeding resolved; cervical os closed
Missed miscarriage	Fetal pole >7 mm (or gestation sac 25 mm) and no fetal heartbeat	PV bleeding and pain

PV, Per vaginam.

Box 47.13 Causes of vaginal bleeding in early pregnancy

- Threatened, inevitable, or incomplete miscarriage
- Bleeding from a viable pregnancy
- Ectopic pregnancy
- Lower genital tract pathology, e.g., cervical polyp or ectropion
- Trophoblastic disease

Bleeding and pain can be severe when products of conception distend the cervical canal. Prompt removal is required using sponge forceps. Severe pain localized to the iliac fossa or peritonism suggests a ruptured ectopic pregnancy, and urgent laparoscopic assessment and management may be needed. However, many ectopic gestations resolve spontaneously by being resorbed or miscarried from the tube into the peritoneal cavity.

Management of miscarriage depends on clinical presentation and patient choice. First-line management of miscarriage in the UK is expectant for 7 to 14 days. Prostaglandins (oral or vaginal misoprostol) induce uterine contractions and expulsion and are cheap and effective. A follow-up urinary pregnancy test or pelvic scan is needed to confirm miscarriage is complete. Patient preference, risk of haemorrhage, previous adverse events, and evidence of infection may warrant surgical management (evacuation of the retained products of conception [ERPC]). ERPC can be performed by suction under general anaesthesia or by manual vacuum aspiration (MVA) under local anaesthesia. Associated morbidity is uncommon but includes uterine perforation, cervical trauma, intrauterine adhesion formation, and postoperative pelvic infection.

Recurrent miscarriage

Recurrent miscarriage is defined as three or more consecutive miscarriages. It affects 1% to 2% of females trying to conceive and is associated with significant psychological morbidity. Investigation considers genetic (parental translocations), anatomical, infective, endocrine, immune, and thrombophilic causes. Most cases remain unexplained, which conveys a good prognosis for future pregnancy outcomes.

Antiphospholipid syndrome is present in up to 20% of recurrent miscarriages. Subsequent pregnancies are managed with a low-dose aspirin, sometimes with addition of low-molecular-weight heparin, achieving a live birth rate of more than 75%.

Females with a history of recurrent miscarriage have an increased risk of pre-eclampsia, fetal growth restriction, and preterm delivery when they achieve a successful pregnancy, presumed to be caused by factors related to the quality and depth of early implantation. There is also an increased risk of stroke at an earlier age than females with no miscarriage history.

Miscarriages can lead to anxiety, depression, denial, anger, blame, severed relationships, and a sense of loss and inadequacy. Compassionate counselling services and access to support are needed.

Stillbirth

Various definitions exist that distinguish stillbirth from miscarriage, generally based on gestational age (varying from 20–28 weeks). The World Health Organization (WHO) defines stillbirth as a pregnancy loss with a fetal weight of 1000 g or more, an assumed equivalent of 28 weeks' gestation. Worldwide, there were 2.6 million third-trimester stillbirths in 2015. Despite reductions in maternal and child mortality rates, the number of stillbirths remains high. This includes a high number of intrapartum losses (1.3 million), many of which are preventable.

Pregnancy

Complications that arise in pregnancy and confer a risk of future disease include:

- ***Pre-eclampsia*** and ***pregnancy-induced hypertension*** resolve after delivery but are associated with an increased risk of ischaemic heart, cerebrovascular disease, and chronic kidney disease later in life.
- Approximately 50% of those with ***gestational diabetes*** will develop type 2 diabetes within 10 years. Annual screening for diabetes should take place after pregnancy, along with inclusion in a diabetes risk register and diabetes prevention programme in primary care. Children born of pregnancies affected by diabetes are more likely to develop diabetes later in life.
- ***Teenage pregnancies*** and ***preterm deliveries*** repeat across generations.
- Perinatal ***mental health disorders*** affect one in five females and are the leading direct cause of maternal death in the first postpartum year. The 2022 Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the UK (MBRRACE-UK) report into maternal mortality in 2018 to 2020 showed death by suicide during or up to 6 weeks after the end of pregnancy was three times higher compared with 2017 to 2019. Psychiatric and cardiovascular disorders are now responsible for the same number of maternal deaths in the UK.

Pregnancy should be viewed as the healthcare opportunity of two lifetimes, offering significant potential for population health gain and an opportunity to tackle and interrupt cross-generational transmission of ill-health.

The postnatal visit

The postnatal visit is an ideal time to plan future healthcare needs for both parent and baby. It can positively impact lifestyle, including factors such as obesity, exercise, dental health, contraception, smoking,

and drug misuse. A review of the recent pregnancy will provide valuable information on the risk of future morbidity and offers an opportunity to prevent and screen for diabetes, cardiovascular disease (CVD), and recurrent pregnancy complications. This visit also provides a pivotal opportunity to assess mental health, including the postnatal blues, postnatal depression, and puerperal psychosis.

Contraception

Preventing unplanned pregnancy is essential for sexual, physical, and mental wellbeing. Those who lack access to contraceptive methods are at increased risk of morbidity and mortality because of obstetric complications and the consequences of illegal abortion. More than 30% of maternal deaths and 10% of child deaths can be prevented by ensuring a 2-year interval between pregnancies.

Efficacy of contraception methods depends on mechanism of action and ease of use (**Box 47.14**). Failure rates of different contraceptive methods are reported according to 'perfect use' and 'typical use'. 'Perfect use' represents correct and consistent use. However, 'typical use' should be presumed because it considers human error (e.g., split condom, forgotten contraceptive pill). Each contraceptive option has advantages and disadvantages. The UK Medical Eligibility Criteria for Contraceptive Use (UK-MEC) criteria provide evidence-based guidance on the safe use of contraception in those with underlying medical conditions. Side-effects must be judged against the hazards of pregnancy, especially if other contraceptive methods are not practicable or acceptable.

Hormonal contraception

Hormonal contraception includes pills, transdermal patches, vaginal rings, subdermal implants, and intrauterine devices (IUDs). They can be either a combination preparation (oestrogen and progesterone) or progesterone alone.

- ***Combined oestrogen and progesterone contraceptives*** prevent ovulation, make the endometrium hostile to implantation, and alter cervical mucus. Oestrogen suppression by gonadotrophins prevents follicular development, ovulation, and luteinization. The side-effects of these preparations are shown in **Box 47.15**. Most serious side-effects are rare with oestrogen doses of 20 to 30 mcg. Thromboembolism may be slightly more common with newer third-generation pills containing desogestrel and gestodene (30 in 100 000 patient-years) compared with second-generation pills containing levonorgestrel and norgestrel (15 in 100 000 patient-years) and no treatment (5 in 100 000 patient-years), although overall incidence is low. The risks of the combined pill are increased in smokers and those with obesity or cardiovascular risk factors.
- ***Progestogen-only preparations*** act on cervical mucus thickening and thin the endometrium. Some preparations (e.g., desogestrel) also inhibit ovulation. They avoid the side-effects of oestrogen and are suitable for those with risk factors for VTE and CVD. Common side-effects include irregular bleeding, simple ovarian cysts, mood swings, breast tenderness, and acne.

Long-acting reversible contraception

Long-acting reversible contraceptive methods include both progesterone-only methods (subdermal implants, injectables, and IUDs) and non-hormonal methods (copper coil). They have lower failure rates and better continuation rates than user-dependent contraception. They are more cost-effective than oral contraceptives.

- ***Subdermal implants*** are inserted in the upper arm under local anaesthetic and last 3 years. There is return of fertility after removal. Irregular bleeding is common in the initial period and sustained for some.
- ***Depot injectables*** are given intramuscularly and are effective for 12 weeks. Side-effects include irregular periods and a delay in the return of fertility of up to 6 months.
- ***IUDs*** are inserted into the uterine cavity by trained personnel. A thread is left protruding from the cervix into the vagina, allowing removal by traction.
  - Levonorgestrel-releasing intrauterine systems (e.g., Mirena) are licensed for contraception, for treatment of HMB, and as part of hormonal replacement therapy regimens. The duration of use is 3 to 5 years, depending on the device. Irregular vaginal spotting tends to resolve by 6 months after insertion but can be troublesome and is the most common reason for removal, aside from wanting to conceive. Other side-effects may include acne, breast tenderness, and mood swings, but these often regress. With use, there is transition to amenorrhoea or lighter, less painful periods, making them effective treatment for patients with pelvic pain caused by endometriosis and adenomyosis.
  - Copper IUDs are cheap and effective for up to 10 years. They are toxic to both eggs and sperm (spermicidal) before fertilization can occur. They are suitable for those in whom hormonal use is contraindicated or unwanted. Patients should be counselled about the possibility of heavier or more painful periods.

Barrier methods

Condoms, diaphragms, spermicides, and sponges require consistently correct use. They have high typical-use failure rates but do offer protection against STIs.

Emergency contraception

Emergency contraception can be used after unprotected intercourse to prevent unwanted pregnancy. The earlier the use after unprotected sexual intercourse, the greater the efficacy. Levonorgestrel needs to be taken within 72 hours and is available without prescription in the UK. Ulipristal acetate delays ovulation and can be used up to 120 hours after intercourse. It requires a prescription in the UK. The failure rate of both pills is 1% to 2%, and a repeat dose should be given if vomiting occurs within 3 hours. Copper IUD insertion within 5 days of unprotected intercourse is a highly effective emergency contraceptive and provides ongoing effective contraception for up to 10 years.

Sterilization

Male and female sterilization offers irreversible contraception, with low failure rates of 1 in 2000 and 1 in 200, respectively. Male vasectomy can be performed under local anaesthetic and carries fewer risks than tubal ligation, clipping, and salpingectomy in females.

Termination of pregnancy

Unplanned pregnancy is common, and termination of pregnancy is a frequently performed gynaecological procedure. One in three females will have a termination in their lifetime in the UK. Termination of pregnancy continues to generate ethical, cultural, and political debate, and legal frameworks governing abortion services vary considerably between jurisdictions. Globally, 50 million pregnancies end in termination, of which 20 million are illegal. Approximately 70 000 maternal deaths occur each year because of unsafe abortions.

Box 47.14 Contraceptive methods, advantages, disadvantages, and effectiveness

	Type of contraception and mode of action	Advantages	Disadvantages	Contraindications	Typical use failure rate (%)[a]
Non-hormonal	**Fertility awareness** Intercourse is restricted to non-fertile times using: 1. Body temperature (rises 0.2°–0.4°C after ovulation) 2. Cervical mucus changes 3. Menstrual cycle length	No physical side-effects No co-morbidity effect or consequence Acceptable across faiths and cultures	Relies on regular menstrual cycles, record-keeping, and commitment Can take three to six cycles to learn effectively Illness, stress, and travel may alter fertility indicators No protection against STIs	Nil	24
	Withdrawal Penile withdrawal before ejaculation ('coitus interruptus')	No physical side-effects No co-morbidity effect or consequence	Variable control of ejaculation and presence of sperm within pre-ejaculatory fluid		22
	Barrier methods Condom Femidom Diaphragm Cervical cap	Effective if used correctly No systemic side-effects Widely available Protection from STI and HIV transmission with condoms and femidoms	Must be applied before penetration Can reduce sensation Diaphragm and cap must be fitted and checked by a trained professional Placement can be incorrect Condoms can split with incorrect use	Latex allergy for latex-containing products (non-latex polyurethane and polyisoprene products are widely available) Concurrent use of spermicide (e.g., nonoxynol-9) does not increase protection from STI and may increase HIV transmission	Male condom: 18 Femidom: 21 Female diaphragm: 12
	Copper coil	No hormonal side-effects Fertility resumes after removal	Heavier or more painful periods Low risk of expulsion, uterine perforation and 'lost threads' requiring hysteroscopic retrieval	48 hours to 4 weeks postpartum Current PID	0.8
	Female sterilization (tubal ligation)	No hormonal side-effects Permanent contraception	Irreversible	Possible future fertility wishes	0.5
	Male sterilization (vasectomy)	No hormonal side-effects Permanent contraception	Delay to azoospermia, which requires confirmation before unprotected intercourse Irreversible Low risk of chronic testicular pain	Possible future fertility wishes	0.15
Hormonal	**Combined hormonal contraception** Combined oral contraceptive pill Patch Vaginal ring	Reliable if taken correctly Convenient and not intercourse related Improves dysmenorrhoea, menorrhagia, and premenstrual symptoms Reduced functional ovarian cysts Reduced incidence of ovarian, endometrial, and colon cancers	VTE Hypertension Relative increase in cardiovascular and cerebrovascular disease risk Small increase in cervical intraepithelial neoplasia and cervical cancer after prolonged use Mixed evidence regarding breast cancer risk Breakthrough bleeding, headaches, nausea, breast tenderness, mood changes Does not protect against STIs	History of VTE Atrial fibrillation Reduced effectiveness with enzyme-inducing medication Reduced effectiveness with vomiting or diarrhoea for oral methods	9
	Progesterone-only pill	Can be used if contraindication to oestrogen methods Safe use in lactation Improved dysmenorrhoea or menorrhagia	Irregular breakthrough bleeding in early use Acne, breast tenderness, headaches	Breast cancer	9
	Progesterone-containing intrauterine system (e.g., Mirena, Jaydess)	Shorter, lighter periods; amenorrhoea Fertility resumes after removal	Uncomfortable insertion Uncommon complications expulsion, uterine perforation, lost threads requiring hysteroscopic retrieval If pregnancy occurs, risk of ectopic pregnancy	48 hours to 4 weeks postpartum Current PID Breast cancer	0.2
	Subdermal implant (e.g., Nexplanon, Implanon)	Shorter, lighter periods; amenorrhoea	Breakthrough bleeding	Breast cancer	0.05
	Depot progesterone injections	Shorter, lighter periods; amenorrhoea Can use with enzyme-inducing medication	Can delay fertility for up to 1 year after stopping Acne, breast tenderness, breakthrough bleeding, headache	Breast cancer	6

[a]Percentage of females conceiving during the first year of typical use.

HIV, Human immunodeficiency virus; *PID*, pelvic inflammatory disease; *STI*, sexually transmitted infection; *VTE*, venous thromboembolism.

Box 47.15 Combined oestrogen–progesterone oral contraceptives: adverse effects

General
- Loss of libido
- Pigmentation (chloasma)
- Breast tenderness

Cardiovascular
- Increased blood pressure
- Myocardial infarction
- Stroke (migraine with aura is a risk factor)

Gastrointestinal
- Nausea and vomiting
- Gallstones
- Abnormal liver biochemistry
- Hepatic adenoma

Nervous system
- Headache
- Migraine
- Mood changes

Malignancy
- Increased risk of breast cancer (reduced risk of ovarian and endometrial cancer)

Gynaecological
- Amenorrhoea
- 'Spotting'
- Cervical erosion (ectropion)

Haematological
- Increased risk of venous thromboembolism

Endocrine or metabolic
- Conflicting data on glucose tolerance
- Dyslipidaemia

Drug interactions
- Enzyme-inducing antibiotics, e.g., rifampicin
- Carbamazepine
- Phenytoin
- St John's wort

Legalized termination in high-income countries is safe. The risk of death from an early surgical termination of pregnancy is less than 1 per 100 000, far lower than the maternal mortality rate associated with pregnancy. Of the 190 000 procedures performed annually in the UK, 95% of them are performed under Clause C of the Abortion Act, which states that pregnancy has not exceeded its 24th week and that continuance of the pregnancy would either involve more risk than termination or injury to the physical or mental health of the pregnant patient. The earlier an abortion is performed, the safer it is. Currently, 91% of abortions in the UK are carried out before 13 weeks' gestation. Only 1% of terminations are performed for a fetal abnormality. Contraception should be discussed before termination and started immediately after the procedure to avoid a further unintended pregnancy.

Early medical termination (before 9 weeks' gestation), using mifepristone for cervical preparation and misoprostol to expel the products, is complete in more than 80% of cases. Patients may be observed for 4 to 6 hours in a clinical setting after misoprostol insertion, although early medical termination at home is increasingly supported following UK legislation passed in 2018. Later medical termination requires careful counselling. Feticide with intracardiac potassium injection is performed before medical termination after 21 weeks and 6 days' gestation to ensure a live birth does not occur.

Termination of pregnancy can be undertaken surgically under local or general anaesthesia. The type of procedure depends on the gestation, availability, and patient preference. Early surgical terminations before 7 weeks' gestation can be performed by MVA syringe under local anaesthesia in suitable patients. Surgical terminations before 14 weeks' gestation are usually performed as suction terminations under general anaesthesia. Preoperative priming of the cervix with either oral or vaginal misoprostol reduces the risk of cervical trauma and haemorrhage; osmotic cervical dilators may be considered in later gestations or if there are contraindications to misoprostol. Surgical terminations after 14 weeks' gestation are done via a specialist service in the UK.

Contemporary techniques and routine screening for pelvic infection in high-risk females mean that the risk of subfertility after termination is low. Later terminations are associated with more complications, including an incomplete procedure with retained products of conception, uterine perforation, intrauterine adhesion formation (Asherman's syndrome), pelvic infection, and trauma to the genital tract.

Many females are emotionally vulnerable after termination. Feelings of guilt and regret frequently mix with relief. However, there is no evidence of increased severe psychiatric disease after termination. Psychological sequelae can be reduced with careful counselling before the procedure and postabortion support.

British Pregnancy Advisory Service (BPAS) https://www.bpas.org/abortion-care/abortion-aftercare/.

Menopause

Menopause, or cessation of periods, occurs naturally at 45 to 55 years old. During the fifth decade of life, FSH and then LH concentrations rise, probably as follicle supply diminishes. Oestrogen concentrations fall, and the menstrual cycle becomes disrupted. Most females notice a gradual change to irregular, scanty periods, although sudden amenorrhoea or menorrhagia occur in some. Eventually, the menopausal pattern of low oestradiol concentrations with elevated LH and FSH (usually >50 and >30 U/L, respectively) is established. Premature menopause may occur because of surgery, radiotherapy to the ovaries, or ovarian disease.

In patients older than 45 years of age, the following can be diagnosed without laboratory tests:
- ***Perimenopause:*** vasomotor symptoms (hot flushes, night sweats) and irregular menstrual periods
- ***Menopause:*** no period for at least 12 months without the use of hormonal contraception (or based on symptoms in those without a uterus)

Features of oestrogen deficiency are hot flushes (which occur in most and can be disabling), vaginal dryness, and breast atrophy. There may also be loss of libido, self-esteem, non-specific aches and pains, sleep disturbance, irritability, depression, loss of concentration, and weight gain. There is a rapid loss of bone density in the 10 years after menopause, and the female premenopausal protection against ischemic heart disease and stroke disappears.

Management of menopause should include explanations with information detailing:
- The stages of menopause
- Common symptoms
- Lifestyle changes to help general health and wellbeing, such as cessation of smoking, increased aerobic exercise, and avoidance of food triggers
- The benefits and risks of treatments
- The long-term implications of menopause

Box 47.16 Risks and benefits of hormone replacement therapy (HRT)

Benefits

- Symptomatic improvement in menopausal symptoms
  - Oestrogen-deficient symptoms respond well to systemic oestrogen replacement
  - Vaginal symptoms respond to local oestrogen (e.g., oestriol vaginal creams, pessaries)
- Protection against osteoporotic fractures of the wrist, spine, and hip
- Reduced risk of colorectal cancer
- Possible improvement in general wellbeing and mood
- Improved libido
- Reduced risks of coronary heart disease and Alzheimer's disease when oestrogen is started early
- Reduced risk of type 2 diabetes mellitus

Risks

- Oestrogen only HRT used when the uterus has been removed has little or no increased risk of breast cancer
- Combined oestrogen and progestogen HRT is associated with a higher risk of breast cancer comparable to other lifestyle factors (see **Box 47.17**)
- Oral HRT tablets increase the risk of VTE; transdermal (e.g., patch, gel, spray) preparations do not increase risk of VTE
- Possible increase in ischaemic heart disease when combined HRT started after 60 years of age or with pre-existing IHD. The first 10 years after menopause is considered the cardiovascular 'window of opportunity'
- Increased stroke risk with oral HRT started after 60 years of age

IHD, Ischaemic heart disease; *VTE,* venous thromboembolism.

Box 47.17 Breast cancer risk attributed to lifestyle factors and hormone replacement therapy (HRT)

Lifestyle risk factors		Absolute excess risk per 1000 females in 5 years aged 50–59 years
Postmenopausal obesity	Overweight vs healthy weight[a] Obese vs healthy weight[a]	+4 +10
Alcohol	4–6 units/day ≥6 units/day	+8 +11
Unopposed oestrogen use for 5 years	WHI study, 2020 NICE Menopause Guidance, 2015 CGHFBC, 2019	–6 +3 +3
Combined HRT use for 5 years	WHI study, 2020 NICE Menopause Guidance, 2015 CGHFBC, 2019	+8 +9 +10

[a]Healthy weight, body mass index (BMI) <25 kg/m^2; overweight BMI, 25–29.9 kg/m^2; obese BMI ≥30 kg/m^2.

CGHFBC, Collaborative Group on Hormonal Factors in Breast Cancer; *NICE,* National Institute for Health and Care Excellence; *WHI,* Women's Health Initiative.

Treatment options include:

- Hormonal (e.g., hormone replacement therapy [HRT])
- Non-hormonal (e.g., clonidine)
- Complementary (e.g., isoflavones, black cohosh)
- Psychological (e.g., CBT)

Hormone replacement therapy

Symptomatic patients are offered HRT with the lowest effective dose. The benefits and risks are detailed in **Box 47.16**. Risks depend on whether oestrogen is used in isolation or in combination with progesterone. Individual risks and benefits also depend on the background risk of specific disease. Transdermal oestrogen preparations are associated with a low risk of VTE, but there is no evidence that different hormone preparations or routes of administration (oral, transdermal, implant) modify cardiovascular and cancer risks. The Women's Health Initiative study estimated that, over 5 years of treatment, 1 extra person in every 100 develops an illness that would not have occurred had they not taken HRT, though the association between long-term HRT and an increased risks of breast cancer, stroke, and VTE has recently been challenged. There is little difference in the risk of breast cancer incurred by lifestyle factors, including current and past use of HRT (**Box 47.17**). Ischaemic heart disease increases after menopause, but this occurs 10 years later than in males. HRT is not recommended for the prevention of postmenopausal osteoporosis in the absence of menopausal symptoms. However, patients with premature ovarian insufficiency (menopause before 40 years of age) should be offered HRT until age 50 for bone and cardiovascular protection.

The decision about HRT is individualized and based on:

- Severity of menopausal symptoms
- Individual risk of conditions that may be prevented or made more likely by HRT
- Patient choice.

Patients with a uterus require both oestrogen and progesterone. Oestrogen provides symptomatic relief, and progesterone provides endometrial protection from unopposed oestrogen, which could lead to endometrial hyperplasia or cancer.

Selective oestrogen receptor modulators (e.g., raloxifene) offer a potentially attractive combination of positive oestrogen effects on the bone and cardiovascular system, with no impact on oestrogen receptors of the uterus and breast associated with cancer incidence; however, long-term outcome studies are awaited.

Tibolone is a once-per-day oral synthetic hormone with combined oestrogenic, progestogenic, and testosterone effects branded as the first 'bleed-free' HRT. Tibolone appears to be particularly helpful for patients with endometriosis and fibroids, reducing the risk of hormonally driven disease flares.

Patients with vaginal atrophy are treated with topical oestrogens, supplemented with vaginal moisturisers and lifestyle modifications (unperfumed soaps and products, water-based lubricant before intercourse). Long-term use is often required.

Female urinary incontinence

Urinary incontinence is common in females with overall population prevalence of 25% to 45% across all ages in adulthood. Prevalence increases with age; 40% of females are affected by the age of 70 years with idiopathic detrusor activity, diabetes, mobility, and medication all possible contributors.

Types of urinary incontinence (Box 47.18) include:

- Stress incontinence
- Overactive bladder and urgency incontinence
- Mixed urinary incontinence.

Urinary incontinence negatively impacts quality of life, with many too embarrassed to seek medical help, leading to underreporting and unsustainable individual-led lifestyle modifications, such as avoiding sexual intercourse or public sporting activities.

Lifestyle interventions, including weight loss, smoking cessation, caffeine reduction, and timed fluid restriction, can significantly reduce symptom burden. Physiotherapy and bladder retraining may be helpful in cases of stress and urgency, respectively. In postmenopausal females, oestrogen deficiency exaggerates urinary symptoms, and topical vaginal or systemic HRT are treatment options. Specialist investigations includes pelvic floor assessment, including exclusion of uterine prolapse, urinary tract imaging, and urodynamic evaluation when appropriate. Further management is based on the type of incontinence and the female patient's preferences and future fertility wishes (Box 47.19).

Box 47.18 Types of urinary incontinence in females

- ***Stress incontinence:*** involuntary urine leakage on effort, exertion, sneezing, or coughing
- ***Urge incontinence:*** involuntary urine leakage accompanied or immediately preceded by a sudden compelling desire to urinate that is difficult to delay; can occur with or without overactive bladder syndrome
- ***Mixed urinary incontinence:*** involuntary urine leakage associated with urgency and exertion, effort, sneezing, or coughing
- ***Other:*** overflow incontinence caused by chronic urinary retention, urogenital fistula, or urethral diverticulum

Uterine fibroids (leiomyomata)

These are the most common benign pelvic tumours in females of reproductive age (Fig. 47.6). Prevalence increases with age and is

Box 47.19 Management of overactive bladder and stress urinary incontinence

Order of treatment	Treatment	Mechanism of action	Contraindications	Side-effects
Overactive bladder				
First	**Oxybutynin**	Anticholinergic and mucosotropic	Glaucoma, ulcerative colitis, myasthenia gravis, severe liver impairment	Dry mouth, confusion
Second	**Tolterodine** **Darifenacin**	Anticholinergic and mucosotropic		
Third	**Mirabegron**	Beta-3 adrenoreceptor agonist	Atrial fibrillation	Vaginitis
Overactive bladder: nocturia				
First	**Desmopressin**	V2-agonist	Aged older than 65 years, hypertension, cardiac disease	Fluid retention, hyponatraemia
Second	**Vaginal oestrogen**	Hormone replacement		
Overactive bladder: failed medical treatment				
First	**Botulinum toxin**	Prevention of bladder contraction	Urinary retention	Urinary retention (intermittent self-catheterization needed in 10%–15%)
Second	**Presacral nerve stimulation with an implant**	Excitatory and inhibitory reflexes on the bladder		Infection or migration of the prosthesis
Third	**Posterior tibial nerve stimulation**	Impulses from tibial nerve block abnormal bladder signals		
Fourth	**Surgical reconstruction**			
Stress incontinence				
First	**Duloxetine**	Selective serotonin-noradrenaline reuptake inhibitor	Urinary hesitancy, glaucoma, liver disease	Nausea and vomiting, change in bowel habits, dry mouth, blurred vision, anorexia
Stress incontinence: failed medical treatment				
First	**Burch colposuspension**			5% risk of need for intermittent self-catheterization Risk of developing an enterocoele (14%)
Second	**Autologous rectus fascial sling or bulking agents**			5% risk of need for intermittent self-catheterization
Third	**Tension-free vaginal tape**			Chronic pelvic pain, 10%; dyspareunia, 10%; bladder injury, 4%; mesh erosion, 1%–2%

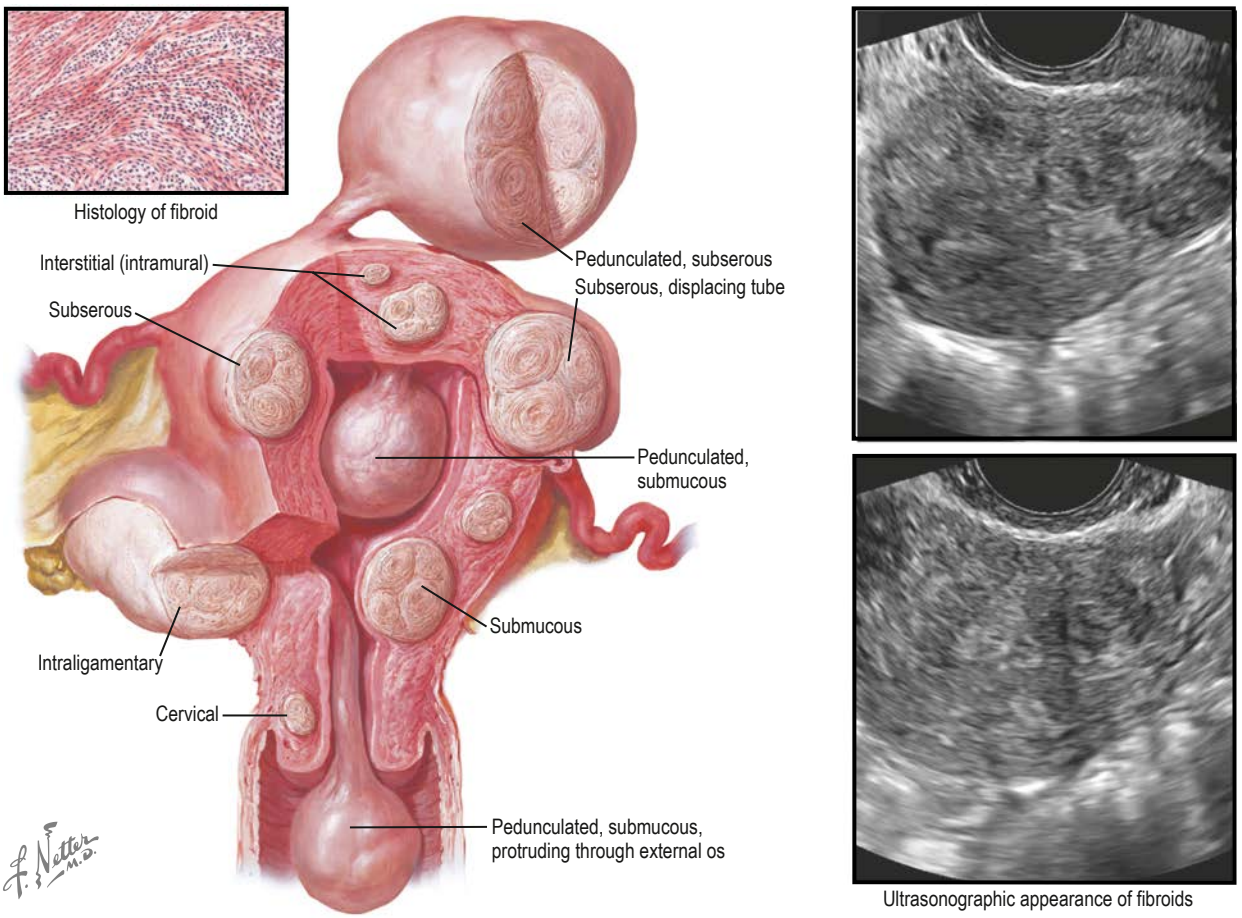

Fig. 47.6 **Uterine fibroids (leiomyomata).**

higher in females of Afro-Caribbean ethnicity. Heavy and prolonged periods, pressure symptoms, and reproductive dysfunction are common presentations. Mechanisms by which fibroids cause HMB are poorly understood, but submucosal lesions within the uterine cavity are particularly troublesome.

Treatment is with:

- Magnetic resonance-guided and -focused ultrasound uterine artery embolization (UAE). Uterine arteries are selectively catheterized via femoral approach, and microbeads are injected until flow is demonstrably reduced. There is a small risk of menopause in which the ovarian circulation arises dominantly from the uterine arteries; this should be screened for with angiography before embolization. Pregnancy after UAE carries an increased risk of abnormal placental implantation; therefore, UAE should generally only be considered if future pregnancy is not intended. Risks of sarcoma with fibroids (0.05%–0.29%) must be presented in a balanced way when considering non-hysterectomy management.
- GnRH agonists can alleviate HMB as a short-term measure, shrinking overall fibroid size and vascularity before surgery.
- Surgical excision. In laparoscopic myomectomy, fibroids are morcellated to allow removal.

Gynaecological malignancy

Gynaecological cancer is any cancer that starts in the female reproductive organs. The five main types of gynaecological cancers are cervical, endometrial, ovarian, vaginal, and vulval cancers (**Box 47.20**). Endometrial and ovarian cancers are most common. Patients with suspected cancers should be referred urgently usually via rapid-access gynaecology or colposcopy clinics, where diagnostic imaging and histology can be obtained.

Endometrial (uterine) cancer is the fourth most common cancer in females in the UK. Most cases present with postmenopausal bleeding. This is considered a 'red flag' symptom with 5% to 10% caused by endometrial cancer. It is estimated that 34% of endometrial cancer cases are preventable. Obesity is a contributing factor; increased peripheral androgen conversion to oestriol in adipose tissue leads to unopposed oestrogen action on the endometrial lining.

Ovarian cancer is the fifth most common cancer in females in the UK. Most occurs in postmenopausal females. Presentation is with late, non-specific symptoms, including abdominal pain, bloating, and weight loss. Management is with specialist surgery and chemotherapy.

Cervical cancer is the 14th most common cancer in females in the UK. Almost all (99.8%) are caused by HPV infection. National cervical cancer screening aims to detect high-risk infections. Females and males aged 12 to 13 years are offered HPV vaccination in the UK; a consequent reduction in incidence of cervical carcinoma *in situ* is already evident.

The management of gynaecological malignancies in discussed in Chapter 41.

Box 47.20 Key clinical characteristics of cervical, endometrial, and ovarian cancers

Cancer	Cervical	Endometrial	Ovarian
UK incidence (cases/year)	3200	9700	7500
5-year survival rate (%)	65	75	46
Peak age of incidence (years)	30–34	75–79	75–79
Ethnicity	Higher mortality rates in minority ethnic populations (excluding White minorities)	Higher incidence in Black ethnic groups Higher mortality rates in minority ethnic populations (excluding White minorities)	
Risk factors (percent of tumours with risk factor)	HPV (>99%) Smoking (21%) HIV	Obesity (34%) Diabetes Endometrial polyps or hyperplasia Unopposed oestrogen PCOS	Genetic (5%–15%): e.g., *BRCA1/2* Obesity (7%) Hormone replacement therapy Endometriosis Diabetes
UK screening	HPV testing for females: every 3 years for ages 25–49 years; every 5 years for ages 50–64 years	None	None; long-term follow-up data awaited
Presenting symptoms	Postcoital bleeding Intermenstrual bleeding Dyspareunia Vaginal discharge Pelvic pain	Postmenopausal bleeding Intermenstrual bleeding Vaginal discharge	Early satiety Loss of appetite Abdominal pain Abdominal bloating Urinary frequency Fatigue Unexplained weight loss Change in bowel habit
Common stage at presentation	1	1	1 in 31%; 3 in 31%
Diagnosis	Cervical biopsy	Endometrial biopsy: target biopsy at hysteroscopy, endometrial Pipelle biopsy	Ultrasonography of the pelvis; CT

CT, Computed tomography; *HIV,* human immunodeficiency virus; *HPV,* human papillomavirus; *LLETZ,* large loop excision of transformation zone; *PCOS,* polycystic ovarian syndrome.

Domestic abuse and violence

Domestic or intimate partner violence includes physical, sexual, emotional, psychological, and emotional abuse and is a significant public health problem. It negatively impacts physical, mental, sexual, and reproductive health and increases the risk of acquiring human immunodeficiency virus (HIV). The WHO estimates that 30% of females worldwide have been subjected to physical or sexual intimate partner violence or non-partner sexual violence in their lifetimes. One in four females in England and Wales experience domestic abuse or violence. Domestic violence accounts for one-third of violent crimes, costing an estimated £23 billion per annum in the UK alone. The recent SARS-CoV-2 pandemic lockdowns highlighted pre-existing domestic abuse problems with an increase in partner and family abuse. Females in poverty, females from minority ethnic groups, trafficked people, and sex workers are more likely to experience violence and abuse. The odds of being a victim of violence are twofold higher in females with physical disabilities and threefold higher in those with mental health conditions. Around 30% of domestic abuse begins or escalates during pregnancy. The prevalence of domestic violence in females requesting a termination of pregnancy is six times higher than among females attending antenatal clinics. Domestic abuse is the second leading cause of trauma during pregnancy after road traffic accidents, with multiple sites of injury likely. Victims of domestic abuse are significantly more likely to commit suicide.

Domestic violence and abuse are serious health concerns. Healthcare professionals are particularly well placed to identify abuse and intervene; 80% of survivors seek help from health services, with victims commonly presenting to emergency medicine, psychiatry, obstetrics, gynaecology, and primary care services. All healthcare workers need to be trained to recognize signs of violence and abuse, use targeted questioning, and know how to act and refer to ensure safety. Key actions to reduce violence against females include:

- ***Protection*** via an effective criminal justice system: investigation, prosecution, victim support or protection, and perpetrator programmes
- ***Provision*** to allow people to continue with their lives: effective advice and support, emergency and acute services, refuges, and safe accommodation
- ***Prevention*** of violence and addressing attitudes toward violence, including awareness campaigns, safeguarding, early identification, and education

Box 47.21 Classification of female genital mutilation

Type	Definition
I	Partial or total removal of the clitoris, the prepuce (clitoridectomy), or both
II	Partial or total removal of the clitoris and the labia minora, with or without excision of the labia majora (excision)
III	Narrowing of the vaginal orifice with creation of a covering seal by cutting and appositioning the labia minora, the labia majora, or both, with or without excision of the clitoris (infibulation)
IV	Other harmful procedures to the female genitalia for non-medical purposes, e.g., pricking, piercing,[a] incising, scraping, and cauterizing

[a]Piercing is part of World Health Organization classification, but the legal status is unclear in the UK.

World Health Organization. Eliminating female genital mutilation: an interagency statement. Geneva: World Health Organization; 2008.

Female genital mutilation

Female genital mutilation (FGM) refers to all procedures involving partial or total removal of external female genitalia or injury to the female genital organs for non-medical reasons. The different classifications of FGM are shown in **Box 47.21**. More than 200 million females have been subjected to FGM in the 30 countries in Africa, the Middle East, and Asia where FGM is concentrated. In the UK, it is estimated that around 137 000 females have undergone FGM, and 60 000 females younger than 15 years of age are at risk. FGM was made illegal in the UK by the Female Genital Mutilation Act of 2003.

FGM has wide-ranging sequelae. Immediate complications include pain, abscess formation, sepsis, tetanus, haemorrhage, urinary retention, and blood-borne virus transmission. Chronic sequalae include dyspareunia, chronic pain, dysmenorrhoea, UTI and urinary outflow obstruction, post-traumatic stress disorder, and difficulty conceiving. In pregnancy, FGM is associated with increased risks of prolonged labour, postpartum haemorrhage, perineal trauma, caesarean delivery, an increased need for neonatal resuscitation, and risks of stillbirth and early neonatal death.

Management of patients with FGM involves a specialist multidisciplinary team. De-infibulation is a minor surgical procedure that divides the scar tissue at the vaginal introitus in type 3 FGM. It can be performed in the elective clinical setting or intrapartum by a trained health professional.

MALE HEALTH

History

An accurate, detailed history of lower urinary tract symptoms (LUTS) includes exacerbating factors and the impact on quality of life. Storage and voiding symptoms can be distinguished (**Box 47.22**). Understanding whether a patient has one or both help determine the underlying pathology and necessary treatment

- *Storage LUTS* are caused by disorders that affect storage of urine due to irritation or inflammation of the bladder lining: lower urinary tract infection (UTI), cystitis, sexually transmitted infection, bladder stones, neurological conditions (e.g., spinal cord damage), consumption of bladder irritants (e.g., caffeine), prostatitis.
- *Voiding LUTS* are caused by disorders that affect voiding. Benign and malignant prostate diseases are most common. 'Overflow' voiding is the frequent passage of small volumes of urine, which may be accompanied by lower abdominal pain, tenderness, and a palpable bladder. Involuntary urinary leakage and nighttime incontinence (nocturnal enuresis) require exclusion of high-pressure chronic urinary retention. Obstructive nephropathy and irreversible kidney damage can result if diagnosis is delayed.

Patient-reported outcome measures can be used to objectively capture and record the experience of symptoms. These remove physician bias and provide numerical data that can be helpful in medical research. Examples include the International Prostate Symptom Score (IPSS; see later) and the International Consultation on Incontinence Urinary Incontinence Short Form (ICIQ-UI SF).

Examination

Digital rectal examination

Complete examination includes inspection and palpation of external genitalia and a digital rectal examination (DRE) of the prostate and for anorectal abnormalities. Informed consent is required, and a chaperone should be offered. The patient should lie in a lateral position with the hips and knees flexed to allow inspection of the anus. Lubricant jelly should be used for insertion of the examiner's gloved finger. The finger is then rotated anteriorly to examine the prostate (**Fig. 47.7**). A fleshy or soft-feeling prostate is likely to be benign, whereas a hard

Box 47.22 Lower urinary tract symptoms

Storage symptoms

Dysuria: pain or burning on urination
Frequency: passing small volumes of urine at frequent intervals
Urgency: a sudden urge to pass urine
Urge incontinence: urgency leading to involuntary loss of urine
Nocturia: waking at night to pass urine

Voiding symptoms (usually in males)

Hesitancy: a longer than usual wait for urine flow to begin
Weak stream: a reduction in urine flow
Intermittency: urine flow that stops and starts
Terminal dribbling: weak urine flow continues after an attempt is made to stop
Straining: the need to increase abdominal pressure to urinate

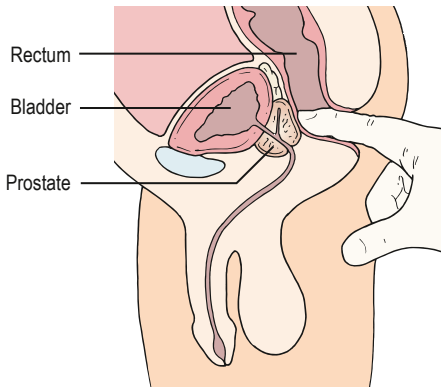

Fig. 47.7 Digital rectal examination. A gloved, lubricated index finger is inserted into the rectum to feel the prostate, which lies anteriorly. (*From Scully C.* Scully's Handbook of Medical Problems in Dentistry. *Elsevier; 2016, with permission.*)

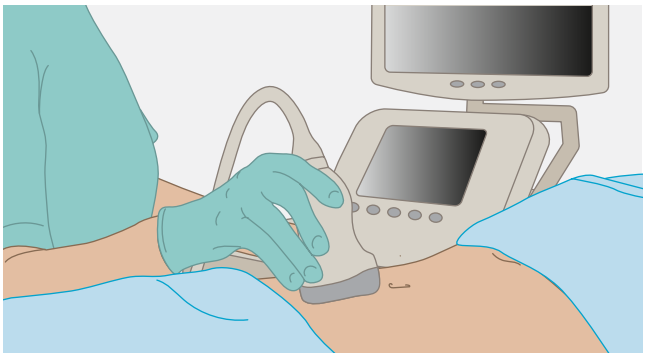

Fig. 47.8 Portable bladder scanner.

Box 47.23 Bladder scanning technique

1. Switch on the bladder scanner.
2. Apply aqueous gel to the head of the transducer.
3. Palpate the symphysis pubis and place the scanner 3 cm above this, pointing down into the pelvis.
4. Hold the transducer steady while pressing the scanning button. The bladder volume is shown on the screen.
5. Repeat the procedure three times, with slight alterations in the position of the transducer.
6. Record the highest volume in the patient's medical record.

or craggy gland is more likely to be malignant. Prostate size can be crudely estimated by measuring the 'finger widths' of the prostate and multiplying it by 10 to provide the approximate size in millilitres. Prostate size assessment by DRE can be correlated with more precise measurements from MRI and transrectal ultrasound examination while the skill is learnt. Tenderness when pressing on the prostate may indicate prostatitis.

Box 47.24 Male catheterization

1. Obtain consent.
2. Use an aseptic no-touch technique.
3. Clean the glans penis with antiseptic solution.
4. Instill lidocaine anaesthetic gel into the urethra.
5. After 5 minutes, insert an appropriately sized catheter (generally 14, 16, or 18 Fr) through the external urethral meatus. When the catheter is inserted to the hilt, urine drains out.
6. Inflate the catheter balloon with 10 mL of saline and withdraw the catheter until the balloon is snug against the bladder neck.
7. Note the volume of urine drained.
8. Replace the foreskin, if present, over the glans penis.

Fig. 47.9 Male catheterization of a mannequin. (*From O'Neill P et al, eds.* Macleod's Clinical OSCEs. *Elsevier; 2016, with permission.*)

Bladder scanning

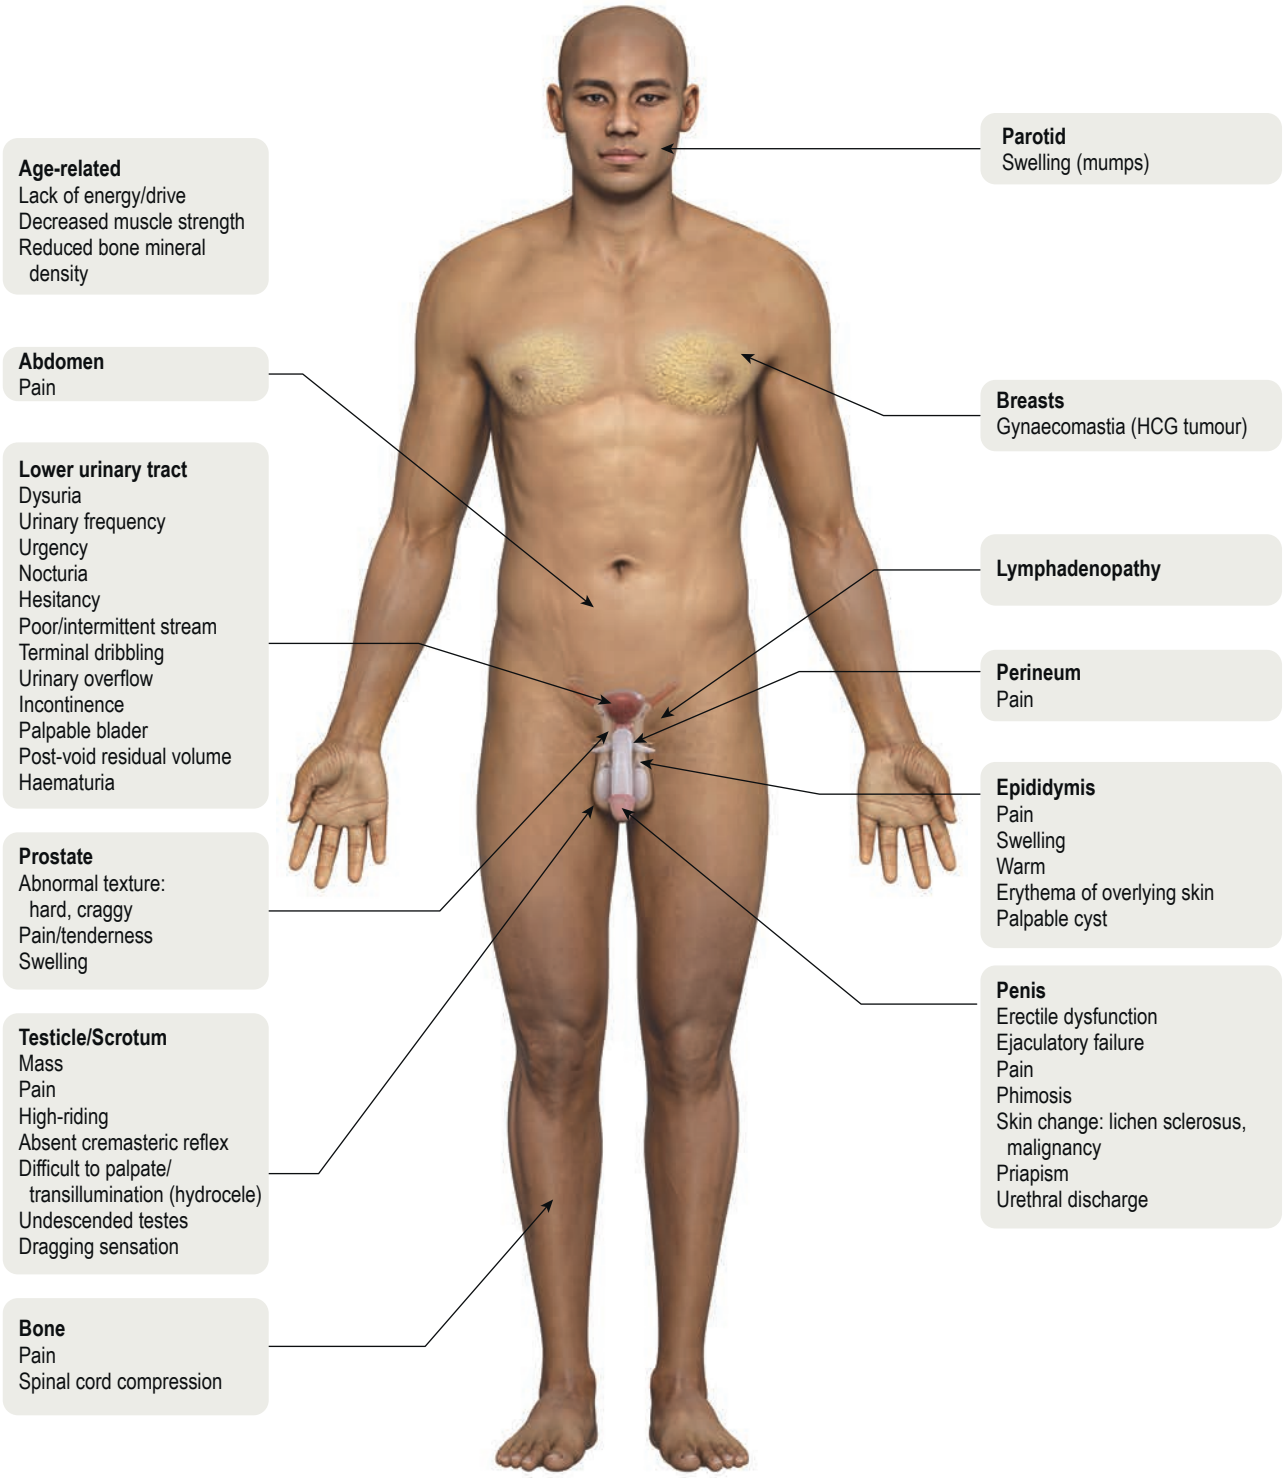
Portable bladder scanners use ultrasound technology to assess bladder volume at the bedside without a requirement for formal training (Fig. 47.8 and Box 47.23). Bladder scans can be used for:

- Diagnosis of urinary retention
- Assessment of successful voiding after catheter removal
- Assessment of complete voiding (post-void residual)

Acute urinary retention is the painful inability to void. Bladder volumes of up to and above 1 L are possible. Urgent urethral catheterization is required (Box 47.24 and Fig. 47.9). A bladder volume of more than 150 mL after attempted voiding is considered significant.

Chronic urinary retention is defined as a painless post-void residual greater than 300 mL, though volumes may be more than this.

Insertion of a urethral catheter is a key clinical skill.



Benign conditions of the prostate

The prostate is an accessory gland of the male reproductive system located under the bladder, through the centre of which passes the first part of the urethra. Alongside the seminal vesicles and other lesser accessory glands, the prostate contributes a small component of the seminal fluid, which helps mature spermatozoa through processes such as semen liquification and sperm head capacitation.

Prostatitis

Prostatitis describes inflammation of the prostate gland. It is divided into three types:

- Acute bacterial prostatitis
- Chronic bacterial prostatitis
- Chronic abacterial prostatitis (a pelvic pain syndrome)

Acute bacterial prostatitis

This condition presents with dysuria, frequency, malaise, fever, and genital region pain. The prostate is swollen and tender on examination. A fluctuant prostate indicates an abscess that warrants either transurethral or transperineal drainage. Infectious agents include Gram-negative uropathogens (chiefly *Escherichia coli*) and organisms that cause STI such as *C. trachomatis* and *Neisseria gonorrhoeae*. Antibiotic treatment is required to prevent sepsis and abscess formation.

Chronic bacterial prostatitis

This is defined as bacterial prostatitis when symptoms persist beyond 3 months. Pain, voiding dysfunction, and ejaculatory problems are the typical features. Longer courses of oral antibiotics with good prostate penetration (e.g., fluoroquinolones) should be prescribed, with awareness of side-effects, including tendinopathy.

Chronic abacterial prostatitis

Chronic abacterial prostatitis is a cause of chronic pelvic pain, the aetiology and pathophysiology of which are poorly understood. Symptoms are present for more than 3 months with no evidence of bacterial colonization in blood, urine, semen, and expressed prostate secretions captured at the time of cystoscopy and prostate massage. The condition generally occurs in males aged 30 to 50 years. Clinical features wax and wane over several years with pain being the main feature but typically include a combination of pain, urinary symptoms, and sexual dysfunction. Pain can be experienced in the penis, scrotum, perineum, or anus. Voiding difficulties are common. Dynamic obstruction to urinary flow can occur in the absence of prostate enlargement, attributed to high levels of adrenergic tone in the smooth muscle of the bladder neck and prostatic urethra. There may be erectile dysfunction or pain on ejaculation. Treatment can be difficult. Options include antibiotics (even in the absence of microbiologically proven infection), low-dose phosphodiesterase-5 (PDE-5) inhibitors (e.g., tadalafil), alpha-blockers (e.g., tamsulosin), 5-alpha-reductase inhibitors (e.g., finasteride), and NSAIDs. Exercise, dietary modification, stress management, relaxation, identification and avoidance of lifestyle triggers, psychotherapies such as CBT, and low-dose amitriptyline may all be beneficial. Chronic pain expertise may be required.

Benign enlargement of the prostate gland

Benign enlargement of the prostate is a very common condition. It occurs most often in males after the age of 60 years. In young males, the normal size of the prostate is 16 mL. Prostatomegaly (enlargement of the prostate) is defined as prostate volume of more than 30 mL. The relationship between prostate size and symptom severity is not reliable nor linear, but the frequency of males requiring intervention does increase with prostate size, particularly when prostate volumes are greater than 100 mL. Endogenous androgens have a key role in pathogenesis, with an absence of prostate enlargement in males with hypogonadism (e.g., Klinefelter syndrome; 47,XXY). The histological appearance is benign hyperplasia affecting glandular and connective tissue elements of the prostate transition zone (the proximal and upper part of the gland that surrounds and can compress the urethra). Enlargement of the prostate gland stretches and distorts the urethra, obstructing bladder outflow.

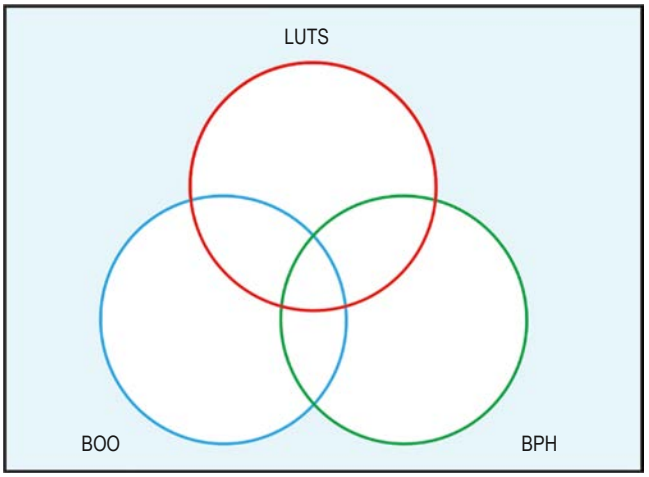


Fig. 47.10 Hald's rings. The three-ring diagram portrays benign prostatic hyperplasia (BPH) as a syndrome of three overlapping yet distinct entities: benign prostatic hyperplasia or enlargement (BPH, *green ring*), bladder outflow obstruction (BOO, *blue ring*), and lower urinary tract symptoms (LUTS, *red ring*).

Symptoms: Frequency of urination, often first noted as a single episode of nocturia, is a common early symptom. Voiding LUTS include hesitancy in initiating urination, a reduced or intermittent urine stream, and post-void dribbling. As the prostate causes bladder outflow obstruction and the pressure required to void increases, hypertrophy of the bladder detrusor muscle can contribute to secondary symptoms including frequency, urgency, and urge incontinence. Hald's rings (Fig. 47.10) provide a diagrammatic conceptual framework to show how symptoms, bladder outflow obstruction, and microscopic tissue changes within the prostate interplay. Acute retention of urine or retention with overflow incontinence may occur. Occasionally, haematuria results from rupture of prostatic veins or because of bacteriuria or bladder stone disease, which occur in conjunction with prostate enlargement. The severity of symptoms is assessed by the IPSS, based on seven questions about urinary symptoms and one question concerning quality of life (Box 47.25). The IPSS is a common patient-reported outcome measure used in the assessment and treatment of male LUTS, reducing clinician bias.

Examination: Abdominal examination for bladder enlargement is performed to exclude urinary retention. DRE is performed as an indicator of prostate size. A benign prostate characteristically feels smooth and firm.

Investigations should include:

- Urine dipstick, microscopy, and culture
- Serum prostate-specific antigen (PSA) concentration
- Kidney function
- Ultrasonography of the kidney, ureters, and bladder with prostate size estimation
- Measurement of urinary flow rate and post-void residual volume.

Treatment: In acute retention or chronic retention with overflow, the priorities are to relieve pain and/or drain the bladder to prevent damage to the kidneys. Both of these aims can be achieved by inserting a urinary catheter. If urethral catheterization is impossible, a suprapubic catheter can be placed.

Box 47.25 The International Prostate Symptom Score

Symptoms

Each question is answered on a Likert score from 0 (not at all) to 5 (almost always over the preceding month).

- Incomplete emptying: How often do you experience incomplete emptying?
- Frequency: How often do you have to urinate again within 2 hours?
- Intermittency: How often do you stop and start during urination?
- Urgency: How often have you found it difficult to postpone urination?
- Weak stream: How often have you had a weak urinary stream?
- Straining: How often have you had to push or strain to begin urination?
- Nocturia: How many times do you typically get up to urinate during the night?

Quality of Life

If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about it? 0 (delighted) to 6 (terrible)

Score: 0 = asymptomatic, 1–7 = mildly symptomatic, 8–19 = moderately symptomatic, 20–35 = severely symptomatic.

Box 47.26 Management of benign prostatic enlargement

Mild symptoms

Lifestyle change: attention to amount and types of fluid ingested

Moderate symptoms

- Alpha-blocker (e.g., tamsulosin): relax prostate and bladder smooth muscle tone
- 5-α-reductase inhibitor (e.g., finasteride): block conversion of testosterone to dihydrotestosterone, which drives prostatic growth
- Combination therapy: e.g., alpha-blocker with an anticholinergic for concomitant overactive bladder

Surgical options

- Transurethral resection of the prostate
- Laser therapy: enucleation or vaporization
- Open prostatectomy: uncommon in high- and middle-income settings because of the availability of laser therapy

Management of benign prostatic enlargement is outlined in **Box 47.26**. The balance between benefits and risks of treatment is largely determined by the degree to which the patient is affected by their symptoms. This can be captured in the IPSS, including an evaluation of how the symptoms impact on quality of life. Typically, medical management includes alpha-blockers (e.g., tamsulosin), 5-alpha reductase inhibitors (e.g., finasteride), anti-cholinergics (e.g., solifenacin), or beta-3 sympathomimetics (e.g., mirabegron). Medical management is considered first-line treatment when symptoms are mild or moderate and when the risks of surgery are high or unacceptable to the patient.

Surgery is reserved for those who develop high-pressure chronic retention of urine requiring catheterization (which cannot be removed without surgical relief of obstruction) and for significant LUTS refractory to lifestyle measures and medication. The type of surgical intervention is based on symptoms, potential side-effects, size of the prostate, safety of general anaesthesia, bleeding risk, and use of concomitant anticoagulation (and the safety of withholding this). Although numerous minimally invasive surgical treatments are available, transurethral resection of prostate is most often performed. It requires a catheter and an overnight stay for most patients. Ejaculatory dysfunction can occur. It is more difficult to perform when the prostate volume is more than 80 mL, when preferential treatment is with enucleation (preferably endoscopically with a laser, e.g., holmium laser enucleation of the prostate), or using open surgical techniques.

Box 47.27 Age-specific prostate-specific antigen (PSA) concentrations requiring investigation for prostate cancer in symptomatic males

Prostate cancer

Prostate cancer accounts for 7% of male cancer and is the sixth most common cancer in the world. In the UK, there are 47 000 new cases per year, representing 1 in every 8 males, with 12 000 deaths per year. The risk of prostate cancer increases with age: 58% of those diagnosed with prostate cancer were 70 years or older in 2022. By the age of 80 years, 80% of males have malignant foci within the gland. Risk is increased in those with a family history of prostate (two to three times the risk for a first-degree relative) or breast cancer and in males of Black ethnicity, for whom the risk is one in four. Histologically, the cancer is almost invariably an adenocarcinoma.

Pathogenesis: Genome-wide association studies have identified more than 100 single-nucleotide polymorphisms associated with prostate cancer. The homeobox gene *HOXB13* predisposes to prostate cancer, and the *BRCA2* gene increases risk by five to seven times.

Clinical features and diagnosis: Most patients with early prostate cancer do not have any symptoms. LUTS may be due to concomitant benign enlargement. The diagnosis is suggested by an increase in serum PSA concentration or an abnormal prostate on examination. Late symptoms of metastatic disease include bone pain, malignant spinal cord compression, abdominal pain caused by hypercalcaemia, weight loss, and anaemia. In 2022, 17% of males diagnosed with prostate cancer had metastatic disease, many with radiological rather than symptomatic metastases at presentation.

PSA is a seminal fluid protein produced exclusively in the prostate and by cancerous prostate cells within the gland and when they metastasize. However, a high PSA concentration is not specific for prostate cancer. It is also associated with benign enlargement of the prostate, thus making it an imperfect screening test. PSA concentration is not currently recommended in the UK as a screening test for prostate cancer in asymptomatic patients. In males with possible symptoms of prostate cancer, PSA thresholds for referral and investigation are available (**Box 47.27**).

Multiparametric MRI (mpMRI) is a contemporary tool use to diagnose prostate cancer. Before the advent of mpMRI, random (typically transrectal) sampling of the prostate led to missed diagnosis and overdiagnosis of 'clinically insignificant' prostate cancer (i.e., indolent disease that did not require intervention). mpMRI can avoid the need for prostate biopsy while improving cancer detection rates. When biopsy is undertaken, transperineal biopsy is now more common than transrectal biopsy. This reduces infection because

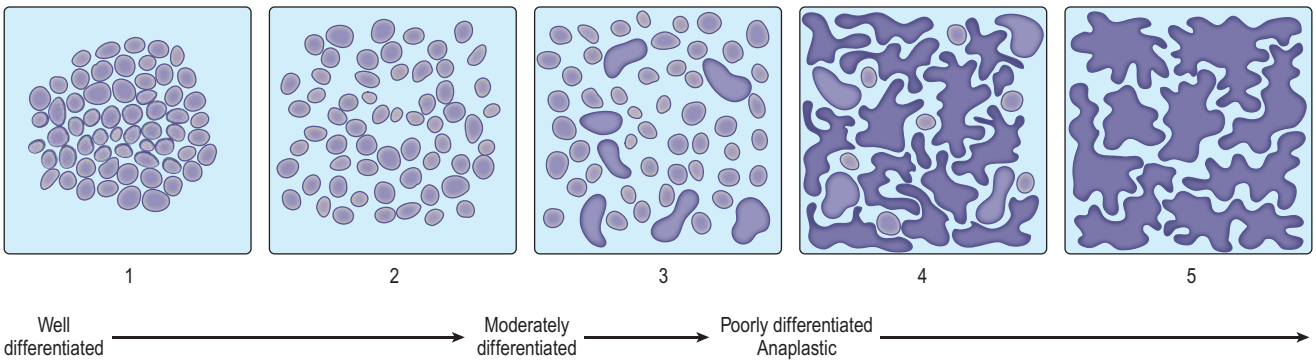

Fig. 47.11 Gleason's pattern scale. The Gleason is a grading scale that runs from 1 to 5, the number indicating the extent of differentiation of the adenocarcinoma cells of the prostate. Because of the multifocal and heterogeneous nature of prostate cancer, the Gleason score is calculated by adding together the two most prevalent grades. A Gleason score of 2 to 6 is considered well differentiated, Gleason 7 is moderately differentiated, and Gleason 8 to 10 is poorly differentiated. *(1)* Small, uniform glands. *(2)* More space (stroma) between glands. *(3)* Distinct infiltration of cells from glands at the margins. *(4)* Irregular masses of neoplastic cells with few glands. *(5)* Lack of pr occasional glands and sheets of cells. Box 47.28 European Association of Urology risk groups for biochemical recurrence of localized and locally advanced prostate cancer after radical treatment

Risk	Low	Intermediate	High	
PSA (ng/mL)	<10	10–20	>20	Any
Biopsy grade	GS <7 (ISUP grade 1)	GS 7 (ISUP grade 2 or 3)	GS >7 (ISUP grade 4 or 5)	Any GS (any ISUP)
Clinical staging based on DRE	T1-2a: limited to less than half of one side of the gland	T2b: within half of the gland	T2c: both sides of the gland	T3-4: extraprostatic (or nodal metastases on CT scan)
Terminology	Localized			Locally advanced

CT, Computed tomography; *DRE,* digital rectal examination; *GS,* Gleason score; *ISUP,* International Society of Urological Pathologists; *PSA,* prostate-specific antigen.

the biopsy needle passes through the colonic mucosa, avoiding inoculation with rectal flora. Prostate cancer commonly metastasizes to bone. Bone metastases appear as osteosclerotic lesions on plain radiography and are also detected by isotopic bone scans.

Prognosis: Histological appearances are graded according to the combined Gleason score (**Fig. 47.11**). The International Society of Urological Pathologists grade group score is used to classify aggressivity of the histological pattern seen. This is combined with serum PSA concentration and accurate T staging of local disease with imaging or final prostatectomy specimen (if radical prostatectomy has been performed) to identify prognostic groups (**Box 47.28**). The long-term prognosis for patients with organ-confined prostate cancer is extremely good: 97% of males survive to 15 years after diagnosis. Treatment decisions therefore balance performance status and age with the predicted behaviour of the cancer (with developments in gene profiling for improved prognostication awaited).

Treatment: In the UK, treatment options are determined by multidisciplinary clinical teams and informed patients (see Chapter 41). A key priority is the avoidance of unnecessary overtreatment (the rate of which has fallen to 7% in the UK). Discussions between patients and clinicians are vital to enable appropriate treatment. Active surveillance entails regular PSA tests and usually yearly mpMRI, with repeat prostate biopsies performed if either test suggests a change that may warrant treatment.

Patients with localized disease that requires treatment are managed with curative intent. In the UK, this most commonly robot-assisted radical prostatectomy, external-beam radiotherapy, or brachytherapy with radioactive iodine implants. All achieve equivalent survival but differ in the spectrum of side-effects, including incontinence and sexual dysfunction. Radiotherapy tends to be used in patients who wish to avoid surgery. Traditionally, therapies with curative intent have targeted the whole gland. However, there is a developing body of evidence for focal therapies, comparable to a 'lumpectomy' for breast cancer. High-intensity focused ultrasound and cryotherapy can be used to ablate part of the prostate harboring a cancer. Treatment of locally advanced and metastatic disease uses endocrine therapy to achieve androgen blockade, alongside systemic chemotherapy (see Chapter 41).

Diseases of the penis

Phimosis

Phimosis is a condition in which the contracted foreskin (prepuce) has a tight, narrow orifice and cannot be retracted over the glans of the penis (Fig. 47.12). A physiological phimosis is present at birth, but penile growth, erection, movement, and accumulation of epithelial debris (smegma) under the foreskin lead to separation, enabling the foreskin to be retracted. By the age of 17 years, only 1% of males have phimosis. Although physiological phimosis is usually asymptomatic, patients may present with ballooning of the foreskin with urination, and there may be trauma to the foreskin during coitus.

Phimosis is typically pathological in adults. Pathological phimosis secondary to infection or inflammatory conditions may cause pain, dysuria, bleeding, or pus discharge from the orifice. Pathological phimosis can be caused by recurrent balanitis (inflammation of the glans penis). In genital lichen sclerosus, hypopigmentation or discoloration of the foreskin is typically associated with pruritic plaques on the foreskin and glans. Severe genital lichen sclerosus is sometimes termed 'balanitis xerotica obliterans' because of the dry glans appearance with destructive changes to architecture. Non-surgical managements include routine attempts at gentle retraction, avoidance of irritant soaps, and topical low-potency corticosteroids. Any infection contributing to phimosis should be treated. If these measures are ineffective, the mainstay of treatment for adults is circumcision. In children, phimosis is usually physiological; the foreskin will invariably become retractile and loosen with age. Indications for circumcision in children include lichen sclerosus, recurrent balanitis, and recurrent UTIs in association with urinary tract abnormalities (e.g., vesico-ureteric reflux, posterior urethral valves, neuropathic bladder dysfunction) because circumcision reduces the frequency of UTI.

Paraphimosis

Paraphimosis is an inability to return retracted foreskin to its resting position (see Fig. 47.12). This can progress to become a urological emergency. Prolonged retraction produces a tight ring of tissue proximal to the corona of the glans. Venous congestion, oedema, and swelling of the glans can then progress to arterial occlusion and necrosis, analogous to compartment syndrome. Treatment of

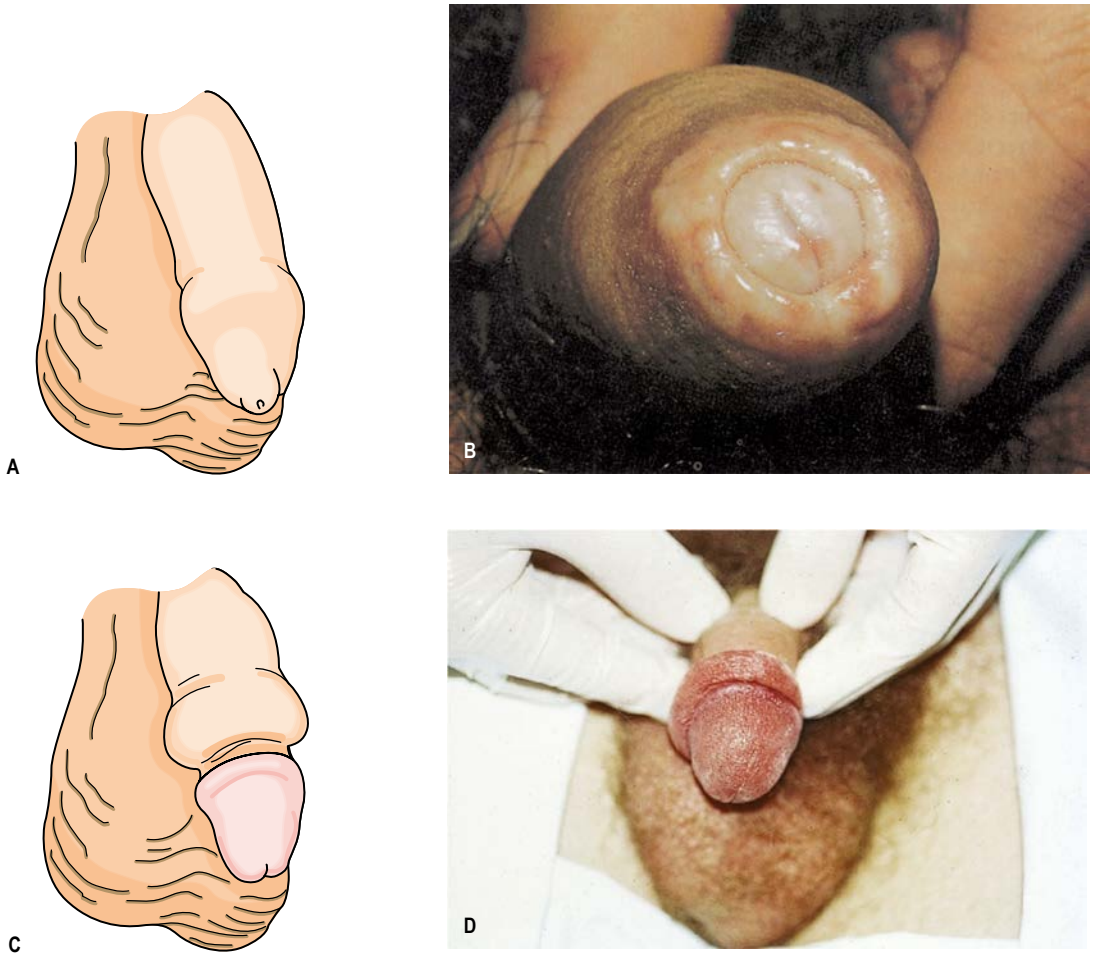

Fig. 47.12 Phimosis and paraphimosis. **(A)** Phimosis: the foreskin has a narrow opening that is not large enough to permit retraction over the glans. **(B)** Phimosis: lesions on the prepuce secondary to infection cause swelling, and retraction of the foreskin may be impossible. Circumcision is usually required. **(C)** Paraphimosis: the foreskin is retracted over the glans but cannot be reduced to its normal position. Here it has formed a constricting band around the penis. **(D)** Oedematous foreskin is the result of paraphimosis. (*From Roberts JR, Hedges JR.* Clinical Procedures in Emergency Medicine*, 5th edn. Saunders; 2009.*)

paraphimosis is with persistent manual compression of the oedematous glans with subsequent attempts to return the retracted foreskin to its normal position. If this manoeuvre fails, a dorsal slit or circumcision is definitive management.

Priapism

Priapism is a prolonged penile erection (>4 hours) maintained without sexual stimulation and persistent despite ejaculation or orgasm. Priapism is a urological emergency requiring an accurate diagnosis and urgent intervention. The two subtypes of priapism are:

- Ischaemic priapism ('low-flow'; more common). This is painful failure of blood supply to the corpora cavernosa caused by sickle cell disease, occult malignancy (priapism with no explanatory features should be investigated for cancer of unknown origin), treatment for erectile dysfunction, or recreational drugs.
- Non-ischaemic priapism ('high-flow'; rare) is caused by a fistula between an artery and the corpora cavernosa and is typically painless. It can occur after perineal or penile injury (e.g., a fall astride a bicycle).

It is important to distinguish ischaemic priapism because prompt intervention to achieve penile detumescence is required to prevent irreversible tissue damage and lifelong erectile dysfunction.

Penile cancer

More than 95% of penile malignancies are squamous cell carcinomas arising from the epithelium of the inner prepuce or the glans. Penile cancer is rare in high-income countries, with an incidence of around 1 per 100 000 in Europe and the USA. In contrast, in South America, South-east Asia, and parts of Africa, the incidence is higher with penile cancer accounting for 1% to 2% of male malignancies. Penile cancer increases with prevalence of HPV most commonly HPV subtypes 6, 16, and 18. Other risk factors include smoking, genital lichen sclerosis, multiple sexual partners, HIV infection, and exposure to ultraviolet light for treatment of psoriasis (rare). Neonatal circumcision reduces the frequency of penile cancer.

The aims of treatment are tumour removal with as much organ and functional preservation as possible to minimize the impact on quality of life. Local recurrence has little influence on long-term survival, so organ preservation strategies are justified. When penile cancer is suspected, examination for groin lymphadenopathy is important. Penile cancer metastasizes in a stepwise manner through the lymphatic system from inguinal to pelvic to distant nodes. Fewer than 5% of patients present with metastases, which have a poor prognosis. The most important prognostic indicator of survival in penile cancer is the presence and extent of nodal metastases with a 5-year survival of approximately 95% for no positive node metastases, 80% for one positive node, 65% for multiple or bilateral lymph node, and 35% for immobile pelvic nodes or when cancer breaches the capsule of the lymph node.

Because penile cancer is rare, management in the UK is centralized to a small number of higher volume referral centres with experience and expertise. When cancer is limited to the prepuce, circumcision can be curative. When the skin of the glans penis is involved, circumcision is necessary alongside treatment options to the lesion, including surgical removal (e.g., excision biopsy, glans resurfacing, glansectomy), liquid treatment (e.g., imiquimod), or superficial laser treatment (e.g., carbon dioxide laser). If the cancer has invaded the deeper structures of the penis, surgical treatment is more extensive. Radiotherapy is rarely used in the UK. Chemotherapy is reserved for cancers with proven metastatic spread.

Testicular and spermatic cord disease

Testicular torsion

Testicular torsion is the lateral to medial inward twisting of the spermatic cord ('torsion twists toward'). This results in strangulation of the blood supply to the testis and the epididymis and is a time-sensitive urological emergency. Testicular torsion occurs most often in the neonatal period and around puberty with peak incidence at 13 to 15 years of age, though it can infrequently occur outside of these ages. Typical presentation a short history (<12 hour) of severe, sudden-onset hemiscrotal pain, which can wake the person from sleep. Pain can radiate to the groin, loin, or epigastrium; cause nausea and vomiting; and lead to an altered, broad-based, 'cowboy' gait. On examination, the classical finding is an absent cremasteric reflex, though this is unreliable in older children and adults. The testicle may be swollen, tense, and exquisitely tender. The testicle may be high riding and in a horizontal lie. Elevation of the testicle does not ameliorate symptoms (negative Prehn's sign). Clinicians should be aware that individual patient circumstances, delays in presentation, and provision of analgesia can obfuscate symptoms and signs. The diagnosis is usually clinical. Doppler ultrasound examination cannot rule out testicular torsion and delays definitive treatment, so it should not be relied on in acute presentations. Management is immediate surgical exploration in patients presenting with less than 24 hours of pain. Delay can result in permanent ischaemic damage and potential loss of the testis. Surgical detorsion (untwisting the spermatic cord) and bilateral orchidopexy (fixation of the testicle to prevent recurrent torsion) are performed in the presence of a viable testicle. If the testicle is non-viable, orchidectomy and contralateral orchidopexy are carried out.

Epididymitis and orchitis

Epididymitis is an inflammatory condition of the epididymis and can be acute or chronic. Often, in the context of infection, inflammation involves the testis at the same time and is termed 'epididymo-orchitis'. Epididymitis is usually caused by a bacterial infection that ascends from the urethra or the bladder. In sexually active males, the infective organism is usually *N. gonorrhoeae*, *C. trachomatis*, or a coliform bacterium. In older males and children, infective organisms are more commonly urinary tract pathogens such as *E. coli*. Viral mumps orchitis can occur, and the patient's vaccination history should be determined.

Acute presentations can mimic testicular torsion though systemic features (e.g., fever) and local symptoms (e.g., preceding dysuria, urethral discharge, urinary frequency) may be helpful distinguishers. The duration of pain is usually longer than that of testicular torsion and has a gradual onset. On examination, the patient may have a fever and appear systemically unwell. The epididymis will be tender and swollen on palpation. If examination is performed

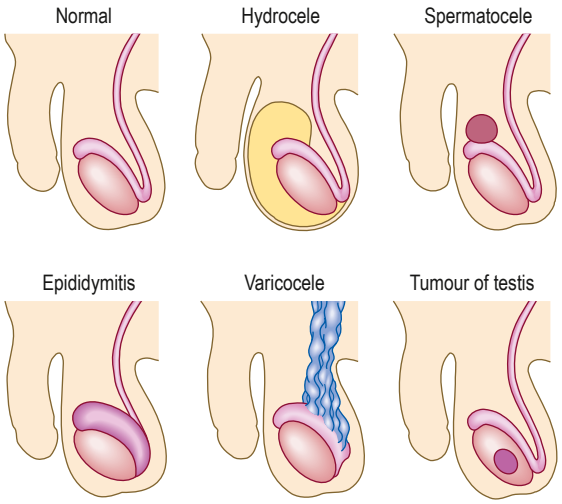

Fig. 47.13 Diseases of the testicle. *(From Innes JA, Dover AR, Fairhurst K, eds.* Macleod's Clinical Examination, *14th edn. Elsevier; 2018, with permission.)*

carefully, tenderness localized to the epididymis but not the testis can be appreciated. Prehn's sign (pain improves when the testis is raised) is classically positive, but this is not reliable for diagnosis and must be interpreted alongside all available clinical information. The hemiscrotum is often swollen and warm to the touch, and erythematous skin changes can be seen. Urinalysis may suggest infection. Examination for parotid swelling is indicated in patients who have not received mumps vaccination or if vaccination history is unclear. Testicular cancer mimics epididymo-orchitis in about 10% of cases. Examination for lymphadenopathy is warranted, which may accompany viral epididymitis.

Patients should be treated for the most likely organism according to local microbiological guidelines, and scrotal elevation is advised to reduce swelling. Advice should be provided about potential complications such as abscess formation, testicular infarction, chronic pain, chronic infection, and infertility. Those who are sexually active should be screened for STIs.

Hydrocele and epididymal cyst

A hydrocele is an abnormal collection of fluid within the tunica vaginalis of the scrotum or along the spermatic cord (Fig. 47.13). It is usually painless, but the testicle is difficult to palpate because of the tense fluid collection. It is possible to transilluminate it because the fluid is clear or straw coloured. Epididymal cysts are benign, fluid-filled cystic swellings that arise from the head of the epididymis. The fluid in the cyst is clear, so differentiation between a large epidydimal cyst and a hydrocele can be challenging for both clinician and ultrasonographer and may only become clear at the time of scrotal exploration to treat the condition. Epididymal cysts can, however, be multiloculated, unlike a hydrocele. The superior margin of a hydrocele and an epididymal cyst is palpable. The clinician being able to 'get above' the lump differentiates from an inguinal hernia. Surgical excision of a hydrocele or epididymal cyst is indicated if it is large and uncomfortable, but small and asymptomatic epidydimal cysts and hydroceles do not require intervention because they do not have an impact on long-term risk or morbidity. If the cyst contains spermatozoa, it is termed 'spermatocele' (see Fig. 47.13).

Varicocele

A varicocele is dilation of the pampiniform plexus of veins surrounding the testis and extending up into the spermatic cord (see Fig. 47.13). Varicoceles are usually small and asymptomatic. They occur more commonly on the left side because of drainage of the gonadal vein into the left renal vein. When symptomatic, patients describe a dragging sensation or dull ache in the scrotum, which classically worsens after long periods of standing, walking, or exercise. Rarely, a new varicocele can be a sign of renal malignancy caused by compression of the gonadal vein and compromised ipsilateral venous drainage. Varicoceles are more common in males with abnormal semen analysis (25%) compared with the overall population (12%). Treatment of a varicocele is therefore recommended in infertile males (unable to conceive with a fertile female partner within 12 months) with abnormal semen analysis parameters. Treatment is not undertaken for subclinical varicoceles with normal semen analysis. Treatments options are embolization or microsurgical ligation of the dilated veins via a small incision at the level of the superficial inguinal ring. Both treatments have high success rates. The selection often depends on local availability. Where available, embolization may be preferred to avoid the need for general anaesthesia.

Cryptorchidism (undescended testes)

In utero, testicular descent from the level of the kidneys into the scrotum is guided by the gubernaculum. This occurs in two phases:

- 7 to 8 weeks' gestation: descent from genital ridge to the internal inguinal ring
- 24 to 28 weeks' gestation: descent through the inguinal canal into the scrotum

Failure of descent is termed 'cryptorchidism' or 'undescended testis'. The incidence in term neonates varies between 1.0% and 4.6% and is up to 45% in preterm neonates. Patients with an intra-abdominal testis have an eightfold increased risk of testicular cancer. There are also increased risks of testicular torsion and inguinal hernia. Fertility may be reduced, although it improves if orchidopexy is performed before 2 years of age, which is routine practice in the UK.

Testicular germ cell tumours

Testicular cancer is the most common solid cancer in young males in high-income populations, representing 1% of male cancers and 5% of urological cancers. The incidence is 3 to 10 per 100 000 per year in high-income countries. Most patients present with a painless unilateral testicular or scrotal mass. Although there are no data to demonstrate regular self-examination for a mass reduces mortality rates, it seems sensible, and it is widely recommended that males examine their testes once a month. Up to 27% of patients have pain or a dragging sensation as their first symptom. A detailed history uncovers the 11% of cases with back and flank pain caused by metastases and the 7% with gynaecomastia caused by tumour secretion of hCG. Presentation mimics epididymo-orchitis in about 10% of cases (see earlier). The investigation and management of testicular cancer is detailed in Chapter 41.

Loss of libido and erectile dysfunction

Loss of libido is a loss of sexual desire. Erectile dysfunction is a complex phenomenon defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance. Loss of libido in males and erectile dysfunction may occur together or separately and can precipitate each other. They affect physical and psychosocial health and have a significant impact on quality of life. In some instances, symptoms are attributed to low serum testosterone concentrations, and both loss of libido and erectile dysfunction occur in patients with hypogonadism. Erectile dysfunction can also occur because of inadequate arterial blood flow, and investigation for underlying cardiovascular disease may be indicated. However, in most cases, testosterone concentrations are normal with no identifiable organic cause identified. Nocturnal emissions and satisfactory morning erections make hormonal and vascular aetiologies unlikely. Psychological factors and lifestyle stresses are thought to be important in pathogenesis, and they may coexist with other causes (**Box 47.29**).

A detailed medical and sexual history should be obtained. Physical examination includes the genitourinary system and for any suspected aetiology (e.g., peripheral pulses). Investigations are determined by the history and risk factors.

Modifiable risk factors, including lifestyle (e.g., smoking, obesity), should be addressed and possible contributing medications reviewed. Treatment of underlying systemic diseases, including diabetes mellitus and hypertension, may be beneficial. If no organic disease is found or if there are psychological contributors, psychosexual counselling should be offered.

Treatments for patients with erectile dysfunction balance invasiveness and efficacy. The most common first-line therapy is an oral PDE-5 inhibitor (e.g., sildenafil, tadalafil, vardenafil, avanafil). These cause smooth muscle relaxation and an increase penile arterial blood flow, enabling an erection. The time from ingestion of medication to effectiveness varies but is generally between 15 and 60 minutes. PDE-5 inhibitors are contraindicated in patients requiring nitrate treatment (e.g., GTN [glyceryl trinitrate], isosorbide mononitrate, isosorbide dinitrate), hypotension (blood pressure <90/50 mmHg), hypertension (blood pressure >170/100 mmHg), unstable angina, angina with sexual intercourse, severe heart failure, within 6 months of a myocardial infarction, stroke, or life-threatening arrhythmia.

Vacuum erection devices provide passive engorgement of the corpora cavernosa. A constrictor ring is then placed at the base of the penis to retain blood within the corpora. This option is contraindicated in patients with bleeding disorders and in those on anticoagulation. It can be offered to those with contraindications to medical management.

Alprostadil is a synthetic prostaglandin E1 analogue that prevents cyclic adenosine monophosphate (cAMP) breakdown, leading to dilation of corpora cavernosa blood vessels via a reduction intracellular calcium. Topical alprostadil is applied to the glans and absorbed via the urethral meatus, or a pellet can also be administered into the navicular fossa of the distal urethra. Patients who do not respond to oral or topical methods can be offered intracavernous alprostadil injections after patient or partner training to ensure the correct technique.

Surgical implantation of a penile prosthesis may be considered in patients who do not respond to pharmacotherapy or who prefer a permanent solution.

? Box 47.29 Causes of erectile dysfunction

Psychogenic
Vascular: peripheral vascular disease, cardiovascular disease
Neurogenic: diabetic neuropathy, spinal cord lesions, nerve damage during radical prostatectomy
Hormonal: hypogonadism, hyperprolactinaemia
Drug induced: finasteride, cyproterone acetate

The ageing male

There is no direct male equivalent to female menopause. However, there is a progressive loss of sexual function, including a reduction in morning erections and frequency of intercourse, with age. Typically, there is a gradual decrease in testicular volume and increase in sex hormone–binding globulin and gonadotrophin concentrations with ageing, but patients may have low testosterone concentrations without elevation of LH or FSH. Low testosterone concentrations increase the risk of osteoporosis with a variable increase in cardiovascular risk in some studies. It remains unclear to what extent general symptoms, including a lack of energy, drive, muscle strength, and general wellbeing, relate to hormonal changes. A recent trial of testosterone replacement showed no benefit for general symptoms, although there was an improvement in sexual function. Loss of libido and erectile dysfunction are common symptoms even when hormone concentrations are normal, and long-term outcome studies of testosterone replacement are awaited. The decision to offer testosterone replacement to an ageing male patient is based on clinical and biochemical assessment, and thorough discussion of potential risks (including prostate disease) as well as possible benefits. If serum testosterone concentration is unequivocally low (<7 pmol/L) with specific symptoms of androgen deficiency (low libido, erectile dysfunction, loss of early morning erections), replacement likely to be recommended. However, few would treat a testosterone concentration over 12 pmol/L with normal LH and FSH. A large proportion of cases have testosterone concentrations 7 to 12 pmol/L, for which the optimum diagnosis and treatment are less clear. There is an increasing move toward measuring fasting testosterone concentrations because food intake may decrease testosterone concentrations, leading to an incorrect diagnosis of androgen deficiency.

Targeted PSA testing from the age of 45 years can be considered for all male patients with risk factors for prostate cancer, including a family history of prostate or breast cancer, African or Caribbean ethnicity, or known genetic predisposition.

TRANSGENDER HEALTH

In gender incongruence and gender dysphoria, a person experiences a significant discordance between their internal sense of gender and the secondary sexual characteristics they possess. People who manage their own gender diversity by changing social expression of gender rather than accessing medical interventions do not require assessment. If assessment is required, it should be carried out by a professional with specific training in this area. Assessment includes gender history and assessment of both mental and physical health.

The science of gender

The development of a person's gender identity involves an interplay of many external influences, including psychological, social, and physical factors. When combined, these factors form a person's internal sense of gender and how they express that gender. Theories of gender development can be divided into three broad categories: biological, social, and cognitive.

Biological theories emphasize the reproductive imperative for survival. In these theories, females are psychologically adapted for nurturing and display empathy, caring, and better verbal fluency. Males are adapted for hunting and so have better visuospatial skills and aggression and are more likely to take risks. There are also biological differences in neuroanatomy. The areas of the brain that are sexually dimorphic accumulate testosterone, which is aromatized to oestradiol. Oestradiol modulates neural pruning by either initiating or inhibiting apoptosis in sexually dimorphic areas of the brain. Animal models show that gender dimorphic behaviours, such as sexual behaviour, can be modified by testosterone exposure or withdrawal during critical windows in development. For example, exposing female rodents in the critical window to testosterone results in male sexual behaviour. This biological model of gender incongruence postulates that lack of testosterone during the critical window for brain masculinization leads to feminine brain development. Conversely, exposure to high testosterone concentrations could result in masculinization. However, the critical window that affects behaviour has not been established in humans.

Social learning theories view gender-specific behaviours as the product of the gender-stereotype messaging that children receive during development. Children get positive reinforcement for 'gender-appropriate' and negative reinforcement for 'gender-atypical' behaviours. This is internalized by children as the way they should perform their genders and creates their gender identities.

Cognitive theories extend the social learning construct as the child self-regulates their behaviour because they have an internal sense of gender and use it to guide their behaviours.

No single theory can explain gender development. A strong interplay between biology, socialization, and cognition forms a person's gender identity.

Sex, gender, and terminology

Terms commonly used to discuss sex and gender in medicine are described in **Box 47.30**. For gender-diverse people, the internal schema of gender is different to the biological sex registered at birth. This creates a dissonance between the internal sense of gender and the societal expectation of their gender role. This dissonance can lead to distress and is termed 'gender dysphoria'.

Box 47.30 Sex and gender terms in medicine

Sex	A collection of biological characteristics that determine whether an organism produces male or female gametes. Sex many be defined based on chromosomes (XX, XY), gonads (ovaries, testes), or secondary sexual characteristics.
Intersex	Individuals with sexual development in which anatomy, reproductive organs, hormonal patterns, and/or chromosomal patterns do not fit binary definitions of male and female.
Gender	The social, behavioural, cultural, and psychological characteristics associated with being a male or female. Gender may be used to describe an individual's perception of themselves ('gender identity') or society's expectations ('gender role').
Gender incongruence	A gender identity that is different to an individual's sex registered at birth. Although gender incongruence may be binary (e.g., an individual who identifies as a female but was registered male at birth), some individuals may identify as non-binary, gender fluid, or non-gendered.
Gender dysphoria	A sense of dissonance between internal sense of gender and an individual's secondary sexual characteristics, resulting in distress and impaired psychosocial functioning.
Gender-affirming care	An approach to medical care that aims to help an individual to live according to the gender with which they identify, supporting social gender role transition and/or the use of hormonal therapy or surgery.
Transgender	A person whose gender identity does not correspond with their registered sex at birth.
Cisgender	A person whose internal sense of gender corresponds with their registered sex at birth. In this chapter, the term is used when required to describe a comparator population of the same registered sex not undergoing gender-affirming care to assess benefits and risk.

Epidemiology of gender incongruence

The epidemiology of gender nonconforming people is difficult to establish. Estimates of prevalence vary widely depending on whether cohorts are community based or those seeking medical interventions. In healthcare systems–based studies, the estimated prevalence is 0.02% to 0.1%. In studies of self-reported transgender identity, estimates range from 0.3% to 0.5% of adults and 1.2% to 2.7% of children and adolescents.

Historically, more people registered male at birth attended gender identity services than those registered female, with a ratio of 3.6 to 1. More recent studies suggest that this ratio has now reduced to 1.4 to 1, and population-based studies suggest that there is no sex bias.

Aetiology of gender incongruence

The aetiology of gender incongruence includes neuroanatomical, genetic, hormonal, neurodevelopmental, and environmental theories.

Neuroanatomical

Despite extensive research, no clear neurological marker of gender incongruence has been found. Postmortem histological studies (e.g., third interstitial nucleus of the anterior hypothalamus, cortical

thickness patterns) and functional MRI studies (response to visuospatial tasks and verbal fluency) suggest that neuroanatomy and possibly the pattern of cerebral activation are more congruent with gender identity (experienced or felt gender) than assigned or registered gender (phenotypic gender).

Genetic

Twin studies suggest that the heritability of gender identity is comparable to that of behaviour and personality traits. The degree of heritability varies between 24% and 50% in monozygotic twins, and the incidence in dizygotic twins is half these values. This suggests that the formation of adult gender identity is caused by both genetic and environmental factors.

Hormonal

Disorders of sexual differentiation give us information about the influence of hormones on behaviour. Girls with congenital adrenal hyperplasia, who are exposed to excess androgen levels *in utero*, display more male 'gender-appropriate' play in childhood, have a decreased desire for maternity, and increased occurrence of bisexuality and homosexuality compared with unaffected siblings. In complete androgen insensitivity, a person is genetically XY, but the androgen receptor is not functional. These children display female gender identity and psychological traits. This suggests that hormone exposure influences gender identity.

Neurodevelopmental

Approximately 10% of gender-diverse people are neuroatypical. This has led to conjecture that gender diversity may be a neurodevelopmental condition, but evidence for this is limited.

Environmental

In the UK, referrals of young people to the Gender Identity Service at the Tavistock Clinic in London rose exponentially from 2014, with the biggest rises in adolescents registered female at birth. The reasons for the marked increase in prevalence is unclear with social media, childhood trauma, changes in society's acceptance of gender diversity, and socializing effects in peer groups and educational institutions hypothesized to be contributing factors. The Cass Review of the Tavistock Clinic in 2024 highlighted the complexity of many of the cases referred, in which gender dysphoria existed alongside mental health problems, neurodiversity, and adverse childhood events; children in the social care system or adopted were overrepresented.

Assessment of gender incongruence

Many people with gender diversity do not present to medical services and manage their gender diversity themselves by changing social expression of gender rather than accessing medical interventions. People in this situation do not require assessment.

It is important that any assessment process does not pathologize the patient. The World Professional Association for Transgender Health (WPATH) has published international standards of care for working with gender-diverse people (currently version 8). When assessing a person, start by establishing their gender identity, preferred name, and pronouns to maintain a respectful approach.

Assessment should identify coexisting mental health and physical or psychosocial concerns and distinguish these from gender dysphoria, gender incongruence, and gender diversity. The clinician should ascertain the patient's expectations of care: what interventions an individual is seeking to achieve an appearance consistent with their internal sense of gender. It is important to discuss the implications of physical changes on the individual's psychological, physical, and social functioning. The important elements of assessment are outlined in **Fig. 47.14**.

History

Gender history

Gender history should document when gender dissonance started and how their sense of gender identity developed. At what age did they start to express their preferred gender, for example, using clothing, makeup, or hairstyles? When did they begin to feel uncomfortable in their body and start thinking about aligning their body with their preferred gender? At what age did they tell others about their gender identity, and what impact did it have on their social relationships? Are they able to occupy the social gender role consistent with their gender identity ('socially transition'), and for how long have they been able to do this? What is the psychological impact of this? Are partner, family, and friends supportive of the person's gender identity? What is their sexual orientation, and how will gender transition affect this?

Mental health history

Gender-diverse people may have had trauma during childhood, including bullying, stigmatization, transphobia, and abuse. Depression and anxiety are extremely common in people with gender incongruence, leading to an increased incidence of deliberate self-harm and suicidal behaviour. Physical therapies can affect mood. It is important to assess mental health and co-morbid psychological conditions, especially self-harm and suicidal ideation. Does the person have any forensic history that is relevant to treatment for gender diversity, such as violence, that could be increased by testosterone treatment?

Medical history

A history of birth and childhood development, including age of puberty, aids identification of ambiguous genitalia or abnormal genital development. People who are registered male sex at birth should be asked about hypogonadism, genital abnormalities (e.g., micropenis, cryptorchidism, hypospadias), gynaecomastia at puberty, reduced facial and body hair, decreased morning erections, and infertility. People registered female sex at birth should be asked about their onset of menarche and usual menstrual pattern and for features of hyperandrogenism such as increased facial hair and body hair, increased clitoral size, oligo- or amenorrhoea, and infertility. It is important to find out if the individual has been taking hormonal treatment before assessment and what effect it had.

Hormone therapies have metabolic consequences and confer thromboembolic and hormone-dependent cancer risks. Cardiovascular status and risk are important because testosterone can increase cholesterol concentrations, and oestrogen can increase insulin resistance. Clinical history should include a personal or family history of myocardial infarction, stroke, or peripheral vascular disease and clinical features of polycystic ovarian syndrome. The use of tobacco and alcohol should be noted. People should be advised to stop smoking before starting hormone therapy and drink alcohol within safe limits. Risk factors for thromboembolism are important because hormone therapy, particularly oestrogen, can increase risk. Hormone-dependent cancers, including breast cancer, endometrial cancer, or prostate cancer, in the individual and their family should be documented.

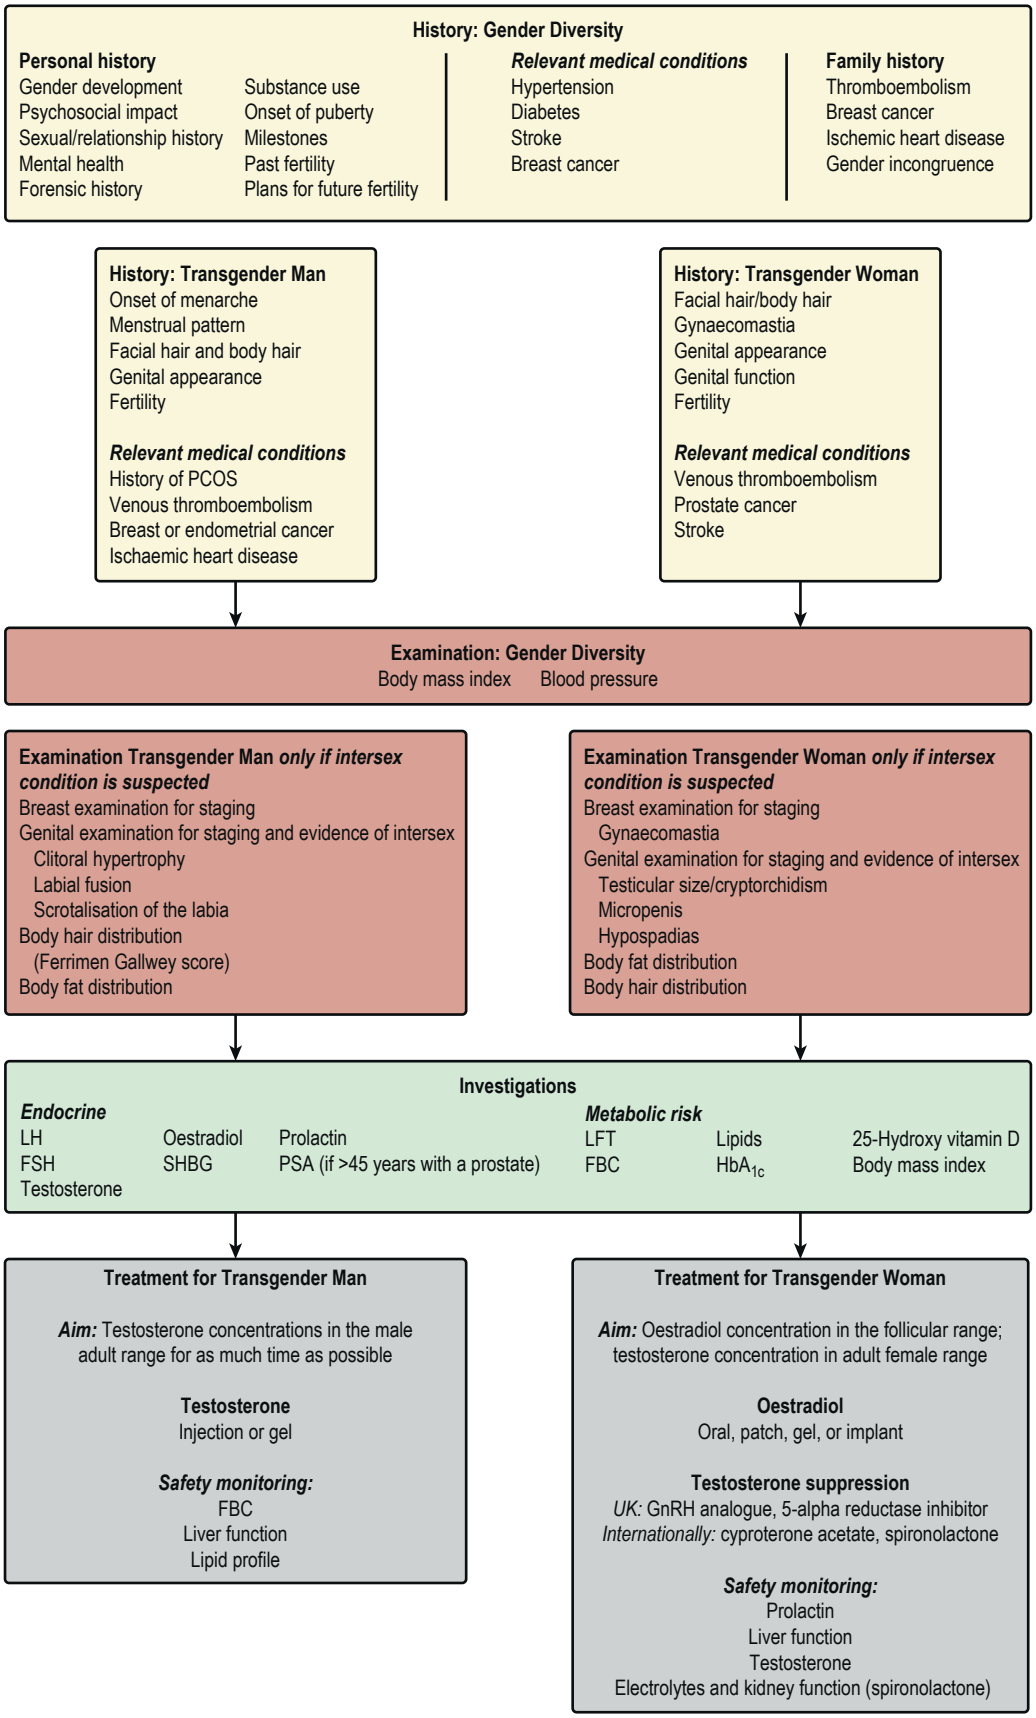

Fig. 47.14 A summary of the history, examination, investigation, and treatment of the medical management of a gender-diverse person. *FBC,* Full blood count; *FSH,* follicle-stimulating hormone; *GnRH,* gonadotrophin-releasing hormone; *HbA_{1c},* hemoglobin A_{1c}; *LH,* luteinizing hormone; *PCOS,* polycystic ovarian syndrome; *PSA,* prostate-specific antigen.

Examination

There are no specific physical features associated with gender incongruence. Clinical assessment has two purposes. First, it can identify individuals who may have a disorder of sexual differentiation who can present with gender confusion. Second, it allows a cardiovascular and metabolic risk assessment of the individual as hormone therapies can increase risk.

Blood pressure and body mass index should be measured as part of the assessment of cardiovascular risk.

Assessment of secondary sexual characteristics, including examination of external genitalia, is only required if a disorder of sexual differentiation is suspected on history or blood tests. This examination is not routine because people with gender diversity can find genital examination distressing. Any intimate examination must be done sensitively and efficiently and in a way that maintains dignity and respects the patient's sense of gender identity. It is important to gain consent for all examinations and to reassure individuals that they can decline examinations. Anatomical terms for genitalia are very gendered. Using gendered terms may cause distress to a gender-diverse person. Ask the person being examined their preferred terms for genitalia and use these words during any examination. Chaperones of an appropriate gender may make the patient more comfortable. It is rarely necessary to perform an internal examination because observation of the external genitalia is usually sufficient to determine whether there is a disorder of sexual differentiation.

The relevant clinical features on examination are outlined in Fig. 47.14.

Investigation

There are no diagnostic tests for gender incongruence or dysphoria. Investigations aim to identify if there is any significant disorder of gonadal function and to assess the metabolic status of the patient. The panel of blood tests is outlined in Fig. 47.14.

Diagnosis of gender incongruence

The clinical features of gender dysphoria and gender incongruence are outlined in Box 47.31. In both diagnoses, the clinical features are broadly similar. To make a diagnosis of gender incongruence or gender dysphoria, a person should experience a significant discordance between their internal sense of gender and the secondary sexual characteristics they possess. In both cases, the feeling of discordance must be present for a minimum of 6 months. Gender incongruence is the most widely used diagnosis in gender medicine practice and does not require dysphoria for diagnosis.

The differential diagnosis of gender incongruence includes bipolar disorder, psychosis, and dysmorphophobia. However, it is very rare for these conditions to be confused with gender incongruence because differences are usually clear, such as rapid onset in the context of a mental health crisis or unhappiness with the body's appearance without significant gender incongruence.

Management of gender incongruence

There is considerable international variation in the recognition, acceptance, and management of gender incongruence within societies. In many liberal societies, health systems have adopted an approach termed ***gender-affirming care***, which aims to support individuals to live in the gender with which they identify.

In adults, there is little high-quality evidence to guide the treatment of people experiencing gender dysphoria (e.g., controlled trials of medical and psychological interventions). Management of patients with gender incongruence is best done in the context of a multidisciplinary team that addresses psychological, social, and physical health. Assessment includes discussion around social functioning and the social gender role that the individual wishes to have.

Recent controversy has focussed on children and young people in the UK. The 2024 Cass Review into gender identity services for children and young people in England and Wales highlighted the paucity of evidence to support use of GnRH analogues and recommended against a medicalized pathway for most young people.

This chapter outlines the principles, benefits, and risks of gender-affirming care in adults. The additional potential vulnerability of young adults, particularly at the time of transfer to adult medical

Box 47.31 Diagnostic criteria for gender dysphoria and gender incongruence

	Gender dysphoria	Gender incongruence
Defined by	*Diagnostic and Statistical Manual,* fifth edition, American Psychiatric Association	International Classification of Disease-11, World Health Organization
Defined where	List of psychiatric conditions	List of sexual health conditions
Diagnostic criteria (at least two should be present for 6 months)		
Incongruence between experienced or expressed gender and primary and/or secondary sex characteristics	☑	☑[a]
A strong desire to be rid of one's primary and/or secondary sex characteristics	☑	☑
A strong desire for the primary and/or secondary sex characteristics of the other gender	☑	☑[b]
A strong desire to be of the other gender	☑	☑[b]
A strong desire to be treated as the other gender	☑	☑[b]
A strong conviction that one has the typical feelings and reactions of the other gender	☑	☑[b]
This condition causes clinically significant distress or impairment in social, occupational, or other important areas of functioning	☑	†

[a]In adolescents, a desire to prevent the development of the anticipated secondary sex characteristics.
[b]Alternative gender different from one's registered gender.

services, should be acknowledged, along with an appreciation that the developmental trajectory of young people may continue into their mid-20s.

Social gender role change

It is important to explore alternatives to physical interventions in addressing gender dissonance. A gender-diverse person may decide to change their social gender role by altering the social cues that people use to read their gender. These changes may include clothing, makeup, and hairstyle. It is also possible for a person to change their name and prefix using a legal instrument such as a deed poll to make their legal name congruent with their gender identity. In many countries, it is also possible for an individual to change their birth certificate to reflect their gender identity. This is done in the UK by provision of a gender recognition certificate.

Physical interventions

If the person is sure that physical interventions are necessary for them to have a body that is congruent with their gender identity, these can be considered. A gender specialist assesses the need for interventions including psychological counselling, facial hair removal, hormone therapy, speech and language therapy, and surgical interventions, with referral to appropriate services.

Hormone therapy

There are three aims of therapy:

- Reduce natal hormone production
- Induce secondary sexual characteristics of the desired gender
- Prevent hypogonadism after a person has undergone gonadectomy.

Hormonal therapy can be recommended by a gender specialist after a period of assessment. A gender specialist will assess capacity to consent to treatment, diagnostic criteria for gender incongruence or dysphoria, longevity of gender identity, expectations of hormone therapy, and whether hormone therapy is in the person's best interest. Before hormone therapy is commenced, psychological and physical health should be optimized.

Fertility, contraception, and sexual health

The impact of therapy on fertility should be discussed before hormone treatment. If fertility is desired in the future, referral for fertility preservation (sperm storage or ova preservation) should be offered.

Hormone therapies are not licensed as contraceptives, so gender-incongruent people on hormone therapy need additional effective contraceptive methods if necessary. Barrier contraception can be used by transgender men and women. Progesterone-based contraceptives (progesterone-only pill, implant, depot, and IUD) are suitable for transgender men and more effective at preventing pregnancy than barrier methods. It is not advisable to use oestrogen-containing methods because they may produce feminization.

It is important to discuss available vaccination programmes including HPV, hepatitis B, and hepatitis A. Transgender men should be encouraged to engage with the national cervical screening programme. It is important to counsel about HIV prevention, including pre- and post-exposure prophylaxis.

Hormone therapy for transgender women

Oestrogen therapy in transgender women initiates the sequences seen in female puberty. Hormone therapy should be individualized with doses that achieve physiological oestrogen and testosterone concentrations. The aim is to achieve an oestradiol concentration in the follicular range, increasing the dose over 6 to 12 months until the correct concentration is achieved. Doses two to five times more than standard hormone replacement for menopausal females are usually required. If oral therapy does not achieve sufficient oestradiol concentrations, gel or patch treatment is used. Ethinylestradiol and conjugated equine oestrogen are avoided because of increased cardiovascular and thromboembolic risk compared with oestradiol. To minimize cardiovascular risk, topical rather than oral oestrogen preparations are used for those older than 45 years of age.

Oestrogen monotherapy reduces testosterone to the female range in approximately 20% of transgender women. Androgen suppression is therefore usually required to achieve a testosterone concentration in the female range. There is international variation in the medications used for androgen suppression. GnRH analogues are used in the UK, cyproterone acetate is used in Europe, and spironolactone is preferred in USA. International variation is largely based on cost. GnRH analogues overstimulate the pituitary gonadotroph cells, causing down-regulation of LH and FSH secretion, which stops testicular testosterone production and spermatogenesis. The usual side-effects of menopausal hot flushes, tiredness, accelerated heart disease, and reduced bone mineralization do not occur because of simultaneous oestrogen replacement. GnRH analogues can prolong the QT interval.

Cyproterone acetate is a progesterone derivative that acts as an androgen receptor antagonist, a progestin receptor agonist (inhibiting LH and FSH), and a partial glucocorticoid agonist. Side-effects include abnormal liver function, insulin resistance, increased BMI, reduced high-density lipoprotein cholesterol, and depression. Long-term use is cautioned because it can induce the development of both meningioma and prolactinoma.

Spironolactone is a mineralocorticoid receptor antagonist, a partial androgen receptor antagonist and an oestrogen receptor agonist. Side-effects include hyperkalaemia through potassium-sparing diuretic action, gastrointestinal bleeding, depression, and abnormal liver function. Spironolactone is less effective than cyproterone acetate or GnRH analogues in reducing testosterone concentrations.

Finasteride prevents the activation of testosterone to dihydrotestosterone by blocking the enzyme 5-alpha reductase. This reduces the action of testosterone on the body and has been used to stabilize scalp hair loss and reduce body hair. Both depression and liver function disturbance have been described as side-effects; however, depression is not as prominent compared with cyproterone acetate use in transgender women.

The WPATH standards of care state that there is insufficient evidence to recommend the use of progesterone in transfeminine HRT. Although there are anecdotal data of improved wellbeing, sleep, and breast development, progesterone in combination with oestrogen increases thromboembolic and cardiovascular risk.

Monitoring in the initial phase is every 3 to 6 months, converting to every 6 months when stable, and then to annual review. Standard therapies and the monitoring required are outlined in **Boxes 47.32 and 47.33**. Other than the change from oral to topical oestrogen treatment at age 45 years, no other adjustments are made for age. After therapy has been started, it should be continued unless the person develops a significant side-effect or a condition that is an absolute contraindication to hormone therapy (e.g., oestrogen-dependent breast cancer).

Box 47.32 Oestrogen preparations used for feminization in UK practice and monitoring required

Route	Preparation	Dose	Frequency	Oestradiol concentration	Monitoring			
					Baseline tests	Therapeutic monitoring	Timing of therapeutic monitoring	Long-term monitoring
Oral	Oestradiol valerate or oestradiol hemihydrate	1–8 mg	Once a day	Midfollicular level: 400–600 pmol/L	LH FSH Testosterone Oestradiol SHBG Prolactin PSA (older than 45 years) LFT FBC Lipid profile HbA_{1c} Vitamin D BMI BP	Oestradiol Testosterone SHBG Prolactin LFT	Blood 4–6 hours after tablets	8 weeks after any change in dose On stable dose: 6 monthly for 2 years; then annually
Patch	Oestradiol	50–200 mcg twice weekly	Change patch(es) twice a week	Midfollicular level: 400–600 pmol/L			Blood 48 hours after patch application	
Topical gel	Oestradiol	0.5–1 mg (sachets) or 0.75 mg (pump actuation; maximum, 5 mg/day)	Once per day (not to breasts)	Midfollicular level: 400–600 pmol/L			Blood 4–6 hours after application and no gel on arms	
Implant	Oestradiol	50–100 mg	6–24 monthly	Trough value: 400–500 pmol/L			5 months after implant; then repeat monthly

Intended beneficial effects of hormone therapy in transgender women

Skin and hair

Oestrogen treatment results in finer skin texture and a reduction in facial and body hair. This effect is maximal after 4 months of treatment. Hormone therapy, including testosterone reduction, is not adequate to control facial hair growth and local measures such as electrolysis, waxing, shaving, sugaring, or laser therapy are needed to facilitate female presentation. Androgenic alopecia does not respond to hormone therapy. Testosterone suppression can stabilize the condition and minoxidil can increase hair density in mild androgenic alopecia. Where scalp hair loss is significant a hairpiece or hair transplant may be needed.

Breast development

Breast development begins about 2 to 3 months after the start of oestrogen treatment with maximum effect after 2 years. Average breast development is 14.5 ± 1.2 cm, which equates to a B cup brassiere size. Genetic factors limit breast development even when HRT is adequate.

Body shape

Body composition changes and there is an average of 3.8 kg weight gain. This is mainly as fat centred on the hips and buttocks giving a more female fat distribution with a decrease in lean body mass.

Genital changes and fertility

Oestrogen therapy reduces libido, decreases genital size, and inhibits fertility. Erectile dysfunction will occur. For most transgender women this does not require treatment. If there is a wish to retain genital function, PDE-5 inhibitors such as sildenafil can be used.

Mood and cognition

Transgender women using oestrogen therapy generally find a positive effect on their mood. Many transgender women report an increased feeling of femininity and a calmer mood.

Cancer risk

Prostate cancer is unusual in transgender women due to the use of androgen blockade. One study estimated the odds ratio for prostate cancer in transgender women to be 0.2–0.3 compared to cisgender men.

Adverse effects of hormone therapy in transgender women

Venous thromboembolism

The risk of thromboembolism increases by two- to fivefold compared with the background rate. This risk can be reduced by stopping smoking, maintaining a normal BMI, using topical rather than oral oestrogen (especially after the age of 45 years), and using oestradiol rather than ethinylestradiol or conjugated equine oestrogen.

Hyperprolactinaemia

This is reported in 4% to 15% of transgender women treated with oestrogen. Cyproterone acetate for androgen suppression has been associated with an increased risk of prolactinoma and is avoided in UK practice.

Abnormal liver function

Oestrogen treatment causes obstructive liver dysfunction in approximately 4% of transgender women. However, it is usually transient and resolves spontaneously in 3 to 6 months. Oestrogen therapy is associated with a fivefold increased risk of gallstones.

Cardiovascular risk

Oestrogen therapy leads to an increase in triglyceride concentrations, so a healthy diet is advised. Oestrogen therapy is also associated with an increase in insulin resistance.

Osteoporosis

Standard HRT regimens maintain bone mineralization for transgender women. However, vitamin D deficiency is common in transgender people, and bone mineralization may be reduced even before hormone treatment. Good bone health is promoted with weight-bearing exercise, not smoking, and maintaining vitamin D concentrations. If vitamin D deficiency is present, supplementation is required.

Cancer risk

The odds ratio for developing invasive breast cancer in transgender women is 46.7 (95% confidence interval [CI], 27.2–75.4) compared with cisgender men but 0.3 (95% CI, 0.2–0.4) compared with cisgender women. Because breast cancer risk is lower than in cisgender women, oestrogen therapy is usually lifelong for transgender women.

Hormone therapy for transgender men

Masculinization of a transgender man is achieved by giving testosterone. Physical changes follow a male puberty pattern and take 2 to 5 years to complete. Doses of testosterone used are the same as for a hypogonadal cisgender man. Short-acting mixed testosterone ester injections are the only preparation licensed for use in transgender medicine in the UK. Newer preparations, including topical gels and longer acting injections, are also effective. The common testosterone products used, monitoring, and effects are outlined in **Boxes 47.34 and 47.35**.

There should be regular monitoring of hormone concentrations until stable adult hormone concentrations are achieved followed by annual review of blood tests, weight, height, and blood pressure. After therapy has been started, it should be continued unless the person develops a significant side-effect or a condition that is an absolute contraindication to hormone therapy (e.g., severe polycythaemia).

Intended beneficial effects of hormone therapy in transgender men

Facial and body hair

Testosterone treatment in transgender men results in an increase in body hair and a change to a masculine hair pattern with hair growth on the face, chest, abdomen, lower back, and inner thighs. The onset of this is typically 6 to 9 months after starting testosterone treatment and is complete by 48 to 56 months. The skin texture coarsens, and acne can occur. Androgenic alopecia occurs in susceptible individuals.

Body shape

Testosterone increases lean body mass and upper body strength, with a concomitant reduction in body fat mass. This results in a masculine body shape with more muscle definition, increased upper body strength, and a decrease in hip-to-waist ratio. These are the same changes that occur in cisgender men taking testosterone.

Genital changes and fertility

The first physical change usually noticed by a transgender man on testosterone treatment is clitoral enlargement. Onset is by 3 to 4 months and is largely complete by 1 year with final clitoral length of 4 to 5 cm. This amount of growth is not usually sufficient for penetrative intercourse. Menstruation usually ceases after 3 to 4 months of treatment. Ovarian morphology becomes polycystic after 6 months of testosterone exposure, but it is not known if these changes affect ovarian function. Testosterone treatment is not an effective contraceptive, and appropriate contraception should be recommended whenever it is required.

Mood and cognition

Testosterone therapy has important effects on behaviour. Assertiveness, aggression, and general drive are increased when testosterone is given to cisgender men. Transgender men report higher levels of energy, aggression, and libido. Studies show that

Box 47.34 Medications used for masculinization in UK practice and monitoring required

Route	Preparation	Dose	Frequency	Testosterone concentrations	Monitoring			
					Baseline tests	Therapeutic monitoring	Timing of therapeutic monitoring	Long-term monitoring

CVD, Cardiovascular disease; *HDL*, high-density lipoprotein; *LDL*, low-density lipoprotein; *N/A*, not applicable.

transgender men taking testosterone have improved visuospatial ability.

Voice

Testosterone causes growth of the larynx and thickening of the vocal cords, resulting in a lower vocal pitch. Usually the voice 'breaks' after 9 to 12 months of testosterone treatment, but voice change can take up to 2 years to complete.

Bone density

Most studies in transgender men show that testosterone therapy appears to maintain bone mineralization.

Cancer risk

Breast cancer risk after masculinizing chest surgery is approximately one-third of the risk in cisgender women. However, transgender men should be offered the same breast cancer screening as females if they have not had male chest reconstructive surgery.

Adverse effects of hormone therapy in transgender men

Lipid profile

Despite cisgender men having a more adverse lipid profile than cisgender women, testosterone therapy for transgender men results in no change in total cholesterol or low-density lipoprotein cholesterol concentrations. There is a minor increase in triglycerides and a minor decrease in blood high-density lipoprotein concentrations that does not translate to a significant increase in cardiovascular risk with an odds ratio for myocardial infarction of 0.3 to 1.0 compared with cisgender men.

Polycythaemia

Testosterone increases the production of red blood cells by increasing plasma erythropoietin levels. Testosterone therapy increases haematocrit by 8% to 12%, conferring a 3% to 5% risk of polycythaemia. This risk is higher with injectable than topical testosterone. Polycythaemia is managed with hydration and changing from injectable to gel therapy. If indicated, therapeutic venesection may be performed.

Abnormal liver blood tests

Increased concentrations of transaminases are seen in about 4% to 7% of transgender men. Treatment is continued provided concentrations are less than three times the upper limit of the reference range.

Cancer risk

Testosterone can be aromatized to oestradiol, which could theoretically result in endometrial hyperplasia. However, in clinical practice, reports of endometrial hyperplasia are rare, and endometrial cancer is extremely rare in transgender men. In the UK, endometrial surveillance using interval ultrasonography is recommended. Internationally, monitoring is only carried out if the patient has pelvic symptoms such as bleeding or pain. Transgender men may elect to have a hysterectomy to prevent any risk of endometrial hyperplasia. Ovarian cancer risk appears to be very low. Transgender men should be offered cervical screening as per the national screening programme for females.

Menstruation

Testosterone monotherapy may not be sufficient to suppress ovarian function. Menstrual activity can be suppressed with continuous progestin such as medroxyprogesterone acetate. If this is not adequate or tolerated, a GnRH analogue can be used.

Speech and language therapy

The larynx is not significantly affected by hormone therapy in transgender women. Speech and language therapy is needed for a transgender woman to feminize the voice. Voice therapy can help with altering the pitch, timbre, cadence, and modulation of voice, all of which are important elements in voice feminization. Communication therapy is important in feminizing vocal patterns, which vary between genders. Testosterone does lead to change to the larynx in transgender men, but speech and language therapy may augment masculinization.

Surgical Intervention

Gender-affirming surgical procedures are designed to make a person's body more congruent with their internal sense of gender identity. The assessment for surgical interventions is the same as for hormone treatment, but the person should also be stable on hormone therapy for at least 6 months. Some surgical procedures require a longer duration of hormone therapy to achieve an optimal result (e.g., metoidioplasty in which clitoral tissue hypertrophied using testosterone is used to fashion a penis). In the UK, masculinizing chest surgery and masculinizing and feminizing genital surgery are provided through NHS-funded services. Other gender-affirming surgical procedures, including breast augmentation, facial surgery (either masculinizing or feminizing), or phonosurgery (to increase voice pitch), are not currently funded by the NHS.

Masculinizing surgeries

Masculinizing chest surgery involves the removal of the breast tissue (mastectomy) and recontouring of the chest wall and nipple complex to achieve a masculine chest appearance. Chest surgery has been shown to improve quality of life and decrease gender dysphoria.

Genital surgery in which a new phallus is created is done by metoidioplasty or phalloplasty. Metoidioplasty is often a single-stage procedure. The new phallus created is not large enough for penetrative sexual function, but it usually allows the individual to urinate standing up. Phalloplasty is a multistage procedure allowing the formation of a new phallus that is large enough for sexual function, using skin from a donor site. Genital surgery may include hysterectomy and oophorectomy, rendering the person permanently hypogonadal. Testosterone therapy is usually continued during the perioperative period. Because testosterone therapy suppresses ovarian function, the dose of testosterone usually does not change after genital surgery unless oophorectomy has been performed.

Feminizing surgeries

Feminizing genital surgery usually involves orchidectomy. Although this may be performed as a standalone procedure, it is usually accompanied by penectomy, vulvoplasty, and formation of a neo clitoris. If the person desires sexual function, then vaginoplasty can also be performed. It is usual for hormone therapy to be stopped 6 weeks before genital surgery to decrease thromboembolic risk. It is restarted when the person is mobile, usually 2 weeks after surgery. Androgen suppression treatment continues during the perioperative period, and patients may experience menopausal symptoms during this time. Because most patients have their testosterone

suppressed into the female range before surgery, the dose of oestrogen does not change after surgery.

Treatment of non-binary people

Approximately 10% of people attending a gender identity clinic have a gender identity that does not sit within the gender binary of male or female. A non-binary sense of gender may include people who feel their gender identity is partially male and partially female. Other people may have a gender identity that fluctuates with time termed gender fluidity. Some people have a sense of no gender at all, termed 'agender' or 'neutroid'. For other non-binary people, their sense of gender does not have a descriptive term in the English language (e.g., the two-spirit people of native North American communities).

Cultural competence is important when working with people with a non-binary identity. The usual pronouns of he/him and she/her usually do not apply; neutral pronouns such as they/them or neo-pronouns such as ze/zir may be preferred.

There are no clearly established guidelines for the hormonal treatment of non-binary people; it is therefore best that the treatment of an individual with physical measures such as hormone or surgical interventions is done in the context of a multidisciplinary team. The assessment process should establish the ideal mix (or lack) of masculine and feminine physical features for the individual. It should also explore how fluid the gender identity is and if this is likely to change with time. The final stage of assessment is to explore whether physical changes are feasible, achievable, and safe using available hormone and surgical treatments.

Many non-binary people wish to have a partial degree of masculinization or feminization to allow them to have an androgenous gender presentation. This is achieved either by using lower doses of masculinizing or feminizing hormone therapy than those used in binary gender transition or by using full-dose therapy for a limited period to achieve partial pubertal development. For people who wish to have a neutral gender expression, removal of sex steroid production using GnRH analogues may be undertaken. Side-effects include a reduction in bone mineralization and the adverse metabolic effects of dyslipidaemia. It is important to counsel about these risks. People should have monitoring of their lipid profile and dual-energy X-ray absorptiometry (DEXA) scanning. If metabolic abnormalities or reduced bone mineralization develop, they should be treated. As with people undergoing a binary gender transition, people with a non-binary gender identity should be counselled about the impact on their fertility and offered fertility preservation before starting treatment

CORE SKILLS AND KNOWLEDGE

Obstetric medicine refers to the care of pregnant persons with medical problems. These include the 10% who enter pregnancy with pre-existing diseases (e.g., asthma, epilepsy, hypertension, and diabetes), as well as those with diseases that arise acutely in pregnancy (e.g., pneumonia and venous thrombosis).

Obstetric medicine is a new and growing medical specialty composed of physicians who specialize in providing care in pregnancy complicated by medical conditions and who increasingly work alongside specialist obstetricians (who have also received specialist training in obstetric medicine), specialist obstetric anaesthetists, and specialist midwives. Historically (and currently in many centres without an obstetric physician), this care was provided by general obstetricians alongside general adult physicians. Training programmes in most medical specialties require trainees to learn about the care of patients within this specialty in the context of pregnancy. General practitioners also have a crucial role because they provide continuity of care before and after pregnancies.

Special skills necessary for physicians to practice obstetric medicine include:

- The ability to take a detailed obstetric history
- An understanding of the relevance of chronic medical diseases to the physiological adaptations required for pregnancy
- An understanding of how to interpret blood results and other investigations in pregnancy
- An in-depth knowledge of the safety of radiological investigations and medications in pregnancy and breast-feeding, balanced with the risks of not investigating or treating in the same way as outside of pregnancy.

Opportunities to learn obstetric medicine may arise by completing training attachments in obstetrics and gynaecology, by attending obstetric medicine multidisciplinary team meetings or clinics if they exist, and by seeking out pregnancies under close surveillance because of coexisting medical problems. A diploma in obstetric medicine is now available through the Royal College of Physicians, with specific training posts available in England.

CLINICAL SKILLS

History

Many symptoms occur in normal pregnancy, including fatigue, nausea, vomiting, palpitations, breathlessness, gastro-oesophageal reflux, constipation, and oedema. A careful history is required to discriminate pathology from physiology. Typically, pathological symptoms arise suddenly, differ from those experienced in previous pregnancies or before pregnancy, and can be particularly severe. Even with significant experience, differentiating pathological from physiological symptoms in pregnancy can be challenging.

Examination

Physiological changes occurring in pregnancy are illustrated in the figure on the next page. They contribute to the clinical signs in normal pregnancy, including a resting tachycardia of up to 110 beats/min, relative hypotension, and oedema.

Investigations

Blood tests need interpreting based on pregnancy reference ranges, which differ from those outside pregnancy because of underlying changes in physiology. Serum creatinine falls below 77 μmol/L, there is a physiological anaemia related to haemodilution, and alkaline phosphatase is raised because of placental production (**Box 48.1**).

Screening

Healthcare systems vary as to which screening tests are carried out during pregnancy, according to local prevalence of different diseases and availability of resources. **Box 48.2** describes tests routinely performed in the UK. Clinic appointments are usually made at booking (generally 8–12 weeks' gestation) and then at 16, 25, 28, 31, 34, 36, 38, 40, 41, and 42 weeks' gestation in healthy pregnancies, with fetal ultrasonography at 12 and 20 (and in some units 36) weeks' gestation.

i Box 48.1 Reference values in pregnancy

Test	Reference interval in pregnancy	Reference interval in non-pregnant population
Haemoglobin (Hb)	105–140 g/L	115–155 g/L
Mean corpuscular volume (MCV)	80–100 fL	80–96 fL
White cell count (WCC)	6–16 × 10^9/L	4–11 × 10^9/L
Platelets	150–400 × 10^9/L	150–400 × 10^9/L
Sodium	130–140 mmol/L	135–146 mmol/L
Potassium	3.3–4.1 mmol/L	3.5–5.0 mmol/L
Urea	<4.5 mmol/L	2.5–6.7 mmol/L (8–25 mg/dL)
Creatinine	<77 μmol/L	45–90 μmol/L (0.5–1.0 mg/dL)
Bilirubin	<16 μmol/L	<17 μmol/L (0.3–1.5 mg/dL)
Aspartate aminotransferase	10–30 U/L	12–40 U/L
Alanine aminotransferase	6–32 U/L	<40 U/L
Alkaline phosphatase	30–418 U/L	39–117 U/L
Albumin	28–37 g/L	35–50 g/L

i Box 48.2 Screening tests in pregnancy

Confirmation of pregnancy
- Urine beta-human chorionic gonadotrophin (β-hCG) testing kits are highly sensitive for confirming pregnancy in the context of a missed period (and need not be repeated if a female has performed a test that has proved positive at home).
- A serum β-hCG level is not used in routine practice for diagnosing pregnancy but is used in managing certain conditions, including ectopic pregnancy and molar pregnancy.

Infectious diseases
- Human immunodeficiency virus, hepatitis B, and syphilis are screened for in early pregnancy so treatment can be instituted to reduce the risk of transmission to the fetus.

Obesity
- Body mass index is calculated from height and weight measured at the booking visit.
- Lifestyle advice to encourage healthy behaviour is given at this point and repeated throughout pregnancy.

Hypertension and pre-eclampsia
- BP measurement and urine dipstick examination are performed at each antenatal appointment.
- Pregnancies complicated by hypertension or proteinuria require close monitoring; kidney and liver function is measured.

Anaemia
- An FBC is measured at booking and at the 28-week visit.
- Haemoglobin concentrations are lower during pregnancy.
- Ferritin, folate, and vitamin B_{12} concentrations are measured if anaemia is diagnosed. Iron deficiency is common.

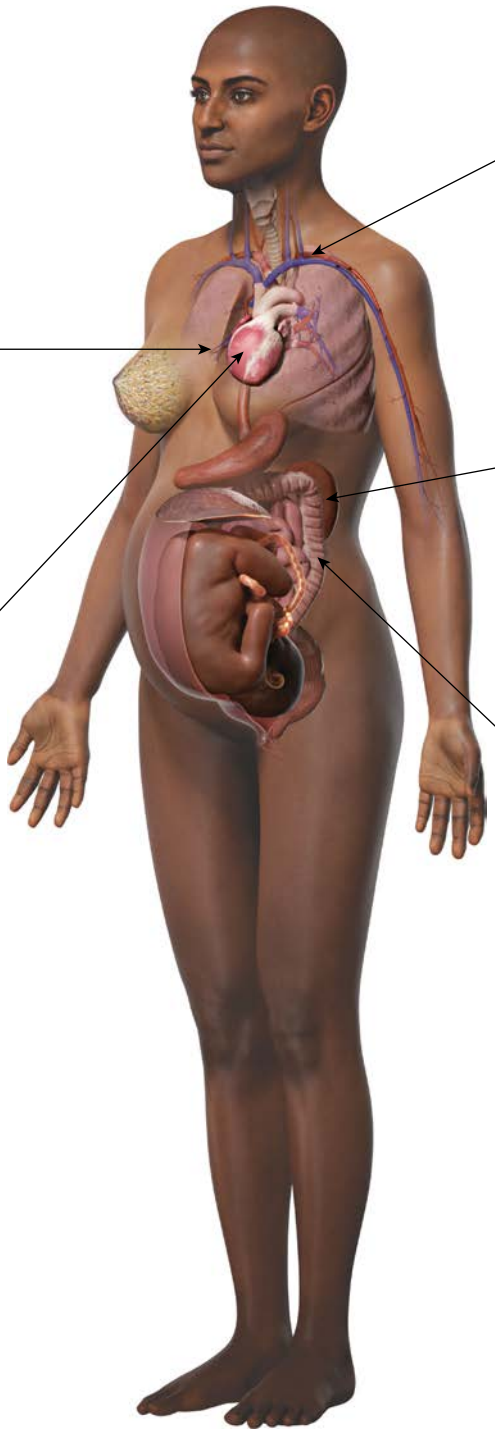
Gestational diabetes mellitus
- An oral glucose tolerance test is offered at 24 to 28 weeks' gestation to all who have risk factors, including those with previous gestational diabetes mellitus, previous high-birth-weight babies, or a family history of type 2 diabetes.

Blood group and Rhesus status
- Blood group is recorded in case there is a transfusion requirement after delivery.
- Females who are Rhesus negative are offered anti-D in the third trimester to prevent formation of Rhesus antibodies (from transfer of Rhesus-positive blood from a Rhesus-positive baby), which may cause haemolytic disease of the newborn in a subsequent pregnancy (see Chapter 38). Free fetal DNA is increasingly used to target the prophylaxis only to those with Rhesus-positive babies.

Screening for inherited diseases
- Thalassaemia and sickle cell screening is offered in all pregnancies to those in high-risk populations to identify (via partner screening if the female is a carrier) the risk of disease in the fetus, which can be confirmed by chorionic villous sampling.

Screening for fetal chromosomal abnormalities

Physiological changes in pregnancy



Respiratory
↑ Oxygen consumption (by 20%)
↑ Minute ventilation (by 40%–50%)
↑ PO_2
↓ PCO_2
↓ Forced vital capacity (third trimester)

Cardiac
↑ Cardiac output (by 40%)
↑ Stroke volume
↑ Heart rate (by 10–20 bpm)
↓ Blood pressure (↓ in first and second trimesters)
↓ Systemic vascular resistance (by 25%–30%)
↓ Serum colloid osmotic pressure (by 10%–15%)

Endocrine
Insulin resistance
↑ Prolactin (10-fold)
↑ Cortisol
↑ Renin, angiotensin, aldosterone

Haematology
↑ Plasma volume (by 50%)
↓ Haemoglobin
↓ Platelets
↑ Fibrinogen (by 50%)
↑ Clotting factors VIII, IX, X
Venous stasis (left leg > right leg)

Renal
↑ Renal blood flow (by 60%–80%)
↑ Glomerular filtration rate (by 55%)
↑ Protein excretion (up to 300 mg/24 h)
↓ Serum creatinine (max = 77 μmol/L)
Glycosuria
Physiological renal tract dilation

Gastroenterology
↓ Gut motility
↑ Alkaline phosphatase
↓ Albumin (by 25%)

General
Fatigue
Weight gain
Nausea/vomiting
Constipation
Breathlessness
Palpitations
Ankle oedema

Skin
Palmar erythema
Dry skin
Telangiectasia
Pruritus (in 20%)

BACKGROUND

The prevalence of medical conditions that complicate pregnancy is increasing, partly because:

- Females in high-income countries are delaying childbearing.
- Fifty percent of pregnant persons are now overweight or obese, resulting in more patients with diabetes, hypertension, and associated co-morbidities.
- Those with chronic medical conditions, including congenital heart disease, diabetes, chronic kidney disease (CKD), and cystic fibrosis (CF), now survive into their childbearing years because of better medical care.
- Widening access to assisted conception, including use of donor eggs, means that age is no longer a barrier to pregnancy.

Death during or soon after pregnancy in the UK is now more often caused by medical conditions than obstetric complications. Confidential enquiries show that inadequate knowledge and care are implicated in one-quarter of deaths from medical conditions in pregnancy.

The anatomical and physiological changes that occur as an adaptation to normal pregnancy result in symptoms and signs that can overlap with clinical features of disease outside pregnancy. Many symptoms and signs are benign, but clinicians need to be aware of those that warrant further investigation and may be associated underlying pathology.

Females with pre-existing disease should be made aware of the required physiological adaptation to pregnancy, and symptoms may worsen or improve, depending on the body system involved. The physiological stress of pregnancy may also result in previously subclinical disease presenting for the first time.

Infectious diseases are a major problem in pregnancy leading to increased maternal and fetal mortality, particularly in low- and middle-income countries.

HYPERTENSIVE DISORDERS

During normal pregnancy, there is a reduction in blood pressure (BP) because of a decrease in systemic vascular resistance; this is maximal by gestational weeks 18 to 20.

Chronic or pre-existing hypertension

This presents with a raised BP before 20 weeks or with treated high BP if the patient was taking medication for hypertension before pregnancy.

Management

- ***Angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs)***, and ***thiazide diuretics*** are associated with congenital abnormalities and should be discontinued.
- ***Dietary salt*** intake should be kept low (<2 g or 100 mmol daily).
- ***Aspirin*** 150 mg should be given from 12 weeks' gestation to those at risk of pre-eclampsia (see later).
- ***Oral labetalol*** is first-line therapy during pregnancy in the UK. Alternative agents are modified-release nifedipine and methyldopa.
- BP is treated in pregnancy when it is sustained at 140/90 mmHg or more.
- After treatment, ***target BP*** is less than 135 mmHg systolic and less than 85 mmHg diastolic. Difficulty controlling BP may be an indication for delivery.

Box 48.3 Risk factors for pre-eclampsia

- Age older than 40 years
- Obesity: body mass index >30 kg/m^2
- Family history
- Primiparity
- Multiple pregnancy
- Previous pre-eclampsia
- Long birth interval
- Hydrops with a large placenta
- Hydatidiform mole
- Triploidy (particular association with pre-eclampsia of very early onset—before 24 weeks' gestation)
- Medical disorders
  - Pre-existing hypertension
  - Kidney disease
  - Pre-existing diabetes mellitus
  - Antiphospholipid syndrome
  - Autoimmune rheumatic diseases
  - Sickle cell disease

In ***breast-feeding***, ACE inhibitors (enalapril), beta-blockers, modified-release nifedipine, and amlodipine are safe. Methyldopa should be avoided because of the risk of depression.

Gestational hypertension

This is defined as BP of 140/90 mmHg or more after 20 weeks' gestation in a previously normotensive female.

Investigations and management are aimed at distinguishing gestational hypertension from pre-eclampsia and maintaining a safe maternal BP for pregnancy:

- ***Blood tests:*** full blood count (FBC), serum creatinine and electrolytes, and liver biochemistry; estimated glomerular filtration rate (eGFR) is not validated for use in pregnancy
- ***BP measurements*** once a week
- ***Urine tests*** for protein
- ***Treatment*** of BP of 140/90 mmHg or more (which may be required for up to 3 months postpartum)
- ***Admission to hospital*** if BP of severe maternal hypertension (≥160/110 mmHg)

Pre-eclampsia

Pre-eclampsia is a common direct (obstetric) cause of maternal and perinatal death and a cause of significant morbidity. The risk factors are shown in **Box 48.3**. It is a heterogeneous multisystem endothelial disorder that has widespread effects.

There is good evidence that low-dose aspirin is beneficial in preventing preterm pre-eclampsia; it is safe in pregnancy. It is given from 12 weeks' gestation and is usually stopped at 36 weeks' gestation or sooner if the patient goes into labour or develops pre-eclampsia.

Clinical features

Pre-eclampsia varies in severity, timing, progression, and order of onset of different clinical features. Symptoms include:

- Severe or persistent headache
- Visual blurring or flashing
- Nausea and vomiting
- Severe epigastric or right upper quadrant pain
- Rapidly progressive oedema of the hands, feet, and face.

Signs include new hypertension (140/90 mmHg or more) after 20 weeks' gestation, oedema, and proteinuria (urinary protein:creatinine ratio >30 mg/mmol). Hyper-reflexia, clonus, and seizures (eclampsia) may occur.

Pre-eclampsia (including eclampsia) may present antenatally or intra- or postpartum. Postpartum disease is more likely to be associated with symptoms, particularly headache. Complications and crises are shown in **Box 48.4**.

Box 48.4 Complications and crises seen in pre-eclampsia

- Eclampsia
- HELLP syndrome (*h*aemolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets)
- Pulmonary oedema
- Placental abruption
- Cerebral haemorrhage
- Cortical blindness
- Disseminated intravascular coagulation
- Acute kidney injury
- Hepatic rupture
- Transient left ventricular systolic or diastolic dysfunction

Investigations

- ***FBC:*** thrombocytopenia
- ***Serum electrolytes and creatinine:*** acute kidney injury (AKI)
- ***Liver biochemistry:*** transaminitis
- ***Urine protein:creatinine ratio:*** new proteinuria
- ***Ultrasonography for fetal growth:*** to assess for placental dysfunction and inform timing of delivery
- ***Plasma placental growth factor (PlGF) concentration alone or as a ratio to soluble fms-like tyrosine kinase-1 (sFlt1:PlGF):*** novel immunoassays recommended by the National Institute for Health and Care Excellence (NICE) to diagnose or rule out pre-eclampsia after clinical assessment

Management

Close monitoring is required to ensure BP control and to assess for the development of severe disease features. This is required at least twice per week. Hospital admission may be indicated if BP control is difficult, if severe features develop, or if there is any other clinical concern. Close fetal monitoring is required because of the risks of placental insufficiency and intrauterine growth restriction.

If a patient develops eclampsia (convulsions or coma) or HELLP syndrome (see next section), she should be admitted to a critical care or high-dependency unit. Intravenous antihypertensives (labetalol, hydralazine) can be used if oral medications are ineffective or the oral route is not safe or possible. In eclampsia (or when there is risk of developing eclampsia), magnesium sulphate (4 g bolus dose followed by an infusion of 1 g/h) is used to treat and provide prophylaxis of seizures. Patients should be given steroids (intramuscular betamethasone/dexamethasone 12 mg repeated at 24 hours) for fetal lung maturation if delivery before 35 weeks' is likely within 7 days. Delivery is the only cure for pre-eclampsia, and this may be indicated for either fetal or maternal reasons. The recurrence risk of pre-eclampsia is increased with early-onset disease. Those whose pregnancy has been complicated by pre-eclampsia are significantly more likely to develop hypertension, ischaemic heart disease, cerebrovascular disease, and CKD in later life.

HELLP

HELLP is a syndrome describing ***h***aemolysis, ***e***levated ***l***iver enzymes, and ***l***ow ***p***latelets (<100 × 10^9/L) in a pregnant female. It is a form of severe pre-eclampsia, more common in multiparous females, and can occur in the second and third trimesters or postpartum. The haemolysis is caused by a microangiopathic haemolytic anaemia. Hypertension and proteinuria may be absent or mild. Clinically, patients complain of epigastric or right upper quadrant pain, nausea, vomiting, and jaundice (5%). Prompt delivery is usual and advised in all patients who are beyond 34 weeks' gestation.

National Institute for Health and Care Excellence. *NICE Clinical Guideline 133: Hypertension in pregnancy: Diagnosis and management*. NICE 2019; http://www.nice.org.uk/guidance/ng133.

LIVER DISEASE

Liver function is not impaired in normal pregnancy. Pregnancy-specific liver diseases include intrahepatic cholestasis and acute fatty liver of pregnancy. In addition, liver disease from any cause can occur incidentally and coincide with pregnancy. For example, viral hepatitis accounts for 40% of all cases of jaundice during pregnancy. Pregnancy does not necessarily exacerbate established liver disease. It is less common for females with advanced liver disease to conceive.

The following effects are seen:

- Plasma and blood volumes increase during pregnancy, but the hepatic blood flow remains constant.
- The proportion of cardiac output delivered to the liver therefore falls from 35% to 29% in late pregnancy; drug metabolism can thus be affected.
- The size of the liver remains constant.
- Liver biochemistry remains unchanged, apart from a rise in serum alkaline phosphatase from the placenta (up to three to four times increased) and a decrease in total protein and albumin concentration owing to increased plasma volume.
- Triglyceride, cholesterol, caeruloplasmin, transferrin, α_1-antitrypsin, and fibrinogen concentrations are elevated because of increased hepatic synthesis.
- Pregnancy and the postpartum period confer an increased risk of venous thromboembolism (VTE). Acute Budd–Chiari syndrome can occur.

Hyperemesis gravidarum

Pathological vomiting during pregnancy can be associated with liver dysfunction and jaundice. Liver dysfunction resolves when vomiting subsides.

Intrahepatic cholestasis of pregnancy

This condition of unknown aetiology usually presents with pruritus in the third trimester. It has a familial tendency, and there is a higher prevalence in Scandinavia, Chile, and Bolivia.

Liver biochemistry shows raised serum bile acids that may or may not be associated with raised aminotransferase concentrations. Gamma-glutamyl transferase may also be slightly raised. Jaundice is rare. Liver biopsy is not indicated but would show centrilobular cholestasis. The prognosis is usually excellent for the pregnant person, but there is increased risk of fetal loss in those with serum bile acids greater than 100 μmol/L and an increased risk of preterm labour in those with serum bile acids greater than 40 μmol/L.

Treatment with ursodeoxycholic acid 1 to 2 g daily in divided doses may reduce spontaneous preterm labour but does not treat itch or improve liver biochemistry. Delivery is timed to try to avoid

Box 48.5 Pregnancy-associated risks of different cardiac diseases

Low risk
- Uncomplicated small or mild pulmonary stenosis, PDA, or MVP
- Successfully repaired ASD, VSD, or PDA
- Atrial and ventricular ectopic beats

Small increased risk of death and moderate increased risk of morbidity
- Unrepaired ASD or VSD
- Repaired tetralogy of Fallot
- Most arrhythmias

Moderate increased risk of death or severe morbidity
- Mild LV dysfunction (LVEF >45%), hypertrophic cardiomyopathy
- Repaired coarctation
- Most native or tissue valve disease (except those with extremely high risk)

Significant increased risk of death or severe morbidity
- Mechanical valves
- Systemic RV with good or mildly impaired ventricular function
- Fontan circulation
- Unrepaired cyanotic congenital heart disease

Extremely high risk of death or severe morbidity
- Pulmonary arterial hypertension
- Severe systemic ventricular dysfunction: LVEF <30% (NYHA class III or IV; see **Box 17.20**)
- Previous peripartum cardiomyopathy with residual LV impairment
- Severe mitral stenosis or symptomatic aortic stenosis
- Severe aortic (re)coarctation
- Systemic RV with moderate or severely decreased ventricular function
- Dilated aortic root
  - Marfan's syndrome >45 mm
  - Turner's syndrome with ASI >25 mm/m^2
  - Tetralogy of Fallot >50 mm
  - Ascending aorta >50 mm with bicuspid aortic valve
- Vascular Ehlers–Danlos syndrome
- Fontan circulation with any complication

ASD, Atrial septal defect; *ASI,* aortic size index; *LV,* left ventricular; *LVEF,* left ventricular ejection fraction; *MVP,* mitral valve prolapse; *NYHA,* New York Heart Association; *PDA,* patent ductus arteriosus; *RV,* right ventricle; *VSD,* ventricular septal defect.

the increased risk of fetal loss, depending on disease severity. The condition resolves after delivery. Recurrent cholestasis may occur during subsequent pregnancies or with the ingestion of oestrogen-containing oral contraceptive pills.

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare but serious condition occurring in the third trimester and affecting 1 in 6000 to 20 000 pregnancies. It is more common in slim females with multiple gestations. Patients present with abdominal pain, vomiting, and jaundice. Polyuria and polydipsia caused by diabetes insipidus may occur because of reduced breakdown of placentally derived vasopressinase. AKI and lactic acidosis are commonly seen. In fulminant AFLP, encephalopathy, coagulopathy, and hypoglycaemia can occur. AFLP may be associated with features of pre-eclampsia.

Investigations

- FBC: neutrophilia
- Serum electrolytes and creatinine: AKI
- Plasma glucose: hypoglycaemia
- Serum uric acid: increased
- Liver biochemistry: hepatocellular damage: raised serum aminotransferases and raised bilirubin
- Coagulopathy: increased prothrombin time
- ***Liver biopsy:*** rarely performed and not necessary for diagnosis but would show fine droplets of fat (microvesicular) in the hepatocytes with little necrosis

Treatment includes delivery and supportive care as for acute liver failure (see Chapter 23). *N*-acetyl cysteine is safe in pregnancy. Early diagnosis and treatment have reduced the mortality rate to less than 20%.

Further reading

EASL Clinical Practice Guideline. *Liver Disease in Pregnancy* (published July 3rd 2023). https://easl.eu/publications/clinical-practice-guidelines/.

CARDIAC DISEASE

Cardiac disease, both congenital and acquired, is commonly encountered in pregnancy and is mostly benign. Many pregnant patients experience palpitations and breathlessness because of awareness of physiological sinus tachycardia, ventricular premature or ectopic beats, and increased minute ventilation.

Cardiac disease, predominantly acquired, is the most common cause of maternal death in the UK. The main conditions causing severe morbidity and mortality are as follows:

- ***Myocardial infarction (MI)*** in pregnancy is more often caused by coronary artery dissection or thrombus compared with non-pregnant patients. Intervention with primary angioplasty and coronary artery stenting is appropriate.
- ***Peripartum cardiomyopathy*** is defined as the development of heart failure with left ventricular ejection fraction (LVEF) less than 45% at the end of pregnancy or in the months after delivery when no other cause of heart failure is found. It is a dilated cardiomyopathy and is associated with obesity and multiparity. It is treated with conventional heart failure therapy (including thromboprophylaxis) except ACE inhibitors and ARBs are withheld until after delivery. Nearly half of patients recover to normal within 6 months, but many are found to have a pre-existing but undiagnosed dilated cardiomyopathy that became symptomatic in pregnancy.
- ***Pulmonary hypertension*** and fixed pulmonary vascular resistance are dangerous and often (10%–20%) fatal in pregnancy.

Females with significant heart disease need multidisciplinary care in a specialist centre that includes obstetricians, cardiologists, and anaesthetists with expertise in the care of heart disease in pregnancy. The levels of risk associated with pregnancy for individual conditions are summarized in **Box 48.5** based on the European Society of Cardiology's guidelines.

Pregnancy may be contraindicated where there is a high risk of death or serious morbidity (**Box 48.5**). Absolute and relative contraindications to pregnancy include a dilated aortic root of more than 4.5 cm, severe left heart obstruction from critical mitral or aortic stenosis, and severe impairment of left ventricular function. If pregnancy is contraindicated, contraceptive advice and provision is essential.

Pregnancy and prosthetic heart valves

Any strategy for anticoagulation of a mechanical heart valve in pregnancy is associated with risks to the pregnant person, fetus, or both. ***Pre-pregnancy counselling*** is essential, explaining that

Box 48.6 Risk factors for venous thromboembolism in pregnancy

- Previous venous thromboembolism
- Thrombophilia
- Active inflammatory disease, e.g., inflammatory bowel disease, systemic lupus erythematosus, pyelonephritis, nephrotic syndrome
- Age older than 35 years
- Obesity (body mass index >30 kg/m^2) before or in early pregnancy
- Parity of three or more previous deliveries
- Smoking
- Gross varicose veins (symptomatic or above the knee or with associated phlebitis, oedema, or skin changes)
- Dehydration, hyperemesis gravidarum, ovarian hyperstimulation syndrome
- Paraplegia, immobility
- Multiple pregnancy
- Current pre-eclampsia
- Caesarean section
- Prolonged labour (>24 hours)
- Mid-cavity rotational operative delivery
- Stillbirth
- Preterm birth
- Postpartum haemorrhage (>1 L or requiring transfusion)
- Surgery in pregnancy or the puerperium

warfarin is the safest option for the pregnant person but is associated with a 5% risk of warfarin embryopathy and increased risks of miscarriage, stillbirth, and fetal intracranial haemorrhage. The alternative is full anticoagulant doses of low-molecular-weight heparin (LMWH), given twice daily and titrated upward in pregnancy, based on ***regular monitoring of anti-factor Xa*** levels. This is safe for fetuses but may offer less effective anticoagulation, conferring a risk for valve thrombosis.

THROMBOEMBOLIC DISEASE

Pulmonary embolism (PE) is the most common direct cause of death in pregnancy and the puerperium. Pregnancy and especially the puerperium are associated with a sixfold increased risk of thrombosis. Although the risks are highest after emergency caesarean section, those with risk factors (**Box 48.6**) are at risk antenatally, especially if admitted to hospital, and after vaginal delivery.

Diagnosis

The diagnosis of deep vein thrombosis (DVT) and PE must be made in those with a suggestive history. ***D-dimers*** are not useful because concentrations are often raised in normal pregnancies. DVT is much more common in the left leg (ratio, 9:1) in pregnancy because the gravid uterus compresses the left common iliac vein, which lies under the right common iliac artery. ***Ventilation/perfusion (V/Q) scans*** and computed tomography ***pulmonary angiography*** are associated with negligible radiation to the fetus and are safe, but V/Q scans may be preferred because of reduced radiation to the breast.

Management

Treatment of VTE in pregnancy involves:

- LMWHs (e.g., enoxaparin, dalteparin, tinzaparin) continued for the rest of the pregnancy and the puerperium. Higher doses are required compared to outside of pregnancy.
- Avoidance of warfarin and direct oral anticoagulants.

Decisions regarding thromboprophylaxis in pregnancy relate to a past history of VTE, the presence of thrombophilia, and other risk factors (see **Box 48.6**). Antenatal and postnatal thromboprophylaxis with LMWH should be offered to those with a history of previous VTE and in those with significant risk factors for VTE. This should begin as early in pregnancy as possible. LMWH and warfarin are safe in lactation.

RESPIRATORY DISEASE

Asthma

The treatment of asthma in pregnancy does not differ from that in non-pregnant patients. Pregnancy itself does not usually influence the severity of asthma. For the majority, asthma has no adverse effect on pregnancy outcomes. Key messages for asthma in pregnancy include:

- Poorly controlled severe asthma presents more of a risk to the fetus than the medication used to prevent or treat it. Risk is minimized with good control.
- Education and reassurance, ideally before pregnancy, concerning the safety of asthma medications during pregnancy are integral parts of management.
- Decreasing or stopping inhaled anti-inflammatory therapy during pregnancy can cause a deterioration in disease control.
- Corticosteroids (inhaled, oral, and intravenous) and β_2-agonists (short- and long-acting, inhaled, nebulized, and intravenous) and the leukotriene receptor antagonist montelukast are safe to use in pregnancy and while breast-feeding. Data for omalizumab and other newer biologics used for asthma and eczema suggest no adverse effects in pregnancy, with significant benefit for maintaining disease control.
- Effective control of asthma and its accompanying symptoms is a priority. An increase in the dose or frequency of inhaled steroids should be the first step if symptoms are not optimally controlled and the inhaler technique is good.

Pneumonia

The bacteria that cause pneumonia are no different in pregnancy. Chest radiographs are safe in pregnancy. Most antibiotics are safe to use in pregnancy and during lactation, though tetracycline and doxycycline should not be given. Varicella, influenza, and COVID-19 pneumonia may be fatal in pregnancy, and active steps must be taken to prevent chickenpox infection. Non-immune pregnant females exposed to varicella in pregnancy should be given varicella zoster immunoglobulin. If a pregnant female does contract chickenpox, she should be treated with aciclovir as soon as possible. All pregnant females should receive immunization against seasonal influenza and SARS-CoV-2.

Tuberculosis

Tuberculosis (TB) is common, particularly in Africa and Asia. A chest radiograph should be performed if TB is suspected, and the advice of a respiratory physician should be sought. Extrapulmonary TB is as common as pulmonary TB in pregnancy. The diagnosis must be confirmed bacteriologically, which may necessitate bronchoscopy or biopsy, which are safe in pregnancy but is often delayed because of inappropriate reluctance to perform invasive investigations in pregnancy. The neonate should be given Bacille Calmette–Guérin vaccination.

Sarcoidosis

The course of sarcoidosis is unaltered by pregnancy. Disease flare is more likely postpartum. Erythema nodosum may occur in a normal pregnancy. Serum ACE is not reliable for the diagnosis of sarcoidosis in pregnancy. Systemic steroids should be used if indicated (see Chapter 20).

Cystic fibrosis

Females with CF often reach reproductive age with adequate lung function or will have received a lung transplant and be able to consider pregnancy. Pre-pregnancy counselling, with consideration of lung function and concomitant diabetes, is required. Joint care with a CF centre should be maintained throughout pregnancy. Pregnancy outcome is related to pre-pregnancy lung function. Perinatal outcome is usually good but preterm delivery rates are high. Maternal outcome is variable and worse in the presence of pulmonary hypertension. Specialist dietary advice with additional energy supplements should be given. Chest physiotherapy can and should be continued in pregnancy, and infective exacerbations should be treated aggressively. There is an increased risk of gestational diabetes. The advent of cystic fibrosis transmembrane conductance regulator modulators has revolutionized the lives of many people with CF, and pregnancy outcomes have improved as a result. The significant benefits of these medications mean that they are continued in pregnancy in the absence of evidence of harm.

Severe restrictive lung disease

Females with severe lung disease are better able to tolerate pregnancy than females with severe cardiac insufficiency. If the forced vital capacity is over 1 L, a successful pregnancy is usually possible, but individual assessment is necessary. Immunosuppression for diffuse parenchymal lung disease should be continued in pregnancy, with the exception of mycophenolate which is teratogenic. Respiratory diseases complicated by pulmonary hypertension have a poor prognosis in pregnancy.

NEUROLOGICAL DISEASE

Epilepsy

In most, the frequency of seizures is not altered in pregnancy, provided there is *adherence* with antiepileptic drugs (AEDs). Free drug concentrations tend to fall in pregnancy, so increased doses of AEDs, particularly lamotrigine, may be required. The risk to the fetus of uncontrolled seizures is greater than the risks of continuing AED treatment; poorly controlled epilepsy and recurrent seizures are associated with adverse outcomes for both pregnant person *and* fetus, including an increased risk of sudden unexplained death in epilepsy. Monotherapy at the minimum effective dose is preferable when this offers effective disease control.

Birth defects

The overall risk of birth defects in people without epilepsy is 3%. The risk with lamotrigine and levetiracetam is not increased. The risk with carbamazepine and topiramate is 4% to 5% and with phenytoin and phenobarbital is about 6%. Sodium valproate is associated with the highest rate of serious malformations (e.g., neural tube defects) and long-term neurodevelopmental defects (e.g., reduced IQ, increased risk of autism spectrum disorder and attention-deficit disorder), and it should be stopped and substituted if necessary before conception.

Management

Counselling before conception is essential. Folic acid (5 mg/day) supplements should be taken before conception and throughout the first trimester. Antenatal screening for congenital abnormalities is necessary. Patients with epilepsy are advised to shower rather than bathe and should not be left unattended in the peripartum period. Taking AEDs is compatible with breast-feeding, though precautions regarding breast-feeding, changing the baby at floor level, and only using shallow water to wash the baby are advised.

Contraception and epilepsy

AEDs that induce hepatic enzymes (e.g., carbamazepine, phenytoin, and phenobarbital) reduce the efficacy of oral contraceptives. A combined contraceptive pill containing a higher dose of oestrogen or the progesterone-only pill provides greater contraceptive security. An intrauterine device or progesterone implant is often recommended in preference to oral contraceptives.

Migraine

Migraine can occur as a pregnancy-related phenomenon without a prior history of migraine. Those with pre-existing migraine can improve in pregnancy. Hemiplegic migraine, particularly aura without headache, can mimic transient ischaemic attacks. Sumatriptan may be used to treat migraine. Low-dose aspirin, beta-blockers, tricyclic antidepressants, and pizotifen are used for prophylaxis. Greater occipital nerve injections are safe in pregnancy. Ergotamine should be avoided in pregnancy.

Multiple sclerosis

Pregnancy has no effect on the long-term prognosis of patients with multiple sclerosis. Relapses are less likely during pregnancy but more likely in the postpartum period. Prophylactic treatments, such as interferon-beta, glatiramer, and natalizumab, may be used in pregnancy and breast-feeding. Discontinuation of natalizumab may result in flare-ups in pregnancy and is not advised, but the injections can be spaced and interrupted in late pregnancy to avoid excessive transfer to the fetus. Vitamin D supplements of at least 4000 units daily should be given to all. Those with disability may require extra help during pregnancy and while caring for their infants after delivery. There is no contraindication to epidural anaesthesia except that documentation of a pre-existing neurological deficit in the legs is necessary to avoid any postpartum exacerbation of multiple sclerosis being inappropriately attributed to a regional block.

Myasthenia gravis

The course of myasthenia gravis in pregnancy is unpredictable, but in those with stable disease, pregnancy outcomes are usually good. Postpartum exacerbations occur in 30%. Usual immunosuppressant therapy with steroids, azathioprine, intravenous immunoglobulin, and calcineurin inhibitors should be continued. Plasmapheresis is not contraindicated in pregnancy. Increased doses of long-acting anticholinesterases may be required. Many drugs should be avoided in myasthenia gravis, and an experienced obstetric anaesthetist should be consulted. Transient neonatal myasthenia gravis may develop in up to 10% of neonates because of transplacental passage of immunoglobulin G acetylcholine receptor antibodies.

Stroke

The risks of arterial ischaemic stroke, cerebral venous thrombosis, and intracranial haemorrhage are increased, particularly in the puerperium. In pregnancy, the prevalence of haemorrhagic stroke equals that of ischaemic stroke, in contrast to outside of pregnancy, when ischaemic stroke is more common (>75% of strokes). Causes of stroke in pregnancy are listed in **Box 48.7**.

? Box 48.7 Some causes of stroke in pregnancy

Ischaemic
- Cardiac causes, e.g., arterial emboli or arrhythmias
- Peripartum or dilated cardiomyopathy
- Paradoxical embolus through an atrial septal defect or patent foramen ovale
- Aortic or carotid artery dissection
- Antiphospholipid syndrome
- Sickle cell disease

Haemorrhagic
- Pre-eclampsia or eclampsia
- Ruptured arteriovenous malformation or berry aneurysm

ENDOCRINE DISEASE

Type 1 and 2 diabetes

Diabetes is one of the most common medical conditions in pregnancy, affecting up to 5% of pregnancies. The epidemiology of pre-existing diabetes in pregnancy is changing because of trends of delaying pregnancy and the increased prevalence of obesity and type 2 diabetes at reproductive age. Whereas 30 years ago, type 2 diabetes was rare in pregnancy, the latest UK national audit has indicated that type 2 diabetes is now more prevalent than type 1 diabetes in pregnancy.

Adverse effects of diabetes in pregnancy

Pregnancy complications increase with maternal hyperglycaemia. Pre-existing diabetes may make it more difficult to conceive, with higher rates of miscarriage and congenital anomalies (twice those of the background population). The risk of congenital malformations is directly proportional to the pre-pregnancy hemoglobin A_{1c} (HbA_{1c}) concentration. Females with diabetes who are planning pregnancy are therefore advised to aim for a HbA_{1c} below 48 mmol/mol, provided it can be achieved without hypoglycaemia. Those with an HbA_{1c} greater than 86 mmol/mol are advised not to conceive because of the high risk of congenital malformation. Because congenital malformations occur as early as 5 to 6 weeks after conception, the importance of pre-pregnancy counselling cannot be understated. Pre-pregnancy counselling affords the opportunity to:

- Discuss the need for optimized glycaemic control and safe and effective contraception until this is achieved.
- Provide high dose folic acid (5 mg/day) to reduce the risk of neural tube defects.
- Assess for microvascular (retinopathy and nephropathy) complications.
- Review medication and make a plan for pregnancy including discontinuation of oral antidiabetes drugs, glucagon-like peptide-1 receptor agonists, ACE inhibitors, ARBs, and statins.
- Offer an opportunity for structured diabetes education.

Other fetal risks include macrosomia with associated shoulder dystocia and birth injury, polyhydramnios, neonatal unit admission, stillbirth, and perinatal death. Impaired postnatal metabolic adaptation leads to higher rates of neonatal hypoglycaemia, jaundice, and respiratory distress. Maternal glucose crosses the placenta, but insulin does not; this leads the fetal islets to hypersecrete insulin to combat maternal hyperglycaemia, so rebound hypoglycaemia may occur when the umbilical cord is cut. In the longer term, the offspring of pregnant persons with diabetes have a higher risk of obesity and diabetes in adulthood.

Maternal risks include increased rates of pre-eclampsia, hypoglycaemia, diabetic ketoacidosis (which occurs at lower glucose concentrations compared with outside of pregnancy and is associated with a 40% risk of fetal death), and worsening of microvascular complications.

Management of diabetes during pregnancy

Maintaining normoglycaemia without causing hypoglycaemia is the main aim of treatment. A multidisciplinary team including a physician, obstetrician, and diabetes specialist nurse or midwife undertakes a clinical review at least every 2 weeks in pregnancy.

Antenatal glucose concentration targets are less than 5.3 mmol/L fasting (95 mg/dL), less than 7.8 mmol/L (140 mg/dL) 1 hour after meals, and less than 6.4 mmol/L (115 mg/dL) 2 hours after meals. Continuous glucose monitoring increases the time in the target glucose range and is associated with improved fetal outcomes. This is recommended for females with type I diabetes in pregnancy. Closed-loop systems with insulin pumps also improve glycaemic control, and they should be offered where available. Females with type II diabetes typically monitor by capillary blood testing. HbA_{1c} is not used to monitor blood glucose control in the second and third trimesters of pregnancy.

Glycaemic control is challenging in pregnancy because insulin requirements change. In the first trimester, insulin requirement decrease as a result of hormonal changes and reduced appetite from pregnancy-associated nausea and vomiting. For reasons that are not entirely clear, early pregnancy is also associated with impaired awareness of hypoglycaemia, which increases the risk and severity of hypoglycaemia. Understanding this risk and the self-management of hypoglycaemia is important. In the second and third trimesters, pregnancy induces a state of insulin resistance, which typically increases insulin requirements by 50% to 100%. Ketoacidosis in pregnancy carries a 40% fetal mortality rate, and it should therefore be diagnosed and managed rapidly. Self-monitoring of blood ketone concentrations is taught at the outset of pregnancy.

Pregnancy can accelerate the progression of retinopathy, so screening is undertaken in the first and third trimester and in the second trimester if retinopathy is present.

Low-dose aspirin (150 mg/day) from the 12th week of pregnancy reduces the risk of preterm pre-eclampsia.

Enhanced fetal surveillance is needed, and a detailed ultrasound scan for fetal anomalies, including a four-chamber view of the fetal heart and outflow tracts, should be offered at 18 to 20 weeks' gestation. Growth scans and other tests of fetal wellbeing should be performed during the third trimester.

Most babies are born before term after an induction of labour or elective caesarean section to reduce the risk of stillbirth. Glycaemic control during labour in those with type 1 diabetes is usually maintained by a variable rate intravenous insulin infusion, but pumps are being increasingly used as an alternative.

After birth, maternal insulin requirements drop rapidly to preconception levels within hours of the birth and may even be lower if a female chooses to breast-feed. Because neonates are at increased risk of hypoglycaemia, early feeding should be encouraged and neonatal glucose checked regularly until it is clear that the pre-feeding glucose levels are being maintained.

Gestational diabetes

Gestational diabetes is defined as diabetes occurring for the first time in pregnancy, not caused by diabetes before pregnancy. It is usually diagnosed in the second and third trimester of pregnancy after a 75-g oral glucose tolerance test. Gestational diabetes occurs when pancreatic β cells are unable to secrete sufficient insulin to counter pregnancy-induced insulin resistance. Risk factors for gestational diabetes are the same as for type 2 diabetes. Gestational diabetes therefore reveal risk for the development of future type 2 diabetes. Not all diabetes presenting in pregnancy is gestational. Screening may identify previously undiagnosed type 2 diabetes. Less commonly, gestational diabetes may unmask pre-clinical type 1 diabetes or maturity-onset diabetes of the young.

Diagnosis of gestational diabetes

There is no international consensus regarding diagnosis with varying diagnostic thresholds (**Box 48.8**). Universal screening for diabetes is recommended in many countries, but in the UK, NICE recommends screening only when there are risk factors (**Box 48.9**) and considering screening when urine dipstick testing shows glycosuria of 2+ or above on 1 occasion or glycosuria of 1+ or above on two or more occasions.

Management of gestational diabetes

Glucose targets are the same as for pre-existing diabetes, but management begins with diet and lifestyle modifications including healthier carbohydrates (low glycaemic index), reduced sugar intake, normal meal portions sizes, and daily exercise. If this does not achieve adequate maternal glycaemia within 1 to 2 weeks, pharmacological therapy is indicated, typically with metformin and insulin if indicated.

HbA_{1c} testing should be undertaken 3 months after delivery to exclude undiagnosed pre-existing type 2 diabetes. Gestational diabetes confers a 50% chance of developing diabetes within 10 years of the pregnancy. This risk and the measures needed to reduce it should be discussed. Screening with an annual HbA_{1c} is recommended. At present, the uptake of postnatal interventions and screening is low, and research into more effective risk management is needed.

Box 48.8 Comparison of the NICE and IADPSG diagnostic criteria for gestational diabetes

Association	Glucose load (g)	No. of high readings needed	Fasting glucose	1-h glucose	2-h glucose
IADPSG/WHO	75	≥1	5.1 mmol/L (92 mg/dL)	10.0 mmol/L (180 mg/dL)	8.5 mmol/L 153 mg/dL)
NICE	75	≥1	5.6 mmol/L (100 mg/dL)		7.8 mmol/L (140 mg/dL)

IADPSG, International Association of Diabetes and Pregnancy Study Groups; *NICE*, National Institute for Health and Care Excellence; *WHO*, World Health Organization.

Box 48.9 Risk factors for gestational diabetes: National Institute for Health and Care Excellence (NICE) recommendations for the 75-g oral glucose tolerance test

NICE recommends undertaking a 75-g oral glucose tolerance test at 24 to 28 weeks' gestation in those with the following risk factors:

- Body mass index >30 kg/m^2
- Previous macrosomic baby (≥4.5 kg)
- Previous gestational diabetes
- First-degree relative with diabetes
- Family origin with a high prevalence of diabetes, e.g., South Asian, Black Caribbean, Middle Eastern

Thyroid and parathyroid disease

Thyrotoxicosis

Untreated thyrotoxicosis is dangerous for both the pregnant person and fetus, increasing the risk of miscarriage, fetal growth restriction (FGR), and preterm delivery. Graves' disease affects about 0.2% of pregnancies and often improves during pregnancy, but there is a risk of postpartum flare. Both carbimazole and propylthiouracil (PTU) cross the placenta and in high doses may cause fetal hypothyroidism and goitre. The lowest possible maintenance dose of anti-thyroid drug should be used. Guidelines advise avoidance of carbimazole in the first trimester because of the risk of teratogenesis. PTU is usually not given because of the risk of liver failure in the general population but may be used specifically in those planning pregnancy or in the first trimester. Switch from one anti-thyroid drug to another is not indicated before or during pregnancy because of the risk that switch compromises disease control, with no evidence for improved outcomes. For those with disease controlled with dosages of carbimazole of less than 15 mg/day or PTU less than 150 mg/day, pregnancy outcomes are usually good. Breast-feeding is safe on these doses of anti-thyroid drugs. Beta-blockers are also safe if required for thyrotoxic symptoms. Neonatal or fetal thyrotoxicosis caused by transplacental passage of thyroid-stimulating antibodies is rare but occurs most commonly in those with active disease in pregnancy and those with high concentrations of thyroid-stimulating antibodies.

Hypothyroidism

Hypothyroidism affects about 1% of pregnancies. Severe untreated hypothyroidism is associated with infertility, an increased rate of miscarriage, and fetal loss. For those on adequate replacement therapy, maternal and fetal outcomes are usually good and unaffected by hypothyroidism. Very little thyroxine crosses the placenta, and the fetus is not at risk of thyrotoxicosis from maternal thyroxine replacement therapy. Those who are euthyroid at the beginning of pregnancy usually do not require any adjustment to thyroxine dose during pregnancy or in the puerperium. Dose changes should be based on thyroid function tests, interpreted using pregnancy-specific reference intervals (or thyroid-stimulating hormone [TSH] <4.0 mU/L after 7 weeks' gestation). There is no evidence to support older recommendations for a target TSH of less than 2.5 mU/L in pregnancy.

Subclinical hypothyroidism affects 5% of the general population and is more common in females, particularly those who have antithyroid antibodies. Studies fail to demonstrate a consistent association between any adverse pregnancy outcome and subclinical hypothyroidism in pregnancy, and there is insufficient evidence that thyroxine replacement in subclinical hypothyroidism benefits pregnancy outcome. However, most authorities advocate thyroxine replacement if the TSH is greater than 4.0 mU/L.

Postpartum thyroiditis has a prevalence of 5% to 7% and is more common in those with a family history of hypothyroidism, thyroid peroxidase antibodies, and type 1 diabetes. Presentation is usually between 3 and 4 months postpartum. Disease may present with symptoms of hyper- or hypothyroidism, but a high index of suspicion is needed. The condition is caused by a destructive autoimmune lymphocytic thyroiditis. In most cases, treatment is not required, and recovery is complete, but in a small proportion, progression to permanent hypothyroidism will occur. Postpartum thyroiditis often recurs and is a significant predictor of future hypothyroidism.

Hyperparathyroidism

Hypercalcaemia may be improved by pregnancy and the fetal demand for calcium. Risks include acute pancreatitis and hypercalcaemic crisis, especially postpartum, when maternal transfer of calcium to the fetus stops abruptly. There are also increased risks of miscarriage, intrauterine death, and preterm labour. Fetal mortality rates are up to 40% when the maternal hypercalcaemia is severe (>3.5 mmol/L). Up to 25% of pregnancies complicated by hyperparathyroidism develop hypertension or pre-eclampsia. Suppression of fetal parathyroid hormone by high maternal calcium concentrations confers a risk of neonatal tetany and hypocalcaemic convulsions secondary to hypocalcaemia, usually presenting 5 to 14 days after birth but delayed by up to 1 month if the infant is breast-fed. The ideal treatment is surgical removal of the parathyroid adenoma. This may be safely performed in pregnancy, usually in the second trimester, which removes the maternal and neonatal risks associated with hypercalcaemia.

Pituitary disease

Prolactinomas

Prolactinomas are the most common pituitary tumours encountered in pregnancy but rarely cause problems. The prolactin concentration should not be measured during pregnancy or breast-feeding because it is invariably raised. Those with microprolactinomas usually have no problems in pregnancy. The risk of tumour enlargement

during pregnancy is increased with macroprolactinomas. Dopamine receptor agonists are safe for use in pregnancy and are usually continued for macroprolactinomas. Visual fields should be measured in each trimester in those with macroprolactinomas. If tumour enlargement is suspected, magnetic resonance imaging (MRI) of the pituitary is indicated. If those with macroprolactinomas wish to breast-feed, their dopamine receptor agonists may be discontinued in the last few weeks of pregnancy and during breast-feeding, but serial visual field examinations and pituitary MRI are required, and cabergoline or bromocriptine should be re-introduced if there is concern regarding tumour expansion.

Diabetes insipidus

Established or subclinical diabetes insipidus may worsen in pregnancy because of increased vasopressinase production by the placenta or decreased vasopressinase breakdown by the liver. Extended fluid deprivation tests should be avoided in pregnancy. Close observation with paired urine and plasma osmolality measurements may be sufficient to exclude DI. Desmopressin is safe for use in pregnancy for diagnosis or treatment of DI. Transient DI may occur in pregnancy often associated with acute fatty liver of pregnancy and, more rarely, with pre-eclampsia and HELLP syndrome.

Hypopituitarism

Hypopituitarism is rare in pregnancy but may be caused by:

- Pituitary surgery
- Radiotherapy
- Pituitary or hypothalamic tumours
- Pituitary haemorrhage
- Postpartum pituitary infarction (Sheehan's syndrome)
- Lymphocytic hypophysitis

Sheehan's syndrome usually presents after delivery after postpartum haemorrhage and may lead to partial or complete pituitary failure. There may be a delay in diagnosis because the symptoms may be attributed to the postpartum state.

Lymphocytic hypophysitis is an uncommon autoimmune disorder caused by extensive infiltration of the anterior pituitary by chronic inflammatory cells, predominantly lymphocytes, causing pituitary expansion. Most patients present in the last month of pregnancy or the first 2 weeks postpartum. It presents with features suggestive of an expanding pituitary tumour, and 85% of cases have endocrine hypofunction.

Adrenal disease

Conn's syndrome and hyperaldosteronism

This is rare in pregnancy, but hypertension that is difficult to control, the absence of a positive family history, and pre-pregnancy hypokalaemia are indications for screening. Renin and aldosterone concentrations are increased in pregnancy, and diagnosis requires the use of pregnancy-specific reference ranges, which are not commonly available. High concentrations of progesterone in pregnancy may antagonize aldosterone and ameliorate the hypokalaemia. Screening is therefore usually undertaken postpartum. Hypertension is controlled using labetalol, modified-release nifedipine, and/or methyldopa. Patients with hypokalaemia are treated with potassium supplementation or potassium-sparing diuretics. Amiloride is safe to use in pregnancy, and high doses (e.g., 20 mg) may be needed. Spironolactone should be avoided because of the risk of feminization of a male fetus because of antiandrogen effects. Surgery for adrenal adenomas is usually deferred until after delivery.

Phaeochromocytoma and paraganglioma

Phaeochromocytoma and paraganglioma are rare but dangerous causes of hypertension in pregnancy. Those with hypertension associated with unusual features of palpitations, anxiety, sweating, or headache should be screened. Management involves adequate α-blockade with phenoxybenzamine or doxazosin to control hypertension followed by β-blockade, if required, to control tachycardia. α-Blockade is imperative before delivery. Surgical removal is the only cure, and optimal timing of tumour resection depends on the gestational age when the diagnosis is made. There is an increasing vogue to delay tumour resection until the puerperium provided control with medical management is possible.

KIDNEY DISEASE

Urinary tract infection

Asymptomatic bacteriuria is detected in 2% to 6% of pregnancies, with concern that this increases the risks of pyelonephritis and preterm delivery. However, treatment of asymptomatic bacteriuria is based on historical data, with no contemporary randomized control data to guide practice. Symptomatic bacteriuria is always treated, regardless of symptoms.

Chronic kidney disease

Females with CKD are at increased risk of pre-eclampsia, FGR, preterm delivery, neonatal death, and the risk of permanent deterioration in kidney function. The risks of preterm delivery are increased by the presence of hypertension.

In females with ***moderate or severe kidney impairment*** (pre-pregnancy CKD stage 3–5, eGFR <60 mL/min/1.73 m^2), 20% to 90% of infants are born preterm, and there is a risk of accelerated decline in kidney function equivalent to 2 to 5 years of kidney disease in the absence of pregnancy. An increase in the degree of proteinuria is very common in pregnancy and does not necessarily imply pre-eclampsia or worsening kidney disease.

Management should include regular monitoring of BP, kidney function, and fetal wellbeing. In view of the increased risk of pre-eclampsia, treatment is with low-dose aspirin (150 mg/day from week 12–36 weeks).

Kidney transplantation

If graft function is normal, pregnancy outcomes are excellent, and there is no adverse long-term effect on kidney allograft function or survival. The chance of successful pregnancy outcome is reduced and the risk of long-term deterioration in graft function increased with poor baseline graft function. Pregnancy outcome is optimal in those without hypertension, proteinuria, or recent episodes of graft rejection.

Doses of immunosuppressive drugs should maintain pre-pregnancy concentrations. Prednisolone, azathioprine, ciclosporin, and tacrolimus are safe for use in pregnancy without any reported increase in risk of congenital malformations. Mycophenolate mofetil and sirolimus are contraindicated. Prophylactic antibiotics should

be given if there is urinary tract infection in pregnancy. The risks of pre-eclampsia, graft rejection, FGR, preterm delivery, and infection are increased. Caesarean section is required for obstetric indications, but the rate is increased.

Acute kidney injury

Because serum creatinine concentration falls in pregnancy, AKI is defined as an abrupt deterioration in kidney function with a serum creatinine of more than 77 μmol/L. Mild degrees of AKI are not uncommon, particularly in the immediate postpartum period. The most common underlying causes are:

- ***Infection:*** septic abortion, puerperal sepsis, acute pyelonephritis
- ***Blood loss:*** postpartum haemorrhage, placental abruption
- ***Volume contraction:*** pre-eclampsia, hyperemesis gravidarum, diarrhoea
- ***Renal tract obstruction:*** ureteric damage or obstruction
- ***Drugs:*** non-steroidal anti-inflammatory drugs (NSAIDs), antibiotics (e.g., aminoglycosides)

Females with pre-eclampsia are particularly prone to pulmonary oedema; therefore, management protocols include fluid restriction, even in the presence of oliguria. If these patients develop AKI, this is usually rapidly reversible on recovery and less dangerous than pulmonary oedema, which may result from repeated fluid challenges.

SKIN DISORDERS

Common skin changes that occur in pregnancy include striae, spider naevi, melasma (pigmentation on the face), and linea nigra (midline pigmentation on the abdomen). A shift in maternal immune profile from predominantly Th1 to Th2 may underlie the tendency for atopic dermatitis to develop or worsen during pregnancy. Psoriasis usually improves. Up to 20% of pregnant females develop pruritus, which is most common on the lower legs. Intrahepatic cholestasis (see 'Intrahepatic cholestasis of pregnancy' section) of pregnancy should be excluded by measuring bile acid concentrations.

The specific dermatoses of pregnancy are classified as shown in **Box 48.10**.

RHEUMATIC DISEASE

Systemic lupus erythematosus and rheumatoid arthritis are the commonest rheumatic diseases encountered in pregnancy. Active inflammatory disease reduces fertility, and active disease at the time of conception increases the risk of miscarriage, pre-eclampsia, FGR, and preterm delivery. Therefore, the emphasis should be on achieving good disease control before conception and throughout pregnancy. Up to 50% of females with rheumatoid arthritis go into remission in pregnancy, but 50% flare during the postpartum period. The risk of lupus flare is increased in pregnancy. Many disease-modifying anti-rheumatic drugs are compatible with pregnancy. Females should take advice from their rheumatologists, obstetric physicians, and obstetricians ***before*** conception. **Box 48.11** shows the use of drugs for rheumatoid arthritis in pregnancy.

Box 48.10 Classification of specific dermatoses of pregnancy

Dermatosis	Description	Management
Atopic eruption of pregnancy Atopic eczema Prurigo of pregnancy Pruritic folliculitis of pregnancy	Usually starts on the abdomen in the third trimester but may persist for some months after delivery Clustered excoriated papules (prurigo-like lesions) occur on the abdomen and extensor surfaces of the limbs Cause is unknown Can recur in subsequent pregnancies Itchy folliculitis that looks similar to steroid-induced 'acne' Not associated with any increased risk	Topical steroids and oral antihistamines Topical benzoyl peroxide Topical hydrocortisone cream
Polymorphic eruption of pregnancy (pruritic urticated papules of pregnancy)	A relatively common, intensely itchy rash that starts on the abdomen, often within striae, in the third trimester Associated with multiple births Uncomfortable but harmless	Symptomatic topical therapy and antihistamines are helpful until after delivery, when the rash resolves
Pemphigoid gestationis	A rare disease analogous to bullous pemphigoid (see Chapter 45) Associated with prematurity and stillbirth; transplacental passage of pathogenic immunoglobulin G antibodies can lead to transient blistering in the neonate Often starts around the umbilicus with itchy, inflamed papules; then blistering appears and becomes generalized Onset in the first or second trimester; typically flares postpartum Diagnosis confirmed with direct immunofluorescence Recurrences may occur with subsequent pregnancies and oral contraceptive pill, which should be avoided	Systemic steroid therapy is required

Box 48.11 Drug use during pregnancy in treatment of patients with rheumatoid arthritis and systemic lupus erythematosus

- ***Paracetamol:*** the oral analgesic of choice
- ***Oral NSAIDs and selective COX-2 inhibitors:*** can be used short term up until 30 weeks' gestation if symptoms justify their use
- ***Corticosteroids:*** may be used to control disease flares (main risks are hypertension, glucose intolerance, infection, and preterm premature rupture of membranes)
- ***DMARDs***
  - ***Considered safe:*** sulfasalazine, hydroxychloroquine, azathioprine, ciclosporin, tacrolimus
  - ***Unsafe:*** mycophenolate mofetil, methotrexate, leflunomide, and cyclophosphamide (in the first trimester)
  - ***Biological agents:*** good safety data during pregnancy for infliximab, adalimumab, etanercept, and certolizumab pegol
  - Safety for newer agents (e.g., belimumab, tocilizumab, abatacept) not yet established; used if benefit outweighs risk
- ***Contraindicated in breast-feeding:*** methotrexate, leflunomide, cyclophosphamide, mycophenolate mofetil

COX, Cyclo-oxygenase; *DMARD,* disease-modifying anti-rheumatic drug; *NSAID,* non-steroidal anti-inflammatory drug.

PRESCRIBING IN PREGNANCY

Many clinicians are reluctant to prescribe drugs in pregnancy. This relates mainly to concern regarding teratogenic risk. The following general principles should be remembered:

- ***Older generic drugs.*** Consider older generic drugs within each class because there are likely to be more data on use in pregnancy.
- ***Dosages.*** Resist the temptation to prescribe lower doses. Higher doses may be required because of increased kidney and liver clearance.
- ***Disease control.*** Appropriate drug therapy to control underlying diseases, including arthritis, inflammatory bowel disease, lupus, epilepsy, asthma, and thyrotoxicosis, is likely to improve fetal and neonatal outcomes, including reductions in FGR and preterm deliveries.
- ***Treatment for unfamiliar diseases.*** Ask the specialist physician, 'What would you do if this female was not pregnant'? Then assess the risks of this strategy in pregnancy.
- ***Risks to the fetus.*** These must be balanced against potential benefits to the pregnant person (and therefore indirectly to the fetus).

The ***teratogenic potential*** of some drugs classified as ***absolutely contraindicated*** is sufficiently high to justify discussion of termination of a pregnancy after inadvertent exposure; these drugs include mycophenolate mofetil, sodium valproate, and thalidomide. For others, there are theoretical reasons to avoid their use in pregnancy, but they carry a low risk of teratogenesis, so there is no justification for termination (e.g., rubella vaccine, simvastatin, ACE inhibitors).

For drugs that are ***relatively contraindicated***, there are situations in which use is appropriate when no safer alternative exists (e.g., warfarin in prosthetic heart valves or AEDs in epilepsy). ***Diuretics*** are avoided in the treatment of patients with hypertension but are appropriate in the treatment of those with pulmonary oedema.

CORE SKILLS AND KNOWLEDGE

Geriatric medicine focuses on the medical care of older people. Increasingly, the criteria for specialist geriatric care are defined by the presence of multiple problems or frailty rather than chronological age. Medical care is provided within a multidisciplinary team (MDT).

Geriatricians cover the range of general medicine in older adults from acute hospital settings (emergency departments and specialist wards) to the community (rehabilitation wards and patients' homes). Geriatricians support other specialists with specific issues such as the management of multimorbidity, delirium, and complex discharge planning. Subspecialty work includes falls, orthogeriatrics, stroke medicine, and Parkinson's disease, along with evolving areas such as oncogeriatrics and surgical liaison.

Key skills in geriatric medicine include:

- Managing the complexity inherent in ageing physiological systems with interacting diseases and treatments
- Making pragmatic and holistic decisions for individual patients in the face of uncertainty, including understanding and individualizing the evidence base
- Working with allied health professionals to create holistic multidisciplinary plans to optimize patients' function and independence
- Caring and advocating for the most vulnerable and frail adult patients.

BACKGROUND

There have been incredible changes in human life expectancy over the past 200 years, with increasing numbers of people enjoying fulfilling lives up until their 90s and beyond. These changes reflect numerous factors from improved sanitation and nutrition to the development of antibiotics. Preventative measures, such as reductions in cardiovascular disease through blood pressure (BP) control, can postpone the onset of disease. Many diseases that previously killed in middle age are now treatable or even curable, including many cancers and chronic infections such as human immunodeficiency virus (HIV). In turn, many people are living into older age with one or more chronic conditions, which may require ongoing treatment and intervention to reduce negative impacts on the individual's quality of life. These interventions may have their own side-effects, and ageing itself has an impact on the body and its function, requiring a specific approach.

In the 1960s, Bernard Isaacs described four ***'geriatric giants'***, a fifth being added later as medical interventions progressed:

1. Incontinence
2. Immobility
3. Intellectual impairment
4. Instability
5. Iatrogenesis (when patients may experience harm as a result of medical interventions)

More recently, ***'5 Ms'*** have been proposed by Mary Tinnetti (Box 49.1).

Presentations of illnesses often differ in older age. For example, the physical symptoms and signs associated with depression are too common and non-specific to be easily differentiated from organic causes. A diagnosis of depression may be signalled by reduced social interaction and by the fact that the patient does not leave their home when this is unexplained by any co-morbidities or physical disability.

Box 49.1 The five Ms of geriatric medicine

- ***Mind:*** mentation, dementia, delirium, depression
- ***Mobilization:*** impaired gait and balance, fall injury prevention
- ***Medications:*** polypharmacy, optimal prescribing and deprescribing, adverse drug reactions
- ***Multicomplexity:*** multimorbidity, complex bio- or psychosocial situations
- ***Matters most:*** each individual's own meaningful health outcome goals and care preferences

Adapted from Tinetti M, Huang A, Molnar F. The geriatrics 5M's: A new way of communicating what we do. J Am Geriatr Soc *65(9): 2017.*

Investigation and interpretation of results must also be balanced against pragmatic considerations. For example, finding a pulmonary nodule in a frail person should prompt the questions, 'If this were malignant, what would the patient want? Are they fit for surgery or chemo- or radiotherapy? Will their present co-morbidities and disabilities allow them to tolerate further investigations? Will it increase their life expectancy'? Another common scenario is a person who is experiencing postural hypotension because of antihypertensives. It may be better to accept a higher BP than guidelines would suggest to stop the patient's falling or living in fear. These decisions must be discussed with the patient as part of shared decision-making, but finding a balance can prove difficult for patient and clinicians alike. At its heart, geriatric medicine is the interplay between the patient, the medical teams, and the declining physiology of the ageing process.

AGEING

Ageing is a progressive physiological decline associated with living beyond roughly the age of 30 years. Bernhard Strehler defined ageing as:

- ***Universal:*** The process must happen to all members of a species.
- ***Intrinsic:*** It takes place via endogenous processes and does not depend on extrinsic factors.
- ***Progressive:*** Changes leading to ageing must occur progressively throughout a person's lifespan.
- ***Deleterious:*** It is bad for the individual.

Virtually all physiological mechanisms lose efficiency with ageing and lose the capacity to maintain homeostasis when faced by external challenges. Whereas a younger person stumbling over a kerb would have the strength and reflexes to adjust and maintain their balance, an older person is more likely to fall.

Ageing happens at differing rates between individuals. Some aspects are easily apparent, such as the hair turning grey. Other aspects are less obvious, such as accumulation of atheromatous plaques within blood vessels. Ageing eventually occurs in all of us but can be influenced by a number of factors, from genetic make-up to physical activity levels and the external environment. Some factors are associated with accelerated ageing, such as smoking and diabetes. Others are protective and slow the ageing process, such as a balanced diet and regular exercise.

Why do we age?

Theories of ageing can broadly be split into two: those concerned with the limited replication of cells and those related to evolution.

Theories related to limited cell replication

Telomere shortening

With each cell replication, a small piece of the telomere is removed until it eventually becomes too short to continue dividing without risk of damage to the chromosome. At this stage, it is no longer able to prevent errors in DNA replication, which may lead to the development of cancer.

Damage accumulation theory

Ageing is a result of fault accumulation at cellular and molecular levels caused by a limitation of maintenance and repair mechanisms. The primary problems do not lie with the cells themselves but with the regulation of mechanisms keeping the cell division process efficient and safe.

Free radical theory

Free radicals, derived from chemical reactions involving oxygen molecules (oxidation), occur more frequently in older cells. Species with high levels of free radicals have shorter life expectancies. Free radicals are balanced by antioxidants, which protect against oxidative damage to proteins, DNA, and lipids, all of which are vital for normal cell function.

The mitochondrial theory of free radicals in ageing suggests that damage by reactive oxygen species causes oxidative stress that overwhelms the antioxidant cellular defences, leading to ***cellular senescence*** (see later). Chronic oxidative stress throughout the lifespan plays a critical role in ageing overall. There is some evidence that antioxidants can reduce this damage, but no clinically relevant outcomes have been observed from their use.

Theories related to evolution

Evolutionary theories are based on the idea that the biological processes associated with ageing provide an advantage earlier in life in terms of reproduction and survival of the species. Because humans now regularly survive beyond reproductive age, the negative biological changes for the individual that occur later in life may be seen as payback for this group advantage.

Disposable soma theory

This suggests that an organism must budget for the limited energy available to it and preferentially focus on reproduction rather than maintaining the mature body (or soma, i.e., the rest of the body that is not directly involved with reproduction), leading to inefficiencies in cell replication later in life, when the soma is no longer needed because the organism is beyond reproductive age.

Mutation accumulation theory

This theory supports the disposable soma idea by asserting that DNA mutations taking place after reproductive age cannot affect future generations, meaning that there is no evolutionary imperative to correct them or develop protection against consequent defects.

Antagonistic pleiotropy theory

Pleiotropy is when a single gene can have two different effects. The antagonistic pleiotropy theory takes the idea one step further, suggesting that genes that are protective or beneficial in early life become detrimental (i.e., antagonistic) later in life. An example is sickle cell disease, which is protective against malaria in earlier life.

Calorie restriction

Calorie restriction is thought to prolong life expectancy, mediated through reduction of oxidative damage and anti-inflammatory benefits. This is supported by animal studies and by the example of the population of the Japanese island of Okinawa, where there are cultural calorie restriction and the highest prevalence of centenarians worldwide.

Cell senescence

Cell senescence, when cells stop dividing but remain metabolically active, leads to a pro-inflammatory state. Cells with senescent properties are seen in the tissues of those with age-related diseases, such as osteoarthritis, pulmonary fibrosis, atherosclerosis, and Alzheimer's disease. Exactly what the mechanism is that leads cells to become senescent is unclear.

Senescence is different from apoptosis, which is programmed cellular death followed by removal of the cell from the system in an organized way. Senescent cells are resistant to apoptosis and may instead continue to remain metabolically active, secreting pro-inflammatory cytokines, or may undergo necrosis instead, which is in itself pro-inflammatory.

Senescence is not just seen in the context of ageing. Another example is wound healing. After a wound is healed, the myofibroblast cells go into acute senescence to prevent excessive fibrosis at the site. Senescence also occurs when the blood supply for an embryo is being built. In these circumstances, it is a programmed process, triggered by specific stimuli and targeting specific types of cells. In ageing, the process appears unscheduled and more random. Clearance of aged cells that have undergone senescence is much less efficient. This may be attributable to the reduced immune function associated with ageing.

APPLIED ANATOMY AND PHYSIOLOGY OF AGEING

One of the key aspects of providing medical care for older people is distinguishing between normal ageing and disease. Ageing affects each organ differently. Presentations that probably arise as single-organ pathology in younger adults are likely to have more than one cause in older adults. For example, anaemia in a young woman is likely to be related to menstrual bleeding. In an older woman, anaemia might represent chronic disease, such as myelofibrotic bone marrow that is unable to respond quickly, exacerbated by a poor nutritional state with low iron and folate levels. Older adults need to have their physical conditions assessed and managed alongside their functional and social circumstances.

What commonly differentiates people with the same apparent condition(s) is the ability of their whole system to balance these conditions in a way that keeps the person functioning. This difference is usually explained by the presence of frailty as an underlying physiological process.

As we age, our organs function less well, with the percentage function of each individual system reducing by the order of 0.5% to 1% per organ system per year from the age of 30 years, as demonstrated by changes in respiratory function in a large international cohorts (Fig. 49.1). Similar graphs can be drawn for maximum usage of oxygen (VO_2 max), cardiac output, maximum heart rate, or renal function.

CLINICAL APPROACH TO THE OLDER ADULT

When symptoms can be non-specific and many conditions present in an atypical manner, it can be difficult to know where to start. Asking open questions such as, 'What is your biggest concern today'? can help. In those with confusion, timelines of presentation may not be reliable, but you can usually get a feel for immediate concerns, such as pain or breathlessness. Do not be afraid to ask about difficult issues (e.g., bladder and bowel dysfunction, death and dying); patients often want to explore these areas but are hesitant to bring them up themselves.

A key aspect of geriatric medicine is the ability to think in detail about the current issue while maintaining a longer-term, bigger picture of the person and their life. Geriatricians often manage patients with interacting multimorbidity, polypharmacy, and physiological decline. They need the ability to focus on aspects that might be troubling the patient (e.g., constipation or a dry mouth) while being aware of overall progressive decline, reservations about interventions, and the potential need for advanced care planning.

FRAILTY, MULTIMORBIDITY, AND DISABILITY

These are distinct entities that often coexist. The difference is important in the management of patients.

- ***Frailty*** describes a risk of a deterioration when faced with a physiological stressor.
- ***Multimorbidity*** involves two or more medical conditions that may or may not interact.
- ***Disability*** is physical or mental impairment that has a substantial and long-term negative effect on a person's ability to carry out normal daily activities.

Frailty

Frailty is 'a state of increased vulnerability to stressors due to age-related declines in physiologic reserve across neuromuscular, metabolic, and immune systems'. It is the effect of systemic ageing (the underlying biological ageing process) rather than chronological age. It is possible to be chronologically old and not be frail and likewise to be young and very frail. As an individual organ's ability to react to a physiological stressor reduces with age, the impact of a given illness on that organ system has a greater effect. A minor infection (e.g., an uncomplicated urinary tract infection [UTI]) has little impact on a young and fit patient but may cause serious delirium and morbidity in those with long-term cognitive impairment, especially when combined with frailty or serious multimorbidity.

Identifying frailty

A number of models have been developed to describe frailty and the manner in which it evolves. Frailty is relatively simple to recognize when it is severe but more challenging when mild. Its recognition ensures that patients are managed according to their functional level rather than their chronological age.

Frailty recognition is an effective way of identifying people who may be at greater risk of future hospital admission, care home placement, or death; those with severe frailty have more than a four times greater annual risk for these outcomes than individuals of the same biological age who are not frail. Interventions targeted at actively managing frailty around a stressor, such as elective surgery, show better outcomes.

The key benefits to patients of a definition of frailty and an active search for it are twofold:

- It identifies those who might benefit from an objective detailed and evidence-based assessment (Comprehensive Geriatric Assessment [CGA]; see later)
- It acts as a trigger for the point at which medicine stops following standardized protocols and becomes a balance between the two questions that Edmund Pellegrino termed 'prudential': 'What *can* be done for this patient'? and 'What *should* be done for this patient'?

Identification and stratification of population-level frailty could assist in planning for future demands on health and social care while allowing targeted interventions to help people age well. Upskilling all those working with older adults is a priority. This runs in parallel with geriatric teams supporting specialist services, from perioperative care to specific patient populations in areas such as oncogeriatrics and HIV medicine.

Two main theories can also be used to identify frailty—frailty as a phenotype and frailty as an accumulation of deficits.

Frailty phenotype

In 2001, Linda Fried published her model of frailty and demonstrated that becoming frail was associated with negative outcomes in terms of length of life and institutionalization (**Box 49.2**).

Frailty index

The Frailty Index (FI) defines frailty from a list of medical conditions, physiological parameters, and observations on factors that become more common with increasing age and are associated with negative health outcomes. This method has been used largely in research, but now with the development (in the UK) of the e-Frailty Index, it can be run on routinely collected data from general practitioners' (GPs') records.

Box 49.2 Fried's phenotypic frailty assessment[a]

Domain	Suggested assessment
Weight loss	Loss of ≥4.5 kg or ≥5% of body mass in the previous year
Gait speed	6 sec or more to walk 4 m (0.66 m/sec) (slowest 20% by gender, height)
Energy expenditure	Low levels of energy expenditure or physical activity in lowest 20% of population (males, <383 kcal/week; females, <270 kcal/week)
Subjective feeling of lethargy	Subjective feeling of exhaustion: Felt that everything they did was 'an effort' in the past week Could not 'get going' in the past week
Muscle strength	Grip strength as a score within the lowest 20%, stratified by gender and body mass index

[a]Three or more define frailty.

From Fried LP, Tangen CM, Walston J et al., Cardiovascular Health Study Collaborative Research Group. Frailty in older adults: evidence for a phenotype. Gerontol A Biol Sci Med Sci *2001; 56(3):M146–156.*

The Clinical Frailty Scale

The Clinical Frailty Scale (CFS) correlates with the more in-depth FI. It uses clinical descriptors and images to stratify older adults according to level of vulnerability. It has been validated in a number of clinical settings but only after a CGA has been carried out. It is increasingly being used for identification purposes, however, because of its ease of use (**Fig. 49.2**).

Multimorbidity

Older people are more likely to have multiple medical issues. By 2035, around two-thirds of people older than 65 years of age will have multimorbidity. Within the UK, for example, such patients currently account for 50% of general practitioner consultations, 55% of hospital admissions, and 80% of prescriptions. Each condition often requires a number of medications, with treatments potentially interacting adversely. This can lead to ***prescribing cascades***, whereby medications are given for one condition and then further medications are required to counter the side-effects (e.g., the co-prescription of a proton pump inhibitor with aspirin).

Meanwhile, traditional healthcare models were usually designed around single-organ pathology. For example, a patient is admitted under cardiology for their acute coronary syndrome and treated well for this, with a selection of medications to reduce the risk of further cardiac events. However, angiotensin-converting enzyme (ACE) inhibitors may cause a cough, which might aggravate their stress incontinence, which could then increase their frequency of falls, and the beta-blockers may aggravate their longstanding depression. A more holistic approach could be to be more selective in medication choices rather than automatically starting all the usual medications given after a cardiac event and focusing on patient priorities and goals for optimizing their quality of life. This would include a discussion with the person about the benefits and harms from each while also involving the rest of the MDT for further ways optimize their independence, for example, to reduce their risk of falls and explore ways to counter depression.

Rockwood Frailty Scale

Clinical Frailty Scale

1 Very Fit – People who are robust, active, energetic and motivated. These people commonly exercise regularly. They are among the fittest for their age.

2 Well – People who have no active disease symptoms but are less fit than category 1. Often, they exercise or are very active occasionally, e.g., seasonally.

3 Managing Well – People whose medical problems are well controlled, but are not regularly active beyond routine walking.

4 Vulnerable – While not dependent on others for daily help, often symptoms limit activities. A common complaint is being "slowed up", and/or being tired during the day.

5 Mildly Frail – These people often have more evident slowing, and need help in high order IADLs (finances, transportation, heavy housework, medications). Typically, mild frailty progressively impairs shopping and walking outside alone, meal preparation and housework.

6 Moderately Frail – People need help with all outside activities and with keeping house. Inside, they often have problems with stairs and need help with bathing and might need minimal assistance (cuing, standby) with dressing.

7 Severely Frail – Completely dependent for personal care, from whatever cause (physical or cognitive). Even so, they seem stable and not at high risk of dying (within ~ 6 months).

8 Very Severely Frail – Completely dependent, approaching the end of life. Typically, they could not recover even from a minor illness.

9 Terminally Ill – Approaching the end of life. This category applies to people with a life expectancy <6 months, who are not otherwise evidently frail.

Scoring frailty in people with dementia

The degree of frailty corresponds to the degree of dementia. Common **symptoms in mild dementia** include forgetting the details of a recent event, though still remembering the event itself, repeating the same question/story and social withdrawal.

In **moderate dementia,** recent memory is very impaired, even though they seemingly can remember their past life events well. They can do personal care with prompting.

In **severe dementia,** they cannot do personal care without help.

Fig 49.2 The Clinical Frailty Scale. *IADL,* Instrumental activity of daily living. *(© 2007–2009 Version 1.2 All rights reserved. Geriatric Medicine Research, Dalhousie University, Halifax, Canada.)*

Sarcopenia

Sarcopenia is closely related to frailty (**Box 49.3**). It is a progressive and generalized muscle disorder associated with an increased risk of adverse outcomes, including falls and fractures. Muscle fibres reduce in number, fast-twitch type II muscle fibres in particular. The result is loss of explosive power, which is needed for functions such as sprinting, standing from a chair, or even coughing.

In sarcopenia, VO_2 max within muscle reduces, as does gait speed. Reduction in physical activity leads to a reduction in energy usage; when coupled with the relative anorexia of ageing, this leads to an energy deficit. With this energy deficit, cells that are predetermined to undergo apoptosis do not have sufficient free adenosine triphosphate (ATP) to allow this process to occur. Instead, the cells undergo necrosis, which uses more ATP and worsens the energy deficit. When this occurs in muscle tissue, it leads to worsening sarcopenia and development of the cycle of frailty (**Fig. 49.3**).

INVESTIGATIONS IN OLDER ADULTS

Physiological parameters have different implications and require different interpretation in older adults compared with younger people. For example, there is a 'U-shaped' association between BP and death in older people, and aggressive lowering of BP into 'normal' ranges is inappropriate in those at risk for falls. Similarly, oxygen saturations can fall with age and co-morbidities, so levels of 92% to 95% may be more physiologically normal.

Normal ranges stated by laboratories account for the values expected for the majority of the population, but older adults (like children) are outliers compared with the whole population. The altered anatomy and physiology in older adults mean that routine investigations need to be interpreted with this in mind (**Box 49.4**).

An unenhanced computed tomography (CT) scan of the head is often used to investigate confusion or cognitive impairment and may reveal non-specific findings of cerebral atrophy or findings suggestive of specific causes of dementia (e.g., small vessel disease or atrophy of the temporal horns, suggesting Alzheimer's disease).

Box 49.3 European Working Group on Sarcopenia in Older People (2018)

Criterion	Definition
1. Low muscle strength 2. Low muscle quantity or quality 3. Low physical performance	***Probable sarcopenia*** is identified by criterion 1. ***Confirmed sarcopenia*** requires criteria 1 and 2. ***Severe sarcopenia*** requires criteria 1, 2 and 3.

Small vessel disease is a common finding on CT scans in older adults and is often dismissed, though it is associated with cognitive impairment, a higher risk of delirium, gait dyspraxia and instability, and incontinence. There may be evidence of specific and potentially reversible causes of acute confusion (e.g., a subdural haematoma or space-occupying lesion).

COMPREHENSIVE GERIATRIC ASSESSMENT

After a patient is identified as being frail, what should be done? Although some evidence suggests that people can transition from more frail to less frail, the vast majority progress through advancing stages of frailty. There is usually no single treatment to cure frailty, but multicomponent interventions may slow progression and even reverse the decline. Inaction is likely to result in worsening frailty, functional impairment, and disability. Therefore, a proactive assessment of each of the potential clinical and subclinical deficits is needed.

CGA is not something that is just delivered by doctors; it is a multidimensional, interdisciplinary diagnostic *process* focused on determining a person's medical, psychological, and functional capability to develop a coordinated and integrated plan for treatment and long-term follow-up. As such, it is firmly rooted in the biological,

Box 49.4 Blood tests in older adults

Blood test	Normal ranges in older adults	High values	Low values
Full blood count			
Haemoglobin	Often lower in advanced ages	**Higher concentration per volume** May suggest dehydration **Increased production** Polycythaemia (rubra) vera Secondary polycythaemia caused by chronic hypoxia	**Blood loss** Review medication for antiplatelets and anticoagulation that increase bleeding risk and for gastric irritants, e.g., corticosteroids or NSAIDs **Inadequate nutrients or substrates** Haematinic deficiencies, e.g., pernicious anaemia **Reduced production** Bone marrow disorders Anaemia of chronic disease
White blood cell count	Remains normal	**Increased need** Infection **Increased production** Haematological malignancies; commonest in older adults is CLL, causing chronically high lymphocyte counts Steroid use or stress-induced release	**Reduced production** *Acute* Overwhelming sepsis *Subacute or chronic* Bone marrow failure, e.g., myelodysplasia, myelofibrosis, infiltration of bone marrow by malignancy **Bone marrow suppression** Medication related **Ethnicity** Black people have lower total WBC counts; this presents over the course of their lives, so check past results
Platelets	Remain normal	**Increased need (acute)** Acute-phase reactant to inflammation **Increased production (subacute and chronic)** Essential thrombocythaemia	**Reduced production** Medications Bone marrow failures Liver failure **Increased consumption** Sepsis **Decreased survival** Hypersplenism Autoimmune
Serum creatinine and electrolytes			
Sodium	Remains normal	Dehydration associated with reduced homeostasis of thirst axis Hyperosmolar, hyperglycaemic states	Addisonism Fluid overload Medications, e.g., diuretics, SSRIs
Potassium	Remains normal	Renal failure Artefact (haemolysed sample) Medications e.g., ACE inhibitors, aldosterone antagonists, heparin Haemolysis High platelet counts (pseudohyperkalaemia)	Medications, e.g., thiazide diuretics, salbutamol GI losses: diarrhoea and vomiting **Low values may impair muscle function:** Skeletal muscle: reduced mobility, falls Smooth muscle: constipation Cardiac muscle: arrhythmias
Creatinine	'Normal' values may hide kidney injury in those with low muscle mass	AKI: often dehydration, sepsis, or urinary retention CKD Medication related, e.g., trimethoprim	Low muscle mass from sarcopenia
Estimated glomerular filtration rate	Reduction may indicate normal ageing, as well as renal disease Consider calculating creatinine clearance, especially in very frail and very old patients		Less useful in the very underweight and very overweight

Box 49.4 Blood tests in older adults—cont'd

Blood test	Normal ranges in older adults	High values	Low values
Liver function tests			
Total protein		**Myeloma**	**Malnutrition**
Albumin	Remains normal		*Acute:* catabolic states, e.g., infection, cancer *Chronic:* poor nutritional state
ALP	Remain normal	*Subacute or chronic:* Bony metastases (prostate, breast), vitamin D deficiency, Paget's disease *Acute:* acute-phase reactant, bone fracture	
AST, ALT, GGT	Remain normal	Chronic alcohol excess Hepatic congestion caused by right heart failure Hepatotoxic medications MAFLD Ischaemic hepatitis	
Bilirubin	Remains normal	Obstructive bile duct disease, e.g., gallstones, pancreatic cancer	
Bone profile			
Calcium	Normal range, though often at the lower end	Dehydration Malignancy Primary hyperparathyroidism Calcium or vitamin D supplements	Poor dietary intake Recent parenteral treatment for osteoporosis (e.g., denosumab, zoledronic acid) Magnesium deficiency
Vitamin D	Normal range, but low levels common	Supplements, not usually of clinical significance	Nutritional deficiency Reduced sunlight exposure Fat malabsorption
Other			
Erythrocyte sedimentation rate	Normal values increase with age	>100 mm/hour should prompt investigation for malignancy or vasculitis, e.g., polymyalgia rheumatica or giant cell arteritis	
Creatine kinase	Normal range	Rhabdomyolysis after fall and long lie Medications, e.g., statins, neuroleptics	
C-reactive protein	Normal range	Sepsis Inflammatory disorders Physiological stress, e.g., surgery Malignancy	
Thyroid function (TSH, T_4)	Normal range	Various causes of hyperthyroidism May cause confusion, delusions, tremor	Various causes of hypothyroidism May cause confusion, constipation, myopathy
Iron studies (ferritin or TI)	Normal range	Ferritin is an acute-phase reactant; consider checking TI	Ferritin low in iron-deficient anaemia (may be disproportionately normal in acute infection and iron-deficiency anaemia)

ACE, Angiotensin-converting enzyme; *AKI,* acute kidney injury; *ALP,* alkaline phosphatase; *ALT,* alanine transaminase; *AST,* aspartate aminotransferase; *CKD,* chronic kidney disease; *CLL,* chronic lymphocytic leukaemia; *GGT,* gamma-glutamyl transferase; *GI,* gastrointestinal; *MAFLD,* metabolic dysfunction–associated fatty liver disease; *NSAID,* non-steroidal anti-inflammatory drug; *SSRI,* selective serotonin reuptake inhibitor; T_4, thyroxine; *TI,* transferrin index; *TSH,* thyroid-stimulating hormone.

psychological, and sociological approach to thinking about patients and their conditions. CGA involves exploring a number of domains (**Box 49.5**). The further roles of the MDT are explored later.

In older adults with frailty, there is often a large overlap between symptoms caused by disease, by treatment of disease, by normal ageing, and by accelerated ageing. More practically, CGA can be thought of as a process of good holistic care delivered by a focused MDT, which goes above and beyond simply managing the acute problem with which the person has presented. If an older person is not managed in this way, care becomes reactive to a series of acute problems rather than a proactive problem-solving process.

Compared with those given 'usual' care, those who undergo CGA during an acute admission have favourable outcomes. At 6

Box 49.5 Domains of the Comprehensive Geriatric Assessment

Domain	Assessment area	Assessment	Examples of assessment tools
Physical symptoms	Pain	Location, severity, impact on quality of life	Numerical scales Visual scales, e.g., Abbey Pain Scale (for patients with dementia)
	Continence	Exploration of both storage and voiding; lower urinary tract symptoms	Bladder diary *or* Postvoid residual bladder volume
	Sensory impairment	Hearing assessment Check for ear wax	
		Visual assessment	Snellen chart Optician or ophthalmology review (including glaucoma, cataracts, macular degeneration)
	Musculoskeletal problems	Mobility, range of movement	Berg Balance Scale Timed Up and Go test 6-m walk test
	Multimorbidity management	Multimorbidity management approach Identify disease vs treatment burden Discuss with patient and agree a shared management plan Review on a regular basis	Polypharmacy assessment tools, e.g., STOPP-START, Beers criteria Ascertain patient's priorities of care: symptom relief (AF rate control) versus future prevention (AF anticoagulation)
Mental health symptoms	Mood assessment	Mental health assessment, including full mental state examination	Geriatric Depression Scale (GDS) Hospital Anxiety and Depression Scale (HADS) Cornell Depression Scale (for patients with cognitive impairment)
	Cognitive assessment	Detailed cognitive assessment, including collateral history from a relative or carer	Abbreviated Mental Test score Mini-Mental State Examination (MMSE) Six-item Cognitive Impairment Test (6-CIT) Montreal Cognitive Assessment (MOCA) Clock drawing task (e.g., CLOX 1) Addenbrooke's Cognitive Assessment-Revised (ACE-R) (more detail; 15 min) Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE)
Functional abilities	Activities of daily living (ADL) assessment	Personal ADLs: Washing and dressing Bed transfers Toileting needs Domestic ADLs: Food preparation Housework	Barthel Index (personal ADLs) Nottingham Extended ADL Scale (includes domestic ADLs and higher-level functional assessments)
Living environment	Home visit or access visit Usually led by occupational therapists	Assessment for hazards around home (e.g., lighting, flooring)	
		Assessment for safety (e.g., heating, safe use of cooker, stair rails)	
Social support network	Financial assessment	Often performed by social services	
	Carers' assessment	Care Act (UK)	
Future wishes	Advanced care planning	Nomination of power of attorney, CPR decisions and advance decision to refuse treatment (see Chapter 3, 'Advance decisions' section)	DNA CPR; ceilings of treatment (e.g., ward-based ceiling of care) ReSPECT document Locally agreed advanced care plan

AF, Atrial fibrillation; *CPR,* cardiopulmonary resuscitation; *ReSPECT,* Recommended Summary Plan for Emergency Care and Treatment; *STOPP-START,* Screening Tool Of Older People's Prescriptions (STOPP)-Screening Tool to Alert to Right Treatment (START).

Box 49.6 Common members of the multidisciplinary team and their roles

Job	Role	Clinical examples
Dietician	Assessment of nutritional status and support of healthy weight during illness and health	Falls: ensuring adequate calorie and protein intake for muscle maintenance Cognition: adaptations to meal routine to optimize nutrition, e.g., opportunistic mealtimes
Discharge coordinator	In-hospital coordination of complex discharges	Coordination of multiple agencies, e.g., social services, specialist equipment, funding streams, safeguarding
Doctor	Medical diagnoses and optimization, including reversible conditions and prescribing Prognostication	Falls: causes and interventions, bone health assessment and prescription Polypharmacy: medication review Inputs into most Comprehensive Geriatric Assessment domains
Nurse	Delivery of hands-on care for older patients; assessment of holistic and physical needs, including medication compliance, skin care, continence	Continence: assessment and management Skin: wound care and pressure damage Medication: delivery and compliance
Occupational therapist	Functional assessments and management (including cognition) aiming for a greater degree of independence	Falls: assessments and adaptations for maximizing independence; optimization of environment, e.g., ensuring furniture of a reasonable height to stand from easily; movement-sensitive lighting, pendant alarms, 'key safe' (small box with combination lock outside property containing house keys for carers) Cognition: cognitive assessment, activities of daily living assessments, kitchen function and safety assessments
Pharmacist	Optimization of medicine concordance Addressing polypharmacy and interactions	Falls: review of contributing medications
Physiotherapist	Optimization of physical functioning in relation to musculoskeletal function	Falls: gait analysis, exercise programmes to improve balance and strength, walking aids Continence: pelvic floor exercises
Podiatrist	Assessment and management of foot health	Falls: reduction of foot pain, suitable footwear for deformities
Psychologist	Instigation and direction of talking therapies, e.g., cognitive-behavioural therapy	Falls: fear of falling counseling Mood: talking therapies, including in early dementia
Social worker	Assessment of social functioning and safety	Falls: home adaptations, provision of care Cognition: capacity assessments in relation to welfare and finances Carer strain: assessments as part of Care Act (UK) Welfare: assistance with finances
Speech and language therapist	Swallowing and communication	Communication strategies, support for capacity decisions when communication is impaired Dysphagia: recommendations for minimizing risks and advance care planning
Volunteers	Supporting social interaction and function	Falls: exercise classes Cognition: dementia cafés, dementia friends Nutrition: assistance with shopping

and 12 months, respectively, the numbers needed to treat (NNTs) are 20 and 25 to prevent institutionalization and 17 for unnecessary death. The NNT for many medications is in the hundreds to thousands range.

One area that remains to be fully explored is how best to identify patients who would benefit from a CGA who are not in an acute hospital. The proactive assessment of patient frailty is one means of doing this. After patients are identified as frail (or becoming frailer), then a proactive CGA, in the community, day hospital, or inpatient setting, seems to be a pragmatic approach.

Multidisciplinary team working

To deliver true CGA, geriatricians need to work as part of an expert MDT. Communication between the whole of the MDT is essential to ensure that patient care plans are discussed and developed together. Each team member's specialist skills are better used, making for a more egalitarian approach to care rather than the traditional hierarchical one with the consultant as the leader (Box 49.6). Learning about geriatric medicine therefore requires an understanding not only of the role of the doctor in delivering CGA but also of the roles of each member of the MDT.

ADVANCE CARE PLANNING

Advance care planning (ACP) involves discussing the approach to a patient's future care, often before their becoming unwell or more unwell (see Chapter 50, 'Advance care planning: planning for the future' section). ACP is a continuous process of communication between patients, their loved ones, and healthcare professionals. It is not always possible or appropriate to cover everything in one conversation, so this may take some time and be an iterative process. Patients may want to think through often complex issues and discuss their plans with their loved ones. Plans should also be subject to regular review as a person's priorities and goals change.

ACPs ideally should be offered to all older people if they wish to explore their future wishes for care. ACP discussions can be started at any time if the patient is willing and ready. They should be specifically considered in patients diagnosed with progressive conditions, such as neurodegenerative diseases (e.g., dementia, Parkinson's disease), when there is the potential for capacity to be lost in the latter stages. This is particularly different to younger patients in whom terminal diagnoses (e.g., cancer) may preserve cognitive function for much longer.

This can also be a good time to highlight the importance of ensuring that wills and power of attorney are considered. These legal frameworks vary between countries but broadly speaking allow a person to either state what sort of interventions they would not like in the future or allocate someone to decide on their behalf in the event they become unable in the future.

ACPs often focus on the dying phase but should be expanded to include what constitutes living well and matters most for that person. Statements of wishes and preferences can range from where a person lives (e.g., in their own home or in a care home) to their favourite foods.

One of the most common decisions concerns resuscitation status. Many older people recognize that they are coming toward the end of their lives (around one in five people older than 70 years old die within 1 year of an emergency admission). Even though they are in good health, many would like to be allowed a natural death in the event of a cardiorespiratory arrest. Others may want to live for as long as possible and ask for all that medicine can do to prolong their lives. Events that may precede resuscitation should be planned for, too, such as hospitalization for treatment of infections.

Knowing when to start this process can be tricky: too early, and it may not feel relevant to the patient; too late, and they may have missed out on the chance to make their wishes clear. Patients, though, are very often happy to have a discussion about the process even if they do not wish to record their views at that point in time. Starting such a discussion with people gives them the ability to be able to be involved with decisions around their future medical care while they are still able to communicate their wishes. Taking this proactive approach allows a discussion of care toward the end of life and complex choices such as resuscitation to be thought about in detail.

In the UK, ACPs are now commonly recorded in a ReSPECT (Recommended Summary Plan for Emergency Care and Treatment) form, which is kept by the patient in their home. This allows the patient to choose their level of care on a scale from an approach in which prolongation of life should be done at all costs, including surgery and intensive care if needed, to being kept at home and palliated if they were to deteriorate. The balance is sometimes between length of life and quality of life, though it is important to realize that this is not a binary choice.

Any outcomes agreed upon should be documented and available to all who need access to them, including the patient and their family, ambulance staff, GPs, community teams, and hospital teams.

COMMON ISSUES FACING OLDER PEOPLE

Polypharmacy

Prescribing in older people

Although prescribing for older people is largely the same as for younger people, there are some key differences. The approach should be based around the patient's physiological rather than chronological age. There are numerous mechanisms behind the altered pharmacokinetics in older people (**Box 49.7**), but the net result is that older patients tend to have increased side-effects from their medications.

Drug interactions

One-third of patients older than 65 years of age living in the UK take 6 or more medications, with 5% taking more than 10. Polypharmacy leads to increased drug interactions and increased potential for ***drug–drug*** (e.g., cholinesterase inhibitors and anticholinergics) and ***drug–disease*** (e.g., non-steroidal anti-inflammatory drugs worsening hypertension) interactions. Polypharmacy accounts in part for up to 6.5% of all iatrogenic hospital admissions.

Box 49.7 Reasons for altered pharmacokinetics in older people

Drug absorption
- Gastric pH gradually increases with age (exacerbated by medications such as proton-pump inhibitors).
- Gastric emptying slows.

Drug distribution

The main physiological changes that occur with ageing and lead to adverse drug reactions include:
- Increased body fat and decreased body water (as a proportion of total body weight)
- Increased volume of distribution for fat-soluble drugs, so medications may accumulate because of an increased elimination half-life; this means that their effects may continue even though the drug has been stopped
- Decreased volume of distribution for water-soluble drugs, so drugs such as digoxin need a reduced loading dose
- Altered permeability of the blood–brain barrier, so the brain of an older adult can be exposed to higher levels of medication

Drug metabolism
- Reduced hepatic blood flow (and hence clearance) of medications that have high hepatic excretion ratio, e.g., amitriptyline

Elimination by the kidneys
- With age, there is a reduction in renal mass and renal blood flow.
- eGFR decreases by 0.5% per year after the age of 20 years, so 'normal' creatinine may be associated with significant renal impairment.
- This affects clearance of water-soluble drugs such as diuretics, NSAIDs, and digoxin.

eGFR, Estimated glomerular filtration rate; *NSAID*, non-steroidal anti-inflammatory drug.

Box 49.8 Optimizing compliance and concordance

Understand what medications are and are not being taken
- The patient may not be taking all prescribed medications.
- Why might they not want particular medications?
- Exercise caution when increasing medications without understanding what is currently being taken to avoid causing iatrogenic complications.
- Review side-effects (e.g., diuretics causing incontinence).
- Review the aims of treatment (see later).

Understand problems around taking the medications
- Dysphagia: Is there a liquid or patch alternative?
- Dexterity: Can the patient take the medication from the packaging? Aids are available for inhalers and eye drops.
- Cognition: Is the patient forgetting to take the medication or taking a second dose of one already taken? Are they managing complicated instructions, e.g., for oral bisphosphonates, or variable-dosing medications such as insulin or warfarin?
- Visual impairment: Consider large-font labelling.

Simplify regimens
- Is a particular time of day better to take the medications?
- Consider once-a-day, modified-release preparations.
- Reduce inappropriate polypharmacy.
- Agree which medications the patient wishes to take.
- Use compliance aids (e.g., 'dosette boxes') to reduce the need to coordinate multiple medications and aid monitoring of concordance.

Review care needs
- Is supervision or prompting required?

Patient choice

Polypharmacy may leave patients unhappy with their medication burden, which can lead to poor concordance overall (**Box 49.8**). Many prefer to take fewer medicines, accepting an increased risk of further events and potentially shortened life expectancy (e.g., foregoing a statin after acute coronary syndrome). A patient's priorities of care (what is most important to them) often rate immediate symptom control over preventative interventions. When prescribing, clarifying the goals and educating patients about the benefits of treatment are key to supporting them in making treatment choices.

Evidence base

Few clinical trials involve patients older than 80 years old, and those who are included tend to be fitter than those encountered in clinical practice, especially those in secondary care. Reported levels of benefit and risk of harm from medications studied in younger, non-frail, non–co-morbid groups cannot therefore be assumed to be the same as in older, frailer cohorts with higher levels of co-morbidity. Research that includes frailer populations with multimorbidity is inherently very difficult because of the confounding issues seen in such cohorts and the practicalities of obtaining consent or attending follow-up visits. However, it would be wrong to deny patients the benefits of treatment on the grounds that there is no evidence base; the absence of an evidence base is not the same as the absence of benefit.

Benefits of therapy

The levels of benefit from interventions differ between age groups. For example, there is increasing evidence in older patients with type 2 diabetes treated with insulin that tighter target hemoglobin (A_{1c}) HbA_{1c} levels below 50 mmol/mol (<6.7%) are associated with worse outcomes (increased mortality, increased weight gain) than in those patients with a more relaxed target HbA_{1c}. In older people with diabetes, the avoidance of immediate complications (e.g., hypoglycaemic events) should be prioritized over prevention of longer-term consequences, although this must be balanced with minimizing hyperosmolar symptoms (e.g., polydipsia, polyuria, recurrent infections, fatigue), which are seen when glycaemic control is very poor.

Similarly, although targets for BP tend to be around 130/80 mmHg in younger patients, outcomes for older and frailer patients are better with a higher target; there is a U-shaped curve with an optimum of 160/90 mmHg (i.e., there is an increased risk of adverse events and mortality when BP is significantly higher or lower than this; **Fig. 49.4**). Some of these adverse events relate to the side-effects of antihypertensives, such as orthostatic hypotension, falls, and associated morbidity and mortality.

Clinical decision-making

Many tools exist to aid clinical decision-making with respect to polypharmacy. They aim to summarize the evidence for a given medication in older adults and allow a negotiated approach between patient and clinician regarding the stopping and starting of medications. Examples include the Beers criteria, Screening Tool of Older People's potentially inappropriate Prescriptions-Screening Tool to Alert doctors to Right Treatments (STOPP-START), anticholinergic burden index, and Scottish polypharmacy app (see **Box 49.5**). **Fig. 49.5** shows the potential hierarchy of utility for medications that might be considered when undertaking a polypharmacy review.

Falls and instability

Most of us take for granted the amazing complexity of the process that maintains an upright posture. High levels of functioning are needed across multiple systems, including musculoskeletal, neurological, and cardiovascular. Although anyone of any age can fall, it is said that 'young people trip; old people fall'. For many older or frail adults, there are numerous, cumulative risk factors for falling that, individually, would be unlikely to produce major instability (**Boxes 49.9 and 49.10**; **Fig. 49.6**). Assessment of falls is one of the most complex areas for geriatricians and can take significant time. Asking about falls should nevertheless be part of routine practice for all professionals working with older people.

Approximately 5% of fallers older than 65 years of age sustain an injury that is serious enough to limit normal activities. Most falls occur during the daytime, when people are most active, and only around 20% take place overnight. Risk factors include cognitive impairment, medications, alcohol excess, and a change of environment (e.g., being admitted to hospital or moving to new accommodation).

Breaking down the contributing risk factors helps provide some structure for assessing and developing a management plan for a person who has fallen (**Box 49.11** and **Fig. 49.7**) and for targeting modifiable risk factors. An approach to the assessment of falls is summarized in **Box 49.12**. After clarifying the risk factors, it is then important to recognize which are reversible (e.g., cataracts), which are modifiable (e.g., glaucoma), and which are untreatable (e.g., dry macular degeneration).

Transient loss of consciousness (TLOC) is a worrying symptom, but of patients who do actually lose consciousness, more than 30% are unaware that it occurred. Often patients try to rationalize what has happened, stating, 'I must have tripped.' Normally, people put their arms out when falling to protect themselves. Be suspicious that a transient loss of consciousness may have caused falls when this has not happened and there are facial injuries. Items to check include lying and standing BP,

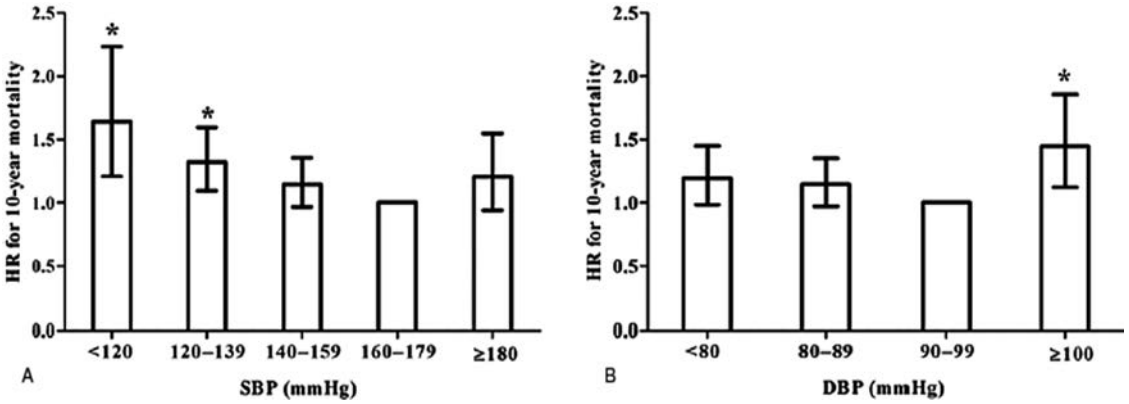

Fig. 49.4 Risk of 10-year mortality in systolic blood pressure (SBP) and diastolic blood pressure (DBP) categories. Bars represent hazard ratios (95% confidence interval). The category of SBP 160 to 179 mmHg and the category of DBP 90 to 99 mmHg were set as references in A and B, respectively. (*Taken from: Giulia Ogliari et al 2015, Blood pressure and 10-year mortality risk in the Milan Geriatrics 75+ Cohort Study: role of functional and cognitive status.* Age and Ageing. *44 [6], 932–937.*)

Utility	Medications that:	Examples
More useful	Provide immediate relief for distressing symptoms	Analgesics, antiemetics
	Modify an acute condition that is life-threatening or will soon result in distressing symptoms if not treated	Antibiotics for severe sepsis Diuretics for acute heart failure
	Modify a chronic condition that may progress to become life-threatening or progress to cause significant symptoms if not treated	Methotrexate for rheumatoid arthritis
Less useful	Have the potential to prevent serious disease without a symptomatic benefit	Antihypertensives, antiplatelet agents
	Are unlikely to be useful in either the short or the long term	Fish oils, glucosamine
	Are used for indications where non-pharmacological therapy is equally or more effective	Physiotherapy for back pain Sleep hygiene vs long-term benzodiazepines

Fig. 49.5 Hierarchy of utility of medications. *(Adapted from Scott IA, et al. Deciding when to stop: towards evidence-based deprescribing of drugs in older populations.* Evid Based Med *2013 18[4]: 121–24.)*

i Box 49.9 Falls in the UK

- One-third of people older than 65 years fall at least once per year.
- Half of people aged older than 80 years fall at least once per year.
- More than 250 000 emergency hospital admissions each year relate to falls.
- Falls are estimated to cost the National Health Service £2.3 billion per year.
- Falls from 2 m or less are the most common mechanisms of injury for major trauma in older people in the UK.

i Box 49.10 Categories of falls

Category	Optimizable	Static
Intrinsic	Concurrent illness, cardiac syncope, medications	Weakness from previous stroke
Extrinsic	Trip hazards, grab rails	Stairs into the house

electrocardiogram, and medications such as antihypertensives or diuretics. Management of TLOC is largely the same at all ages (see Chapter 11, 'Dizziness and blackouts' section).

Consequences of falls

Most falls result in minor or no injuries. However, consequences can include fractures and trauma.

Fear of falling

Even after minor falls, patients can develop a fear of falling (reduced 'falls efficacy'). This is characterized by anxiety around mobilizing and is associated with an increasing loss of confidence and a hesitant gait (see **Box 49.10**). As a result, people often reduce the amount of walking they do and stop going out of the house. In turn, they develop reduced muscle strength and an increased risk of falling. There is also a danger of social isolation and depression. Arguably, fear of falling is not all bad; it can just reflect an increased need for caution.

Fragility fractures

Fragility fractures occur after an injury from a standing height or lower and range from vertebral fractures (when there may even be no fall) to wrist, proximal humeral, pubic rami, and neck of femur fractures. Most of these are associated with osteoporosis, and enquiry should be made about:

- Previous fractures, including site, history, and age at the time
- Age of menopause for female patients
- History of previous osteoporosis treatment

After this is known, an assessment of osteoporosis risk can be calculated by using the FRAX (fracture risk assessment) score (see Box 33.8). This is widely available, and risk is adjusted for a number of countries around the world.

Sometimes there is no history of trauma. These atraumatic fractures can be caused by severe osteoporosis, but other causes should be considered, particularly malignancy (e.g., breast, prostate, myeloma, lung), and investigated accordingly. Long-term antiresorptive bone therapy (i.e., bisphosphonates or denosumab) can cause bones to become unnaturally brittle, especially if it is given as a parenteral treatment or at high doses for malignancy. This can result in unusual fractures, often atraumatic ones, such as fractures of the femoral shaft.

Neck of femur fractures

In England, there are approximately 60 000 neck of femur fractures per year, accounting for 15% of all fragility fractures (**Fig. 49.8**). They represent a significant injury for older persons:

- They account for 1.8 million inpatient bed days per year.
- Some 20% of patients sustaining a neck of femur fracture require transfer to long-term care within 1 year.
- The mortality rates are 5% at 30 days and 30% at 1 year.

In a number of countries, there has been a drive to develop geriatric liaison services to deliver CGA for patients with hip fractures. The geriatrician's role in perioperative care covers the issues outlined in **Box 49.12** and includes:

- Pain management
- Management of venous thrombotic risk

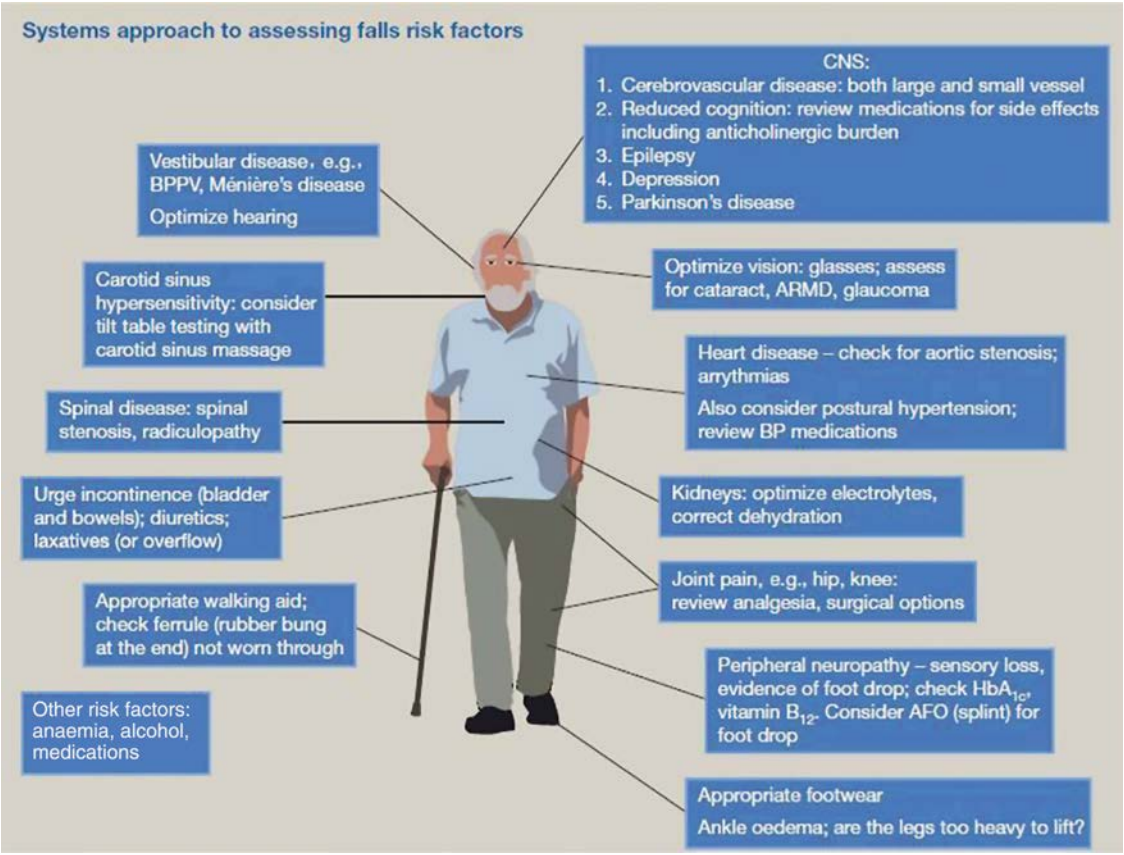

Fig. 49.6 Systems approach to assessing falls risk factors. *AFO,* ankle-foot orthosis; *ARMD,* age-related macular degeneration; *BP,* blood pressure; *BPPV,* benign paroxysmal positional vertigo; *CNS,* central nervous system.

Box 49.11 Some risk factors for falls with possible management strategies

Risk factor	Causes	Management
Unsteady gait or poor balance	Varied: Gait assessment for speed, sway, hesitancy, degree of heel strike, time with both feet on the ground Balance assessment, including cerebellar examination	Physiotherapy assessment: Balance and strength exercises Review of walking aids Encouragement to keep active Appropriate and well-fitting footwear
Leg weakness	Multiple causes Spinal disease Sarcopenia Disuse or deconditioning Motor neurone disease Myopathy	Neurological assessment Clinical assessment Imaging, e.g., MRI Physiological, e.g., EMG or nerve conduction studies Targeted physiotherapy
Peripheral sensory impairment	Peripheral neuropathy, e.g., diabetes, vitamin B_{12} deficiency Reduced proprioception	Optimization of risk factors Physiotherapy and occupational therapy for adaptive measures
Joint instability	Greater likelihood of tripping and falling because of pain or reduced range of movement of hips and knees in osteoarthritis	Analgesia: topical, oral, intra-articular; consider joint replacement Walking aids to reduce stress though joint Physiotherapy to improve strength around joint
Pain	Antalgic gait Side-effects of pain medication, e.g., drowsiness from opioids	Optimization and individualization of pain control
Cerebrovascular disease	Large vessel: causing focal visual, sensory, and motor deficits Small vessel: frequently dismissed Both associated with: Gait dyspraxia Marche à petits pas Cognitive impairment Urinary incontinence	Optimization of vascular risk factors
Cognitive impairment	Inability to pre-empt hazards, resulting in reduced safety awareness Impaired executive function in planning complex tasks Increased activity: 'wandering' Inability to use or remember walking aids	Screening for reversible causes of confusion Review of medication, e.g., opiates, sedatives, anticholinergic burden Occupational therapy for home safety
Depression	Association with reduced activity and consequent weakness, poor nutritional intake and poor sleep Impact on cognitive or executive function Interplay between depression and fear of falling	Activity can improve mood and increase interaction with social world Antidepressants may be required but can contribute further to falls Avoidance of medications most associated with postural hypotension (e.g., tricyclics) Monitoring for hyponatraemia and QTc prolongation
Visual impairment	Visual field defects: stroke, macular degeneration, glaucoma Visual neglect: stroke Reduced visual acuity: lens changes, retinopathy *Reduced hazard awareness*	Optician review, ideally annually Improvement of lighting around house; consider movement-sensitive lights for nocturia
Hearing impairment	Conductive: wax Sensorineural loss: commonly age-related plus other causes Social isolation *Reduced hazard awareness*	Audiological assessment for hearing aids Treatment for ear wax
Medications and polypharmacy	Exacerbation of postural hypotension Dehydration Electrolyte imbalances Confusion and sedating effects	Medication review (see earlier) Over-the-counter medications Alcohol history
Postural hypotension	Frequent association with antihypertensive treatment; may be intermittent Symptoms can be vague	Ambulatory BP monitoring if associated with hypertension Review of target BP—loosening control is often a pragmatic solution Minimization of vasodilating and dehydrating medications, e.g., ACE inhibitors, diuretics, nitrates

Box 49.11 Some risk factors for falls with possible management strategies—cont'd

Risk factor	Causes	Management
Electrolyte imbalances	Mild–moderate derangements often dismissed but associated with non-specific muscle weakness, malaise, constipation Severe derangements can lead to arrhythmias, seizures, myopathies presenting as a fall Often medication or hydration related	Blood tests Correction of abnormalities Review of medications Review of diet
Anaemia	Causes fatigue, weakness, and breathlessness Increased risk of postural hypotension if volume loss-associated Pernicious anaemia causes vitamin B_{12} deficiency, which can lead to peripheral sensory neuropathy and SACD Frequent association with chronic disease and iron deficiency	Establishment of underlying cause Consideration of: Blood transfusion Iron replacement Vitamin B_{12} and folate supplementation
Urinary incontinence	Overactive bladder Results in rushing to toilet—especially problematic if there are also gait problems	Treatment of continence; consider specialist referral Minimization of diuretics
Diabetes mellitus	Multiple falls risk, including: Hypoglycaemic episodes Visual impairment: retinopathy or cataracts Peripheral sensory neuropathy and autonomic dysfunction	Check of blood sugar levels: diary HbA_{1c} higher target for frail older adults: higher mortality rate associated with HbA_{1c} <50 Retinal screening Check for neuropathy and postural BP
Brady- and tachyarrhythmia (e.g., AF or CHB)	Reduction of cerebral perfusion and increase in falls risk	If ECG is abnormal, cardiac monitoring may be required (e.g., 24-h/7-day tape, implantable loop recorder)
Fear of falling	Very common, especially after major falls, but can be independent of falling Association with changes in gait pattern to be less steady, further potentiating fear Physical activity may reduce, exacerbating muscle weakness Complex interplay between depression and fear of falling	Cognitive-behavioural therapy Exercise (particularly tai chi) Treatment of underlying anxiety or depression Review of walking aids to aid confidence and independence
Vertigo, e.g., BPPV	Vestibular disorders in older people common and frequently unrecognized	Head impulse test: peripheral vs central cause Dix–Hallpike: BPPV Epley manœuvres or vestibular exercises (e.g., Cooksey–Cawthorne) ENT or specialist physiotherapy input
Foot health	Foot deformities and pain contribute to falls risk and poorly fitting footwear Leg length discrepancies	Podiatry referral Trimming of toenails Well-fitting footwear; may need specialist input

- Recognition and management of delirium
- Management of bowels and bladder
- Assessment and management of bone health and osteoporosis.

In the UK, the widespread establishment of multidisciplinary orthogeriatric services has contributed to a halving of 1-month mortality for hip fractures (from ~10% to ~5%), and similar models of care are increasingly being developed for other cohorts of surgical patients.

Institutionalization

Falls and their consequences contribute to approximately 40% of admissions to care homes. The fact of being in a care home does not in itself improve gait or remove the risk of falling; indeed, the risk of falling may initially increase on moving into a care home because this is a new and unfamiliar environment. However, it does mean that there are people on hand to help reduce the risk and to assist if someone does fall.

Box 49.12 Assessment of falls

Immediate management
- Treatment of acute illness (ABC approach)
- Assessment for injuries
- Pain control: consider regional anaesthesia (fascia iliaca nerve block for hip fractures) to minimize opiate use
- Preparation for safer surgery if required, e.g., optimizing fluid balance, correcting clotting (if on anticoagulants)

History and examination (ideally including collateral information)
- Events before the fall; previous falls or near misses; baseline mobility (e.g., any aids, asking why they are needed—muscle weakness, balance, other)
- Any loss of consciousness
- Medication review; alcohol history
- Full examination; consider risk factors, e.g., aortic stenosis, evidence of Parkinsonism, cerebellar issues, visual screen
- Postural blood pressure
- Inspect gait: even without formal training, think about how unsteady this looks, including turning, and how well a walking aid is used and whether the patient looks comfortable with it
- List risk factors for falls; address when possible
- Evidence of harm resulting from fall: pain, bruising, deformity, evidence of head injury

Investigations
- Bloods tests:
  - Full blood count (e.g., anaemia, evidence of sepsis; fractures can cause a neutrophilia)
  - Serum creatinine and electrolytes (evidence of acute kidney injury, electrolyte imbalance)
  - Glucose and hemoglobin A_{1c}
  - Bone profile and vitamin D
  - Thyroid function, micronutrient levels (vitamin B_{12}, folic acid, iron studies)
- Electrocardiogram (ECG), e.g., conduction abnormalities
- Imaging
  - Plain X-rays and cross-sectional imaging for possible fractures
  - Computed tomography of the head (evidence of large- or small-vessel cerebrovascular disease; exclusion of trauma, e.g., subdural haemorrhage)

Consider need for acute hospital admission
- Major trauma, including 'silver trauma' (older people with multiple injuries, often from low-impact trauma, such as falling from standing height), head injuries, fractures (e.g., hip)
- Possible or likely acute illness requiring inpatient care (e.g., intravenous antibiotics, fluids)
- Inability to mobilize safely
- Care needs that cannot be met in the community
- Not all fractures require admission, depending on mobility and social circumstances (e.g., wrist, neck of humerus, pubic rami can be managed in the community).

Factors that should prompt further assessment
- Frequent falls without recent input from a specialist team when the risk of further falls is believed to be high
- Possible syncope
- Polypharmacy
- Referral to relevant specialists, depending on findings from assessments (e.g., Parkinson's disease specialist)

Further management
- Provide oral and written information about falls
- Assess for and manage osteoporosis (e.g., DEXA scan, optimization of calcium/vitamin D levels, anti-resorptive bone medications or teriparatide)
- Advise regular optician review (e.g., screen for cataract, glaucoma)

DEXA, Dual-energy X-ray absorptiometry.

Postural hypotension

Cerebral autoregulation is responsible for maintaining stable blood flow through the brain. As we age, this becomes less well controlled, causing the brain to become more vulnerable to changes in systemic BP and in turn to postural instability and falls. The prevalence of postural (orthostatic) hypotension in the community is one in five older adults.

On standing, physiological responses should ensure that BP remains the same. This requires:
- Normal plasma volume, i.e., the person must not be dehydrated (younger people compensate well for this)
- Intact baroreceptors and reflexes
- Venomotor and arterial tone, i.e., the ability of blood vessels to respond to changes in blood flow.

All of these factors may be impaired in older people. Symptoms of postural hypotension (**Box 49.13**) typically occur on or soon after standing; they are rare when a person is sitting or lying down unless they have been lying for a long period and then attempt to sit upright or stand. Some definitions of 'significant drop' are provided in **Box 49.14**.

Aetiology

Acute postural hypotension is seen with a reduced intravascular volume, such as decreased oral intake, excessive diuresis, or excessive fluid losses as in diarrhoea, vomiting, or haemorrhage.

Chronic causes are principally:
- ***Medications:*** classically, diuretics, beta-blockers and other anti-arrhythmics, antihypertensives, and vasodilators.
- ***Autonomic dysfunction:*** associated with diabetes mellitus, Parkinson's disease, and multisystem atrophy. (Medications for Parkinson's disease may exacerbate this further.) Some autoimmune conditions can also cause autonomic dysfunction.
- ***Poor vascular compliance:*** seen in ageing blood vessels caused by a reduction in elasticity and increased calcification.

Management

The evidence base behind management of postural hypotension is poor, and only a couple of medications are licensed for use. The goals are to minimize symptoms and improve standing time to enable activities of daily living through improvement of standing BP without excessive supine hypertension (**Box 49.15**).

Delirium

The prevalence of cognitive impairment increases with age, which is reflected in older populations both at home and in hospital (up to 75% of inpatients older than 90 years old in some cohorts). This adds an additional layer of complexity to their healthcare management, with cognitive impairment being associated with an increase in mortality rate and the risk of dependency.

The presence of cognitive impairment makes ongoing management more challenging because of the potential lack of clarity in the patient's recollection of events and their history, their ability to comply with complex treatment pathways, and the increased levels of care that may be needed. For this reason, it is important when assessing an older person to have an objective assessment of their cognition. A number of cognitive screening and assessment tools can be used for this (see **Box 49.5** for some examples).

A collateral history around a baseline functional level is also vital. This helps distinguish dementia, a chronic progressive and typically

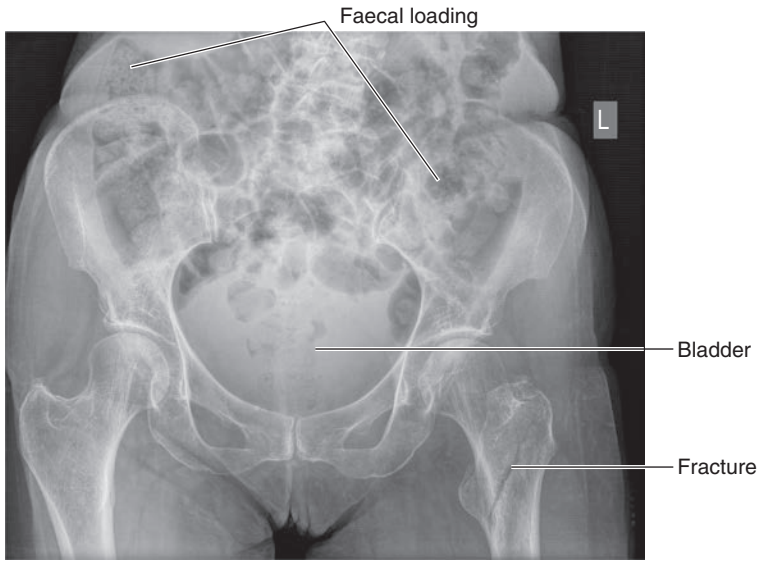

Fig. 49.8 A left-sided intertrochanteric hip fracture. Also of note, there is a large bladder (smooth shadowing in the lower pelvis), likely associated with urinary retention, for which the patient would need a catheter. Faecal loading is also visible, so laxatives should be started.

Box 49.13 Measurement of postural blood pressure

Preparation
- Use a manual sphygmomanometer.
- Lie the patient flat for 5 minutes before starting measurements.

Lying measurement
- With the patient's arm at the level of their heart, record blood pressure.

Standing measurement
- Ask the patient to stand up slowly and steadily.
- Be ready to support the patient if they feel dizzy or faint.
- Measure the blood pressure 1 minute and 3 minutes after standing.
- If the blood pressure continues to drop, continue to record at 2-minute intervals until it stabilizes.
- Record any symptoms the patient experiences.

Interpretation
- A drop of >20 mmHg systolic or >10 mmHg between lying and standing is generally considered to be significant drop.

Box 49.14 Definitions of a 'significant' drop in blood pressure

- ***Classic:*** reduction of 20/10 mmHg within 3 min of standing
- ***Initial:*** reduction of 40/20 mmHg in first 15 sec—a beat-to-beat recording is required
- ***Delayed:*** no agreed definition but occurring >3 min
- ***In hypertensive patients:*** reduction of 30 mmHg systolic; variability is higher in this group

untreatable neurodegenerative disease, from delirium, a short-term change in cognitive function often associated with reversible pathology. The collateral history also helps guide longer-term outcomes and realistic goals for the future. One tool to aid collateral history is MAPLE-V (Fig. 49.9).

People with cognitive impairment are at higher risk for the development of delirium when there is additional physiological load (e.g., in the presence of infection or constipation). In this context, delirium can be particularly long-lasting and florid.

Treatment for the cause of the delirium should be considered for older people as for younger people, depending on the balance of benefits and harms from the treatments and the patient's wishes when they can be ascertained. It is important to have a clear, honest, and supportive explanation of dementia (if applicable) and its effects in older people with the patient and their advocates. An acute hospital setting is not the ideal time for this because delirium may significantly change the patient's presentation, so any cognitive and functional assessments at this time are unlikely to give an accurate representation of their true baseline and may lead to inaccurate or inappropriate diagnoses.

When people are living with dementia, their healthcare can be complex, and optimal management requires multiprofessional input (skilled nursing, therapy, and perhaps psychiatry inputs in particular). Similar to the management of falls, the management of a patient living with dementia in the acute setting is an example of CGA in action. For example, if a person with dementia stops eating and drinking during a hospital admission, the assessment and management of this is complex and needs to take into account numerous factors, such as their general physical health, their oral health, the presence or absence of delirium, medication-related factors, and being in an unusual environment. Skilled specialist healthcare teams learn to work through this complexity while keeping family, carers, and patients up to date.

For patients in hospital with pre-existing cognitive impairment, there are a number of ways to minimize their risks for delirium. These are aimed at optimizing a patient's orientation while addressing any health needs, including nutrition, analgesia, and bowel and bladder care. These relatively simple strategies can reduce the risk of delirium by 35% (Box 49.16).

Managing challenging behaviours

When a person living with dementia starts to experience different or exaggerated behaviours that would not have been usual for them, it can have a significant impact not just for the person with dementia but also their family or carers.

Many of the behaviours, which are called 'behavioural and psychological' symptoms of dementia (BPSD), are not actually

Box 49.15 Management options in postural hypotension

Recommendation	Detail	Explanation
***A*bdominal and leg binders**	'Corsets' beneficial in ~50%; usefulness comes down to practicalities Compression stockings (TEDs): full-length, grade 2 and above; logistically difficult to put on or to tolerate; below-knee TEDS unhelpful because amount of blood in the calves is relatively small	Large volume of blood and baroreceptors in splanchnic and mesenteric circulation
***B*olus of water**	Drinking water: conflicting evidence: needs to be fluid bolus, 500 mL of water within 5 min with benefit lasting around 90 min; useful if timing of hypotension is predictable, e.g., first thing in the morning	Fluid bolus causes a change in the osmolality of the portal blood supply and induces an autonomic response in blood pressure
***B*ed elevation**	Elevating head of bed to 30 degrees from horizontal	Lower renal perfusion pressure leading to decreased diuresis and therefore fluid retention to maintain peripheral capillary pressure on standing up Another benefit is avoidance of supine hypertension in patient with impaired baroreceptor responsiveness lying flat
***C*ounter-manœuvres**	Standing on the toes; pelvic and abdominal clenches Crossing the legs and squeezing the buttocks, thighs, and calves while standing Standing slowly: education programmes with physiotherapy	Physical manœuvres to increase blood return to the heart by improving peripheral resistance Engaging venous return of mesenteric and splanchnic blood volume Unclear mechanism
***D*rugs (limited evidence)**	Fludrocortisone Midodrine	Increases fluid retention; can lower potassium Alpha-adrenergic agonist increasing peripheral vascular resistance: can cause dangerous supine hypertension, aggravate angina, or precipitate urinary retention
***E*ducation for self-management**	STOP what you are doing when you recognize symptoms coming on SIT down: allow blood pressure to recover DRINK some water, the most modifiable factor in the immediate term THINK about triggers: recognize patterns to manage	Patient understanding that their blood pressure responses are not normal and that they need to find ways to adapt to live with this in longer term
***E*xercise**	Moderate exercise Practicing standing slowly to avoid symptoms and getting up from floor	Improves orthostatic tolerance
***F*luid intake**	Keeping well hydrated	Maintains plasma volume

symptoms of dementia itself but are other symptoms or problems that cannot be communicated because of the impact of dementia on language and communication. BPSD can affect up to 90% of people with dementia at some course in their illness, and symptoms can include:

- Agitation: up to 75%
- Wandering: up to 60%
- Depression: up to 50%
- Psychosis: up to 30%
- Screaming or calling out: up to 25%
- Aggression: up to 20%
- Sexual disinhibition: up to 10%
- Others: inappropriate urination or defecation, disrobing, perseveration, repetitive questioning, hoarding or hiding, eating inedible objects, resisting personal care

It can be difficult sometimes to determine if symptoms may be related to delirium or BPSD. The latter is more likely if the answers to all of these questions are yes:

- Does the person have known dementia?
- Is it in the severe stages?
- Are the behaviors present for a longer than a short period?
- Has a physical cause been ruled out?
- Is there significant persistent agitation, psychosis, or apathy?

Understanding potential causes guides management and the PIECES framework help provide a structure for this (see **Box 49.17**).

Using the information gained in **Box 49.16** will help to piece together patterns and a better understanding of the situation and therefore how it can be managed in a person-centred way. It is important to understand exactly what the 'problem' is, in a similar way that you would approach understanding someone's pain: What are the behaviours that challenge, and for how long have they been present?

- Are there triggers, alleviators, or exacerbators?
- What has been the natural course of this?
- What, if anything, is tipping the balance now?
- Where does this sit in terms of a person's premorbid personality, any known diagnoses of dementia, its severity, and existing support informally and formally (including medications)? Where are the opportunities for optimizing these?

Urinary tract infections

UTIs are common in older adults. However, they are also commonly misdiagnosed or overdiagnosed without clear evidence. This can result in potentially dangerous overuse of antibiotics and overlooking (or missing) the actual cause of the patient's presentation.

Fig. 49.9 **Taking a collateral history for cognition.**

'Recurrent' UTIs in particular should be questioned. Often evidence is lacking, and alternative diagnoses, such as vulvovaginal atrophy, should be investigated.

A diagnosis of UTI is likely with a short history of new-onset dysuria alone or two or more of:

- Frequency or urgency
- Incontinence
- Delirium
- Worsening mobility
- Suprapubic discomfort
- Fever
- Visible haematuria

Investigations

Urinalysis in the form of a urine dipstick, looking for nitrites, white blood cells (WBCs), or protein, has traditionally been used to 'diagnose' UTIs, but a positive result for presence of bacteria may indicate colonization rather than infection. A negative result has a better predictive value for the absence of an infection.

A midstream specimen of urine (MSU) should guide antibiotic use before their initiation if there is diagnostic uncertainty. This may help reduce microbial resistance in the longer term. Urine dipstick analysis is of limited value (**Box 49.18**).

Asymptomatic bacteriuria is bacterial colonization without active infection in the urinary tract. It can cause false-positive results on urine dipsticks and raised WBC counts on MSU samples.

Management

- If possible, wait for urinary culture result and tailor initial antibiotics to this.
- If treatment is needed earlier (e.g., in sepsis) or if clinical suspicion is high, treat with empirical antibiotics until the MSU is available; then review with MSU sensitivities.
- Consider changing a catheter as soon as possible if it has been *in situ* for more than 7 days before the onset of infection.

Box 49.16 Management of cognitive impairment in the hospital setting

Interpersonal skills	Introduce yourself each time you see them and talk through what you are doing. Use visual clues as you go through the history (e.g., point to the abdomen when asking about bowels or bladder function). Think about validation therapy (e.g., if the patient is asking for their parents who are known to be deceased, ask the patient to talk about them; this fosters a similar feeling to their being present). Use non-verbal communication techniques. Use distraction and behavioural approaches when agitation builds.
Orientation	Ensure hearing aids are *in situ* and have a functional battery. Examine for ear wax and address it if necessary. Clean glasses and put them on. Make calendars and clocks available, accurate, and clearly visible. Provide orientation boards (with name of location, date, names of staff, and so on). Avoid moves either within the ward or between wards.
Bowels and bladder	Ensure the bowels are open regularly. Remove urinary catheters whenever possible, Encourage regular toileting.
Medication use	Avoid sedation and long-term antipsychotics. Avoid opioids unless needed for analgesia. Review changed medications (including alcohol withdrawal). Minimize anticholinergic burden.
Pain	Regular paracetamol has been shown to reduce agitation in those who may have pain they are unable to articulate. Non-verbal pain scales (e.g., Bolton or Abbey) may be helpful in assessment.
Promote a regular daily cycle, including sleep–wake pattern	Keep to regular routines on the ward or care setting. Keep disturbances overnight to a minimum (e.g., lights off, healthcare staff not chatting loudly, routine observations not done while the patient sleeps). Ensure mealtimes are regular. Try to avoid long or late siestas. Melatonin can be used in the short term to correct day–night reversal.

Recurrent suspected urinary tract infections

- Hold off antibiotics if possible and send two or three MSU samples.
- Consider alternative diagnoses if MSUs are repeatedly negative, including vulvovaginal atrophy in peri- and postmenopausal females, sexually transmitted infections, urethritis, and prostatitis.
- Prostatitis should also be considered in males with recurrent UTIs and positive MSUs, and a longer course of antibiotics may be required.
- Ensure that non-specific symptoms are not being inappropriately attributed to UTIs.
- In truly recurrent UTIs, specific management is often required (**Box 49.19**).

Box 49.17 PIECES Framework for assessment in behavioural and psychological' symptoms of dementia

Physical problem or discomfort	Acute medical problem: delirium Drugs (polypharmacy, side-effects), alcohol, other substances Chronic disease symptoms Pain (under-recognized and undertreated) Basic human needs (e.g., tiredness, hunger, thirst
Intellectual or cognitive changes	Type of dementia The As: anosognosia, amnesia, aphasia, apraxia, agnosia, altered perceptions, apathy
Emotional	Depression Anxiety Psychosis Psychological trauma from earlier experiences Adjustment difficulties Difficult interactions with carers (important to identify burnout in carers; acute presentation to services may not actually be because of the behaviour getting worse but because of carers being worn out or having their own mental health problems) Aggression
Capacities	Boredom Unused energy or previous habits (e.g., 'wandering' may actually be quite purposeful even if mistimed or out of sync with other care home routines) Changes in interest or difficulty keeping up with previous interests Demands exceed capabilities (frustration and catastrophic reactions)
Environment	Relocation, feeling lost, needing to get 'home' Ambience: excessive or distressing noise, unfriendly, confusing environment, poor lighting
Spiritual and cultural	Spiritual and cultural needs Language (e.g., carers not speaking the right language) Returning to previous language Family and friends

Urinary incontinence

Up to 50% of females will be incontinent at some time in their lives. For males, urinary tract symptoms and difficulty passing urine are also common but less well studied. Incontinence is under-recognized and undertreated. Many people do not volunteer their symptoms; even if asked directly, not everyone is comfortable talking about it.

Incontinence has a huge impact on a person's quality of life and often on their relationships with partners and family. Poorly controlled urinary and faecal incontinence are common reasons for admissions to residential care because of carer strain. It is independently associated with falls and is a modifiable risk factor for them. For those who are bedbound, incontinence can cause local irritation in areas prone to pressure damage, increasing the risk of breakdown of skin integrity.

Box 49.18 Urine dipsticks in the diagnosis of urinary tract infection

Public Health England guidance (2018) suggests not using urine dipsticks in the over-65 population.

- In conjunction with symptoms, dipsticks have a sensitivity of around 77%.
- In the absence of symptoms (e.g., as a screen in a patient with confusion), sensitivity falls to 44%.
- The frequency of positive urine dips in institutional care is very high: up to 50% of females in nursing homes have asymptomatic bacteriuria. In non–care-home residents, the figure is lower, ranging from 6% to 16% in females aged 65–90 years.
- The negative predictive value of dipsticks is 100% for nursing home residents.
- In the presence of long-term catheters, dipsticks will almost always be positive (colonization).

There are four main types of urinary incontinence, but there is often overlap between them.

Stress incontinence

Urine leaks from the bladder due to higher pressures than the pelvic muscles are able to contain. This is commonly caused by weakness or damage to the pelvic floor muscles, and previous pregnancy is a risk factor. Typically, stress incontinence occurs on coughing, laughing, or straining.

Management may be conservative or surgical. Conservative measures can cure stress incontinence and so are first-line treatment (**Box 49.20**). If they fail, surgical referral should be considered. Surgery aims to support the pelvic floor either through suspension of the bladder higher up from the external sphincter or by bulking the pelvic floor itself.

Urge incontinence (overactive bladder)

The bladder becomes irritable, causing the person to feel that they urgently need to empty it when the bladder is not actually full. Symptoms include frequency, urgency, and nocturia. If these are of new onset, the trigger may be a UTI. Chronic infection should be excluded as a cause.

When a history is taken, the questions need to be broader than in stress incontinence. Many people will have adapted their lifestyles to minimize the risk of being incontinent, so questions might include:

- Do you ever not make it to the toilet in time?
- When you feel the urge to go to the toilet, are you able to hold it, or do you need to go quickly? What happens if you do not?
- If you are going out, do you plan your day around the availability of toilets?
- Do you use continence pads?

Urodynamic studies can be used to monitor the pressure within the bladder, and electrical activity of the bladder muscles. Intravesicular pressure monitoring shows inappropriate pressure rises associated with electromyography (EMG) evidence of bladder muscle contraction despite small bladder volumes.

Management begins with conservative measures, as for stress incontinence (see **Box 49.20**) Additionally, it includes avoiding bladder irritants, including dehydration (concentrated urine) and caffeine. Bladder training aims for a slow increase of the amount of time from feeling the urge to pass urine to micturition. If these measures fail, some patients benefit from medications such as antimuscarinics (e.g., oxybutynin, tolterodine). Around half of patients will have stopped taking the medication by 3 months, and only one-third will

Box 49.19 Recurrent urinary tract infection

- ***Structural abnormalities*** require imaging ± urological referral for cystoscopy.
- ***Vulvovaginal atrophy*** mimics symptoms, as well as increasing the risk of urinary tract infections; topical oestrogen reduces frequency.
- ***Constipation*** is a cause of obstruction.
- ***Hygiene practices*** require a review of care needs if not self-caring.
- ***Post-treatment midstream specimen of urine*** permits a check for bacteriuria and resistances.
- ***Prophylactic antibiotics*** may reduce events; however, there are risks from long-term antibiotic use (e.g., pulmonary fibrosis from nitrofurantoin).
- ***Increased infection susceptibility*** is associated with poorly controlled diabetes and immunosuppression.

Box 49.20 Conservative measures for managing stress incontinence

- ***Pelvic floor strengthening*** has a higher success rate when supervised but can be performed independently.
- A ***bladder diary*** determines whether any other types of overactive bladder are present that require treatment.
- ***Review of fluid intake*** will note caffeine, high fluid intake, and diuretics, which increase urine output and therefore enhance the potential for stress incontinence.
- ***Weight loss*** (body mass index >30 kg/m^2) puts less strain on muscles.
- ***Optimization of respiratory disease management*** reduces coughing, if present; stop angiotensin-converting enzyme inhibitors.

still be taking it at 1 year because of anticholinergic side-effects, which include dry eyes or mouth, constipation, and confusion. The latter means that these drugs are relatively contraindicated in those with cognitive impairment. Beta-3-agonists, such as mirabegron, should not be used in people with significant hypertension.

Overflow incontinence

This is caused by bladder outflow tract obstruction. The most common cause is prostate enlargement, and thus this is a disorder commonly seen in older males (see Chapter 47, 'Benign enlargement of the prostate gland' section). Other precipitants include medications (e.g., anticholinergics) and constipation. Symptoms include difficulty initiating micturition, poor stream, and terminal dribbling (i.e., further urinary leakage after completion of micturition). Overflow incontinence can be associated with renal failure caused by obstructive uropathy when the system is under high pressure. It can be overlooked because patients still pass some urine but without complete bladder emptying; often patients pass small volumes of urine frequently. Catheterization may be required, either in the short or long term, to alleviate the obstruction.

Functional incontinence

This involves the patient's being physically unable to reach the toilet rather than there being a primary urogenital problem. For example, someone with poor mobility may be unable to get to the toilet in time but would otherwise be continent if their mobility improved. In states of impaired cognition, such as delirium or advanced dementia, the signals for micturition are no longer interpreted normally, resulting in the passing of urine without conscious processing and thus incontinence. Management requires CGA to address any modifiable components, such as pain control, to allow improved mobilization. This can include environmental adaptations, which may make toileting easier. Regular toileting can be helpful for those with advanced dementia and good mobility; this involves prompting the person to go to the toilet at regular intervals, before they need to go urgently, to minimize the risk of incontinence.

Box 49.21 Non–home-based living options in the UK

- ***Care home:*** This can mean a residential or nursing home.
- ***Residential home:*** This is suitable for people who need minimal assistance with mobility, transfers, and some personal care.
- ***Nursing home:*** This is suitable for people requiring significant support, supervision, and care, with trained nurses present to support delivery.
- ***Warden-assisted living or sheltered accommodation:*** Residents have their own flats. A warden is accessible at certain times and is able to provide some support, but not with personal care. Often there are communal areas.
- ***Extra-care sheltered accommodation:*** This is sheltered accommodation that also has on-site carers who can provide additional care more flexibly.
- ***EMI home:*** These homes are for the 'elderly mentally infirm' and specialize in caring for patients with challenging behaviours, typically caused by dementia.

COMPLEX DISCHARGE PLANNING

Complex discharge planning does not just refer to a process that will need a lot of paperwork. It is also a complex balance of managing risk, expectations, and resources. It requires close multidisciplinary working across primary and secondary care to fit best with a patient's priorities for the way they wish to live their lives to the fullest.

In its simplest form, discharge destination from an acute hospital can be directly to home or to an intermediate care facility for further rehabilitation or convalescence. (The most common discharge destinations in the UK are outlined in **Box 49.21**.) A number of factors affect a patient's discharge and destination, which interact to make it potentially complex (**Box 49.22**). There is often very little for patients to do in hospital or a rehabilitation unit, so they do not do very much. Meanwhile, at home, they are more likely to do more, with day-to-day 'pottering around' in their own homes contributing to enhanced recovery, provided they have the necessary support in place to do so.

For discharge planning to be truly effective, it needs to be started at the beginning of a patient's admission and regularly reviewed with the MDT caring for the patient, with an understanding that the initial plans may be adapted and changed. Regular discussion with both patients and their relatives and carers is important. Traditionally, when patients are preparing for discharge, assessments are carried out in hospital; however, this may involve exploring the patient's mobility in a place where distances may be significantly greater than at home, and kitchen assessments take place in an unfamiliar environment. Occupational therapy home visits evaluate a patient's ability to function within their own home environments, and people often do significantly better there. Some schemes, such as the original Discharge to Assess (D2A) programme, complete all assessments in the patient's home on the presumption that they will do better in their own environment, with essential equipment and care being put in place on the same day if they are going to stay there. This can reduce time spent in hospital and often results in lower care needs than were predicted from hospital-based assessments.

Important considerations

Rehabilitation goals

Rehabilitation is a multidisciplinary process through which an individual's functional level is optimized, including physical, psychological,

Box 49.22 Factors affecting discharge planning

Patient factors

- ***Patient wishes:*** For some people, their priority is to remain in their own homes for as long as possible, but others may feel very trapped and isolated there, preferring somewhere that has other people around, such as a care home.
- ***Medical issues and prognosis:*** Has the issue leading to hospital admission resolved (e.g., hip fracture, pneumonia), or is it likely to be progressive (e.g., lung cancer)? What is the likely prognosis? For those with a short prognosis (e.g., a few weeks), it may be better to take more risks and maximize time at home as opposed to aiming for rehabilitation when there is a longer prognosis.
- ***Functional status:*** How much are patients able to do for themselves? If a patient can walk to the toilet and back, support can be put in place for most other issues. Were they struggling at home before admission? What support do they need overnight, such as with toileting or wandering behaviours? If there are issues with continence, this can make things particularly difficult at home, with faecal incontinence in particular. Mobility is a major issue, with falls being some of the leading reasons for admission to a care home. Falls can occur anywhere, including at home, in hospital, or in a care home, though the latter two have staff to reduce the risk or help after the event.
- ***Cognition:*** This affects a patient's ability to care for themselves and their safety awareness, as well as their ability to call for help appropriately, either through pendant alarms or telephones. Some may need increasing support with meals, either ready-made for the oven or microwave or delivered to the home. Some patients may forget or have poor insight into their cognitive problems, in which case options such as turning off the gas supply to the cooker can make discharge home safer. Reversal of a patient's sleep pattern (day–night reversal) can make it much harder for a spouse to offer support because their own sleep pattern will also be affected. Patients with cognitive impairment tend to function far better in a familiar environment than elsewhere, and home visits from the occupational therapists should be considered before any permanent moves to a care home.

Home factors

- ***Suitability for frailer people or those with cognitive impairment:*** Some homes are more suitable than others. Cramped spaces can be difficult, although it is easier for people with reduced mobility to hold on to the walls. Some beautiful rickety cottages with little steps between each room can be a challenge! Modern purpose-built flats for older people are usually fine.
- ***Stairs:*** These can be a challenge, though having a toilet on every floor makes things easier.
- ***Potential for adaptations:*** Is there space for a hoist? Can the bathroom be adapted to house a walk-in shower? Can a stairlift be installed?

Social factors

- ***Co-habitation:*** This can provide physical support, such as assistance with activities of daily living (from washing and dressing to housework), as well as someone to call for help if there are any problems. Be aware of the physical and cognitive level of the spouse, who may also be frail with multiple co-morbidities. Live-in carers are another option, though they are expensive.
- ***Financial status:*** Is the patient able to pay for support and equipment?
- ***Family wishes:*** Although patient wishes are vitally important, the family members are the ones who pick up the pieces when things do not work out. Balancing a patient's wishes with what is realistic can be tricky, as can balancing them with the family's wishes, which may not be the same as the patient's. When a patient has capacity for decisions regarding specific issues, these should be respected wherever possible. Beware of abuse (financial abuse and neglect) when the family agree only to an insufficient care package in their attempts to preserve their inheritance.

Resources

- Availability of and funds for carers
- Availability of and funds for equipment
- Access to rehabilitation units
- Local schemes for domiciliary care: can rehabilitation be done from the patient's own home?

and social aspects of function. It can take place anywhere, from the patient's home to acute inpatient settings and even in an intensive care unit, where there are interventions to help preserve longer-term function. Rehabilitation is dependent on working closely with the patient and the wider MDT, including (where relevant) community- and hospital-based services.

Although the emphasis is on returning patients to their premorbid function, a limitation of functional regain, such as after a major stroke, must be recognized. In such cases, helping the patient adjust to the new functional level is a fundamental aspect of the process.

Most commonly, we think of rehabilitation occurring after an acute illness, such as a stroke or pneumonia. However, it also plays a key part in chronic conditions, such as Parkinson's disease and reduced mobility. Increasingly, its role in preparing people for interventions such as surgery is being recognized; this is known as 'prehabilitation' and aims to expedite recovery and improve longer-term outcomes.

A number of factors affect the likely outcome from rehabilitation:

- ***Premorbid status.*** A frailer patient is less likely to improve as much as those who are stronger before their acute illness.
- ***Reasons for deterioration.*** An acute injury or illness, from which full or nearly full recovery might be expected, should be compared with progressive underlying illness, such as cancer or motor neurone disease, in which it is possible to achieve short-term gains, but patients deteriorate over the longer term.
- ***Co-morbidities.*** When possible, these should be addressed through CGA. Areas that bring particular benefit include pain management (e.g., in arthritis of the knee), BP (too low can increase falls risk), and Parkinson's disease (timing sessions to periods of the day when control is better).
- ***Cognitive impairment.*** This may reduce the patient's ability to follow instructions in the intervals between sessions. However, significant improvements may occur, and cognition alone should not preclude rehabilitation. The clinician should also be aware that recognizing and treating pain in patients with dementia can be difficult but that poor control has an impact on progress.
- ***Depression.*** Be suspicious when patients do not progress as expected. Trying to discriminate between depression and an adjustment reaction after an acute illness (e.g., loss of function after a stroke) can be difficult, and monitoring over a period of weeks is often necessary.
- ***Motivation.*** Rehabilitation takes effort on the part of the patient, and there is great variability in how much individuals are willing to engage.

A distinction should be made between patients who have a realistic chance of making a meaningful improvement and those who have no realistic chance of seeing a significant change. One of the key principles of rehabilitation is goal setting, with clear and achievable targets over appropriate timescales. For example, in a patient needing a Zimmer frame and assistance from two people to transfer between a bed and a chair, rather than the goal being 'To improve transferring', a better target would be 'To be able to transfer with assistance of one person and a Zimmer frame within 3 weeks'.

Managing risk

Managing risk is a crucial part of discharge planning. Just as life itself inherently contains risk, risk cannot be removed completely from any discharge. The aim is to recognize harmful, predictable risks and offer ways to minimize them. It is important to remember that everyone has different priorities for what they consider a true risk to be and have differing levels of risk tolerance. Respect should

be shown for people's autonomy to make unwise decisions. The key here is to ensure that the person is informed as to the options so they can make their own decision.

Cognitive impairment

Cognitive impairment can impact decisions about discharge in a few different ways. Regarding decision-making and risk evaluation, the right to autonomy is fundamental but is closely linked with the mental capacity to understand and weigh up these risks. If a risk is not perceived to be real, then an informed decision around it and implications for optimizing safety cannot be made. In this circumstance, involving an advocate is vital. This can be anyone who knows the person well enough to share what the person would be likely to express for themselves if they were able to. This is usually a family member but does not need to be; it can be any person who knows the patient well enough to act in their best interests. Under UK law, 'next of kin' has no legal standing, but their opinion should be given significant weighting in decision-making; legally, only an allocated power of attorney or court of protection–appointed guardian can make a decision on behalf of a person, as though they are that person.

When considering discharges for those with cognitive impairment, it is important to consider whether the current presentation is caused by delirium or established dementia. In the latter, care and support needs are likely to be relatively stable and predictable. If the person has delirium, then their care and support needs are likely to change as they recover, and a higher intensity support option in the shorter term is likely to be necessary. Remaining in hospital may be the physically safest option but may hinder cognitive recovery. Hospitals can be inherently 'deliriogenic' and disrupt a person's usual orientation and coping mechanisms, so the two need to be balanced carefully.

Incontinence can become a particular challenge posed to being able to be at home, especially in advanced dementia. If a person is no longer able to recognize when they need to go to the toilet or are unable to get to the toilet unaided or obtain help when needed, incontinence of both urine and faeces may occur. This is challenging for those caring for, providing support to, or living with this person from many perspectives by affecting hygiene, physical health, mental wellbeing, and relationships. When someone needs assistance to go to the toilet in a home environment, a key discharge decision will need to include what will happen if they are alone and unable to toilet themselves (e.g., between care calls, when a caregiver is out, overnight). This is often a deciding factor in opting to move into residential support.

Social and functional support

If someone is returning home or a decision is being made between returning home or to another environment, the availability of social and functional support needs to be clear so an informed decision can be made. This might include the use of equipment and adaptations around the home to make activities of daily living easier and provide formal health or social care support (e.g., community nursing for complex medications or skin care, carer visits for personal care). Ensuring the right level of support from the right people is particularly important when an individual is physically, psychologically, or cognitively vulnerable and may not be able to advocate for themselves fully to ensure the maintenance of their wellbeing and safety.

Carer strain

In the UK, there are around 5 million unpaid carers who provide informal support to family or friends and around 1 million paid carers working in the social care workforce. Many unpaid carers may struggle with the demands of their role. They may lose their sense of self and their own wellbeing or experience an enhanced level of anxiety and stress, particularly if they are subject to physical or verbal abuse or being woken during the night.

Other factors that have a major impact include depression in the patient and incontinence, with faecal incontinence being particularly difficult for carers to manage. Carers may, in addition, have medical issues of their own. Assumptions should not be made regarding a carer's capacity or willingness either to start taking responsibility or to continue to care for a person. Carers should be actively involved in decisions surrounding a patient's care.

Ways to help reduce carer strain include:

- Recognition and appreciation of what the carer is doing
- **Financial support**, e.g., a carer or attendance allowance
- **Maximizing performance status**, e.g., making transfers easier
- **Addressing co-morbidities**, e.g., treating depression
- **Periods of respite**, e.g., day centres, where the carer can take some time off; a sitting service, where someone besides the main carer stays with the patient for a few hours to give the main carer a break; rolling respite, where the patient spends 1–2 weeks every 2 months (e.g., in a care home); and asking friends and family to help for periods, either regularly or on a more ad hoc basis
- Holidays, provided by companies who specialize in holidays for people with health conditions, with carers on site; often, the patient and carer will travel together.

Older adult abuse and safeguarding

Abuse of older adults is defined as a single or repeated act that causes harm or distress to an older person or as a lack of appropriate action. It can take place within any relationship in which there is an expectation of trust. There are a number of different types of abuse (**Box 49.23**), and it is quite common for a number of these to occur simultaneously.

Older people are particularly vulnerable to abuse. Worldwide, the World Health Organization (WHO) has found that approximately 1 in 10 older people experiences abuse each month. The WHO found that two-thirds of older people with dementia have been abused. Obtaining clear data is very difficult, and there is concern that these figures are underestimates. Some risk factors for abuse are shown in **Box 49.24**.

Older people are often afraid to talk about cases of abuse to family, friends, or the authorities, with fewer than 1 in 20 cases being reported. Even when abuse is recognized, many victims are unwilling to discuss or pursue complaints, especially if family members are involved.

Cognitive impairment is a major risk factor for abuse, in which recall of specific issues around the abuse is patchy and unreliable, making clarification of concerns difficult. It is essential to be aware of the issues and to have a low threshold for escalating possible concerns.

Although older males have the same risk of abuse as females, older females are at higher risk of neglect and financial abuse in some cultures where females have unequal social status, particularly when they are widowed. Females may also be at higher risk of more persistent and severe forms of abuse and injury.

Safeguarding is the protection of people's health and wellbeing, enabling them to live safely and free from neglect or abuse in conjunction with their own wishes and beliefs. Preventative strategies include:

Box 49.23 Some types of abuse

Type	Features	What to look for
Physical	Hitting, scratching Misuse of medicine, both undermedicating (e.g., inadequate analgesia) and overmedicating (e.g., excessive sedation) Forcible feeding or withholding of food Restraint	Unusual pattern of injuries Absence of clear explanation Frequent injuries for which medical treatment has not been sought
Sexual	Any sexual activity the patient cannot or does not consent to	Bruising, particularly to the thighs, buttocks, and upper arms Bleeding, infections, pain, sexually transmitted disease, or itching in the genital region
Psychological or emotional	Social isolation Removal of mobility or communication aids Preventing the patient from meeting their religious needs	Change in psychological state in the presence of another person Low self-esteem or withdrawn appearance
Financial or material	Preventing the patient from accessing their own money or assets Arranging less care than is needed to save money (e.g., to maximize an inheritance) Moving into a person's home rent-free or under duress	Recent changes, e.g., to property ownership Obtaining lasting power of attorney after patient is assessed as lacking mental capacity to manage their finances
Discriminatory	Unequal treatment based on age, cognition, and so on	
Organizational or institutional	Settings such as nursing and residential homes or hospitals Lack of respect for dignity and privacy, e.g., during bathing or toileting	Inappropriately prioritizing care of younger patients Precluding all patients with dementia from rehabilitation regardless of their potential to improve
Neglect or acts of omission	Denial of access to basic needs, including food, shelter, clothing, heating, and personal and medical care Failure to administer medications appropriately	Malnourished appearance Untreated medical conditions or injuries Pressure damage
Self-neglect	Failure to carry out personal hygiene, when behaviour impacts on safety Squalid or unsanitary conditions Unkempt appearance Non-compliance with care	Health risk to neighbours

Box 49.24 Risk factors for abuse

Patient factors
- Frailty or any serious health condition
- Physical or sensory disability, e.g., reduced mobility, poor vision
- Memory problems or dementia, other mental health problems, learning disability
- Previous episodes of abuse
- Low income or socioeconomic status

Social factors
- Substance misuse by abuser
- Mental health problems in abuser
- Shared living situation
- Abuser's dependency on the older person (often financial)
- Difficult family relationships
- Social isolation

Care provider factors
- Poor staff training or support, e.g., in institutions
- Policies operating in the interests of the institution rather than the residents
- Poor resources, e.g., to pay for carers or provide suitable environment

- Clear support, education, and guidance for patients and caregivers
- Education at an institutional level and clear guidelines on the management of specific conditions, e.g., BPSD
- Involvement of patients and advocates in the development of policies and guidelines
- External assessments or care providers, e.g., inspections by the Care Quality Commission within the UK.

Recognizing abuse can be difficult. There should be a low threshold for escalating concerns to relevant specialists, who can then investigate and act when necessary. Often, this is led by social services.

Loneliness

As people age and experience associated disability and frailty, their personal worlds may progressively shrink, in some cases to a single room. This is commonly associated with an increase in social isolation and loneliness. Approximately 50% of the population older than 75 years of age in the UK live alone, with around 10% of older people reporting loneliness. There are two main facets to loneliness:

- ***Emotional:*** stemming from the absence of an intimate relationship or a close emotional attachment (e.g., a partner or a best friend)
- ***Social:*** stemming from the absence of a broader group of contacts or an engaging social network (e.g., friends, colleagues, and people in the neighbourhood)

Loneliness may be regarded as a new 'geriatric giant' and is linked with numerous negative health outcomes. The negative impact of loneliness on health is substantial: it is equivalent to smoking 15 cigarettes a day, and people who have a high degree of loneliness are twice as likely to develop Alzheimer's disease. Conversely, people taking part in health- and independence-maintaining behaviours are less likely to feel isolated and more likely to feel that their community is a good one to grow old in. Loneliness has complex causes, and the most effective schemes to deal with it take a broad view, targeting higher-risk groups, including those from lower socioeconomic backgrounds, widowed people, the physically

isolated, people who have given up driving, and people with sensory impairments.

AGEING WELL AND ADVANTAGES OF AGEING

Amid the common negative rhetoric around the challenges that face healthcare and society at large, we should not forget that older adults are exactly that: adults who have grown to an older age, bringing their personalities, experiences, and individuality with them. The National Health Service in the UK was originally set up to deliver emergency and life-saving treatments for predominantly single-organ conditions. Emergency department attendances are increasingly characterized by relapses in chronic conditions, the consequences of a fall, a breakdown in social care, or functional difficulties such as a decrease in mobility. The nature of inpatient work has shifted because of the incredible successes that healthcare has delivered over the past century, reflecting its fundamental goals: to help all members of society live their lives to their greatest participation within society and to optimize their wellbeing.

Societal and economic advantages of an active older population

In high-income countries, there is an increasing and active population of older people who are making major contributions to society. An Age UK study found that in 2013, older people contributed an estimated £61 billion to the economy in England (>5% of gross domestic product), which was six times the amount spent by local authorities on social care. The main financial contributions came through continued working, informal caring, providing childcare for grandchildren to enable their children to work, and volunteering. Clearly, the benefits extend far beyond the financial aspects, with older people's skills, knowledge, and experience supporting many aspects of society.

Health and wellbeing

The Institute for Public Policy Research (2009) has identified five essential elements of wellbeing:

- Resilience
- Independence
- Health
- Income and wealth
- Having a role and time

Building resilience within an individual and their support network is increasingly seen as a buffer against the effects of frailty. This may be achieved by optimizing cognition, mood, social networks, mobility, and physical reserves.

The presence of disease should not be equated with a lack of wellbeing or meaningful life. A study by Strawbridge et al. in 2002 found that 50.3% of older adults considered themselves to be ageing successfully compared with 18.8% classified as ageing successfully using 'objective' criteria. Although absence of chronic conditions and maintenance of functioning were positively associated with successful ageing on both definitions, many participants with chronic conditions and with functional difficulties still rated themselves as ageing successfully.

There is good evidence to support mid-life interventions as being beneficial in improving health and reducing frailty in later life. These include:

- Smoking cessation
- Promotion of physical activity
- Reduction of alcohol consumption
- Improvement of diet
- Maintenance of a healthy weight

Healthcare systems need to adapt to the changing demographics of the ageing population, shifting towards greater prevention of disease and proactive care with better integration of health and social care services. This would mean that older people age well and stay well and will have the support they need for the management of complex co-morbidities. Key to this is information sharing because older people's healthcare is highly complex and integrated.

CORE SKILLS AND KNOWLEDGE

Palliative care is the active total care of patients who have advanced, progressive, life-shortening disease. It is based on needs, not diagnosis, and is required in non-malignant conditions as well as cancer. Knowledge of the principles of palliative medicine is essential for all healthcare professionals and can be applied throughout medical practice so that all patients, across all care settings, have access to and receive good care. All specialties treat people who are sick enough to die, and the recent COVID-19 pandemic has highlighted the importance of clinicians' ability to provide good end-of-life care.

Palliative care is delivered by multidisciplinary teams (MDTs) that include doctors, nurses, therapists, chaplains, psychologists, and social workers. It may be delivered in patients' own homes; during hospital admissions or clinic visits; and through hospices, which provide both inpatient and outpatient services. It aims to address all aspects of a patient's care needs, promote independence, and support patients and their families through the dying process.

Key skills to acquire in palliative care include:

- Learning to talk openly and sensitively with patients and families about disability, uncertainty, deterioration, and death
- Learning to manage common symptoms such as pain and nausea
- Working within an MDT to provide holistic care for patients.

BACKGROUND AND GENERAL ASPECTS

A palliative care approach is relevant to both malignant and non-malignant conditions and may be applicable well beyond the last weeks of life. It is increasingly common for palliative care to be delivered alongside active treatment in recognition that palliative and active approaches may have complementary effects. This dual approach is particularly relevant for patients with chronic non-malignant disease, such as organ failures (heart, lung, and kidney) and neurodegenerative diseases, who may live many years with a symptom burden similar to or greater than people with cancer, as well as the increasing numbers of cancer patients who are surviving longer but requiring support with long-term sequelae of their disease and its treatment. An early palliative care approach with access to specialist palliative care (SPC) teams for complex problems may therefore be beneficial (**Box 50.1**).

The ***goal*** of palliative care is to achieve the best possible quality of life for patients and their carers by:

- Managing physical, psychological, social, and spiritual problems to provide excellent symptom control
- Enabling patients to be cared for and to have the best chance of dying in their preferred place
- Enabling the acceptance of death as a normal process when life-prolonging treatments no longer improve or maintain quality of life
- Providing the opportunity to say goodbye and reduce complicated grief.

Box 50.1 Key points in palliative care and key components of a modern palliative care service

Key points in palliative care

- Patients should always be involved in decisions about their care.
- Quality of life is increased when treatment goals are clearly understood by everyone, including the patient and carer.
- The multidisciplinary team provide a high standard of care, but there must be realism and honesty about what can be achieved.
- End-of-life care is delivered in all settings: the patient's usual place of residence, hospitals, and hospices.
- Care at home should be encouraged for as long as possible, even if the patient's preferred place of death is elsewhere.
- Discussions about end-of-life care planning are best held outside times of crisis, with clinicians with whom the patient has a good relationship. An unplanned admission can be a trigger for advance care planning discussions.
- Discussions must be recorded and made known to everyone involved in the patient's care.

Key components of a modern palliative care service

- Management based on *needs*, not diagnosis: the symptom burden of non-malignant disease often equals that of cancer.
- Care that is independent of the patient's location and that helps patients to remain at home if possible, avoiding unwanted admissions to hospital.
- Rehabilitation for people with advanced disease.
- Support for carers.
- Bereavement care for people with complicated grief.
- Advice for other clinicians; dissemination of palliative care knowledge.
- Education (surrounding palliative and end-of-life care) for clinicians of all disciplines and all levels.

Who provides palliative care?

All healthcare providers should have basic palliative care skills and know how to access SPC services (see **Box 50.1**) for support with more complex problems. A hallmark of a SPC service is the MDT because single professionals cannot provide the breadth of necessary expertise. The emotional demands of working in this area require team support to enable balanced, compassionate, and professional care. Members of the team can include clinical nurse specialists, doctors, psychologists, therapists (occupational, physical, music, and creative), chaplains, and social workers. In some centres, the term ***supportive care*** is used instead of 'palliative care'. Teams may be based in hospitals, hospices, or in the community because palliative care crosses all healthcare settings. Clinicians should be aware of the services that their local SPC teams offer and recognize when referral is appropriate.

Patients may have close relationships with their usual medical team(s), and an integrated approach, across a number of settings, may be needed to allow optimization of disease-directed interventions as well as palliative care. Patients may have access to supportive and palliative care clinics, sometimes called 'enhanced supportive care', alongside hospital medical clinics early in their healthcare journey. They may use inpatient SPC services in hospices for a limited period (days to weeks) for complex problems to be intensively addressed, or they may be supported by community palliative care teams in their homes. Excellent communication between all members of the healthcare team and between the patient and carer underpins the successful management of advanced disease and end-of-life care. Effective liaison between the hospital and community teams is also essential.

Box 50.2 Problems arising when specialist palliative care is delayed until the end of life

- There is insufficient time to achieve good symptom control by combining non-pharmacological and pharmacological components.
- Specialist palliative care services are deemed less acceptable by patient and family, being associated with 'dying', 'giving up', or 'giving in' to illness.
- Psychological distress and physical symptoms become intractable and contribute to complex grief.
- It becomes too late to adopt a rehabilitative approach or teach or use non-pharmacological interventions that need a degree of training and patient motivation (e.g., cognitive-behavioural approaches, mindfulness meditation, attendance at day therapy).

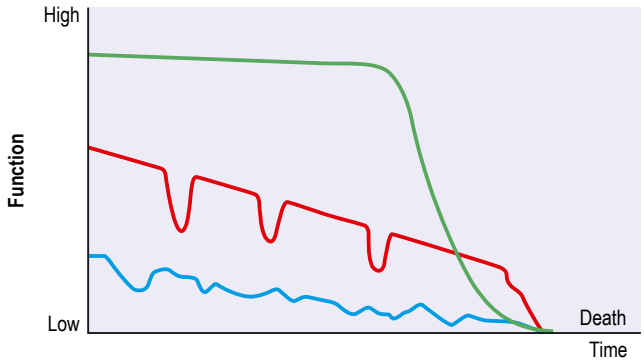

Fig. 50.1 Trajectories of different disease types. *Green* indicates cancer, *red* indicates chronic non-malignant disease, and *blue* indicates multimorbidity and increasing frailty. *(From Murray SA, Kendall M, Boyd K et al. Illness trajectories and palliative care.* BMJ *2005; 330:1007.)*

When should palliative care needs be assessed: problems rather than prognosis?

Palliative care can be beneficial from the time of diagnosis of potentially life-threatening or life-limiting illness even when cure is considered possible ('hoping for the best, preparing for the worst'). A problem-based approach to disease management ensures that patients and carers obtain access to appropriate support services, including SPC, and avoid an either/or approach ('either curative treatment or palliative care'). Palliative care is most effective when considered as part of routine care alongside disease-specific therapy. Early referral links palliative care with quality-of-life improvements; positive associations increase the likelihood that patients and families continue to use palliative care services when they need them over the course of the illness. In cancer, there is good evidence that integrating palliative care and anti-tumour treatment soon after diagnosis reduces long-term distress and even increases survival in selected cases.

If palliative care is seen as relevant only to the end-of-life phase, patients may be denied expert help for complex symptoms. Timely management of physical and psychosocial issues earlier in the course of disease prevents intractable problems later (see **Box 50.2**). It can be difficult to know when to consider palliative care in non-malignant conditions because of their variable disease trajectories (**Fig. 50.1**), but using the 'Surprise Question' (**Box 50.3**) may help clinicians decide. This forms the basis of the UK's ***Gold Standards***

Framework tool that is commonly used to help tailor care to the right time and place.

What are the patient's needs, and what is the patient's understanding?

The causes of a patient's symptoms are often multifactorial, and a holistic assessment (**Box 50.4**) is central to optimum management. Assessing the patient's grasp of the disease, understanding their wishes, and acknowledging their concerns help the team plan and implement effective support. Validated questionnaires, such as the integrated Palliative care Outcome Scale (iPOS), have been developed and are routinely used to aid this.

ADVANCE CARE PLANNING: PLANNING FOR THE FUTURE

Throughout the course of illness, it is essential to give patients and families a chance to discuss their possible future options and wishes. Having the skills to support these conversations is everybody's responsibility. These conversations can be had at any point, but they should not be left to the last weeks and days of a patient's life: early discussion of difficult choices and management of uncertainty surrounding their condition(s) is helpful. These discussions are ideally held when the patient is relatively well and outside an acute episode of care. Discussions delayed until the crisis of acute admission may lead to acceptance of invasive and potentially non-beneficial treatment that is later regretted by the patient or their loved ones (see **Box 50.2**).

One in three adults admitted to hospital and 80% of care home residents in the UK are in their last year of life. Talking about dying is not easy, but it allows for future care planning, which can improve patients' quality of life, reduce burdensome treatments at the end of life, and reduce emergency hospital admissions. If a patient is anticipated to lose capacity or the ability to communicate, healthcare professionals must be proactive in initiating discussions.

The content of the conversation may cover ways that patients can plan their care and support in advance, perhaps by recording advance statements, decisions to refuse specific treatments, or assigning lasting power of attorney to individuals important to them who could make decisions on their behalf (see Chapter 3 for more details).

Box 50.3 The 'Surprise Question'

Would you be surprised if this patient died within the next 12 months?

The Gold Standards Framework. https://www.goldstandardsframework.org.uk.

Difficult conversations

Finding a quiet place and allocating plenty of time for the conversation are necessary first steps. It is important to note that conversations may need to take place over several consultations and may not reach a firm conclusion. This is especially the case if there is uncertainty in the trajectory of the medical condition(s) and outcome of current treatments. Honesty and sensitivity are key, and patients generally appreciate it if there is no firm or 'correct' answer to a question as long as it is accompanied by a careful explanation. Before sharing information, it is important to check the patient's understanding of their disease(s), to clarify how much information they would like to receive, and to check if they would like to have a family member or friend present. Patients have differing needs for information and deal with 'bad news' in different ways. A sensitive approach, respecting individual requirements,

Box 50.4 Domains of a holistic assessment[a]

Mnemonic	Domain	Things to consider
P	Physical	Symptom assessment: may involve specific symptom assessment tools or assessment by other professionals (e.g., physiotherapists, specialist clinicians)
E	Emotional	Psychological assessment, including understanding patient expectations: may involve psychological assessment tools (e.g., distress thermometer) and onward referral for appropriate support
P	Personal	Cultural, ethnic, spiritual, and religious needs
S	Social support	Work and finance, family and close relationships, recreational activities: may benefit from social services referral or occupational therapy advice
I	Information and communication	Patient understanding of the plan, multidisciplinary team outcomes communicated, identification of key workers
C	Control and autonomy	Mental capacity to make decisions, patient choice regarding treatment options and plans, preferred place of care and death
O	Out of hours	Advance care planning, awareness of where to access services out of hours
L	Living with your illness	Rehabilitation, management of activities of daily living, future expectations, and end-of-life care planning
A	Aftercare	Funeral arrangements, bereavement needs, future support for the family

[a]In each domain, the tool identifies potential anticipated patient issues and concerns, cue questions to ask patients and carers, and resources for professionals to signpost to.
Adapted from the Gold Standards Framework. https://www.goldstandardsframework.org.uk.

is crucial. Language must be clear and euphemisms avoided, both in discussion and subsequent documentation of the conversation. The importance of silence should not be underestimated; it can be hugely comforting, and pauses can invite a response from the patient. Involving other relevant health professionals in the conversation may also be useful and appropriate.

Do not attempt cardiopulmonary resuscitation orders and treatment escalation plans

Part of talking about the future may include discussion about resuscitation and appropriate escalation plans. The resuscitation status of every patient should be discussed by senior doctors at the time of admission to hospital or when deterioration is noted that is not thought to be reversible. This decision must be clearly documented in the notes. Treatment escalation plans and 'ceilings of care' determining what treatments are likely to be beneficial or futile should be discussed at the same time in line with patient wishes.

Deciding a person's resuscitation status is a careful balance of risk versus benefit. Co-morbidities, pre-morbid quality of life, and the patient's wishes should be taken into account. Although Do Not Attempt Cardiopulmonary Resuscitation (DNACPR) orders and treatment escalation plans are medical treatment decisions, the patient and family must be involved in discussions unless they have specifically requested not to be, and the reasoning behind decisions should be explained. In the UK in 2014, the Court of Appeal ruled in the case of *Tracey v Cambridge University Hospitals NHS Foundation Trust* that a failure to discuss the making of a DNACPR order with a patient who had expressed a wish to be involved in decision-making around their care constitutes a breach of their human rights. Concern regarding possible patient distress is no justification for not discussing resuscitation, though it will guide the way the subject is considered with the patient. Only if it is thought that there will be significant psychological or physical harm resulting from the discussion can it be postponed. If the patient requests that cardiopulmonary resuscitation is not performed in the event of cardiopulmonary arrest, this should be respected.

Remember that a decision not to resuscitate a patient is *not* the same as a decision to withhold other treatment. Patients may still benefit from active treatments such as antibiotics, fluids, endoscopy, and even surgery. Management should remain positive and proactive, allowing the patient to die free of distress and with dignity.

ReSPECT (Recommended Summary Plan for Emergency Care and Treatment) is an initiative implemented in many hospitals and communities. It is a process that creates and records personalized recommendations for a person's clinical care in a future emergency when they are unable to make or express choices. It is useful in those with complex health needs, integrating discussion surrounding DNACPR and treatment escalation.

Box 50.5 Examples of reversible problems that can be treated to improve symptoms

Patient 1
A patient with metastatic prostate cancer has known spinal metastases at multiple levels. He complains of worsening back pain and leg weakness. This warrants urgent magnetic resonance imaging to rule out metastatic spinal cord compression, which could be treated with steroids and radiotherapy, leading to an improvement in his symptoms and functioning.

Patient 2
A woman with metastatic breast cancer describes a history of general deterioration, nausea, abdominal pain, constipation, and low mood. This warrants a set of blood tests that may reveal hypercalcaemia, which can improve with intravenous fluids and bisphosphonates; there may even be resolution of symptoms.

Patient 3
A woman with metastatic ovarian cancer has a similar history to patient 2. A thorough clinical examination may reveal tense ascites as a cause of abdominal discomfort, nausea, and constipation, which could be alleviated by paracentesis.

SYMPTOM CONTROL

Good palliative care integrates non-pharmacological approaches, such as anxiety management and rehabilitation, with pharmacological control of symptoms. Medications should be rationalized to reduce polypharmacy. A key, and usually initial, component of palliative care is actively identifying and managing reversible problems that could be contributing to inadequate symptom control (**Box 50.5**). Symptom management runs in parallel with these active treatments.

Pain

The International Association for the Study of Pain defines pain as 'an unpleasant sensory and emotional experience associated with or resembling that associated with actual or potential tissue damage'. It may be classified as 'acute pain' (see Chapter 28) and 'chronic pain'. Chronic pain is 'pain that persists or recurs for longer than 3 months' (ICD-11). It may be **further** subclassified as 'chronic secondary pain', when it is caused by an underlying disease, or 'chronic primary pain', when there is no identified underlying disease. It is extremely important to make this distinction because the management of 'chronic secondary pain' caused by cancer or advanced disease differs significantly from the management of 'chronic primary pain', which requires a distinct approach, focusing on a range of multidisciplinary non-pharmacological therapies. Importantly, opioids and other commonly used adjuvant analgesic agents are not recommended for use in patients with 'chronic primary pain'.

Chronic secondary pain is the subcategory of pain usually seen in the palliative care setting, where it is most commonly caused by cancer, though it can also have non-cancer causes. At least two-thirds of people with cancer have significant pain, and it is the most feared symptom at the end of life. It may be caused by the cancer directly (e.g., pressure on surrounding structures) or indirectly (e.g., caused by weight loss or pressure ulcers) and can result from co-morbidity such as arthritis. Within each of these aetiologies, pain mechanisms may be nociceptive (visceral or somatic) or neuropathic (see Chapter 28), generating different pain characteristics, which can require different treatment approaches. Various scales can be used to assess a patient's pain (**Fig. 50.2**). Emotional and spiritual distress may be expressed as and can exacerbate physical pain.

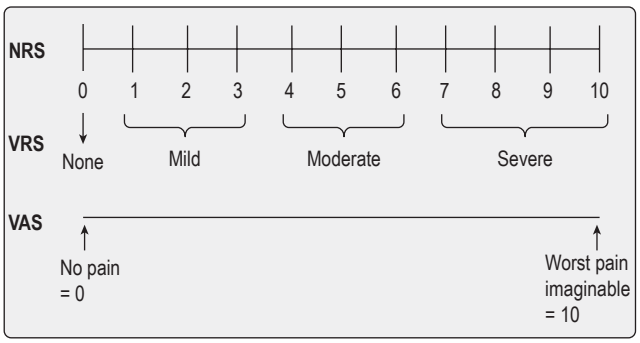

Fig. 50.2 Commonly used one-dimensional scales for pain assessment: an 11-point numerical rating scale (NRS), visual analogue scale (VAS, which can be 0–10 or 0–100), and verbal rating scale (VRS). *(Adapted from Breivik H, Borchgrevink PC, Allen SM et al. Assessment of pain.* Br J Anaesthesia *2008; 101:17–24.)*

The term 'total pain' encompasses a variety of influences that contribute to pain:

- ***Biological:*** the disease itself, disease-modifying therapy (drugs, surgery, radiotherapy)
- ***Social:*** family distress, loss of independence, financial problems
- ***Psychological:*** fear of dying, of pain, or of being in hospital; anger at dying or at the process of diagnosis and perceived delays, with anxiety or depression stemming from all of these
- ***Spiritual:*** fear of death, questions about life's meaning, guilt, asking 'why me'?

Pain and the use of opioids

Opioids are effective for the control of acute pain (see Chapter 28) and in the management of severe chronic cancer pain. They may also have a role in the short-term management of chronic non-cancer pain in the last weeks of life. In general, they should not be used outside of these contexts and are likely to cause more harm than benefit if used long-term in chronic non-cancer pain. This is because they have limited efficacy in chronic non-cancer pain, and there is a high risk of developing tolerance, addiction, and long-term side-effects. This cannot be overemphasized in the wake of the recent opioid epidemic in the USA, where there were 6000 deaths from opioid overdose in 2018.

Cancer pain and the World Health Organization analgesic ladder

Most cancer pain can be managed with oral or commonly used transdermal preparations. The World Health Organization (WHO) cancer pain relief ladder guides the choice of analgesic according to pain *severity* (Fig. 50.3).

If *regular* use of optimum dosing (e.g., paracetamol 1 g four times daily) for step 1 does not control pain, then an analgesic from the next step of the ladder is prescribed. Because pain has different physical aetiologies, an adjuvant analgesic may be needed, for example, a gabapentinoid for neuropathic pain (see Box 50.9).

Strong opioid drugs

Dose titration and route

Morphine is the drug of choice and in most circumstances should be given regularly by mouth. The dose should be tailored to the individual's needs by allowing 'as required' doses up to every 1 to 2 hours. If a patient has needed further doses in addition to the regular daily dose *and* they have been effective, then the amount in the additional doses can be added to the following day's regular dose. This up-titration can be repeated until the daily requirement becomes stable (Box 50.6). When a stable daily dose requirement has been established, the morphine can be changed to a modified-release preparation and the patient given 'as required' doses of immediate-release morphine, which are usually one-sixth of their total daily morphine dose.

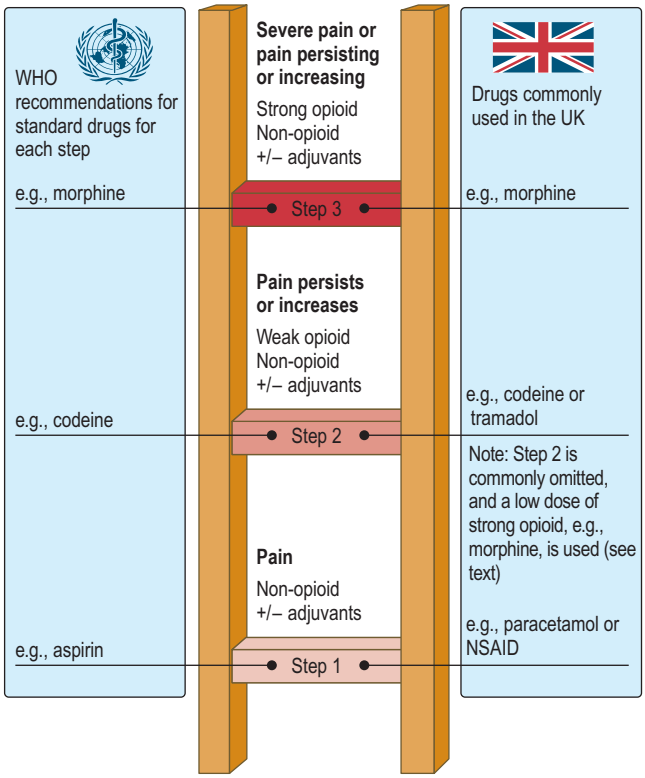

Fig. 50.3 The World Health Organization (WHO) analgesic ladder for cancer and other chronic pain. Adjuvant drugs are listed in Box 50.9. *NSAID,* Non-steroidal anti-inflammatory drug.

The starting dose of morphine is usually 2.5 to 5 mg every 4 hours, depending on patient size, renal function, and whether a weak opioid is already being given. If an individual is already on step 2 of the WHO ladder, explaining conversions between medications can be helpful to gain patient confidence. For example, maximum-dose codeine (60 mg four times daily) is equivalent to a total of 24 mg morphine per day (Box 50.7). If there is renal dysfunction, morphine should be used in low doses or oxycodone considered in mild to moderate renal dysfunction (hepatic metabolism). However, if renal dysfunction is significant (estimated glomerular filtration rate <30 mL/min), an alternative opioid, such as alfentanil, should be considered because of the risk of metabolite accumulation. If there is concurrent significant hepatic dysfunction, oxycodone should be avoided. Dosing is not an exact science in palliative care; advice can be sought from the SPC team.

Strong opioids come in transdermal preparations, such as buprenorphine or fentanyl *patches* (Box 50.8). These are useful in patients with stable pain. Serum levels do not change quickly with transdermal patches; they can therefore be hazardous if the pain stimulus is removed and are cumbersome to titrate in patients with escalating or unstable pain. The patient should be reassessed and reasons for the escalation in pain sought. Be aware that transdermal

Box 50.6 Opioid titration examples

Scenario 1

A patient regularly takes 20 mg of morphine sulphate immediate release every 4 hours. What long-acting preparation could they be started on?

20 mg every 4 hours =120 mg morphine per day

= 60 mg twice daily of a 12-h morphine sulphate modified-release (MR) preparation

Scenario 2

The same patient has started morphine sulphate MR 60 mg twice a day with 'as required' immediate-release morphine 20 mg every 1–2 hours. A few months later, their pain escalates because of disease progression, and they require an additional four doses per day of immediate-release morphine. What should their long-acting morphine be increased to?

20 mg × 4 = additional 80 mg morphine per day

Total daily morphine dose including morphine MR = 200 mg

= 100 mg twice daily of a 12-h morphine sulphate MR

Top tip: Always thoroughly check dose conversions. Dosing is not an exact science; discuss with specialist palliative care if unsure.

Box 50.7 Opioid equivalences

Drug and route	Dose (mg)	Potency to oral morphine equivalent
Oral codeine	100	1 : 10
Subcutaneous diamorphine	3	3 : 1
Oral morphine	10	1 : 1
Subcutaneous morphine	5	2 : 1
Oral oxycodone	6.6	1.5–2 : 1
Subcutaneous oxycodone	3.3	3 : 1
Oral tramadol	100	1 : 10
Subcutaneous alfentanil	0.3	30 : 1

Adapted from National Institute for Health and Care Excellence. https://bnf.nice.org.uk/medicines-guidance/prescribing-in-palliative-care/.

patches may be administered every 72 hours or weekly, depending on the dose and brand; always check this when prescribing.

If a patient is unable to take oral medication because of weakness, swallowing difficulties, or nausea and vomiting, opioids can be given parenterally. This may be via continuous subcutaneous infusion, whereby the opioid dose is administered continuously via a syringe pump over the course of 24 hours.

Doctors and patients may have worries, such as the fear of addiction, which mean that adequate doses of opioids are not prescribed or taken. Iatrogenic addiction in the context of cancer pain is very rare (<0.01% risk), and the adverse effects and morbidity from uncontrolled pain are much higher. Patients and carers should be reassured about their medications and the rationales for their use, and it is good practice to provide written information regarding opioids. Regular review is necessary to achieve optimal pain control, including regular assessment to distinguish pain severity from distress caused by pain.

Side-effects

The most common side-effects of strong opioids are:

- ***Nausea and vomiting*.** These can be managed with use of antiemetics.

Box 50.8 Buprenorphine and fentanyl patches

Oral morphine equivalent/day	Patch
12 mg	Buprenorphine 5 μg/h
24 mg	Buprenorphine 10 μg/h
36 mg	Buprenorphine 15 μg/h
30 mg	Fentanyl 12 μg/h
60 mg	Fentanyl 25 μg/h
120 mg	Fentanyl 50 μg/h
180 mg	Fentanyl 75 μg/h

Adapted from National Institute for Health and Care Excellence. https://bnf.nice.org.uk/medicines-guidance/prescribing-in-palliative-care/.

- ***Constipation*.** This is common and should be anticipated; best practice guidelines advocate that *all* opioids should be co-prescribed with laxatives. Laxatives for opioid-induced constipation, peripheral mu-receptor opioid antagonists, can be used if response to other laxatives is inadequate.

  If side-effects are intractable, a change of opioid is often helpful. Some patients find transdermal preparations of opioids less constipating.

Toxicity

Confusion, persistent and undue drowsiness, myoclonus, nightmares, and hallucinations indicate opioid toxicity. This may follow rapid dose escalation and respond to dose reduction and slower retitration. It may indicate pain that is poorly responsive to opioids and the need for adjuvant analgesics. Patients should be assessed for reversible factors contributing to reduced tolerance of opioids, such as sepsis. Importantly, respiratory depression (respiratory rate <8 breaths/min) is a late sign and indicates significant toxicity that needs management as an emergency. Consider stopping any long-acting opioid preparation and administering naloxone if respiratory depression is severe. Dependency on opioids used in the longer term does occur and means that, unless absolutely necessary, sudden reversal (with naloxone) or withdrawal of opioids is not advisable.
Antipsychotics such as haloperidol may help settle the patient's distress while waiting for toxicity to resolve. Some individuals tolerate an alternative opioid such as oxycodone better or an alternative route such as subcutaneous injection.

Adjuvants and alternatives

Box 50.9 outlines the most commonly used adjuvant analgesics. Neuropathic pain often responds well to adjuvants in the antiepileptic or tricyclic antidepressant class. Other treatments, such as radio- or chemotherapy, interventional pain strategies (e.g., nerve blocks, epidurals), and transcutaneous electrical nerve stimulation, may be useful in selected patients. MDT working is essential to manage patients' pain optimally, and joint working between palliative care and pain teams, sometimes via specialist pain clinics, helps to achieve this.

Additionally, to improve their symptoms and wellbeing, patients facing incurable illness are increasingly turning to complementary therapies to serve as alternatives to prescribed medical treatments. These include acupuncture and herbal and massage therapies. Although there may not be a strong evidence base to support some of these, this does not mean that they do not have a beneficial contribution to make to the holistic care of patients. For example, research into cannabinoids suggests they may be beneficial in a

Box 50.9 Commonly used adjuvant analgesics

Drugs	Indication
NSAIDs, e.g., naproxen (250–500 mg twice daily)	Bone pain, inflammatory pain
Antiepileptics, e.g., gabapentin (300–3600 mg/day in divided doses) or pregabalin (50–600 mg/day in divided doses)	Neuropathic pain
TCAs, e.g., amitriptyline (10–75 mg/day)	Neuropathic pain
Bisphosphonates, e.g., zoledronic acid, denosumab (a RANKL inhibitor)	Metastatic bone disease
Dexamethasone	Neuropathic pain, inflammatory pain (e.g., liver capsule pain), headache from cerebral oedema caused by brain metastases

NSAID, Non-steroidal anti-inflammatory drug; *RANKL,* receptor activator of nuclear factor kappa-B ligand; *TCA,* tricyclic antidepressant.

variety of conditions; can modulate symptoms, including pain, nausea and vomiting, and sleep disorders; and have a good risk-to-benefit profile. Certain countries have legalized cannabis to allow its prescription. As ever, more research is needed into these compounds and therapies to demonstrate their effectiveness clearly, and the picture will evolve over time.

Gastrointestinal symptoms

Nausea and vomiting

These symptoms are common and may have numerous causes: both physical and psychological factors can contribute. Careful choice of antiemetic targeted toward the underlying cause of the nausea or vomiting is essential.

Nausea and vomiting are associated with:

- ***Chemotherapy*.** Certain agents confer a high risk of nausea and vomiting. A 5-hydroxytryptamine (5-HT_3) antagonist, such as ondansetron 4–8 mg up to three times daily, may help during the acute emetic stimulus of chemotherapy administration. Aprepitant, a neurokinin-1 antagonist, can also be given.
- ***Chemical causes***, e.g., hypercalcaemia, hepatic failure, uraemia or drugs. Haloperidol 0.5–1.5 mg as required every 4 hours, up to a maximum of 5 mg/day, is the first choice.
- ***Gastric stasis and distension*.** Metoclopramide 10 mg three times daily is a prokinetic and promotes gastric emptying. The prokinetic effects can also ameliorate constipation.
- ***Raised intracranial pressure***, e.g., brain tumour. Cyclizine 50 mg three times daily is most useful.
- ***Mechanical causes of vomiting*.** It may be necessary to start antiemetic therapy parenterally by continuous subcutaneous infusion to gain control. If the patient has gastrointestinal (GI) obstruction or poor oral or GI absorption, this route may need to be continued. Haloperidol is the antiemetic of choice in patients with complete malignant bowel obstruction. Levomepromazine is a second-line antiemetic if initial therapy is not successful; 6.25 mg as required, up to a maximum of 25 mg/day, is recommended. Other medications to aid nausea and vomiting include corticosteroids, particularly in the case of bowel obstruction, in which reducing tumour oedema may alleviate the obstruction and improve symptoms.

Constipation

This is common, occurring in up to 45% of hospice patients and 90% of patients taking opioids. It is best managed with a combination of pharmacological and non-pharmacological strategies. Non-pharmacological measures can include maintaining hydration, mobility, dietary advice, optimal positioning, privacy, and comfort to aid relaxation when trying to open the bowels.

Pharmacological strategies including laxatives (**Box 50.10**) are targeted to the cause of the constipation, and a careful history is required. Often, patients with opioid-induced constipation respond to a combination of stool softener and stimulant (e.g., docusate and senna). Doses require individual titration. Some patients may need suppositories or enemas. Those with reduced sensation and mobility (e.g., caused by spinal cord compression) may require a bowel regimen of regular suppositories and maintenance of a relatively firm stool to facilitate best care. Many are likely to need to continue regular laxatives because they will develop troublesome constipation again on cessation of these medications.

Bowel obstruction

This is common in advanced cancer (3%–15%), especially gynaecological (<42%) and colorectal (<24%) cancers. It is caused by mechanical obstruction of the bowel lumen or peristaltic failure caused by infiltration of the nerves. Presenting symptoms include pain, vomiting, colic, and constipation. It can be partial or complete, at single or multiple sites, and carries a poor prognosis. Management of bowel obstruction should be individualized, focussing on improving symptoms (which may involve medications) and interventions to decompress the upper GI tract (e.g., a large-bore nasogastric tube). Consideration should be paid to hydration and nutrition, including using artificial methods (e.g., intravenous fluid) when appropriate. The patient's prognosis, performance status, and further treatment options, among other things, should be taken into account.

Metoclopramide's prokinetic effect can be used in partial obstruction to encourage the bowels to function again. However, it should be avoided in complete obstruction when the bowel is physically blocked because it will worsen colic. In this situation, an antispasmodic, such as hyoscine butylbromide, is preferred, along with regular analgesia and an antiemetic such as haloperidol. A dose of 60–120 mg/24 hours subcutaneously is usually recommended, but much higher doses (<300 mg) may be needed because parenteral hyoscine butylbromide can be rapidly inactivated.

Octreotide (a somatostatin analogue) is used as second-line treatment in bowel obstruction to improve symptoms, which it does by reducing gut secretions and the volume of vomitus.

Physical measures, such as a defunctioning colostomy or a venting gastrostomy, may be helpful. Occasionally, a lower bowel obstruction is resolved with insertion of a stent or transrectal resection of tumour in selected individuals.

Box 50.10 Types of laxatives

Type	Name	Suggested dosage
Stimulant	Senna Bisacodyl	15–22.5 mg at night 5–10 mg
Softener	Docusate sodium	100 mg twice daily
Osmotic	Macrogol	1–3 sachets daily
Suppository: soft loading	Bisacodyl Phosphate enema	10 mg 1
Suppository: hard loading	Glycerol	1

In ***advanced disease***, when the obstruction is irreversible, patients should be encouraged to drink and take small amounts of a soft diet for comfort as they wish. With good mouth care (see later), the sensation of thirst can be managed, and parenteral fluids may not be needed. If oral food and fluids are taken, they can be introduced as a trial to improve symptoms and patients counselled about the benefits and risks, including their possible contribution to increased gut secretions and volume of vomitus; in this case, the fluids may be ceased.

Anorexia, weight loss, and malaise

These result from the cachexia syndrome of advanced disease and are poor prognostic factors. Although attention must be paid to nutrition, the syndrome is mediated through chronic stimulation of the acute phase response and tumour-secreted substances. Thus, calorie–protein support alone gives limited benefit; parenteral feeding has been shown to make no difference to patient survival and can lead to increased complications such as infections.

Management is generally supportive, and advice from dieticians may be helpful. Patients and their carers should be reassured that decreased appetite is to be expected, and advising 'little and often' and 'what you want, when you want' can be useful.

Corticosteroids are occasionally used as appetite stimulants. However, the weight gained is usually fluid retention, and muscle catabolism is accelerated, causing proximal myopathy. Any benefit in appetite stimulation tends to be short-lived, which must be explained clearly to patients and carers. Thus, use of corticosteroids should be limited to the short term and reviewed regularly.

Other interventions, such as a rehabilitative palliative care programme encompassing nutritional supplementation and exercise in advanced cancer, are being trialled.

Respiratory symptoms

Breathlessness

Chronic breathlessness (dyspnoea) is a common but frightening symptom of many advanced malignant and non-malignant diseases but often goes unrecognized and untreated. Its features have been described as 'breathlessness that persists despite optimal treatment of the underlying pathophysiology and that results in disability'. It is distressing for carers, who often feel helpless. Carer anxiety may exacerbate a patient's breathlessness, and it is therefore essential to involve them in treatment strategies and support them in their own right. Recent advances have helped to establish effective treatments to reduce the impact of breathlessness, but palliative care or specialist breathlessness services are often needed to provide optimal care.

The sensation of being breathless is generated in the central nervous system through the integration of peripheral and central signals by a complex network involving structures in the midbrain, higher cortical regions, and the limbic system (**Fig. 50.4**). Individual assessment is key, as is reversal of any contributory factors, such as optimizing treatment of underlying medical conditions, although in advanced disease, many of these are irreversible.

The first step in assessing breathlessness (**Box 50.11**) is to ask directly about it because many patients with severe breathlessness are not troubled at rest. Best practice in managing breathlessness rests on a complex intervention composed of a number of non-pharmacological and pharmacological approaches (**Boxes 50.11 and 50.12**). Careful assessment of the patient—for example, using the 'Breathing, Thinking, Functioning' clinical model (**Fig. 50.5**)—guides the choice of initial non-pharmacological approach (see **Box 50.12**). Pharmacological measures should be reserved for those with severe breathlessness and end-stage progressive disease. Morphine is the drug that has been most studied; other treatments, such as mirtazapine, are being investigated. Benzodiazepines should not be used routinely to manage breathlessness because there is no evidence of their benefit; they may, however, be prescribed in those at the end of life or when there is a limited prognosis. Oxygen is not helpful in relieving the sensation of breathlessness but may be essential in managing the underlying medical condition and improving exercise capacity when hypoxia is present. There are specific assessment tools, such as the Dyspnoea-12 and numerical rating scales, which can help initial management and subsequent monitoring of treatment strategies.

Cough

Cough is an unpleasant symptom that can affect the lives of both the patient and carer. Drug approaches (e.g., opioids or gabapentin) have limited impact but may be needed. Non-pharmacological interventions can include breathing exercises, cough suppression techniques, education, and counselling to help patients gain greater control of their cough.

Secretions

Excessive respiratory secretions at the end of life can be treated with ***glycopyrronium*** 200 to 400 μg every 2 to 4 hours (maximum, 1.2–2.4 mg per 24 hours) or ***hyoscine butylbromide*** 20 mg every 1 to 2 hours (maximum, 120 mg per 24 hours). These can be given by continuous subcutaneous infusion. Both give a dry mouth, and care must be taken not to dry secretions significantly in a patient who is still able to cough well because they may become too sticky to expectorate, leading to significant discomfort.

Other physical symptoms

People with cancer may develop other physical symptoms caused by the tumour directly (e.g., hemiplegia caused by brain metastases) or indirectly (e.g., bleeding or venous thromboembolism caused by coagulopathy). Symptoms may also result from treatment, such as lymphoedema in breast cancer or heart failure secondary to chemotherapy. The principles of holistic assessment, treatment of reversible factors, and appropriate involvement of the multiprofessional team should be applied.

Fatigue

Fatigue is a significant and debilitating problem for palliative patients. It has physical, cognitive, and affective components; unlike normal tiredness, it is not relieved by usual sleep or rest. An assessment for reversible contributory factors, such as anaemia, hypokalaemia, or over-sedation caused by poorly optimized medication, should be undertaken. Management strategies are mainly non-pharmacological: relaxation, sleep hygiene, resting 'proactively' rather than collapsing when exhausted, planning, pacing and prioritizing daily activities, and use of aids and adaptations.

Mouth symptoms

Dry mouth is common in advanced disease and may be a result of medications used to treat other symptoms, such as pain or nausea. It can be managed with artificial saliva substitutes and good mouth care to keep mucous membranes moist. Careful inspection of the mouth identifies any reversible causes contributing to oral discomfort (e.g., candidiasis, which is common in immunocompromised patients but treatable with antifungals). As patients lose weight, dentures may become ill-fitting, causing ulceration to the gums. This can be managed with analgesia, denture cushions, and topical treatments to numb the sore parts of the mouth.

Patients receiving courses of radiotherapy for haematological disorders or head and neck cancers can develop painful mucositis (pain and inflammation of the mucous membrane, which may present as painful mouth ulceration affecting any or all intraoral surfaces). This is a common reason for referral to hospital palliative care teams even when the treatment aims are curative. Management is with meticulous mouth care, including mouthwashes to maintain oral hygiene and to provide pain relief. Some patients with severe mucositis require enteral feeding and management of their pain with continuous subcutaneous infusion until it settles.

Loss of function, disability, and rehabilitation

Some of the most pressing concerns include increasing physical frailty, loss of independence, and a perception of being a burden on others. Evidence suggests that functional problems are not routinely assessed and not as well managed as other symptoms.

Palliative rehabilitation in long-term incurable illness aims to enable patients to achieve their functional and social priorities in the context of physical decline, as well as to adjust to changes in their physical ability, role, and sense of self. Patients and carers often appreciate a focus on what is still possible rather than what is lost.

Rehabilitation may include exercise to address reversible physical decline and fatigue, which may be especially evident after an exacerbation or relapse. Understandably, sustaining motivation to maintain physical activity can be difficult. Setting small and achievable goals may help maintain motivation and promote self-efficacy. Involving carers in rehabilitation sessions may reduce over-protectiveness.

Rehabilitation includes supporting adaptation by encouraging patients to do things differently, including the use of mobility aids or equipment. Aids and adaptations may be seen as symbols of 'giving up' by some patients. They need to be presented in a positive light as 'enablers' that assist people to achieve their goals and that may also reduce carer burden. Psychological support to accept change may be required, such as acceptance and commitment therapy.

Hospices take a 'rehabilitative approach', with most having physical and occupational therapists and exercise equipment.

Box 50.11 Assessment and management of breathlessness

Step 1

- Ask directly about breathlessness: 'Are you troubled by breathlessness'?
- Ask about other respiratory symptoms: 'Are you troubled by a cough'?
- Ask about fatigue: 'Are you troubled by fatigue or extreme tiredness that does not go away with rest or sleep'?
- Take a full history of each symptom; aggravating and easing factors; and 24-hour pattern, including nocturnal symptoms.
- Ask about the carer's views, thoughts, and feelings relating to the patient's breathlessness.
- Find out what happens when the patient has an 'attack' of breathlessness, including related emotions such as panic, anxiety, or frustration and what helps and what doesn't help.

Step 2

- Assess which component of breathlessness is the most troubling or disabling for the patient: the breathlessness itself ('Breathing'), deconditioning, or difficulty managing activities of daily living ('Functioning'), or the patient's thoughts and feelings about being breathless ('Thinking').
- Choose an initial treatment based on that.

Initial treatment

All patients

- Handheld fan
- Education about breathlessness and its causes

Breathing cycle

- Breathing techniques and breathing retraining from physiotherapist
- Positioning

Functioning cycle

- Pulmonary rehabilitation
- Individual exercise programme from palliative care or community therapy or groups
- Fatigue management advice from occupational therapist
- Aids and adaptations for mobility and activities of daily living

Thinking cycle (both patient and carer)

- Address misconceptions
- Relaxation exercises and mindfulness
- Specialist psychological help

Pharmacological treatment for severe breathlessness or at end of life (seek specialist palliative care advice)

- Use oral or parenteral opioids.
- Consider mirtazapine.
- Consider benzodiazepines.
- Dying patients with breathlessness need subcutaneous opioids and midazolam.

Referral to hospice day therapy (sometimes known as a Living Well service), pulmonary rehabilitation, community exercise groups, or community physical or occupational therapy may be appropriate. Some group programmes may have the option of being delivered virtually for those who find it difficult to leave the home. However, patients must have an active desire to engage in rehabilitation. Some may see therapy as an additional unwanted drain on their time, and their wishes should be ascertained, as well as discussing the merits and disadvantages of engaging.

Functional problems and fatigue should not be seen as inevitable, unavoidable, and insoluble. All healthcare professionals have a role in promoting the benefits of patients keeping as active as they are able to help maintain their strength and ability in long-term incurable illness. Barriers to this, including misconceptions about exercise and activity being harmful, should be discussed and addressed, as well as considering psychological barriers such as anxiety and depression. Throughout illness, there is a need to take into account changing performance status, as well as changes in goals and priorities.

Poor sleep

This is common, and patients may have longstanding difficulties with sleep that worsen during their illness. Discomfort in bed, leading to worsening symptoms, and psychological concerns surrounding their condition and the future, can compound the problem. Eliciting and listening to patients' concerns, explaining the concept of sleep hygiene, and discouraging lengthy day-time naps can be helpful, as well as therapy team review of the bed and provision of equipment that will optimize symptom management. Pharmacological measures (e.g., hypnotics such as zopiclone or melatonin) should be used only temporarily and are not long-term solutions to sleep problems. Complementary therapies are available in hospices and some hospitals and may aid sleep.

Psychosocial issues

Depression is a common feature of life-limiting and disabling illness and is often missed or dismissed as 'understandable'. However, it may respond to antidepressant drugs or to non-pharmacological measures such as cognitive-behavioural therapy, increased social support, and support for family relationships. Antidepressants can take several weeks to take effect, and a patient's prognosis must therefore be considered if they are initiated. The 'side-effects' of certain antidepressant medications are sometimes used to benefit patients. For example, mirtazapine can improve sleep, anxiety, appetite, and low mood but may also be helpful to treat pain and nausea; evidence is also emerging for its benefits in gastroparesis. Such interventions can make a big difference to the patient's quality of life and ability to manage their situation.

PALLIATIVE CARE IN NON-MALIGNANT DISEASE

Heart failure

There are special considerations with respect to cardiac medication in advanced disease:

- ***Drugs.*** Many commonly used palliative care medications can prolong the QT interval and should be used with caution in patients with heart failure; they include amitriptyline and many antiemetics. Others may precipitate worsening symptoms; for example, non-steroidal anti-inflammatory drugs (NSAIDs) may exacerbate fluid retention. However, use of certain medications that can be harmful in the long term may become appropriate when the patient is dying, and the risks and benefits are weighed up and discussed with the patient and family.
- ***Sudden death.*** This is more common than in patients with malignancy. There are increasing numbers of patients with implanted defibrillators because the indications for them has expanded. If present, the device should be reprogrammed to pacemaker mode in people with advanced disease. Implanted

Box 50.12 Key non-pharmacological interventions for breathlessness

Intervention	Putative mechanism of action	Most useful
Facial cooling with a handheld fan	Cools area served by second and third branches of trigeminal nerve	For reducing length of episodes of SOB on exertion or at rest
	Reduces temperature of air flowing over nasal receptors, altering signal to brainstem respiratory complex	For giving patient and carer confidence by having an intervention they can use Use and evidence base need to be explained
Breathing techniques (e.g., pursed-lip breathing, diaphragmatic breathing)	Improves mechanical effectiveness of respiratory system	Any breathlessness caused by chronic pathology
Breathing pattern retraining	Improves mechanical efficiency of breathing pattern	When breathlessness is disproportionate to disease severity because of breathing pattern disorder
Walking aids	Improves the mechanical effectiveness of respiratory system through forward lean and upper limb positioning	For breathlessness during walking; four-wheeled walkers may also provide a portable seat to rest
Exercise	Stops spiral of disability developing	In patients who are still quite mobile to maintain independence and to maintain function and comfort in those who are less mobile
	Changes muscle structure: less lactic acid produced	Lessening or deferring symptoms by reducing deconditioning
Pacing (finding a balance between activity and rest, prioritizing daily activities)	Avoids over-exertion, which can lead to exhaustion, inactivity, and subsequent deconditioning	In patients who are able and willing to modify daily routines
Anxiety reduction, e.g., CBT (needs a skilled clinician to administer) or simple relaxation therapy	Works on central perception of breathlessness, reducing the impact	In people with higher levels of anxiety at baseline (i.e., when first seen)
	Interrupts the panic–anxiety cycle	In patients willing to persevere with learning a new skill
Carer support	Reduces carer anxiety and distress, which are part of 'total' anxiety–panic cycle	When the carer is isolated or under extra pressures (e.g., looking after an older adult parent, going through divorce)

CBT, Cognitive-behavioural therapy; *SOB*, shortness of breath (breathlessness).

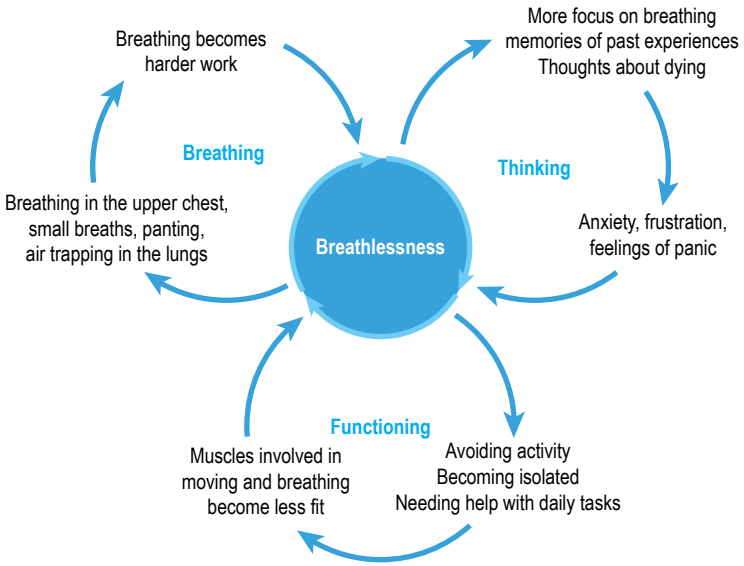

Fig. 50.5 The Breathing, Thinking, Functioning clinical model. *(From Spathis A, Booth S, Moffat C et al. The Breathing, Thinking, Functioning clinical model: a proposal to facilitate evidence-based breathlessness management in chronic respiratory disease.* NPJ Prim Care Respir Med *2017; 27:27. Reproduced with kind permission of Dr Anna Spathis, University of Cambridge and Cambridge University Hospitals NHS Foundation Trust.)*

defibrillators have not been shown to improve survival in patients with severe heart failure, and it could be distressing for patient, family, and staff if the defibrillator discharges as the patient is dying.

- ***Peripheral oedema.*** This can become a major problem and may be more resistant to diuretic therapy; careful balancing of medication regimens is required. Ultimately, symptom relief is prioritized over renal function.
- ***Cardiac medications.*** Drugs should be regularly rationalized to reduce polypharmacy. Those prescribed to reduce long-term secondary risk (e.g., statins) can be stopped, but those that help with symptom control (including angiotensin-converting enzyme

inhibitors, which also benefit survival) can be continued. Antihypertensives may have to be stopped if patients experience symptomatic hypotension.

Chronic respiratory disease

Chronic obstructive pulmonary disease (COPD) is the most common chronic respiratory disease. Patients with COPD may live increasingly restricted lives for years, rather than months or weeks, when they become breathless. This can lead to depression, isolation, frustration, and sometimes guilt associated with previous smoking habits. As with many chronic conditions, patients can reach older age before becoming very disabled, and an older spouse often has to carry significant physical carer burdens.

Palliative care breathlessness support services can be very helpful for patients unable to manage pulmonary rehabilitation or those with complex psychosocial needs that require individual assessment. Emergency admissions to hospital for non-medical reasons are often caused by severe anxiety (in the patient or carer), and the support offered by community palliative care services or breathlessness services working with respiratory teams can help reduce these.

In advanced disease, patients may use non-invasive ventilation (NIV) regularly at home. This may provide considerable symptom relief, but early discussions should take place regarding management of NIV during exacerbations of COPD and at the end of life.

Patients with interstitial lung diseases are often troubled by dry cough as well as breathlessness and may rapidly deteriorate at the end of life. Early palliative care should be considered to help with symptom control and anxiety. Ambulatory or long-term oxygen therapy may be necessary to manage severe hypoxaemia and maintain function in these patients.

Opioid titration in non-malignant respiratory disease

In non-malignant respiratory disease, opioids may be considered after non-pharmacological management of breathlessness has been maximized or if a patient is in the terminal phase. Individual assessment is essential. When starting opioids, a cautious approach with regular monitoring is recommended. Lower doses tend to be used (e.g., 1 mg of oral morphine twice a day and as required <10 mg/24 hours). Titration may need to follow a different pattern from that used in patients with malignant disease because many patients with cancer are already taking opioids for pain control before they develop breathlessness. Significant respiratory depression has not been noted in various trials of opioids in advanced respiratory disease, but other side-effects such as constipation should be anticipated.

COVID-19

The COVID-19 pandemic placed significant demands on health systems and led to a huge increase in deaths globally. There was a need to adapt quickly in response to service delivery challenges, and it became clear that skills for managing patients at the end of life were essential to all healthcare professionals. Palliative care services were a vital part of the pandemic response, not just in caring for patients but also in providing support to staff not used to dealing with high numbers of deaths. Medications used to manage symptoms, such as breathlessness, anxiety, and agitation, were largely similar to those used before COVID-19. However, communication with patients and families in the context of layers of personal protective equipment, lockdowns, social isolation, fear of contracting the virus, and restricted visiting was challenging. When difficult conversations would have previously taken place face to face with relatives present to support patients, telephone conversations and alternative methods, such as video calls, became the norm, and guidance for having compassionate phone conversations has been developed (Fig. 50.6). Finally, palliative care services continue to support patients in managing troubling symptoms such as chronic breathlessness caused by long COVID.

Renal disease

There is limited evidence that dialysis improves either quality or length of life in older patients or those with significant co-morbidity, so frailer patients with advanced chronic kidney disease (CKD) should be supported to receive maximum supportive care rather than renal replacement therapy if it is their choice. This may preserve independence and time spent at home and limit unnecessary hospital visits and procedures.

Palliative care in this context consists of managing the complications of advanced renal insufficiency (including nausea, itch, anaemia, oedema, and restless legs syndrome) while preserving residual renal function for as long as possible.

Prescribing is complicated, particularly in those receiving dialysis. Drugs are variably removed by dialysis and this must be taken into account; the renal drug database (see Further reading) is helpful. Specific considerations may be relevant for analgesia: NSAIDs may dramatically reduce residual renal function and should be avoided. Morphine is renally excreted and can accumulate in those with advanced CKD, so alternatives such as oxycodone or alfentanil may be preferred.

Withdrawal of dialysis

Withdrawal of dialysis is necessary when the effort of attendance becomes burdensome, there is little improvement in quality of life, and the impact of other co-morbidities becomes intrusive.

If there is no residual renal function (i.e., the patient is anuric), survival after withdrawal of dialysis may be only a few days, but if there is some residual function, survival may be several weeks. Patients and carers need to understand these differences to make informed choices.

https://renaldrugdatabase.com *Prescribing guide for renal practitioners*.

Liver disease

Symptom burden in patients with advanced liver disease is high, and mortality rates from chronic liver disease are rising. Decompensated cirrhosis requiring admission to hospital is associated with a 50% mortality rate at 12 months. Early discussion with patients and their families is important to understand their priorities, allow for advanced care planning, and optimise symptom management. Palliative care is useful in conjunction with active management of chronic liver disease to improve quality of life and can provide support when patients deteriorate. Additionally, patients with advanced liver disease and their carers often have significant psychological,

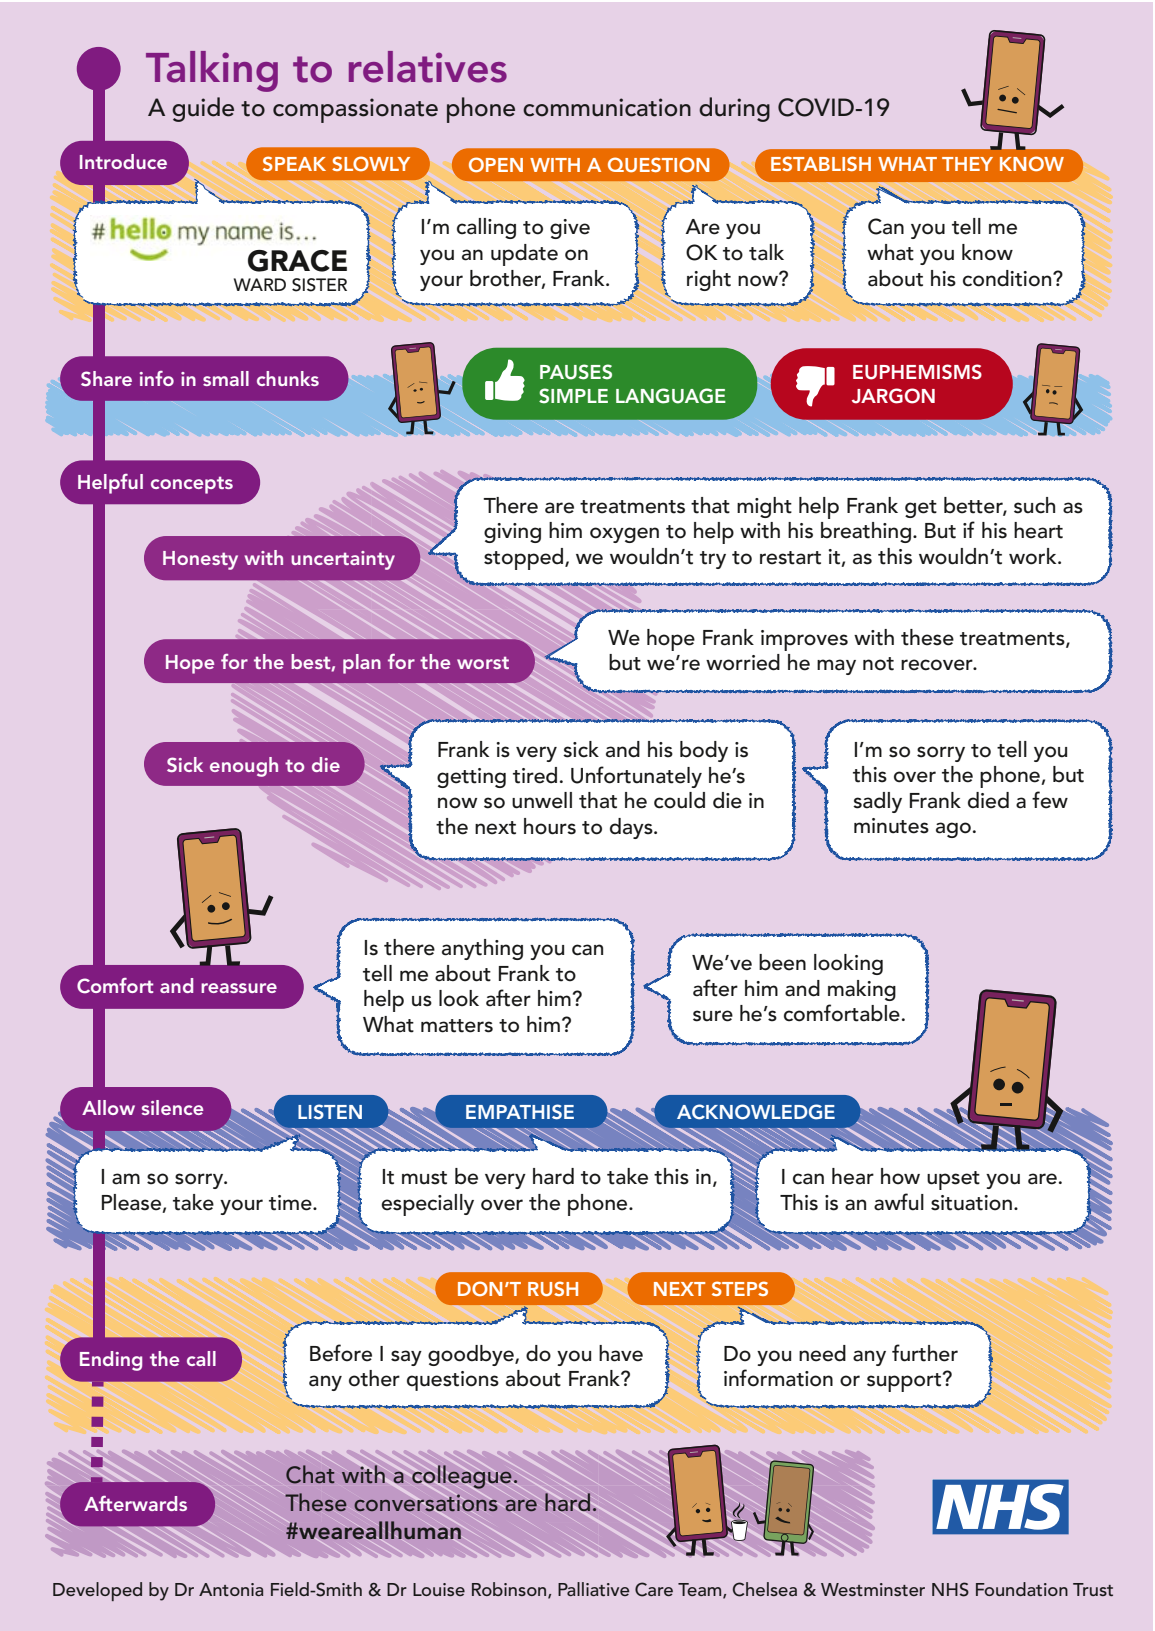

Fig. 50.6 Talking to relatives. A guide to compassionate phone communication during COVID-19.

social, and financial needs that need to be identified and supported as part of their holistic management.

Many commonly used medications are hepatotoxic, and there may be concurrent renal impairment. Therefore, drug choice and dosing must be considered carefully, with dose reductions often required. Regular monitoring is important, especially when titrating medications, and SPC advice should be sought.

Neurological disease

People with chronic degenerative neurological diseases have a considerable burden of palliative care needs, which may include:

- Difficulties in swallowing (e.g., in motor neurone disease and multiple sclerosis)
- Excessive difficulty clearing secretions and weak cough, leading to a fear of choking
- Progressive loss of physical function with associated pain and vulnerable pressure areas
- Loss of mental capacity, anxiety, and depression

The MDT is vital to the care of these patients and may provide physiotherapy and occupational therapy to manage loss of function, as well as speech and language therapy to optimize communication. Discussions regarding the patient's care preferences and practical wishes (e.g., writing a will) should take place early so that these can be supported if the patient is able to participate and when communication is easier.

Motor neurone disease

Motor neurone disease is usually rapidly progressive, often requiring hospice support. Percutaneous endoscopic gastrostomy feeding may be needed. Secretions, such as excess saliva, can be problematic, and treatment may entail careful titration of an anti-secretory medication such as hyoscine hydrobromide, which is available as a transdermal preparation. In addition, if ventilatory failure develops, NIV may be offered. Patients and their families need to understand:

- Why this treatment has been offered (to prevent hypercapnia and associated morning headache and confusion; it can confer a survival benefit)
- When this treatment will be withdrawn (when it is no longer helping to maintain or improve quality of life in the face of advancing disease; guidelines are widely available to help with these specialist discussions)

Patients need to have a clear understanding of what alternative symptom control will be offered at withdrawal.

Multiple sclerosis

Pain is often prominent because of muscle spasm. This is managed with regular physiotherapy; medications; and in severe cases, botulinum toxin, nerve blocks, or surgery. Patients may become too disabled to attend outpatient clinics, requiring a proactive palliative care approach to ensure they do not miss out on surveillance or support. Hospice day therapy services, rehabilitation, and support for the family can have a huge impact on quality of life. A person can live for many years disabled and symptomatic, and regular surveillance and support are essential.

Dementia

Dementia-related palliative care needs arise in the context of neurological conditions that:

- Tend to occur in older people (Alzheimer's disease and vascular dementia)
- Also affect younger people (e.g., Parkinson's disease, multiple sclerosis, Huntington's disease).

It is often difficult to ascertain whether these patients are in pain. A tool that assesses behavioural response to pain can be useful, such as the Abbey or Doloplus pain scale; these are based on vocalization (e.g., groaning), facial expression (e.g., frowning), and body language (fidgeting, rocking), behaviour (e.g., confusion, refusal to eat), and physical changes.

In England and Wales, Deprivation of Liberty Safeguards (DoLS) may need to be considered for people lacking mental capacity to consent to care arrangements in a care home or hospital to ensure any deprivation of liberty is necessary to keep them safe from harm and in the person's best interest.

Palliative care for young adults

Increasing numbers of children reach adulthood with life-threatening and life-limiting illness, such as cystic fibrosis and severe cerebral palsy. Palliative care supports these young adults and their families to achieve the best possible quality of life and care. The model of palliative care in young people is different to that in services built for older adults because many young people are supported for years by hospices; generally, they are cared for in their own homes, and the number of inpatient deaths is small compared with that in older adults. Many conditions are extremely rare and may be familial. As well as symptom management, hospices can provide short respite breaks for families caring for seriously ill young people. Ensuring a smooth transition from paediatric to adult palliative care services is an evolving area of development.

RECOGNIZING DYING

After reversible causes of deterioration have been excluded, the dying phase can be recognized from a combination of the features in **Box 50.13**. It is important to recognize this phase to enable the right support to be given to patients and families.

Care of the dying

Most people express a wish to die in their own homes, provided their symptoms are controlled and their families are supported. However, patients may die in any setting, and all healthcare professionals should therefore be proficient in end-of-life care.

Hospitals and communities have developed individualized or personalized care plans for the last days of life that help to prompt

Box 50.13 Recognizing dying

	Features
Weeks ↓ Days	Ongoing deterioration despite active treatments may indicate irreversibility
	Extreme tiredness or weakness, meaning help with all personal care is required
	Becoming bedbound
	Little interest in food or fluids, weight loss
	Sleeping for most of the day or being comatose
	Difficulty swallowing medications
	Skin changes caused by peripheral vasoconstriction
	Noisy breathing from secretions collecting in the throat or chest
	Changes in breathing pattern, e.g., irregular rate, apnoeic pauses

discussions surrounding the dying process and how physical, psychological, social, spiritual, and family concerns will be addressed (**Box 50.14**). The decision to provide support through a personalized care plan for the last days of life is reached by a multiprofessional team through careful assessment of the patient, exclusion of reversible causes of deterioration, and excellent communication with family.

Box 50.14 Components of personalized care plans for the last days of life

- Recognition of the dying phase and communication with patient and carers
- Initial assessment (which includes the patient's and carers' understanding, wishes, and psychological state)
- Resuscitation status and treatment escalation plans
- Discussion surrounding how symptoms will be managed
- Discussion about feeding and fluids
- Ongoing assessment and monitoring
- Support for the carers after the patient's death

Questions for this chapter can be found on Elsevier eBooks+.

A Chapter questions

Chapter 2: Clinical communication

1. Professional–patient communication is a form of institutional communication. What is the best way to prevent difficulties arising from institutional communication in healthcare settings?
   a. Confirm appointment times with the patient before attendance.
   b. Have a policy that all healthcare staff wear name badges.
   c. Make the healthcare setting look as welcoming as possible.
   d. Provide information to the patient about what is going to happen.
   e. Put up signs explaining the different uniforms that health professionals wear.
2. Medical empathy is an important feature of healthcare communication. What is the single best way to determine whether the health professional has been empathic in a consultation?
   a. Ask the patient if they felt understood.
   b. Confirm the professional's tone of voice became softer when discussing emotional content.
   c. Determine that there has been more eye contact time than non–eye contact time between the professional and patient during the consultation.
   d. Get the health professional to complete a reliable and valid empathy questionnaire.
   e. Note the presence of 'empathic touch'.
3. Patients need good-quality information to make decisions about their healthcare. What is the single best way for a health professional to share information?
   a. Ensure there are plenty of pauses between sentences.
   b. Give medical terms first and then the lay explanation.
   c. Go sufficiently slowly so that there is no need to repeat information.
   d. Provide information first and then ask for questions at the end.
   e. Start with what the patient already knows and build from there.
4. A patient attends their GP to discuss a new medical problem. What is the single best way for the health professional to gather information?
   a. Ask a series of specific questions using a clerking checklist.
   b. Have the patient explain their problem to the receptionist when booking the appointment.
   c. Review the patient's previous medical problems with the patient.
   d. Start with open questions.
   e. Use plenty of silence and eye contact.
5. Medical treatments may have adverse side-effects. Which is the single best way to communicate the likelihood that a treatment will have side-effects?
   a. Use commonly understood words (e.g., 'sometimes', 'usually', 'occasionally').
   b. Use natural frequencies (e.g., 4 of 10 people).
   c. Use percentages (e.g., 40% of people).
   d. Use reassuring language (e.g., 'hardly any side-effects').
   e. Use relative risks (e.g., half the side-effects of other treatments).

Chapter 3: Medical ethics

1. The GMC states that doctors have a 'duty of candour'. Which is the best definition of 'candour'?
   a. Speaking openly without trying to conceal information
   b. Voluntarily telling the truth, especially about difficult or embarrassing subjects
   c. Answering questions honestly, without hiding important information
   d. Raising concerns about patient safety even if it means disclosing information about the performance of colleagues
   e. Being honest and telling the truth, especially about difficult or embarrassing subjects, and speaking frankly without trying to conceal information or put a positive spin on it for our own advantage
2. The GMC blog called 'Making decisions together—the implications of the Montgomery judgement' gives advice on how to ensure clinical practice is compliant with the judgement: 'Discussing **risk** with a patient shouldn't be limited to a numbers game; it should be part of a dialogue. The key is to understand what matters—or is likely to matter—to the individual patient'. What term is used to discuss **risk** that matters or is likely to matter to a patient?
   a. Qualifying risk
   b. Material risk
   c. Legal risk
   d. Evidential risk
   e. Specific risk
3. If a case of clinical negligence occurs, which body administers the indemnity scheme for NHS Trusts in England?
   a. British Medical Association
   b. Department of Health
   c. NHS Resolution
   d. Clinical Negligence Indemnity Scheme
   e. Clinical Negligence Scheme for Trusts

Chapter 4: Evidence-based practice

1. Which of the following is a primary source of evidence?
   a. Medline
   b. Cochrane Database of Systematic Reviews
   c. Research papers
2. Which of the following is not a component in the PICO approach to developing structured clinical questions?
   a. Patient
   b. Comparison
   c. Observations
3. Which of these three study types is regarded as the strongest form of evidence in the 'hierarchy of evidence'?
   a. Randomized controlled trials
   b. Case series
   c. Observational studies

4. What is the goal of randomization in randomized controlled trials?
   a. To ensure that study groups are as similar as possible
   b. To ensure that allocation to the intervention or control arm is fair
   c. To ensure that similar numbers of participants are allocated to each study arm
5. Which of the following is not true of pragmatic randomized controlled trials?
   a. Outcome measures chosen represent the full range of health gains relevant to patients and clinicians.
   b. Pragmatic trials should represent the spectrum of patients to whom the treatment will be applied.
   c. Patients and clinicians must be blinded to the intervention that is being delivered.
6. Which of the following statements is true of cohort studies?
   a. No adjustments are made to participants' treatments or lifestyle.
   b. Cohort studies are always retrospective (i.e., looking back in time).
   c. Cohort studies cannot be used to study rare outcomes.
7. Which of the following statements is true of case-control studies?
   a. There is a high risk of recall bias affecting the results.
   b. Careful matching of cases and controls eliminates the risk of unknown confounding factors affecting the results.
   c. Information is usually gathered from cases and controls via focus groups.
8. Qualitative research methods (e.g., interviews and focus groups) can be useful to explore which of the following type of question?
   a. The number of patients living with a condition
   b. Whether a new intervention is acceptable to patients
   c. The likely length of time between diagnosis of a condition and death
9. In a study with high internal validity, which of the following is correct?
   a. The study findings are relevant to patients in other settings.
   b. The study is sufficiently free from bias.
   c. The study team is reputable.
10. In a study with high external validity, which of the following is correct?
    a. The study findings are relevant to patients in other settings.
    b. The study is sufficiently free from bias.
    c. The study team is reputable.
11. Which of the following is an example of potential information bias?
    a. Participants in a cohort study are all patients at a major teaching hospital.
    b. Participants in a case-control study are more likely to remember relevant past history if they have the disease of interest.
    c. The average age of participants in the intervention arm of a randomized controlled trial is 10 years younger than that in the control group.
12. What does an odds ratio describe?
    a. The odds of an event occurring in the intervention group divided by the odds in the control group
    b. The frequency with which an event occurs in the intervention group versus the control group
    c. The probability of seeing a result, such as the one obtained if the intervention had no real effect
13. What does a risk ratio describe?
    a. The number of people to whom the treatment would have to be given to see an effect
    b. The proportion of people in the treatment group who experience the outcome event divided by the same proportion in the control group
    c. The likelihood that an intervention will have no effect versus the control
14. In a study of all-cause mortality in patients who have received a novel cancer drug, compared with conventional medication, the odds ratio is 1.14. What does this suggest?
    a. There is no difference between the intervention and the control.
    b. The control performs better than the intervention.
    c. The intervention performs better than the control.
15. What does a 95% confidence interval tell us?
    a. There is a 95% probability that the 95% confidence interval contains the true value.
    b. The results are 95% correct, which is sufficient for us to be confident in their validity.
    c. The study has involved 95% of the possible participants in the population, so we can confidently report that the results are true for this group.
16. The *P* value reported for a randomized controlled trial is .01. What does this tell us?
    a. There is strong statistical evidence against the null hypothesis.
    b. The intervention is not effective.
    c. The intervention should be used in routine clinical practice.

Chapter 5: Human genetics

1. A patient presents with palmoplantar keratoderma and seeks a genetic diagnosis. What would be an appropriate first test to pursue?
   a. Whole-genome sequencing.
   b. Targeted panel of genes.
   c. SNP array.
   d. Single-cell RNA sequencing.
   e. Methylation array.
2. A genetic test report is returned on a neonate and reveals a new pathogenic variant in keratin 1, compatible with a diagnosis of epidermolytic ichthyosis. Neither parent is known to be affected. Which one is not a possible explanation?
   a. Gonadal mosaicism.
   b. Cutaneous and gonadal mosaicism.
   c. Nonpaternity.
   d. Both parents are unaffected carriers.
   e. *De novo* postzygotic mutation.
3. A mother and son attend the dermatogenetic clinic with a history of familial melanoma. The son, aged 38 years, has just had his first melanoma, which was a stage 1B tumour. His mother had a stage 3 tumour with lymph node involvement at age 58 years, has received immunotherapy, and is now in remission. Her father died of pancreatic cancer at the age of 42 years. What would you do next?
   a. Family history questionnaire.
   b. Test the mother's germline DNA.
   c. Test the son's germline DNA.
   d. Do not offer a test.
   e. Test the mother's archival skin tumour.
4. A couple are referred to the genetic counselling clinic because they are planning to have a family in the near future. The wife, who is healthy, has a family history of haemophilia A with both her brothers having the diagnosis. After a genetic test, the wife

but not the husband is a carrier for the common haemophilia A pathogenic variant. Which statement is true?
   a. The factor VIII gene is located on chromosome 2.
   b. Fifty percent of girls will be carriers.
   c. All boys will be affected.
   d. It is an X-linked dominant condition.
   e. There is no risk of passing on haemophilia A to the boys.

5. A saliva sample is taken from a boy with congenital hearing loss. Both parents have normal hearing. The sample is sent to the laboratory for a *GJB2* gene test involving polymerase chain reaction and sequencing. What is not needed to perform this genetic test?
   a. DNA.
   b. Oligonucleotide primers.
   c. Bisulphite modification of DNA.
   d. Capillary electrophoresis.
   e. Heat-stable DNA polymerase.

Chapter 6: Immunity

1. Which of the following is a key cellular component of the innate immune system responsible for phagocytosis and the initial defense against microbial infections?
   a. T cells
   b. B cells
   c. Natural killer cells
   d. Macrophages
   e. Helper T cells

2. Which of the following cells is primarily responsible for presenting antigens to T cells and initiating the adaptive immune response?
   a. Neutrophils
   b. Macrophages
   c. Natural killer cells
   d. B cells
   e. Dendritic cells

3. What is the primary function of antibodies in the immune system?
   a. Phagocytosis
   b. Cytokine production
   c. Antigen presentation
   d. Neutralization of pathogens
   e. Oxygen transport

4. Checkpoint inhibitors in the immune system primarily function by
   a. enhancing phagocytosis.
   b. suppressing cytokine production.
   c. inhibiting T-cell activation.
   d. blocking the activity of antibodies.
   e. releasing the brakes on T-cell activity.

5. Anaphylaxis is a severe and potentially life-threatening allergic reaction that involves the release of large amounts of histamine and other mediators from
   a. neutrophils.
   b. B cells.
   c. T cells.
   d. mast cells.
   e. macrophages.

Chapter 7: Therapeutics and prescribing

1. Which route of administration is associated with the highest bioavailability?
   a. Oral
   b. Intravenous
   c. Buccal
   d. Intramuscular
   e. Topical

2. Which of these is not a recognized phase in pharmacokinetics?
   a. Absorption
   b. Distribution
   c. Metabolism
   d. Inhibition
   e. Excretion

3. Which of the following features is most closely associated to a type B adverse reaction?
   a. Dose independent
   b. Cause teratogenicity
   c. Occurs on drug cessation
   d. Occurs only after prolonged exposure only
   e. Invariably benign in clinical outcome

4. For a drug X at steady state that has an elimination half-life of 4 hours, how long would it take for effective complete drug elimination after stopping the medication?
   a. 2 hours
   b. 4 hours
   c. 12 hours
   d. 20 hours
   e. 48 hours

5. Postmarketing studies to evaluate drug safety are most commonly referred to as what phase drug study?
   a. I
   b. II
   c. III
   d. IV
   e. V

Chapter 8: Radiology

1. What is the investigation of choice for the initial identification of gallstones in a patient?
   a. CT of the abdomen
   b. HIDA scan
   c. MRI of the abdomen or MR cholangiopancreatogram (MRCP)
   d. Ultrasonography of the abdomen
   e. X-ray of the abdomen

2. What is the first investigation if the clinical concern is bacterial meningitis?
   a. CT of the brain
   b. X-ray of the brain
   c. CT angiography of the brain
   d. MRI of the brain
   e. None of the above

3. Which of the following examinations is contraindicated if the patient has renal impairment (estimated glomerular filtration rate of <30 mls/min/1.73 m^2)?
   a. Non-contrast CT
   b. Non-contrast MRI
   c. Ultrasonography
   d. Contrast-enhanced CT
   e. Contrast-enhanced MRI (gadolinium)

4. Which of the following statements is false on a normal chest X-ray (CXR)?
   a. You can estimate the heart size only on a CXR taken with posteroanterior (PA) projection.
   b. A well-inspired CXR has 8 to 10 posterior or 5 to 6 anterior ribs visible.
   c. The mediastinum measures 10 cm.
   d. Lucency (or 'blackness') between the lungs could be different because of patient rotation on CXR.
   e. The trachea should be equidistant between the medial ends of the clavicles in a non-rotated CXR.

5. Which of the following regarding MRI is not true?
   a. The MRI scanner is never switched off.
   b. Pacemakers are contraindicated for MRI.
   c. Cochlear implants are contraindicated for MRI.
   d. Pregnancy is an example of relative contraindication for MRI.
   e. Implanted metallic objects (e.g., bullets, shrapnel, occupational iron embedded in the eyes) are contraindicated for MRI.

Chapter 9: Public health

1. The Bradford Hill criteria on the strength of an association between a disease and its proposed cause state that causality is more likely if
   a. the effect size is small.
   b. the effect occurs before the cause.
   c. the association is demonstrable in only a specific timeframe.
   d. greater exposure leads to an equivalent effect.
   e. the effects could be proposed to be similar to other situations.
2. The Wilson and Jungner screening criteria include
   a. there should be an inexpensive treatment.
   b. the condition should be rare.
   c. there should be no latent stage.
   d. the natural history of the condition should be well understood.
   e. case finding should occur annually.
3. Which of the following is a property of screening tests?
   a. False-positive results occur when individuals test negative but do have disease.
   b. False-negative results occur when individuals with no disease test positive.
   c. Sensitivity is the percentage of true negatives.
   d. Positive predictive value varies with prevalence of the disease.
   e. Specificity is the ability of the test to detect all cases of disease.
4. What is currently included within the *routine* UK vaccination schedule for *school-aged* children?
   a. Rotavirus
   b. Influenza
   c. Pertussis
   d. Measles, mumps, and rubella
   e. Hepatitis B
5. The Index of Multiple Deprivation can be used to
   a. compare small areas across England.
   b. quantify how deprived a small area is.
   c. explore the causes of deprivation.
   d. identify individuals who are deprived.
   e. look at change in absolute deprivation over time.

Chapter 10: Global and planetary health

1. Over the period 2000 to 2020, average life expectancy
   a. has increased by 10 years for women and men.
   b. is between 60 and 65 years in lower- and middle-income countries.
   c. has decreased because of economic austerity.
   d. mirrors the increase in healthy life expectancy.
   e. is directly related to the per capita spend on healthcare provision.
2. Which of the following is a Bellwether procedure in global surgery?
   a. Treatment of 'closed' fractures
   b. Laparotomy
   c. Placement of chest drains
   d. Amputation for diabetic gangrene
   e. Haemostasis for major arterial bleeding
3. Which of the following statement is true for global food security?
   a. Deficiencies in transport and storage of food account for 10% of food wastage in lower- and middle-income countries.
   b. Land exploitation is beneficial for food production.
   c. Child malnutrition is responsible for 20% of deaths in children up to 5 years of age.
   d. One-third of all food produced is wasted each year.
   e. Food security is promoted by industrial development.
4. With regard to the security of water and sanitation 2023, which of the following statements is false?
   a. Seventy percent of the global population now has access to a 'safely managed drinking water source'.
   b. Access to water supplies is a hazardous process for women.
   c. Access to water and sanitation is not a UN-recognized human right.
   d. Collection of water is usually undertaken by child labourers.
   e. One billion people collect water from unprotected sources.
5. The following international agreements are not legally binding:
   a. The International Covenant on Civil and Political Rights.
   b. The Committee on the Elimination of Discrimination against Women.
   c. The UN Convention on the Rights of the Child.
   d. The Universal Declaration of Human Rights.
   e. The International Covenant on Economic, Social and Cultural Rights.

Chapter 11: Acute medicine

1. A 64-year-old male with a body weight of 125 kg is referred to Same Day Emergency Care (SDEC) with a 4-day history of pleuritic chest pain and breathlessness. He has a history of deep vein thrombosis (DVT) previously, which had been treated at that time with warfarin therapy for 6 months.

On examination, he has a raised JVP and oxygen saturation of 90% (94%–98%) breathing room air.

Investigations:

ECG	Sinus rhythm, 105 beats/min with right bundle branch block
CXR	Normal
CTPA	Dilated right ventricle and pulmonary arteries; bilateral filling defects in segmental branches of upper and lower pulmonary artery

What is the single most appropriate measurement to help decide if he can be considered for management in an ambulatory fashion?
   a. Body mass index (BMI)
   b. D-dimer value
   c. QRS duration on ECG
   d. Simplified PE severity index (SPESI)
   e. Wells score
2. An 83-year-old male with a history of dementia and reduced mobility presents with shortness of breath and right-sided chest pain. Clinical examination reveals a dull right base, with reduced breath sounds and bronchial breathing above the area. It is 20:00 on a Friday evening. Which of the following features

is most likely to make the treating clinician consider inserting a chest drain out of hours?

a. CXR showing right-sided pleural effusion occupying the lower half of the thoracic cavity
b. Clinical evidence of a deep vein thrombosis (DVT)
c. Needle aspiration showing pleural fluid with a pH of 7.3
d. Requiring 24% oxygen to keep oxygen saturations above 94%
e. Septations and debris on the right side on point-of-care ultrasound (POCUS)

3. A 41-year-old female with no known medical history is admitted with jaundice and pruritus (itching). She recently had dark coloured urine and had been treated for pneumonia with amoxicillin and clavulanic acid 2 weeks previously. She had also been taking paracetamol up to a maximum dose of 1000 mg four times a day for the past 5 days. She regularly drinks approximately 12 units of alcohol per week.

On examination, she has a BMI of 29.0 kg/m^2 (18.0–25.0). She is icteric with excoriations. There is no organomegaly noted. The respiratory examination is unremarkable.

Investigations:

Haemoglobin	127 g/L (130–180)
White blood cells	8.0 × 10^9/L (4.0–11.0)
Neutrophils	4.9 × 10^9/L (1.5–7.0)
Lymphocytes	1.7 × 10^9/L (1.5–4.0)
Platelets	360 × 10^9/L (150–400)
Serum total bilirubin	152 μmol/L (1–22)
Serum alanine aminotransferase	85 U/L (5–35)
Serum aspartate aminotransferase	65 U/L (1–31)
Serum alkaline phosphatase	99 U/L (45–105)
Serum CRP	5 mg/L (<10)
Ultrasound scan of abdomen	Thin-walled gallbladder, multiple gallstones; common bile duct measuring 4 mm

What is the most likely cause of her jaundice?

a. Chronic liver disease caused by steatosis
b. Cytomegalovirus (CMV) primary infection
c. Idiosyncratic reaction to amoxicillin and clavulanic acid
d. Recently passed impacted gallstones
e. Staggered paracetamol overdose

4. A 22-year-old female presents with shortness of breath associated with nausea and vomiting. She has had diabetes mellitus since the age of 12 years. Her diabetes has been treated by basal bolus insulin regimen, but she has not taken it today because of not being able to eat. She weighs 60 kg.

Examination shows a soft, non-tender abdomen but clinical dehydration. Chest examination is unremarkable apart from a respiratory rate of 28 breaths/min.

Investigations:

Haemoglobin	161 g/L (130–180)
White blood cells	7.0 × 10^9/L (4.0–11.0)
Neutrophils	4.9 × 10^9/L (1.5–7.0)
Lymphocytes	1.2 × 10^9/L (1.5–4.0)
Platelets	210 × 10^9/L (150–400)
Serum sodium	124 mmol/L (137–144)
Serum potassium	2.8 mmol/L (3.5–4.9)
Serum urea	13.8 mmol/L (2.5–7.0)
Serum creatinine	140 μmol/L (60–110)
Serum CRP	4 mg/L (<10)
Fasting plasma glucose	28.0 mmol/L (3.0–6.0)
Haemoglobin A_{1c}	66 mmol/mol (20–42)
Blood ketones	6.0 mmol/L (<0.6)

Arterial blood gases, breathing air:

PaO_2	14.1 kPa (11.3–12.6)
$PaCO_2$	2.8 kPa (4.7–6.0)
pH	7.02 (7.35–7.45)
Bicarbonate	14 mmol/L (21–29)
Base excess	–8.0 mmol/L (±2.0)
Lactate	3.0 mmol/L (0.5–1.6)
Oxygen saturation	99% (94–98)
Serum cortisol (22.00 h)	92 nmol/L (50–180)

With regular monitoring, what is the best management strategy?

a. 0.9% saline only
b. 0.9% saline with potassium and 3 units per hour of fixed-rate insulin and usual long-acting insulin
c. 0.9% saline with 3 units per hour fixed-rate insulin and i.v. hydrocortisone
d. 0.9% saline with potassium and 6 units per hour of fixed-rate insulin
e. 0.9% saline with potassium and 6 units per hour of fixed-rate insulin and usual long-acting insulin

5. The acute medicine team receives an alert from the on-call biochemist that a 62-year-old female with baseline eGFR of 28 mL/min/1.73 m^2 (>60) had an acute kidney injury on blood tests from the outpatient clinic. She has stage 4 chronic kidney disease and has blood taken in the outpatient clinic, where she is being seen regularly for long-standing osteomyelitis of the foot. The observations from the clinic were within normal limits, and it is noted that she has a long-term catheter in situ.

Investigations 2 weeks previously:

Serum sodium	142 mmol/L (137–144)
Serum potassium	4.2 mmol/L (3.5–4.9)
Serum urea	7.9 mmol/L (2.5–7.0)
Serum creatinine	280 μmol/L (60–110)

Investigations from today:

Serum sodium	145 mmol/L (137–144)
Serum potassium	6.1 mmol/L (3.5–4.9)
Serum urea	8.1 mmol/L (2.5–7.0)
Serum creatinine	370 μmol/L (60–110)

What is the most likely reason for the worsening of her biochemistry results?

a. Co-trimoxazole therapy
b. Dehydration
c. Potassium permanganate soaks
d. Red flag sepsis
e. Urinary obstruction

Chapter 12: Sepsis and the treatment of bacterial infection

1. A ventilated patient in the intensive care unit develops progressive respiratory failure. They have already received 5 days of treatment with piperacillin/tazobactam, and *Acinetobacter baumannii* has now been isolated from a sputum sample. Which of the following antibiotics could be used as empirical treatment of ventilator-associated pneumonia?

a. Azithromycin
b. Ceftazidime
c. Meropenem
d. Ampicillin/sulbactam
e. Ceftolozone/tazobactam

2. Which of the following antibiotics are likely to be active against *Enterococcus faecium* and could be used as monotherapy for a complicated intra-abdominal infection.
   a. Teicoplanin
   b. Amoxicillin/clavulanate
   c. Cefotaxime
   d. Metronidazole
   e. Tigecycline
3. A 35-year-old male presents with a 3-day history of lower limb cellulitis. He has no known penicillin allergy. On examination, he has cellulitis from his ankle to his midthigh. He is referred to the OPAT service. Which intravenous antibiotic should he be given?
   a. Benzylpenicillin
   b. Ceftriaxone
   c. Daptomycin
   d. Flucloxacillin
   e. Teicoplanin
4. A 45-year-old female presents with a 5-day history of fever, rigors, and left flank pain. On examination, she is alert and orientated, and her blood pressure is 135/75 mmHg. Blood cultures grow *Escherichia coli* (ESBL positive), susceptible to meropenem, ertapenem, and amikacin. The patient is referred to the OPAT service. Which intravenous antibiotic should she be given?
   a. Amikacin
   b. Ceftriaxone
   c. Ertapenem
   d. Meropenem
   e. Tazocin
5. Septic shock is best defined as
   a. septic cardiomyopathy leading to distributive shock.
   b. positive blood cultures and low blood pressure.
   c. sepsis with an unsupported mean arterial blood pressure below 65 mmHg at presentation.
   d. sepsis with an unsupported mean arterial blood pressure below 65 mmHg and an arterial blood lactate concentration above 2 mmol/L after fluid resuscitation.
   e. sepsis with an arterial blood lactate concentration above 2 mmol/L.

Chapter 13: Critical care medicine

1. A previously fit and well 25-year-old female has been admitted to the intensive care unit with sepsis secondary to a urinary tract infection. Despite appropriate fluid therapy, she remains hypotensive. She has both invasive arterial and central venous pressure monitoring. She has a pulse of 120 beats/min, blood pressure of 80/40 mmHg, and central venous pressure of 10 mmHg. A cardiac output monitor demonstrates a cardiac index of 4.9 L/min/m^2 with a stroke volume variation of less than 5%. Her urine output has been only 20 mL for the past 4 hours. Arterial blood gas analysis demonstrates a lactate of 4.6 mmol/L. What is the most appropriate next intervention?
   a. Administration of a further fluid bolus of 250 mL of compound sodium lactate.
   b. Start an infusion of dobutamine.
   c. Administer a bolus of furosemide 40 mg i.v.
   d. Start an infusion of norepinephrine.
   e. Start an infusion of vasopressin.
2. A 74-year-old male is admitted in cardiac arrest after collapsing at home shortly after complaining of some chest pain. CPR has been ongoing for 20 minutes, and he has been intubated by the pre-hospital team. Mechanical ventilation is ongoing on 100% oxygen. He is in ventricular fibrillation on his arrival and successfully cardioverted with a single 360J DC shock. An arterial blood gas is obtained shortly after return of circulation:

pH	7.12
$PaCO_2$	4.75 kPa
PaO_2	61.20 kPa
$CHCO_3$	8 mmol/L
Base excess	–15 mmol/L

Which statement best describes this patient's metabolic disturbance?
   a. Respiratory acidosis
   b. Respiratory alkalosis
   c. Metabolic acidosis with associated hypoxia
   d. Metabolic acidosis without associated hypoxia
   e. Metabolic alkalosis
3. Concerning the acute respiratory distress syndrome:
   a. the syndrome can be defined by clinical parameters alone when the radiology findings are clear.
   b. steroids have been shown to be effective in the initial treatment of patients with the condition.
   c. a PaO_2/FiO_2 ratio of less than or equal to 300 mmHg without PEEP is diagnostic of ARDS.
   d. the condition does not occur in patients who are immunosuppressed because it is primarily mediated by an adverse immune reaction.
   e. improved survival has been demonstrated with lower ventilatory tidal volumes.
4. A 22-year-old male is admitted acutely unwell to hospital. His blood results show the following:

pH	7.10
$PaCO_2$	4.23 kPa
PaO_2	12.08 kPa
$CHCO_3$	12 mmol/L
Base excess	–10 mmol/L
Na	143 mmol/L
K	4.9 mmol/L
Cl	95 mmol/L
Urea	4.8 mmol/L
Creatinine	143 micromol/L
Glucose	4.9 mmol/L
Urine ketones	negative

What is the likely diagnosis?
   a. Lactic acidosis
   b. Diabetic ketoacidosis
   c. Salicylate poisoning
   d. Diarrhoea
   e. Ethylene glycol toxicity
5. A 45-year-old male is an inpatient on intensive care after an inferior myocardial infarction. On examination, his pulse is 100 beats/min, and blood pressure is 80/40 mmHg. Clinical examination reveals an elevated JVP.

   A Swan-Ganz catheter is inserted, and the following values are obtained:

Right atrial pressure	10 mmHg	(8–12)
Pulmonary artery pressure	24/0 mmHg	(20/0–35/0)
Pulmonary capillary wedge pressure	5 mmHg	(5–10)
Mixed venous oxygen saturation	62%	(62%–65%)
Cardiac index	3.4 L/min/m^2	(>2.5)

These findings are consistent with what diagnosis?

a. Cardiac tamponade
b. Hypovolaemia
c. Ventricular septal defect
d. Mitral regurgitation
e. Cardiogenic shock

Chapter 14: Anaesthesia and perioperative medicine

1. A 75-year-old male patient with type 2 diabetes mellitus and hypertension underwent elective open right hemicolectomy for bowel cancer 3 days ago. It was surgically complex and lasted 5 hours. He has not yet mobilized from bed because of pain and is struggling to cough effectively. His oxygen saturations have fallen over the past 12 hours, such that he now needs 10 L/min of oxygen to maintain SpO_2 above 94%. What is the most likely cause of his hypoxia?

a. Pneumothorax
b. Myocardial infarction
c. Pneumonia
d. Pleural effusion
e. Anaphylaxis

2. An 82-year-old female is scheduled for elective lumpectomy of a breast lesion under general anaesthetic. She takes amlodipine for hypertension, with a preoperative BP of 131/78 mmHg, senna, and vitamin D supplements. Which is the most accurate ASA score for this patient?

a. 1
b. 2
c. 3
d. 4
e. 5

3. A 63-year-old male is scheduled for elective radical cystectomy for bladder cancer. He has a body mass index of 34.1 kg/m^2, smokes 10 cigarettes per day, and has had a previous myocardial infarction with percutaneous stent insertion. He is referred to the local prehabilitation service. Select the best description of the core components of prehabilitation.

a. Psychology, exercise, and nutrition
b. Psychology, chemotherapy, and occupational therapy
c. Exercise, blood testing, and echocardiography
d. Echocardiography, psychology, and smoking cessation
e. Drinking, eating, and mobilizing

4. A 72-year-old female undergoes elective right nephrectomy for a renal cell carcinoma, with planned enhanced recovery. She receives total intravenous anaesthetic (TIVA) and is intubated easily. The surgeon requests placement of a nasogastric tube. She is given 2 L of balanced crystalloid, during the surgery. Thromboprophylaxis is with intermittent compression devices, then low-molecular-weight heparin postoperatively. Which element of her care should have been avoided based on the plan for enhanced recovery?

a. TIVA
b. Intubation
c. Nasogastric tube
d. Balanced crystalloid
e. Intermittent compression devices

5. A 53-year-old female is being assessed by the perioperative team in advance of a major head and neck cancer surgery. Which of the following would be the best way for the team to provide risk stratification for this patient?

a. Acute Physiology and Chronic Health Evaluation (APACHE)
b. European System for Cardiac Operative Risk Evaluation (EuroSCORE)
c. C-reactive protein levels
d. Surgical Outcome Risk Tool (SORT)
e. Montreal Cognitive Assessment (MOCA)

Chapter 15: Toxicology

1. What is the preferred antidotal treatment for a patient presenting within 2 hours of ingestion of 100 mL of antifreeze (100% ethylene glycol)?

a. Ethanol
b. Acetylcysteine
c. Fomepizole
d. Pralidoxime
e. Sodium bicarbonate

2. Which toxic gas is produced when the rodenticide aluminium phosphide reacts with moisture in the air?

a. Carbon monoxide
b. Chlorine
c. Hydrogen cyanide
d. Phosphine
e. Hydrogen sulfide

3. Which of the following is NOT a clinical sign of organophosphate pesticide poisoning?

a. Bradycardia
b. Miosis
c. Dry mouth
d. Bronchorrhea
e. Muscle fasciculations

4. Which electrocardiographic changes are consistent with severe tricyclic antidepressant toxicity?

a. Prolonged PR interval
b. Prolonged QT interval
c. Prolonged QRS duration
d. Peaked T waves
e. Down-sloping ST segment depression ('reverse tick')

5. Which of the following antidotes does not work by forming an inert complex with the poison?

a. Desferrioxamine
b. Digoxin-specific antibody fragments
c. Hydroxocobalamin
d. Succimer (dimercaptosuccinic acid)
e. Methylthioninium chloride ('methylene blue')

Chapter 16: Environmental medicine

1. Which of the following can be a medical problem in relation to aviation and space medicine?

a. Acceleration
b. Radiation exposure
c. Circadian dysrhythmia
d. Thermal stress
e. All of the above

2. In relation to acute high-altitude cerebral oedema, which of the following is the best treatment?

a. Dexamethasone and immediate descent to a lower altitude
b. Dexamethasone and atenolol
c. Nifedipine and oxygen
d. Sildenafil and a non-steroidal anti-inflammatory drug
e. None of the above

3. Hypothermia is defined as a core temperature of less than 35°C. Which of the following occurs in hypothermia?
   a. Oxygen dissociation curve shifts to the right
   b. Pulse rate rises
   c. Respiratory rate rises
   d. Coordination is lost
   e. QT interval shortens
4. In the diagnosis of heat stroke,
   a. the core temperature must be above 42°C.
   b. sweating will always be present.
   c. hypersalivation is common.
   d. intravascular coagulation and multiorgan failure can occur.
   e. neurological symptoms and signs are not present.
5. A person is rescued from immersion in water. Which of the following apply?
   a. The most common cause of death is from hypothermia.
   b. Immediate treatment is to drain water from the victim's lungs.
   c. The victim must be lifted vertically from the water.
   d. Immediate treatment is to give rescue breaths and oxygen if available.
6. In relation to human lightning strikes, which of the following is true?
   a. Fifty percent of humans struck by lightning die.
   b. Fern-shaped patterns on the skin should be treated as burns.
   c. Bystanders are at risk of electric shock from touching the patient after a lightning strike.
   d. Prolonged CPR may be required because of respiratory muscle paralysis.
   e. A defibrillator should not be used because of the thermal damage to the heart.

Chapter 17: Cardiology

1. A 40-year-old smoker presents to the emergency department with a 1-hour history of crushing central chest pain that radiates to his jaw. He is not on any regular medication. His heart rate is 90 beats/min, blood pressure is 145/95 mmHg and oxygen saturations are 98% on room air. What is the most appropriate next investigation?
   a. Cardiac enzymes
   b. Computed tomography pulmonary angiography
   c. D-dimer
   d. Echocardiogram
   e. Electrocardiography
2. A 76-year-old female is referred to cardiology outpatients with palpitations, which have been intermittent for the past week. She is on treatment for hypertension (perindopril 4 mg) and type 2 diabetes (metformin 1 g). Her electrocardiogram shows atrial fibrillation with a ventricular rate of 110 beats/min. Her blood pressure is 140/85 mmHg. Her total cholesterol is 6.4 mmol/L. Her HbA_{1c} is 7% or 53 mmol/mol. What is the best next management step to reduce her risk of future stroke?
   a. Atrial fibrillation ablation
   b. Clopidogrel
   c. Direct oral anticoagulant
   d. Left atrial appendage occlusion device
   e. Statin therapy
3. A 65-year-old male with ischaemic cardiomyopathy is being seen in the outpatient department. He develops shortness of breath after walking 50 m on the flat. His medications include ramipril, bisoprolol, eplerenone, aspirin, and atorvastatin. He has severely impaired left ventricular systolic function. He has moderate mitral regurgitation. His blood pressure is 110/75 mmHg, and his heart rate is 65 beats/min. His electrocardiogram confirms sinus rhythm and a narrow QRS duration. What is the next most appropriate step to reduce his risk of cardiovascular death and heart failure admission?
   a. Internal cardioverter-defibrillator
   b. Ivabradine
   c. Sodium-glucose transport protein 2 inhibitor
   d. Transcatheter mitral valve intervention
   e. Vericiguat
4. A 25-year-old healthy male is referred for a new diagnosis of hypertension. A 24-hour ambulatory blood pressure monitor has confirmed a daytime average of 150/95 mmHg. Clinical examination reveals a regular right radial pulse and a systolic murmur. It is difficult to palpate his femoral pulse. What is the likely relevant diagnosis?
   a. Aortic stenosis
   b. Coarctation of the aorta
   c. Conn's disease
   d. Mitral regurgitation
   e. Peripheral vascular disease
5. A 19-year-old university student presents to the emergency department with 3 hours of severe chest pain. It is worse with inspiration and better sitting up. There is ST segment elevation on the electrocardiograph. The troponin I assay is negative at 1 hour after arrival in the department. The remaining blood tests, including a full blood count, renal function, C-reactive protein, and D-dimer, are grossly unremarkable. What is the best management?
   a. Aspirin and prednisolone
   b. Aspirin and clopidogrel
   c. Direct oral anticoagulant
   d. Ibuprofen and colchicine
   e. Penicillin G injection

Chapter 18: Hypertension

1. Which of these medications is most likely to interfere with blood pressure control?
   a. Paracetamol
   b. Ibuprofen
   c. Chlorphenamine
   d. Codeine
   e. Omeprazole
2. Which of these dietary patterns is associated with hypertension?
   a. Low salt intake
   b. Low vegetable and fruit intake
   c. Low saturated fat intake
   d. Low simple carbohydrate intake
   e. Low animal protein intake
3. Which of these parameters is measured in millimetres of mercury (mmHg)?
   a. Jugular venous pressure
   b. Central venous pressure
   c. Diastolic blood pressure
   d. Heart rate
   e. Respiratory rate
4. Which of the following medications is least appropriate to prescribe to uncomplicated hypertension?
   a. Amlodipine
   b. Clonidine
   c. Lisinopril
   d. Spironolactone
   e. Indapamide

5. A patient with a daytime ambulatory blood pressure of 137/80 mmHg is best classified as having what type of blood pressure or hypertension?
   a. Normal blood pressure
   b. Elevated blood pressure
   c. Grade 1 hypertension
   d. Grade 2 hypertension
   e. Severe hypertension

Chapter 19: Lipid and metabolic disorders

1. Which of the proteins below is found only in chylomicron particles?
   a. Apolipoprotein B48
   b. Apolipoprotein B100
   c. Apolipoprotein A1
   d. Apolipoprotein E
   e. Apolipoprotein C3
2. Which lipid sub-fraction shows the strongest association with risk of cardiovascular events?
   a. High-density lipoprotein cholesterol (HDL-C)
   b. Low-density lipoprotein cholesterol (LDL-C)
   c. Non-HDL cholesterol
   d. Remnant cholesterol
   e. Triglycerides
3. Which of the following conditions is NOT associated with a secondary elevation in cholesterol?
   a. Excess alcohol
   b. Newly diagnosed diabetes
   c. Hypothyroidism
   d. Leukaemia
   e. Extreme weight loss
4. Which of the following conditions commonly shows autosomal dominant inheritance?
   a. Familial chylomicronaemia syndrome
   b. Familial hypercholesterolaemia
   c. Lecithin-cholesterol acyltransferase deficiency
   d. Abetalipoproteinemia
   e. Familial combined hyperlipidaemia
5. Which of the following medications does not lower low-density lipoprotein cholesterol (LDL-C) levels?
   a. A statin (HMG-CoA reductase inhibitor)
   b. Ezetimibe
   c. Proprotein-convertase subtilisin kexin-9 (PCSK9) inhibitor
   d. Icosapent ethyl (omega-3 fatty acid)
   e. Bempedoic acid

Chapter 20: Respiratory medicine

1. A 18-year-old male with a history of childhood asthma repeatedly attends the emergency department (ED) with symptoms of wheeze, cough, and shortness of breath. He is well enough to be discharged from the ED after salbutamol nebulizer because his peak expiratory flow is 80% of predicted. What is the best plan on hospital discharge?
   a. Prescribe oral prednisolone. He should also use a salbutamol inhaler hourly, see his general practitioner in 1 month, and seek medical advice if he deteriorates in the interim.
   b. Prescribe oral prednisolone, ensure a preventer and reliever therapy prescription, and advise to see general practitioner within 1 week and seek medical advice if his condition fails to improve.
   c. Advise follow-up with his general practitioner as soon as possible and make an urgent referral to the respiratory team for an outpatient review.
   d. Advise to re-attend the ED if he has further symptoms.
   e. Arrange an ambulatory care review the next day and make a referral to the respiratory clinic.
2. A 74-year-old male presents with pneumonia. Which of the following statements is correct?
   a. The most common causative agent is *Streptococcus pneumoniae.*
   b. Severity of pneumonia may be assessed with CURB 65.
   c. A follow-up chest radiograph should be requested in 6 weeks.
   d. Cigarette smoking is an independent risk factor for community-acquired pneumonia.
   e. All of the above.
3. A 38-year-old female who has recently moved to the UK is seen in the emergency department with fever, cough, night sweats, haemoptysis, and weight loss over a 6-week period. The chest radiograph shows upper lobe consolidation. Which of the following is TRUE?
   a. The patient should have care in a side room.
   b. One sputum sample that is negative for acid-fast bacilli excludes tuberculosis.
   c. The likely diagnosis is non-tuberculous mycobacterial disease.
   d. Bronchoscopy is mandatory to make the diagnosis.
   e. A positive pregnancy test result means that treatment for tuberculosis should be delayed.
4. A 54-year-old male attends the general practitioner surgery. He has a 40-pack-year smoking history. He has had a cough for 4 weeks. He may have lost some weight. What are your next steps?
   a. Assess for postnasal drip and prescribe a nasal steroid spray.
   b. Trial a proton pump inhibitor and review again in a few weeks.
   c. Order a chest radiograph and blood tests and send a 2-week wait referral for suspected lung cancer.
   d. Prescribe a course of antibiotics.
   e. Reassure and ask to make another appointment if the symptoms do not resolve.
5. A 68-year-old male who is a 40 pack-year smoker has a new diagnosis of chronic obstructive pulmonary disease with no previous history of asthma or atopy. Lung function tests shows an FEV_1/FVC ratio of 55%. What feature of his clinical history helps guide initial inhaled treatment?
   a. Symptomatic improvement when treated with oral prednisolone
   b. A breathlessness score (e.g., MRC or CAT) and frequency of exacerbations
   c. Whether he has received influenza and SARS-CoV-2 vaccinations within the past 12 months
   d. Whether he has completed pulmonary rehabilitation
   e. How often he uses a salbutamol inhaler

Chapter 21: Ear, nose, and throat

1. A 54-year-old male develops an upper respiratory tract infection (URTI) with nasal obstruction and rhinorrhea. A few days later, he develops hearing loss and tinnitus in his right ear, although this is not painful. The general practitioner performs tuning fork tests. Weber's test lateralizes to the right ear. Rinne's test is positive on the left and negative on the right. What should you tell the patient?
   a. This is sudden sensorineural hearing loss on the left, and urgent steroids are required.
   b. This is sudden sensorineural hearing loss on the right, and urgent steroids are required.
   c. This is 'glue ear' on the right and should resolve in the next few weeks.
   d. This is 'glue ear' on the left and should resolve in the next few weeks.
   e. The best treatment is antibiotics and steroids for 1 week.

2. A 67-year-old female falls and hits her head. A few weeks later, she wakes up with dizzy spells lasting several seconds, which continue to occur multiple times a day, particularly when she reaches up for items in the kitchen. She denies vomiting and hearing loss. She is otherwise fit and well. Which is the correct diagnosis?
   a. Posterior fossa mass
   b. Ménière's disease
   c. Vestibular migraine
   d. Benign paroxysmal positional vertigo
   e. Multiple sclerosis
3. An 87-year-old male with a history of chronic hypertension develops sudden-onset disabling dizziness and vomiting, which lasts all day. His hearing is also reduced. He is unable to get up to walk to the toilet. His head thrust test shows no catch-up saccade, but he does have direction changing nystagmus. A test for skew is positive. What is the most likely diagnosis?
   a. Vestibular neuritis
   b. Ménière's disease
   c. Persistent postural perceptual dizziness
   d. Posterior circulation stroke
   e. Benign paroxysmal positional vertigo
4. A 45-year-old male presents with a 6-week history of persistent right unilateral throat pain and difficulty swallowing. He gets occasional pain radiating to the right ear. On examination, there are a unilaterally enlarged tonsil and palpable lymph nodes in the neck. Which test is most likely to be diagnostic?
   a. Throat swab for microscopy and culture
   b. Computed tomography imaging of the neck
   c. Fine-needle aspiration of the lymph node
   d. Serum sample for inflammatory markers
   e. Skin-prick testing
5. A 30-year-old builder has a 1-year history of left-sided hearing loss and tinnitus. An audiogram shows a 40-DB sensorineural hearing loss on the left. What would you do next?
   a. Repeat a hearing test in 3 months.
   b. Give the patient a course of nasal steroids and antibiotics.
   c. Give the patient oral steroids for 1 week.
   d. Request an MRI scan of the internal auditory meatus.
   e. Refer for hearing aids.

Chapter 22: Gastroenterology

1. Which of the following pathogens is not a common cause of acute diarrhoea?
   a. Norovirus
   b. *Escherichia coli*
   c. *Giardia* spp.
   d. *Streptococcus* spp.
   e. *Clostridium difficile*
2. Which of the following is not an 'alarm' sign or symptom that should prompt urgent upper gastrointestinal endoscopy?
   a. Weight loss
   b. Belching
   c. Persistent vomiting
   d. Iron-deficiency anaemia
   e. Epigastric mass
3. Which of the following genes is most commonly associated with coeliac disease?
   a. *HLA-DQ2*
   b. *HLA-DQ8*
   c. *HLA-DR2*
   d. *HLA-DR3*
   e. *HLA-DP3*
4. Infliximab and adalimumab target which pro-inflammatory molecule?
   a. IL-6
   b. CD20
   c. TNF-α
   d. IL-2
   e. IL-23
5. Which of the following best describes the action of the gut regulatory peptide ghrelin?
   a. Stimulates gastric acid secretion
   b. Inhibits glucagon secretion and gastric emptying and stimulates insulin synthesis
   c. Inhibits secretion and action of most gut hormones
   d. Stimulates appetite and increases gastric emptying
   e. Causes gallbladder contraction and sphincter of Oddi relaxation

Chapter 23: Hepatology

1. If a patient is hepatitis C antibody positive and hepatitis C RNA positive, which of the following is true?
   a. The patient has been exposed to hepatitis C and requires monitoring.
   b. The patient is at risk of cirrhosis within the next few months.
   c. The patient's sexual contacts should be immunized against hepatitis C.
   d. The patient should be informed that curative tablet-based therapy is available.
   e. A liver biopsy must be performed.
2. In a patient with chronic hepatitis B (HBsAg positive, HBeAg negative, HBV DNA = 800 000 IU/mL), which of the following is true?
   a. The patient's family should be offered prophylactic medication.
   b. A liver biopsy is mandatory.
   c. The risk of live cancer is minimal, and no screening is indicated.
   d. An HIV test should be performed before initiation of therapy.
   e. Treatment with interferon should be introduced.
3. In a patient with abnormal liver function test results, which of the following is NOT immediately required?
   a. A liver ultrasound scan
   b. An assessment of body mass index and diabetes
   c. A careful drug history
   d. An endoscopic retrograde cholangiopancreatography examination
   e. A family history, including details of any neurological disorders
4. The ALT:AST ratio is a useful clinical indicator, but which of the following is NOT true?
   a. In patients with viral hepatitis, ALT is greater than AST unless cirrhosis is present, in which case AST is greater than ALT.
   b. In patients with alcoholic liver disease and steatohepatitis, the ALT is often greater than the AST.
   c. In patients with viral hepatitis, an AST:ALT ratio of more than 1 indicates cirrhosis.
   d. In patients with liver disease without cirrhosis in whom AST is greater than ALT, alcohol or obesity is the most likely aetiological agent.

5. Which of the following is NOT true?
   a. Ascites is the most common complication of cirrhosis, and this clinical presentation represents a watershed moment with patients' median survival falling from greater than 12 years for compensated cirrhosis to approximately 2 years.
   b. The Model for End-stage Liver Disease (MELD) focuses on serum bilirubin, creatinine, and the International Normalized Ratio and is widely used as a predictor of death in patients awaiting liver transplantation.
   c. After liver transplantation for autoimmune hepatitis, the disease never recurs.
   d. Elective liver transplantation in low-risk patients has a 90% 1-year survival rate and a 70% to 85% 5-year survival rate.
   e. Approximately 90% of patients with cirrhosis develop gastro-oesophageal varices over 10 years, but only one-third of these will bleed.

Chapter 24: Biliary tract and pancreatic disease

1. A 42-year-old female presents with colicky right hypochondrium pain, associated with nausea and vomiting. The pain was precipitated when she was eating her dinner and is controlled with analgesics. She denies any fever or rigors, and Murphy's sign is negative. What is the diagnosis?
   a. Typical peptic ulcer disease
   b. Renal colic
   c. Cholecystitis
   d. Ascending cholangitis
   e. Biliary colic
2. A 40-year-old patient with a history of alcohol dependence presents with upper abdominal pain. The pain started in the epigastric region and is associated with nausea and vomiting with radiation through to the back. The pain began after an alcoholic binge. What is the diagnosis?
   a. Peptic ulcer
   b. Acute pancreatitis
   c. Biliary colic
   d. Acute cholecystitis
   e. Mirizzi syndrome
3. A 40-year-old female presents with 3-month history of dull abdominal pain that radiates to the back and is associated with weight loss and progressive anorexia. She describes how she obtains partial relief by sitting forward. What is her diagnosis?
   a. Chronic pancreatitis
   b. Acute pancreatitis
   c. Carcinoma of the head of the pancreas
   d. Carcinoma of the ampulla of Vater
   e. Carcinoma localized to the body or tail of the pancreas
4. A 40-year-old male presents with 3-month history of worsening abdominal pain radiating to the back and associated weight loss and progressive anorexia. He describes how his wife has told him that he is looking more yellow. What is the diagnosis?
   a. Chronic pancreatitis
   b. Acute pancreatitis
   c. Carcinoma of the head of the pancreas
   d. Carcinoma localized to the body or tail of the pancreas
   e. Gastric tumour
5. The pancreas can be associated with cysts and some are predisposed to becoming malignant. Which one of the following is NOT known to become malignant?
   a. Pseudocyst
   b. Serous cyst
   c. Mucinous cyst
   d. Intraductal papillary mucinous cyst
   e. None of the above

Chapter 25: Nutrition

1. Which of the following statements regarding re-feeding syndrome is correct?
   a. Re-introduction of carbohydrate after a period of starvation leads to suppression of insulin release.
   b. A high body mass index is a risk factor for re-feeding syndrome.
   c. Intravenous vitamin K should be administered to patients at high risk of re-feeding syndrome.
   d. Re-feeding results in hypokalaemia, hypomagnesemia, hypophosphatemia, and thiamine deficiency.
   e. Patients at risk of re-feeding syndrome should be fed with excessive calories to account for their period of starvation.
2. The clinical syndrome of pellagra is associated with deficiency of which vitamin?
   a. B_1
   b. B_3
   c. Vitamin C
   d. Folate
   e. B_{12}
3. Which of the following is NOT a cause of intestinal failure?
   a. Short bowel syndrome
   b. Extensive small bowel Crohn's disease
   c. Acute severe ulcerative colitis
   d. Postoperative ileus
   e. Radiation enteropathy
4. What is the support a patient with 75 cm of short bowel to a jejunostomy will likely require?
   a. Nasogastric feeding
   b. Intravenous fluids
   c. Parenteral nutrition with or without intravenous fluids
   d. Parenteral nutrition
   e. Oral glucose solution
5. Which of the following is NOT considered an indication for intestinal transplant?
   a. Intestinal failure–associated liver disease
   b. Metastatic colorectal cancer
   c. Ultra-short bowel syndrome
   d. Frequent catheter-related bloodstream infections
   e. Central venous thrombosis of two or more central veins

Chapter 26: Kidney and urinary tract disease

1. A 29-year-old male presents with joint pain and a rash over his legs, having had a sore throat in the preceding week. He has a blood pressure of 155/93 mmHg and urine dipstick testing shows haematuria and proteinuria. What is the most likely diagnosis?
   a. Urinary tract infection
   b. IgA nephropathy
   c. Hypertensive crisis
   d. Meningococcal septicaemia
   e. Systemic Lupus Erythematosus

2. A 21-year-old female presents with fever, rigors, and left-sided flank pain. On examination, she is febrile (38.5°C) and has both suprapubic and left renal angle tenderness. What is the most likely diagnosis?
   a. Renal cell carcinoma
   b. Pyelonephritis
   c. Pancreatitis
   d. Acute renal colic
   e. Pelvic inflammatory disease
3. A 60-year-old male presents with visible, painless haematuria. Blood tests show a haemoglobin of 191 g/L. What is the most likely diagnosis?
   a. Renal calculi
   b. Renal cell carcinoma
   c. Prostate carcinoma
   d. Bladder carcinoma
   e. Haemolysis
4. A 71-year-old female presents with a severe headache. She is known to have chronic hypertension, diabetes, and coronary artery disease. Her blood pressure is 170/95 mmHg. Test results show:

Haemoglobin	99 g/L
Creatinine	212 μmol/L
Urine protein:creatinine ratio	410 mg/mmol
Ultrasound	normal-size kidneys

What is the most likely diagnosis?
   a. Hypertensive kidney disease
   b. Renal artery stenosis
   c. Reflux nephropathy
   d. Diabetic nephropathy
   e. Polycystic kidney disease
5. A previously fit 83-year-old male with stage 5 chronic kidney disease on peritoneal dialysis presents with confusion and constipation. On examination, his abdomen is tender, and there is a yellow discharge at his peritoneal catheter exit site. What is the most likely diagnosis?
   a. Ischaemic bowel disease
   b. Lower urinary tract infection
   c. Peritoneal dialysis-associated peritonitis
   d. Bowel obstruction
   e. Abdominal wall cellulitis

Chapter 27: Water balance, fluids, and electrolytes

1. Which of the following diuretics blocks the epithelial sodium channels in the distal collecting duct?
   a. Furosemide
   b. Acetazolamide
   c. Metolazone
   d. Amiloride
   e. Spironolactone
2. Arginine vasopressin (AVP) leads to urinary concentration through what mechanism?
   a. Inhibition of the sodium glucose co-transporter in the proximal tubule delivering sodium to the distal nephron
   b. Increasing the water permeability of the cortical and medullary collecting ducts
   c. Activation of the renin–angiotensin–aldosterone system
   d. Inhibition of the sodium–potassium-2-chloride channel in the thick ascending limb of Henle
   e. Inhibition of the sodium potassium ATP pump to allow more filtrate to flow to the collecting duct
3. Which is not a biological effect of SGLT2 inhibitors?
   a. Weight loss
   b. Hyperglycaemia
   c. Caloric deficit
   d. Hypotension
   e. Natriuresis
4. Hypophosphataemia is not associated with which of these conditions?
   a. Post-parathyroidectomy
   b. Dent's disease
   c. Re-feeding syndrome
   d. Vitamin D deficiency
   e. Respiratory acidosis

Chapter 28: Neurology

1. A 20-year-old male is brought into hospital by his friends. His friends state that he has not got out of bed for 3 days after celebrating his birthday. He admits to drinking alcohol and taking drugs at the time. He is now complaining of headaches and myalgia and states that sometimes he can hear voices. On examination, he becomes aggressive and makes a detailed neurological examination impossible, but he is noticed to be febrile. There is no rash on examination. What is the likely diagnosis?
   a. Cocaine-induced cerebrovascular event
   b. Drug-induced psychosis
   c. Herpes simplex encephalitis
   d. Subdural haemorrhage
   e. Variant Creutzfeldt–Jakob disease
2. A 34-year-old male presents to the emergency department with a severe left-sided headache that woke him from his sleep. He is now complaining of severe pain on the back of his left eye. He states that he has had this before, and it typically lasts for some minutes. He has had these attacks for the past few nights. On this occasion, he denies vomiting but states that he has vomited with previous episodes. He is also complaining that his left nostril feels congested. On examination, you find nothing abnormal. What is the likely diagnosis?
   a. Cluster headache
   b. Migraine
   c. Tension headache
   d. Subarachnoid haemorrhage
   e. Sinusitis
3. A 55-year-old female goes to see her primary care physician complaining of right-sided headaches and a transient episode of right-sided blindness 1 day ago, which has completely resolved. She notices that the pain in her head is exacerbated when she is combing her hair. On neurological examination, you find nothing abnormal. What is the likely diagnosis?
   a. Horner's syndrome
   b. Giant cell arteritis
   c. Malignant hypertension
   d. Amaurosis fugax
   e. Migraine
4. A 35-year-old female is referred to the neurologist with a 3-year history of progressive, perceptive deafness, with worsening symptoms of rotation dizziness and new onset of left facial weakness. Further examination reveals left facial numbness and a wide gait on walking. What is the likely diagnosis?
   a. Left parietal lobe glioma
   b. Cerebrovascular event
   c. Schwannoma (acoustic neuroma)
   d. Left cerebellar haemangioblastoma
   e. Glomus tumour of the jugular bulb

5. A 30-year-old obese female presents to her doctor with symptoms of headaches and complaining of some visual blurring. On fundoscopy, you notice papilloedema. Computed tomography is arranged for her, and the results do not show any mass or any increase in ventricular size. What condition is most likely?
   a. Idiopathic intracranial hypertension
   b. Sagittal sinus thrombosis
   c. Glioma
   d. Meningioma
   e. Subdural haematoma
6. A 25-year-old female presents to her primary care physician with pain in both her upper limbs, which is worse when coughing. You notice that she has burn marks in different areas of her upper arm, which she hasn't really noticed. On examination, her light touch is still intact, but she has loss of sensation to temperature. She has reduced upper limb reflexes bilaterally, and you notice some muscle wasting in the thenar muscle bilaterally. What is the likely diagnosis?
   a. Glioma of the spinal cord
   b. Vitamin B_{12} deficiency
   c. Syringomyelia
   d. Syringobulbia
   e. Spinal infarct
7. A 46-year-old male with a history of excess alcohol consumption presents to the emergency department with confusion and loss of sensation in his lower limbs and having an ataxic gait and nystagmus. He also complains of weakness in his lower limbs. What is the likely diagnosis?
   a. Lathyrism
   b. Konzo
   c. Vitamin B_{12} deficiency
   d. Vitamin B_1 deficiency
   e. Diabetic neuropathy
8. A 34-year-old female has been referred to the neurologist with symptoms of nasal regurgitation of fluids and choking. She is otherwise fit and well and has no other past medical history. On examination, you find she has a fibrillating tongue and a weak palate. What condition is most likely?
   a. Acute cerebrovascular accident
   b. Myasthenia gravis
   c. Progressive bulbar palsy
   d. Progressive muscular atrophy
   e. Cerebellar ataxia
9. A 20-year-old male presents to the doctor because he has noticed some lumps on his skin. He states that he has always had a few, but they have increased in number the older he gets. He is otherwise fit and well. He states that this seems to run in the family, and his father and grandfather both had a similar condition. On examination, there is nothing abnormal except that you notice some patches of skin that seem darker than the rest of his skin. What is the likely diagnosis?
   a. Neurofibromatosis type II
   b. Neurofibromatosis type I
   c. Tuberous sclerosis
   d. Sturge–Weber syndrome
   e. Vitiligo

Chapter 29: Stroke medicine

1. A 75-year-old male presents with a basal ganglia haemorrhage. His past medical history includes hypertension, and diabetes. He has a family history of aneurysm. Which of the following is the most likely cause of the intracranial haemorrhage?
   a. Cerebral amyloid angiopathy
   b. Arteriovenous malformation
   c. Cerebral aneurysm rupture
   d. Hypertension
   e. Venous sinus thrombosis
2. A 70-year-old smoker presents with mild right-sided facial weakness and mild word-finding difficulties (NIH Stroke Scale score, 2). His history includes diabetes and high cholesterol. Magnetic resonance imaging of the brain confirms a small infarct in the left frontal lobe without associated haemorrhage. MR angiography shows no evidence of intracranial stenosis but identifies a 20% to 49% left carotid stenosis. Twenty-four hours of cardiac rhythm monitoring shows normal sinus rhythm. Renal function is normal. What is the optimal antithrombotic strategy for secondary stroke prevention in this case?
   a. Prescribe warfarin with an international normalized ratio (INR) target of 2 to 3.
   b. Start apixaban immediately.
   c. Start aspirin 300 mg/day continued for 2 weeks then low-dose aspirin life-long
   d. Start aspirin and clopidogrel mg for 3 weeks and then single-antiplatelet treatment.
   e. Start aspirin and clopidogrel for 3 months and then single-antiplatelet treatment.
3. A 65-year-old female smoker presents with acute onset of an unsteady gait and vertigo. Blood pressure is normal. Electrocardiogram shows normal sinus rhythm. Computed tomography (CT) of the brain shows hypoattenuation in the left cerebellum without haemorrhage. CT angiography on admission confirmed left carotid stenosis (50%–69%) and a small-calibre left vertebral artery. What is the optimal intervention strategy?
   a. Left vertebral artery stenting
   b. Left carotid artery endarterectomy within 2 weeks
   c. Left carotid artery stenting within 2 weeks
   d. Left carotid endarterectomy within 24 hours
   e. Aggressive vascular risk factor control
4. A 24-year-old pregnant female (24 weeks' gestation) presents with right-hand weakness, headache, and drowsiness with a subsequent episode of seizure. Computed tomography of the brain identifies a left juxtacortical 1-cm haemorrhage. Taking into consideration the most likely diagnosis, what is the most appropriate treatment plan?
   a. Basilar thrombectomy
   b. Immediate neurosurgical decompression
   c. Commence immediate heparin
   d. Commence immediate aspirin
   e. Treat seizures and observe

Chapter 30: General hospital psychiatry

1. You are called to see a confused elderly male on the acute admissions medical ward. He had a high temperature (38.1°C) recorded last night on presentation to the emergency department. He refused physical examination then and now (4 a.m.). You are under pressure to examine his vital signs and his chest, as well as ruling out any injury. How will you proceed?
   a. Let him be and leave it until the morning shift comes in, just 4 hours from now.
   b. Ask psychiatry to place him under Mental Health Act legislation so you can examine him and give intravenous antibiotics.
   c. Phone the hospital legal department and ask for a case conference.
   d. Establish if he has the mental capacity to refuse vital signs and examination; document that he does not have capacity to refuse a basic examination and make a *best interests decision* to examine him.
   e. Call security to restrain him; then examine him.

2. The same patient (71-year-old male, known diabetes with angioplasty last year) is confused on presentation. Other than a fast heart rate, his temperature and vital signs are normal, and your physical examination did not find a source of infection. What features establish a delirium diagnosis?
   a. High blood glucose
   b. Auditory hallucinations recorded in his pre-angioplasty assessment last year, and he looks like he might be hearing voices right now
   c. Fluctuating consciousness, disorientated in time, and fleeting visual hallucinations
   d. Taking six different medications (polypharmacy), and his prescription differs from hospital records
   e. He is angry that you woke him up and is getting aggressive with nursing staff and you
3. In relation to prescribing a new psychiatric medication for your patient, which of the following is a source of potential harm to him or her?
   a. Asking for allergies, drug reactions, and intolerances to previous medications
   b. Changing to haloperidol from newly prescribed olanzapine because the hospital has run out
   c. Checking hospital and community records, including pharmacy if available, for current and past medications
   d. Reducing their selective serotonin reuptake inhibitor slowly over weeks before introducing a second-line antidepressant
   e. With new lithium prescription, requesting weekly blood levels with a renal profile
4. Identify the option that features only the cognitive symptoms of anxiety.
   a. Chest tightness, palpitations, and 'latchkey' urinary urgency
   b. Difficulties with concentration, episodes of the mind going blank, and indecision
   c. Fear of dying, fearing the worst, and a conviction that something bad is going to happen
   d. Hypervigilance, performance anxiety, and avoiding situations that provoke(d) anxiety
   e. Low mood, anger or irritability, and flashbacks

Chapter 31: Ophthalmology

1. Which of the following will not give a relative afferent pupillary defect?
   a. Retinal detachment
   b. Diabetic macular oedema
   c. Optic neuritis
   d. Non-arteritic anterior ischaemic optic neuropathy
   e. Ischaemic central retinal vein occlusion
2. Binocular diplopia is not caused by
   a. third nerve palsy.
   b. orbital floor fracture.
   c. sixth nerve palsy.
   d. thyroid eye disease.
   e. cataract.
3. Misuse of contact lens wear may lead to
   a. endophthalmitis.
   b. orbital cellulitis.
   c. acute glaucoma.
   d. keratitis.
   e. uveitis.
4. Sudden painless central loss of vision is likely caused by
   a. central retinal artery occlusion.
   b. retinal detachment.
   c. central retinal vein occlusion.
   d. wet macular degeneration.
   e. papilloedema.
5. Which of the following will not lead to optic disc swelling?
   a. Anterior ischaemic optic neuropathy
   b. Diabetic papillopathy
   c. Papilloedema
   d. Central retinal artery occlusion
   e. Central retinal vein occlusion

Chapter 32: Rheumatology

1. A 49-year-old female presents to her general practitioner with pain in her hands. The pain began gradually 5 weeks ago, is worse in the morning, and is associated with 1 hour of stiffness when she wakes from sleeping. The pain improves after activity. What is the most likely diagnosis in this patient?
   a. Psoriatic arthritis
   b. Axial spondylarthritis
   c. Osteoarthritis
   d. Gout
   e. Rheumatoid arthritis
2. A 73-year-old female presents to her general practitioner with 12 months of increasing pain in her left knee. There are no other joint symptoms. The knee pain began gradually and is worse after activity. It has begun to restrict her ability to climb stairs. What is the most likely finding on knee X-ray in this patient?
   a. Marginal erosions
   b. Marginal osteophytes
   c. Syndesmophytes
   d. Periarticular bone resorption
   e. Preserved joint space
3. A 23-year-old male under rheumatology care with axial spondylarthritis has ongoing severe inflammatory low back pain, fatigue, and prolonged morning stiffness. He has tried two different non-selective non-steroidal anti-inflammatory drugs at full doses for 3 months each with no improvement in symptoms. He does not have any joint pain in his arms or legs. What is the most appropriate treatment to consider next?
   a. Adalimumab
   b. Etoricoxib
   c. Hydrotherapy
   d. Methotrexate
   e. Prednisolone
4. A 35-year-old female presents to her general practitioner with pain all over her body for the past 2 years. Her sleep is disturbed, and she feels unrefreshed on waking. There are multiple tender spots on her body but no swollen joints. All blood tests and X-ray findings are normal. What is the most likely diagnosis in this patient?
   a. Polymyalgia rheumatica
   b. Fibromyalgia
   c. Osteoarthritis
   d. Polymyositis
   e. Rheumatoid arthritis
5. A 25-year-old female presents to an emergency department with bilateral ankle oedema, raised blood pressure, and a rash over her face. She has a previous history of pleural effusion

and recurrent mouth ulcers. Investigations show raised anti–double-stranded DNA levels, low albumin, and a high urine protein-creatinine ratio. What is the most likely diagnosis in this patient?

a. Rheumatoid arthritis
b. Sjögren's syndrome
c. Systemic sclerosis
d. Granulomatosis with polyangiitis
e. Systemic lupus erythematosus

Chapter 33: Bone disease

1. Which of the following is a risk factor for osteoporosis?
a. Age
b. Early menopause
c. Coeliac disease
d. Glucocorticoids
e. All of the above

2. Symptoms of osteoporosis include
a. bone pain.
b. fracture.
c. fatigue.
d. weakness.
e. all of the above.

3. Diagnosis of osteoporosis can be made by
a. DEXA scan.
b. fracture history.
c. bone biopsy.
d. a or c.
e. a, b, or c.

4. Which of the following is not a recommended initial treatment for an individual with T-score of –2.6 and no fractures?
a. Alendronate
b. Denosumab
c. Teriparatide
d. Zoledronate
e. c and d

5. Which of the following is the correct course of action after 5 years of denosumab treatment?
a. Drug holiday; monitor dual-energy x-ray absorptiometry (DXA) scan
b. Change to teriparatide
c. Change to alendronate
d. Continue denosumab
e. Change to zoledronate

Chapter 34: Endocrinology

1. A young female is referred by the primary care physician with oligomenorrhoea and galactorrhoea. On examination, she has bitemporal hemianopia.

Which one of the following is the best radiological investigation for pituitary tumours?
a. Computed tomography (CT) of the head
b. Lateral skull X-ray
c. Positron emission tomography (PET)
d. Magnetic resonance imaging (MRI) of the pituitary
e. Nuclear uptake scan

2. A 23-year-old Filipino female presents with irritability, weight loss of 6.5 kg in the past month, dry eyes, and increased sweating and thirst. On examination, you note that she is tremulous and warm. She has a heart rate of 100 beats/min, respiratory rate of 16 breaths/min, and blood pressure of 140/80 mmHg. There is a palpable diffuse lump in her neck with mild exophthalmos.

Results of thyroid function tests for this female are as follows:

Investigations:

Thyroid-stimulating hormone	<0.05 mU/L (0.3–3.5 mU/L)
Free T_4	49 pmol/L (10–25 pmol/L)
T_3	6.2 nmol/L (1.2–3.1 nmol/L)

What do these results imply?
a. Primary hypothyroidism
b. Thyroid-stimulating hormone deficiency
c. TSH-oma
d. Thyrotoxicosis
e. Compensated euthyroidism

3. Which one of the following statements about primary hyperparathyroidism is true?
a. Parathyroid hormone (PTH) is usually low
b. A high phosphate level is common
c. Conservative management is never appropriate
d. Histology usually reveals parathyroid hyperplasia
e. It is commonly seen in patients with multiple endocrine neoplasia type 1 (MEN 1)

4. A 20-year-old male presents to the emergency department with severe palpitations, headache, sweatiness, nausea, and panic attacks. On examination, his blood pressure is 200/120 mmHg with a heart rate of 125 beats/min. Computed tomography shows a calcified 6-cm adrenal mass. Which one of the following is the most likely diagnosis?
a. Primary hyperaldosteronism
b. Essential hypertension
c. Congenital adrenal hyperplasia
d. Renal artery stenosis
e. Phaeochromocytoma

5. A 40-year-old female complains of depression and insomnia, easy bruising, and weakness at the tops of her muscles. On examination, her skin is thin, and there are multiple abdominal striae. What is the most likely diagnosis?
a. Conn's syndrome
b. Cushing's syndrome
c. Addison's disease
d. Hypopituitarism
e. Prolactinoma

Chapter 35: Diabetes mellitus

1. A 21-year-old student presents with a 4-week history of thirst, polyuria, polydipsia, and weight loss. The laboratory glucose level is 24.3 mmol/L. The clinical diagnosis is type 1 diabetes. What is the investigation of choice to confirm he has type 1 diabetes?
a. HbA_{1c}
b. Blood ketones
c. Islet autoantibodies
d. C-peptide
e. Genetic testing

2. A 56-year-old female has a 10-year history of type 2 diabetes and has chronic kidney disease stage 3. Which class of oral antidiabetes agent would be the treatment of choice?
a. Metformin
b. Thiazolidinedione
c. Sulfonylurea
d. SGLT-2 inhibitor
e. GLP-1 receptor agonist

3. Cancer has recently overtaken cardiovascular disease as the leading cause of death in people with diabetes in several high-income countries. Which cancer occurs more commonly in people with diabetes?
   a. Lung
   b. Pancreatic
   c. Prostate
   d. Melanoma
   e. Colon
4. Insulin is the primary treatment of type 1 diabetes. The most commonly used regimen is a basal-bolus regimen, which can be administered by multiple daily injections or an insulin pump. Which of the following is true about pump therapy?
   a. Pump therapy reduces HbA_{1c} in those with elevated HbA_{1c}.
   b. Pump therapy is cheaper than multiple daily injections.
   c. Pump therapy is associated with a higher rate of hypoglycaemia.
   d. Hybrid closed loop systems are no more effective than standard pump therapy.
   e. Pump therapy can only be used for people with type 1 diabetes.
5. The pregnancy outcomes in females with pre-existing diabetes are worse than females without diabetes.

What interventions have been shown to improve pregnancy outcomes in females with pre-existing diabetes?
   a. Interventions to improve glucose levels starting before conception
   b. Prepregnancy folic acid 5 mg/day
   c. Use of continuous glucose monitoring
   d. Regular contact with a specialist multidisciplinary team jointly led by a physician and obstetrician
   e. All of the above

Chapter 36: Metabolic disease

1. Which of the following statements is not true?
   a. Pregnancy in a person with phenylketonuria should be treated as a medical emergency.
   b. Ammonia should be measured as a first-line test in all patients presenting with encephalopathy.
   c. Acute metabolic decompensation in several inherited metabolic diseases can be triggered by fasting or decreased calorie intake.
   d. A diagnosis of inherited metabolic disease is very unlikely in patients presenting with symptoms for the first time in adulthood.
   e. Acute decompensation in several inherited metabolic diseases is treated by giving adequate calorie intake in the form of oral carbohydrates and intravenous 10% dextrose.
2. Immediate management of a patient presenting with high ammonia in suspected or confirmed inherited metabolic disease includes
   a. stopping all oral protein intake.
   b. ensuring adequate calorie intake through oral or intravenous glucose.
   c. ammonia scavenger drugs.
   d. hemofiltration.
   e. all of the above.
3. Which of the following does not present with symptoms of acute porphyria?
   a. Acute intermittent porphyria
   b. Variegate porphyria
   c. Hereditary coproporphyria
   d. ALA dehydratase deficiency porphyria
   e. Porphyria cutanea tarda
4. Which of the following statements about Fabry disease is FALSE?
   a. It is caused by a deficiency of alpha-galactosidase A enzyme.
   b. It has an X-linked inheritance.
   c. Females are not clinically affected.
   d. Genetic confirmation in females is needed because biochemistry is unreliable.
   e. Treatment options include enzyme replacement therapy and symptomatic management.
5. Which of the following is not a feature of carbohydrate metabolism disorders?
   a. Hypoglycaemia
   b. Cardiomyopathy
   c. Myalgia
   d. Liver disease
   e. Hyperammonemia

Chapter 37: Obesity

1. A 34-year-old female presents to the general practitioner with weight gain, tiredness, and occasional constipation for the past few weeks. She does not get her periods because she has a progesterone implant. Her blood pressure is 150/90 mmHg, pulse is 65 beats/min, temperature is 36.5°C, and oxygen saturation is 96%. She eats a healthy proportion of food and is physically active. Which of the following conditions will you consider excluding first in this female?
   a. Hypothyroidism
   b. Cushing's syndrome
   c. Type 2 diabetes mellitus
   d. Dyslipidemia
   e. Vitamin D deficiency
2. Which of the following presents with early-onset obesity and hyperphagia (insatiable hunger)?
   a. Monogenic obesity
   b. Polygenic obesity
   c. Hormonal obesity
   d. Drug-associated obesity
   e. Endocrine-disrupting chemical–associated obesity
3. Which of the following complications arise from obesity?
   a. Hypertension
   b. Obstructive sleep apnoea
   c. Osteoarthritis
   d. Type 2 diabetes
   e. All of the above
4. A 35-year-old female with anxiety, type 1 diabetes, asthma, and schizophrenia presents to the obesity clinic with an inability to lose weight. Her blood pressure is 130/75 mmHg, pulse is 100 beats/minute, temperature is 37°C, and oxygen saturation is 97%. Her body mass index is 55 kg/m^2. She takes insulin, olanzapine, a regular steroid inhaler, and fluoxetine. Her full blood count, serum biochemistry, and HbA_{1c} are normal. Endocrine tests are completed, and her thyroid-stimulating hormone, and 9 a.m. serum cortisol are normal; however, her prolactin is 700 miU/L. What do you think could possibly be causing her weight gain?
   a. Prolactin
   b. Olanzapine
   c. Insulin
   d. Fluoxetine
   e. Options b, c, and d

5. A 50-year-old male presents to the general practitioner with tiredness and generalized pain. He is a vegetarian, is physically active, doesn't smoke, drinks two to four glasses of alcohol daily, and works full time. His body mass index is 45 kg/m^2, blood pressure is 155/100 mmHg, pulse is 69 beats/min, temperature is 36.5°C, and oxygen saturation is 97%. On examination, he has a plethoric, round face; a hump at the back of his neck; and increased abdominal girth with purple stretch marks. His investigations reveal a thyroid-stimulating hormone level of 2.05 mU/L, 9 a.m. serum cortisol of 700 nmol/L, low vitamin D level, and a low testosterone. After a dexamethasone suppression test, the cortisol is reduced to 35 nmol/L. What is the likely diagnosis?
   a. Cushing's syndrome
   b. Hypothyroidism
   c. Obesity
   d. Hypogonadism
   e. Pseudo-Cushing's syndrome

Chapter 38: Haematology

1. In trying to determine the cause of a patient's anaemia:
   a. A low MCV (mean cell volume) is diagnostic of iron deficiency anaemia.
   b. A raised reticulocyte count indicates that the bone marrow is working.
   c. A bone marrow biopsy is a last-resort test.
   d. A blood film is only helpful if the white blood cell or platelet counts are also abnormal.
   e. A low serum iron concentration is sufficient to indicate the presence of iron deficiency.
2. In haemolytic anaemias:
   a. G6PD deficiency cannot manifest in female patients as the gene is on the X-chromosome.
   b. Pyruvate kinase deficiency requires splenectomy to avoid blood transfusions.
   c. Drug-induced haemolytic anaemias are usually diagnosed by detecting the presence of drug-induced red cell antibodies.
   d. A low haptoglobin concentration rules out extravascular haemolysis.
   e. High LDH concentrations suggest increased red cell destruction.
3. For patients with haemoglobinopathies:
   a. The most severe form of beta thalassaemia major presents *in utero*.
   b. Patients with sickle cell disease and thalassaemia are at increased risk of strokes in childhood.
   c. Iron overload in transfusion-dependent thalassaemia can only be avoided by bone marrow transplantation at an early age.
   d. In sickle cell disease, patients are at risk of repeated parvovirus B19-induced aplastic crises.
   e. HbF concentrations can be naturally elevated in patients with sickle cell disease and thalassaemia.
4. Concerning red cell antibodies:
   a. Destruction of red cells by IgG autoantibodies requires complement fixation.
   b. A positive DAT is diagnostic of autoimmune haemolytic anaemia.
   c. A blood film showing spherocytes in conjunction with a negative DAT is sufficient to diagnose hereditary spherocytosis.
   d. A delayed transfusion reaction is unlikely to happen after a patient's first ever transfusion.
   e. Haemolytic disease of the newborn is best diagnosed with a cord sample at birth.
5. Concerning clotting disorders:
   a. Some types of malabsorption can mimic warfarin treatment on clotting tests.
   b. An elevated fibrinogen concentration is a sign of disseminated intravascular coagulation.
   c. Platelet transfusions are indicated to prevent bleeding in thrombotic thrombocytopenic purpura if the platelet count falls to less than 10 × 10^9/L.
   d. Lupus anticoagulants, which prolong the APTT, are associated with intra-articular bleeds.
   e. Patients with Type 2 Von Willebrand disease are at increased risk of postoperative thrombosis and require high doses of low molecular weight heparin to prevent venous thromboembolism.

Chapter 39: Haematological oncology

1. A 48-year-old male presents to the emergency department with a wrist fracture after being hit by a car while cycling home after work on a Friday night. A routine blood test shows:
   - Haemoglobin: 130 g/L
   - White blood cell count: 96 × 10^9/L
   - Platelet count: 250 × 10^9/L

   Results of biochemistry and clotting tests are normal. Apart from his wrist fracture, he feels well. He has never had a blood test before. Which of the following tests will give the most helpful information?
   a. Bone marrow investigation
   b. Blood film
   c. PET/CT scan
   d. Immunophenotyping on peripheral blood sample
   e. Blood tests for infection: CRP, ESR, and blood culture
2. A 23-year-old female goes to her general practitioner for the third time with persistent fevers and feeling run-down. She thinks she has lost weight. She has completed two courses of antibiotics for tonsillitis. She has noted a lump in her neck, which is not painful. She had COVID-19 5 months ago. She is not worried and thinks that being a single parent while trying to finish her degree are contributing to her symptoms. On examination, she has prominent, non-tender lymph nodes in her neck, the largest of which is 1.5 cm. What is the best course of action for the general practitioner?
   a. Reassure her and give her antibiotic treatment that covers atypical bacteria.
   b. Reassure her that her symptoms are likely caused by her previous COVID-19 infection and that no treatment is required.
   c. Request imaging of her neck and arrange to see her when the results are available.
   d. Refer her to the ear, nose, and throat team for their assessment and opinion.
   e. Request imaging of her neck and refer via the suspected cancer pathway.
3. A 78-year-old female requests an emergency general practitioner appointment on a Monday morning after developing increasingly severe back pain over the weekend. She had been advised to do this by the out-of-hours service when she contacted them for advice on Sunday. She feels the pain might be improving, but she is following up on the advice she was given. She last attended the general practitioner for a routine health check 1 year ago, but she has had two telephone appointments about back pain in the past 4 months. Blood tests were requested, but she had not been able to attend to have them done because she is the sole career for her husband, who has recently been unwell. She feels that the pain is higher up than the pain she experienced in her

hip and lower back before a successful hip replacement 5 years ago. She is reluctant to take analgesia because she has been constipated for the past few weeks. She thinks that her mind has not been as sharp as usual for the past few weeks. What is the best course of action?

a. Organize blood tests and arrange to ring her with the results in a couple of weeks.
b. Refer her for assessment by the community physiotherapy team and advise her that if her pain becomes more severe, she should go to the local emergency department.
c. Reassure her and organize assessment by the district nursing team to see if she could benefit from additional support at home. You will ask the district nurses to do blood tests at the same time.
d. You are worried about her back pain and request an urgent magnetic resonance imaging scan to take place within the next few weeks. You will then see her face to face with the results.
e. You give her an urgent appointment for face-to-face review and blood tests to take place the next day. You ask her to come in the morning so that her results are available the same day.

4. At the end of your busy emergency department (ED) shift, one of the nurses gives you a print-out of test results on a patient who came in overnight but left before being seen. The patient had presented with leg pain after flying back from holiday. Tests showed:

- Haemoglobin: 130 g/L
- White blood cell count: 9.8 × 10^9/L
- Platelet count: 1173 × 10^9/L
- Biochemistry: not processed because the sample was haemolyzed

What is the best course of action?

a. Nothing. She self-discharged, so her symptoms can't have been that bad. She will likely present to the ED again if her symptoms get worse.
b. You ask your colleague to contact the patient by telephone to inform her that she needs to make an appointment with her general practitioner. You document the test results and this plan.
c. You telephone the patient and ask her to come back. You explain that you are worried about a deep vein thrombosis (DVT), and you need to examine her and repeat her blood tests.
d. You write a letter to her general practitioner informing them that self-discharged from the ED and ask that they see her urgently.
e. You requests a Doppler scan to take place the same day and for the report to be sent urgently to her general practitioner so they can organize treatment if needed.

5. While working as a doctor in training, you receive a call on Thursday morning from the hospital laboratory about a blood test result on a 56-year-old female, sent non-urgently by her general practitioner on Tuesday. The request form states '?hypothyroidism'. The full blood count shows:

- Haemoglobin: 98 g/L
- White blood cell count: 38 × 10^9/L
- Platelet count: 21 × 10^9/L
- White blood cell count differential: not available; 'flag' raised by analyzer and blood film made
- Blood film: report awaiting authorization

The full blood count result was communicated by telephone to the out-of-hours general practitioner service late on Tuesday evening. Her home address is between two different hospitals (with different computer systems). No repeat blood test or clinical assessment has taken place at the hospital where you work, though she could have attended the other nearby hospital. What is the best course of action?

a. You do not need to do anything further. The out-of-hours general practitioner service was contacted appropriately, and a message would have been communicated to her usual general practitioner.
b. You contact the patient's general practitioner to ensure that the results have been communicated to them to action.
c. You requested that the blood film is examined and that that result is communicated to the general practitioner the same day for them to action.
d. You telephone your colleague who was on call on Tuesday evening and ask them look at the blood film and follow-up the result.
e. You go to the laboratory to look at the blood film yourself. You contact the patient with the result.

Chapter 40: Venous thromboembolic disease

1. What is the best combination of anticoagulant and reversal agent for a patient with life-threatening gastrointestinal bleeding?

a. Rivaroxaban and intravenous vitamin K
b. Low-molecular-weight heparin and intravenous vitamin K
c. Dabigatran and andexanet alfa
d. Rivaroxaban and andexanet alfa
e. Low-molecular-weight heparin and prothrombin complex concentrate

2. Which of the following is true?

a. Heterozygous factor V Leiden is rare (less than 1%) in individuals of White European ethnicity.
b. Antithrombin deficiency is the most common heritable thrombophilic tendency.
c. It is important to test for heritable thrombophilia in individuals who have had a deep vein thrombosis after major surgery.
d. Detection of a heritable thrombophilia in a patient with venous thromboembolism indicates the need for life-long anticoagulation.
e. Thrombosis in people with antiphospholipid syndrome can be venous, arterial, or microvascular.

3. Which of the following statements is true in patients presenting with a suspected deep vein thrombosis (DVT) or pulmonary embolism (PE)?

a. A normal D-dimer concentration excludes a diagnosis of DVT or PE.
b. Lower limb DVT can be excluded by a single negative ultrasound scan of the proximal venous system in a patient whose two-level Wells score is 'DVT likely'.
c. A normal resting oxygen saturation on air excludes the diagnosis of PE.
d. Superficial femoral vein thrombosis requires treatment as a DVT.
e. Most patients with a PE have an associated symptomatic DVT.

4. Which of the following is true regarding venous thromboembolism (VTE)?

a. The annual incidence of VTE in the population is about 1 per 1000 people.
b. The annual incidence of VTE peaks in middle age.
c. About 10% of episodes of VTE are unprovoked.

d. All patients with an unprovoked episode of VTE should be screened for underlying cancer with a computed tomography scan of the chest, abdomen, and pelvis.
e. Long-haul travel is a stronger risk factor for VTE than major surgery.

Chapter 41: Malignant disease

1. An 80-year-old male presents to the emergency department with a fall. On questioning, he complains of progressive worsening back pain and sudden weakness in his legs in the past week. He tells you he has a history of hypertension and prostate cancer. What is the most important diagnosis to exclude?
   a. Disc prolapse
   b. Discitis
   c. Metastatic spinal cord compression
   d. Acute spinal fracture
   e. Guillan-Barré syndrome
2. A 53-year-old female presents to her general practitioner with a change in bowel habit and weight loss. She is suspected to have bowel cancer, and a computed tomography scan and colonoscopy confirm this on biopsy. What tumour marker is associated with bowel cancer?
   a. CA 19-9
   b. PSA
   c. CA 125
   d. LDH
   e. CEA
3. You are the ward doctor assessing an male with a history of a cough with blood-stained sputum. He is a smoker and has become so breathless he cannot leave the house. Which of these conditions are most associated with small cell lung cancer?
   a. Lambert-Eaton syndrome
   b. Amyloidosis
   c. Dermatomyositis
   d. Endocarditis
   e. Hypoglycaemia
4. A 34-year-old female presents to her general practitioner with a breast lump. She is referred via her general practitioner to a one-stop clinic. Ultrasonography, magnetic resonance imaging, and biopsy confirm a triple-negative breast cancer with lymph node involvement. She is started on both chemotherapy and immunotherapy while awaiting genetic testing. Which genetic disorder is most associated with breast cancer?
   a. Gorlin's syndrome
   b. Lynch syndrome
   c. *BRCA* mutation
   d. von Hippel-Lindau
   e. Hereditary non-polyposis colorectal cancer
5. A 47-year-old male with base of tongue cancer sees you in the accident and emergency department with a fever and productive cough. He is currently receiving chemotherapy and had his last chemotherapy 7 days ago. His heart rate is 124 beats/min, and his blood pressure is 97/64 mmHg with a temperature of 38.6°C. What is the most appropriate initial step in management?
   a. Order chest computed tomography
   b. Await his blood test and lactate results before starting intravenous fluids and antibiotics
   c. Start intravenous antibiotics and fluids without waiting for blood results
   d. Start intravenous fluids and paracetamol
   e. Obtain a sputum culture

Chapter 42: Infectious disease

1. A 42-year-old female presents to primary care in the UK with a 2-day history of fever with uncontrollable chills, dry cough, loose stools, and vomiting. She had returned 2 weeks previously from a 1 month stay in Lagos, Nigeria, visiting her friend and relatives in the city and in a village 3 hours out of town. Apart from a temperature of 39°C and a heart rate of 106 beats/min, the examination is unremarkable. Which of the following is the recommended management?
   a. Send the patient to the nearest emergency department for urgent malaria rapid diagnostic test and blood film.
   b. Obtain routine blood tests, including FBC, U&E, LFTs, and reassess in 48 hours.
   c. Obtain chest X-ray to exclude bacterial pneumonia and TB. Obtain stool analysis for *Salmonella* spp. and other bacterial pathogens.
   d. Start a presumptive antibiotic course to treat travellers' diarrhoea.
2. A 54-year-old patient with insulin-dependent diabetes presents to the emergency department with a 2-day history of fever and confusion. On examination, he is febrile, with a signs of meningism and a reduced conscious level but no focal neurology. There is no rash nor any murmurs. Investigations reveal a raised neutrophil count of 16×10^9/ml and a C-reactive protein (CRP) of 175 mg/L. A computed tomography scan of the head is normal, and a lumbar puncture is planned. What is the appropriate combination of urgent intravenous antimicrobial therapy?
   a. Ceftriaxone and aciclovir
   b. Ceftriaxone, amoxicillin, and aciclovir
   c. Amoxicillin and aciclovir
   d. Ceftriaxone and amoxicillin
   e. Benzylpenicillin and acyclovir

Chapter 43: Sexually transmitted infections

1. A 25-year-old female presents with an unpleasant-smelling vaginal discharge. She has no vulval symptoms and no abnormal bleeding. Her last unprotected vaginal sex was 4 weeks ago with a casual male. She did online chlamydia and gonorrhoea testing 10 days ago, and the results were negative. What is the most likely cause of her vaginal discharge?
   a. Bacterial vaginosis
   b. Candidiasis
   c. Cervical cancer
   d. Retained tampon
   e. Trichomonas vaginalis
2. A 19-year-old male from Leeds, UK, has never been tested for sexually transmitted infections (STIs). He has no symptoms but has had unprotected vaginal sex with several female partners also from Leeds. What STIs would you recommend he is tested for?
   a. Chlamydia and gonorrhoea
   b. Chlamydia, gonorrhoea, syphilis, and HIV
   c. Chlamydia, gonorrhoea, syphilis, HIV, and hepatitis B
   d. Chlamydia, gonorrhoea, syphilis, HIV, and hepatitis C
   e. Chlamydia, gonorrhoea, syphilis, HIV, and hepatitis B and C
3. In 2020, how many people did the World Health Organization (WHO) estimate acquired a sexually transmitted infection each day?
   a. About 50 000
   b. About 100 000
   c. About 500 000
   d. About 1 000 000
   e. About 5 000 000

4. A 24-year-old male presents with burning when passing urine and a whitish urethral discharge for 5 days. Microscopy of Gram-stained urethral secretion shows greater than 5 polymorphonuclear leucocytes per high-power field, but no bacteria are seen. What is the most likely cause of his urethral discharge?
   a. *Chlamydia trachomatis*
   b. Herpes simplex virus
   c. *Neisseria gonorrhoeae*
   d. *Trichomonas vaginalis*
   e. Urinary tract infection
5. *Neisseria gonorrhoeae* antimicrobial resistance is increasing worldwide, so gonococcal culture for antibiotic susceptibility testing should be taken before treatment. When antimicrobial susceptibility is not known before treatment, which antibiotic should be used?
   a. Azithromycin
   b. Ceftriaxone
   c. Ciprofloxacin
   d. Doxycycline
   e. Gentamycin

Chapter 44: Human immunodeficiency virus

1. An HIV antibody test is indicated in all adults diagnosed with what condition?
   a. Viral pneumonitis
   b. Pancreatitis
   c. Type I diabetes
   d. Non-Hodgkin's lymphoma
   e. Crohn's disease
2. A 20-year-old male has fever, sore throat, and lymphadenopathy. He has had condomless sex with several males in the preceding 3 weeks. Investigations show:
   Total white blood cell count: 6.6×10^9/L
   Neutrophils: 5.0×10^9/L
   Lymphocyte 0.5×10^9/L
   What is the most likely diagnosis?
   a. Acute Epstein-Barr virus infection
   b. Gonorrhoea
   c. Syphilis
   d. Acute HIV infection
   e. Acute cytomegalovirus infection
3. Excluding those with evidence of recent infection, the threshold definition of late HIV diagnosis currently used in the UK is a CD4 count within 91 days of diagnosis in what range?
   a. Below 500 cells/mm^3 of blood
   b. Below 450 cells/mm^3 of blood
   c. Below 400 cells/mm^3 of blood
   d. Below 350 cells/mm^3 of blood
   e. Below 200 cells/mm^3 of blood
4. A 60-year-old male with HIV is diagnosed with deep vein thrombosis. He is taking darunavir/cobicistat/emtricitabine/tenofovir alafenamide (Symtuza). Which drug should not be prescribed?
   a. Heparin
   b. Streptokinase
   c. Aspirin
   d. Warfarin
   e. Tinzaparin
5. A 48-year-old female with HIV has been virally suppressed for several years on stable anti-retroviral therapy. She describes gradual onset of poor sleep, night sweats, difficulty in concentrating at work, and low mood. What is the most likely diagnosis?
   a. HIV-associated dementia
   b. Progressive multifocal leucoencephalopathy
   c. Clinical depression
   d. Perimenopause
   e. Anti-retroviral toxicity

Chapter 45: Dermatology

1. When considering dermatological disease, what is TRUE?
   a. Skin diseases are never fatal.
   b. Skin cancer is the second most common cancer for patients of all ages.
   c. Patients with psoriasis are 2.0 to 2.5 times more likely to consider suicide than patients who do not have psoriasis.
   d. Prenatal diagnosis of skin disease is not possible because access to the fetal skin in only available after delivery of the child.
   e. Photodermatoses (skin diseases related to visible and ultraviolet light exposure) do not affect patients with skin of colour.
2. A 26-year-old chef presents to the outpatient clinic with a 2-month history of a scaly, itchy dermatitis on the hands. He has been applying a moisturizer after washing his hands. What is the best therapeutic option to offer next?
   a. Narrowband UVB phototherapy 3 times a week for 20 treatments
   b. 1 week of oral anti-staphylococcal antibiotics
   c. Topical permethrin 5% cream applied as two applications 1 week apart
   d. Moderately potent topical steroid applied daily for 2 to 4 weeks
   e. Weekly oral methotrexate 0.4 mg/kg
3. In bullous pemphigoid, which of the following statement is FALSE?
   a. Bullous pemphigoid predominantly affects older adult patients.
   b. Blisters form within the epidermis and present as flaccid erosions with mucosal involvement.
   c. Autoantibodies against 230 kDA and ColXVII can be found.
   d. Localized disease can be treated with high-potency topical corticosteroids.
   e. Intact blisters are best drained.
4. Which of the following statements related to skin cancer is TRUE?
   a. Basal cell carcinoma is the most common skin cancer in people with lighter skin tones, is more common in immunocompromised people, and metastasizes more frequently than cutaneous squamous cell carcinoma.
   b. The incidence of cutaneous squamous cell carcinoma is reducing in most countries because of more widespread use of sunscreen and other photoprotective measures.
   c. Atypical mole syndrome is only associated with an increased risk of melanoma if there is also a family history of melanoma.
   d. Mycosis fungoides is the most common form of primary cutaneous lymphoma.
   e. Cutaneous squamous cell carcinoma in situ (Bowen's disease) progresses to invasive cutaneous squamous cell carcinoma in at least 50% to 60% of cases.

Chapter 46: Young adult medicine

1. A 14-year-old female asks to be prescribed an oral contraceptive without her parent's knowledge. Which of the following is the best approach?
   a. Sexual activity with a 14-year-old is a criminal offense. You refuse to prescribe an oral contraceptive and make a child protection referral.
   b. It is not in the best interests of a 14-year-old to take an oral contraceptive, so you do not prescribe it. You inform whoever has parental responsibility for the young person about their request.
   c. You establish a rapport with the young person. You judge her to be competent and prescribe the oral contraceptive. You try to persuade her to inform her parents.
   d. You establish a rapport with the young person and judge her to be competent. You advise that she can collect a prescription for the oral contraceptive when she has informed her parents.
   e. You do not prescribe the oral contraceptive. You advise using a barrier contraceptive method instead.
2. Which of the following best applies in the UK in relation to legal rights, duties, powers, responsibilities, and authorities a parent has in relation to their child?
   a. The local council has full parental responsibility for looked after children.
   b. No more than two people can have parental responsibility for the same child.
   c. Same-sex partners automatically have joint parental responsibility of their children.
   d. A father only has parental responsibility if he is married to the mother or named as the father on the child's birth certificate.
   e. A father no longer has legal parental responsibility if he divorces his child's mother.
3. Which of the following best describes the transfer of care from paediatric to adult services for long-term medical conditions?
   a. Most young adults do not need to continue to attend healthcare services regularly after moving to adult care.
   b. A period of preparation, ideally starting in the early teenage years, is an important determinant of improved long-term outcomes.
   c. Parents need to relinquish responsibility so that young people can take on the management of their health needs.
   d. Transition is a single event in which young people and their carers meet with the adult team to hand over their ongoing care.
   e. Young people should have their care transferred to adult services before their 17th birthday.
4. Which of the following statements is TRUE about smoking and vaping in the UK?
   a. Increasing numbers of young people smoke cigarettes.
   b. It is illegal to sell any vaping product, whether it contains nicotine or not, to those younger than 18 years of age.
   c. Most young people who vape do so to help them give up smoking.
   d. Vaping nicotine-containing products is not as addictive as smoking nicotine-containing cigarettes.
   e. Most smokers need to use a nicotine replacement product to enable them to give up smoking.
5. Which of the following is most accurate in relation to risk-taking behaviour among young people in the UK?
   a. Alcohol use is associated with unplanned pregnancy.
   b. Death from intentional self-harm is more common than accidental death.
   c. Cannabis use is unlikely to progress to wider substance misuse behaviours.
   d. Alcohol misuse is an increasing healthcare problem.
   e. Delayed sleep phase syndrome is a rare cause of difficulty getting to sleep at night and waking in the morning.

Chapter 47: Sex and gender in medicine

1. A 23-year-old female presents 100 hours after unprotected sexual intercourse. She has epilepsy and takes levetiracetam for this. She is allergic to penicillin. She has had two previous surgical terminations. What is the best emergency contraception for her?
   a. Levonelle 1.5 mg (levonorgestrel)
   b. EllaOne (ulipristal acetate 30 mg)
   c. Combined oral contraceptive pill tricycle
   d. Intrauterine copper device
   e. Levonelle 3 mg (levonorgestrel)
2. A 35-year-old nulliparous female presents with a history of heavy, regular menstrual bleeding with associated dysmenorrhoea. She does not experience intermenstrual or postcoital bleeding. She does not have any non-cyclical pelvic pain. Her human papillomavirus (HPV) screening was normal 2 years ago. She has one regular male sexual partner who uses condoms for contraception. On examination, her abdomen is soft, and there is a pelvic mass palpable to the level of the umbilicus.

Investigations show:

Plasma haemoglobin: 85 g/dL

Urine bHCG test: negative

What is the most appropriate next investigation for this patient?
   a. HPV (smear) test
   b. Computed tomography scan of the abdomen and pelvis
   c. Pelvic ultrasound scan
   d. Hysteroscopy
   e. Pelvic magnetic resonance imaging
3. In male patients, chronic urinary retention is suggested by
   a. postvoid bladder volume of 150 mL.
   b. pelvic pain with visible haematuria.
   c. painless inability to void.
   d. terminal dribbling.
   e. prostate volume greater than 80 cc.
4. Which of the following statements about testicular torsion is true?
   a. It requires urgent treatment with antibiotics.
   b. It is a time-critical surgical emergency.
   c. It is not seen in adult males.
   d. It requires confirmation with ultrasound examination of the testes.
   e. It is typically caused by uropathogens in males older than 35 years of age.
5. Hormonal management of gender incongruence
   a. is required for all people who change the social expression of their gender.
   b. requires ongoing assessment of cardiovascular risk.
   c. means additional hormonal contraception is no longer required to prevent unplanned pregnancy.
   d. leads to maximal breast development within 3 to 6 months of treatment in transgender females.
   e. leads to an increase in the risk of breast cancer in transgender females compared with cisgender females.

Chapter 48: Obstetric medicine

1. Which of the following conditions is an indication for the use of low-dose aspirin from 12 weeks' gestation to prevent preterm pre-eclampsia?
   a. Grave's disease
   b. Hypothyroidism
   c. Previous venous thromboembolism provoked by the contraceptive pill
   d. Chronic hypertension
   e. Epilepsy
2. A female with type 2 diabetes mellitus presents for pre-pregnancy counselling. Which of the following medications should she be advised to continue in pregnancy?
   a. Metformin
   b. Empagliflozin
   c. Semaglutide
   d. Ramipril
   e. Simvastatin
3. Which of the following physiological parameters are unaffected by pregnancy?
   a. Heart rate
   b. Blood pressure
   c. Respiratory rate
   d. Glomerular filtration rate
   e. Cardiac output
4. Which of the following antiepileptics drugs carries the highest risk of congenital malformations?
   a. Lamotrigine
   b. Levetiracetam
   c. Carbamazepine
   d. Sodium valproate
   e. Phenytoin
5. Which of the following test results do not influence pregnancy outcome in females with systemic lupus?
   a. Protein:creatinine ratio
   b. Anti-Ro/SSA
   c. Double-stranded DNA
   d. Lupus anticoagulant antibody
   e. Alkaline phosphatase

Chapter 49: Medicine of the older adult

1. An 82-year-old female tripped on a curb and fractured her hip. She denies losing consciousness. She has a medical history including diabetes, hypertension, osteoarthritis of her knee, and atrial fibrillation. She normally walks with a stick. Her medications include metformin, losartan, tramadol, bisoprolol, and apixaban. On examination, she is in pain. Her abbreviated mental test score is 8 of 10. Her left leg is shortened and externally rotated. She has a graze on her left palm where she had landed. What is the most likely cause of her fall?
   a. Arrythmia
   b. Hypoglycaemia
   c. Mechanical fall
   d. Multifactorial fall
   e. Simple trip
2. A 95-year-old female is admitted with increasing confusion. Her medical history includes hypertension, arthritis of her spine, and gallstones. Her medications include aspirin and amlodipine. She was recently started on a low–dose buprenorphine patch. On examination, she looks well. Her abbreviated mental test score is 4 of 10. Cardiovascular, respiratory, and abdominal examinations are unremarkable, apart from some mild abdominal distension. Her weight is 40 kg.
   Her blood results include:
   Haemoglobin: 105 g/L (115–165 g/L)
   White blood cell count: 8.6 × 10^9/L (4–10 × 10^9/L)
   Urea: 5.3 mmol/L (2.8–8.1 mmol/L)
   Creatinine: 85 μmol/L (44–80 μmol/)
   Alkaline phosphatase: 130 IU/L (35–104 IU/L)
   Bilirubin: 22 μmol/L (0–21 μmol/L)
   Thyroid-stimulating hormone: 6.23 μ/L (0.27–4.2 μ/L)
   Free T_4: 16 pmol/L (11.1–22)
   What is the most likely cause of her confusion?
   a. Hypothyroidism
   b. Inappropriate dosing
   c. Liver dysfunction
   d. Reduced body fat
   e. Renal impairment
3. A 80-year-old female complains of urinary incontinence. She gets very little warning of when she needs to pass urine, and she finds it difficult to control. She is independent with her activities of daily living, though she gets out less than she used to because of the incontinence. She walks with a stick. There is no evidence of current urinary infection. A postvoid bladder scan shows a residual volume of 130 mL. What is the cause of her incontinence?
   a. Functional incontinence
   b. Mixed incontinence
   c. Overflow incontinence
   d. Stress incontinence
   e. Urge incontinence
4. A 76-year-old male has been struggling at home after the death of his wife 6 months previously. His daughter helps where she can, but she has three young children and struggles to help with his needs. He walks with a stick, though he is occasionally a bit wobbly on his feet and has nearly fallen on a couple of occasions. He occasionally gets breathless when walking to the shops. His daughter is worried about him doing his own cooking because his memory is not as sharp as it used to be, and he left the oven on once. She also says there have been occasions when he has not changed his clothes or washed as much as he used to. He has also stopped getting out as much as usual, and his daughter is worried that he is getting depressed after his wife's death. What is the most important next step with his management?
   a. Comprehensive geriatric assessment
   b. Geriatrician assessment
   c. Occupational therapist assessment
   d. Physiotherapy assessment
   e. Social worker assessment
5. An 87-year-old male is struggling at home because of early dementia. He previously did well with a twice-daily care package to help with his meals and washing and dressing. This was stopped 1 month ago. When asked, he said that he did like them coming round and had felt quite lonely since they stopped calling in. However, his daughter had been worried about how expensive it was and that 'it would use up all my inheritance'. She had stopped this and started claiming benefits for providing his care herself. Social services called a few days after the care package was cancelled and had no concerns. However, he mentioned that she had not been able to call in very often because she was often too busy and had just returned from a holiday. After a fall at

home, the ambulance crew that attended raised a safeguarding alert because the patient appeared unkempt, and the house was very dirty. What is the main type of abuse seen here?

a. Emotional abuse
b. Financial abuse
c. Neglect
d. No concerns
e. Organizational abuse

Chapter 50: Palliative care and symptom control

1. Which of these patients is appropriate for referral to a palliative care team?

a. An actively dying patient in the last days of life
b. A patient with metastatic lung cancer with no further oncological treatment options
c. A patient undergoing curative chemotherapy for acute myeloid leukemia with extensive and painful oral mucositis
d. A patient with severe heart failure and troublesome breathlessness who would like to talk about his wishes for the future
e. All of the above

2. A 75-year-old female has severe chronic obstructive pulmonary disease on maximal treatment and repeated hospital admissions with exacerbations. She has discontinued pulmonary rehabilitation; she finds fresh air gives some relief but is increasingly housebound. She is distressed by breathlessness, and has made repeated calls to the general practitioner. What would you consider first?

a. Prescribe morphine immediate release orally 2.5 mg four times daily and as required.
b. Prescribe lorazepam 0.5 mg sublingually as required up to 2 mg/24 hours.
c. Prescribe oxygen therapy at 2 L/min.
d. Refer to community palliative care team to consider non-pharmacological interventions (e.g., a handheld fan and breathing exercises).
e. Prescribe morphine sulphate tablets 5 mg twice daily.

3. Advanced care planning discussions

a. are ideally held during a patient's last weeks of life.
b. are best had during an acute admission.
c. should be considered proactively at every healthcare interaction.
d. must involve completion of an Advanced Decision to Refuse Treatment.
e. can only be completed in one conversation.

4. An 85-year-old nursing home resident with a background of advanced dementia was admitted to hospital with drowsiness, fever, and shortness of breath. He has completed a course of intravenous antibiotics for an aspiration pneumonia, but his condition has continued to deteriorate, and he is bedbound, drowsy, and drinking minimal amounts of fluid. The treating team meets with the family and communicates that they think he is dying and may be in the last days of life. A best interests decision is made to focus on comfort measures, and his ReSPECT form is completed indicating that he will not receive cardiopulmonary resuscitation. What is the most appropriate next step?

a. Start a syringe driver with morphine and midazolam.
b. Cross off all his regular medications.
c. Prescribe i.v. fluids to maintain hydration.
d. Refer to chaplaincy.
e. Develop a personalized care plan, in discussion with his family, to support individualized decisions about hydration and nutrition, spiritual care, and symptom control.

5. A 64-year-old female with metastatic breast cancer and bone metastases attends the oncology clinic with progressive right hip pain. A computed tomography scan confirms a bone metastasis corresponding to the pain site and rules out a fracture. She is treated with palliative radiotherapy and continues on her chemotherapy. She is reviewed 2 months later and continues to report significant pain. She is frightened that her disease is progressing and cannot sleep at night. She is now on morphine MR 30 mg twice daily, which has been titrated up with little effect. She is not experiencing any side-effects and is mobilizing well. What would be the most appropriate next step?

a. Increase the morphine MR dose further because there is no ceiling effect.
b. Switch to a fentanyl patch because it may be stronger.
c. Referral to the hospital palliative care team for advice on starting a syringe driver.
d. Start amitriptyline at night for low mood and nerve pain.
e. Refer to the hospital palliative care team for assessment of other pain dimensions and consideration of adjuvant analgesics and psychological support.

B Answers to chapter questions

Chapter 2: Clinical communication

1. d. Provide information to the patient about what is going to happen.
2. a. Ask the patient if they felt understood.
3. e. Start with what the patient already knows and build from there.
4. d. Start with open questions.
5. b. Use natural frequencies (e.g., 4 of 10 people).

Chapter 3: Medical ethics

1. e. Being honest and telling the truth, especially about difficult or embarrassing subjects, and speaking frankly without trying to conceal information or put a positive spin on it for our own advantage. Summarized from GMC Duty of Candour https://www.gmc-uk.org/ethical-guidance/ethical-guidance-for-doctors/candour---openness-and-honesty-when-things-go-wrong/being-open-and-honest-with-patients-in-your-care-and-those-close-to-them-when-things-go-wrong. Each option listed is accurate in part, but only E covers the full meaning of the GMC guidance.
2. b. Material risk
3. c. NHS Resolution

Chapter 4: Evidence-based practice

1. c. Research papers
2. c. Observations
3. a. Randomized controlled trials
4. a. To ensure that study groups are as similar as possible
5. c. Patients and clinicians must be blinded to the intervention that is being delivered
6. a. No adjustments are made to participants' treatments or lifestyle
7. a. There is a high risk of recall bias affecting the results.
8. b. Whether a new intervention is acceptable to patients
9. b. The study is sufficiently free from bias.
10. a. The study findings are relevant to patients in other settings.
11. b. Participants in a case-control study are more likely to remember relevant past history if they have the disease of interest.
12. a. The odds of an event occurring in the intervention group divided by the odds in the control group
13. b. The proportion of people in the treatment group who experience the outcome event divided by the same proportion in the control group
14. b. The control performs better than the intervention.
15. a. There is a 95% probability that the 95% confidence interval contains the true value.
16. a. There is strong statistical evidence against the null hypothesis.

Chapter 5: Human genetics

1. b. Targeted panel of genes. These panels are updated to reflect the latest informative genes to study for given phenotypes and would be the first choice. Whole-genome sequencing would yield the answer but typically is selected after a targeted panel, especially if the targeted panel did not reveal a result. SNP array would not target rare single nucleotide variants. Single-cell RNA sequencing would not give genetic sequence data required. Methylation array would provide only epigenetic data.
2. d. Both parents are unaffected carriers. Epidermolytic ichthyosis is a dominantly inherited ichthyosis, so this is an explanation for recessive ichthyoses. Gonadal mosaicism is possible and may be revealed by testing of sperm in the father and may help future family planning. Cutaneous and gonadal mosaicism is also possible and both parents should have a complete skin examination; the presence of a linear birthmark would be a clinical clue of cutaneous mosaicism and can be confirmed with a biopsy and testing of the skin for the same pathogenic variant. Nonpaternity is a possible explanation that needs to be addressed with sensitivity. A *de novo* postzygotic mutation is an early genetic event in the forming embryo and could account for the genetic result.
3. a. Family history questionnaire. This is the first step and would identify the youngest person with the most melanomas, who would be the preferred first person to test in the pedigree if this was feasible. Testing the mother's germline DNA may not be conclusive as in familial melanoma some affected parents may not carry the familial pathogenic variant. Testing the son's germline DNA would be the next step if a family history did not reveal anyone else that was affected. To not offer a test may be the appropriate outcome if the patient had an informed discussion and chose this; although typically this would follow a full family history and skin examination of the affected members. Testing the mother's archival skin tumour would give information on somatic changes in the mother's skin tumour but these would need to be demonstrated in the germline to be useful for genetic counselling of the family.
4. b. Fifty percent of girls will be carriers. Haemophilia A is inherited as an X-linked recessive trait and so fifty percent of girls will be carriers if they inherit either affected X chromosome from the mother or 50% non-carriers if they inherit the normal maternal allele. Fifty percent of boys will have haemophilia because they will inherit the pathogenic allele from their mother (and the Y chromosome from their father); the other 50% will be normal because they inherit the normal allele from their mother (and the Y chromosome from their father).
5. c. Bisulphite modification of DNA. This step is used when testing for DNA methylation, which is not needed here. DNA is used to amplify the single protein coding exon of the *GJB2* gene. Oligonucleotide primers that are complementary to the sequences on different strands at each end of the *GJB2* gene are used. Capillary electrophoresis separates the different-sized sequence fragments and captures the fluorescent signals to allow the DNA sequence to be analyzed. The heat-stable DNA polymerase enzyme allows the repeated amplification of the *GJB2* gene, which includes 30 to 35 denaturing cycling steps at a high temperature.

Chapter 6: Immunity

1. d. Macrophages
2. e. Dendritic cells
3. d. Neutralization of pathogens
4. e. releasing the brakes on T-cell activity.
5. d. mast cells.

Chapter 7: Therapeutics and prescribing

1. b. Intravenous. By definition, intravenous administration gives 100% bioavailability.
2. d. Inhibition. Pharmacokinetics is what the body does to the drug. Inhibition is one mechanism by which drugs exert pharmacodynamic effect.
3. a. Dose independent. Type B reactions are idiosyncractic, dose independent, unpredictable, and often serious.
4. d. 20 hours. In four to five half-lives, more than 97% of drug will be eliminated.
5. d. IV. Phase IV refers to post-marketing studies that usually evaluate drug safety but can be used to evaluate real world effectiveness as well.

Chapter 8: Radiology

1. d. Ultrasonography of the abdomen. Ultrasonography is an excellent (>90% sensitivity and specificity) modality at detecting gallstones, which has the added benefits of being readily available, economical, and comfortable for patients. MRCP is excellent (>90% sensitivity and specificity) at detecting choledocholithiasis (bile duct calculus). HIDA uses the intravenous injection of a radioactive tracer to investigate the physiological function of the biliary system. Some indications include biliary leak (e.g., after transplant or gallbladder surgery), chronic abdominal pain (sphincter of Oddi dysfunction or chronic cholecystitis), and biliary atresia (paediatric patient group). Only about 15% of gallstones are visible on X-ray. This is why CT is also poor at identifying gallstones. CT is, however, able to detect complications of gallstones (e.g., biliary obstruction, severe cholecystitis, gallbladder perforation).
2. e. None of the above. Bacterial meningitis is a rapidly evolving condition (see Chapter 11). Confirm a diagnosis of bacterial meningitis based on: clinical features, blood test results and lumbar puncture results. Neuroimaging is indicated only if the person has risk factors for or symptoms or signs of raised intracranial pressure. These include new focal neurological features (including seizures or posturing), abnormal pupillary reactions, a Glasgow Coma Scale score of 9 or less, or a progressive and sustained or rapid fall in level of consciousness. Do not perform a lumbar puncture until these factors have been resolved because of the risk of tonsillar herniation ('coning'). Take bloods, give antibiotics, and stabilize the person before imaging.
3. e. Contrast-enhanced MRI (gadolinium). Gadolinium-based contrast media use in patients with severe chronic kidney disease (CKD) was demonstrated to very rarely cause nephrogenic systemic fibrosis (NSF). Restrictive policies of gadolinium use in CKD and selective use of contrast agents that bind free gadolinium more strongly have resulted in the virtual elimination of cases of NSF. Concerns of gadolinium use in renal impairment are magnified by recent observations demonstrating gadolinium deposition in the brain and a possible systemic syndrome attributed to gadolinium contrast agents. Discuss with radiologists if you think gadolinium-enhanced imaging is required for your patient. Ultrasonography is often indicated if a patient has renal impairment to exclude a structural cause for the impairment (e.g., renal obstruction). Risk of CT iodinated contrast-induced acute injury is estimated to be near 0% at an eGFR greater than 45, 0% to 2% at an eGFR of 30 to 44, and 0% to 17% at an eGFR less than 30 mL/min. Prophylaxis with intravenous fluid therapy may be indicated (Davenport MS et al. Consensus statement American College of Radiology and National Kidney Foundation 2020).
4. c. The mediastinum measures 10 cm. A mediastinum larger than 9 cm on a supine (where the image is magnified when compared to PA) CXR is considered abnormal, and CT should be considered.
5. b. Pacemakers are contraindicated for MRI. Older implanted pacemakers are contraindicated, but newer pacemakers may be conditionally safe. Please discuss which category your patient's pacemaker falls into with MRI technicians.

Chapter 9: Public health

1. e. The effects could be proposed to be similar to other situations.
2. d. The natural history of the condition should be well understood.
3. d. Positive predictive value varies with prevalence of the disease.
4. b. Influenza
5. a. compare small areas across England.

Chapter 10: Global and planetary health

1. c. has decreased because of economic austerity.
2. b. Laparotomy
3. d. One-third of all food produced is wasted each year.
4. c. Access to water and sanitation is not a UN-recognized human right.
5. d. The Universal Declaration of Human Rights.

Chapter 11: Acute medicine

1. d. Simplified PE severity index (SPESI). The SPESI, or PE severity index (PESI), can be used to decide which patients need admission. Additional factors may include immobility and other barriers to treating in the community such as homelessness. The weight and therefore the BMI may affect which anticoagulant can be used (DOAC vs warfarin) or dosage (e.g., split-dose LMWH if weight markedly increased). The D-dimer level is non-specific but may help with ruling out the diagnosis of thromboembolic disease if negative, although in this case, the patient has already undergone a diagnostic test (CTPA). A prolonged QRS duration, most commonly right bundle branch block, raises concern for right ventricular strain but may be present as a normal variant. The Wells score for pulmonary embolism should be used to calculate the risk for possible pulmonary embolism and the need for further investigation. It is not used after diagnosis.
2. e. Septations and debris on the right side on point-of-care ultrasound (POCUS). Debris and septations on POCUS are strongly suggestive of an empyema and as such would support the decision to insert an appropriately sized chest drain in an urgent manner; there may be a need to perform CT to elucidate if it is

loculated. The size of the effusion is not useful when deciding whether to intervene out of hours because the patient may be stable enough to monitor overnight, especially if the condition is chronic. Thromboembolic disease does not usually present as a large pleural effusion unless there is other underlying pathology. Use of anticoagulants may need careful consideration when contemplating a procedure. A pleural pH of 7.2 or below requires urgent management because this is suggestive of empyema. The requirement for relatively low-level oxygen therapy overnight, if monitored closely, would not make an urgent procedure more likely.

3. c. Idiosyncratic reaction to amoxicillin and clavulanic acid. Idiosyncratic reactions to amoxicillin and clavulanic acid classically occur 2 weeks after treatment and can present with a cholestatic picture. Although the BMI is raised, it is not over 30 kg/m^2, and the alcohol consumption is within accepted advisory limits (14 units/week). Primary CMV infection is often asymptomatic and frequently earlier in life than the fifth decade, and it is less common to have organ involvement if immunocompetent. Initial blood tests in acute CMV or EBV infection might show a leucocytosis and thrombocytopenia. Serological tests can be sent to help with the diagnosis. A recently passed gallstone may present with biliary colic and may lead to a dilated bile duct (1 mm per decade is often deemed within normal limits). A staggered paracetamol overdose (or therapeutic misadventure if caused by apparent clinical need) is unlikely here unless the body weight is less than 50 kg or malnutrition, when dose reduction may be needed (to e.g., 500 mg four times a day).

4. e. 0.9% saline with potassium and 6 units per hour fixed-rate insulin and usual long-acting insulin. The patient has diabetic ketoacidosis (DKA) as evidenced by their diabetes history, likely Kussmaul breathing, low bicarbonate and pH, and high plasma glucose and blood ketone levels. Initial rehydration should include i.v. fluids (of note, the sodium may appear low because of pseudohyponatraemia from high blood glucose) to correct dehydration. The fixed rate of insulin therapy for DKA is 0.1 units/kg/hour. Long-acting insulin should be considered at a normal dose to maintain a background level of insulin. The patient's blood potassium level will drop further with insulin therapy driving it intracellularly, so replacement is required here. The cortisol level is in the normal range and is taken at 10 p.m. (rather than in the morning); therefore, it is unlikely that this is an Addisonian crisis.

5. a. Co-trimoxazole therapy. As an acute physician, it is common to be called with abnormal blood results. Co-trimoxazole is a combination of sulfamethoxazole and trimethoprim, which are often combined because they have a synergistic effect on bacteria. A relatively common side-effect of this medication is to increase potassium levels (due to an amiloride-like effect of trimethoprim in the distal renal tubule) as well as cause a rise in serum creatinine because of competitive inhibition of creatinine's tubular excretion. In dehydration, it might be expected that the urea would rise more relatively than the creatinine. Potassium permanganate soaks would not be absorbed in any meaningful fashion and should not affect potassium or creatinine measurements. If the patient had sepsis, they should have had abnormal observations and would have been reviewed for this in the clinic. Urinary obstruction is less likely in the female population, especially because in this case she is catheterized.

Chapter 12: Sepsis and the treatment of bacterial infection

1. d. Ampicillin/sulbactam

2. e. Tigecycline

3. b. Ceftriaxone

4. c. Ertapenem

5. d. sepsis with an unsupported mean arterial blood pressure below 65 mmHg and an arterial blood lactate concentration above 2 mmol/L after fluid resuscitation.

Chapter 13: Critical care medicine

1. d. Start an infusion of norepinephrine. Norepinephrine is a predominantly α1-active agent and will reverse the sepsis-related loss of arterial tone. This patient's CVP of 10 mmHg and stroke volume variation of less than 10% suggest adequate venous filling pressures, and further fluid at this point is unlikely to help. Dobutamine is a predominantly β1-active compound, therefore having effects on heart rate and contractility. The major issue here is of loss of α1-mediated arterial tone. Dobutamine will worsen her tachycardia and may cause some further loss of arterial tone. This patient's poor urine output relates to a lack of renal perfusion that should be corrected. Furosemide will worsen this and may cause further hypotension. Vasopressin may be used to increase arterial tone, but current recommendations suggest it should be used as an adjunct to norepinephrine rather than in place of it.

2. d. Metabolic acidosis without associated hypoxia. The blood gas shows an acidosis because the pH is less than 7.35, which is metabolic in nature. This is evidenced by the normal $PaCO_2$ and low $cHCO_3$. This is most likely caused by a build-up of lactic acid in tissues not perfused during his cardiac arrest. CPR will never be as effective as normal cardiac output in perfusing body tissues. If the patient had respiratory acidosis, we would expect the $PaCO_2$ to be high. The patient is acidotic, not alkalotic, and we would expect the $PaCO_2$ to be low. Although the blood gas shows a metabolic acidosis, the patient is not hypoxic; he is hyperoxic, and we should turn down the oxygen. The patient is acidotic, not alkalotic, and we would also expect the $cHCO_3$ to be high.

3. e. Improved survival has been demonstrated with lower ventilatory tidal volumes. The ARDSnet trial showed that survival was greater with tidal volumes of 6 to 10 mL/kg. This suggests that some of what was initially thought to be ARDS may in fact have been ventilatory-associated lung injury. The diagnosis of ARDS requires the triad of hypoxia, low lung compliance, and widespread infiltrates on chest imaging. Steroids may be useful in later fibrosing disease but have no place in the acute management of the condition, which is largely supportive. A PaO_2/FiO_2 ratio of less than 300 mmHg with a minimum PEEP of 5 cmH_2O is required to diagnose ARDS. Immunosuppression offers no protection against ARDS.

4. d. Diarrhoea. This causes a normal anion gap with acidosis caused by gastrointestinal bicarbonate loss. Lactic acidosis causes a raised anion gap. Diabetic ketoacidosis causes a raised anion gap and is ruled out by the negative ketones. Salicylate poisoning would cause a raised anion gap. Ethylene glycol toxicity causes a raised anion gap.

5. b. Hypovolaemia. The best guide of this is the wedge pressure representative of left atrial filling pressure. Right atrial or central venous pressure is not always representative of this, particularly

in right ventricular dysfunction such as after myocardial infarction. Cardiac tamponade would produce an elevated right atrial pressure, normal or high wedge pressure, and low cardiac index. Ventricular septal defect would produce a significant fall in venous oxygen saturation caused by right-to-left shunt. A low saturation can also be seen in low cardiac output states or anaemia. Mitral regurgitation produces left atrial hypertension, so the wedge pressure and pulmonary artery pressures should be high. Cardiogenic shock produces a fall in cardiac index, usually with elevated wedge pressure.

Chapter 14: Anaesthesia and perioperative medicine

1. c. Pneumonia. This patient has a number of risk factors for postoperative pulmonary complications, including major abdominal surgery, age, and undergoing a prolonged procedure. He has not mobilized and is not coughing well to clear his secretions. He is likely to have postoperative pneumonia caused by atelectasis and sputum retention.

2. b. 2. This patient has mild systemic disease, so has an ASA score of 2. She is only using a single medication for her hypertension and appears to have good blood pressure control, so the score of 3 (severe systemic disease) does not apply here.

3. a. Psychology, exercise, and nutrition. Prehabilitation is built around psychological preparation of the patient for major surgery, structured exercise to improve cardiorespiratory fitness, and nutritional support to optimize metabolic status. Smoking cessation may additionally be relevant, as could be occupational therapy assessment and medical optimization (including investigations such as echocardiography). However, these are not the core parts of a true prehabilitation programme.

4. c. Nasogastric tube. Enhanced recovery or fast-track protocols vary by centre and by type of surgery. However, most advise minimizing lines, drains, and tubes where possible, including nasogastric tubes. Patients are better able to achieve early drinking, eating, and mobilizing ('DrEaMing') in this way.

5. d. Surgical Outcome Risk Tool (SORT). The SORT models 30-day mortality risk for a wide variety of surgeries, including head and neck procedures. APACHE is predominantly used to assess outcome risk in critical care patients, EuroSCORE is for cardiac surgery, and MOCA is for assessing a patient's cognitive condition (e.g., in dementia or delirium). C-reactive protein levels are not useful in isolation for risk prediction in surgery.

Chapter 15: Toxicology

1. c. Fomepizole
2. d. Phosphine
3. c. Dry mouth
4. c. Prolonged QRS duration
5. e. Methylthioninium chloride ('methylene blue')

Chapter 16: Environmental medicine

1. e. All of the above
2. a. Dexamethasone and immediate descent to a lower altitude
3. d. Coordination is lost
4. d. intravascular coagulation and multiorgan failure can occur.
5. d. Immediate treatment is to give rescue breaths and oxygen if available.
6. d. Prolonged CPR may be required because of respiratory muscle paralysis.

Chapter 17: Cardiology

1. e. Electrocardiography
2. c. Direct oral anticoagulant
3. c. Sodium-glucose transport protein 2 inhibitor
4. b. Coarctation of the aorta
5. d. Ibuprofen and colchicine

Chapter 18: Hypertension

1. b. Ibuprofen. Non-steroidal anti-inflammatory drugs interfere with salt and water handling in the kidney and elevate blood pressure.

2. b. Low vegetable and fruit intake. The other patterns are associated with improved blood pressure control.

3. c. Diastolic blood pressure. The unit measure of arterial pressure is millimetres of mercury (mmHg). Venous pressure is measured in centimetres (of water).

4. b. Clonidine. Central agents should be reserved for expert use and are not one of the first four to six classes of medications recommended for routine use in patients with hypertension.

5. c. Grade 1 hypertension. Although the diastolic blood pressure is normal, systolic blood pressure is greater than 135 mmHg, defining grade 1 hypertension for out-of-office methods.

Chapter 19: Lipid and metabolic disorders

1. a. Apolipoprotein B48. Apolipoprotein B48 is made by gut enterocytes and is only found in chylomicron particles.

2. c. Non-HDL cholesterol. This is the best epidemiological predictor of cardiovascular disease risk and is superior to LDL-C.

3. d. Leukaemia. Leukaemia, like many cancers, is not associated with a cholesterol elevation but usually with reduced cholesterol.

4. b. Familial hypercholesterolaemia. The vast majority of cases of familial hypercholesterolaemia are autosomally dominantly inherited. One very rare condition affecting the low-density lipoprotein receptor adaptor protein-1 (LDLRAP1) in lysosomes shows recessive inheritance and is associated with high cholesterol levels.

5. d. Icosapent ethyl (omega-3 fatty acid). Omega-3 fatty acid preparations have no effects on LDL-C levels or may slightly raise them.

Chapter 20: Respiratory medicine

1. b. Prescribe oral prednisolone, ensure a preventer and reliever therapy prescription, and advise to see general practitioner within 1 week and seek medical advice if his condition fails to improve.

2. e. All of the above.

3. a. The patient should have care in a side room.

4. c. Order a chest radiograph and blood tests and send a 2-week wait referral for suspected lung cancer.

5. b. A breathlessness score (e.g., MRC or CAT) and frequency of exacerbations

Chapter 21: Ear, nose, and throat

1. c. This is 'glue ear' on the right and should resolve in the next few weeks. The negative Rinne's test result on the right, with the Weber's lateralizing to the right is suggestive of a conductive hearing loss on the right. In the context of a recent URTI, this is suggestive of glue ear and should resolve. Antibiotics and steroids are not routinely recommended.

2. d. Benign paroxysmal positional vertigo. A vertigo history where episodes last for seconds, triggered by head movement, are typical for benign paroxysmal positional vertigo. This

condition is known to be triggered by head injuries, among other insults (e.g., vestibular neuritis).

3. d. Posterior circulation stroke. This question references parts of the HINTS exam. In an older adult patient, disabling acute vertigo that lasts all day is concerning for a posterior circulation stroke. Other clues are direction changing nystagmus, a positive test of skew, and negative head thrust test result.

4. c. Fine-needle aspiration of the lymph node. Unilateral throat pain and dysphagia with otalgia are head and neck red flag symptoms for cancer. The enlarged tonsil and palpable lymph nodes are concerning for oropharyngeal cancer. Fine-needle aspiration cytology is the only option that provides a cytological diagnosis of cancer.

5. d. Request an MRI scan of the internal auditory meatus. This question refers to a history of asymmetrical hearing loss. This is the most common way in which vestibular schwannomas present and should be investigated with magnetic resonance imaging of the internal auditory meatus. Referring for hearing aids may be appropriate if the patient wants to try these, but this should be done alongside or after the diagnostic investigations, which should be prioritized. There is no role for steroids in hearing loss that has been present for 1 year.

Chapter 22: Gastroenterology

1. d. *Streptococcus* spp.
2. b. Belching
3. a. *HLA-DQ2*
4. c. TNF-α
5. d. Stimulates appetite and increases gastric emptying

Chapter 23: Hepatology

1. d. The patient should be informed that curative tablet-based therapy is available.
2. d. An HIV test should be performed before initiation of therapy
3. d. An endoscopic retrograde cholangiopancreatography examination
4. b. In patients with alcoholic liver disease and steatohepatitis, the ALT is often greater than the AST.
5. c. After liver transplantation for autoimmune hepatitis, the disease never recurs.

Chapter 24: Biliary tract and pancreatic disease

1. e. Biliary colic
2. b. Acute pancreatitis
3. e. Carcinoma localized to the body or tail of the pancreas
4. c. Carcinoma of the head of the pancreas
5. a. Pseudocyst

Chapter 25: Nutrition

1. d. Re-feeding results in hypokalaemia, hypomagnesemia, hypophosphatemia, and thiamine deficiency.
2. b. B_3
3. c. Acute severe ulcerative colitis
4. c. Parenteral nutrition with or without intravenous fluids
5. b. Metastatic colorectal cancer

Chapter 26: Kidney and urinary tract disease

1. b. IgA nephropathy
2. b. Pyelonephritis
3. b. Renal cell carcinoma
4. d. Diabetic nephropathy
5. c. Peritoneal dialysis-associated peritonitis

Chapter 27: Water balance, fluids, and electrolytes

1. d. Amiloride
2. b. Increasing the water permeability of the cortical and medullary collecting ducts
3. b. Hyperglycaemia
4. e. Respiratory acidosis

Chapter 28: Neurology

1. c. Herpes simplex encephalitis
2. a. Cluster headache
3. b. Giant cell arteritis
4. c. Schwannoma (acoustic neuroma)
5. a. Idiopathic intracranial hypertension
6. c. Syringomyelia
7. d. Vitamin B_1 deficiency
8. c. Progressive bulbar palsy
9. a. Neurofibromatosis type II

Chapter 29: Stroke medicine

1. d. Hypertension
2. d. Start aspirin and clopidogrel mg for 3 weeks and then single-antiplatelet treatment.
3. e. Aggressive vascular risk factor control
4. c. Commence immediate heparin

Chapter 30: General hospital psychiatry

1. d. Establish if he has the mental capacity to refuse vital signs and examination; document that he does not have capacity to refuse a basic examination and make a *best interests decision* to examine him. This is a common occurrence in out-of-hours hospital work. You must document that your patient does not have capacity, recording which component(s) is missing AND why you are making a best interests decision. A treatable infection seems likely here, and you cannot wait hours for his team to arrive; they have no greater legal or other powers than you. Security would not be your first call; this would be to ignore the least restraint principle. Medicine never sleeps, but lawyers do. Even if psychiatry (illegally) placed him under mental health legal holding powers, these do not allow for physical health treatments to be administered against a patient's wishes. (There is one exception to this: intravenous fluids, supplements, and enteral feeding are given under mental health law in severe emaciation, including anorexia nervosa and severe depression.)

2. c. Fluctuating consciousness, disorientated in time, and fleeting visual hallucinations. Delirium is a clinical diagnosis, not a laboratory or past medical history one. The latter description points to a psychosis diagnosis, and these voices (delusions, too) are stable over many years, unlike delirium. Although most delirium is related to drugs and illegal substances or alcohol, the cause is not the diagnosis. Lots of people get angry in hospital; this does not establish a delirium or mental disorder diagnosis.

3. b. Changing to haloperidol from newly prescribed olanzapine because the hospital has run out. Patients who are new to antipsychotic agents struggle with side-effects, especially older agents such as haloperidol. Abrupt switching here also risks the rare neuroleptic malignant syndrome. Consider alternative sedation. Asking for allergies, drug reactions, and intolerances to previous medications and checking hospital and community records, including pharmacy if available, for

current and past medications, are best practices; there are no shortcuts in safe prescribing. The other two answers are cautious, safe prescribing. We are aware of both discontinuation syndrome and the potential interactions of antidepressants from different classes, notably monoamine oxidase inhibitors. This is an agreed protocol when prescribing lithium for the first time. You will need thyroid function testing, too.

4. b. Difficulties with concentration, episodes of the mind going blank, and indecision. Chest tightness, palpitations, and 'latchkey' urinary urgency are physical manifestations of anxiety: urgency of urine is rare in anxiety, and latchkey usually points to bladder problems. Fear of dying, fearing the worst, and a conviction that something bad is going to happen are affective symptoms. Hypervigilance, performance anxiety, and avoiding situations that provoke(d) anxiety are behavioural symptoms. Low mood and anger or irritability are affective symptoms, and flashbacks are a cognitive manifestation of anxiety.

Chapter 31: Ophthalmology

1. b. Diabetic macular oedema
2. e. cataract
3. d. keratitis.
4. a. central retinal artery occlusion.
5. d. Central retinal artery occlusion

Chapter 32: Rheumatology

1. e. Rheumatoid arthritis. Although all of these conditions cause joint pain, only psoriatic arthritis, axial spondylarthritis, and rheumatoid arthritis cause this inflammatory pattern of pain and stiffness. Axial spondylarthritis more typically affects the spine, and there is no reported history or family history of psoriasis. Osteoarthritis and gout are not typical in someone of this age and sex and are less likely to present with symmetrical symptoms. Therefore, rheumatoid arthritis is the most likely diagnosis.

2. b. Marginal osteophytes. The correct answer is marginal osteophytes because this person has mechanical knee pain that is most likely to be caused by osteoarthritis in someone of this age with no other reported joint pain. Other radiologic signs of osteoarthritis include loss rather than preservation of joint space. Marginal erosions are more typically found in rheumatoid arthritis, and syndesmophytes are inflammatory spinal lesions found in axial spondylarthritis and periarticular bone resorption and characteristic of psoriatic arthritis.

3. a. Adalimumab. The correct answer is adalimumab because it is a tumor necrosis factor-α–blocking agent and biologic disease-modifying anti-rheumatic drugs (bDMARDs) should be considered to treat patients with persistently active axial spondylarthritis when two different non-steroidal anti-inflammatory drugs (NSAIDs) have failed. Although etoricoxib (a cyclo-oxygenase-2 selective NSAID) and hydrotherapy may also be recommended, the patient must first be offered bDMARD therapy. Methotrexate and prednisolone are not helpful for managing spinal arthritis.

4. b. Fibromyalgia. The correct answer is fibromyalgia because of the history of chronic widespread pain with unrefreshing sleep and normal investigations. Polymyalgia rheumatica is almost never seen before the age of 50 years and usually has a short history and raised inflammatory markers. In osteoarthritis and rheumatoid arthritis, the pain is usually more localized to joints, and tender spots over the body are not usually a feature. Polymyositis typically presents with weakness rather than pain and with abnormal blood test results such as raised creatine kinase.

5. e. Systemic lupus erythematosus. The correct answer is systemic lupus erythematosus (SLE) because although all the other conditions listed can cause multiorgan effects, only SLE fits all the clinical information given. The patient has an acute kidney problem requiring urgent treatment and is likely to need a renal biopsy. The combination of oedema, proteinuria, and hypoalbuminaemia constitutes nephrotic syndrome, which is very unlikely to occur in systemic sclerosis, rheumatoid arthritis, or Sjögren's syndrome but can be a presenting feature of SLE. Granulomatosis with polyangiitis frequently involves the kidneys but does not cause nephrotic syndrome. The butterfly rash over the face and recurrent mouth ulcers are typical features of SLE, which can also cause both pleural and pericardial inflammation. Antibodies to double-stranded DNA are highly specific for SLE.

Chapter 33: Bone disease

1. e. All of the above.
2. b. fracture.
3. e. a, b, or c.
4. c. Teriparatide
5. d. Continue denosumab

Chapter 34: Endocrinology

1. d. Magnetic resonance imaging (MRI) of the pituitary. MRI is preferable to CT for imaging of the pituitary fossa. Lateral skull X-ray is now considered old-fashioned.
2. d. Thyrotoxicosis
3. e. It is commonly seen in patients with multiple endocrine neoplasia type 1 (MEN 1). Hyperparathyroidism is seen in most patients with MEN 1. Histology usually shows an adenoma rather than hyperplasia.
4. e. Phaeochromocytoma
5. b. Cushing's syndrome

Chapter 35: Diabetes mellitus

1. c. Islet autoantibodies
2. d. SGLT-2 inhibitor
3. b. Pancreatic
4. a. Pump therapy reduces HbA_{1c} in those with elevated HbA_{1c}.
5. e. All of the above

Chapter 36: Metabolic disease

1. d. A diagnosis of inherited metabolic disease is very unlikely in patients presenting with symptoms for the first time in adulthood.
2. e. all of the above.
3. e. Porphyria cutanea tarda
4. c. Females are not clinically affected.
5. e. Hyperammonemia

Chapter 37: Obesity

1. a. Hypothyroidism. Her symptoms of weight gain and constipation along with decreased heart rate and low body temperature should prompt you to consider hypothyroidism as a possible cause. Screening thyroid function tests are worth thinking about when seeing such a patient in the obesity clinic. Hypothyroidism does not typically cause marked weight gain but may be a concern for some individuals.

2. a. Monogenic obesity. Monogenic obesity is a rare cause of obesity in which early-onset obesity and hyperphagia are almost always present.

3. e. All of the above.

4. e. Options b, c, and d. All three drugs cause weight gain. The prolactin is raised because of olanzapine; antipsychotics cause hyperprolactinemia. However, raised prolactin in isolation does not cause weight gain.

5. e. Pseudo-Cushing's syndrome. This is associated with hypercortisolism, but the cortisol is suppressed by the overnight dexamethasone suppression test as opposed to in Cushing's syndrome in which endogenously produced cortisol is not suppressed with dexamethasone. This male patient has a high alcohol intake, which is one of the causes of pseudo-Cushing's syndrome. The clinical features overlap with that of Cushing's syndrome.

Chapter 38: Haematology

1. b. A raised reticulocyte count indicates that the bone marrow is working.

2. e. High LDH concentrations suggest increased red cell destruction.

3. e. HbF concentrations can be naturally elevated in patients with sickle cell disease and thalassaemia.

4. d. A delayed transfusion reaction is unlikely to happen after a patient's first ever transfusion.

5. a. Some types of malabsorption can mimic warfarin treatment on clotting tests.

Chapter 39: Haematological oncology

1. b. Blood film. It is a Friday evening. Most specialist investigations are not available out of hours or at the weekend. However, a blood film can be made and examined at any time. Most laboratory staff are trained to look at blood films; a haematologist is on duty to assist if needed. A WCC this high in someone who is otherwise well is almost certainly an incidental finding of haematological malignancy. A blood film (together with the WCC differential) will differentiate between a chronic (chronic lymphocytic leukaemia [CML] or chronic myeloid leukaemia) or acute leukaemia (acute lymphoblastic leukaemia or acute myeloid leukaemia) in almost all cases and may also determine the subtype. If the blood film shows likely CML, the patient can go home and attend an emergency haematology outpatient appointment after the weekend. If the blood film shows acute leukaemia, then hospital admission is required. The patient will very likely need a bone marrow investigation and immunophenotyping, but they are not instantly available, and results can take some time. Imaging (other than for the wrist fracture) has no role in this scenario. Although infection markers will likely be done, the WCC is too high for an isolated infection. This patient was diagnosed with CML on blood film, confirmed after attending a haematology outpatient clinic after the weekend.

2. e. Request imaging of her neck and refer via the suspected cancer pathway. Underlying malignancy needs to be excluded. Nontender lymphadenopathy is worrying (infective and reactive lymph nodes are often tender or painful). She has persistent classical B-symptoms: fever and weight loss. She should be referred via an urgent suspected cancer pathway to the local hospital. This action should be explained so she is aware to attend for further tests. This patient was diagnosed with classical Hodgkin lymphoma on excision biopsy.

3. e. You give her an urgent appointment for face-to-face review and blood tests to take place the next day. You ask her to come in the morning so that her results are available the same day. There are numerous red flags in this scenario:

- Multiple contacts, including out-of-hours contact for persistent symptoms in someone who has rarely sought help in the past.
- Her pain not being in her lower back but higher up is unusual.
- Her mention of her cognition and new constipation are worrying.

This patient had undiagnosed multiple myeloma with anaemia, spinal lesions (causing her back pain), hypercalcaemia (explaining her cognition and constipation), and acute kidney injury.

4. c. You telephone the patient and ask her to come back. You explain that you are worried about a deep vein thrombosis (DVT), and you need to examine her and repeat her blood tests. Clinical assessment is needed. A DVT needs to be excluded with a Doppler scan in a hospital. Her platelet count is significantly raised, and although this could be reactive, it needs to be confirmed and investigated. This patient had an extensive left leg DVT. She was also diagnosed with essential thrombocythaemia (ET), a myeloproliferative neoplasm. ET increases the risk of venous thromboembolism and is often incidentally diagnosed.

5. e. You go to the laboratory to look at the blood film yourself. You contact the patient with the result. This full blood count result is worrying. An analyzer 'flag' regarding a white blood cell count (WCC) differential means that the machine cannot confidently recognize different white blood cells. This happens when the morphology of the cells is abnormal (e.g., leukaemia cells or blasts). A patient with a high WCC without a differential, anaemia, and significant thrombocytopaenia has acute leukaemia until proven otherwise. This is a medical emergency, and responsibility cannot be diverted to someone else. Direct contact with the patient ensures that appropriate urgent assessment occurs. This patient's blood film confirmed she had acute myeloid leukaemia. She was sent to the emergency department, where the haematology team were expecting her.

Chapter 40: Venous thromboembolic disease

1. d. Rivaroxaban and andexanet alfa. Andexanet is licensed for rivaroxaban and apixaban reversal and approved by the National Institute for Health and Care Excellence for use in life-threatening gastrointestinal bleeding.

2. e. Thrombosis in people with antiphospholipid syndrome can be venous, arterial, or microvascular. Heterozygous factor V Leiden is present in around 5% of populations of White European origin. Its discovery changed the concept of thrombophilia from rare disorders with high clinical penetrance to more common disorders with lower clinical penetrance. Antithrombin deficiency is rare. Thrombophilia testing not indicated when venous thromboembolism occurs after major surgery. Most common thrombophilias do not influence duration of anticoagulation.

3. d. Superficial femoral vein thrombosis requires treatment as a DVT. The first step in the diagnostic algorithm for venous thromboembolism is clinical probability score (Wells). Normal

D-dimer excludes DVT and PE only if the Wells score is 'unlikely'. A single negative proximal US excludes DVT if Wells 'unlikely' and D-dimer is positive, but if Wells is 'likely', the scan should be repeated after 1 week.

4. a. The annual incidence of VTE in the population is about 1 per 1000 people. The annual incidence of VTE increases with age. About 40% of VTE are unprovoked. 'Routine' computed tomography scanning of chest, abdomen, and pelvis is not clinically useful. A long-haul flight increases the risk of VTE by two- to threefold. Major surgery increases risk by more than 50-fold.

Chapter 41: Malignant disease

1. c. Metastatic spinal cord compression
2. e. CEA
3. a. Lambert-Eaton syndrome
4. c. *BRCA* mutation
5. c. Start intravenous antibiotics and fluids without waiting for blood results

Chapter 42: Infectious disease

1. a. Send the patient to the nearest emergency department for urgent malaria rapid diagnostic test and blood film. Fever on return from sub-Saharan Africa is malaria until proven otherwise, and patients can deteriorate rapidly without treatment. The turnaround time for malaria diagnostics outside of hospital settings is unlikely to be rapid enough, and assessment in a hospital setting (if the malaria film result is negative) is important to exclude high-consequence pathogens such as Lassa fever and bacterial sepsis (with blood cultures). Symptoms such as cough and diarrhoea can be 'false-localizing symptoms' that should not detract from the need to exclude malaria and other causes of systemic sepsis.

2. d. Ceftriaxone and amoxicillin. This patient appears to have bacterial meningitis, as evidenced by features of meningitis and a neutrophilia with a high CRP. He also may have features of concurrent encephalitis. The most common cause of bacterial meningitis in this age group is *Streptococcal pneumoniae*, although it is important also to cover *Neisseria meningitidis* and *Haemophilus influenzae*; all respond to ceftriaxone. He has diabetes, which also puts him at risk of *Listeria monocytogenes* meningoencephalitis, which does not respond to ceftriaxone, and hence national guidance recommends adding amoxicillin in those in high-risk groups including those with diabetes. Aciclovir is the recommended treatment for patients with herpes simplex encephalitis, which is not associated with features of meningis or neutrophilia and high CRP. Although herpes simplex is a cause of viral meningitis, there is no evidence of benefit of aciclovir in what is usually a self-limiting condition.

Chapter 43: Sexually transmitted infections

1. a. Bacterial vaginosis. Bacterial vaginosis is the most common cause of vaginal discharge in females of reproductive age. It typically presents with an unpleasant-smelling vaginal discharge but no vulval irritation.

2. b. Chlamydia, gonorrhoea, syphilis, and HIV. The minimum investigations are tests for chlamydia, gonorrhoea, syphilis, and HIV. Hepatitis B and C testing should be performed in those at increased risk, but this person had no risk factors for hepatitis.

3. d. About 1 000 000. WHO estimated in 2020 that more than 1 million people acquired an STI every day. Each year, there are an estimated 374 million new infections in people aged 15 to 49 years with one of the four major curable STIs (chlamydia, gonorrhoea, syphilis, and trichomoniasis) worldwide.

4. a. *Chlamydia trachomatis*. The diagnosis is non-gonococcal urethritis (NGU) because no bacteria are seen. There are several causes of NGU, and the most common is *C. trachomatis*. Other causes include *T. vaginalis*, herpes simplex virus, and urinary tract infections, but these are less common.

5. b. Ceftriaxone. Resistance to all these antibiotics has been reported in the UK, but ceftriaxone resistance is very rare. When antimicrobial susceptibility is not known before treatment, single-dose ceftriaxone 1 g intramuscularly is the recommended treatment.

Chapter 44: Human immunodeficiency virus

1. d. Non-Hodgkin's lymphoma
2. d. Acute HIV infection
3. d. Below 350 cells/mm^3 of blood
4. d. Warfarin
5. d. Perimenopause

Chapter 45: Dermatology

1. c. Patients with psoriasis are 2.0 to 2.5 times more likely to consider suicide than patients who do not have psoriasis.

2. d. Moderately potent topical steroid applied daily for 2 to 4 weeks

3. b. Blisters form within the epidermis and present as flaccid erosions with mucosal involvement.

4. d. Mycosis fungoides is the most common form of primary cutaneous lymphoma.

Chapter 46: Young adult medicine

1. c. You establish a rapport with the young person. You judge her to be competent and prescribe the oral contraceptive. You try to persuade her to inform her parents.

2. d. A father only has parental responsibility if he is married to the mother or named as the father on the child's birth certificate.

3. b. A period of preparation, ideally starting in the early teenage years, is an important determinant of improved long-term outcomes.

4. b. It is illegal to sell any vaping product, whether it contains nicotine or not, to those younger than 18 years of age.

5. a. Alcohol use is associated with unplanned pregnancy.

Chapter 47: Sex and gender in medicine

1. d. Intrauterine copper device
2. c. Pelvic ultrasound scan
3. c. painless inability to void.
4. b. It is a time-critical surgical emergency.
5. b. requires ongoing assessment of cardiovascular risk.

Chapter 48: Obstetric medicine

1. d. Chronic hypertension. Chronic hypertension increases the risk of superimposed pre-eclampsia sevenfold. The other medical conditions are not associated with an increased risk of pre-eclampsia.

2. a. Metformin. Metformin is used to treat both pre-existing and gestational diabetes. There are good safety data to support its use in pregnancy. The other medications either lack adequate

safety data or have been proven to be harmful in pregnancy and should therefore be avoided.

3. c. Respiratory rate. Heart rate and cardiac output increase in pregnancy. Blood pressure falls in pregnancy. Renal blood flow increases in pregnancy, leading to an increase in glomerular filtration (such that estimated glomerular filtration rate equations cannot be used in pregnancy). Respiratory rate does not change in pregnancy; an increase in respiratory rate requires clinical assessment.

4. d. Sodium valproate. Sodium valproate carries at least a 10% risk of congenital malformation and is therefore avoided in pregnancy. Carbamazepine is associated with a 4% to 5% risk of malformation and phenytoin with a 6% risk. Lamotrigine and levetiracetam are not thought to increase the risk of malformations above the background rate in the population.

5. d. Lupus anticoagulant antibody. Lupus disease activity at the time of conception or in pregnancy adversely affects pregnancy outcome. High concentrations of double-stranded DNA may indicate disease activity. Anti-Ro/SSA is associated with a 2% risk of congenital heart block and a 5% risk of neonatal cutaneous lupus. Lupus anticoagulant positivity is a marker for thrombosis risk and adverse pregnancy outcome. Protein:creatinine ratio is used to quantify proteinuria in pregnancy. Pre-existing proteinuria may be caused by lupus nephritis, which increases the risk of adverse pregnancy outcome. New proteinuria in pregnancy can be a sign of pre-eclampsia or new lupus nephritis. Alkaline phosphatase is secreted by the placenta, and serum levels are increased in normal pregnancy.

Chapter 49: Medicine of the older adult

1. d. Multifactorial fall. The terms ‘mechanical fall’ and ‘simple fall’ are generally unhelpful, not least because doctors often stop looking for falls risk factors, some of which may be reversible or modifiable. This patient’s risk factors for falling include her medications (the tramadol could make her drowsy or confused; the losartan can cause the blood pressure to drop); her arthritis, which may be painful if she tries bending her knee, so she is less likely to lift her foot over the curb as well, and she may be suitable for a knee replacement; her diabetes, which could cause falls through peripheral or autonomic neuropathy or retinopathy. Patients with diabetes being treated with insulin or gliclazide may also become hypoglycaemic, though metformin would not cause this. Her atrial fibrillation can be associated with syncopal falls if too fast or too slow, but she denies losing consciousness (not always reliable), and the graze on her hand suggests that she reached out to break her fall, which wouldn’t have been seen if she lost consciousness.

2. b. Inappropriate dosing. Always be suspicious of any new medication being started. Buprenorphine is a commonly used opiate. Despite normal-looking kidney function, her creatinine clearance is just 22 mL/min (reference range, >60), reflecting her age and weight. The reduced body fat won’t help but is not the key issue here. Gallstones when causing problems are more likely to increase the liver function test results more than is given here, even if patients don’t have the abdominal classical symptoms. Her thyroid function is only marginally abnormal and would not cause these problems; it may be worth repeating them in 6 months or so.

3. e. Urge incontinence. Her history is typical for urge incontinence. Functional incontinence is when a patient is unable to physically get to the toilet because of reduced mobility. Stress incontinence is associated with briefly raised intra-abdominal pressures, such as with coughing; there is nothing to suggest that here. Mixed incontinence is a combination of stress and urge incontinence. A bladder would be expected to empty to a residual volume of less than 180 mL; her result is normal.

4. a. Comprehensive geriatric assessment. He needs assessment across a range of areas, from his medical issues (breathlessness, mood, cognition) to his mobility (physiotherapy) to his coping within his own environment with appropriate support (social worker and occupational therapist.)

5. b. Financial abuse. Although the main problem is with financial abuse, this case typifies how there is so much overlap with the different types of abuse. There is self-neglect (though this was not a problem until the care package stopped), and there is emotional abuse (withdrawal of interaction). Arguably, from an organizational perspective, social services closed the case too early; an initial visit was appropriate, but further follow-up for this vulnerable patient may also have been appropriate.

Chapter 50: Palliative care and symptom control

1. e. All of the above

2. d. Refer to community palliative care team to consider non-pharmacological interventions (e.g., a handheld fan and breathing exercises).

3. c. should be considered proactively at every healthcare interaction.

4. e. Develop a personalized care plan, in discussion with his family, to support individualized decisions about hydration and nutrition, spiritual care, and symptom control.

5. e. Refer to the hospital palliative care team for assessment of other pain dimensions and consideration of adjuvant analgesics and psychological support.

REFERENCE INTERVALS *(These vary: please check with your local laboratory)*

Haematology

Haemoglobin
- Male 135–175 g/L
- Female 115–155 g/L

Mean corpuscular haemoglobin (MCH) 27–32 pg

Mean corpuscular haemoglobin concentration (MCHC) 320–360 g/L

Mean corpuscular volume (MCV) 80–96 fL

Packed cell volume (PCV) or haematocrit
- Male 0.40–0.54 L/L
- Female 0.37–0.47 L/L

White blood count (WBC) 4–11 × 10^9/L
- Basophil granulocytes 0.01–0.1 × 10^9/L
- Eosinophil granulocytes 0.04–0.4 ×10^9/L
- Lymphocytes 1.5–4.0 ×10^9/L
- Monocytes 0.2–0.8 ×10^9/L
- Neutrophil granulocytes 2.0–7.5 × 10^9/L

Platelet count 150–400 × 10^9/L

Serum B_{12} 160–925 ng/L (150–675 pmol/L)

Serum folate 4–18 μg/L (5–63 nmol/L)

Red cell folate 160–640 μg/L

Reticulocyte count 50–100 × 10^9/L

Erythrocyte sedimentation rate (ESR) <20 mm/h

Plasma viscosity 1.5–1.72 mPa.s

Coagulation

Activated partial thromboplastin time (APTT) 26–37 s

Prothrombin time 11.5–13.5 s

International Normalized Ratio (INR) 1.0–1.3

D-dimer <500 μg/L (0.50 μg/mL) pulmonary embolism unlikely

Biochemistry

(Serum/plasma in alphabetical order)

Alanine aminotransferase (ALT) <40 U/L

Albumin 35–50 g/L

Alkaline phosphatase 35–129 U/L

Amylase 25–125 U/L

Angiotensin-converting enzymes 10–70 U/L

α_1-antitrypsin 2–4 g/L

Aspartate aminotransferase (AST) 12–40 U/L

Bilirubin <17 μmol/L (0.3–1.5 mg/dL)

Brain natriuretic peptide (BNP) threshold 100 pg/mL

Caeruloplasmin 1.5–2.9 μmol/L

Calcium 2.15–2.55 mmol/L

Chloride 98–107 mmol/L

Complement
- C3 0.75–1.65 g/L
- C4 0.20–0.60 g/L

Copper 11–20 μmol/L (100–200 mg/dL)

C-reactive protein 0–4 mg/L

Creatine kinase (CPK)
- Female 20–170 U/L
- Male 30–200 U/L

Creatinine 45–90 μmol/L (0.5–1.0 mg/dL)

Ferritin
- Female 30–200 μg/L
- Male 30–300 μg/L

α-fetoprotein <10 k U/L

Fructosamine 205–285 μmol/L

Gamma-glutamyl transpeptidase (γ-GT)
- Male 4–72 IU/L
- Female 4–60 IU/L

Glucose (fasting) 3.9–5.6 mmol/L (70–100 mg/dL)

Glycosylated (glycated) haemoglobin (HbA_{1c}) 20–41 mmol/mol (4.0–5.9%)

Immunoglobulins (11 years and over)
- IgA 0.8–4.0 g/L
- IgG 6.0–16.0 g/L
- IgM 0.5–2.0 g/L

Iron 13–32 μmol/L (50–150 μg/dL)

Iron binding capacity (total) (TIBC) 42–80 μmol/L (250–410 μg/dL

Lactate 0.6–2.0 mmol/L

Lactate dehydrogenase 240–480 U/L

Magnesium 0.7–1.1 mmol/L

β_2-microglobulin 1.0–3.0 mg/L

Osmolality 285–295 mOsm/kg

Phosphate 0.8–1.5 mmol/L

Potassium 3.5–5.0 mmol/L

Prostate-specific antigen (PSA) up to 4.0 μg/L

Procalcitonin 0.00–0.05 μg/L (bacterial infection likely if ≥0.25 [or ≥0.50 in ITU])

Protein (total) 62–77 g/L

Sodium 135–145 mmol/L

Tryptase <13 ng/mL

Urate 0.18–0.42 mmol/L (3.0–7.0 mg/dL)

Urea 2.5–6.7 mmol/L (8–25 mg/dL)

Vitamin A 0.5–2.01 μmol/L

Vitamin D (seasonal variation) 25-hydroxy 37–200 nmol/L (0.15–0.80 ng/L)

Zinc 11–24 μmol/L

Lipids and lipoproteins

Cholesterol <5 mmol/L

HDL cholesterol
- Male >1 mmol/L
- Female >1.2 mmol/L

LDL cholesterol <3.0 mmol/L

Triglycerides
- Fasting <1.7 mmol/L
- Non-fasting <2.3 mmol/L

Thyroid function tests
- Thyroxine (free T4) 9–21 pmol/L
- Tri-iodothyronine (free T3) 0.9–2.4 nmol/L
- Thyroid stimulating hormone 0.2–4.2 mU/L

Blood gases (arterial)

P_aCO_2 4.8–6.1 kPa (36–46 mmHg)

P_aO_2 10.6–13.3 kPa (80–100 mmHg)

$[H^+]$ 35–45 nmol/L

pH 7.35–7.45

Bicarbonate 22–26 mmol/L

Urine values

Calcium 7.5 mmol/24 h or less (<300 mg daily)

Copper 0.2–1.0 μmol/24 h (15–40 mg/24 h)

Creatinine 0.13–0.22 mmol/kg body weight per day

5-hydroxyindole acetic acid (5HIAA) <47 μmol daily; amounts lower in females than males

Protein (quantitative) <0.15 g/24 h

Sodium 60–180 mmol/24 h

Serum/urine values

Estimated glomerular filtration rate (eGFR)
- Male 90–140 mL/min
- Female 80–125 mL/min

Albumin mg/Creatinine mmol (ACR)
- Female <3.5
- Male <2.5
